Impact Factor (2023): 3.1
Volume 13 (2025) ISSN 2291-9694 Editor in Chief: Christian Lovis, MD, MPH, FACMI

Contents

Reviews

Trends and Trajectories in the Rise of Large Language Models in Radiology: Scoping Review (e78041)
Adhari Al Zaabi, Rashid Alshibli, Abdullah AlAmri, Ibrahim AlRuheili, Syaheerah Lutfi. 27

Predictive Performance of Radiomics-Based Machine Learning for Colorectal Cancer Recurrence Risk: Systematic Review and Meta-Analysis (e78644)
Yuan Sun, Bo Li, Chuanlan Ju, Liming Hu, Huiyi Sun, Jing An, Tae-Hun Kim, Zhijun Bu, Zeyang Shi, Jianping Liu, Zhaolan Liu. 44

Using Large Language Models for Chronic Disease Management Tasks: Scoping Review (e66905)
Henry Serugunda, Ouyang Jianquan, Hasifah Kasujja Namatovu, Paul Ssemaluulu, Nasser Kimbugwe, Christopher Garimoi Orach, Peter Waiswa. 63

Acceptability, Needs, Concerns, and Barriers to Digital-Based Interventions for the Prevention of Mother-to-Child Transmission of HIV: Systematic Review and Qualitative Meta-Aggregation (e64816)
Sidik Maulana, Kusman Ibrahim, Rachel Arbing, Iqbal Pramukti, Annisa Nugrahani, Luh Armini, Muhammad Iqhrammullah, Wei-Ti Chen. . . 86

Validation of Telehealth Outcome Categories for Patient Safety: Systematic Literature Review (e75486)
Sari Palojoki, Lasse Lehtonen, Riikka Vuokko. 101

Diagnostic Prediction Models for Primary Care, Based on AI and Electronic Health Records: Systematic Review (e62862)
Liesbeth Hunik, Asma Chaabouni, Twan van Laarhoven, Tim Olde Hartman, Ralph Leijenaar, Jochen Cals, Annemarie Uijen, Henk Schers. . 112

Performance of Natural Language Processing for Information Extraction From Electronic Health Records Within Cancer: Systematic Review (e68707)
Simon Dahl, Martin Bøgsted, Tomer Sagi, Charles Vesteghem. 127

The Role of AI in Cardiovascular Event Monitoring and Early Detection: Scoping Literature Review (e64349)
Luis Elvas, Ana Almeida, Joao Ferreira. 141

Comparing Diagnostic Accuracy of Clinical Professionals and Large Language Models: Systematic Review and Meta-Analysis (e64963)
Guxue Shan, Xiaonan Chen, Chen Wang, Li Liu, Yuanjing Gu, Huiping Jiang, Tingqi Shi. 154

Using Large Language Models to Enhance Exercise Recommendations and Physical Activity in Clinical and Healthy Populations: Scoping Review (e59309)
Xiangxun Lai, Jiacheng Chen, Yue Lai, Shengqi Huang, Yongdong Cai, Zhifeng Sun, Xueding Wang, Kaijiang Pan, Qi Gao, Caihua Huang. . . 170

Machine Learning and Deep Learning Techniques for Prediction and Diagnosis of Leptospirosis: Systematic Literature Review (e67859)
Suhila Sawesi, Arya Jadhav, Bushra Rashrash. . . . 184

Preclinical Cognitive Markers of Alzheimer Disease and Early Diagnosis Using Virtual Reality and Artificial Intelligence: Literature Review (e62914)
María Scribano Parada, Fátima González Palau, Sonia Valladares Rodríguez, Mariano Rincon, Maria Rico Barroeta, Marta García Rodriguez, Yolanda Bueno Aguado, Ana Herrero Blanco, Estela Díaz-López, Margarita Bachiller Mayoral, Raquel Losada Durán. . . . 203

Current Landscape and Future Directions for Mental Health Conversational Agents for Youth: Scoping Review (e62758)
Jinkyung Park, Vivek Singh, Pamela Wisniewski. . . . 224

The Use of Machine Learning for Analyzing Real-World Data in Disease Prediction and Management: Systematic Review (e68898)
Norah Alhumaidi, Doni Dermawan, Hanin Kamaruzaman, Nasser Alotaiq. . . . 249

Current Landscape and Future Directions Regarding Generative Large Language Models in Stroke Care: Scoping Review (e76636)
XingCe Zhu, Wei Dai, Richard Evans, Xueyu Geng, Aruhan Mu, Zhiyong Liu. . . . 271

Evidence for the Use of Patient-Reported Outcome Measures in the Treatment of Patients With Noncommunicable Diseases: Systematic Review (e66160)
Marie Villumsen, Benedikte von Osmanski, Kirsten Lomborg, Kirstine Benthien. . . . 295

Large Language Models in Critical Care Medicine: Scoping Review (e76326)
Tongyue Shi, Jun Ma, Zihan Yu, Haowei Xu, Rongxin Yang, Minqi Xiong, Meirong Xiao, Yilin Li, Huiying Zhao, Guilan Kong. . . . 312

Number of Publications on New Clinical Prediction Models: A Bibliometric Review (e62710)
Banafsheh Arshi, Laure Wynants, Eline Rijnhart, Kelly Reeve, Laura Cowley, Luc Smits. . . . 1907

Predictive Value of Frailty on Outcomes of Patients With Cirrhosis: Systematic Review and Meta-Analysis (e60683)
Wen-Zhen Tang, Sheng-Rui Zhu, Shu-Tian Mo, Yuan-Xi Xie, Zheng-Ke-Ke Tan, Yan-Juan Teng, Kui Jia. . . . 2538

Pharmacoepidemiologic Research Based on Common Data Models: Systematic Review and Bibliometric Analysis (e72225)
Yongqi Zheng, Meng Zhang, Conghui Wang, Ling Gao, Junqing Xie, Peng Shen, Yexiang Sun, Mengling Feng, Seng You, Feng Sun. . . . 3835

Smart Contracts and Shared Platforms in Sustainable Health Care: Systematic Review (e58575)
Carlos Marino, Claudia Diaz Paz. . . . 3850

Original Papers

Coagulation Risk Prediction in Patients With Liver Failure: Integrated Meta-Analysis and Machine Learning Model Study (e76348)
Hao Wang, Tao He, Liang Ren, Tingjun Zhang. . . . 337

Optimizing an Electronic Health Record System Used to Help Health Care Professionals Comply With a Standardized Care Pathway for Heart Failure During the Transition From Hospital To Chronic Care: Qualitative Semistructured Interview Study (e63665)
Marta Font, Nadia Davoody. . . . 435

Interpretable Artificial Intelligence Analysis of Functional Magnetic Resonance Imaging for Migraine Classification: Quantitative Study (e72155)
Guohao Li, Hao Yang, Li He, Guojun Zeng. . . . 457

Cost-Benefit Analysis of Preventing Acute Care Use in Oncology Patients Following Systemic Therapy Using Medicare Claims Data: Retrospective Cohort Study (e77891)
Sara Keller, Maximilian Schuessler, Behzad Naderalvojoud, Tina Seto, Lu Tian, Mohana Roy, Tina Hernandez-Boussard. . . . 528

Implementing Electronic Health Records in Philippine Primary Care Settings: Mixed-Methods Pilot Study (e63036)
Anton Elepaño, Carol Tan-Lim, Mark Javelosa, Regine De Mesa, Mia Rey, Josephine Sanchez, Leonila Dans, Antonio Dans. . . . 581

Artificial Intelligence–Based Computerized Digit Vigilance Test in Community-Dwelling Older Adults: Development and Validation Study (e73038)
Gong-Hong Lin, Dorothy Bai, Yi-Jing Huang, Shih-Chieh Lee, Mai Vu, Tsu-Hsien Chiu. . . . 602

Estimating 10-Year Cardiovascular Disease Risk in Primary Prevention Using UK Electronic Health Records and a Hybrid Multitask BERT Model: Retrospective Cohort Study (e76659)
Tianyi Liu, Lei Lu, Yanzhong Wang, Andrew Krentz, Vasa Curcin. . . . 613

Automated Chronic Obstructive Pulmonary Disease Phenotyping and Control Assessment in Primary Care: Retrospective Multicenter Study Using the Seleida Model (e74932)
José Maya Viejo, Fernando Navarro Ros. . . . 633

Scalable Big Data Platform With End-to-End Traceability for Health Data Monitoring in Older Adults: Development and Performance Evaluation (e81701)
Ander Cejudo, Yone Tellechea, Amaia Calvo, Aitor Almeida, Cristina Martín, Andoni Beristain. . . . 656

A Weighted Voting Approach for Traditional Chinese Medicine Formula Classification Using Large Language Models: Algorithm Development and Validation Study (e69286)
Zhe Wang, Keqian Li, Suyuan Peng, Lihong Liu, Xiaolin Yang, Keyu Yao, Heinrich Herre, Yan Zhu. . . . 675

Federated Analysis With Differential Privacy in Oncology Research: Longitudinal Observational Study Across Hospital Data Warehouses (e59685)
Théo Ryffel, Perrine Créquit, Maëlle Baillet, Jason Paumier, Yasmine Marfoq, Olivier Girardot, Thierry Chanet, Ronan Sy, Louise Bayssat, Julien Mazières, Vincent Vuiblet, Julien Ancel, Maxime Dewolf, François Margraff, Camille Bachot, Jacek Chmiel. . . . 686

Estimating Nurse Workload Using a Predictive Model From Routine Hospital Data: Algorithm Development and Validation (e71666)
Paul Meredith, Christina Saville, Chiara Dall'Ora, Tom Weeks, Sue Wierzbicki, Peter Griffiths. . . . 698

Retracted: A Dynamic Adaptive Ensemble Learning Framework for Noninvasive Mild Cognitive Impairment Detection: Development and Validation Study (e60250)
Aoyu Li, Jingwen Li, Yishan Hu, Yan Geng, Yan Qiang, Juanjuan Zhao. . . . 710

Applying Robotic Process Automation to Monitor Business Processes in Hospital Information Systems: Mixed Method Approach (e59801)
Adam Park, Se Jung, Ilha Yune, Ho-Young Lee. . . . 729

Extracting Multifaceted Characteristics of Patients With Chronic Disease Comorbidity: Framework Development Using Large Language Models (e70096)
Junyan Zhang, Junchen Zhou, Liqin Zhou, Zhichao Ba. . . . 744

Automated Literature Screening for Hepatocellular Carcinoma Treatment Through Integration of 3 Large Language Models: Methodological Study (e76252)
Chen Pan, Wei Lu, Bingliang Chen, Gang Zhang, Zhiming Yang, Jingcheng Hao. . . . 764

Understanding Health Information Systems Utilization Across Public Health Centers in Indonesia: Cross-Sectional Study (e68613)
Dewi Aisyah, Agus Setiawan, Chyntia Mayadewi, Alfiano Lokopessy, Zisis Kozlakidis, Logan Manikam. 777

Nurses' Experience Regarding Barriers to Providing Internet Plus Continuous Nursing: Mixed Methods Study (e65445)
Huanhuan Huang, Zhiyu Chen, Lijuan Chen, Xingyao Du, Qi Huang, Wenbi Jia, Qinghua Zhao. 792

Health Information Systems' Support for Management and Changing Work: Survey Study Among Physicians (e65913)
Tarja Heponiemi, Lotta Virtanen, Emma Kainiemi, Petra Saukkonen, Jarmo Reponen, Tinja Lääveri. 803

Construction and Application of an Information Closed-Loop Management System for Maternal and Neonatal Access and Exit Rooms: Non Randomized Controlled Trial (e66451)
Shafeng Jia, Naifeng Zhu, Jia Liu, Niankai Cheng, Ling Jiang, Jing Yang. 814

Correlation Between Diagnosis-Related Group Weights and Nursing Time in the Cardiology Department: Cross-Sectional Study (e65549)
Chen Lv, Yi-Hong Gong, Xiu-Hua Wang, Jun An, Qian Wang, Jing Han, Xiao-Feng Chen. 826

The Perceptions of Potential Prerequisites for Artificial Intelligence in Danish General Practice: Vignette-Based Interview Study Among General Practitioners (e63895)
Natasha Jørgensen, Camilla Merrild, Martin Jensen, Thomas Moeslund, Kristian Kidholm, Janus Thomsen. 837

Identifying and Optimizing Factors Influencing the Implementation of a Fast Healthcare Interoperability Resources Accelerator: Qualitative Study Using the Consolidated Framework for Implementation Research–Expert Recommendations for Implementing Change Approach (e66421)
Jane Li, Emma Maddock, Michael Hosking, Kate Ebrill, Jeremy Sullivan, Kylynn Loi, Danielle Tavares-Rixon, Rajiv Jayasena, Grahame Grieve, Alana Delaforce. 847

Health Care Professionals' Perspectives on Implementing Patient-Accessible Electronic Health Records in Primary Care: Qualitative Study (e64982)
Irene Muli, Åsa Cajander, Isabella Scandurra, Maria Hägglund. 863

Ensuring General Data Protection Regulation Compliance and Security in a Clinical Data Warehouse From a University Hospital: Implementation Study (e63754)
Christine Riou, Mohamed El Azzouzi, Anne Hespel, Emeric Guillou, Gouenou Coatrieux, Marc Cuggia. 880

Analyzing Sleep Behavior Using BERT-BiLSTM and Fine-Tuned GPT-2 Sentiment Classification: Comparison Study (e70753)
Yihan Deng, Julia van der Meer, Athina Tzovara, Markus Schmidt, Claudio Bassetti, Kerstin Denecke. 893

Large Language Model Versus Manual Review for Clinical Data Curation in Breast Cancer: Retrospective Comparative Study (e73605)
Young-Joon Kang, Hocheol Lee, Jae Yi, Hyobin Kim, Chang Yoon, Jong Baek, Yong-seok Kim, Ye Jeon, Jiyoung Rhu, Su Lim, Hoon Choi, Se Oh. 915

An Extraction Tool for Venous Thromboembolism Symptom Identification in Primary Care Notes to Facilitate Electronic Clinical Quality Measure Reporting: Algorithm Development and Validation Study (e63720)
John Novoa-Laurentiev, Mica Bowen, Avery Pullman, Wenyu Song, Ania Syrowatka, Jin Chen, Michael Sainlaire, Frank Chang, Krissy Gray, Purushottam Panta, Luwei Liu, Khalid Nawab, Shadi Hijjawi, Richard Schreiber, Li Zhou, Patricia Dykes. 929

Natural Language Processing and ICD-10 Coding for Detecting Bleeding Events in Discharge Summaries: Comparative Cross-Sectional Study (e67837)
Frederic Gaspar, Mehdi Zayene, Claire Coumau, Elliott Bertrand, Marie Bettex, Marie Le Pogam, Chantal Csajka. 942

A Machine Learning Approach for Identifying People With Neuroinfectious Diseases in Electronic Health Records: Algorithm Development and Validation (e63157)
Arjun Singh, Shadi Sartipi, Haoqi Sun, Rebecca Milde, Niels Turley, Carson Quinn, G Harrold, Rebecca Gillani, Sarah Turbett, Sudeshna Das, Sahar Zafar, Marta Fernandes, M Westover, Shibani Mukerji. 958

Identifying Transportation Needs in Ophthalmology Clinic Notes Using Natural Language Processing: Retrospective, Cross-Sectional Study (e69216)
Lauren Wasser, Hai-Wei Liang, Chenyu Li, Julie Cassidy, Pooja Tallapaneni, Hunter Osterhoudt, Yanshan Wang, Andrew Williams. 971

Large Language Model–Enhanced Drug Repositioning Knowledge Extraction via Long Chain-of-Thought: Development and Evaluation Study (e77837)
Hongyu Kang, Jiao Li, Li Hou, Xiaowei Xu, Si Zheng, Qin Li. 983

Clinical Information Extraction From Notes of Veterans With Lymphoid Malignancies: Natural Language Processing Study (e63908)
Lu He, Matthew Moldenhauer, Kai Zheng, Helen Ma. 1004

Automated Esophageal Cancer Staging From Free-Text Radiology Reports: Large Language Model Evaluation Study (e75556)
Yao Yao, Xingxing Cen, Lu Gan, Jiehui Jiang, Min Wang, Yinghui Xu, Junyi Yuan. 1015

Large Language Models as a Consulting Hotline for Patients With Breast Cancer and Specialists in China: Cross-Sectional Questionnaire Study (e66429)
Hui Liu, Jialun Peng, Lu Li, Ao Deng, XiangXin Huang, Guobing Yin, Haojun Luo. 1029

Toward Cross-Hospital Deployment of Natural Language Processing Systems: Model Development and Validation of Fine-Tuned Large Language Models for Disease Name Recognition in Japanese (e76773)
Seiji Shimizu, Tomohiro Nishiyama, Hiroyuki Nagai, Shoko Wakamiya, Eiji Aramaki. 1041

Predicting Drug–Side Effect Relationships From Parametric Knowledge Embedded in Biomedical BERT Models: Methodological Study With a Natural Language Processing Approach (e67513)
Woohyuk Jeon, Minjae Park, Doyeon An, Wonshik Nam, Ju-Young Shin, Seunghee Lee, Suehyun Lee. 1053

Performance of Natural Language Processing versus International Classification of Diseases Codes in Building Registries for Patients With Fall Injury: Retrospective Analysis (e66973)
Atta Taseh, Souri Sasanfar, Michelle Chan, Evan Sirls, Ara Nazarian, Kayhan Batmanghelich, Jonathan Bean, Soheil Ashkani-Esfahani. . . .
1 0 6 7

Automated Radiology Report Labeling in Chest X-Ray Pathologies: Development and Evaluation of a Large Language Model Framework (e68618)
Abdullah Abdullah, Seong Kim. 1079

Identifying Patient-Reported Outcome Measure Documentation in Veterans Health Administration Chiropractic Clinic Notes: Natural Language Processing Analysis (e66466)
Brian Coleman, Kelsey Corcoran, Cynthia Brandt, Joseph Goulet, Stephen Luther, Anthony Lisi. 1092

Performance Improvement of a Natural Language Processing Tool for Extracting Patient Narratives Related to Medical States From Japanese Pharmaceutical Care Records by Increasing the Amount of Training Data: Natural Language Processing Analysis and Validation Study (e68863)
Yukiko Ohno, Tohru Aomori, Tomohiro Nishiyama, Riri Kato, Reina Fujiki, Haruki Ishikawa, Keisuke Kiyomiya, Minae Isawa, Mayumi Mochizuki, Eiji Aramaki, Hisakazu Ohtani. 1108

Improving Systematic Review Updates With Natural Language Processing Through Abstract Component Classification and Selection: Algorithm Development and Validation (e65371)
Tatsuki Hasegawa, Hayato Kizaki, Keisho Ikegami, Shungo Imai, Yuki Yanagisawa, Shuntaro Yada, Eiji Aramaki, Satoko Hori. 1125

Improving Phenotyping of Patients With Immune-Mediated Inflammatory Diseases Through Automated Processing of Discharge Summaries: Multicenter Cohort Study (e68704)
Adam Remaki, Jacques Ung, Pierre Pages, Perceval Wajsburt, Elise Liu, Guillaume Faure, Thomas Petit-Jean, Xavier Tannier, Christel Gérardin. 1140

Improving Large Language Models' Summarization Accuracy by Adding Highlights to Discharge Notes: Comparative Evaluation (e66476)
Mahshad Koohi Habibi Dehkordi, Yehoshua Perl, Fadi Deek, Zhe He, Vipina Keloth, Hao Liu, Gai Elhanan, Andrew Einstein. 1158

Generative Models and Sentence Transformers for the Recognition and Normalization of Continuous and Discontinuous Phenotype Mentions: Model Development and Evaluation (e68558)
Areej Alhassan, Viktor Schlegel, Monira Aloud, Riza Batista-Navarro, Goran Nenadic. 1175

Model for Predicting Serious Hematological Adverse Events in Individuals With Ovarian Cancer Receiving Poly (Adenosine Diphosphate Ribose) Polymerase Inhibitor Treatment: Prospective Cohort Study (e72994)
Xiaotong Lian, Yu Lei. 1191

Large Language Model–Based Critical Care Big Data Deployment and Extraction: Descriptive Analysis (e63216)
Zhongbao Yang, Shan-Shan Xu, Xiaozhu Liu, Ningyuan Xu, Yuqing Chen, Shuya Wang, Ming-Yue Miao, Mengxue Hou, Shuai Liu, Yi-Min Zhou, Jian-Xin Zhou, Linlin Zhang. 1205

Comparative Analysis of Outcomes of Influenza and COVID-19 Admissions Among Children With Asthma: A Nationwide Retrospective Cohort Study Using the US National Readmissions Database (e73047)
Ying-Chen Chen, Chia-Pi Cheng, Po-Cheng Chen, Jinn-Li Wang, Chia-Chen Wu, Ying-Chun Lu. 1218

Evaluating the Body Roundness Index as a Novel Digital Biomarker for Psoriasis Risk Prediction: Cross-Sectional Study (e75727)
Pengfei Wen, Xiaoyan Wang, Xiaoxue Zhuo, Siliang Xue. 1230

An Intelligent Trial Eligibility Screening Tool Using Natural Language Processing With a Block-Based Visual Programming Interface: Development and Usability Study (e80072)
Ya-Han Hu, Yi-Ying Cheng, Chung-Ching Lan, Yu-Hsiang Su, Sheng-Feng Sung. 1245

Deep Learning–Based Early Warning Systems in Hospitalized Patients at Risk of Code Blue Events and Length of Stay: Retrospective Real-World Implementation Study (e72232)
Ji-hyun Kim, Eun Cho, Yuhyun Choi, Joo-Yun Won, Se Cheon, Young Kim, Ki-byung Lee, Kwang Kim, Ho Kim, Taeyong Sim. 1260

Using Machine Learning to Predict-Then-Optimize Elective Orthopedic Surgery Scheduling to Improve Operating Room Utilization: Retrospective Study (e70857)
Johnathan Lex, Aazad Abbas, Jacob Mosseri, Jay Singh Toor, Michael Simone, Bheeshma Ravi, Cari Whyne, Elias Khalil. 1272

Optimizing Loop Diuretic Treatment for Mortality Reduction in Patients With Acute Dyspnea Using a Practical Offline Reinforcement Learning Pipeline for Health Care: Retrospective Single-Center Simulation Study (e69145)
Jung Lee, Shengpu Tang, Michael Sjoding, Jenna Wiens. 1284

Development and Validation of an Extra Spindle Pole Bodies–like 1–Based Diagnostic and Prognostic Model for Hepatitis B Virus–Related Hepatocellular Carcinoma: Retrospective Cohort Study (e78354)
Lu-Huai Feng, Hengkai Liang, Bobin Hu, Lu Wei, Qingmei Li, Tumei Su, Qianbing Yin, Yanfei Feng, Long Huang, Hongqian Liang, Minghua Su, Jianning Jiang. . . . 1298

Development and Validation of a Predictive Model for Severe Tubular Atrophy/Interstitial Fibrosis in Patients with IgA Nephropathy: Multicenter Retrospective Study (e78761)
Caizheng Yu, Zhitong Niu, Qin Fang, Qing Lei. . . . 1317

Comparative Analysis of Generative Artificial Intelligence Systems in Solving Clinical Pharmacy Problems: Mixed Methods Study (e76128)
Lulu Li, Pengqiang Du, Xiaojing Huang, Hongwei Zhao, Ming Ni, Meng Yan, Aifeng Wang. . . . 1331

Cardiorenal Interorgan Assessment via a Novel Clustering Method Using Dynamic Time Warping on Electrocardiogram: Model Development and Validation Study (e73353)
Sally Zhao, Zhan Ye, Bhavna Adhin, Matti Vuori, Jari Laukkanen, FinnGen, Sudeshna Fisch. . . . 1344

Assessing the Role of Large Language Models Between ChatGPT and DeepSeek in Asthma Education for Bilingual Individuals: Comparative Study (e65365)
Yaxin Liu, Fangfei Yu, Xiaofei Zhang, Xiaohan Tong, Kui Li, Weikuan Gu, Baiquan Yu. . . . 1361

AI-Driven Integrated System for Burn Depth Prediction With Electronic Medical Records: Algorithm Development and Validation (e68366)
Md Rahman, Mohamed Masry, Surya Gnyawali, Yexiang Xue, Gayle Gordillo, Juan Wachs. . . . 1374

Enhancing Surgery Scheduling in Health Care Settings With Metaheuristic Optimization Models: Algorithm Validation Study (e57231)
João Lopes, Tiago Guimarães, Júlio Duarte, Manuel Santos. . . . 1385

The Construction and Application of a Clinical Decision Support System for Cardiovascular Diseases: Multimodal Data-Driven Development and Validation Study (e63186)
Shumei Miao, Pei Ji, Yongqian Zhu, Haoyu Meng, Mang Jing, Rongrong Sheng, Xiaoliang Zhang, Hailong Ding, Jianjun Guo, Wen Gao, Guanyu Yang, Yun Liu. . . . 1395

Convolutional Neural Network Models for Visual Classification of Pressure Ulcer Stages: Cross-Sectional Study (e62774)
Changbin Lei, Yan Jiang, Ke Xu, Shanshan Liu, Hua Cao, Cong Wang. . . . 1408

Predicting Clinical Outcomes at the Toronto General Hospital Transitional Pain Service via the Manage My Pain App: Machine Learning Approach (e67178)
James Skoric, Anna Lomanowska, Tahir Janmohamed, Heather Lumsden-Ruegg, Joel Katz, Hance Clarke, Quazi Rahman. . . . 1422

Effect of Uncertainty-Aware AI Models on Pharmacists' Reaction Time and Decision-Making in a Web-Based Mock Medication Verification Task: Randomized Controlled Trial (e64902)
Corey Lester, Brigid Rowell, Yifan Zheng, Zoe Co, Vincent Marshall, Jin Kim, Qiyuan Chen, Raed Kontar, X Yang. . . . 1437

Expectations of Intensive Care Physicians Regarding an AI-Based Decision Support System for Weaning From Continuous Renal Replacement Therapy: Predevelopment Survey Study (e63709)
Benjamin Popoff, Sandie Cabon, Marc Cuggia, Guillaume Bouzillé, Thomas Clavier. . . . 1451

Proposal for Using AI to Assess Clinical Data Integrity and Generate Metadata: Algorithm Development and Validation (e60204)
Caroline Bönisch, Christian Schmidt, Dorothea Kesztyüs, Hans Kestler, Tibor Kesztyüs. . . . 1469

Performance of an Electronic Health Record–Based Automated Pulmonary Embolism Severity Index Score Calculator: Cohort Study in the Emergency Department (e58800)
Elizabeth Joyce, James McMullen, Xiaowen Kong, Connor O'Hare, Valerie Gavrila, Anthony Cuttitta, Geoffrey Barnes, Colin Greineder. 1483

Diagnostic Decision-Making Variability Between Novice and Expert Optometrists for Glaucoma: Comparative Analysis to Inform AI System Design (e63109)
Faisal Ghaffar, Nadine Furtado, Imad Ali, Catherine Burns. 1492

Improving AI-Based Clinical Decision Support Systems and Their Integration Into Care From the Perspective of Experts: Interview Study Among Different Stakeholders (e69688)
Godwin Giebel, Pascal Raszke, Hartmuth Nowak, Lars Palmowski, Michael Adamzik, Philipp Heinz, Marianne Tokic, Nina Timmesfeld, Frank Brunkhorst, Jürgen Wasem, Nikola Blase. 1506

Deep Learning and Image Generator Health Tabular Data (IGHT) for Predicting Overall Survival in Patients With Colorectal Cancer: Retrospective Study (e75022)
Seo Oh, Youngho Lee, Jeong-Heum Baek, Woongsang Sunwoo. 1521

Machine Learning–Based Prediction of In-Hospital Falls in Adult Inpatients: Retrospective Observational Multicenter Study (e75958)
Takuya Nishino, Kotone Matsuyama, Yasuo Miyagi, Nari Tanabe, Fumiko Yamaguchi, Hiroki Ito, Shizuka Soh, Ayako Yano, Masako Mizuno, Katsuhito Kato, Hiroshige Jinnouchi, Chol Kim, Yosuke Ishii, Hiroki Yamaguchi, Yukihiro Kondo. 1537

Online Clinical Calculator for Predicting 28-Day Mortality in Older Adult Patients With Sepsis-Associated Encephalopathy: Retrospective Study Using MIMIC-IV (e76417)
Guangyong Jin, Menglu Zhou, Jiayi Chen, Mengyuan Diao, Wei Hu. 1553

Comparison of Risk Factors, Their Interaction Patterns, and Scoring Systems for Liver Cancer Between Patients With and Those Without Diabetes: Retrospective Cohort Study Using Electronic Health Records and Tree-Structured Algorithms (e72239)
Sarah Yau, Chi Hung, Eman Leung, Albert Lee, Eng Yeoh. 1570

Named Entity Recognition for Chinese Cancer Electronic Health Records—Development and Evaluation of a Domain-Specific BERT Model: Quantitative Study (e76912)
Junbai Chen, Butian Zhao, Xiaohan Tian, Zhengkai Zou, Ruojia Wang, Jiarui Wu, Songxing Du, Fengying Guo. 1583

Unsupervised Coverage Sampling to Enhance Clinical Chart Review Coverage for Computable Phenotype Development: Simulation and Empirical Study (e72068)
Zigui Wang, Jillian Hurst, Chuan Hong, Benjamin Goldstein. 1600

Leveraging Machine Learning and Robotic Process Automation to Identify and Convert Unstructured Colonoscopy Results Into Actionable Data: Proof-of-Concept Study (e73504)
Elizabeth Stevens, Jager Hartman, Paul Testa, Ajay Mansukhani, Casey Monina, Amelia Shunk, David Ranson, Yana Imberg, Ann Cote, Dinesha Prabhu, Adam Szerencsy. 1616

Label Accuracy in Electronic Health Records and Its Impact on Machine Learning Models for Early Prediction of Gestational Diabetes: 3-Step Retrospective Validation Study (e72938)
Mark Germaine, Amy O'Higgins, Brendan Egan, Graham Healy. 1627

Co-Opetition Strategies of Superior and Subordinate Hospitals for Integration of Electronic Health Records Within the Medical Consortiums in China Based on Two-Party Evolutionary Game Theory: Mixed Methods Study (e70866)
Shenghu Tian, Rong Jiang, Jianfeng Yao, Yu Chen. 1639

Abstract

Background: The use of large language models (LLMs) in radiology is expanding rapidly, offering new possibilities in report generation, decision support, and workflow optimization. However, a comprehensive evaluation of their applications, performance, and limitations across the radiology domain remains limited.

Objective: This review aimed to map current applications of LLMs in radiology, evaluate their performance across key tasks, and identify prevailing limitations and directions for future research.

Methods: A scoping review was conducted in accordance with the framework by Arksey and O'Malley framework and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines. Three databases—PubMed, ScopusCOPUS, and IEEE Xplore—were searched for peer-reviewed studies published between January 2022 and December 2024. Eligible studies included empirical evaluations of LLMs applied to radiological data or workflows. Commentaries, reviews, and technical model proposals without evaluation were excluded. Two reviewers independently screened studies and extracted data on study characteristics, LLM type, radiological use case, data modality, and evaluation metrics. A thematic synthesis was used to identify key domains of application. No formal risk-of-bias assessment was performed, but a narrative appraisal of dataset representativeness and study quality was included.

Results: A total of 67 studies were included. (n/N, %)GPT-4 was the most frequently used model (n=28, 42%), with text-based corpora as the primary type of data used (n=43, 64%). Identified use cases fell into three thematic domains: (1) decision support (n=39, 58%), (2) report generation and summarization (n=16, 24%), and (3) workflow optimization (n=12, 18%). While LLMs demonstrated strong performance in structured-text tasks (eg, report simplification with >94% accuracy), diagnostic performance varied widely (16%-86%) and was limited by dataset bias, lack of fine tuning, and minimal clinical validation. Most studies (n=53, 79.1%) had single-center, proof-of-concept designs with limited generalizability.

Conclusions: LLMs show strong potential for augmenting radiological workflows, particularly for structured reporting, summarization, and educational tasks. However, their diagnostic performance remains inconsistent, and current implementations lack robust external validation. Future work should prioritize prospective, multicenter validation of domain-adapted and multimodal models to support safe clinical integration.

(JMIR Med Inform 2025;13:e78041) doi:10.2196/78041

KEYWORDS

large language models; GPT-4; scoping review; natural language processing; report generation; clinical decision support; workflow optimization; artificial intelligence; AI; radiology

Introduction

The integration of artificial intelligence (AI) into health care has accelerated over the past decade, with large language models (LLMs) emerging as transformative tools for natural language processing in clinical contexts. Built on transformer architectures, models such as GPT-4, bidirectional encoder representations from transformers (BERT), and Text-to-Text Transfer Transformer (T5) have demonstrated high performance in text-based tasks such as summarization, classification, and information extraction across general and clinical domains [1].

Radiology is inherently data intensive and text rich, making it an ideal domain for the application of LLMs. These models can support a wide range of tasks, including automated report

XSL•FO
RenderX

generation, structured documentation, code assignment, and even preliminary diagnostic reasoning from clinical narratives [2-5] Despite the growing number of pilot studies, there is no unified synthesis evaluating the practical effectiveness, integration readiness, and safety implications of LLMs in real-world radiology settings.

Several prior scoping reviews have investigated the use of LLMs in radiology, but these have typically focused on specific application domains. For example, Reichenpfader et al [6] performed conducted a scoping review focused exclusively on information extraction from radiology reports. Their analysis highlighted that most approaches relied on encoder-based transformer models such as BERT, that datasets were often small and single center, and that performance varied substantially by annotation quality and task definition. They concluded that, while information extraction is promising, generalizability and external validation are lacking [6,7]. Busch et al [8] conducted a narrative overview of approximately 10 studies specifically addressing structured reporting in radiology. They emphasized the potential of GPT-3.5 and GPT-4 to transform free text into structured templates and discussed opportunities for multilingual structured reporting adoption. Their analysis was conceptual, with limited systematic synthesis across tasks. Nakaura et al [9] traced the evolution of deep learning and transformer architectures in radiology; explained key limitations such as hallucinations, bias, and lack of explainability; and emphasized the risks of premature deployment in clinical decision support. Their review highlighted proof-of-concept applications, including report generation, translation of radiology reports into plain language, exam preparation, and early feasibility of protocol selection and research support [9].

Unlike these prior reviews that were narrowly focused on single use cases (information extraction or patient-facing report simplification), our study systematically mapped the full spectrum of LLM applications across radiology—including decision support, report generation, workflow optimization, and education. Furthermore, our work integrated both generative and nongenerative transformer models, multimodal applications, and educational and operational use cases. This broader lens allowed us to identify converging themes; quantify distribution across modalities; and highlight gaps in validation, equity, and clinical integration. Accordingly, this review aimed to systematically map the applications of LLMs in radiology; evaluate their reported outcomes; and provide a thematic synthesis of emerging use cases, methodological trends, and future research priorities.

Methods

Study Design

This scoping review was conducted in accordance with the methodological framework proposed by Arksey and O'Malley [10] and adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist (Checklist 1) to ensure methodological transparency and reproducibility.

Eligibility Criteria (PICOS-Based)

Eligibility criteria were defined using the population, intervention, comparator, outcomes, and study designPICOS framework (Table 1). We included peer-reviewed empirical studies evaluating LLM applications in radiology workflows using models such as GPT-3 and GPT-4, BERT, or domain-specific transformers. Reviews, opinion pieces, and conference abstracts were excluded. Only English-language studies published between January 2022 and December 2024 were included due to resource limitations, which we acknowledge may restrict the generalizability of the findings.

Table . Eligibility criteria for study selection structured using the PICOS framework (population, intervention, comparator, outcomes, study design) with additional filtering criteria related to language and publication date.

PICOS domain or criterion	Inclusion criteria	Exclusion criteria
Population	Studies involving radiology professionals, radiological workflows, or radiology-related data	Studies unrelated to radiology or without reference to radiological applications
Intervention	Use or evaluation of LLMs[a], including GPT-3 and GPT-4, BERT[b], or custom transformer models	Studies using general AI[c] models without a language modeling component
Comparator	—[d]	—
Outcomes	Reported outcomes related to LLM performance, feasibility, integration, or limitations in radiology	Studies lacking outcome data or reporting only theoretical frameworks without application
Study design	Peer-reviewed empirical studies (qualitative, quantitative, or mixed methods)	Reviews, editorials, opinion pieces, letters, and conference abstracts
Language	English	Non-English
Publication date	Published between January 2022 and December 2024	Published before 2022 or after December 2024

[a]LLM: large language model.

[b]BERT: bidirectional encoder representations from transformers.

[c]AI: artificial intelligence.

[d]Not applicable (scoping review design).

XSL•FO
RenderX

Information Sources and Search Strategy

The databases were selected to ensure coverage across clinical (PubMed), multidisciplinary (Scopus), and technical and engineering (IEEE Xplore) domains. The search combined MeSH (Medical Subject Headings) and free-text terms related to LLMs ("large language model," "GPT," "BERT," and "transformer-based AI") and radiology ("radiology," "medical imaging," and "diagnostic imaging").

Database-specific search strings tailored to syntax and operators are provided in Multimedia Appendix 1. Gray literature (eg, arXiv and medRxiv) and conference proceedings were excluded, which may have limited capture of emerging non–peer-reviewed work. Furthermore, the use of MeSH terms in PubMed was optimized but may not have fully captured all relevant variations due to evolving terminology in this rapidly developing field. These limitations may have affected the comprehensiveness of the search and should be considered when interpreting the findings.

Study Selection

All retrieved records were imported into Rayyan [11] (Qatar Computing Research Institute), a web-based tool designed to facilitate systematic and scoping review workflows. Rayyan facilitated duplicate removal and blinded screening. Two reviewers (AA and IR) independently screened titles and abstracts and assessed full texts against the eligibility criteria. Disagreements were resolved through consensus or, if needed, by a third reviewer (RS). To ensure calibration, an initial pilot screening was conducted, and a random 20% sample of the included studies was cross-checked. The study selection process is presented in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram.

Data Extraction Strategy

A structured data extraction form was developed and piloted on a sample of 5 studies. The following data were collected:

- Publication details (year, country, and journal)
- LLM type (eg, GPT-3.5, GPT-4, BERT, or domain-specific models)
- Radiology use case (eg, classification, report generation, decision support)
- Data modalities (text, images, multimodal, or radiology information systems [RISs])
- Evaluation metrics (eg, accuracy, bilingual evaluation understudy [BLEU], recall-oriented understudy for gisting evaluation [ROUGE], Matthews correlation coefficient, area under the curve, and F_1-score)
- Dataset characteristics (size, source, and multicenter vs single center)
- Reported outcomes and limitations

Data extraction was conducted independently by 2 reviewers. A random 20% subset was cross-checked for accuracy, with discrepancies resolved through consensus.

Secondary Data Extraction and Thematic Classification

Data Extraction and Coding

A hybrid thematic analysis was conducted. Initially, themes were extracted manually by 3 independent raters who analyzed and categorized the data. An interrater reliability measure (percentage of agreement) was applied to ensure consistency across raters. Subsequently, GPT-4 was used to assist with clustering recurring patterns using a zero-shot prompt. The prompt applied was as follows: "Act as a pseudo analyst, read this file (Excel file with the raw data), and label abstracts with relevant codes. Provide a summary of recurring themes."

The outputs generated by GPT-4 were then compared and triangulated with the manually derived results by an additional expert reviewer, who was provided with (1) the original raw Microsoft Excel file and (2) GPT-4's preliminary coding and theme map. Discrepancies between manual and AI-assisted outputs were discussed in a consensus meeting, and revisions were made to finalize the thematic framework.

It should be noted that GPT-4 was not used during the initial manual theme extraction, which was conducted independently by the 3 student raters. The use of GPT-4 in the subsequent phase was intended to support rather than replace human analytical judgment and ensure that AI-generated outputs were critically appraised before integration.

Theme Development

Through inductive synthesis, the extracted codes were grouped into broader categories that reflected the primary ways in which LLMs are currently being explored in radiology. After multiple rounds of refinement, three overarching themes were established: (1) decision support, including diagnostic support, case prioritization, and aiding clinical judgments; (2) report generation, encompassing drafting, summarization, and improving clarity or standardization of radiology reports; and (3) workflow optimization, referring to efficiency gains such as automating routine tasks, assisting communication, and integrating radiology processes into clinical workflows.

This thematic classification was not predetermined but derived from recurring patterns across the reviewed material. GPT-4 was used as a supporting tool to enhance coding efficiency and cross-check clustering of concepts, whereas the final themes were reviewed, validated, and confirmed manually by the research team.

By systematically identifying and categorizing these themes, the analysis provided a structured synthesis of the literature while ensuring methodological transparency and reproducibility.

Narrative Quality Assessment

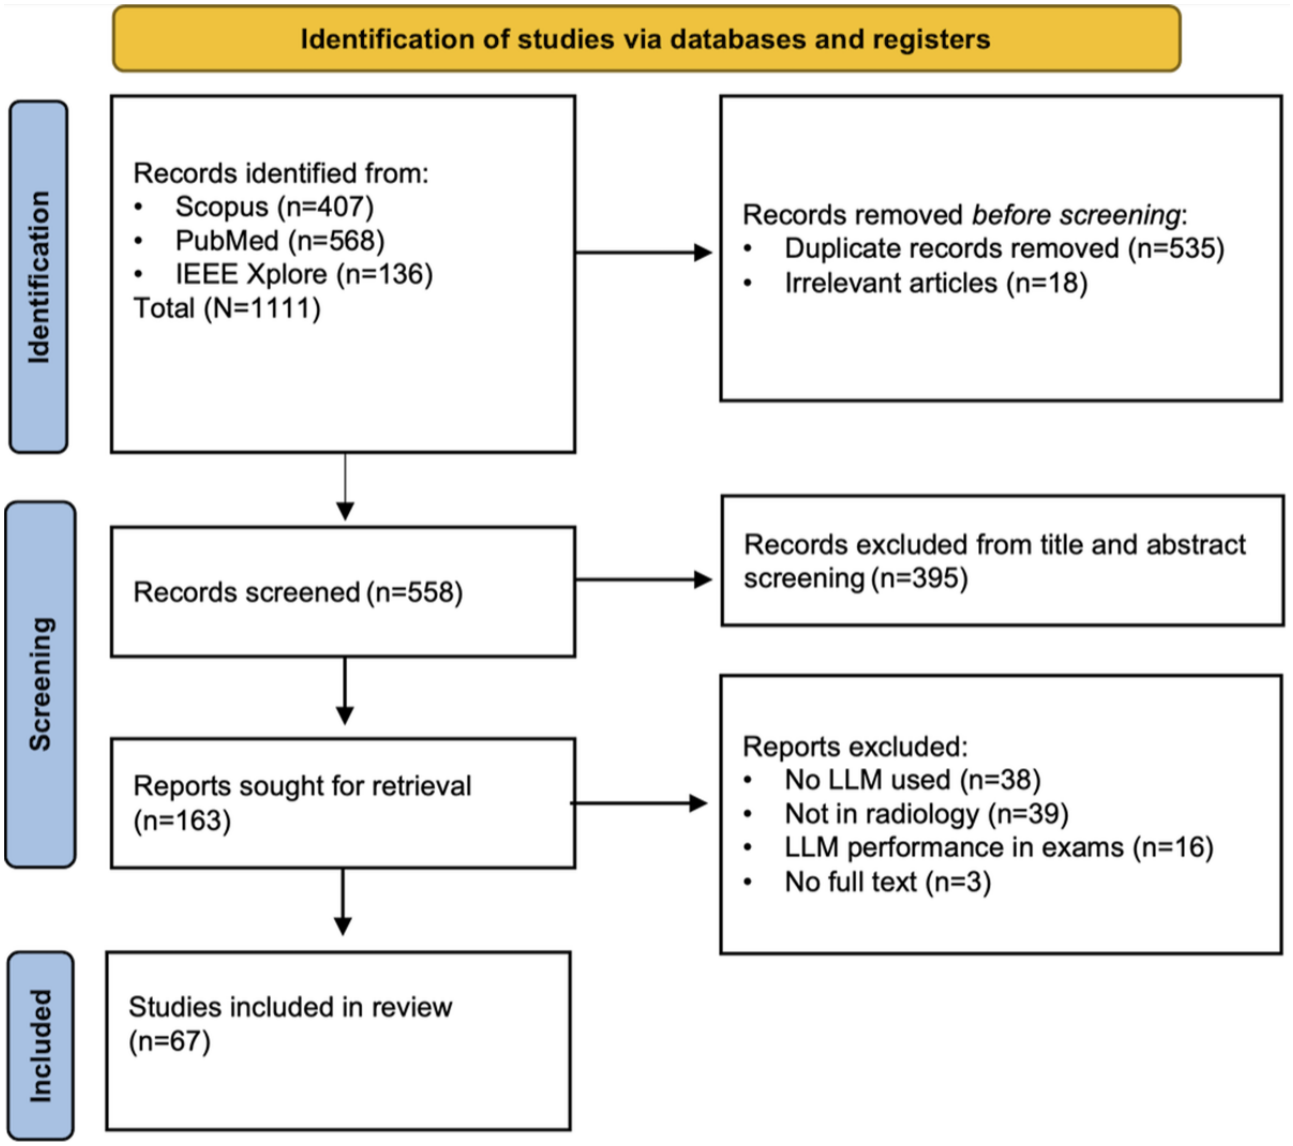
Although a formal risk-of-bias assessment was not performed in accordance with scoping review methodology, a narrative appraisal revealed several recurring limitations in the included studies. Many were small-scale, single-institution implementations or proof-of-concept projects, with limited external validation. Most lacked robust methodological

XSL•FO
RenderX

descriptions or standardized evaluation metrics, making cross-study comparisons challenging.

In terms of dataset size and representativeness, several studies relied on relatively small or synthetic datasets, often drawn from publicly available repositories rather than real-world clinical systems. This raises concerns about generalizability. Geographically, a substantial proportion of the studies originated from North America, Europe, and China, indicating potential regional bias in the development and evaluation of LLMs for radiology. There was limited representation from low- and middle-income countries, which may affect the global applicability of the findings.

Critical Reflection on Methodology



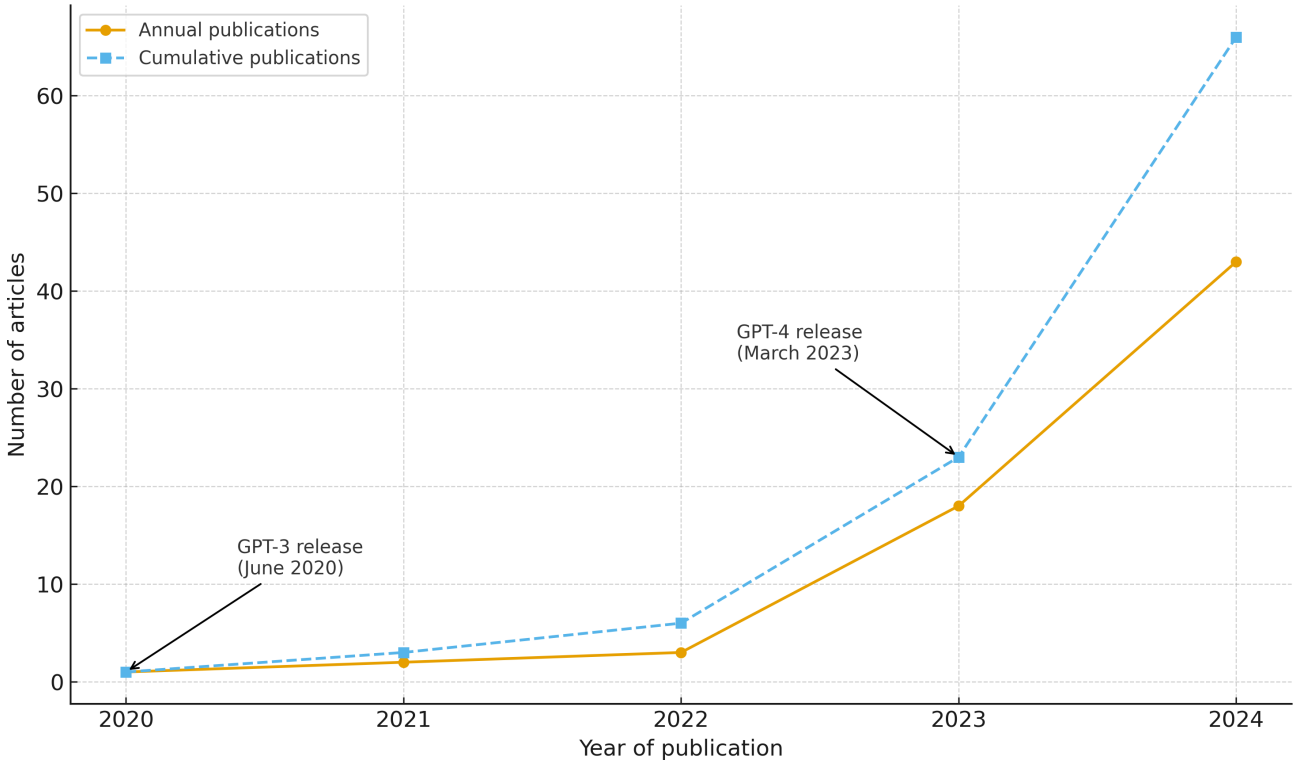
This review used a rigorous and transparent methodology; however, certain limitations must be acknowledged. Restriction to English-language studies and the exclusion of gray literature may have limited comprehensiveness. The fast pace of LLM development also means that new studies may have emerged since the search was conducted. Finally, thematic synthesis, while appropriate for mapping breadth, is interpretive and may introduce subjectivity despite the use of calibration and consensus procedures.

Results

Overview of the Included Studies

A total of 1111 records were retrieved from Scopus (n=407, 36.6%), PubMed (n=568, 51.1%), and IEEE Xplore (n=136, 12.2%). Of these 1111 records, after removing 535 (48.2%) duplicates and 18 (1.6%) irrelevant records, 558 (50.2%) studies remained. Following title and abstract screening, 163 full-text articles were reviewed, and 67 (41.1%) met the inclusion criteria (Figure 1). A summary of all included articles is presented in Multimedia Appendix 2.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram detailing the study selection process for the included records across databases. LLM: large language model.



Most studies (44/67, 65.7%) were published in 2024, reflecting a sharp rise in interest following the release of GPT-4 in March 2023 (Figure 2). Geographically, the United States contributed the most studies (24/67, 35.8%), followed by Japan (10/67,

XSL•FO
RenderX

14.9%) and Germany (10/67, 15%). Very few studies originated from low- and middle-income countries, and a few studies assessed non–English-language corpora (Multimedia Appendix 2).

Figure 2. Annual and cumulative number of publications applying large language models in radiology (2020 - 2024). Data derived from the included studies (N=67). Milestones for the release of GPT-3 (June 2020) and GPT-4 (March 2023) are annotated.

Types of LLMs and Implementation Approaches

GPT-4 was the most frequently studied model (28/67, 42%), followed by GPT-3.5 (14/67, 21%). A smaller proportion (n/N, %)used BERT-based models such as CheXbert and BioBERT or domain-specific variants, including Radiology-Llama2 and RadSpaT5. Multimodal models capable of integrating text and images were reported in 17.9% (12/67) of the studies, although few underwent clinical validation.

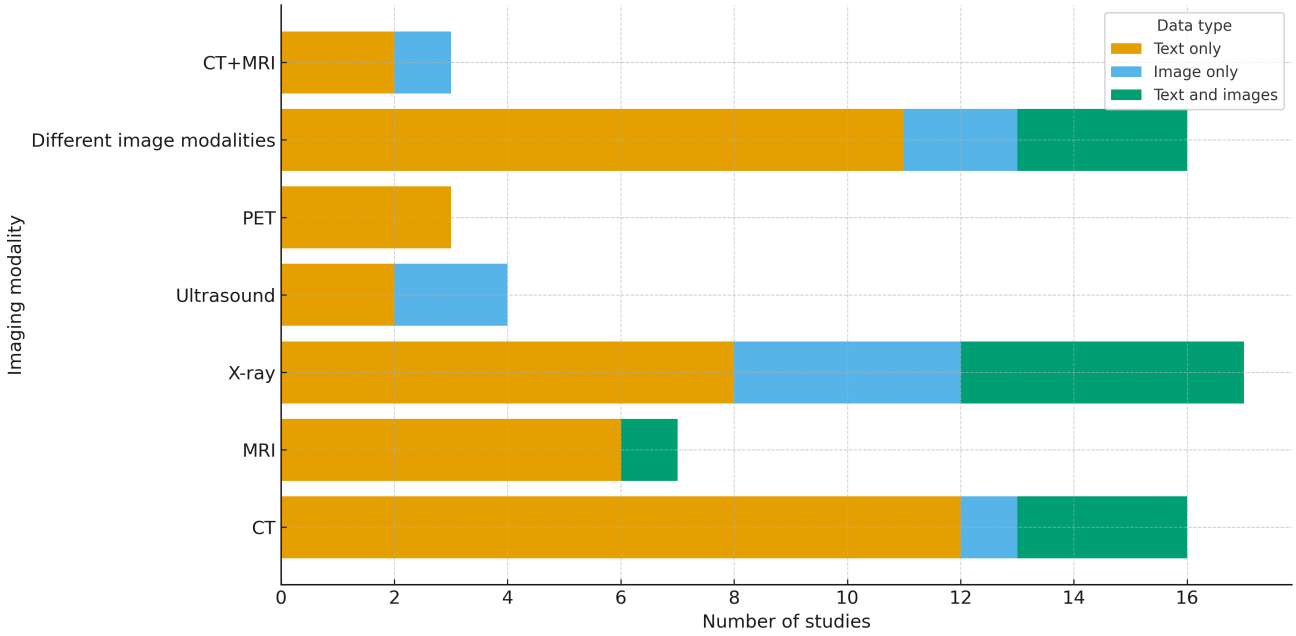
Regarding input data, 64% (43/67) of the studies used text-based corpora such as radiology reports, request forms, or quizzes; 15% (10/67) analyzed images; 18% (12/67) used multimodal datasets; and 3% (2/67) used either RIS data or exam question datasets (Multimedia Appendix 3). Of the 67 studies, 56 (84%) used English-language corpora (English language only: n=50, 89%; mixed English+another language: n=6, 11%), and 11 (16%) used only corpora in non-English languages (German: n=4, 36%; Japanese: n=4, 36%; Italian: n=2, 18%; French: n=1, 9%). Most studies (53/67, 79%) were single center, whereas 21% (14/67) were multicenter.

Imaging Modalities and Radiological Subspecialties

Imaging modality use varied across the studies (Figures 3 and 4). Multimedia Appendix 4 shows the distribution of the 67 studies across various radiology subspecialties. The most represented field was thoracic imaging with 24% (16/67) of the studies, followed by general radiology (13/67, 19%) and oncologic imaging (11/67, 16%).

XSL•FO
RenderX

Figure 3. Imaging modalities used, stratified by data type (N=67). Most studies relied on text-only data (yellow), with fewer using image-only (blue) or multimodal text+image datasets (green) datasets. CT: computed tomography; MRI: magnetic resonance imaging; PET: positron emission tomography.



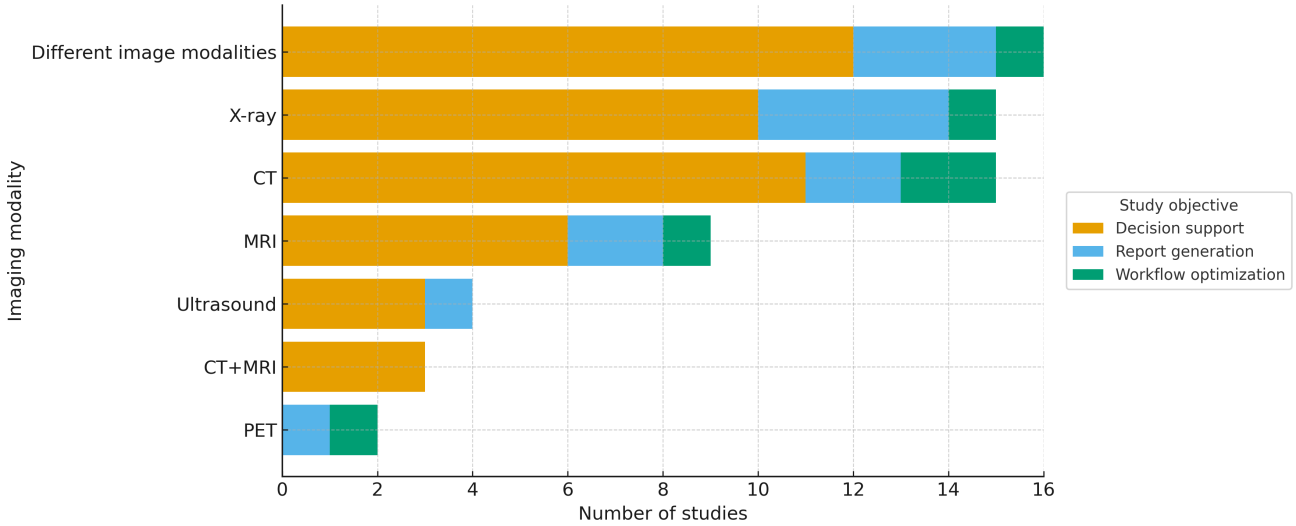


Figure 4. Imaging modality by study objective (N=67). Decision support (yellow) predominated, followed by report generation (blue) and workflow optimization (green). Positron emission tomography (PET) and ultrasound were the least represented. CT: computed tomography; MRI: magnetic resonance imaging.

Thematic Domains of Application

Overview

Table 2 shows the 3 thematic domains that emerged (detailed thematic domains and models are presented in Multimedia Appendix 5).

XSL•FO
RenderX

Table . Thematic classification of large language model applications in radiology across the 67 included studies (2022 - 2024).

Theme 1: AI-Assisted Clinical Decision Support

Four subthemes emerged from this theme.

Classification Tasks

Across radiology classification tasks, domain-tuned transformers remained the most reliable, whereas general LLMs were mixed. BERT-style models standardized the Thyroid Imaging Reporting and Data System and matched or exceeded radiologists for chest x-ray report extraction [18,22], with added interpretability and effectiveness in Italian reports [17]. GPT-3.5 and GPT-4 underperformed or were inconsistent for the Liver Imaging Reporting and Data System and tumor node metastasis staging [14,20], although structured Reporting and Data System categorization showed promise [21]. The multimodal GPT-4V struggled to describe Breast Imaging Reporting and Data System features [15], whereas specialized models such as RadBERT and a 3D vision language model (Merlin) achieved strong document-level COVID-19 classification and surpassed other models. Overall, BERT-family and domain-adapted approaches are currently more dependable than generic LLMs for clinical deployment.

Diagnosis From Clinical Cases

Across clinical case diagnosis, general LLMs remained inconsistent and typically trailed expert radiologists. GPT-4 reached approximately 50% overall accuracy on neuroradiology cases of the week, performing far worse on central nervous system tumors (16%) than on non–central nervous system tumors (62%) [23]. In musculoskeletal cases, text-only GPT-4 was roughly at the resident level but below board-certified radiologists, whereas GPT-4V lagged further [23]. On challenging cases from the Freiburg Neuropathology Case Conference, both GPT-4 and GPT-4V underperformed compared to radiologists [24]. Among Anthropic models, Claude 3.5 Sonnet outperformed Claude 3 Opus, with accuracy improving when both clinical history and imaging were provided, yet differential diagnosis listing remained limited [26]. Targeted prompt engineering and confidence thresholds measurably boosted GPT-4 Turbo's diagnostic accuracy, highlighting the value of workflow tuning [27]

Diagnosis From Images

General LLMs were promising but not yet dependable. GPT-4 (via Bing) was able to recognize basic computed tomography (CT) and magnetic resonance imaging (MRI) features but lacked diagnostic reliability [28]. Multimodal and domain-tuned models fared better: mmBERT set a new visual question answering state of the art with interpretable attention maps [29], and self-supervised Contrastive Language-Image Pretraining improved large-vessel occlusion detection over supervised baselines [30]. GPT-4V showed potential across subspecialties but should complement clinicians, not replace them [31], and GPT-3.5 showed variable accuracy and should be considered as supplementary—not stand-alone—for dental panoramic radiographs [32]. Pairing LLMs with image-to-text modules boosted diagnostic performance in thyroid ultrasound [33]. For differential diagnosis, GPT-4 reached 68.8% concordance with experts (93.8% of outputs were acceptable), with best results in neuroradiology and chest x-rays, yet task performance varied [34] and remained limited for specific findings such as pulmonary congestion [35]. Broadly, LLMs were able to propose differentials but were not reliable for independent use [38]; specialized vision models such as KARA-CXR currently outperform ChatGPT in chest x-ray interpretation [36]. GPT-4, even with single-shot prompts, identified incidental findings with high precision and recall from CT scans. In contrast,

XSL•FO
RenderX

multimodal LLMs remain inadequate for pediatric image interpretation [37].

Extracting Information From Reports

Domain-tuned transformers consistently excelled. BERT variants, especially RadBERT, surpassed other text report classifiers with less annotation in extracting findings from intensive care chest radiograph reports [4], and SpERT achieved high anatomy-linked extraction [44]. Large clinical models also performed strongly: GatorTron reached high accuracy for cancer disease response [40], and an information extraction pipeline inferred metastatic sites accurately and explainably [41]. The open-source Vicuna showed excellent accuracy on emergency brain MRI reports without additional training [43].

Theme 2: LLMs for Report Generation and Quality

In total, 22.4% (15/67) of the studies examined LLMs for generating, structuring, or evaluating radiology reports, falling into 2 streams.

Text to Text

These systems converted free text into structured outputs or summaries: T5 and SciFive performed relation extraction to produce clinician-interpretable structured reports [54], fine-tuned T5 yielded near-expert MRI conclusions in Spanish [52], and Llama 2-70B locally structured reports with approximate human accuracy but variable semantics across languages and findings [59]. GPT-4 improved standardization and generated reports with higher clarity and conciseness than those of human reports but lower diagnostic precision [50,55,58]. It produced the most reliable report templates versus Perplexity, GPT-3.5, and Bing [53]. PEGASUS generated clinically acceptable personalized positron emission tomography (PET) impressions [62].

Image to Text

These pipelines enhanced captioning and paired reports. CXR-IRGen outperformed baselines for chest x-ray image-report pairs [54,57], and a Bloomz-7B1 2-step model (image→abnormality→report) was promising and has potential to reduce workload [49]. GPT-4 consistently emerged as the most robust model across multiple benchmarks [55,58], offering both high readability and coherence, although challenges in diagnostic precision and handling rare findings remain. All 4 studies in this theme showed that LLMs matched or exceeded baseline performance metrics such as BLEU, ROUGE, and Consensus-Based Image Description Evaluation for radiology report generation [49,51,56,57]. Integration of domain-adaptive training or prompt tuning improved model performance, underscoring the importance of radiology-specific fine-tuning.

Theme 3: Clinical Workflow Optimization

total of 17.9% (12/67) of the studies evaluated how LLMs can optimize various nondiagnostic tasks in clinical workflows. This theme included 6 subthemes.

Summarization and Simplification

LLMs supported patient - facing and clinician - to - clinician communication. GPT-3.5 reliably simplified radiology reports into plain language while preserving salient clinical details [75]. Text-to-text transformers (eg, RadSpaT5 and T5) achieved expert-level abstractive summaries, producing accurate report conclusions in most cases [68].

Classification of Reports

Fine-tuned BERT models accurately categorized brain MRI reports into treatment-related groups and identified lung cancer pretreatment cases with performance comparable to that of human experts [69,71]. Domain-adapted variants (BioClinicalBERT and RadBERT) further improved PET and CT report classification, highlighting the value of specialty-specific pretraining [70].

Error Detection and Recommendation Extraction

LLMs showed high precision in identifying diagnostic inaccuracies and extracting actionable recommendations. The Augmented Transformer Assisted Radiology Intelligence model, which integrates both vision and language processing, significantly outperformed traditional natural language processing approaches in detecting laterality errors within reports [74]. A BERT-based model identified reports containing recommendations for additional imaging with high precision and recall, enabling automated recommendation extraction [73].

Radiology Protocol Selection and Answering Patient Queries

GPT-4 accurately selected imaging modalities and protocols from referral forms, indicating potential to streamline protocoling tasks [65]. It also answered common patient questions regarding PET and CT preparation and reporting as a supplementary education tool [76].

User Interface Enhancement

User interface enhancement was explored through models such as ChatUI-RIS, which improved the usability of RISs by offering a more intuitive interface and enhanced learning experiences, particularly for trainees and junior radiologists [72].

Image Quality Assessment and Educational Use

Multimodal LLMs with visual understanding (eg, IQAGPT) provided effective CT image quality assessment [66]. For education, GPT-4 generated high-quality board-style multiple-choice questions (ie, questions at the level of those on a board examination) and rationales for radiology curricula [67].

Model Performance Across Applications

Performance varied widely across tasks (Table 3; the full metrics can be found in Multimedia Appendices 2 and 6). Models fine-tuned on domain-specific corpora (eg, RadBERT, BioClinicalBERT, and Japanese BERT variants) consistently outperformed general-purpose LLMs in structured classification and report-based tasks, often achieving accuracies of >95% [69,71,73].

XSL•FO
RenderX

Table . Summary of performance ranges across the included studies. The lowest and highest reported values are shown where available. Data were extracted from Multimedia Appendices 2-4 (N=67).

Task or application domain and metric	Reported range
Classification	
Accuracy (%)	83 - 97
F_1-score	0.66 - 1.00
AUC[a]	0.84 - 0.99
Diagnostic reasoning from clinical cases	
Accuracy (%)	16 - 50
Diagnosis from images	
Accuracy (%)	25 - 84
Match rate (%)	48-62
Concordance (%)	66.7-68.8
Information extraction from radiology reports	
Accuracy (%)	83-97
F_1-score	0.66 - 1.00
AUC	0.84-0.99
Report generation and summarization	
F_1-score	0.29-0.88
Accuracy (%)	67-89
Clinical acceptability (physician rated; %)	89
BLEU[b] or ROUGE[c] scores	Variable, generally modest (BLEU: 0.46 - 0.74; ROUGE-L[d]: 0.37 - 0.61)
Similarity score (%)	98.9-99.3
Quality assessment	
Accuracy (%)	70.2-98.3

[a]AUC: area under the curve.

[b]BLEU: bilingual evaluation understudy.

[c]ROUGE: recall-oriented understudy for gisting evaluation.

[d]ROUGE-L: recall-oriented understudy for gisting evaluation based on the longest common subsequence.

In contrast, performance for diagnostic reasoning and image-based tasks remained modest. For instance, GPT-4V achieved only 27% to 35% accuracy in primary and differential diagnoses [31], and GPT-4 variants reached <25% accuracy in case-based diagnostic challenges [23].

Text-based applications such as error detection [74] and structured report inference [18,73] approached human-level accuracy (≥95%). Image-focused tasks yielded lower values, with rank-1 accuracy as low as 25% [32], area under the curve values between 0.80 and 0.83 [30,33], and F_1-scores below 0.30 in some generative settings [57].

Report generation and simplification tasks demonstrated variable performance depending on evaluation metrics. While BLEU and ROUGE scores remained modest, physician-rated acceptability and utility scores were encouraging [62,77], suggesting that automated metrics may underestimate clinical usability. GPT-4 also showed superior performance in exam question generation [67] and summarization [75].

Discussion

Principal Findings

Overview

This scoping review provides the first comprehensive synthesis of LLM applications across all domains of radiology. By mapping 67 studies, we identified 3 main areas of application: clinical decision support, report generation, and workflow optimization. There is evidence suggesting that LLMs are most reliable in structured tasks such as classification, information extraction, and educational support, whereas diagnostic reasoning and visual interpretation remain underdeveloped.

Decision Support

GPT-based and BERT models showed strong performance in structured classification tasks such as the Thyroid Imaging Reporting and Data System, the Liver Imaging Reporting and Data System [14,15,18,21], fracture coding [42], and tumor node metastasis staging [20], particularly when domain-specific

XSL•FO
RenderX

BERT variants were fine-tuned on radiology data. These models frequently matched or exceeded human performance in multilingual and specialty-specific contexts. In contrast, diagnostic reasoning tasks involving clinical cases or direct image interpretation showed limited and inconsistent performance. General-purpose GPT-4 and GPT-4V models achieved variable accuracy across case-based and imaging tasks, underscoring the immaturity of current multimodal reasoning [15,24,25,27,31].

Report Generation

Transformer models such as T5, PEGASUS, and GPT-4 generated radiology reports that were linguistically coherent and frequently rated as clinically acceptable. Physician-rated outcomes often aligned GPT-4 reports with radiologist-written impressions. However, hallucinations and factual inaccuracies persist, particularly in rare or ambiguous cases. Automated linguistic metrics (BLEU and ROUGE) did not always correlate with clinical usability, highlighting the importance of human-centered evaluation. Without factuality scoring and domain-specific safeguards, unsupervised deployment of report generation tools remains premature.

Workflow Optimization

While our thematic synthesis identified distinct application domains, we acknowledge that the "workflow optimization" category is intentionally broad. It encompasses a range of nondiagnostic use cases, including patient education, radiology report simplification, imaging protocol selection, and user interface enhancement. This thematic grouping reflects the expanding role of LLMs in supporting communication, training, and clinical efficiency beyond core diagnostic tasks. Although its breadth may resemble a "catch-all," we believe that it accurately represents the dynamic and evolving integration of LLMs into radiological practice. Notably, the most reliable use cases for near-term clinical integration were concentrated in workflow support tasks. These included report simplification, protocol selection [73], error identification [74], and RIS user interface enhancement [72]. Such tasks rely primarily on structured reasoning and language fluency rather than on complex diagnostic inference, making them especially suitable for early implementation. Specialized tools such as Augmented Transformer Assisted Radiology Intelligence (for error detection) [74] and ChatUI-RIS (for user interface enhancement) [72] outperformed general-purpose LLMs, reinforcing the value of domain adaptation. Educational uses such as generating board-style multiple-choice questions also proved effective, with high user satisfaction and accuracy [67]. Taken together, these low-risk, high-utility functions offer a promising entry point for safe and meaningful adoption of LLMs in radiology.

Emerging Trends

Two developments were particularly noteworthy. First, multimodal LLMs integrating text and image inputs are moving toward context-aware systems but continue to show high variability in performance and lack prospective validation. Second, domain-specific models such as Radiology-Llama2 and RadSpaT5 demonstrate stronger alignment with radiological terminology but remain underrepresented. Broader external validation and adoption of these models could improve interpretability and clinical fidelity.

Methodological Limitations of the Evidence

Several methodological gaps were consistently observed across the literature. Most studies relied on retrospective, single-center datasets, frequently limited to chest radiographs or neuroradiology, restricting generalizability. Sample sizes were often small, and only 22% of the studies (15/67) reported external validation. Publication bias is likely as studies with positive results may be preferentially published. Heterogeneous reporting of metrics further complicates benchmarking, and the absence of standardized evaluation frameworks for radiology-specific tasks prevents direct comparison across studies.

Equity and Global Applicability

The predominance of English-language publications and Western data sources poses a significant barrier to equitable implementation. Without multilingual evaluation datasets and cross-regional external validation, performance estimates risk being skewed toward English-language and high-resource settings. Ensuring equity and inclusivity in model development and validation is essential for global relevance.

Recommendations and Future Work

Future research should prioritize the following areas:

1. Data and validation; assemble diverse, multicenter, and multilingual datasets to improve generalizability. Conduct prospective evaluations across clinical environments.
2. Evaluation standards; develop radiology-specific factuality and safety benchmarks and ensure standardized reporting of performance and bias assessments.
3. Human factors; implement human-in-the-loop frameworks for oversight, error mitigation, and usability evaluation.
4. Governance; establish clear regulatory guidance and accountability standards to ensure transparency and safety in clinical use.

Limitations

This scoping review has several limitations that should be acknowledged to aid interpretation and guide future research.

First, the search strategy, while designed to be comprehensive, was limited to 3 databases: PubMed, Scopus, and IEEE Xplore. These were selected to capture clinical, biomedical, and technical literature; however, this may have excluded relevant studies indexed in other databases (eg, Embase or Web of Science) or reported in gray literature sources such as arXiv and medRxiv or key conference proceedings (eg, NeurIPS and Medical Image Computing and Computer-Assisted Intervention). This limitation may have led to the omission of emerging or unpublished work.

Second, although efforts were made to use both free-text and controlled vocabulary (eg, MeSH terms in PubMed), the evolving and inconsistent terminology used to describe LLMs may have affected search sensitivity. Terms such as "GPT," "LLM," or "transformer-based AI" may not have been uniformly used across all relevant publications. While the search was

XSL•FO
RenderX

iteratively refined and detailed strategies are included in Multimedia Appendix 1 to improve reproducibility, some studies may have been inadvertently missed due to terminology mismatch.

Third, only English-language articles were included. This decision was made to ensure consistency in interpretation and quality appraisal; however, it introduces language bias and may have excluded valuable contributions from non–English-speaking regions, particularly in a globally active research field such as AI.

Fourth, consistent with the framework by Arksey and O'Malley [10], we did not include a formal quality assessment of the included studies. While appropriate for scoping reviews, future systematic reviews could integrate AI-specific appraisal tools (eg, the Minimum Information About Clinical Artificial Intelligence Modeling checklist and Checklist for Artificial Intelligence in Medical Imaging) to enhance interpretability. Importantly, the performance ranges reported across the studies (Table 3) should be approached with caution due to the heterogeneity of study designs, evaluation metrics, datasets, and model versions. Many included studies had proof-of-concept or single-institution designs with limited generalizability. Without standardized benchmarks or head-to-head comparisons, the reported values are best interpreted as illustrative of the field's current status rather than definitive benchmarks.

Publication bias is a potential concern, particularly given the rapid growth and high visibility of LLM research. Studies with positive or novel findings may be more likely to be published and indexed, whereas negative or inconclusive results may be underrepresented. Although publication bias was not formally assessed, this limitation should be considered when interpreting the results.

Fifth, while thematic synthesis is useful for structuring a heterogeneous literature, it is inherently interpretive. We mitigated bias by having 2 reviewers code independently and resolve discrepancies through consensus; however, subjective judgment may still have influenced the final thematic map. In addition, studies that addressed multiple tasks were assigned to a single primary category to avoid duplication. Certain subthemes—such as classification—appear under 2 overarching themes (decision support and workflow optimization). This placement reflects differences in the primary intent (eg, classifying reports and images to support diagnosis vs to streamline workflow), as detailed in the Results section. Finally, while the initial thematic analysis was conducted manually by human researchers, GPT-4 was later used as a supportive tool to assist in clustering and cross-verifying patterns. Given that GPT-4 is a generative and nondeterministic model, the reproducibility of its suggested outputs cannot be fully guaranteed. Therefore, this hybrid approach may introduce potential bias and variability, which should be considered when interpreting the thematic synthesis.

Conclusions

The integration of LLMs into radiology is accelerating but remains uneven across application domains. Structured tasks such as classification and information extraction are approaching maturity, whereas diagnostic reasoning and multimodal interpretation require substantial improvement. Safe clinical deployment will depend not only on technical performance but also on rigorous validation, global inclusivity, and ethical governance.

Acknowledgments

The authors would like to thank the librarian at Sultan Qaboos University for assistance in refining the search strategy and supporting the review process. The authors used ChatGPT (OpenAI; accessed July 2025) to assist with language refinement and proofreading. All scientific interpretations were conducted by the authors.

Funding

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files.

Abstract

Background: Predicting colorectal cancer (CRC) recurrence risk remains a challenge in clinical practice. Owing to the widespread use of radiomics in CRC diagnosis and treatment, some researchers recently explored the effectiveness of radiomics-based models in forecasting CRC recurrence risk. Nonetheless, the lack of systematic evidence of the efficacy of such models has hampered their clinical adoption.

Objective: This study aimed to explore the value of radiomics in predicting CRC recurrence, providing a scholarly rationale for developing more specific interventions.

Methods: Overall, 4 databases (Embase, PubMed, the Cochrane Library, and Web of Science) were searched for relevant articles from inception to January 1, 2025. We included studies that developed or validated radiomics-based machine learning models for predicting CRC recurrence using computed tomography or magnetic resonance imaging and provided discriminative performance metrics (c-index). Nonoriginal articles, studies that did not develop a model, and those lacking clear outcome measures were excluded from the study. The quality of the included original studies was assessed using the Radiomics Quality Score. A bivariate mixed-effects model was used to conduct a meta-analysis in which the c-index values with 95% CI were pooled. For the meta-analysis, subgroup analyses were conducted separately on the validation and training sets.

Results: This meta-analysis included 17 original studies involving 4600 patients with CRC. The quality of the identified studies was low (mean Radiomics Quality Score 13.23/36, SD 2.56), with limitations in prospective design and biological validation. In the validation set, the c-index values based on clinical features, radiomics features, and radiomics features combined with clinical features were 0.73 (95% CI 0.68 - 0.79), 0.80 (95% CI 0.75 - 0.85), and 0.83 (95% CI 0.79 - 0.87), respectively. In the internal validation set, the c-index values based on clinical features, radiomics features, and radiomics features+clinical features were 0.70 (95% CI 0.61 - 0.79), 0.83 (95% CI 0.78 - 0.88), and 0.83 (95% CI 0.78 - 0.88), respectively. Finally, in the external validation set, the c-index values based on clinical features, radiomics features, and radiomics features combined with clinical features were 0.76 (95% CI 0.70 - 0.83), 0.75 (95% CI 0.66 - 0.83), and 0.83 (95% CI 0.78 - 0.88), respectively.

Conclusions: Radiomics-based machine learning models, especially those integrating radiomics and clinical features, showed promising predictive performance for CRC recurrence risk. However, this study has several limitations, such as moderate study quality, limited sample size, and high heterogeneity in modeling approaches. These findings suggest the potential clinical value of integrated models in risk stratification and their potential to enhance personalized treatment, though further high-quality prospective studies are warranted.

KEYWORDS

colorectal cancer; radiomics; meta-analysis; clinical prediction model; PRISMA; Preferred Reporting Items for Systematic Reviews and Meta-Analyses

Introduction

Colorectal cancer (CRC) is ranked as the third most prevalent malignancy and the second most common cause of cancer-related deaths worldwide [1,2]. According to the International Agency for Research on Cancer, there were 1,926,100 (9.6%) new CRC cases and 903,900 (9.3%) CRC-related deaths in 2022 alone [2], highlighting CRC as a major public health concern. Although notable developments have been reported for targeted therapies, adjuvant chemotherapy, as well as radical surgery, cases of tumor recurrence are still a major issue leading to poor survival outcomes [3]. Therefore, early identification of CRC recurrence risk in clinical practice and the development of precise interventions would be imperative for improved clinical outcomes.

Machine learning (ML) and radiomics have recently gained widespread attention in oncological diagnoses and treatments, including in CRC [4,5]. Radiomics is an interdisciplinary technology that quantitatively analyzes high-dimensional features in medical images (eg, computed tomography [CT], magnetic resonance imaging [MRI], and positron emission tomography) to mine pathological information not visible to the naked eye. It entails segmenting regions of interest (ROIs) from medical images, extracting predefined mathematical features, and integrating them with ML or deep learning (DL) algorithms to generate interpretable clinical prediction models [6]. This technique has been extensively documented in the literature for cancer diagnosis and survival prediction [7-9]. Specifically within CRC, several studies have explored radiomics for recurrence prediction [10], using various image modalities including CT and MRI.

However, the available primary studies adopt diverse methodologies, using different imaging protocols, segmentation methods, feature extraction techniques, and model validation approaches. Therefore, the findings from such studies are inconsistent, making the clinical translation of individual models challenging. Although some reviews have summarized the application of radiomics in CRC management [11,12], none have specifically synthesized and quantitatively evaluated the predictive performance of radiomics-based ML models for CRC recurrence risk through meta-analysis. In addition, most of the previous reviews failed to discuss how integrative modeling, combined with radiomic and clinical variables, facilitates clinical decision-making to mitigate recurrence and improve patient management.

In this meta-analysis, we aimed to systematically assess the predictive performance of radiomics-based ML models on the risk of CRC recurrence, focusing on models incorporating both imaging and clinical features. In addition, we explored whether integrated approaches offer superior predictive accuracy compared to models using either data type alone. By comprehensively evaluating the existing evidence and its limitations, this study aims to provide robust evidence that can inform the development of effective, personalized intervention strategies for CRC.

Methods

Study Registration

This study was submitted to PROSPERO (International Prospective Register of Systematic Reviews; ID: CRD420250656632) and adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines.

Eligibility Criteria

The inclusion and exclusion criteria for study selection are summarized in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Studies enrolling patients with colorectal cancer with no requirement for cancer staging and metastatic resections.
- Studies involving radiomics-based machine learning (ML) predictive models and imaging data (magnetic resonance imaging and computed tomography)–based radiomics models.
- Studies published in English.

Exclusion criteria

- Meta-analyses, reviews, guidelines, expert opinions, and conference abstracts.
- Studies that performed variance factor analysis but did not construct a grammatical ML model.
- Studies without clearly defined endpoint metrics that could make it difficult to assess ML predictive accuracy.
- Studies that only performed image segmentation without constructing a full model.

Data Sources and Search Strategy

We systematically searched 4 databases (Web of Science, Cochrane Library, Embase, and PubMed) from inception to 1 January 2025. The search strategy involved a combination of Medical Subject Heading terms and free-text words. Detailed search strategies are provided in Table S1 in Multimedia Appendix 1 [10,13-28]. The search had no regional restrictions.

Study Selection and Data Extraction

The literature retrieved from the searched databases was imported into EndNote software (Clarivate). After eliminating redundant entries, the remaining articles were systematically screened based on titles and abstracts to discard references that did not meet the predetermined eligibility requirements. The full texts of the remnant studies were screened to obtain additional relevant studies.

Data extracted included titles, year of publication, first author, study type, country, patient sources, study design, treatment regimen, outcome definitions, radiomics source, segmentation method, number of imaging investigators, ROI segmentation software, number of cases and total number of outcome events in the validation and training sets, type of model used, variable screening method, modeling variables, overfitting assessment, and model rating metrics.

Two authors (YS and BL) independently selected the studies and extracted the data, with a third researcher (JA) consulted to resolve any disputes. The interrater agreement between the 2 independent reviewers during the study selection process was excellent, with a Cohen κ value of 0.895.

Study Quality and Risk-of-Bias Assessment

This meta-analysis included studies that used radiomics-based ML models to predict CRC recurrence risk. The Radiomics Quality Score (RQS) was used to determine the reporting completeness and methodological robustness of the included articles [29]. This 16-item scoring system, with a maximum score of 36, is specifically designed to facilitate radiomics studies that encompass various aspects, including image protocol quality, multiple segmentation processes, phantom studies across all scanners, imaging conducted at multiple time points, feature reduction techniques, and multivariable analyses incorporating nonradiomics features. In addition, it addresses the detection and discussion of biological correlates, cut-off analyses, discrimination statistics, calibration statistics, and prospective studies registered in trial databases. Furthermore, the system emphasizes the importance of validation, comparison against established “gold standards,” potential clinical use, cost-effectiveness analyses, and adherence to principles of open science and data sharing. Existing radiological studies are challenging to evaluate within the RQS framework, as they often lack phantom studies across different scanners, imaging at multiple time points, identification and discussion of biological correlates, prospective trial registration, and cost-effectiveness analyses.

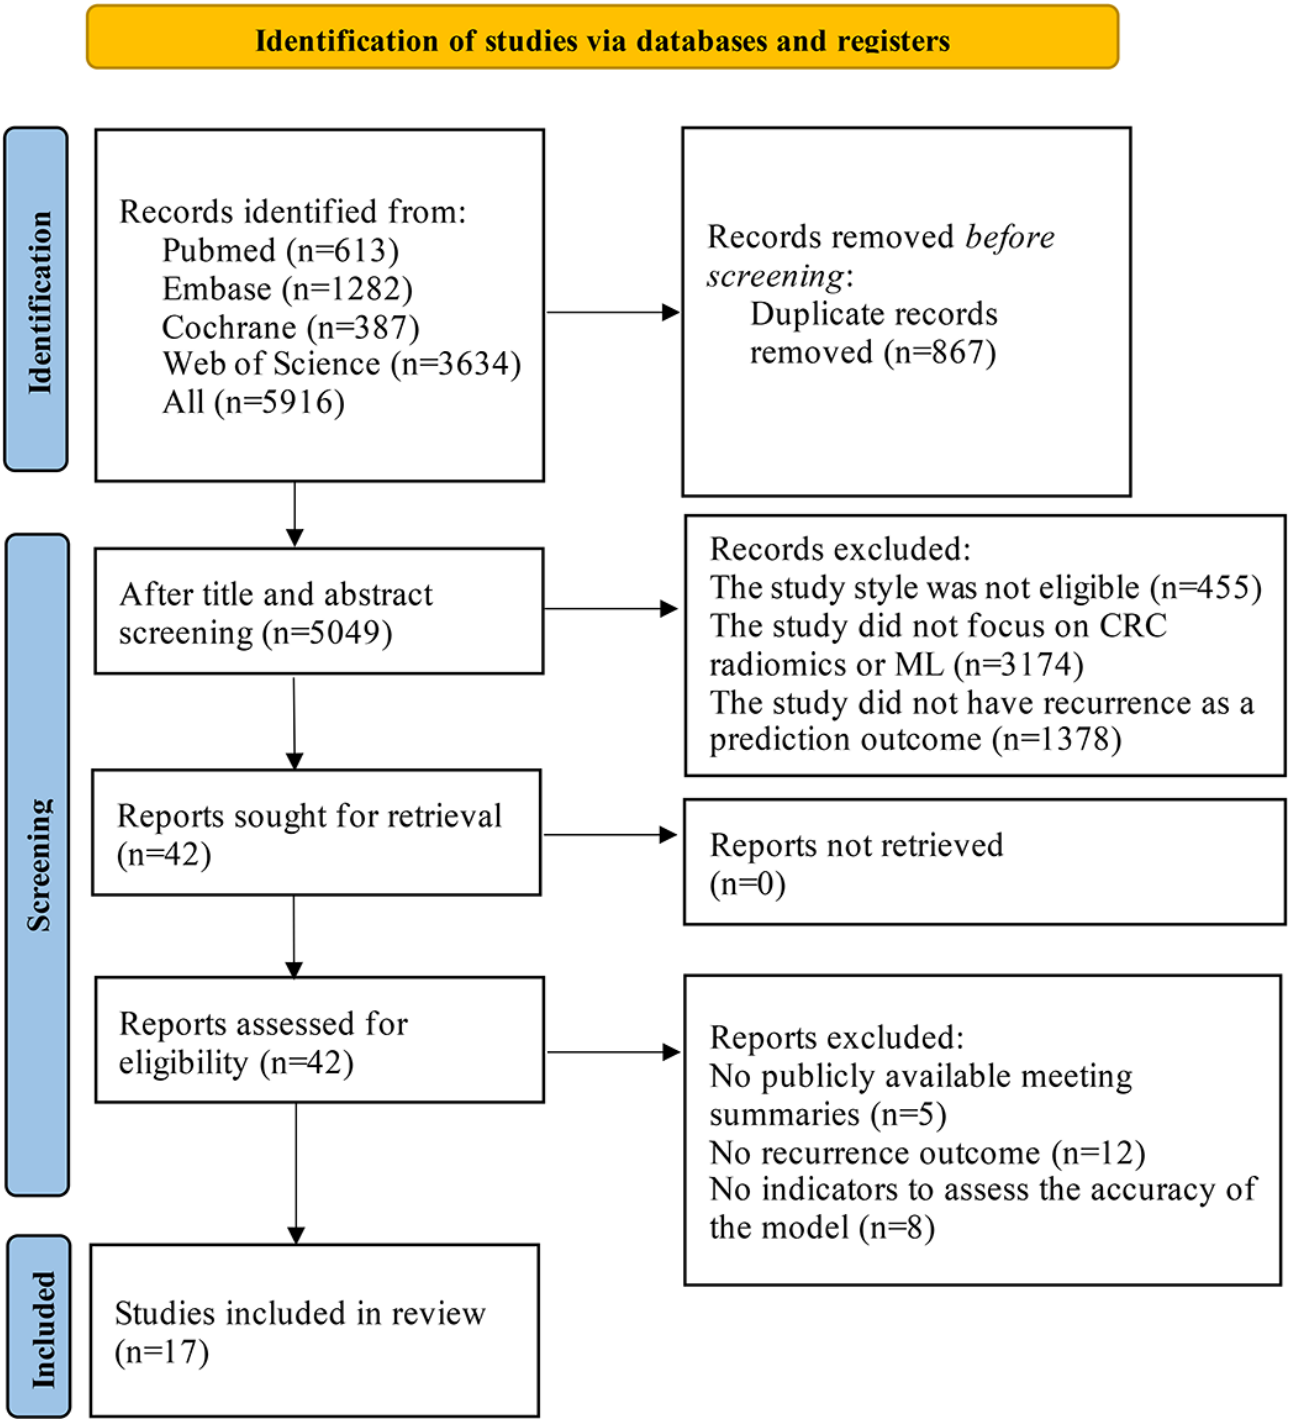
Two investigators (YS and CJ) administered the RQS measure and cross-checked the results upon completion. A third investigator (HS) was consulted to resolve any disputes.

Synthesis Methods

This meta-analysis aimed to synthesize the discrimination metrics (c-index) for evaluating the overall accuracy of ML models. For primary studies with 95% CI values or SEs for c-index values, the standard errors were estimated using Debray et al [30] methodological framework. Heterogeneity across studies was evaluated quantitatively using the I^2 index. The restricted maximum likelihood method was used to estimate between-group variance, which is recommended for its improved performance in handling heterogeneity, particularly when the number of studies is limited [31]. Given significant heterogeneity (defined as I^2>50%), a random-effects model was adopted for meta-analysis, and sensitivity analyses were performed. Publication bias was assessed through funnel plot asymmetry analysis and Egger test. Subgroup analyses were conducted to further detect possible sources of heterogeneity. Subgroup analyses were conducted based on imaging modality (CT vs MRI) and dataset type (training vs validation sets). The meta-analysis was conducted in Stata 15 (StataCorp LLC). In addition, to calculate the 95% prediction intervals, which estimate the range within which the true effect of a future study would be expected to fall, we used R software (version 4.4.3; R Development Core Team).

Quality of the Evidence (Grading of Recommendations, Assessment, Development, and Evaluation Assessment)

The GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) approach was used to determine the overall certainty of evidence for our primary outcome (predictive performance measured by c-index) [32]. Given that the included studies were observational in design, the initial evidence level was low. Therefore, we evaluated the evidence across the 5 GRADE domains (risk of bias [RoB], inconsistency, indirectness, imprecision, and publication bias), creating a final certainty rating for each model comparison.



Results

Study Selection

The initial search of the 4 databases yielded 5916 articles, of which 5049 remained after removing duplicates. Two reviewers independently assessed the title and abstract of all remaining articles, of which 5007 were excluded due to inconsistencies with the study goals. Reasons for exclusion were primarily nonrelevant study type (eg, reviews), not focusing on CRC radiomics or ML, or not having recurrence as a prediction outcome. The remaining articles were further subjected to a careful full-text review, after which 25 articles (5 conference abstracts, 12 articles without CRC recurrence endpoints, and 8 articles missing indicators for assessing model accuracy) were removed. Therefore, only 17 articles [10,13-28] were included in the study’s analyses. Figure 1 shows the study selection process.

RenderX

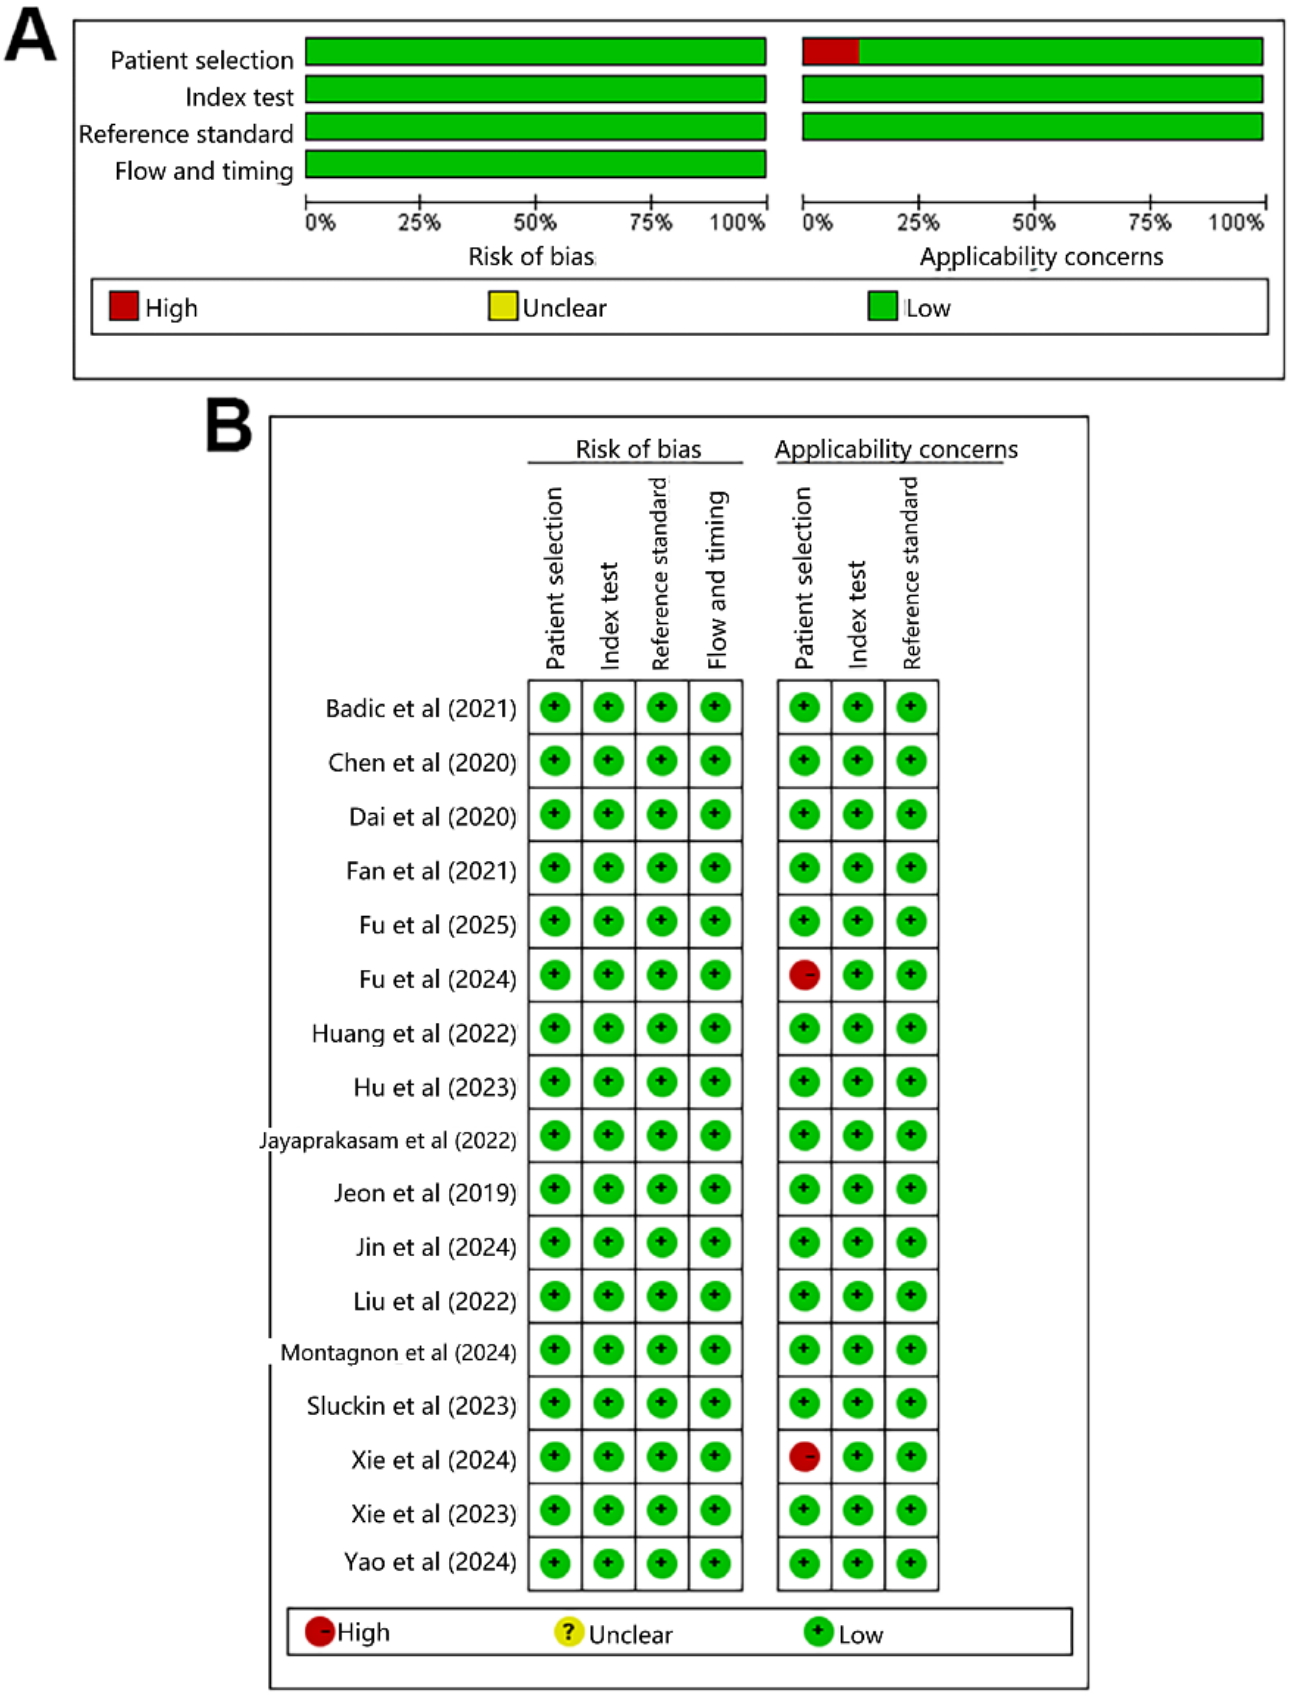
Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the study selection procedure for this systematic review and meta-analysis. CRC: colorectal cancer; ML: machine learning.

Features of the Included Study

This meta-analysis included 17 studies (involving 4600 patients with CRC) [10,13-28], which were published between 2019 and 2025. All 17 studies were cohort investigations, of which 12 were conducted in China [10,13-15,17,18,20,21,23,25-27], and the rest were conducted in Canada [16], France [24], South Korea [28], the Netherlands [19], and the United States [22]. Furthermore, 8 [16,20,22,23,25-28] and 9 [10,13-15,17-19,21,24] studies were single- and multicenter investigations, respectively. In addition, 7 [16-18,20,23-25], 9 [10,13-15,19,21,22,26,28], and 1 [27] studies involved patients with CRC, rectal cancer, and colon cancer, respectively. The included studies encompassed patients from stage I to IV, with the majority involving stages II and III. Most patients underwent curative-intent surgery, and 2 [18,20] studies specifically included cases with resectable metastases. All studies conducted radiomics analysis, of which 8 [13-15,19,21,22,26,28] and 9 [10,16-18,20,23-25,27] were based on MRI and CT images, respectively. Only 1 included study applied a DL model [16], while the remaining used diverse traditional ML algorithms [10,13-15,17-28]. Regarding the number of researchers involved in image segmentation, 2 studies [24,28] had only 1 imaging researcher, 9 studies [10,13,14,17-21,23] had 2 researchers

XSL•FO
RenderX

working together, 4 studies [15,22,25,26] had 3 researchers working together, and 2 studies [16,27] did not report the number of imaging researchers. Regarding the segmentation software used for ROI regions, ITK-SNAP and 3D Slicer were used in 8 [10,13-15,17,18,20,21] and 3 studies [20,24,25], respectively, with the rest of the studies using The Medical Imaging Interaction Toolkit (MITK) [16], Gold LX [22], INFINITE PACS [23], Radcloud radiomics platform, and the Eclipse system. Two studies [16,27] did not perform validation set partitioning, 1 study [22] performed 5-fold cross-validation, and 8 studies [10,13-15,17-21,25] had a separate external validation cohort [10,13-15,17-19,21], of which 5 studies [13-15,17,18] had 2 cohorts (internal and external). In 14 studies [10,13-21,23-25,28], clinical factors were combined with radiomics features to construct models, while the rest of the studies developed models using radiomics features or clinical factors alone [22,26,27]. Table S2 in Multimedia Appendix 1 [10,13-28] shows the basic characteristics of the included studies. Table S4 in Multimedia Appendix 1 [10,13-28] shows essential data for pooled analysis.



Study Quality and RoB Assessment

The average and median RQS scores of all 17 studies were 13.23 (SD 2.56) and 13 (IQR 6-16), respectively. All studies had "Image protocol quality," "Discrimination statistics," and "Cut-off analyses" items. In addition, 16 [10,14-28] out of 17 studies (94%) had "Calibration statistics" and "Validation" items [10,13-26,28]. On the other hand, 13 [10,13-15,17-23,25,26] out of 17 studies (77%) conducted "Multiple segmentations." Fourteen [10,13-21,23-25,27,28] out of 17 studies (82%) performed multivariable analysis and incorporated nonradiomics features [10,13,14,16-18,21-28], potentially yielding a more holistic model. A total of 11 [10,13,15,17-21,26-28] out of 17 studies (65%) reported potential clinical use and generated clinical decision curves. Two [15,16] studies provided open science and data access, and only 1 study [23] detected and discussed biological correlations. There were no phantom studies, and none of the studies used the comparison to the "gold standard," adjustment for multiple testing or feature reduction, prospective designs, imaging at multiple time points, or cost-effectiveness analysis. Supplementary material provides the detailed RQS scores for all included studies (Table S3 in Multimedia Appendix 1) [10,13-28].

The RoB and concerns regarding applicability for each included study were rigorously assessed using the Quality Assessment of Diagnostic Accuracy Studies (QUADAS-2) tool [33]. Notably, the included studies were cohort studies, and most of them were not excluded, which avoided the low RoB in case selection. Furthermore, considering that the included studies primarily used supervised ML with clearly defined outcomes, they had a low RoB. The implementation and interpretation of gold standards were performed by using clear criteria for recurrence, and the blinding did not influence outcomes; hence, the RoB was minimal. In addition, there was low RoB in case selection, given that known gold standards were applied. However, given that both studies enrolled cases of CRC-related metastases, there was a high RoB in the clinical applicability. A traffic-light plot summarizing the QUADAS-2 assessment for each study is presented in Figure 2.

Meta Analysis

Training Set

In total, 8 studies [10,13-15,18-20,25] compared models constructed to predict recurrence based on clinical factors, and a c-index of 0.73 (95% CI 0.69 - 0.78; GRADE=low) was obtained using a random-effects model (Figure 3A; Table S5 in Multimedia Appendix 1) [10,13-28]. Furthermore, 13 radiomics-based ML models had a pooled c-index of 0.83 (95% CI 0.77 - 0.89; GRADE=very low, due to inconsistency; Figure 3B; Table S5 in Multimedia Appendix 1) [10,13-28]. The c-index values of the CT-based and MRI-based radiomics summaries were 0.84 (95% CI 0.74 - 0.94; GRADE=very low, due to inconsistency) and 0.81 (95% CI 0.71 - 0.91; GRADE=very low, due to inconsistency), respectively. In addition, 12 studies [10,13-21,25,27] developed ML models based on radiomics features plus clinical features, with a pooled c-index of 0.82 (95% CI 0.72 - 0.91; GRADE=very low, due to inconsistency; Figure 3C; Table S5 in Multimedia Appendix 1) [10,13-28].

Validation Set

Eight studies [10,13-15,18-20,25] compared models constructed to predict recurrence based on clinical factors, and a pooled c-index of 0.73 (95% CI 0.68 - 0.79; GRADE=very low, due to inconsistency) was obtained using a random-effects model (Figure 4A; Table S5 in Multimedia Appendix 1) [10,13-28]. Publication bias was not detected by the Egger test (*P*=.11) and funnel plot (Multimedia Appendix 2). Furthermore, 16 radiomics features–based ML models had a pooled c-index of 0.80 (95% CI 0.75 - 0.85; GRADE=very low, due to inconsistency; Figure 4B; Table S5 in Multimedia Appendix 1) [10,13-28]. Publication bias was not detected by Egger test (*P*=.73) and funnel plot (Multimedia Appendix 3). The c-index values of the CT-based and MRI-based radiomic summaries were 0.83 (95% CI 0.80 - 0.87; GRADE=low) and 0.78 (95% CI 0.70 - 0.86; GRADE=very low, due to inconsistency), respectively. In addition, ML models based on radiomics features plus clinical features had a pooled c-index of 0.83 (95% CI 0.79 - 0.87; GRADE=very low, due to inconsistency; Figure 4C; Table S5 in Multimedia Appendix 1) [10,13-28]. Publication bias was detected by the Egger test (*P*=.01) and funnel plot (Multimedia Appendix 4).

XSL•FO
RenderX

Internal Validation Set

Overall, 6 studies [13-15,18,20,25] compared models constructed to predict recurrence based on clinical factors, and a pooled c-index of 0.70 (95% CI 0.61 - 0.79; GRADE=very low, due to inconsistency) was obtained using the random-effects model (Multimedia Appendix 5; Table S5 in Multimedia Appendix 1) [10,13-28]. Furthermore, 9 radiomics features–based ML models had a pooled c-index of 0.83 (95% CI 0.78 - 0.88; GRADE=very low, due to inconsistency; Multimedia Appendix 6; Table S5 in Multimedia Appendix 1) [10,13-28]. The c-index values for the CT-based and MRI-based models were 0.84 (95% CI 0.80 - 0.88; GRADE=low) and 0.82 (95% CI 0.71 - 0.92; GRADE=very low, due to inconsistency), respectively. In addition, ML models based on radiomics features plus clinical features had a pooled c-index of 0.83 (95% CI 0.78 - 0.88; GRADE=very low, due to inconsistency; Multimedia Appendix 7; Table S5 in Multimedia Appendix 1) [10,13-28].

External Validation Set

A total of 5 studies [10,14,15,18,19] compared models constructed to predict recurrence based on clinical factors and a pooled c-index of 0.76 (95% CI 0.70 - 0.83; GRADE=very low, due to inconsistency) was obtained using the random-effects model (Multimedia Appendix 8; Table S5 in Multimedia Appendix 1) [10,13-28]. Furthermore, 7 ML models established using radiomics features showed a pooled c-index of 0.75 (95% CI 0.66 - 0.83; GRADE=very low, due to inconsistency; Multimedia Appendix 9; Table S5 in Multimedia Appendix 1) [10,13-28], while that of MRI-based radiomics models was 0.74 (95% CI 0.62 - 0.85; GRADE=very low, due to inconsistency) and that for CT-based was 0.79 (95% CI 0.71 - 0.88; GRADE=low). In addition, the ML models derived from radiomics features plus clinical features had a pooled c-index of 0.83 (95% CI 0.78 - 0.88; GRADE=low; Multimedia Appendix 10; Table S5 in Multimedia Appendix 1) [10,13-28].

Sensitivity Analysis

The robustness of the pooled estimates was determined using leave-one-out sensitivity analyses applied to the validation set results. It was observed that, while the point estimate of the pooled c-index showed minor fluctuations upon the sequential removal of each study, the overall estimates remained stable and within a consistent range. The results of the sensitivity analysis are visualized in Figure 5.

Discussion

Principal Findings

This meta-analysis systematically evaluated and compared the predictive performance of different radiomics-based ML models for CRC recurrence risk. We postulated that models integrating both radiomic features and clinical variables may show superior predictive accuracy compared to either modality alone. The results revealed that the integrated models achieved the highest pooled c-index of 0.83 (95% CI 0.79 - 0.87) in the validation set, outperforming models based solely on radiomics features (c-index: 0.80; 95% CI 0.75 - 0.85) or clinical features (c-index: 0.73; 95% CI 0.68 - 0.79). Collectively, the findings of this study underscore the complementary value of combining quantitative imaging biomarkers with clinical data to enhance recurrence risk stratification in patients with CRC.

Notably, research on cancer diagnosis has seen a proliferation of systematic reviews and meta-analyses, particularly concerning CRC diagnosis, treatment response, and prognosis [34,35]. While this reflects the high clinical interest in radiomics, it also underscores the challenge of demonstrating novel and impactful contributions. Our study addresses a specific and clinically pertinent niche within this saturated field. Unlike previous reviews that often focus on a broader diagnostic or prognostic scope, this meta-analysis provides a dedicated quantitative synthesis focused exclusively on ML-based models for recurrence risk prediction. More importantly, we placed a particular emphasis on evaluating the incremental value of integrating radiomics with clinical features, a comparative approach that is less commonly the central focus of existing reviews. Therefore, we believe this work offers a nuanced and actionable insight: that the future of radiomics in clinical decision-making may lie not in replacing clinical factors, but in synergistically combining with them. This promising finding, however, should be considered in light of the detected publication bias, which indicates that the literature may lack smaller studies with negative results. Therefore, there is an urgent need for prospective validation studies in the future to confirm these promising findings.

Comparison to Prior Work

Multiple reviews and meta-analyses have reported the clinical use of potential biomarkers in predicting CRC recurrence postsurgery [36,37]. Nonetheless, the predictive value of radiomics remains inadequately assessed. Several studies have constructed different clinical prediction models for CRC recurrence risk. For instance, Alinia constructed a predictive model and validated its predictive efficacy using 7 ML algorithms based solely on clinicopathological features (eg, disease stage and treatment type) in a cohort of 284 patients with CRC [38]. In addition, Mohammadian Rad predicted recurrence risk using a gradient-boosting model that combined clinicopathological features (eg, carcinoembryonic antigen level) and demographic data [39]. Furthermore, Seong et al [40] integrated unstructured textual information from colonoscopy reports with clinical data for CRC risk stratification.

Despite their good predictive results, these studies had some limitations, which could be attributed to several factors. First, the performance of the models based on clinical data alone in predicting CRC recurrence risk was lower than that of the fusion model integrating radiomics features, highlighting the significance of combining imaging features for an improved predictive ability. Second, colonoscopy is highly invasive and relies largely on the endoscopist's experience and skill level; hence, its images are mainly based on morphological features, which lack quantitative analysis of deep infiltration or the tumor's metastatic potential, thus limiting the model's clinical applicability. Conversely, radiomics can extract hundreds of quantitative features (eg, texture and grayscale covariance matrix) from CT and MRI, among other images, reflecting tumor heterogeneity more comprehensively and providing a more reliable individualized treatment basis.

Herein, the CT and MRI images were predominantly used to predict CRC recurrence risk. Notably, there were no significant differences between the CT and MRI radiomics-based prediction models in the validation set. Nonetheless, MRI radiomics studies often require integrated multisequence image segmentation and feature extraction, whereas CT radiomics is usually based on a single modality (eg, enhanced CT) and features a relatively simplified process. In other words, MRI image segmentation has a greater workload [41]. Given that there is no significant difference in the predictive value between the 2, CT-based radiomics, despite its simplicity, can still be considered in the future in constructing radiomics-based ML prediction models.

Selecting ML algorithms remains a notable challenge when constructing radiomics-based predictive models, especially for image-processing tasks. Notably, ML models could be influenced by traditional ML and DL algorithms [42]. Traditional ML relies on the (manual) segmentation of images, image texture screening for model construction, and model validation. When extracting and screening image textures, some of the image information may be lost, somewhat impacting the model's accuracy [43]. On the other hand, DL can intelligently segment images or be trained directly on segmented images. Furthermore, it incorporates the extraction and screening of image texture features into the training process, maximizing image information retention and providing better accuracy [44,45]. Here, manual segmentation was used owing to the few enrolled studies. Therefore, future studies should further explore the application of DL methods in constructing radiomics-based predictive models, potentially improving image recognition.

The role of clinical and demographic characteristics is particularly important when constructing prediction models based on radiomics, as they can accurately reflect disease progression. Some studies reported a significant correlation between laboratory test results and tumor staging and prognosis information, including tumor markers [46,47]. In addition, social factors such as marital status and family income were markedly linked to the prognosis of patients with tumors [48,49]. These studies highlight the potential significance of screening and incorporating meaningful clinical and sociodemographic characteristics when constructing radiomics-based prediction models. To effectively integrate these multimodal models into clinical practice, future efforts should focus on developing interoperable digital health platforms that can seamlessly combine radiomic features with real-time clinical and

XSL•FO
RenderX

demographic data. Such systems should be designed to interface with existing electronic health records, support automated image analysis, and generate interpretable risk scores that can be readily used by clinicians for personalized recurrence risk assessment. In addition, implementation studies are needed to evaluate the usability, workflow integration, and clinical impact of these tools in routine care settings.

When constructing a clinical prediction model, validation is often conducted both internally and externally. For internal validation, both the training and validation sets are often derived from the same dataset and split through random sampling, among other methods [50]. Notably, internal validation often has limitations on the model's interpretation and generalizability, especially in radiomics research that is highly dependent on images. Consequently, external validation, which involves datasets from different sources, is often recommended [51]. Herein, internal and external validation performances were assessed separately, revealing that the latter exhibited desirable prediction accuracy.

The significant statistical heterogeneity observed in our meta-analysis, while addressed by the use of a random-effects model, warrants a deeper qualitative discussion regarding its potential sources. The methodological diversity across the included studies likely introduced substantial variability that influences the interpretation of our pooled estimates. For instance, differences in imaging protocols (eg, CT vs MRI, scanner manufacturers, and contrast-enhancement phases) directly affect radiomics feature values, making it challenging to harmonize models across studies. Variations in patient characteristics, such as the inclusion of different cancer stages (I-IV), alter the underlying recurrence risk profiles of the cohorts. Simpler models, such as logistic regression, offer high interpretability but may fail to capture intricate, nonlinear relationships in the radiomics data. In contrast, more complex traditional ML algorithms (eg, random forest and support vector machines) can model these nonlinearities and often achieve higher accuracy, albeit at the cost of increased computational demand and potential overfitting if not properly regularized. While DL models hold the promise of end-to-end feature learning and potentially superior performance by automatically discovering relevant patterns from image data, they were scarcely represented in our included studies and require large datasets to train effectively. Finally, the definition of the recurrence outcome itself varied, encompassing disease-free survival, local recurrence, or time-to-recurrence, each capturing a slightly different clinical endpoint. Despite the methodological heterogeneity, our meta-analysis offers a comprehensive and robust synthesis of the current evidence. The fact that a consistently strong discriminative performance (c-index >0.80) was maintained across such varied technical and clinical contexts is a key finding, underscoring the robustness of radiomics-based prediction for CRC recurrence.

Study Limitations

Despite its valuable insights, this study had some limitations. First, the number of eligible studies was limited, which constrained more granular subgroup analyses. In addition, the geographic origin of the evidence base was imbalanced, with 12 of the 17 included studies conducted in China. While this provides a robust assessment within that specific context, it may limit the generalizability of our findings to other populations with different genetic backgrounds, ethnicities, and healthcare systems (eg, in terms of screening protocols, treatment strategies, and staging criteria). Therefore, further multinational studies are advocated to validate the broader applicability of these radiomics models and to investigate potential geographic or ethnic variations in their performance. Second, the limited number of studies resulted in even less data for the subgroup analysis of images, possibly affecting result interpretation. Third, although subgroup analyses based on the image source (CT vs MRI) were performed in the validation set, thereby explaining some of the heterogeneity, there was significant heterogeneity. This likely reflects the clinical and methodological diversity across studies, including differences in imaging protocols, patient characteristics, model types, clinical variables, and recurrence definitions. These factors, compounded by the limited number of studies, make it difficult to quantitatively identify other potential sources of heterogeneity and highlight the challenges in achieving standardized validation across independent cohorts. Furthermore, regarding reproducibility, only 2 studies provided open-source code or datasets. This lack of transparency prevents independent validation of the proposed models and limits the clinical translation of our findings. In the future, researchers should promote open science practices by sharing code and data where possible to facilitate verification and build upon existing work. Finally, the assessment of model performance was primarily based on the c-index due to inconsistent reporting of calibration metrics (eg, Brier score and calibration slope) and time-dependent discrimination measures (eg, time-dependent–area under the curve) across studies. While the c-index provides valuable evidence of the models' ability to stratify risk, this assessment should be complemented by future evaluations of calibration to ensure the accuracy of predicted probabilities for individual patients. Establishing robust calibration will be a crucial next step in translating these promising discriminative models into reliable clinical tools. These aspects represent important limitations that should be addressed in future studies with larger and more standardized datasets.

Conclusions

This study demonstrates that ML models based on radiomics and incorporating clinical features exhibit superior performance in predicting the risk of CRC recurrence, with a significantly higher discriminative ability (c-index) than models relying only on a single data source. This finding highlights the significant value of multimodal data fusion in improving prediction accuracy. However, most of the existing studies use traditional ML methods that rely on manual feature extraction and screening, which may lead to information loss and limited model generalization ability. Future studies should further explore the potential of end-to-end feature learning methods, such as DL, to improve model robustness and clinical translational value by automatically extracting high-level image features and reducing manual intervention, and prioritize prospective, multicenter validation with standardized protocols and explainable AI to facilitate clinical adoption.

Abstract

Background: Chronic diseases present significant challenges in health care, requiring effective management to reduce morbidity and mortality. While digital technologies like wearable devices and mobile applications have been widely adopted, large language models (LLMs) such as ChatGPT are emerging as promising technologies with the potential to enhance chronic disease management. However, the scope of their current applications in chronic disease management and associated challenges remains underexplored.

Objective: This scoping review investigates LLM applications in chronic disease management, identifies challenges, and proposes actionable recommendations.

Methods: A systematic search for English-language primary studies on LLM use in chronic disease management was conducted across PubMed, IEEE Xplore, Scopus, and Google Scholar to identify articles published between January 1, 2023, and January 15, 2025. Of the 605 screened records, 29 studies met the inclusion criteria. Data on study objectives, LLMs used, health care settings, study designs, users, disease management tasks, and challenges were extracted and thematically analyzed using the Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews guidelines.

Results: LLMs were primarily used for patient-centered tasks, including patient education and information provision (18/29, 62%) of studies, diagnosis and treatment (6/29, 21%), self-management and disease monitoring (8/29, 28%), and emotional support and therapeutic conversations (4/29, 14%). Practitioner-centered tasks included clinical decision support (8/29, 28%) and medical predictions (6/29, 21%). Challenges identified include inaccurate and inconsistent LLM responses (18/29, 62%), limited datasets (6/29, 21%), computational and technical (6/29, 21%), usability and accessibility (9/29, 31%), LLM evaluation (5/29, 17%), and legal, ethical, privacy, and regulatory (10/29, 35%). While models like ChatGPT, Llama, and Bard demonstrated use in diabetes management and mental health support, performance issues were evident across studies and use cases.

Conclusions: LLMs show promising potential for enhancing chronic disease management across patient and practitioner-centered tasks. However, challenges related to accuracy, data scarcity, usability, and ethical concerns must be addressed to ensure patient safety and equitable use. Future studies should prioritize the integration of LLMs with low-resource platforms, wearable and mobile technologies, developing culturally and age-appropriate interfaces, and establishing robust regulatory and evaluation frameworks to support safe, effective, and inclusive use in health care.

RenderX

Introduction

Chronic diseases, such as diabetes, heart disease, asthma, lung disease, depression, hypertension, Alzheimer disorder, and cancer, are a significant global burden on health care systems [1-3]. These conditions often lead to long-term health issues and have profound physical, psychological, and social impacts on patients [1,2]. Chronic diseases demand continuous, personalized care, often resource-intensive and difficult to scale [1]. Therefore, disease management, which encompasses screenings, regular check-ups, monitoring, coordination of treatment, medication adherence, lifestyle modifications, and patient education, is crucial for improving patient outcomes, enhancing quality of life, and reducing the overall burden on health care systems [1]. However, the resource-intensive nature of personalized, continuous care often makes it inaccessible to many patients, particularly in underserved populations where limited access to health care professionals and resources creates significant barriers to effective disease management [3].

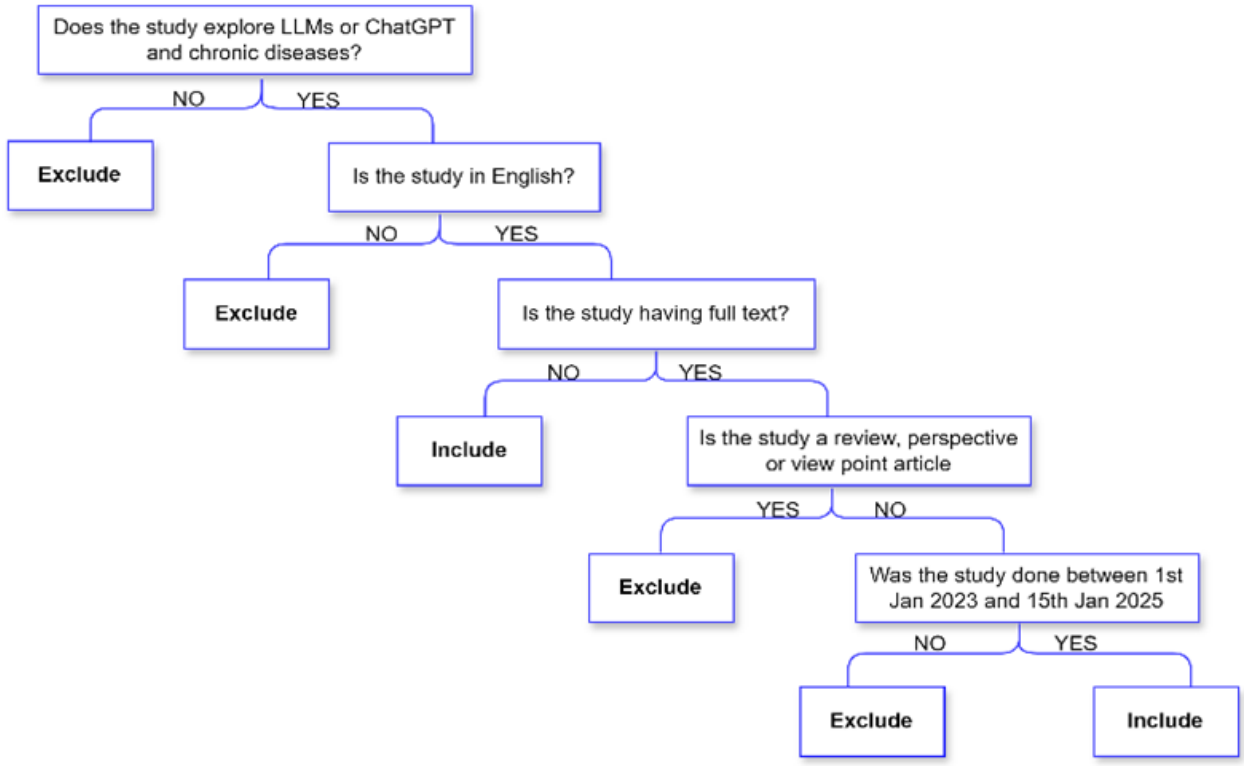
In recent years, the use of digital technologies such as wearable devices [4], mobile apps [5], and chatbots [6,7] has grown significantly in the management of chronic diseases. These have mainly been used for health care tasks, including patient education, symptom monitoring, and medication management [4-7]. The recent emergence of large language models (LLMs) such as GPT, Palm, Llama, and LaMDA [8-11] has demonstrated growing potential in health care applications. These models have been applied in health care for tasks such as personalized treatment recommendations, medical diagnosis, medical record summarization, and interpretation of clinical data to support clinical decision-making and disease management [12-16].

Chronic disease management requires continuous monitoring, patient education, treatment coordination, and personalized care strategies [1]. Recent advancements in LLMs have introduced new possibilities for improving these tasks. For instance, ChatGPT has been explored in providing personalized health advice, enhancing patient engagement, and supporting symptom monitoring [12,13]. In diabetes management, GPT-based models have been investigated for interpreting continuous glucose monitoring data, providing personalized lifestyle recommendations [17], and assessing individualized risk profiles for complications such as retinopathy [17]. Beyond diabetes, LLMs such as LLaMA and GPT have been investigated for mental health support [18], blood pressure measurement using wearable bio signals [19], management of sickle cell anemia [20], and dissemination of information on inflammatory bowel diseases to patients and health care professionals [21].

Despite these applications, several challenges affect the effectiveness of LLMs in chronic disease management, including inaccurate responses, limited and biased datasets, and ethical concerns [17,22,23]. These issues raise concerns regarding the accuracy, reliability, and clinical applicability of LLM-generated recommendations [24]. Given these challenges, a comprehensive review is essential to assess the current applications, identify key limitations, and propose strategies to enhance the effectiveness and safety of LLMs in chronic disease care. While existing reviews explore LLMs in general health care, this scoping review uniquely focuses on their role in chronic disease management. It synthesizes evidence across patient- and practitioner-centered applications, domain-specific challenges, and provides actionable recommendations. Specifically, this review aims to evaluate the current applications of LLM in chronic disease management tasks, identify key challenges, and provide actionable recommendations to address identified challenges.

Methods

Search Strategy and Information Sources



This scoping review explored the use of LLMs in chronic disease management following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) [25]. A comprehensive search was conducted in PubMed, Scopus, IEEE Xplore, and Google Scholar, selected for their coverage of peer-reviewed medical, technical, and AI-related research. Google Scholar was included to capture a broad range of academic publications, including preprints and conference papers that may not be covered by traditional databases. Search terms included combinations of “Large language models,” “LLMs,” “ChatGPT,” “chronic diseases,” and “chronic disease management.” The search targeted both published and unpublished English-language articles from January 1, 2023, to January 15, 2025, ensuring a focus on recent advancements in LLM applications in health care.

Article Selection

Studies were included if they focused on applications of LLM in chronic disease management, provided full-text access, were published in English, and appeared between January 2023 and January 15, 2025. Exclusion criteria eliminated nonprimary research (reviews, editorials, viewpoints, and commentaries), abstracts without full text, non-English publications, and articles outside the date range. To capture emerging research and potentially studies, reputable non-peer–reviewed preprints from established repositories such as arXiv and medRxiv were included. Figure 1 illustrates the eligibility screening process with a decision tree.

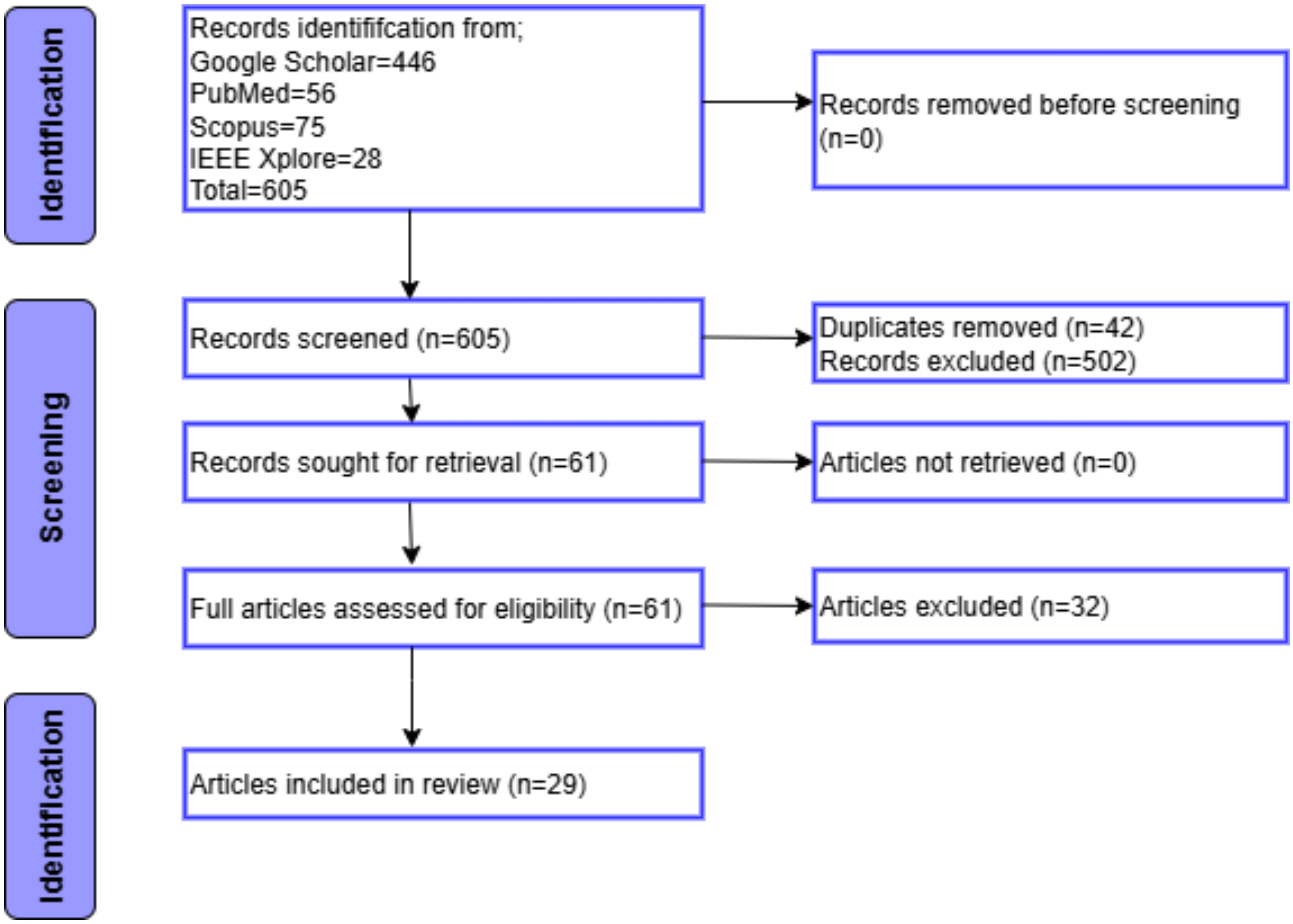
XSL•FO
RenderX

Figure 1. Decision tree for assessing article eligibility. The exclusion of certain publication types was necessary to ensure the review focused on primary research and empirical studies that directly address the application of large language models in chronic disease management.

Data Extraction and Synthesis

The data from selected studies were extracted into a structured form that captured study objectives, the LLMs used, health care settings, study designs, disease management tasks, identified challenges, evaluation methods, and target users. These extracted data points were selected to ensure a structured and objective analysis aligned with the study's aims. Study objectives provided insight into the intended applications of LLMs in chronic disease management, while health care settings contextualized their use across clinical and patient-centered environments. Study design and evaluation methods were included to assess methodological rigor and the validity of findings. In addition, data on LLM models, disease management tasks, and key challenges enabled a systematic evaluation of current applications, limitations, and areas for future research.

The Mixed Methods Appraisal Tool (MMAT, version 2018) [26] was used to perform a formal methodological quality assessment. The MMAT was selected due to its flexibility in evaluating diverse study designs included in the review. Two reviewers independently appraised each study using the 5 criteria relevant to its methodological design, with discrepancies resolved through discussion and reached consensus on final ratings. Consistent with scoping review methodology, the studies were not excluded based on quality, but results inform the interpretation of findings [25]. The findings from the included studies were synthesized and presented in alignment with the study objectives. A thematic analysis approach was used to categorize qualitative insights, grouping findings into patient-centered tasks, practitioner-centered tasks, and challenges. Discrepancies in data interpretation were resolved through consensus among the reviewers. Reference management and citation generation were conducted using Mendeley.



Results

Included Studies

The PRISMA flow diagram (Figure 2) outlines each stage of the study selection process. The PRISMA-ScR framework was followed to ensure transparency and reproducibility, incorporating detailed search strategies and clearly defined exclusion criteria. A total of 446 records were identified from Google Scholar, 75 from Scopus, 56 from PubMed, and 28 from IEEE Xplore. After removing duplicates, 242 unique records underwent title and abstract screening, resulting in 61 articles for full-text review. Following the application of eligibility criteria, 29 articles were included in the final analysis.

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.

Characteristics of Included Articles

Table 1 provides the characteristics of the 29 articles included in this scoping review. The articles were categorized based on publication type, with the majority of the studies being journal articles (n=18), followed by conference papers (n=8), and preprints (n=3). The studies used a variety of research designs, including experimental (n=10), qualitative research (n=3), comparative studies (n=4), cross-sectional study (n=2), case study (n=1), observational (n=3), retrospective cohort designs (n=3), mixed methods (n=1), pilot study (n=1), and prospective study (n=1). Table 1 provides more details on the characteristics of the reviewed studies.

Table . Study characteristics (n=29).

Study	Country	Article category	Study objective	Health care setting	Study design	Evaluation
Montagna et al [6]	Italy	Conference paper	To design and implement a system architecture for a chatbot-based home blood pressure monitoring solution.	Home care setting	Experimental (system design and prototype development)	Human evaluation
Yang et al [16]	China	Preprint	To explore the application of a fine-tuned model-based outpatient treatment support system for treating patients with diabetes and to evaluate its effectiveness and potential value.	Clinical (West China Hospital) home care	Experimental (fine-tuning)	Human evaluation and automated evaluation metrics
Raghu et al [17]	India	Journal article	To evaluate the ability of ChatGPT to predict the diabetic retinopathy risk.	—[a]	Comparative study	Human evaluation
Song et al [18]	The Republic of Korea	Preprint	To investigate the experiences of individuals using LLM[b] chatbots for mental health support.	Korea Advanced Institute of Science and Technology	Qualitative study	Human evaluation
Liu et al [19]	China	Conference paper	Explore the use of LLMs for cuffless blood pressure measurement using wearable bio signals	Home care settings	Experimental (cuffless blood pressure measurement using LLMs)	Human evaluation
Ogundare et al [20]	Nigeria	Conference paper	To investigate the potential of LLMs in ambulatory devices for sickle cell anemia management.	Home care setting	Case study	Automated evaluation metrics
Cankurtaran et al [21]	Turkey	Journal article	To evaluate the performance of ChatGPT within the context of inflammatory bowel disease.	—	Cross-sectional study	Human evaluation
Wang et al [22]	China	Conference paper	To enhance the diagnosis and treatment of depression.	Clinical and home-care settings	Experimental (pre-training and fine-tuning)	Human evaluation
Abdullahi et al [23]	Germany	Journal article	To explore the potential of three popular Large Language Models in medical education to enhance the diagnosis of rare and complex diseases.	Home care setting	Qualitative study	Human evaluation and automated evaluation metrics

XSL•FO
RenderX

Study	Country	Article category	Study objective	Health care setting	Study design	Evaluation
Al Anezi [24]	Saudi Arabia	Journal article	To analyze the use of ChatGPT as a virtual health coach for chronic disease management.	Home care setting	Quasi-experimental design	Human evaluation
Athavale et al [27]	United States	Journal article	To assess whether chatbots could assist with answering patient questions and electronic health record inbox management	Clinical (Division of Vascular Surgery, Stanford University School of Medicine in Palo Alto)	Experimental (chatbot assistance in chronic venous disease management)	Human evaluation
Soto-Chávez et al [28]	Colombia	Journal article	To evaluate the reliability and readability of Spanish chronic disease information presented to ChatGPT	—	Cross-sectional study	Human evaluation
Abbas et al [29]	Pakistan	Journal article	To assess the predictive accuracy of ChatGPT-assisted machine learning models for various chronic diseases.	Clinical (Tertiary hospital)	Observational study	Automated evaluation metrics
Anderson et al [30]	United States	Conference paper	The study aims to discover and rank novel relationships between various aspects of this condition.	—	Experimental	Human evaluation and automated evaluation metrics
Ding et al [31]	Taiwan	Conference paper	To develop and evaluate Large Language Multimodal Models that integrate clinical notes and laboratory test results for predicting the risk of chronic diseases, particularly type 2 diabetes mellitus	Clinical (Eastern Memorial Hospital in Taiwan	Retrospective cohort study	Automated evaluation metrics
Jairoun et al [32]	Malaysia	Journal article	To investigate the benefits and risks associated with the application of ChatGPT in managing diabetes and metabolic illnesses	—	Qualitative study	Human evaluation
Mondal and Naskar [33]	India	Journal article	To evaluate GPT-4's competency in reviewing diabetic patient management plans compared to expert reviews.	General medical setting	Comparative study	Human evaluation and automated evaluation metrics

XSL•FO
RenderX

Study	Country	Article category	Study objective	Health care setting	Study design	Evaluation
Liu et al [34]	N/S[a]	Journal article	To leverage LLMs and multi-prompt engineering for chronic disease management, specifically for detecting mental disorders through user-generated textual content.	Online platforms	Experimental (few-shot learning)	Automated evaluation metrics
Liao et al [35]	Taiwan	Conference paper	To develop an EHR-based chronic disease prediction platform using LLMs for diabetes, heart disease, and hypertension.	Clinical (Far Eastern Memorial Hospital, Taiwan)	Retrospective cohort study	Automated evaluation metrics
Ding et al [36]	Taiwan	Journal article	Predict new-onset type 2 diabetes using large language multimodal models with EHR data	Clinical (Far Eastern Memorial Hospital, Taiwan)	Retrospective cohort study	Automated evaluation metrics
Dao et al [37]	Ireland and Singapore	Conference paper	Design and evaluate an AI chatbot system using GPT-3.5 for proactive diabetes prevention	Community-based setting	Experimental (AI design and evaluation)	Automated evaluation metrics
Khan [38]	United States	Journal article	Assess the efficacy of ChatGPT in facilitating self-management strategies for diabetic patients.	Outpatient diabetes care	Observational study	Human evaluation
Mondal et al [39]	India	Journal article	To evaluate the effectiveness of ChatGPT, an LLM, in providing answers to queries related to lifestyle-related diseases or disorders	Clinical and academic settings	Observational study	Human evaluation
Young et al [40]	United States	Journal article	Assess LLMs' capacity to deliver age-appropriate explanations of chronic pediatric conditions to enhance patient understanding.	Clinical (Boston Children's Hospital)	Pilot study	Human evaluation
Li et al [41]	China	Journal article	Develop DeepDR-LLM, an integrated AI system for primary diabetes care and diabetic retinopathy (DR) screening	Low-resource primary care settings	Experimental	Human evaluation and automated evaluation metrics
Ying et al [42]	China	Preprint	To evaluate the feasibility and utility of ChatGPT in diabetes education using retrospective and real-world patient questions.	Outpatient setting	Mixed methods	Human evaluation

XSL•FO

Study	Country	Article category	Study objective	Health care setting	Study design	Evaluation
Li et al [43]	China	Journal article	To evaluate the performance of LLMs in diabetes-related queries and their potential to assist in diabetes training for primary care physicians	Primary diabetes care, endocrinology, and diabetes management.	Prospective study	Human evaluation and automated evaluation metrics
Hussain and Grundy [44]	Australia	Journal article	Evaluate the responses of ChatGPT models to queries from diabetes patients, assessing their accuracy, biases, and limitations in providing self-management advice.	Home care setting	Comparative study	Human evaluation
Wang et al [45]	China	Journal article	To evaluate the potential of the RISE framework to improve LLMs' performance in accurately and safely responding to diabetes-related inquiries.	Home care setting	Comparative study	Human evaluation

[a]Not available.

[b] LLM: large language model.

As shown in Table 1, most studies were conducted in China (7/29, 24%) and the United States (4/29, 14%), with limited representation of low-resource settings. Experimental designs were predominant (10/29, 35%), and nearly half of the studies (14/29, 48%) focused on diabetes management. The studies primarily focused on adult populations (28/29, 96%), with only 1 study (1/29, 4%) specifically addressing pediatric applications. Human evaluation was the most common evaluation method (16/29, 55%), followed by automated evaluation metrics (10/29, 35%) used in prototype evaluation, with some studies using both approaches (3/29, 10%). Studies were carried out in diverse health care settings, with home care settings (10/29, 35%) and clinical settings (9/29, 31%) being the most common. This diversity in study characteristics reflects the broad application of LLMs across various health care contexts for chronic disease management.

Methodological Quality Assessment

Using the Mixed Methods Appraisal Tool [26], the studies were categorized as quantitative descriptive studies (19/29, 66%), comprizing observational, cross-sectional, case study, system development, prototype evaluation, and comparative analyses. Quantitative nonrandomized studies (3/29, 10%) included retrospective cohort and quasi-experimental designs, qualitative studies (5/29, 17%), and 2 studies with mixed methods design (2/29, 7%). Of the 29 studies, 18 studies (62.1%) were classified as high quality (meeting ≥4 of 5 criteria), 9 studies (31.1%) as moderate quality (meeting 2 - 3 criteria), and 2 studies (6.9%) as low quality (meeting ≤1 criterion). The most common methodological limitations identified across studies included inadequate sampling strategy descriptions, limited participant demographic reporting, use of synthetic clinical data, and lack of external validation. Detailed quality appraisal results for each study are provided in Multimedia Appendix 1. Table 2 provides an overview of the LLM types, users, tasks, and challenges identified across the included studies.

XSL•FO
RenderX

Table . Large language model tasks and challenges (N=29).

Study	LLM[a]	Users	Disease management tasks	Challenges
Montagna et al [6]	GPT-3	Individuals with hypertension	Patient engagement blood pressure monitoring and management.	• The incorrect way patients measure their blood pressure
Yang et al [16]	ChatGLM-6B	Patients diagnosed with diabetes	Treatment recommendations, suggesting appropriate laboratory tests, and medication	• Inadequate understanding of complex medical records • The small size of the training data
Raghu et al [17]	ChatGPT	Practitioner (ophthalmologist)	Patient education, medical reports: diagnoses and predictions	• Incorrect information, privacy and protection of patient data
Song et al [18]	ChatGPT Llama	Individuals who have used LLM chatbots for mental health support	• Providing emotional support, engaging in therapeutic conversations, and offering recommendations tailored to individual contexts. • Addressing specific stressors or challenges faced by individuals.	• Cultural Misalignments: Participants noted that recommendations from LLM chatbots often felt like they were translated from stereotypical American responses. • Linguistic Biases: Participants often felt compelled to use English when interacting with LLM chatbots. • Therapeutic Misalignment.
Liu et al [19]	Gemma-7B, Mistral-7B, Yi-6B, MedAlpaca-7B, LLaMA2-7B, LLaMA3-8B, Qwen2-7B, PalmyraMed-20B, PMCLLaMA13B, OpenBioLLM-8B	Patients with hypertension	Cardiovascular disease management via cuffless blood pressure measurement.	• Dataset imbalances diminish accuracy • Privacy concerns in real-world deployment • Need for calibration to mitigate individual variability
Ogundare et al [20]	Unspecified	Sickle cell patients and clinicians	Assessing anemia severity in real-time, predicting time to vaso-occlusive episodes, and communicating with emergency personnel.	• Creation of a reliable non-invasive tool for angiogenic level assessment, development of a biophysics model, and practical considerations of LLM communication with emergency personnel
Cankurtaran et al [21]	ChatGPT	Inflammatory bowel disease patients and health care professionals.	• Tailored responses, educational resources • monitoring and follow-up, patient empowerment • Decision support	• Insufficient responses • Limited scope of knowledge (up-to-date information)
Wang et al [22]	LLaMA-7B, ChatGLM-6B Alpaca.	Individuals with depression.	Diagnosis and treatment of depression	• Absence of pretraining data sets on depression • Hallucination problem • Evaluation methodologies emphasize predictive performance and lack • Quantification of the impact on patient treatment

XSL•FO
RenderX

Study	LLM[a]	Users	Disease management tasks	Challenges
Abdullahi et al [23]	Bard ChatGPT 3.5 and GPT-4	• Physicians • Medical Students Resident Nurses • Nurse Practitioners	• Clinical Decision Support • Medical Education • Disease Diagnosis	• Inconsistency in Responses, LLMs do not always explicitly indicate their level of uncertainty due to Limited Scope, Sample Size, and knowledge. ChatGPT-3.5 and GPT-4 were limited to health care data available up to 2021 • LLMs may generate different responses for the same prompt
Al Anezi [24]	ChatGPT	Outpatients with chronic diseases	• Providing information about patient conditions, treatment plans, and medication schedules. Reminders for medication intake, appointments, or lifestyle adjustments. • Assisting in behavior change efforts by providing evidence-based strategies, personalized goal-setting techniques, and reminders for healthy habits. • Identifying barriers to behavior change and exploring solutions to overcome them. • Monitoring blood pressure, blood glucose levels, or weight and providing feedback based on shared data.	• Limited physical examination, Lack of human connection and empathy • Complexity of individual cases • Privacy and security concerns • Legal and ethical challenges, language and cultural barriers, technical limitations, diagnostic limitations, and lack of reliability and trust • Ineffectiveness in emergencies
Athavale et al [27]	ChatGPT 4.0	Patient	Answered administrative and non-complex medical questions well, and electronic health record inbox management. Answering complex medical questions	• Hallucinations • Need for extensive supervised training by subject experts • No regulatory approval
Soto-Chávez et al [28]	ChatGPT	Patients with chronic diseases using the Spanish language	Evaluating the reliability and readability of ChatGPT-generated patient information on chronic diseases in Spanish.	• ChatGPT was trained in English, which affects the accuracy of responses in Spanish • Lower reliability on chronic diseases like heart failure and chronic kidney disease
Abbas et al [29]	GPT-3.5	Machine Learning engineers, clinical researchers	Chronic disease prediction	• lack of longitudinal data • limited generalizability
Anderson et al [30]	GPT (Generative Pre-trained Transformer)	Practitioners	Discover and rank novel relationships between various aspects of chronic lower back pain.	

XSL•FO
RenderX

Study	LLM[a]	Users	Disease management tasks	Challenges
				• The GPT-based approach took around half an hour to process approximately 500 pairs, making it computationally intensive. • Achieving strong agreement among human evaluators
Ding et al [31]	MedAlpaca	• Patients with early diabetes • Patients with multiclass chronic diseases	Early prediction of diabetes Prediction of multiclass chronic diseases	• Lower positive rates when using only laboratory blood values • Missing tests for most patients when using only laboratory blood values. • Integrating multimodal data from clinical notes and laboratory test results • Difficulty in model explainability for early disease prediction
Jairoun et al [32]	ChatGPT	diabetes and metabolic illnesses, endocrinologists and diabetologists	Patient support and education Tailored treatment	• Diagnostic mistakes • Patient data security and privacy • Limitations on generalizability • Integration difficulties and workflow errors, and Compliance with laws and regulations • Absence of empathy and human contact
Mondal et al [33]	GPT-4	Health care professionals	Reviewing and evaluating diabetes management plans for guideline adherence	• GPT-4's difficulties in handling complex clinical judgments, such as medication adjustments and treatment modifications in varied clinical scenarios
Liu et al [34]	GPT-2 and T5	Patients with mental disorders	Detection of mental disorders (depression, anorexia, pathological gambling, self-harm) through user-generated textual content.	• Need for personalized prompts to capture individual user characteristics. • Integration of medical knowledge into prompts for accurate detection. • Handling noisy and lengthy user-generated content. Few-shot learning with minimal labeled data
Liao et al [35]	BERT BiomedBERT Flan-T5-large-770M GPT-2	Physicians, health care providers	Prediction of chronic diseases (diabetes, heart disease, hypertension) using EHR data.	

XSL•FO
RenderX

Study	LLM[a]	Users	Disease management tasks	Challenges
				• Difficulty in classifying diseases with lower positive rates (eg, hypertension) • Need for interpretability in model predictions • Integration of multimodal data (clinical notes and blood test results) for accurate predictions
Ding et al [36]	BERT, Roberta, Biomed-BERT, Flan-T5, GPT-2	Researchers, health care professionals	Predict new-onset T2DM, early detection, and risk assessment	• Handling multimodal data, missing values, and model interpretability
Dao et al [37]	GPT-3.5	Individuals at risk of diabetes or with prediabetes	Instant Q&A and advice Personalized reminders Data analysis for tailored guidance Health resource aggregation Emotional support	• Engagement barriers in prevention programs (eg, transportation, personal responsibilities) • Lack of research on AI in diabetes prevention • Need for reliable, context-aware AI responses
Khan [38]	ChatGPT	Diabetic patients	Real-time education and support Blood glucose monitoring guidance Medication adherence advice Lifestyle/diet recommendations Emergency detection	• Inaccuracies in medical information (eg, insulin storage guidelines, trial data mix-ups) • Lack of emotional support/empathy • Limited to pre-2021 knowledge • Difficulty distinguishing medical terminologies • Low adoption among older adults
Mondal et al [39]	ChatGPT-4	Patients and health care professionals	Answering patient questions (causes, symptoms, treatment, diet) Providing information on managing Crohn's disease (CD) and ulcerative colitis (UC). Addressing professional queries (classification, diagnosis, disease activity, prognostic markers, complications)	• Insufficient elaboration on medical agents and surgical indications • Inadequate information for patients. ChatGPT provided different answers to the same question across sessions • Lower reliability/usefulness scores for patient-directed questions compared to professional-focused ones. • Outdated information
Young et al [40]	GPT-4 Gemini 1.0 Ultra	Pediatric patients, health care providers, and caregivers	Generating explanations for chronic conditions	• Age-appropriateness discrepancies between models (GPT-4 versus Gemini) • Lack of direct feedback from pediatric patients; reliance on clinician evaluations.

Study	LLM[a]	Users	Disease management tasks	Challenges
li et al [41]	LLaMA	Primary care physicians	Individualized diabetes management recommendations	• Underdiagnosis and poor primary diabetes management
Ying et al [42]	GPT-3.5	Physicians, laypersons, and type 2 diabetes patients	Diabetes education and personalized Q&A support	• Lower real-world performance, variability by prompt, trust, and safety concerns
Li et al [43]	ChatGPT-3.5 ChatGPT-4.0 Google Bard MedGPT LlaMA2-7B	Researchers Primary care physicians	Answering diabetes-related exam questions and assisting in diabetes training.	• Poor performance in both Chinese and English diabetes-related questions • LLMs may provide misleading explanations and difficulty with multiple-choice and case analysis questions
Hussain and Grundy [44]	ChatGPT-3.5 ChatGPT-4	Diabetes patients and health care providers	Patient education, treatment recommendations, insulin management, dietary advice	• Inaccuracies in medical advice • Lack of personalization • Failure to recognize regional variations • Incorrect assumptions about blood glucose units limitations in addressing complex patient histories
Wang et al [45]	GPT-4 Anthropic Claude 2 Google Bard	• Clinicians • Diabetes patients	Responding to diabetes-related inquiries and providing accurate and comprehensive information for diabetes self-management.	• Lack of specialized medical knowledge in commercially available LLMs • Susceptibility to generating inaccurate or misleading information • Need for real-time, domain-specific knowledge to improve accuracy and reliability • Ensuring responses are safe, accurate, and understandable for patients

[a] LLM: large language model.

As shown in Table 2, GPT models were the most commonly used (14/29, 48%), followed by LLaMA variants (5/29, 17%), the Bard model (3/29, 10%), and BERT-based models (2/29, 7%). LLMs were primarily used for patient education and information provision (18/29, 62%), with most studies targeting patients (18/29, 62%) rather than health care providers (11/29, 38%). Inaccurate and inconsistencies in responses (18/29, 62 %) were the most frequently reported challenge across studies.

Objective 1: The Tasks in Chronic Disease Management Performed by LLMs

Our literature synthesis revealed that LLMs have significant potential to improve various chronic disease management tasks. The tasks identified have been broadly categorized into patient-centered tasks and practitioner-centered tasks.

Patient-Centered Tasks

Patient Education and Information Provision

Eighteen studies (n=18) delved into the use of LLMs in providing health information to enhance patient health literacy [16,17,21,23,24,27,28,32,33,37-41]. Key applications included using ChatGPT to provide personalized guidance on diabetes management [16,38,39,42], educational content for diabetic retinopathy and inflammatory bowel disease patients [17,21], generating age-appropriate explanations of chronic pediatric conditions [40], and supporting physician training in diabetes management [43]. In addition, LLMs supported treatment adherence through tools like ChatGPT and GPT-3.5, offering tailored medication reminders, appointment scheduling, and strategies for behavior change [24,37]. For Spanish-speaking

XSL•FO
RenderX

populations, ChatGPT was evaluated for reliability and readability of chronic disease information [28], while multiple ChatGPT versions were assessed for regional variations in diabetes education quality [44].

Diagnosis and Treatment

Six studies (n=6) examined the role of LLMs in assisting with diagnosis and treatment recommendations. These studies explored the potential of LLMs to suggest appropriate laboratory tests, generating differential diagnoses and medication options tailored to the individual patient's condition [16,22,32,34]. Notable applications included enhancing depression diagnosis and treatment through fine-tuning of models like LLaMA-7B and ChatGLM-6B [22], supporting the diagnosis of rare and complex diseases [23], and detecting mental disorder patterns through analysis of user-generated content [34]. Furthermore, integrating AI-driven diagnostic and treatment capabilities with diabetes management systems showed particular promise in low-resource primary care settings [41].

Self-Management and Disease Monitoring

Eight studies (n=8) addressed using LLMs for self-management and disease monitoring. These studies explored how LLMs provide guidance on managing chronic conditions, promote patient engagement, and support home disease monitoring [6,18,20,21,24,37,38,42]. Key applications included developing chatbot architectures for home blood pressure monitoring [6], creating cuffless blood pressure measurement systems using wearable biosignals [19], and assessing real-time disease severity in sickle cell anemia [20]. LLMs also demonstrated value in detecting emergencies such as hypoglycemic episodes in diabetic patients and guiding appropriate actions [38]. Additional applications encompassed monitoring tools for inflammatory bowel disease management [21], personalized reminders for diabetes prevention [37], and comprehensive health parameter tracking with feedback based on patient-shared data [24]. These implementations highlight the potential of LLMs to enhance patient self-management through continuous monitoring and timely intervention guidance.

Emotional Support and Therapeutic Conversations

Four studies (n=4) explored the role of LLMs in providing emotional support and engaging in therapeutic conversations for patients managing chronic diseases. The review identified several key applications, including investigating LLM chatbots for mental health support with tailored recommendations addressing specific stressors [18], evaluating ChatGPT as a virtual health coach identifying barriers to behavior change [24], assessing GPT-3.5's emotional support capabilities in proactive diabetes prevention [37], and examining ChatGPT's ability to provide coping strategies for diabetic patients [38].

Practitioner-Centered Tasks

Clinical Decision Support

Eight studies (n=8) investigated the use of LLMs for clinical decision support. The review identified several key applications, including generating personalized medical reports with treatment options and diagnostic procedures for conditions like diabetic retinopathy [17] and inflammatory bowel disease [21], assessing LLMs' diagnostic accuracy compared with human experts in rare and complex diseases [23], and exploring potential use for electronic health record inbox management [27]. Other applications included using GPT to discover and rank novel relationships between aspects of chronic lower back pain [30], evaluating diabetes management plans using GPT-4 [33], disease classification and prognosis [39], and evaluating LLMs' competency in answering diabetes-related exam questions for physician training [43].

Medical Predictions

Six studies (n=6) explored the predictive capabilities of LLMs in chronic disease management. The review identified several key applications, including predicting diabetic retinopathy risk [17], developing ChatGPT-assisted machine learning models for chronic disease classification [29], and integrating multimodal data from electronic health records and laboratory tests to predict new-onset type 2 diabetes [31,36]. Additional applications included creating an EHR-based prediction platform for diabetes, heart disease, and hypertension [35] and implementing integrated AI systems for diabetes risk assessment in primary care settings [41].

LLMs in chronic disease management are predominantly utilized for patient education and information provision, accounting for (18/29) of reported applications. Self-management and disease monitoring and clinical decision support each account for 28% (8/29) of applications. Diagnosis and treatment tasks, along with medical predictions, both constitute 21% (6/29) of applications, while emotional support and therapeutic conversations account for 14% (4/29). Percentages exceed 100% due to thematic overlaps where individual studies addressed multiple tasks.

LLMs in chronic disease management are predominantly utilized for patient education and information provision, accounting for (18/29) of reported applications. Self-management and disease monitoring and clinical decision support each account for 28% (8/29) of applications. Diagnosis and treatment tasks, along with medical predictions, both constitute 21% (6/29) of applications, while emotional support and therapeutic conversations account for 14% (4/29). Percentages exceed 100% due to thematic overlaps where individual studies addressed multiple tasks.

Objective 2: Challenges Associated With Using LLMs for Chronic Disease Management

The challenges identified and presented in Table 2 were categorized as follows.

Inaccurate and Inconsistencies in Responses

Eighteen studies (n=18) highlighted issues with hallucinations, diagnostic errors, and unreliable outputs [6,16,17,21-23,27-29,32-34,38,39,42-45]. The review identified several key challenges, including hallucinations where models like ChatGPT and LLaMA generate reasonable but factually incorrect information [22,45], diagnostic errors in conditions ranging from depression to inflammatory bowel disease [21,32,44], and inconsistent responses to identical prompts without indicating uncertainty levels [23,39,42]. In addition,

XSL•FO
RenderX

models demonstrated limited understanding of complex medical records [16], struggled with regional variations in medical practice [44], provided insufficient elaboration on medical treatments [39], and showed difficulty distinguishing medical terminologies [38]. Further challenges included lower reliability in the Spanish language for specific chronic conditions like heart failure and chronic kidney disease [28] as well as limited generalizability due to restricted training populations [29,32]. These inaccuracies stem from erroneous input data, such as incomplete or incorrect test results [6,21,22,27,31].

Limited Datasets and Knowledge

Six studies (n=6) identified challenges related to limited datasets and knowledge cutoffs in LLM applications for chronic disease management. The review highlighted several key limitations, including scarcity of disease-specific datasets [16,22], dataset imbalances affecting predictions for conditions like hypertension [19], and knowledge limitations that restrict LLM awareness of the current medical guidelines [21,23,39].

Computational and Technical Challenges

Six studies (n=6) highlight significant computational and technical challenges in deploying LLMs for chronic disease management. The review identified several key limitations, including resource-intensive processing that results in prolonged training time in resource-constrained environments [30]. In addition, technical challenges include integrating multimodal data from clinical notes and laboratory results [31,36], ensuring model explainability for early disease prediction [35], and handling noisy user-generated content in mental health applications [31,34]. Further challenges involve difficulties in integrating LLMs into clinical workflows [32] and managing complex clinical judgments, such as medication adjustments and treatment modifications [33].

Usability and Accessibility Concerns

Nine studies (n=9) identified usability and accessibility concerns surrounding LLMs in chronic disease management tasks. Notably, the restriction to textual inputs limits use for tasks involving multimodal diagnostic tasks [28,40] language and cultural misalignments [18,28], while age-inappropriate outputs pose challenges for pediatric care [40]. In addition, poor interpretability of model predictions for early disease prediction and risk assessment [31,35,36]. Additional challenges included a lack of empathy and ineffectiveness in emergencies [24,29], digital literacy gaps restricting adoption among older adults [29,38]. Furthermore, these studies also noted how insufficient transparency in model decision-making processes hindered trust and clinical acceptance [35,36].

LLM Evaluation

Five studies (n=5) noted challenges involving LLM evaluation. Notable challenges identified included that automated evaluation metrics primarily focus on predictive performance and fail to assess the impact on patient treatment outcomes [22], difficulties in achieving consensus among human evaluators when assessing LLM outputs [30], discrepancies between model performance in test environments versus real-world applications [42], difficulties in consistently evaluating language models across different diabetes-related tasks [43], and significant variations in age-appropriateness scoring between different LLM platforms [40].

Legal, Ethical, Privacy, and Regulatory Concerns

Ten studies (n=10) identified legal, ethical, privacy, and regulatory challenges of using LLMs in chronic disease management. The review highlighted several critical concerns, including privacy and data security vulnerabilities [17,19,24,27,28,32], absence of regulatory approval and standardized guidelines [27], and compliance issues with health care laws across different jurisdictions [27,32]. In addition, language and cultural barriers posed additional challenges, particularly for non-English speakers [18,28], while bias and equity issues stemming from limited training data diversity raised concerns about health care disparities [24,32,42]. Studies also noted ethical challenges around accountability for errors [24], lack of transparency in decision-making [22,27], and limitations in addressing complex ethical dilemmas in clinical care [44,45].

The most prevalent challenge identified was inaccurate and inconsistent responses, reported in 62% (18/29) of studies. Legal, ethical, privacy, and regulatory concerns followed, appearing in 35% (10/29) of studies. Usability and accessibility issues were noted in 31% (9/29) of studies. Computational and technical limitations, as well as dataset and knowledge constraints, were each reported in 21% (6/29) of studies. Additionally, 17% (5/29) of studies highlighted limitations in evaluation methodologies.

Discussion

Principal Findings

This scoping review presents 3 significant findings from the 29 included studies (n=29): (1) LLMs are mostly used for both patient-centered (18/29, 62%) and practitioner-centered (11/29, 38%) tasks, with patient education and information provision emerging as the major application (18/29, 62%); (2) despite promising applications, significant challenges still exist, particularly regarding LLM response accuracy (18/29, 62% of studies), ethical concerns (10/29, 35%), and usability issues (9/29, 31%); and (3) methodological quality varies considerably across studies, with journal articles demonstrating higher quality (13/18, 72%) compared with conference papers (3/8, 38%) and preprints (1/3, 33%). These findings highlight both the considerable promise and significant limitations of current LLM applications in chronic disease management, which are examined in detail below.

Chronic Disease Management Tasks

Chronic disease management is an approach to managing chronic illnesses involving screenings, regular check-ups, monitoring, coordination of treatment, medication adherence, lifestyle modifications, and patient education [1]. The findings from this scoping review reveal an increasing interest in leveraging LLMs like ChatGPT to support both patient-centered and practitioner-centered tasks [6,16,22-24,30,31].

XSL•FO
RenderX

Patient-Centered Tasks

The majority of the studies (18/29, 62%) focused on patient-centered tasks, reflecting the emphasis on patient active engagement in chronic disease management [3,46]. Patients' active engagement enables them to monitor their symptoms, disease progress, weight, and adverse drug effects, and adhere to medication and visits [3,46]. This review found that LLMs support various patient-centered applications, including patient education and information provision, disease monitoring and self-management, emotional support and therapeutic conversations, and diagnosis and treatment assistance.

Patient education and information provision emerged as the most prominent application (18/29, 62%), with LLMs providing health information about conditions, treatment plans, and medication schedules [16,17,21,23,24,27,28,32,33,37-41]. With the right health information, individuals with chronic diseases can easily self-manage their conditions. Diagnosis and treatment applications accounted for (6/29, 21%). Studies experimented using LLMs to suggest laboratory tests, for diagnosis, and for medication generation tailored to individual patient conditions [16,22,23,32,34,41]. However, using LLMs for diagnostic and treatment has been criticized due to concerns about hallucinations and misinterpretations of clinical guidelines [22,23], highlighting the need for continued research to ensure patient safety. Therefore, LLM usage should not replace health practitioners but instead serve as complementary tools.

Self-management and disease monitoring applications (8/29, 28%) demonstrated how LLMs can facilitate home-based monitoring of various physiological parameters [6,19-21,24,37,38,42]. Recent studies have highlighted that patient engagement with health monitoring technologies is crucial for improving health outcomes in chronic disease management [47]. Studies have also shown that wearable technologies integrated with LLMs provide real-time patient-centered health data that can better inform self-management decision-making [48]. However, ensuring consistent long-term engagement is still a challenge.

Emotional support and therapeutic conversations (4/29, 14%) represented an emerging application area [18,24,37,38]. Studies showed that LLMs can provide psychological support through tailored recommendations addressing specific stressors [18], identifying barriers to behavior change [24], and offering coping strategies for patients with diabetes [38]. Emotional support is increasingly recognized as essential in chronic disease management [49], which helps patients overcome psychological barriers to treatment adherence and lifestyle modifications.

Practitioner-Centered Tasks

Practitioner-centered tasks (11/29, 38%) mainly revolved around clinical decision support and medical predictions. Clinical decision support applications (8/29, 28%) provided health care practitioners with actionable information to enhance decision-making. Studies demonstrated that LLMs can generate personalized medical reports, generate treatment recommendations, and support diagnostic processes that assist health care specialists in making informed decisions [17,21]. However, while LLMs enhance diagnostic efficiency, concerns regarding inconsistent outputs pose barriers to clinical adoption. Medical prediction applications account for (7/29, 24%) of LLM use in chronic disease management, showing strong potential for early disease detection and risk stratification. By integrating structured and unstructured clinical data, such as lab results, clinical notes, and imaging, LLMs enable more comprehensive and accurate predictive models compared with traditional methods [17,29,31,34-36].

Notably, real-time risk assessment tools, like the ambulatory device developed for sickle cell anemia management [20], demonstrate how LLMs can predict complications before symptoms appear. However, challenges relating to medical accuracy still limit their seamless integration into clinical workflows [6,16,17,21-23,27]. A significant emerging trend is the development of retrieval-augmented generation (RAG) frameworks that enhance prediction accuracy by dynamically incorporating up-to-date medical knowledge [22,35,50-53]. Future advancements should focus on seamless integration of LLMs with existing medical systems, wearable health technologies, and mobile health applications to improve interoperability and trustworthiness.

Methodological Quality and Strength of Evidence

The methodological quality assessment revealed notable trends that should be considered while interpreting the results of this scoping review. High-quality studies (18/29, 62%) were not uniformly distributed across LLM application tasks, studies examining medical prediction applications [29,31,35,36] and patient education and information provision [28,32,38,39] had significantly stronger methodological rigor. Studies investigating emotional support showed mixed quality, with some high-quality qualitative research [18,24], a quantitative descriptive study [37] alongside a moderate-quality mixed study [38]. Notably, self-management and disease monitoring studies showed significant methodological heterogeneity, with quality ratings ranging from low to high.

Journal articles demonstrated a substantially higher proportion of high-quality studies (13/18, 72%) compared with conference papers (3/8, 38%) and preprints (1/3, 33%), suggesting that peer-review processes enhance methodological quality. The identified common limitations, including inadequate sampling strategies, limited participant demographic reporting, and insufficient methodological transparency, were more prevalent in lower-tier publication sources, including conference papers and preprints. Quantitative descriptive studies, especially those focused on system design and prototype testing (10/29, 34.5%), showed mixed quality ratings ranging from low to high, with a common limitation being the use of synthetic data, lack of clinical validation, as they commonly prioritized technical utility. These methodological patterns significantly influence the reliability of the findings.

Challenges and Corresponding Recommendations

This section discusses the key challenges identified in the review and presents corresponding recommendations to mitigate these issues. Each challenge is followed by practical solutions to enhance the applicability of LLMs in chronic disease management.

XSL•FO
RenderX

Inaccurate Data and Inconsistencies in Responses

Inaccurate and inconsistent responses emerged as a significant challenge (18/29, 62%), primarily due to poor data quality, inherent biases in training datasets, and the limited scope of knowledge constrained by the model's training cutoff [6,22,23,31]. Given that LLM performance is intrinsically linked to data quality, flawed datasets inevitably propagate errors in outputs, a manifestation of the "garbage in, garbage out" principle [54-56]. The issue of biases in AI models has gathered significant attention in recent literature [54-56], prompting possible migration strategies [57-59]. These limitations carry critical implications for health care, as erroneous LLM outputs may lead to incorrect clinical decisions, posing significant risks to patient safety [8,12]. Hence, researchers are exploring technical solutions such as advancing domain-specific fine-tuning techniques [60,61], leveraging retrieval-augmented generation (RAG) frameworks [22,50-52], and refining outputs through reinforcement learning (RL) and prompt engineering techniques [62-64]. In addition, implementing expert validation protocols has emerged as a crucial safeguard to ensure adherence to evidence-based practice.

Limited Datasets

The scarcity of high-quality datasets for chronic diseases accounted for (6/29, 21%). Studies highlighted limitations and narrow coverage of publicly accessible clinical training datasets due to data privacy and institutional restrictions [16,19,21-23,39]. Given that experimental studies often require substantial model training datasets, the absence of adequate data poses a significant challenge to the effectiveness and success of these studies. Therefore, to address this gap, synthetic datasets and data augmentation techniques have been explored by studies [15,65]. However, these methods risk amplifying pre-existing biases in source data [54-56]. Therefore, dataset validation is essential to ensure quality, collaborative partnerships with health care institutions to access real-world clinical datasets and knowledge distillation techniques, where smaller models can be trained on outputs from larger, clinically validated models, reducing dependency on raw data volume, can be explored [66].

Computational Resources and Technical Challenges

The computational demands of training LLMs for health care applications remain a significant challenge (6/29, 21%). Consequently, low computing resources approaches, such as quantization, parameter-efficient fine-tuning (PEFT) techniques like Low-Rank Adaptation (LORA), Quantized LoRA (QLORA), Weight-Decomposed Low-Rank Adaptation, and REFT [67-73], are evolving and are popularly used in fine-tuning LLMs in low-resource computing environments. In addition, adapter-based tuning methods provide lightweight alternatives by injecting trainable adapter layers into frozen pretrained models, enabling task-specific fine-tuning without updating the entire model parameters [74,75]. Building on these advances, the development of lightweight LLMs optimized for mobile devices presents a promising direction for extending AI-based chronic disease management to resource-constrained settings [76].

Usability and Accessibility Concerns

Usability and accessibility concerns accounted for (9/29, 31%), including issues with text-only interfaces for some LLMs, cultural misalignments, and outputs ill-suited for pediatric or elderly populations [18,28,40]. While studies highlighted text-only interfaces as a critical limitation of LLMs in health care [28,40], recent advances in multimodal architectures have addressed this gap. These models now integrate and interpret diverse data modalities, including medical images, audio, and structured documents, while generating composite textual and visual outputs [31,77-79]. In addition, having dynamic and simplified interfaces to accommodate low-digital-literacy users, pediatric users, and for different cultural and language settings could further improve LLM usability and adaptation.

Legal, Ethical Issues, and Regulatory Issues

Legal, ethical, and regulatory concerns (10/29, 35%) remain a key issue in LLM adoption in health care. Studies identified data privacy, biases, misinformation, responsibility, and accountability for LLM-generated content as key concerns. Although several AI frameworks have been proposed, the absence of standardized guidelines and regulatory approvals creates significant gaps [27,80-82]. This regulatory vacuum risks inconsistent model development and validation practices, unaddressed ethical dilemmas regarding accountability for AI-generated recommendations, and potential mismatches between rapidly evolving LLM capabilities and static health care regulations [27,83]. Addressing these ethical concerns requires standard guidelines and rules to ensure responsible use in health care settings[84]. Therefore, future efforts must prioritize the development of a comprehensive regulatory framework.

LLM Evaluation

Evaluation gaps accounted for (5/29, 17%), reflecting critical shortcomings in current methodologies for assessing LLM performance in clinical contexts. The existing automated evaluation metrics mainly focus on predictive performance using metrics such as accuracy and F_1-scores that lack medical and treatment knowledge [22,85]. These metrics may produce misleading conclusions if not appropriately selected [85]. Furthermore, human evaluation, although valuable, introduces subjectivity and interrater variability, yet the absence of a standardized LLM evaluation framework makes attaining consensus among human raters challenging [30,85]. A promising direction involves a hybrid evaluation approach that integrates human expert reviews with automated metrics. Future efforts should prioritize the development of standardized LLM evaluation frameworks tailored to health care settings. Table 3 summarizes the challenges associated with applying LLMs in chronic disease management with proposed recommendations.

XSL•FO
RenderX

Table . Key challenges and recommendations.

Challenge	Key observations	Recommendation
Inaccurate and inconsistent responses	Hallucinations, inconsistent responses, outdated knowledge	Adopting RAG frameworks, fine-tuning, and prompt engineering. RL, expert validation of LLM-generated recommendations
Limited datasets	Scarcity of datasets, missing data, and dataset imbalances.	Use synthetic data, data augmentation, partnerships with health care institutions, knowledge distillation
Computational demands	High computational demands	Adopt PEFT (LORA and QLORA), quantization use lightweight models for mobile devices
Ethical and privacy concerns	Privacy concerns, language and cultural barriers, and lack of regulatory oversight	Develop a regulatory framework
Usability issues	Restriction to textual inputs, lack of empathy, ineffectiveness in emergencies Age-appropriate interaction	Use multimodal LLMs. Dynamic interfaces to accommodate low-digital-literacy users, age-appropriate interaction modes customize to different cultural settings Integrate with wearable devices and mobile health apps
Evaluation challenges	Predictive performance metrics, subjectivity, and interrater variability	Develop a standardized LLM evaluation framework for health care.

Limitations of the Study

Although quality assessment was conducted using MMAT, studies were not excluded based on their methodological rigor. As a result, including moderate and low-quality studies may have influenced the reliability and consistency of the reviewer's findings. The varied methodological designs across studies may have affected the interpretation of results and conclusions drawn. Furthermore, the review was limited to only English-language publications, which may have introduced language bias and limited the generalizability of our findings, particularly in contexts where LLMs are being adapted to local languages or integrated into culturally specific health care practices. The exclusion of databases such as Embase and Web of Science may have limited the comprehensiveness of the search. Future research can consider broader database coverage and non-English sources to enhance diversity and scope.

Implications for Practice and Future Research

This scoping review reveals several critical implications for the integration of LLMs in chronic disease management. First, it is essential to address the accuracy issues identified in 18/29, 62% of studies. This calls for both technical solutions (domain-specific fine-tuning, reinforcement learning (RL), and retrieval-augmented generation (RAG) frameworks [61,64]) and nontechnical solutions (expert validation and collaborative partnerships with health care institutions to access and use real-world clinical data). Second, enhancing accessibility across diverse patient populations requires developing culturally adapted LLM interfaces, implementing age-appropriate interaction modes [40], and integrating with low-resource platforms such as SMS-based systems and lightweight mobile apps for various populations [76]. Third, robust governance frameworks must be established to address the ethical, legal, and privacy concerns noted in 10/29, 35% of studies to ensure regulatory compliance.

Finally, future research should focus on multimodal LLMs that can synthesize diverse data inputs from wearable devices and mobile health applications for holistic patient monitoring [19,31,35] and develop resource-efficient deployment techniques. The predominance of diabetes-focused studies (14/29, 48%) highlights a potential research gap in addressing other prevalent chronic conditions. Similarly, there is a research gap in age-inclusive LLM design, given the overwhelming focus on adult populations (28/29, 96%) and the lack of pediatric studies. Addressing these gaps would enhance the clinical relevance and equitable application of LLMs across the full spectrum of chronic disease management.

Conclusion

This scoping review highlights the growing potential of LLMs in supporting chronic disease management through patient education, diagnosis and treatment, emotional support, self-management support, decision support, and prediction tasks. While LLMs offer promising capabilities, their effective integration into health care still requires addressing key challenges related to accuracy, accessibility, usability, and ethical and privacy concerns. Future research should focus on integrating LLMs with mobile and wearable technologies, creating culturally and age-appropriate interfaces, and exploring integration with low-resource platforms. Addressing these research gaps will ensure equitable and safe use of LLMs across diverse health care settings.

Acknowledgments

The authors acknowledge the valuable inputs of the reviewers and the editor, and the support of Mr. Bazekketa Datson of Ndejje University, Faculty of Science and Computing, for illustrating the figures used in this scoping review. The authors did not receive any funding for this review study. During the preparation of this work, the authors used Grammarly to improve the readability

Abstract

Background: Digital-based interventions have the potential to support initiatives for the prevention of mother-to-child HIV transmission (PMTCT). Nevertheless, reviews to explore experiences and perspectives toward digital-based interventions in mothers living with HIV remain limited.

Objective: The aim of the study was to explore the experiences and perspectives toward digital-based interventions in promoting PMTCT services in mothers living with HIV.

Methods: This study conducted a systematic review and qualitative meta-aggregation and adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) and the Joanna Briggs Institute (JBI) Reviewer's Manual. Electronic databases such as Scopus, PubMed, the Cumulative Index to Nursing and Allied Health Literature (CINAHL), and Wiley Online Library were systematically searched on July 5, 2024. The eligibility criteria included qualitative studies that focus on mothers living with HIV and health care providers, exploring their experiences and attitudes toward digital-based interventions for the PMTCT of HIV. The quality of the studies was assessed using the JBI Critical Appraisal tools for qualitative research and the Mixed Methods Appraisal Tool (MMAT) for mixed methods studies. The meta-aggregation was used to synthesize findings from included qualitative studies.

Results: The 8 included studies (3 qualitative and 5 mixed-methods studies) were conducted in Kenya, South Africa, and India and evaluated mobile-based interventions such as SMS, phone calls, and mobile apps. The findings were synthesized into overarching themes: (1) positive acceptability of digital-based intervention for PMTCT services; (2) the need for integrating education, support systems, and reminders into digital-based intervention among mothers living with HIV; (3) concerns about confidentiality; and (4) personal, interpersonal, and health care–related barriers to care adherence. These themes were divided into 9 categories, including perceived satisfaction, improved adherence, the need for education, support systems, reminders, concerns about their privacy, lack of family support, financial constraints, and negative provider attitudes.

Conclusion: Although most included studies were limited, their findings highlight the insight that the integration of digital-based interventions is perceived as acceptable and beneficial in strengthening PMTCT services delivery among mothers living with HIV. Mobile-based tools were valued for delivering education and reminders and facilitating communication with providers. However, concerns about confidentiality and persistent structural barriers must be addressed. To strengthen PMTCT services, it is essential to integrate user-centered digital tools into maternal care, supported by policies that ensure data privacy and equitable access.

KEYWORDS

attitude; digital health intervention; HIV; mother-to-child transmission; acceptability; systematic review; HIV transmission; patient experiences; qualitative; meta-analysis; patient needs education; support

Introduction

Since the onset of the epidemic, an estimated 88.4 million individuals are living with HIV, and approximately 42.3 million have died from HIV-related causes [1]. By the end of 2023, around 39.9 million individuals were living with HIV globally [1]. Although the global HIV prevalence among adults aged 15 - 49 years is approximately 0.8%, the burden of the epidemic varies significantly across regions and countries [1]. Pregnant and breastfeeding women, particularly in high-risk areas, remain a vulnerable group for HIV transmission [2]. HIV can be transmitted from a mother living with HIV to her child during pregnancy, childbirth, or breastfeeding [3,4]. Furthermore, pregnancies complicated by HIV infection are associated with an increased risk of miscarriage [5]. Numerous studies have shown that, without treatment, maternal HIV infection significantly raises the likelihood of stillbirth, premature birth, low birth weight, and infants being small for their gestational age [2,5-7].

Mother-to-child transmission (MTCT) of infectious diseases remains a significant global public health concern, with the prevention of HIV transmission from mother to child being one of the most pressing challenges [8]. In 2013, the World Health Organization (WHO) recommended lifelong antiretroviral therapy (ART) for all pregnant and breastfeeding women, and since 2016, also recommended its use before conception, as part of its strategy to prevent mother-to-child HIV transmission (PMTCT) [9]. To accelerate progress, the WHO Regional Office for Southeast Asia developed the “Regional Framework for Triple Elimination of MTCT in Asia and the Pacific 2018 - 2030” aiming for zero new infections in children by 2030 [10]. Supporting this initiative, WHO released the third edition of its global guidelines, which detail the standards and procedures for validating the elimination of MTCT of HIV, syphilis, and hepatitis B (triple elimination). These guidelines provide uniform targets and criteria for evaluating national progress toward the elimination of one or more of these infections [10,11].

The PMTCT program is the standard of care for mothers living with HIV, which aims to enhance both maternal and infant outcomes [12]. It includes the integration of ART during pregnancy to manage HIV viremia, support retention in care, and reduce the risk of vertical transmission [13]. Continued engagement during the postpartum period is crucial for maintaining retention and achieving viral suppression, which are essential for optimal long-term health outcomes [14]. Providing ART during pregnancy and extending prophylaxis to infants during the first 6 weeks of breastfeeding has been shown to significantly reduce the risk of MTCT [15]. However, despite ongoing efforts, treatment coverage for mothers living with HIV and their children remains below the Joint United Nations Program on HIV/AIDS (UNAIDS) 95-95-95 targets for 2030 [11,16]. These gaps highlight the urgent need for effective strategies to expand access to evidence-based interventions, particularly for pregnant women, to ensure timely treatment and improve health outcomes [16].

Digital-based interventions, such as mobile health (mHealth) and telemedicine, have emerged as promising tools to support PMTCT services [17-22]. Digital-based interventions involve the use of telecommunications technologies to deliver health services remotely, encompassing a range of platforms including text messaging, websites, mobile apps, and health-related devices. Over the past decade, the integration of digital health technologies into the standard of care has grown rapidly across the continuum of HIV care [23-25]. There is growing interest in leveraging these tools to improve maternal and child health outcomes [26,27]. In low- and middle-income countries (LMIC), digital-based interventions offer innovative solutions to persistent barriers in HIV care, such as a shortage of trained health care providers, limited infrastructure, and high out-of-pocket costs for facility-based services [28]. During the HIV epidemic, digital-based interventions were widely adopted and improved provider-patient and interprovider communication, overcoming disparities in global HIV responses [29,30].

Despite the growing interest in digital-based interventions for PMTCT, evidence regarding their acceptability remains limited. Many studies have reported positive outcomes, such as increased uptake of HIV testing and adherence to ART [19,20,27,31,31-33]. Nevertheless, the feasibility and experimental aspects have often been overlooked [19,20,27,31,31-33]. A recent systematic review of 27 studies on text messaging and phone call interventions for HIV care and treatment in LMICs found showed significant favorable effects on ART adherence and increase in retention in care [34]. In addition, a meta-analysis of phone-based interventions integrating into PMTCT services showed a moderate improvement in ART [35]. These findings highlight the importance of integrating qualitative perspectives into digital-based interventions to better understand the experiences, preferences, and barriers faced by mothers living with HIV. Nurses and other health care professionals play a critical role in delivering ongoing support and personalized education through digital platforms. This approach not only fosters mothers living with HIV engagement, but also bridges the gap between technological innovation and practical, person-centered care, thereby improving maternal and their children’s health outcomes.

Understanding the feasibility of integrating digital-based interventions into PMTCT services is essential for their successful implementation. While quantitative studies provide valuable evidence on effectiveness, qualitative studies are equally important to understand the acceptability, usability, and contextual relevance of these interventions within the target population. Therefore, there is a pressing need for review studies

XSL•FO
RenderX

that synthesize the experiences and perspectives of both mothers living with HIV and health care providers regarding integrating digital-based interventions into PMTCT services. This study explored the acceptability, perceived needs, and barriers related to digital-based interventions used in antenatal care (ANC) services, HIV testing, and ART adherence to support the PMTCT services. Specifically, this study aimed to: (1) identify the barriers and facilitators to the uptake and use of these interventions, (2) assess their acceptability among mothers living with HIV and health care providers, and (3) understand the treatment-related needs of mothers living with HIV.

Methods

Study Design

The study used a systematic review and qualitative meta-aggregation. The study adheres to the PRISMA (Preferred Report Items for Systematic Review and Meta-Analysis; see Checklist 1) and the Joanna Briggs Institute (JBI) Reviewer's Manual [36,37]. Meta-aggregation, based on the philosophical traditions of pragmatism and Husserlian transcendental phenomenology, aims to produce generalizable recommendations to guide practitioners and policymakers [37,38].

Eligibility Criteria

Inclusion criteria were established for this study according to the PCC (population, content, and context) framework. The population of interest consisted of mothers living with HIV and their health care providers. The content experiences and perspectives toward integrating digital-based interventions into PMTCT of HIV. Studies that reported on both positive and negative experiences and perspectives were included. Context was defined as any type of digital-based intervention (synchronous and asynchronous), such as text messaging, mobile health apps, telemedicine, or internet-based programs.

The exclusion criteria were quantitative studies of articles published in nonpeer-reviewed journals. Conference abstracts, posters, editorials, commentaries, and reviews were excluded. The articles not written in English were excluded. In addition, no date restrictions were applied to ensure the inclusion of all relevant studies regardless of their publication year. All database searches were conducted on July 5, 2024.

Search Strategy and Study Selection

A comprehensive search of multiple databases was conducted to identify relevant studies. Scopus, PubMed, Medline, the Cumulative Index to Nursing and Allied Health Literature (CINAHL), and Wiley Online Library were searched from their inception up to 5 July 2024. The search strategy was developed using a combination of keywords and Medical Subject Headings (MeSH) terms related to digital-based interventions and MTCT of HIV. The search terms used were ([HIV OR "Human Immunodeficiency Virus" OR "Human Immunodeficiency Viruses"] AND ["Digital technology" OR "mobile health" OR mhealth OR ehealth OR telehealth OR telemedicine OR telenursing OR "mobile apps" OR "mobile application"] AND ["medication adherence" OR adherence OR "medication nonadherence" OR "medication compliance" OR "medication noncompliance"]). See Multimedia Appendix 1 for the search strategy. Additional relevant studies were identified through snowballing searches, using the "related articles" feature and the reference lists of the included articles. A total of 2 independent reviewers (SM and ADN) assessed all articles for eligibility, with any discrepancies resolved through consultation with a third reviewer (LNA). Studies were included if they contained original qualitative data on the experiences and perspectives of mothers living with HIV, health care providers, or other relevant stakeholders of digital-based interventions in PMTCT services.

Data Extraction and Quality Appraisal

A total of 2 reviewers conducted data extraction independently using a standardized tabulation table. The table included study details such as author and year, study design, country, participant characteristics, model of digital technology, superordinate themes, subordinate themes, and quotes. Reviewers independently evaluated the studies, considering potential sources of bias, the research questions, the appropriateness of methodology, data collection, ethical considerations, rigor, data analysis, and findings. Any discrepancies between the authors were resolved through discussion and consensus.

The quality of the included studies was assessed using the JBI Critical Appraisal tools for qualitative research, and the Mixed Methods Appraisal Tool (MMAT; version 2018) for mixed methods studies [38,39]. The use of both tools was necessary due to the inclusion of qualitative and mixed methods studies. The JBI checklist is designed to evaluate the methodological validity of studies and to determine the extent to which a study has addressed the possibility of bias in its design, conduct, and analysis [38]. The MMAT is a comprehensive tool that allows for the simultaneous appraisal of qualitative, quantitative, and mixed methods studies [39]. It includes criteria tailored to assess the methodological quality of mixed methods research, such as the integration of the qualitative and quantitative components, the coherence between the research question and methodological approach, and the adequacy of the data collection and analysis methods. The authors assigned a total score to each study and divided them into three categories of quality: high (≥75%), some concerns (50% - 74%), and low (≤49%).

Data Synthesis

Following the JBI Reviewer's Manual, the study used a 3-step meta-aggregation approach to synthesize qualitative study findings [38]. Initially, 2 reviewers independently and repeatedly analyzed the reports of the selected studies, extracting findings and illustrative examples from the results sections. They identified themes, metaphors, and concepts described by the original authors. The credibility of the findings was then assessed and categorized as unequivocal, credible, or unsupported, based on how well the findings matched their supporting illustrations. Second, the reviewers independently grouped the unequivocal or credible findings into categories based on similar meanings. They discussed any differences and clarified the descriptions of the categories until they reached a consensus. Finally, they created synthesized findings by summarizing the categories that shared common features.

RenderX

Results

Study Selection

A total of 2063 records were identified through database searches, including Scopus (n=625), PubMed (n=868), CINAHL (n=273), and Wiley Online Library (n=297). After removing 33 duplicates, 2030 records remained for title and abstract screening. Of these, 2009 records were excluded because they did not meet the inclusion criteria (eg, not focused on PMTCT, not HIV-related, not involving digital-based interventions, or not qualitative in design). These records are reported collectively as "not relevant" in the PRISMA flow diagram, resulting in 21 reports identified for full-text retrieval. Among these 21, one study was a registered protocol or rationale paper without complete study findings and therefore excluded from the eligibility assessment. Thus, 20 full-text articles were assessed for eligibility. After full-text review, 13 studies were excluded due to reasons such as reporting outcomes only (n=1), being randomized controlled trials (n=10), and protocol studies (n=2). Consequently, 7 studies met the inclusion criteria and were included in the synthesis. An additional study was identified through snowballing, bringing the total to 8 studies included in the final synthesis. A detailed breakdown of the study selection process and exclusion reasons is presented in the PRISMA flow diagram (see Figure 1) [40-47].

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) flow diagram of the study selection process. Adapted from Page et al [36] (The PRISMA 2020 statement: an updated guideline for reporting systematic reviews).

Characteristics and Quality of Included Studies

Included studies were diverse in terms of the study design, study location, and digital-based intervention model used. Among the 8 studies included, 3 were qualitative studies [41,43,44] and 5 used mixed methods [40,42,45-47]. The studies were conducted in Kenya, South Africa, and India and aligned with areas with high HIV prevalence. Digital-based interventions evaluated in these studies included mobile SMS, mobile phone calls, and mobile apps. The maternal age distribution of the study participants ranged from 18 to 32 years old. The diversity of study designs and intervention models included provided an understanding of the experiences and perspective toward digital-based interventions that addressed PMTCT of HIV (see Table 1).

Furthermore, the characteristics of the intervention model in the included studies are presented in Table 2. The interventions predominantly used mobile phone technology, including SMS-based messaging, voice calls, and mobile applications. Messaging formats ranged from unidirectional updates to interactive, bidirectional communication, enabling users to engage more actively with the system. Some interventions used group messaging platforms or private phone calls, while others relied on mobile apps specifically designed for maternal and child health support. The content of these interventions varied widely, covering areas such as appointment reminders, early infant diagnosis follow-up, counseling on ART and PMTCT, educational messages on pregnancy, breastfeeding, and disclosure, as well as support for general health and well-being. Many models also incorporated treatment adherence support and emotional or social support mechanisms. These services primarily targeted pregnant, postpartum, and breastfeeding women. They were delivered by a range of providers, including nurses, general practitioners, HIV specialists, nutritionists, trained mentors, and community health workers.

[e]CHW: community health worker.

Quality Appraisal

Based on the quality assessment of the included qualitative studies, a study was categorized as "Low" and another 2 were categorized as "Some concerns" (see Multimedia Appendix 2). The analysis revealed that most biases were identified in the research components related to alignment between the research methodology and the question or objectives, methods used to collect data, data analysis, and the interpretation of results.

The MMAT assessment revealed that while all studies clearly stated their research questions and collected sufficient data to address them, several methodological concerns were noted. In particular, the alignment between research questions and methodologies was often weak. The qualitative components showed unclear justification for the chosen approaches, and in the quantitative (nonrandomized and descriptive) components, issues such as limited sample representativeness, potential nonresponse bias, and inadequate statistical analyses were identified. Furthermore, the rationale for adopting a mixed methods design was frequently insufficient, with many studies failing to justify how combining methods addressed their research aims. These findings, detailed in the MMAT assessment matrix (see Multimedia Appendix 2), highlight the need for more rigorous methodological justification, especially in studies using mixed methods designs.

Study Outcome

A total of 4 synthesized findings emerged, and 9 categories from 17 findings of this study. Table 3 shows detailed information about findings, categories, and synthesized findings. Multimedia Appendix 3 shows detailed information with original quotes.

Table . Findings, categories, and synthesized findings. S5

Finding	Category (code[s])	**Synthesized findings**
Enhances knowledge	Perceived satisfaction (S1, S2, and S4-S8)	Acceptability of digital-based intervention for PMTCT[a] services: Mothers living with HIV have experienced positive acceptability, expressed good perceived satisfaction, and enhanced adherence (S1, S2, and S4-S7).
Enhances motivation		
Usefulness		
Easy to use		
Enhanced support system		
Helpful		
Promotes adherence	Improved adherence (S5-S7)	
Need information related to ART[b] side effects	Need for education (S1 and S2)	Need for integrating education, support system, and reminders into digital-based intervention among mothers living with HIV: Mothers living with HIV have expressed a desire for education related to prevention and care for themselves and their baby; support system; reminders (S1, S2, S4, and S8).
Need information related to MTCT[c]		
Need information related to infant prophylaxis		
Mothers living with HIV desire support group	Support systems (S2)	
Mothers living with HIV need reminders for medication and clinical visits	Reminders (S4)	
Other people may read the message	Concern about their privacy (S1 and S2)	Concern about confidentiality: Mothers living with HIV are concerned about their privacy (S1 and S2).
Family caregiver is indifferent.	Lack of family support (S5)	Personal, interpersonal, and healthcare-related barriers to care adherence: Mothers living with HIV express that they face barriers related to family support, financial, and provider attitudes during the program (S5).
Visit to clinic when women have money	Financial constraints (S5)	
Women do not have money for meals		
Providers were displeased and even argued with mothers living with HIV	Negative provider attitudes (S5)	

[a]PMTCT: prevention of mother-to-child transmission.

[b]ART: antiretroviral therapy.

[c]MTCT: mother-to-child transmission.

Synthesis 1: Acceptability of Digital-Based Intervention for PMTCT Services

The findings of this study explored the acceptability of using digital-based interventions to deliver health information among mothers living with HIV. The findings revealed that the use of digital-based interventions was perceived as acceptable by the participants. Perceived satisfaction emerged as the central theme, with participants expressing that the information delivered through digital-based interventions was helpful and informative. The content included messages on pregnancy nutrition, the importance of breastfeeding, and reassurance about the

XSL•FO
RenderX

possibility of giving birth to a healthy baby despite being HIV positive [41-47]. Another prominent theme was motivation, as participants described feeling encouraged and supported by health care providers who maintained regular phone contact [41,44]. The usefulness of mobile phones was also emphasized, with participants reporting that these tools facilitated data collection and task completion at work [40,43,44]. The ease of use of mobile phones was another major theme, with participants finding them easy to operate and flexible to interact with [40,43]. Therefore, the use of mobile phones was highly acceptable and perceived as helpful, informative, and supportive by mothers living with HIV [44].

This study yielded several findings related to care adherence among mothers living with HIV. Participants reported that counseling services remotely played a supportive role in reminding them to attend clinic appointments, adhere to medication regimens, and follow appropriate infant feeding practices [44,45]. Specifically, participants reported that counselors encouraged regular clinic visits for medication and infant weight monitoring and provided guidance on exclusive breastfeeding for the first 6 months and the importance of avoiding supplemental water [44]. Participants also reported adherence to the recommended immunization schedule [44]. These findings suggest that digital-based intervention services were both acceptable and effective in enhancing adherence to maternal and child health recommendations. In addition, the previously mentioned quotes by Suryavanshi et al [45] reported that reminder messages helped the women to remember to go get medications, demonstrating the positive impact of the counseling service on adherence to medication regimens. Another participant from Suryavanshi and colleague's [45] study expressed their care commitment by keeping track of medication and testing schedules even without reminders [45]. These findings highlight the role of digital-based intervention in fostering a sense of responsibility and self-management among participants.

Synthesis 2: The Need for Integrating Education, Support System, and Reminders Into Digital-Based Intervention Among Mothers Living With HIV

This study revealed that mothers living with HIV have specific needs related to digital-based interventions, particularly in education, support systems, and reminders. In terms of education, participants expressed a desire to receive information on ART side effects [41,42], MTCT of HIV [41], infant prophylaxis [41], and the importance of medication adherence [43]. In terms of support systems, mothers living with HIV found that receiving information about peer support groups helped reduce feelings of isolation and fostered a sense of belonging [42]. In addition, digital reminders were perceived as effective tools for improving adherence to clinical appointments and medication schedules [43].

Synthesis 3: Concerns About Confidentiality

Concerns related to the digital integration of treatment emerged as a key theme in this study, with confidentiality identified as a prominent subtheme. Participants expressed concerns about the privacy of their HIV status and potential for stigma and discrimination if their status was disclosed [41,42]. For example, some mothers living with HIV were uncomfortable receiving SMS messages about their treatment in the presence of others who were unaware of their HIV status, fearing that this could lead to unintentional disclosure and social repercussions [41]. Similarly, some participants expressed concerns about taking ART in public places, where their status could be revealed to others unaware of their status [42].

Synthesis 4: Personal, Interpersonal, and Health Care-Related Barriers to Care Adherence

The findings of this study revealed that limited family support, financial constraints, and negative provider attitudes influenced access and use of HIV care integrated with digital-based interventions among mothers living with HIV. In terms of lack of family support, participants reported that having support from their family members was crucial in encouraging them to attend clinic appointments [37]. Some participants expressed how their family members would encourage them to seek treatment when they were feeling unwell. Financial barriers also emerged as a major concern, as some participants delayed treatment due to insufficient funds for transportation or medication, often relying on family members for financial assistance [37]. Furthermore, provider attitudes impacted service use, with participants reporting experiences of disrespect or poor communication from health care providers that led them to miss appointments or avoid seeking care.

Discussion

Principal Findings

This study identified 4 key themes that reflect the experiences and perspectives of mothers living with HIV and health care providers regarding integration of digital-based interventions into PMTCT of HIV services. First, digital interventions were perceived as acceptable, supported by subthemes such as perceived satisfaction, ease of use, usefulness, increased motivation, and improved adherence to care. Second, mothers living with HIV expressed specific needs for education, support systems, and reminders. They desired information about ART side effects, MTCT, and infant prophylaxis. Subthemes also included the importance of peer support groups and timely reminders for clinic visits and medication use. Third, concerns about confidentiality emerged as a barrier, particularly the fear of unintended HIV status disclosure through text messages received in the presence of others. Finally, participants highlighted personal, interpersonal, and health system barriers that hindered digital care adherence. These included a lack of family support, financial hardship, and negative attitudes from health care providers.

The use of digital-based interventions in health care has grown rapidly in recent years, and this study highlights their benefits in promoting adherence to maternal and child health interventions [41-47]. These interventions have increasingly become a critical component of health care delivery, even in resource-limited settings, and are now embedded within modern society [48,49]. Although some mothers living with HIV expressed concerns about confidentiality, this study found that the integration of digital-based interventions into PMTCT of

XSL•FO
RenderX

HIV services enhanced their satisfaction with care and supported better adherence to treatment. This suggests the use of digital technology as an effective platform to reach and engage mothers living with HIV and their infants. As suggested previously, a high level of acceptability significantly determines successful linkage to and retention in care [50]. The findings align with the growing body of evidence on the usefulness of mobile technology in enhancing health care services across the HIV care continuum and among key populations [34,51-55].

The health care–related needs of mothers living with HIV, particularly in the context of digital-based interventions, primarily focus on education, support systems, and reminders [41-47]. This study found that mothers expressed a desire for digital-based interventions that provide educational content related to treatment, maternal health, and infant care [41]. These digital platforms can serve as valuable tools by delivering reliable information on health conditions, treatment options, medication usage, and self-care practices, thereby supporting improved health literacy and better health outcomes [56,57]. Empowering mothers with such knowledge enables them to make more informed decisions regarding their own health and that of their children.

Furthermore, mothers living with HIV, who often face complex medical and psychosocial challenges, frequently seek emotional and psychological support [58]. The theme of self-isolation frequently emerged in relation to experiences of HIV-related stigma and coping mechanisms [59]. Digital interventions that include support features, such as online communities, chat groups, or direct messaging with health care professionals can provide emotional support, reduce feelings of isolation, and foster a sense of belonging [60]. However, some participants may avoid participating in peer groups due to concerns about confidentiality.

Although mobile phone–based platforms, as digital-based interventions, were generally acceptable and facilitated care engagement, concerns specifically related to SMS were frequently reported [41,42]. These concerns were primarily driven by fears of unintended HIV status disclosure through visible text messages, particularly in shared phone settings or when notifications appeared on locked screens [41,42]. This contrast highlights that while the device itself was acceptable, the mode of digital communication, such as SMS, may introduce risks that affect trust and usability. Therefore, this is not a contradiction but rather a reflection of how acceptability is influenced by the specific design features of digital interventions.

Retention in care and adherence to treatment and care are essential for effectively managing mothers living with HIV and reducing the risk of vertical transmission through viral suppression [61,62]. In this study, mothers living with HIV frequently expressed the need for digital applications that provide timely reminders for taking and refilling medications, clinic appointments, and daily health routines. Such features can significantly enhance treatment adherence and contribute to improved health outcomes for both mothers living with HIV and their babies [55,63].

Although digital health interventions show promise in improving PMTCT outcomes, this study identified confidentiality as a major concern among mothers living with HIV [41,42]. This concern highlights the critical importance of protecting the privacy and confidentiality of health information for mothers living with HIV, especially their HIV status. This underscores the need for health care systems to protect the privacy of individuals' health information, particularly HIV status, by implementing robust privacy policies and upholding legal and ethical standards [64]. This includes securing medical records, limiting access to sensitive data, and obtaining informed consent before disclosing health information to others, including family members or partners.

Barriers to treatment, such as lack of family support, financial difficulties, and negative provider attitudes, are critical factors influencing access to and use of digital-based HIV care interventions among mothers living with HIV. Within the context of ANC, regular clinical visits are essential; however, limited family support and financial problems often make it difficult for mothers to undergo HIV testing and access necessary health care services [65]. The cost of transportation and medical services, combined with poverty-related issues such as food insecurity, further hinders treatment adherence [66]. In addition, partner notification and effective couples counseling are essential as an entry point to identify serodiscordant partners, facilitate mutual disclosure of HIV status, and link those living with HIV to appropriate care and treatment services [67].

A strategic approach involves encouraging national HIV program leaders to advocate long-term policy changes that support the home delivery of antiretrovirals [68]. In addition, targeted financial incentives—such as unconditional cash transfers—have been shown to improve access to care and support treatment adherence, including assistance with ART initiation and transportation to health care facilities [66]. To further address economic barriers, livelihood programs and vocational training, such as microcredit initiatives, can empower mothers living with HIV [66].

In addition, provider attitudes and communication styles can significantly influence the willingness of mothers living with HIV to seek health care services. When mothers living with HIV feel judged, disrespected, or misunderstood—whether during in-person visits or digital interactions—they may be hesitant to participate fully in care or may withhold important health information. Cultural competence and empathy are essential for building trust, particularly given the unique vulnerabilities and stigma often experienced by this population [69]. Negative provider attitudes can contribute to disparities in health care access, leading to reduced quality of care and poorer health outcomes for certain patient populations [69]. To address these challenges, health care professionals should receive training in cultural sensitivity, empathetic communication, and care tailored to mothers living with HIV—both in traditional and digital settings—to ensure that integration of digital-based interventions into PMTCT services is delivered in a supportive and inclusive manner [69].

XSL•FO
RenderX

Implications for Practices and Policies

These findings inform the design of future digital-based interventions for PMTCT of HIV by highlighting the importance of tailoring programs to the specific needs and preferences of both mothers living with HIV and health care providers. To address concerns around confidentiality, policies should ensure robust privacy protections, grounded in the ethical and legal standards of nursing and other health care professions [64]. In addition, government regulations should establish clear guidelines for evaluating the effectiveness and impact of digital health practice [70]. In addition, the national HIV program should consider implementing home delivery of antiretrovirals to address financial barriers. In addition, providing financial incentives to improve linkage to ANC and early infant diagnosis (EID), particularly among low-income populations [71,72], such as covering mobile data costs and offering transportation support for facility visits when ANC or EID is required.

Furthermore, international financial support has played a crucial role in advancing digital-based intervention for HIV care, including PMTCT initiatives. These contributions have supported progress in reducing new HIV infections and lowering maternal and infant mortality related to HIV. However, several major donor countries have announced substantial cuts to their aid budgets for the 2025 - 2026 period. This financial shift may jeopardize the sustainability of PMTCT programs, particularly in low-resource settings. Strategic investment in digital infrastructure is therefore essential to maintaining momentum toward achieving global health targets, especially in remote and underserved areas. The rapid expansion of mobile and communication technologies in LMICs presents an opportunity to optimize service delivery. Digital platforms, such as eHealth and mHealth, can support timely counseling, treatment adherence, follow-up, and remote monitoring for mothers living with HIV and their infants through SMS, video consultations, or online check-ins. Strengthening these systems aligns directly with Sustainable Development Goal 3, which aims to ensure healthy lives and promote well-being for all, including ending the HIV/AIDS epidemic and improving maternal and child health outcomes.

To enhance feasibility, delivery models for PMTCT digital interventions must be tailored to local digital infrastructures and user contexts, ensuring they integrate seamlessly with existing care pathways and uphold privacy standards. In low-connectivity settings, voice calls and SMS reminders offer widely accessible options, while in higher-connectivity areas, smartphone-based tools like apps or chatbots can support more interactive counseling, peer support, and data reporting [73]. These digital platforms should be interoperable with national health information systems to monitor ANC, ART adherence, and EID outcomes. Equitable implementation also demands backup delivery modes, for instance, offering SMS as an alternative for users without smartphones.

Limitations

Despite the valuable insights offered by this study, several limitations must be acknowledged to provide a balanced interpretation of the findings. First, methodological limitations were evident in the included studies, particularly regarding the alignment between philosophical underpinnings and research design. Many studies did not explicitly state the researcher's cultural or theoretical positioning, nor did they reflect on how the researcher may have influenced or been influenced by the research process—an important element in qualitative rigor [74] . Second, the scope of this study was limited to 4 electronic databases (eg, Scopus, PubMed, CINAHL, and Wiley), which may have resulted in the omission of relevant studies published elsewhere, including in scientific search engines (eg, Google Scholar and ScienceDirect) and in the gray literature. This limitation may reduce the comprehensiveness and inclusivity of the synthesized evidence. However, to minimize publication and selection bias, we supplemented our search with manual hand-searching [75,76]. Third, this study included only studies published in English, which may have excluded relevant evidence from non-English sources and introduced language bias.

Fourth, in some themes, the synthesis was informed by only a single primary study, which weakens the transferability and generalizability of the findings. Conclusions drawn from a single context are less robust and may not be applicable across diverse populations or settings. Fifth, considerable variation was observed in the types of digital technologies reported across studies, which may contribute to heterogeneity in outcomes. These differences, ranging from SMS reminders to mobile health apps, can impact the consistency and reliability of the synthesized conclusions. Sixth, the search strategy did not fully use database-specific indexing terms such as PubMed MeSH headings; although MeSH terms were consulted to inform keyword development, reliance on title and abstract keyword searches may have increased the risk of missing relevant studies.

Most interventions in the included studies relied on mobile phone text (SMS) and voice-call technologies. However, 2 SMS-based studies were rated as moderate or lower in quality [41,43], which may introduce potential bias in findings related to SMS delivery models. Also, advanced digital tools were less frequently used and may present different acceptability, usability, and concern profiles compared to simpler technologies. In addition, the barriers identified regarding the integration of digital-based interventions into PMTCT services were predominantly contextual rather than technical in nature. Rather than focusing on usability or platform-specific issues, the findings revealed broader systemic challenges related to the integration of digital interventions into existing health care services. Furthermore, few studies provided technical specifications about the mobile phones used, such as device types, operating systems, or internet requirements. This lack of detail limits our ability to assess disparities in access, particularly in low-resource settings where smartphone ownership, digital literacy, and mobile network coverage are often constrained. These factors should be explored in future research to strengthen the applicability of digital-based interventions for PMTCT of HIV in diverse and underserved contexts.

Conclusions

Findings from this study indicate that digital-based interventions, particularly mobile-based technologies, are highly acceptable

XSL•FO
RenderX

among mothers living with HIV and effectively support adherence to PMTCT-related services. Mothers living with HIV valued digital tools for delivering education, emotional support, and appointments or medication reminders. However, concerns regarding confidentiality and barriers such as limited family support, financial constraints, and provider attitudes were identified as significant challenges to digital intervention uptake. To improve PMTCT outcomes in HIV, future digital strategies must prioritize confidentiality, address women's expressed needs, and consider structural barriers.

Acknowledgments

We would like to express our heartfelt gratitude to Universitas Padjadjaran for providing a database to conduct this systematic review and meta-analysis. We also thank JMIR Medical Informatics for the article processing charges support. This study was supported by Universitas Padjadjaran under grant contract 4269/UN6.3.1/PT.00/2023.

Abstract

Background: Integrating telehealth into established care processes can be challenging. With the integration of telehealth into routine health care practices, there is a growing need to evaluate telehealth outcomes to understand its impact on health care delivery. However, existing literature on telehealth outcomes to support evaluation remains limited.

Objective: This study aimed to analyze recent research from the past decade to develop a categorization of telehealth outcomes. This study seeks to validate a defined set of telehealth outcome categories and examine the broader impact of digital transformation on health care delivery.

Methods: We built the telehealth outcome categories according to the existing literature. During the category-building process, we identified 2 main components: the patient safety outcomes of telehealth and the other care-related outcomes. To validate these categories, we conducted a literature search. The initial search yielded 65 unique articles. Following the screening process, we selected 15 articles for the review. In the review analysis, comprehensive data extraction points established a robust framework for evaluating the scope and impact of telehealth research across multiple dimensions.

Results: On the basis of the analysis, 6 patient safety outcome categories were identified: mortality, adverse effects and harm, complications, hospitalization and readmission, diagnostic and treatment errors, and medication safety. The 9 other care-related outcome categories include cost-effectiveness, access to care, and patient satisfaction. Despite a limited sample, the results on the patient safety outcomes of telehealth indicate a generally positive impact. Several studies have reported that telehealth services are associated with reduced adverse events, complications, and readmissions and enhanced monitoring of patient conditions. The reviewed articles did not include use cases covering all identified preliminary outcome categories, such as medication safety and privacy. However, the review supported patient safety categories being well suited to classifying telehealth outcomes. The other care-related outcomes were not so clearly defined and would require more case examples to support category building.

Conclusions: Further refinement of the main categories identified in this article is necessary to allow for the identification of specific areas and themes that warrant further research initiatives. Future research is essential to evaluate the true benefits and outcomes of telemedicine, offering deeper insights into its real-world impact.

Introduction

The expansion of telehealth signifies a fundamental transformation in the delivery of health care services. The increasing demand for accessible and efficient health care services, especially in light of demographic shifts such as aging populations and rising chronic disease prevalence, as well as a shortage of health care personnel, is among the drivers for the growing implementation of telehealth services. New technological advancements are expected to enhance health care delivery, resulting in more efficient, streamlined, and cohesive care processes [1-3].

Integrating telehealth into existing care processes can be challenging. It is crucial that the transition to telehealth applications is managed carefully to maximize the benefits for all stakeholders, including patients, health care providers, and the broader health care system. Ensuring patient safety is a fundamental priority in health care, and this concern is particularly prominent in the context of telehealth, where the lack of direct physical examinations and in-person interactions can introduce unique challenges and potential risks [3-5].

XSL•FO
RenderX

Despite the potential risks to patient safety, such as miscommunication and preventable harm due to missed or delayed diagnoses, telemedicine has in several studies improved clinical outcomes through timely interventions, reduced mortality, and shortened length of stay [1,4,6-9]. Concerns about the risks associated with telehealth remain, however, since, for example, real-time interactions via telehealth are becoming more common. To date, the literature about the patient safety outcomes of telehealth has not been sufficiently reviewed [4,9]. Although some research exists, comprehensive systematic reviews on alternative modes of delivering telehealth across various care settings remain limited [10].

Although patient safety remains a critical focal point, other outcomes such as clinical efficacy, patient and provider satisfaction, and cost-effectiveness are equally vital in assessing the overall success of telehealth initiatives. With the growing integration of telehealth into routine health care practices, the imperative to thoroughly evaluate these outcomes has become increasingly significant, necessitating a balanced and comprehensive approach to understanding telehealth's broader impact on health care delivery [11-15].

Given the limited scope of existing studies, a literary review could serve as a foundational step in validating telehealth outcomes. Consequently, this systematic review aims to analyze recent research from the past decade to establish a categorization of telehealth outcomes. By examining studies across diverse settings and populations, it seeks to validate a defined set of telehealth outcome categories and explore the broader impact of digital transformation on health care delivery.

Methods

Overview

The rationale for this study lies in the planning phase of an empirical telehealth study. We noticed a lack of comprehensive classifications for telehealth outcomes. Instead, we encountered various reports and studies describing telehealth outcomes and benefits in quite variable ways [eg, 4,16,17]. This led us to compile a categorization of telehealth outcomes based on the existing literature.

Our research question is as follows: Based on the findings of a literature review, can preliminary literature-based telehealth outcome types be systematically built and validated into a categorization?

Conceptualizing Telehealth Outcome Categories

We began by focusing on the core concepts and their definitions. The World Health Organization (WHO) describes telehealth as "the delivery of health care services, where distance is a critical factor, by all health-care professionals using information and communication technologies for the exchange of valid information for diagnosis, treatment, and prevention of disease and injuries, research and evaluation, and for the continuing education of health-care providers, all in the interests of advancing the health of individuals and their communities" [16].

Telehealth can be defined and understood in multiple ways. According to the WHO, telehealth includes 4 main categories: (1) health care consultations between patients and clinicians, (2) the remote monitoring of patient health or diagnostic data by clinicians, (3) the transmission of medical data to clinicians, and (4) case management consultations between clinicians [2,16]. However, for this review, our analysis is informed by the Organization for Economic Co-operation and Development (OECD) categorization [17], as it provides a more detailed classification of telehealth modalities. The classification emphasizes a technical perspective, distinguishing telemedicine as a subset of telehealth. Here, telehealth encompasses not only clinical services provided remotely but also includes broader applications such as distance learning. However, due to our search objective emphasizing patient safety and other care-related outcomes, specifically distance learning telehealth applications were not included in our review. In summary, in this study, we use telehealth as our primary concept, following the definition provided by the WHO [16], while also acknowledging the OECD's [17] distinction of telemedicine as a specific subset within the broader telehealth framework.

For patient safety outcomes, we identified the core concepts primarily based on the Agency for Healthcare Research and Quality (AHRQ) patient safety and quality indicators and monitoring tools, which provided a well-established starting point [18,19]. The patient safety and quality indicators are intended to help health care providers assess, for example, the incidence of adverse events and in-hospital complications and identify issues that might need further study. As a general principle, our aim was to create a generic-level category from individual disease-specific indicators, which are sometimes quite precise, to describe the phenomenon at a general level. Based on the AHRQ indicator materials, broad-level patient safety outcome categories were composed preliminarily as follows: adverse events and harm, diagnostic, treatment errors and complications, visits, hospitalization and readmission, and mortality outcomes. Medication safety was added to the categorization due to its overall importance and relevance in patient safety: medication errors occur throughout the medication use process. Harm due to medicines and therapeutic options accounted for nearly 50% of the overall preventable harm in medical care [20].

We also explored several other outcomes associated with telehealth, including patient and provider satisfaction, as well as cost-effectiveness, as defined in the existing literature. For categorizing the other outcomes, as a starting point, we agreed on using the OECD examples for telehealth impacts, which entail the following themes: continuity of care, improved care coordination, and timelines of care; patient-centered care and health literacy; improved quality of care; increased access to care; avoided travel and reduced costs; and increased knowledge sharing and learning [21].

To test and validate the emerging categories, we performed a literary review on telehealth outcomes. For this, we adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [10,22] to ensure the validity of our review process (Checklist 1).

XSL•FO
RenderX

Applying the Methodology

The literature search was conducted in July 2024 using the PubMed database, which was selected for its comprehensive coverage of the biomedical literature [23]. PubMed with MEDLINE records enables precise and systematic search strategies using Medical Subject Headings terms [24]. Given PubMed's extensive repository, no additional databases were queried. The search was documented in detail to allow for reproducibility.

The search strategy (see Textbox 1) was meticulously crafted based on the key concepts of the study: Telehealth serves as our primary concept in line with the WHO definition [[16]], although we also refer to the OECD's [17] classification. The search was limited to articles published in English and within the past 10 years.

Textbox 1. Search strategy and filters used.

((“patient safety” [Title/Abstract]) AND (“telemedicine” [Title/Abstract] OR

“telehealth” [Title/Abstract])) AND (outcome)

Filters: Abstract, Free full text, in the last 10 years, English

The initial search yielded 65 unique articles. In July 2024, the research team initiated the screening process by reviewing the titles and abstracts of all remaining articles. Following the test reading, the researchers convened to discuss and refine the inclusion and exclusion criteria, ensuring a shared understanding. We defined 3 inclusion criteria for the initial screening: an article must document telehealth use case, report patient safety-related outcomes, and be an original research article. During the screening, we identified 14 review articles. The research team decided to process these review articles separately from the original research articles based on the nature of our research questions [2,4,5,10,25-27]. At the same time, we recognized the importance of analyzing the review articles to ensure that we were fully informed by previous research and to support the development of our telehealth outcome categories.

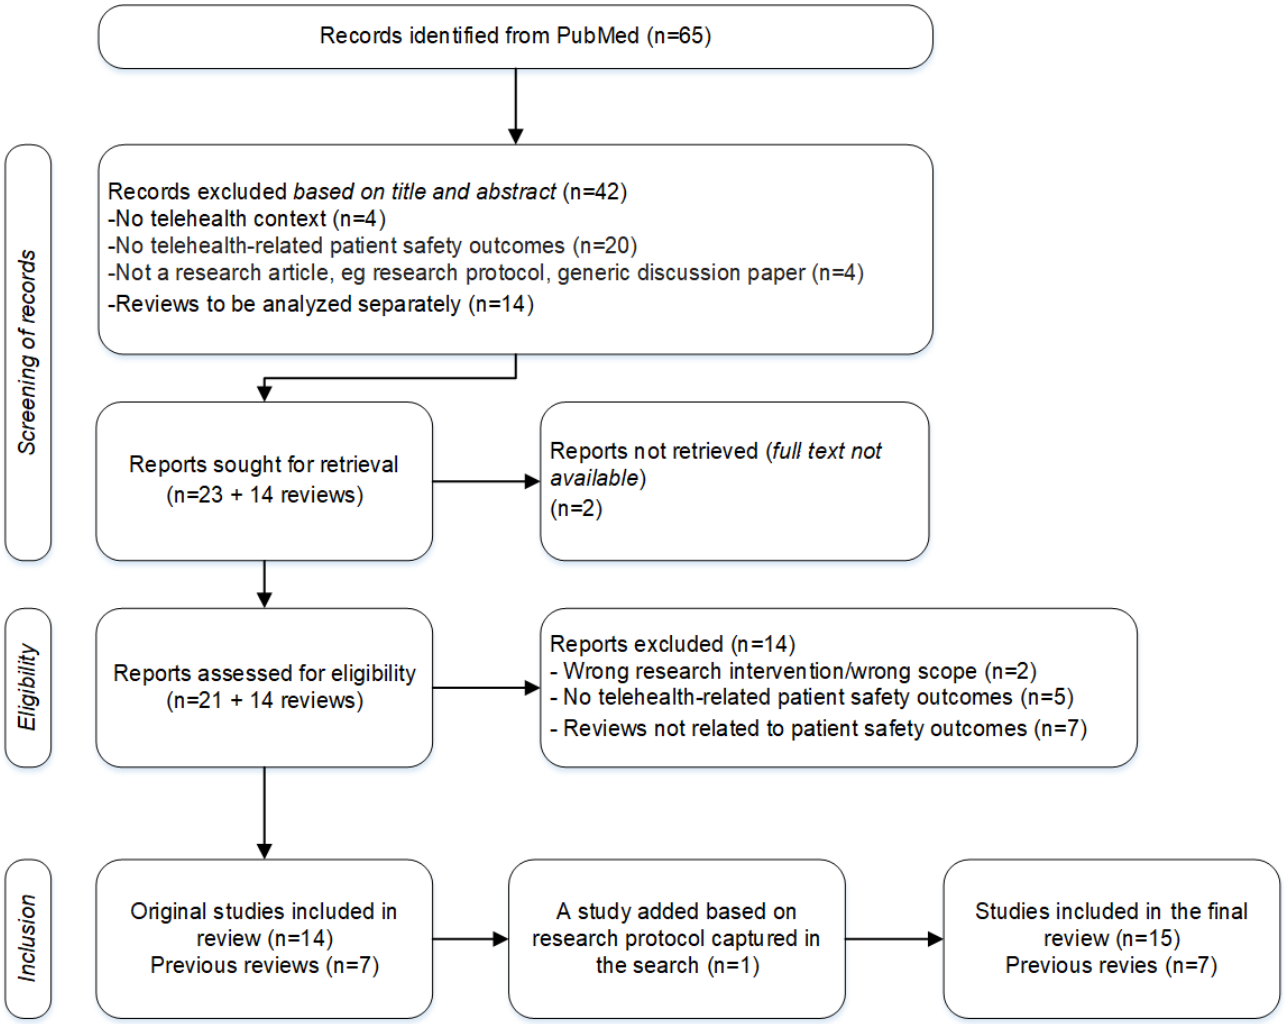
The screening was conducted independently and in a blinded manner, with each researcher applying the criteria separately. Afterward, the results were compared. A match was identified when researchers selected the same option, while a nonmatch occurred if different alternatives were chosen or if a category was not recognized. In 1 borderline case, discussion was required to achieve consensus, but no particularly challenging situations arose. During the initial screening, 42 articles were excluded: 4 of these were due to a lack of telehealth context, 20 due to a lack of patient safety outcomes or other documented health care–related outcomes, and 4 because the paper did not qualify as a research paper (eg, poster).

Ultimately, 23 articles were subjected to a thorough screening process by the authors. For 2 articles, despite being designated as an open access publication, the full text of the article was not accessible. The research team thoroughly reviewed the full texts of the remaining 21 articles to assess their eligibility in July to August 2024. For the final eligibility assessment, the exclusion criteria were defined as follows: the study topic being out of scope or not addressing telehealth outcomes. At this stage, 2 articles were excluded for being out of scope, and an additional 5 articles were excluded for not addressing telehealth-related patient safety outcomes or other health care–related outcomes. Consequently, the eligibility of the identified review articles was also assessed, and 7 previous review articles were included in our study based on their reporting of telehealth outcomes.

The remaining 14 original research articles were systematically analyzed based on specific data extraction criteria following the final inclusion round. One of the included articles described a research protocol where potential result categories were identified. Therefore, our research team agreed to search for an article presenting the results of the study, and this article was included in the review. As a result of this, we had 15 eligible articles for data extraction. The extracted data included the publication year and the journal in which each study was published, providing insight into the academic context of the research. The country of origin of the research and the affiliations of the authors were also documented to assess the geographical distribution.

Each article was further evaluated based on its research goals and motivations, with a focus on the type of telehealth research conducted and whether it pertained to telemedicine or other relevant telehealth innovations. The phase of telehealth intervention within the overall health care process was inspected through 2 categories: prehospital care or posthospital care. Moreover, the clinical domain or specialty, including the specific department involved, was identified to pinpoint the areas of health care most engaged with telehealth solutions. The telehealth application, approach, or method documented in each study was examined to capture the diversity and specificity of the telehealth practices being reported.

Finally, the review recorded patient safety outcomes associated with telehealth interventions, alongside other health care–related outcomes. One of the analyzed articles did not report a specific patient safety outcome despite its research design, instead providing a general discussion on patient safety. Similarly, another article documented patient safety outcomes but did not report other outcomes. After careful consideration and discussion, the research team decided to include both studies due to their valuable content on telehealth outcomes. The content related to these articles is presented in the Results section. These comprehensive data extraction points provided a robust framework for assessing the scope and impact of telehealth research across various dimensions.



XSL•FO

Results

Overview

In total, we analyzed the telehealth outcomes from 15 original articles encompassing 14 distinct studies [28-42]. In total, 2 separate publications addressed the same research topic and project but reported different stages of the study. One of the articles was published in 2016, whereas the remaining articles were published between 2019 and 2024. These articles appeared in 14 peer-reviewed journals and 1 National Health Service publication. The studies were conducted across various countries: 3 (20%) in the USA, 1 (6.7%) in both the USA and Italy, 2 (13.3%) in the Netherlands, 2 (13.3%) in Canada, and 1 (6.7%) in both Canada and Argentina. Other countries of origin included Denmark, the United Kingdom, France, the Republic of Korea, Israel, and Singapore. Regarding the research setting, the articles presented a diverse range of studies, including, for example, cohort studies, a feasibility study, and 2 (13.3%) qualitative studies. Notably, 1 of the articles was a study protocol that outlined preliminary outcome categories (Figure 1).

Figure 1. Flowchart of article identification, screening, and final inclusion.

When analyzing the focus of the telehealth intervention within the overall treatment process, it appeared that the research setting in 9 (60%) studies was posthospital [28-31,33,35,39,41,42] and in 6 (40%) was prehospital [32,34,36-38,40]. The clinical setting of the telehealth intervention was described in all studies at a minimum of specifying the patient group involved. These included 2 (13%) studies related to patients with heart failure [41,42], 2 related to high-risk pregnancy monitoring [37,40], and another 2 related to COVID-19, namely to patients with mild COVID-19 symptoms [33] and clinically healthy COVID-19 patients [34]. One study examined pediatric patients [35] and 1 specifically looked at infant patients with congenital heart disease [39]. One study considered patients in emergency care [38], and another considered remote triage of patients with stroke [32]. Other studies included patients undergoing radiotherapy [28], patients with respiratory tract infection [29], patients undergoing bariatric surgery [31], patients with ureteric colic [35], and chronically ill patients at home [30].

Regarding the telehealth approach implemented, several studies described the utilization of 2 or 3 telehealth approaches. Telemonitoring was used in 7 (46%) studies [29,30,34,37,40-42], store and forward telemedicine in 6 (40%) studies [28,30,33,34,36,40], and interactive telemedicine in 11 (73%) studies [28,29,31-39]. Telecare or assisted living at home was not included in any of these studies.

The Results on Category Building

As outlined in the methods chapter, we developed preliminary categories for telehealth outcomes based on existing categorizations. We used the AHRQ patient safety and quality indicators, along with reported telehealth impact descriptions, as a foundation for developing our telehealth outcome analysis categories [18,21]. To refine the emerging outcome categories, we first enriched them with case examples from the previous review articles identified in our literature search [2,4,5,10,25,26,36] and then standardized the terminology to ensure clearer and more consistent naming.

Our goal was to minimize the overlap between categories. At this stage, in light of the latest research, we decided to add 3 new outcome categories related to clinical outcomes, data protection, and ecological sustainability. The main results of the outcome category building, as used in our review analysis, are presented with references in Multimedia Appendix 1, which contains both key telehealth concepts and the outcome categorization with illustrative examples (on relevant themes in each category) based on previous research. Finally, the telehealth outcome categories are summarized in Textbox 2.

Using the defined set of telehealth outcome categories, we proceeded to analyze the 15 original articles that were included in the review. Detailed results can be found in Multimedia Appendix 2 and Multimedia Appendix 3, as well as in the following 2 result sections.

Textbox 2. The compiled telehealth outcome categories for our review.

1. Patient safety outcomes of telehealth
    a. Mortality outcomes
    b. Adverse effects and harm
    c. Complications
    d. Hospitalization and readmission
    e. Diagnostic and treatment errors
    f. Medication safety

1. Other health care–related outcomes of telehealth
    a. Clinical outcomes
    b. Cost-effectiveness
    c. Quality of care
    d. Access to care
    e. Management and process efficiency
    f. Patient satisfaction
    g. Provider satisfaction
    h. Privacy and confidentiality
    i. Ecological sustainability

The Results on Patient Safety Outcomes of Telehealth

The literature (5/15, 33%) provided references supporting our preliminary categorization of patient safety outcomes related to mortality [29,30,33,37,39]. The analysis of mortality outcomes across the studies suggests that telehealth services may be associated with a reduction in mortality rates for certain diseases. In 1 study, the mortality rate decreased from 16% to 9% [30]. The study on telehealth for infants with congenital heart disease reported no deaths [39], whereas the remaining 3 studies found that telehealth did not result in improved survival or mortality outcomes compared to traditional treatment methods [29,33,37].

The analyzed articles identified an adverse event outcome category that is closely linked to patient safety. Two (13.3%) studies [28,39] reported instances of adverse effects, near misses, or harm associated with telehealth. A study on fully remote radiation oncology care examined patient safety events, defined as staff-reported actual incidents and near misses that could impact patient care [28]. Of the 764 reported safety events, 763 (99.9%) did not reach patients or cause harm to patients, indicating that radiation oncology care provided by fully remote clinicians was safe, with no serious patient events. Another study found no missed events [39].

The reviewed articles supported the complications category, with this outcome identified in 3 (20%) studies [30,37,40]. Our findings suggest that complications among patients receiving telehealth services are relatively rare. In a study on a vital signs telemonitoring system as a regional solution in Italy, the occurrence of major complications decreased from 44% to 30% among the monitored patients [30]. A randomized controlled trial reported a composite of adverse perinatal outcomes as its primary outcome [37]. In the Netherlands, hospitals offering home-based monitoring and telemonitoring for high-risk

XSL•FO
RenderX

pregnancies reported improved patient safety as a key outcome of complication monitoring [40]. The category of diagnostic and treatment errors was identified in 3 (20%) studies [32,34,36]. While telehealth improves access to specialists, it may also contribute to misdiagnoses due to limitations in physical examinations and assessments, highlighting the need for enhanced diagnostic protocols [32,34,36].

The analysis of the papers revealed findings that supported our preliminary category of hospitalization and readmission outcomes in 9 (60%) studies [29-31,33,35,37,39-42]. Specifically, these studies suggest that telehealth has an impact on hospitalization and readmission rates. Notably, some studies reported that patients using telehealth services experienced lower readmission rates, likely due to improved management of chronic conditions and enhanced patient monitoring. An Italian study found a 4% reduction in readmissions within 21 days of discharge [30]. Similarly, a study on bariatric surgery patients reported no readmissions at 30/90 days posttelecare [31].

In 1 of the studies, authors do not demonstrate specific patient safety outcomes but that telemedicine used at triage does not compromise maintaining standard care for chest pain and increasing attention to patient comfort via analgesia. Telescreening in triage is both effective and safe, particularly when extending coverage into previously unstaffed hours. No safety concerns specific to telemedicine use (eg, diagnostic errors) were reported [38]. Despite its central importance to patient safety, medication safety is an aspect that was not addressed in the papers reviewed.

The Results of Other Health Care–Related Outcomes of Telehealth

Other health care–related outcome categories of telehealth were documented in all but 1 of the studies under review (14/15, 93%). Of the 9 outcome categories described in Multimedia Appendix 1 (see also Textbox 2) based on previous telehealth reviews, our reviewed analysis provided research evidence for 8 outcome categories. The category for clinical outcomes [26] was not reported in the studies included in our review, although previous reviews documented examples categorized tentatively as care-related outcomes for telehealth. Feasibility of the tentative outcome category would require more research examples.

The most common other outcome category in our review was cost-effectiveness, which was documented in 11 (73%) of the studies [28,29,31,32,34,37-42]. However, there was no unified way of documenting cost-effectiveness that enables a comparison of telehealth outcomes related to cost reduction. For example, in a telehealth case of radiation oncology, cost savings were calculated per patient [28], whereas another study explored how the intervention costs could be accurately calculated [29]. In this study, clinicians performed telehealth assessments for which average costs were calculated based on the type of contact (telemedicine assessment and domestic visit), number of self-measurements, and severity of alerts. Related to cost-effectiveness, other work-related and occupational benefits were reported [31], such as time saved and no requirement for absence from work to attend a care visit, as well as the possibility to arrange telehealth follow-ups at the workplace. In a telemonitoring case [39], avoidance of emergency department visits contributed to decreasing costs. In addition, indirect cost savings were related to no missed work and no need for transportation. In a COVID-19 telemonitoring case [34], a potential increase in costs and issues of reimbursement were reported, although with no apparent evidence. Another study [38] regarded telehealth costs and a lack of reimbursement as potential barriers to telehealth adoption. Similar reimbursement issues were reported in another case [40]. A high-risk pregnancy telemonitoring case identified patient satisfaction, health-related quality of life, and cost-effectiveness as secondary outcomes of the study [40]. In summary, the results indicate that cost-effectiveness includes many dimensions, especially with regard to telehealth outcomes.

The second most common other telehealth outcome category in our review was patient satisfaction, which was reported in 10 (66.7%) studies [28,29,31,34,35,37-40,42]. In a case of remote management of radiation oncology, nearly all of the patients (n=451, 97.6%) included in the study rated patient satisfaction as good to very good [28]. In a case of a 2-year follow-up after telehealth implementation [31], the satisfaction rate was 80%, with 33% of patients preferring to continue using the telehealth solution. However, 34% of patients felt insecure with telehealth monitoring in relation to health issues that may arise. In a telehealth implementation case [35], 93.1% (n=465) of patients reported satisfaction with the telehealth service. A telescreening case [38] suggested that, in general, patients were happy with telehealth, with a few exceptions. This finding is documented as similar to the evidence gathered from more formal patient satisfaction surveys. Related to patient satisfaction, access to care by remote monitoring was documented as a telehealth outcome only in 1 case [29].

In addition to patient satisfaction, care provider satisfaction was reported as a telehealth outcome in 5 (33%) of the studies [30-32,36,39]. In a case where provider satisfaction was reported, the care personnel were surveyed with 8 different questions to assess their level of satisfaction with the telehealth used in patient care [30]. In an infant congenital heart disease telemonitoring case [39], high levels of provider satisfaction were reported, with physicians expressing an interest in continuing with telemonitoring visits.

The fourth reported health care–related telehealth outcome category was quality of care, which was illustrated in 4 (27%) studies [37,40-42]. In a COVID-19-related telehealth monitoring case [34], the participating professionals reported the possibility to improve the quality of care due to data being measured and shared through the telehealth device. A high-risk pregnancy telemonitoring case [37] reported quality of care related to the advantages of monitoring from home, such as reduced stress and increased rest, including the possible reduction of costs. In a case related to older patients with heart failure [41], home monitoring was expected to improve comfort and quality of life as well as quality of care through the timely detection of possible patient deterioration.

The overall management and process efficiency outcomes related to telehealth were positive, with 4 (26.7%) studies

XSL•FO
RenderX

demonstrating improved operational efficiency and patient management [30,34,38,41]. A reduction in the burden on medical staff was documented as a positive outcome [34,36]. Better communication between members of the care team [41] was included in this category. However, the research evidence was partly ambiguous, stating that, for example, higher level patient compliance and workflow optimization would be beneficial [30].

A telehealth outcome categorized as ecological sustainability was documented in 1 of the studies as a result of less traveling by patients and professionals [28]. Similarly, patient privacy and confidentiality were documented in 1 of the studies [30]. One of the original articles [33] reported only patient safety–related outcomes and did not include other health care–related outcomes.

Discussion

Principal Findings

Digital transformation and advancements in medical technology, such as remote data exchange and mobile communication, are now reshaping health care. This shift is moving health care from an intermittent, acute care model to one that emphasizes continuous, integrated, and comprehensive care and potentially improving patient outcomes. However, previous research suggests that telehealth outcome measures should be standardized to assess and compare different telehealth implementations' and use cases' outcomes more easily [1,10,26]. Despite existing research in this area, an established typology for exploring telehealth outcomes appears to be lacking. Previous research explores telehealth, for example, as a communication means, focusing on its role in facilitating information exchange between patients and health care providers (eg, [11]). Few studies have directly compared different telehealth modalities (eg, [10]). Existing research tends to focus on specific providers or particular conditions [10,25,26,41]. Therefore, we aimed to examine recent research from the past decade to develop an initial categorization for telehealth outcomes.

We built the telehealth outcome categories by using the AHRQ patient safety and quality indicators with an added category for medication safety [18-20] for patient safety outcomes and the OECD telehealth impact categories [21] for other care-related outcomes. During the category building, we checked the overlap between the AHRQ patient safety and quality indicator-based categories and the OECD telehealth impact categories. As the patient safety indicators were described in more detail and were more established, we considered them as guidelines to achieve our data analysis categories for telehealth outcomes. The categories of both groupings were referred to in recent literature reviews, which is why previous reviews were used to further clarify the categories and to refine their naming. Based on a recent review, 3 additional care-related outcome categories were added, namely clinical outcomes, data protection, and ecological sustainability [4,21,25]. Finally, we had 6 outcome categories for patient safety and 9 for other health care–related outcomes (see Multimedia Appendix 1).

The review supported patient safety outcome categories being well suited for classifying telehealth outcomes. However, the medication safety [5,18] category was not met with results in the available study material. Similarly, for other health care–related outcome categories, all were supported with the review except 1 on the clinical outcomes [25]. However, these categories were not so clearly defined originally, and the research team discussed the boundaries and features of the categories to reach a shared interpretation of them. At the same time, the names of the categories were elaborated. Moreover, 2 of the categories were supported with only single examples within the reviewed articles. To summarize, the OECD telehealth impact categories are less clearly defined, being more descriptive and partially parallel to the AHRQ indicators.

On the basis of previous reviews, we decided to introduce new outcome categories related to data protection [4] and ecological sustainability [21]. While no comprehensive validation data were found for these categories in the reviewed literature, their inclusion highlights emerging areas of interest in telemedicine. These categories are particularly relevant, as data protection remains a key concern in health care and ecological sustainability (eg, the need for patient transportation in comparison to digital services) is gaining increasing attention in the context of health care practices [21,28].

The unique nature of telehealth requires patient safety practices specifically tailored to address the risks inherent in virtual care settings. Moreover, the ability to provide safe digital health services anytime and anywhere further underscores the need for robust patient safety practices. Seamless, secure, and universally accessible telehealth services depend on well-integrated safety measures that uphold patient trust while supporting care delivery. In this effort, telehealth outcome data can serve as a starting point for developing virtual care practices, helping to identify and prioritize the most urgent needs for strengthening patient safety measures.

Telehealth outcomes are not always consistent or well integrated, with factors such as device stability and reliability, patient education, accountability, and reimbursement issues impacting the effectiveness of remote patient monitoring [34,40]. While the cost-effectiveness of various telehealth interventions has been studied [28,29,31,32,34,37-42], there are limited data on their long-term efficiency compared to conventional medical practices. In addition, the cost of investment and ongoing maintenance, particularly when multiple stakeholders are involved, may pose significant challenges. Ensuring sustainable implementation requires addressing these financial and logistical barriers while optimizing resource allocation. Future research should focus on evaluating the long-term economic and operational impact of telehealth to guide decision-making and policy development, ultimately enhancing the integration and effectiveness of telehealth solutions.

Our results are significant from multiple perspectives. Our findings have the potential to offer valuable insights for health care providers, policymakers, and researchers, supporting future telemedicine implementations and policies to optimize both safety and other expected outcomes. Moreover, the results could contribute to future telehealth research by providing a systematic

XSL•FO
RenderX

approach for classifying and evaluating telehealth outcomes. Structured data on telehealth outcomes could benefit, for example, the assessment of long-term changes in delivering care [26].

By providing a structured approach, these results can shape the future of telehealth, support evidence-based decision-making, and enhance the integration of telehealth into routine care. Furthermore, the study has significant management implications as health care leaders seek to optimize technology resources to improve efficiency. A well-structured telehealth evaluation framework can contribute to ensuring that patient-centered care remains the cornerstone of medical practice, aligning technological advancements with high-quality, accessible, and equitable health care delivery.

Future research is suggested to focus on delineating its scope, establish clear inclusion criteria, and distinguish it from existing outcome categories to improve the reliability and reproducibility of telehealth outcome assessments. Regarding patient safety outcome categories, medication safety warrants further research, given its critical role in ensuring safe care in, for example, preventing adverse events [20]. In the context of building the outcome categorization, it is possible to consider conducting additional, focused literature searches on medication safety–related topics in the next phase of the study. When viewed more broadly from the perspective of telehealth research, future studies should prioritize identifying specific medication safety risks unique to telehealth settings, developing targeted assessment tools, and evaluating intervention strategies to mitigate these risks. To validate “other outcomes” requires also further refinement to enhance conceptual clarity and methodological consistency. In this review, for example, regarding ecological sustainability, because of its emerging nature, it may be necessary to revisit the theoretical foundations concerning conceptualization and factors before proceeding to examine the outcomes.

Limitations

One limitation of this study is the small number of articles included, which affects the applicability of the findings. More case studies are needed to further validate the results and strengthen the overall evidence base. Incorporating a greater variety of case studies would enhance the robustness of the conclusions drawn. In particular, despite the central importance of medication safety to overall patient safety, this critical aspect was not adequately addressed in the papers reviewed, highlighting a possible gap in the current literature. The same applies to ecological sustainability. Our literature review relied solely on PubMed, which can serve as a primary search tool according to peer-reviewed research [43]. It is, however, essential to acknowledge that the use of a single database may limit the comprehensiveness of the search in areas outside strict biomedicine or in multidisciplinary contexts. While PubMed is the largest biomedical database and citations in PubMed primarily stem from the biomedicine and health fields, and related disciplines such as life sciences, behavioral sciences, chemical sciences, and bioengineering, it has less coverage of fields such as social sciences. For future reviews with broader scope covering also, for example, social sciences, PubMed searches can be complemented with other scientific databases [24,43,44].

Conclusions

To conclude, preliminary validation based on the literature review supported patient safety outcome categories being well suited for classifying telehealth outcomes. Nevertheless, further refinement of the main categories identified in this article is necessary to allow for the identification of specific areas and themes that warrant further research initiatives. Future research would be critical for assessing the true benefits and outcomes of telemedicine, providing a deeper understanding of its real-world impact.

Abstract

Background: Artificial intelligence (AI)–based diagnostic prediction models could aid primary care (PC) in decision-making for faster and more accurate diagnoses. AI has the potential to transform electronic health records (EHRs) data into valuable diagnostic prediction models. Different prediction models based on EHR have been developed. However, there are currently no systematic reviews that evaluate AI-based diagnostic prediction models for PC using EHR data.

Objective: This study aims to evaluate the content of diagnostic prediction models based on AI and EHRs in PC, including risk of bias and applicability.

Methods: This systematic review was performed according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. MEDLINE, Embase, Web of Science, and Cochrane were searched. We included observational and intervention studies using AI and PC EHRs and developing or testing a diagnostic prediction model for health conditions. Two independent reviewers (LH and AC) used a standardized data extraction form. Risk of bias and applicability were assessed using PROBAST (Prediction Model Risk of Bias Assessment Tool).

Results: From 10,657 retrieved records, a total of 15 papers were selected. Most EHR papers focused on 1 chronic health care condition (n=11, 73%). From the 15 papers, 13 (87%) described a study that developed a diagnostic prediction model and 2 (13%) described a study that externally validated and tested the model in a PC setting. Studies used a variety of AI techniques. The predictors used to develop the model were all registered in the EHR. We found no papers with a low risk of bias, and high risk of bias was found in 9 (60%) papers. Biases covered an unjustified small sample size, not excluding predictors from the outcome definition, and the inappropriate evaluation of the performance measures. The risk of bias was unclear in 6 papers, as no information was provided on the handling of missing data and no results were reported from the multivariate analysis. Applicability was unclear in 10 (67%) papers, mainly due to lack of clarity in reporting the time interval between outcomes and predictors.

Conclusions: Most AI-based diagnostic prediction models based on EHR data in PC focused on 1 chronic condition. Only 2 papers tested the model in a PC setting. The lack of sufficiently described methods led to a high risk of bias. Our findings highlight that the currently available diagnostic prediction models are not yet ready for clinical implementation in PC.

Introduction

Background

The diagnostic process is a core task of general practitioners (GPs). However, making a diagnosis may be a challenging task given the diversity, complexity, and early presentation of symptoms. Clinical prediction models are intended to improve the diagnostic process [1]. These models can support the health care provider by predicting serious illness [2]. In the last years, the interest in artificial intelligence (AI) techniques for the development of prediction models has been growing [3,4]. AI-based prediction models could aid in decision-making for faster and more accurate diagnoses, with more diagnostic efficiency that can benefit patients' health [5-8]. Examples are prediction tools that can predict colorectal cancer in patients [9,10].

Clinical prediction models used to be built on data from large databases, such as data collected for research purposes, claim data, or data from electronic health records (EHRs) [11,12]. EHR data consist of structured data, which are data in standardized format, and unstructured data, which are free-text data. Primary care (PC) EHR data provide extensive and longitudinal data from a patient's health trajectory and changes over time. AI might prove to be a valuable method to extract clinically useful and actionable insight from this vast and complex source of patient data [13]. For that reason, AI has the potential to transform EHR data into a valuable tool for predicting diagnosis in daily PC practice.

Reviews on the value of AI in PC are scarce, and previous research had different aims. For example, Kueper et al [14] provided an overview of diagnostic prediction models based on AI in PC. However, the authors did not assess the quality of these diagnostic prediction models. Other research in this field explored AI systems in community-based primary health care [15] or focused on different machine learning (ML)–based diagnostic and prognostic models that predicted a health care condition [16]. As AI has the potential to support and improve the diagnostic process, high-quality and validated prediction models are crucial in order to ensure patient safety after clinical implementation. Although a variety of prediction models for PC have been developed, to our knowledge, there are currently no systematic reviews on AI-based diagnostic prediction models for PC using EHR data.

Objective

Evaluation of the content and quality assessment of AI-based diagnostic prediction models using EHRs in PC was largely lacking in current literature. Therefore, we systematically reviewed the literature in order to critically evaluate the content of these AI-based diagnostic prediction models, including risk of bias and applicability.

Methods

Study Design

We performed a systematic review according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [17] (the PRISMA checklist is provided in Checklist 1). The protocol for this study was registered in PROSPERO (nr: CRD42022320002). The research team included stakeholders such as practicing GPs, researchers, methodologists, and AI experts in the design, analysis, and reporting of the study.

Search Strategy and Study Selection

Our search was adapted from the search strategy developed by Kueper et al [14]. It combines two concepts including a wide range of different terms used to describe the concepts: (1) artificial intelligence and (2) primary care (for full search strategy, see Multimedia Appendix 1, part 1 [18-67]). EHRs were not part of the search strategy, because literature suggests that we might miss important studies when including EHRs or related terms in the search strategy [13]. We searched in the following databases: MEDLINE, Embase, Web of Science, and Cochrane. There were no restrictions concerning the publication date. The last search update was conducted on August 28, 2023. We focused on intervention and observational studies. We excluded systematic reviews, meta-analyses, case studies, editorials, protocols, and conference posters or abstracts. Full text had to be available to be selected for screening. The literature had to be written in English or Dutch. Duplicate publications were removed with EndNote 20.

Inclusion and Exclusion Criteria

Four inclusion criteria were used to select the papers: (1) primary care focus: this included PC data, models that were tested in a PC setting, or PC had to be specifically mentioned in the aim of the study; (2) diagnostic prediction model: models had to predict a health condition applicable during a GP's consultation; prediction models that identified a disease in a database, rather than predicting a disease for an individual, were excluded; (3) AI: this included all ML and deep learning techniques; we directed our focus to data-driven prediction models without using medical images as input data; and (4) EHR-based data: EHR data had to be used for the development or validation of the model. EHRs were defined as PC data from EHRs, medical records, or clinical notes. See Multimedia Appendix 1, part 2 [18-67], for the full screening guidance.

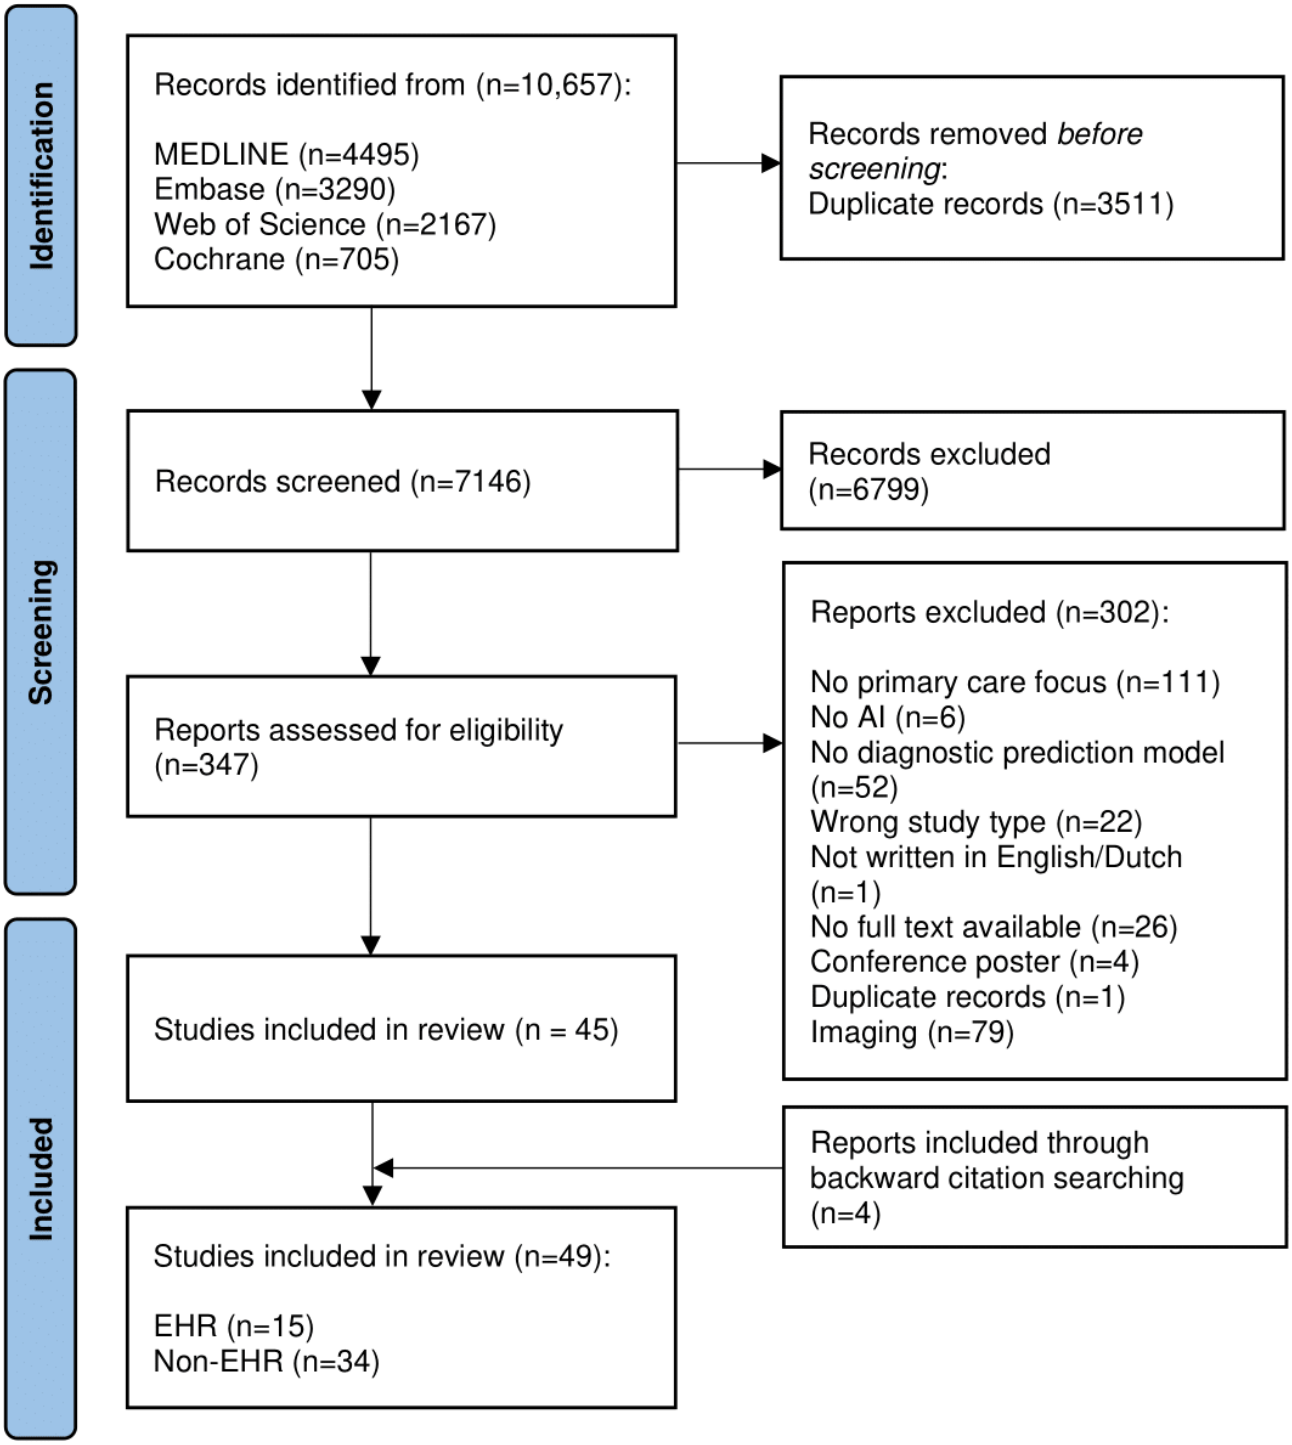
Title and abstract screening was done in management software Rayyan (rayyan.ai) by 2 independent reviewers (LH and LvdH). Conflicts were resolved by a third reviewer (AU). Full-text screening was done by the same independent reviewers. Conflicts were resolved by discussion, and if no consensus was reached, they were resolved by a third reviewer (AU). Backward citation searching was conducted on the included papers and finished on November 7, 2023.

Data Extraction and Quality Assessment

Data extraction of included papers was done by 2 independent reviewers (LH and AC). They used a standardized data extraction form adapted from the Checklist for Critical Appraisal and Data Extraction for Systematic Reviews of Prediction Modelling Studies (CHARMS) [68]. Basic information was extracted from all papers. The extraction of more detailed information was focused on EHR-based papers. For all papers (EHR and non-EHR papers), we extracted general information

XSL•FO
RenderX

(first author, year of publication, title, data source, and country of data source), study design (retrospective or prospective), and outcome (predicted health condition). For the EHR papers, we additionally extracted dataset information (name of the dataset and sample size: number of participants used for model training, testing, or validation), AI technique, and predictors (the potentially used predictors used to develop the model). Risk of bias and applicability were assessed using PROBAST (Prediction Model Risk of Bias Assessment Tool). This tool includes 20 signaling questions divided into 4 domains (participants, predictors, outcome, and analysis) [69,70]. Overall judgment (ie, low, unclear, or high) of risk of bias is based on the 4 domains. If 1 domain is considered to have a high risk of bias, the overall judgment is scored as a high risk of bias. If at least 1 domain is considered to have an unclear risk of bias (without a domain with high risk of bias), the overall judgment is scored as unclear risk of bias. Applicability concern was rated based on 3 domains (participants, predictors, and outcome) and an overall judgment of applicability (ie, low, unclear, or high) was also given with the same approach as the risk-of-bias scoring. Applicability evaluation depends on the review question [69], and we translated applicability assessment as usability of the diagnostic prediction model in a PC setting. Conflicts in data extraction between the 2 reviewers (LH and AC) were resolved by discussion, and if no consensus was reached, they were resolved by a third reviewer (TvL).



Results

Description of Included Studies

We retrieved 10,657 records using our search strategy. After duplicate removal, we conducted title and abstract screening on 7146 records. A total of 347 records met the eligibility criteria for full-text screening. After full-text screening, 45 records were included. Backward citation searching yielded an additional 4 papers. A total of 49 papers were thus included in the review (Figure 1). Of the included papers, we identified 15 EHR papers and 34 non-EHR papers. A detailed description of the 34 non-EHR papers can be found in Multimedia Appendix 1, part 3 [18-67]. The data used in these 34 papers were collected from different sources, including secondary care datasets (n=17), questionnaires (n=4), and the knowledge of different health care providers (n=5).

Overview of the EHR-Based Papers

Of the 15 EHR papers, 13 (87%) included the development of a prediction model [18-30]. In Table 1, the data extraction per paper can be found. The included EHR papers covered various outcomes, mostly chronic conditions (11/15, 73%) [19-28,31]. The most frequent predicted outcomes were dementia (3/15, 20%) [19,20,23], asthma (3/15, 20%), or chronic obstructive pulmonary disease (COPD) (3/15, 20%) [21,26,31]. Other study outcomes are shown in Table 1. All included papers used predictors registered in EHRs. Predictors included findings from clinical examination (n=6) [19,25,26,28,31,32], laboratory results (n=5) [21,22,25,28,32], and medication (n=4) [19,21,24,29]. All models used structured data.

Two papers externally validated and tested a prediction model in a PC setting [31,32]. One paper had a prospective approach and tested the diagnostic performance of a prediction model for asthma and COPD [31]. Ten papers (10/15, 67%) were published after 2020 [18,21-24,26,27,29,31,32]. Most data sources used in the studies originated from Europe (8/15, 53%) [18-22,24,27,31], followed by North America (5/15, 33%) [23,25,28,29,31,32] and Asia (2/15, 13%) [26,30].

Mariani et al (2021) [21]	Netherlands	Developmental	Retrospective cohort study	To diagnose asthma and COPD or asthma-COPD overlap	Data from Dutch primary care laboratory in Groningen	3659 participants with asthma or COPD from 2007 to 2017	Demographics, symptoms, diagnosis, medication, laboratory results, referrals, spirometry results	SVM, RF, KNN
Nemlander et al (2023) [27]	Sweden	Developmental	Nested case-control study	To identify nonmetastatic colorectal cancer	Regional administrative health care database from Västra Götaland Region	2681 participants (542 cases with a cancer diagnosis, 2139 controls)	Nonmetastatic colorectal cancer stage, number of GP consultations, diagnosis codes	Stochastic gradient boosting
Perveen et al (2016) [28]	Canada	Developmental	Retrospective cohort study	To classify diabetes mellitus in 3 adult age groups	EHR data from Canadian Primary Care Sentinel Surveillance Network	4678 participants (377 cases of diabetes, 4301 controls with no diabetes) with all documented risk factors	Demographics blood pressure, laboratory results	Decision tree, bagging, ADAboost
Singh et al (2022) [29]	United States	Developmental	Retrospective cohort study	To predict anterior segment vision-threatening disease (asVTD)	EHRs of the University of Michigan	2942 participants with anterior segment eye complaint (133 cases with asVTD, 2809 controls) with PC notes with ophthalmologist visit	Demographics, history of eye problems, symptoms, medication	Elastic net LR
Su et al (2019) [30]	China	Developmental	Retrospective cohort study	Top 100 diagnoses (within general diagnoses)	National Hospital Ambulatory Medical Care Survey and the National Ambulatory Medical Care Survey	Unknown number of participants, top 100 diagnosis selected from 2,000,000 records	Demographics, symptoms, past medical history	NN

[a]LR: logistic regression.

[b]RF: random forest.

[c]SVM: support vector machine.

[d]NB: naïve Bayes.

[e]XGBoost: extreme gradient boosting.

[f]NN: neural network.

[g]GP: general practitioner.

[h]COPD: chronic obstructive pulmonary disease.

[i]KNN: K-nearest neighbors.

AI Technique

All of the included studies performed at least 1 supervised AI technique (Table 1). The most used AI techniques were random forest (9 papers), logistic regression (7 papers), support vector machines (5 papers), boosting algorithms (5 papers), neural networks (5 papers), and naïve Bayes (4 papers).

Quality Assessment: Risk of Bias

None of the studies assessed by the PROBAST tool had a low risk of bias. We found a high risk of bias in 9 studies (9/15, 60%) and an unclear risk of bias in 6 studies (6/15, 40%; Table 2). In Multimedia Appendix 1, part 4 [18-67], the full assessment of the PROBAST tool can be found.

Singh et al [29]	Low	Low	Unclear	High	High
Su et al [30]	Unclear	Unclear	Unclear	Unclear	Unclear

The most significant source of bias was found in the analysis domain. The main reasons for the high risk of bias in this domain were the insufficient number of participants with the outcome (5/15, 33%) [18,24,26,29,31] and irrelevant model performance measures that were used to evaluate the model (2/15, 13%) [28,31]. The main reasons for an unclear risk of bias in the analysis domain were lack of clarity on how missing data were handled (10/15, 67%) [18-20,22,23,27-30,32], and on how the predictors and their assigned weights in the final model correspond to results from the reported multivariate analysis (9/15, 60%) [18,20,21,25-30]. Although measures of calibration are not part of the signaling questions of the PROBAST, we noticed that only 4 papers (4/15, 27%) [22,23,29,32] used calibration to assess the performance of the model.

The second significant source of bias was found in the outcome domain. The main reasons for the high risk of bias in this domain were the determination of the predictors with a prior knowledge of the outcome (1/15, 7%) [31] and not excluding the predictors from the outcome definition (2/15, 13%). For example, Perveen et al [28] included fasting glucose levels to predict diabetes and Kocks et al [31] included spirometry findings to predict asthma and COPD. The 2 main reasons for an unclear risk of bias in the outcome domain were lack of clarity on the time interval between the outcome and the predictors (9/15, 60%) [20,24-30,32] and the lack of clarity on the outcome definition (7/15, 47%) [20-22,24,26,28,30].

The third domain with risk of bias was the participants domain. A high risk of bias in the participants domain was found because inclusion and exclusion criteria were not appropriate in 2 studies (2/15, 13%) as both studies excluded participants at high risk of the outcome [27,32]. Another reason for the high risk of bias was a nonappropriate data source that was used in 1 study [20] because the authors described the study as a case-control study although the study was not nested as recommended in the PROBAST guidelines [69,70]. The predictors domain was the domain with the lowest risk of bias. The lack of clarity that resulted in an unclear risk of bias covered mainly insufficient information on whether the predictors were defined and assessed in a similar way for all participants (4/15, 27%) [18,20,22,30].

Applicability

Overall, we found an unclear concern for applicability in 10 papers (10/15, 67%) and a low concern for applicability in 5 papers (5/15, 33%; Table 3). The unclear concern for applicability to our research question was mainly noticed in the outcome domain due to a lack of clarity in reporting the time interval between the outcomes and predictors (8/15, 53%) [20,25-30,32].

XSL•FO
RenderX

Perveen et al [28]	Low	Unclear	Unclear	Unclear
Singh et al [29]	Low	Low	Unclear	Unclear
Su et al [30]	Unclear	Unclear	Unclear	Unclear

In the predictors domain we also found an unclear concern for applicability due to the lack of clarity in the definition of the included predictors (5/15, 33%) [18,20,22,28,30]. For example, 1 paper lacked information on how notes were annotated before they were used as predictors in the model [18]. The unclear concern for applicability in the participants' domain was mainly due to lack of information on inclusion and exclusion criteria (3/15, 20%) [25,26,30].

Discussion

Principal Results

We systematically reviewed the literature for studies about AI-based diagnostic prediction models for PC. These models were developed with different data sources, such as questionnaire data, secondary care data, or EHR data. Only 15 out of 49 models were developed using data from EHRs. Most of the models using EHR data focused on just 1 chronic condition. Merely 2 papers tested the model in a PC setting. All of the included studies performed at least 1 supervised AI technique, most often with random forest or logistic regression. Evaluation with the PROBAST guidelines showed an unclear to high risk of bias for all EHR papers. In most of the papers, we found unclear concerns about the applicability to our research question.

Comparison With Prior Work

To the best of our knowledge, only 2 reviews evaluated the risk of bias in clinical prediction models on a wide range of diseases in PC studies [15,16]. Most of the included studies in these reviews showed a high to unclear risk of bias, which is in line with our findings [15,16]. However, there appear to be differences in grading compared with Abdulazeem et al [16]. They considered incomplete reporting and the absence of external validation a high risk of bias, whereas in our systematic review, these points were considered as an unclear risk of bias and no risk of bias, respectively. The study by Abbasgholizadeh et al [15] did not report details on the reasons they coded subdomains as high or unclear risk of bias, for which reason we are unable to make a formal comparison with our results.

Systematic reviews evaluating AI-based clinical prediction models in other medical fields have followed the same grading criteria as we did and found similar flaws in the analysis domain as we did in our systematic review [71,72]. These similarities include the unjustified small sample size in EHR studies, inappropriate evaluation in the performance measures, and flaws in handling of missing data [71-73].

The most used AI techniques were random forest, logistic regression, support vector machines, boosting algorithms, and neural networks. In previous systematic reviews, random forest and support vector machines are also more often found as most used methodology [16,71,73-75]. This might be explained by the well-described strong performance and ease of interpretability of random forests and support vector machines, particularly when working with lower-quality structured data. Most PC EHRs are primarily used for clinical purposes, with secondary purposes for research [69]. Thus, the challenges associated with using such EHRs to develop prediction models have been widely documented and include missing values and inconsistencies in data entry [13]. These challenges are inherent to the data and should be addressed at the preprocessing stage. We did not find papers that used generative AI methods (such as large language models). Our retrieved papers developed or validated tools based only on structured data (numbers or codes such as laboratory results, vital signs, and diagnosis codes from International Classification of Primary Care or *ICD-10* [*International Statistical Classification of Diseases, Tenth Revision*]) rather than unstructured data or written text, where large language models work well on. Literature found it valuable

XSL•FO
RenderX

for the performance of the model to use unstructured data together with structured data for prognostic prediction models [76,77]. We think that future studies about diagnostic prediction tools will increasingly use generative AI methods, although it is still difficult to integrate them into clinical workflows [78].

In general, studies analyzing EHRs are subject to a high risk of bias, because these data are collected for clinical rather than research purposes [69]. Hence, clinical prediction models developed on EHRs are more difficult to reproduce and generalize, given the heterogeneity of coding systems and database infrastructures [16]. In line with models analyzed in previous studies [15,16,73], most of the clinical prediction models were not externally validated. Most of the studies developed in PC were performed in high-income countries and may not have taken into account regional or global differences in the availability of certain predictors [14-16]. For example, some predictors may not be easy to obtain in PC settings in low-income countries (eg, spirometry results for the prediction of asthma or COPD). Furthermore, the lack of stratified analyses in most studies implies that we cannot draw conclusions about how diagnostic models perform across different equity groups. Together, all these factors limit the generalizability of the clinical prediction models.

Strengths and Limitations

The main strength of the study is the extensive search strategy with no date limit in a large and diverse range of studies on AI prediction models in PC. Not including "EHR" in the search strategy added rigor to our study as a recent review suggests that important papers could have been missed when we included EHRs in the search strategy [13]. A second strength is that the findings on the risk of bias were carefully assessed by 2 independent reviewers (LH and AC) with experience in clinical PC, and the conflicts were discussed with other experts in the field of PC and AI. Unlike previous systematic reviews that found a high proportion of studies with a high concern of applicability to the research question [72], we noticed no high concern for applicability in any study. We believe that the findings shared in our review are highly reliable in highlighting the current situation of AI studies in PC using EHRs.

The main limitation of this study is the broad definition of the terminology for the search strategy, which may have prevented us from capturing all relevant studies. For example, we included all studies that used ML and deep learning techniques. Given the lack of a widely accepted definition of AI, other reviews use other criteria for AI or ML [71,73,75]. Similarly, given our definition of diagnostic prediction models, we considered a diagnostic prediction model to be a model that predicts a health condition during a GP's consultation. As a result, multiple prediction models that identified a disease in a database were excluded. The second limitation is the use of the PROBAST guidelines to determine the risk of bias and applicability in evaluating AI prediction models. Although the PROBAST guidelines are highly detailed and reliable in evaluating clinical prediction models [33], PROBAST has been criticized for being less specific and less applicable for AI-based models than traditional statistical methods. Considering this criticism, a protocol on the extension of PROBAST into PROBAST-Artificial Intelligence (PROBAST-AI) has been published with the aim to develop a PROBAST-AI tool to better support evaluation of prediction model studies that applied AI [3]. The PROBAST-AI tool has not yet been published.

Future Research and Practical Implications

The relevance of the applicability of prediction models in clinical practice should be the priority when developing clinical prediction models, as stated in a number of standardized frameworks designed for prediction model developers [79,80]. We found that only 2 models were tested in PC settings. Moreover, most studies included in this review predict chronic conditions. This is also seen in previous reviews evaluating clinical prediction models in PC [14,16]. However, in general, chronic conditions are not known to be difficult to diagnose in PC. Two examples from our included papers are the diagnosis of hypertension predicted on the variable high blood pressure [25] and the diagnosis of diabetes predicted on the variable high glucose levels [28]. These predictions might not be as useful in clinical practice, even if the model performance metrics are excellent. Nevertheless, chronic conditions are highly prevalent in PC and for conditions that are influenced by several and complex factors, prediction models may facilitate the diagnostic process for the GP. As most tools focused on predicting 1 condition, GPs would have to use many prediction tools side by side to predict the correct diagnosis in daily practice. All these findings highlight that involving more practicing GPs and asking what they need are important in developing clinical prediction models with a higher success rate of clinical implementation. We recommend involving relevant stakeholders in the early stages of the development of a new model.

To improve the methodology in future studies, our findings suggest that a special focus is required on reporting areas such as methods for internal validation, appropriate inclusion of participants, and a proper sample size calculation. A high risk of bias mainly found in the analysis and outcome domains should be alarming as this questions the methodology of the included papers. We found an unclear risk of bias and unclear concern for applicability in more than half of the included studies, mainly related to poor reporting, for example, about missing data. Missing data is known as a large challenge for EHR data [13], and extra attention should therefore be paid to reporting this. Researchers can benefit from the use of the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) statement [81] and PROBAST guidelines in communicating their findings [3], particularly now that the TRIPOD-AI extension is released [82]. To enhance the applicability of the prediction model, we highlight the importance of clear reporting on the time interval between predictors and outcome, a clear definition of the outcome and predictors, and a clear description of the inclusion and exclusion criteria. Differences in recording between EHRs might lower the performance of the model in the external validation step, and external validation is a crucial step for generalizable and reliable models [76]. However, we found only 2 papers that performed external validation.

Conclusions

AI-based prediction models using EHR data are not yet ready for implementation into PC daily practice. The number of studies found was limited, and reproducibility and generalizability were insufficient. For a diagnostic prediction model to be used in PC, it is important that GPs and relevant stakeholders are involved in the development, that the model is externally validated, and that it is appropriately recorded.

Acknowledgments

This study was funded by ZonMw file number: 839150005. The authors would like to thank Lori van den Hurk for her help with the screening process.

Conflicts of Interest

None declared.

Abstract

Background: Over the last decade, natural language processing (NLP) has provided various solutions for information extraction (IE) from textual clinical data. In recent years, the use of NLP in cancer research has gained considerable attention, with numerous studies exploring the effectiveness of various NLP techniques for identifying and extracting cancer-related entities from clinical text data.

Objective: We aimed to summarize the performance differences between various NLP models for IE within the context of cancer to provide an overview of the relative performance of existing models.

Methods: This systematic literature review was conducted using 3 databases (PubMed, Scopus, and Web of Science) to search for articles extracting cancer-related entities from clinical texts. In total, 33 articles were eligible for inclusion. We extracted NLP models and their performance by F_1-scores. Each model was categorized into the following categories: rule-based, traditional machine learning, conditional random field-based, neural network, and bidirectional transformer (BT). The average of the performance difference for each combination of categorizations was calculated across all articles.

Results: The articles covered various scenarios, with the best performance for each article ranging from 0.355 to 0.985 in F_1-score. Examining the overall relative performances, the BT category outperformed every other category (average F_1-score between 0.2335 and 0.0439). The percentage of articles on implementing BTs has increased over the years.

Conclusions: NLP has demonstrated the ability to identify and extract cancer-related entities from unstructured textual data. Generally, more advanced models outperform less advanced ones. The BT category performed the best.

Introduction

Electronic health records (EHRs) are increasingly being adopted by health care providers worldwide, as they offer numerous benefits [1]. This has led to an increase in the quantity of data stored in EHRs, consisting of both structured and unstructured data (eg, text, images, and time series). Unstructured textual data from discharge summaries, radiology reports, clinical notes, and patient histories provide valuable information about patients that may not be captured by structured data alone [2]. The extraction of clinical parameters from unstructured textual data, also known as information extraction (IE), has proven to be valuable in health care, such as in clinical research (eg, epidemiology) and decision support systems [3,4].

However, working with unstructured textual data presents several challenges to health care providers and researchers. The volume of free text makes manual extraction and analysis time-consuming and resource-heavy, thereby limiting their utility and requiring automated solutions. Moreover, the lack of standardization and consistency in formatting and terminology makes it difficult to accurately identify and extract the relevant information in an automated manner. Furthermore, free text is prone to spelling errors, resulting in inaccurate or harder-to-find

XSL•FO
RenderX

patient information for methods that rely on keyword extraction or other exact-match search techniques.

Natural language processing (NLP) techniques are well suited for extracting information from free text because of their ability to process, comprehend, and generate human language in a manner that allows for automatic extraction of structured information from free text. In recent years, NLP has gained considerable attention, with numerous studies exploring the effectiveness of various NLP techniques, notably for identifying and extracting cancer-related entities, such as smoking history [2], toxicities [5], and Gleason scores [6], which are only recorded as free text in clinical notes. These techniques are known as named entity recognition, or more generally, IE [7-9].

A variety of techniques and pipelines have been developed for IE from medical free texts, ranging from simple rule-based solutions to advanced machine learning approaches. Rule-based solutions allow domain experts to define a set of linguistic rules and patterns to be implemented to identify and extract relevant information from clinical notes and medical free-form texts. Studies have shown that rule-based approaches can outperform machine-learning models [10-13]. However, rule-based approaches are custom-made for specific datasets and use cases, require manual specification of rules by medical experts, and are therefore difficult to generalize [3]. Moreover, machine learning models allow for multiple methodologies and applications for different IE problems, solved by training specific traditional machine learning models such as support vector machines, decision trees, and neural networks (NNs). Recently, bidirectional transformers (BTs) such as large language models (LLM) have been identified as a possible tool for IE because of their strengths in pattern recognition, text summarization, and generation [14]. LLMs allow for pretraining on large text corpora, which enables them to learn linguistic patterns applicable to different IE tasks. Furthermore, LLMs show promising results for specific tasks because of the domain-specific fine-tuning of pretrained models [15].

Over the years, numerous models have been developed for various IE tasks, but their relative performance across different datasets remains largely unknown. Both rule-based and machine learning approaches often exhibit limited generalizability between tasks, and their results are frequently inconsistent when applied to different datasets. This inconsistency highlights the need for studies that investigate and compare the relative performance of these models.

To the best of our knowledge, no review has been conducted that summarizes the differences in the performance of various types of NLP models for IE within the context of cancer. This review provides an overview of the various NLP methods used for IE and compares them in terms of their performance.

Methods

This systematic review followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines.

We searched 3 databases—PubMed, Scopus, and Web of Science—for relevant literature published between January 1, 2014, and April 19, 2024 (Multimedia Appendix 1). The following search criteria were used for the titles and abstracts:

("information extraction" OR "natural language processing" OR "nlp") AND (EHR OR notes OR reports) AND (cancer OR tumor OR oncology)

The inclusion criterion for articles was the application of 2 or more NLP models to extract identical cancer-related entities from the same unstructured medical text in EHR. Articles were excluded during title and abstract screening if they were as follows: (1) reviews; (2) articles that do not compare 2 or more NLP models; (3) articles whose purpose is not to extract information from free text from EHR; and (4) articles whose purpose is not to develop an NLP cancer-related application.

For further exclusion during the full-text screening, articles were excluded if they were defined as follows: (1) abstract only; (2) text classification without cancer entity extraction; (3) results within the article were not compatible; (4) no NLP application development; (5) not related to cancer IE from EHR; and (6) no comparison with other NLP methods within the article.

Using the exclusion criteria, one author (SCD) performed 2 rounds of article selection: title and abstract screening, followed by a full-text review. A second reviewer (CV) was consulted for unclear cases during the screening.

Data from each of the included articles were extracted by 2 authors (SCD and CV). Both authors independently categorized the NLP models and extracted their performance metrics. Any discrepancies in categorization were resolved through consensus guided by consideration of the primary architectural components of the model. Each model was categorized into the following groups: rule-based, traditional machine learning (ML), conditional random field (CRF)–based, NN, and BT.

The rule-based category includes IE models that use regular expressions (Regex), keywords, and dictionary matching. The CRF-based category includes linear CRF, except bidirectional long short-term memory-CRF, which is in the NN category. The NN category includes NNs, except for BTs, that belong to the BT category. Ensemble models are categorized as the most advanced part of the ensemble. For example, a rule-based model combined with a BT is categorized as a BT model (see Table 1). For articles that included both strict and relaxed keyword matching, the strict F_1-scores were extracted as the performance metric. For articles presenting both macro- and micro-averaged F_1-scores, macro-averaged F_1-scores were extracted.

XSL•FO
RenderX

Table . Method categorization of models.

Category	Included models	Articles using category	Total number of models implemented
Rule-based	• Regular expressions • keyword, term, and dictionary matching	[10-13,16-22] (n=11)	12
CRF[a]-based	• Linear CRF • CRF + Rule-based	[10,12,16-18,20,23,24] (n=8)	26
Bidirectional transformer	• BERT[b] • BlueBERT • BioBERT • CharBERT • Character-BERT • CancerBERT • RoBERTa • MBERT (multilingual BERT) • BETO • XLM-R • ClinicalBERT • XLNet • Bidirectional Transformer + Rule-based • Bidirectional Transformer + BiLSTM[c]-CRF	[11,15-17,21,23-33] (n=16)	60
Neural network	• BiGRU • BiRNN • CNN • LSTM • BiLSTM-CRF • RNN • MLP, • HAN, • SLA, • CNN + Rule-based	[15-20,24-26,28-43] (n=25)	83
Traditional machine learning	• SVM[d] • Random forest • Naïve Bayes • Extreme Gradient Boosting • AdaBoost	[13,22,27,30,34-43] (n=14)	39

[a]CRF: conditional random field.

[b]BERT: Bidirectional Encoder Representations from Transformers.

[c]BiLSTM: bidirectional long short-term memory.

[d]SVM: support vector machine.

To calculate the performance differences for all categories across the included articles, the following steps were executed for all categories.

The best-performing model for each category within each article was selected. The best-performing model within category c for article a is given by maxc,a:

$$\text{maxc,a} = \max(\text{Pc,m1,Pc,m2,}\ldots\text{,Pc,mn})$$

where P is the F_1 performance score of method m within category c. n is the number of methods within category c.

Having the best-performing categories within an article allows for calculation of the category difference for each combination of categories. Category differences for categories c^1 and c^2 within article a are given as category_diffc1,c2,a:

$$\text{category_diffc1,c2,a} = \text{maxc1,a} - \text{maxc2,a}$$

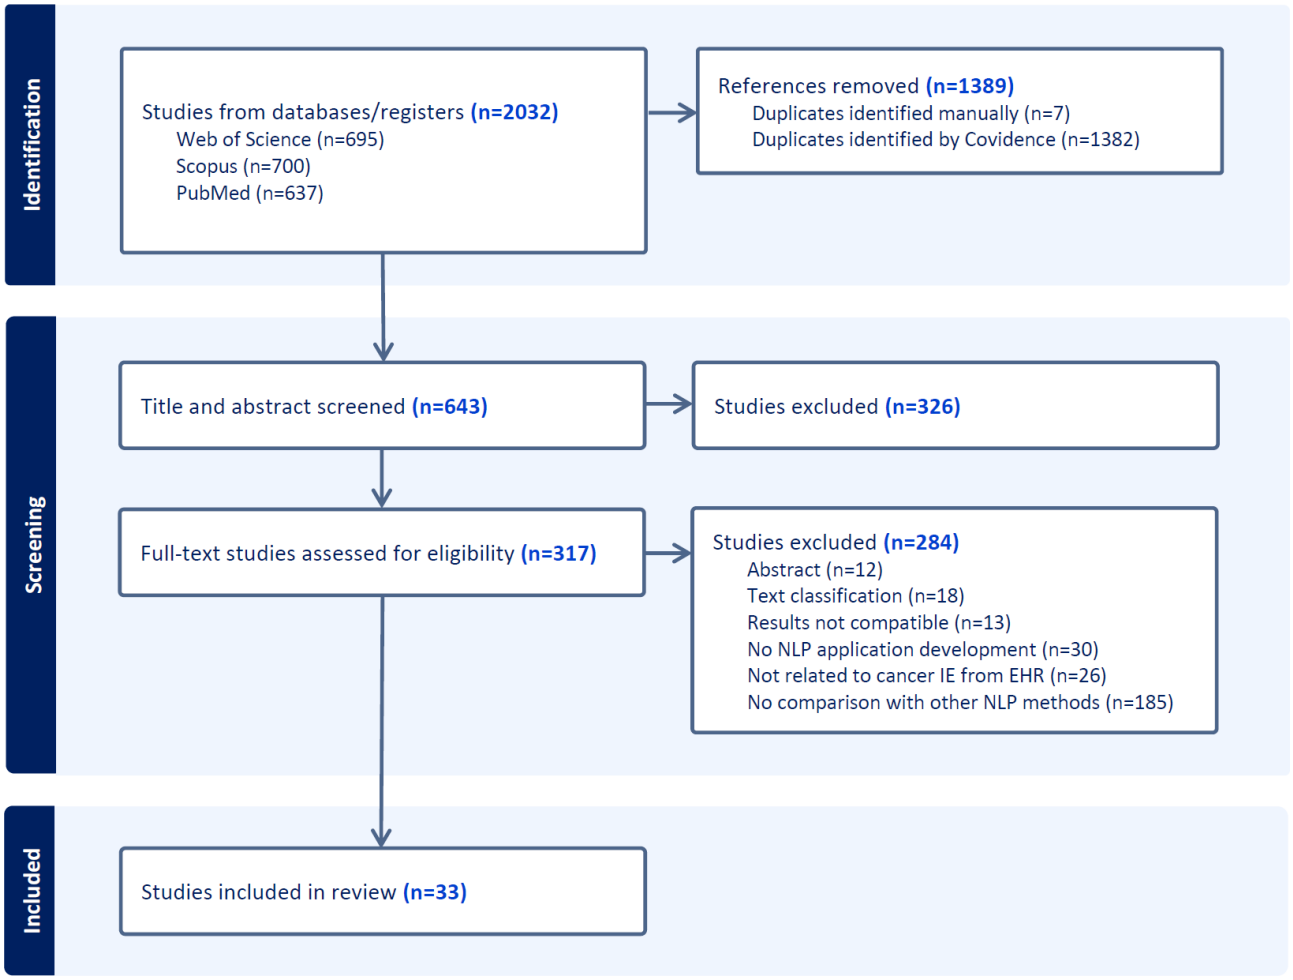
where maxc,a is the best performing model of category c in article a.

All performance differences of the same combination of categories were averaged across all the articles. The average of the category difference for all articles with combination c^1 and c^2 is given as performance_differencec1,c2 :

$$\text{performance_difference c1,c2} = \text{category_diff c1,c2,1} + \text{category_diff c1,c2,2} + \text{category_diff c1,c2,m}$$

XSL•FO
RenderX

where category_diffc1,c2,a is the category difference between c^1 and c^2 in article a. n is the number of articles with a specific category combination.



Statistical significance between categories for each category combination was determined using a t test (P<.05).

Results

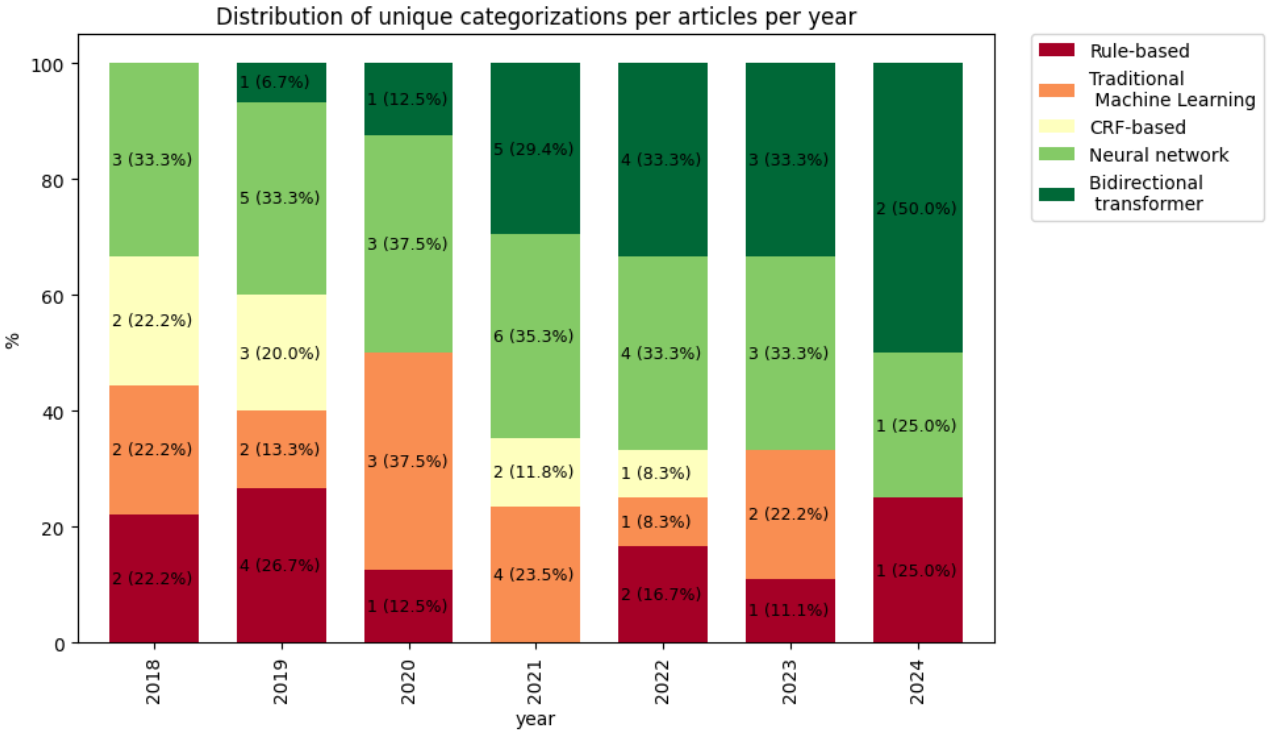
Overview

The article selection process is detailed in a PRISMA flowchart, shown in Figure 1. A total of 2032 articles were identified through searches in Web of Science, Scopus, and PubMed.

Figure 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart for article selection.

In total, 33 articles were included in this review. The articles were published between 2018 and 2024. They compared at least 2 NLP models for cancer-related IE from unstructured medical texts in EHRs. The articles contained a total of 220 implementations of NLP models. Selecting only the best-performing models within each category of each article summarizes 74 implementations.

Models



We categorized each NLP model as rule-based, CRF-based, BT, NN, and ML. Table 1 shows how each model was categorized and the articles in which the categories are contained.

Table 1 shows the categorization of the models, which articles contain the specific categories, and the total number of implemented models within each category.

The most frequently used category was NN, with 25 occurrences, followed by BT and ML with 16 and 11 occurrences, respectively. The most frequently implemented category was NN, with 83 implementations. The distribution of unique categorizations per year shows the variety of models that have been used throughout the years (see Figure 2). Notably, the percentage of articles on the implementation of BTs has increased over the years.

XSL•FO
RenderX

Figure 2. Distribution of unique categorizations per article per year. CRF: conditional random field.

Performance

The performance varied a lot according to specific use cases. Inspecting the best-performing models of the specific articles shows that a total of 5 rule-based models performed best in their articles, with F_1-scores in the range of 0.73-0.887 (see Table 2). ML did not perform best in any article despite being compared in 14 articles with a total of 39 different model implementations, and neither did CRF-based. In total, 14 articles showed that NN performed the best, with F_1-scores ranging from 0.3539 to 0.972. BT performed the best in 13 articles, with F_1-scores ranging from 0.6023 to 0.97. Looking at the raw F_1-scores, more advanced models outperformed less advanced ones.

[a]This is the best F_1-score for the article.

[b]CRF: conditional random field.

[c]ML: traditional machine learning.

[d]NN: neural network.

[e]BT: bidirectional transformer.

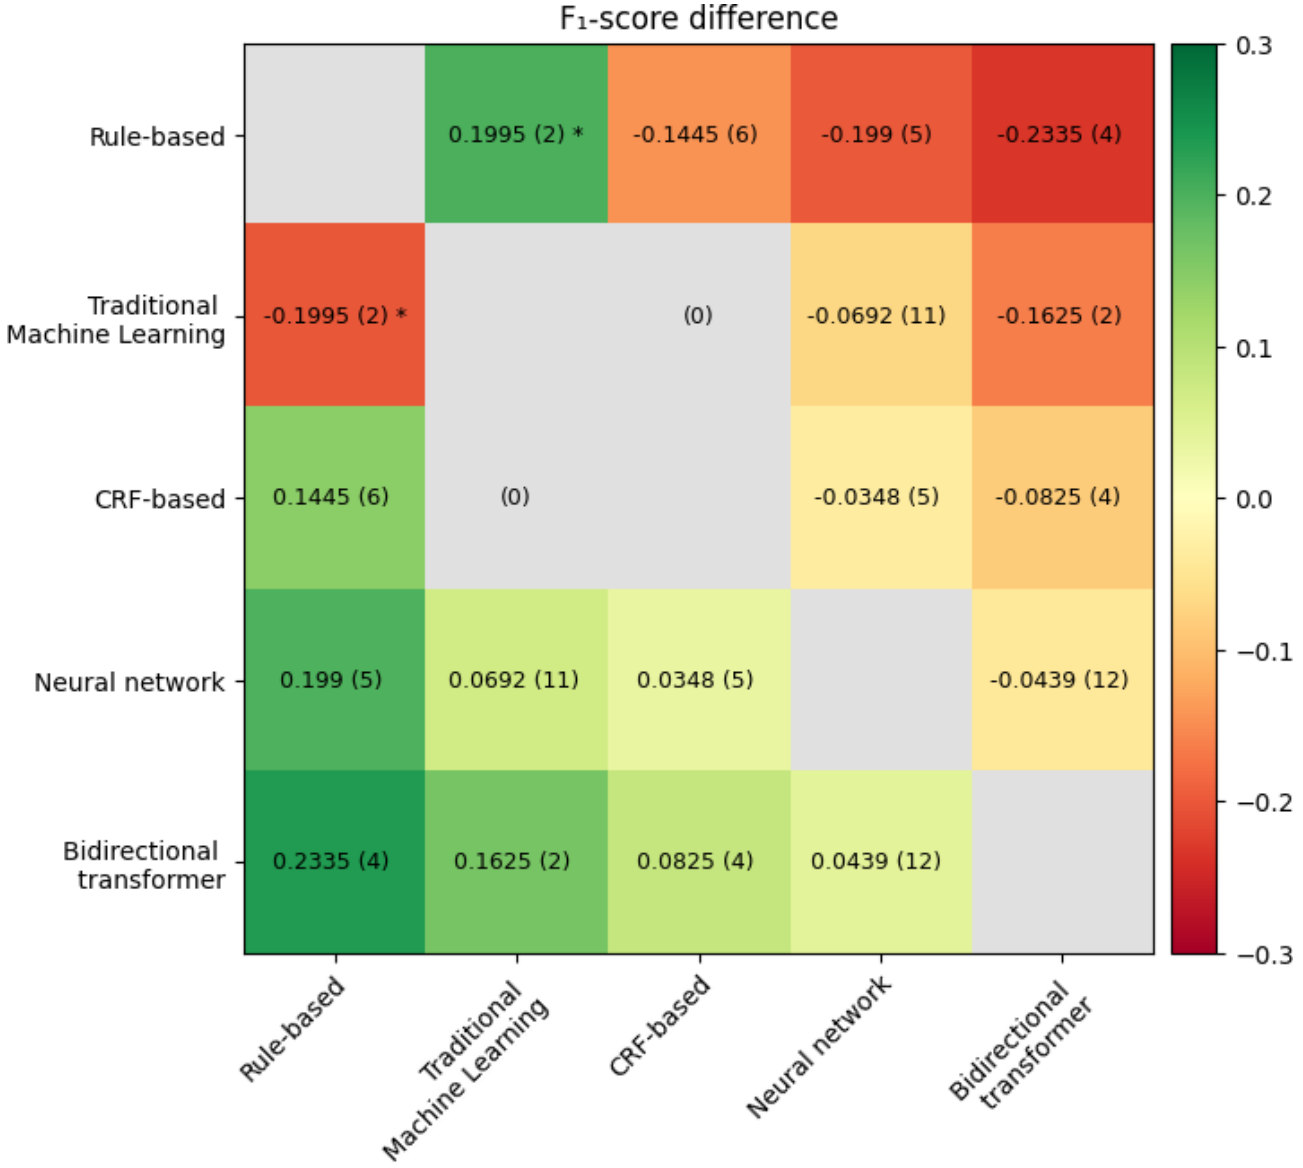

Table 2 shows each article and the number of models in each category within the article. Parentheses show the best F_1-score for each category. The best F_1-score for each article is marked by a footnote.

Some variations between the average F_1-score performance differences were observed (see Figure 3).

Our results show that more advanced models outperform less advanced ones. The largest difference between the category performance F_1-scores was observed between the BT category and the rule-based category. BT models were compared with rule-based models in 4 studies, yielding an average performance difference of 0.2335 in terms of F_1-score. BT was the best-performing category. NN outperformed CRF-based, ML, and rule-based models, while CRF-based outperformed rule-based models, and rule-based outperformed ML models. The only statistically significant difference between categories is observed when comparing rule-based and ML; see Multimedia Appendix 2 for *P* values.

XSL•FO
RenderX

Figure 3. Illustration of the average F_1-score performance differences for all combinations of the best model within each category. The parentheses indicate the number of comparisons between the categories. CRF: conditional random field. *P<.05.

Discussion

Principal Findings

This study provides an overview of the models used for IE in cancer and their performance in terms of the F_1-score. By including only articles with 2 or more NLP models for IE, we were able to evaluate the relative performance of each NLP within categories: rule-based, CRF-based, BT, NN, and ML.

The search string for this review combined keywords for techniques (IE and NLP), data sources (EHR, notes, reports), and the domain (cancer, tumor, and oncology) using Boolean operators to limit irrelevant results. The initial yield of 2032 articles suggests a reasonable balance, considering the stringent inclusion criteria. The "AND" clauses effectively limit the search while still including the relevant articles for the screening process. Although our search strategy included articles published from 01/01/2014, no articles prior to 2018 were included in the analysis. The reason for this discrepancy is not addressed within the scope of this review, which focused on quantifying performance differences between our categories. Notably, the most frequent reason for full-text exclusion was "No comparison with other NLP methods within the article (185 articles)." Arguing for common benchmark testing of the implemented NLP models.

Without considering a dataset or specific extraction entities, our results show that BT is the best performing category, followed by NN, CRF-based, rule-based, and ML in written order. We observed an increasing number of transformer-based models developed in recent years, with promising results. Our results highlight a pivotal moment in which BTs, such as language models, are on the verge of demonstrating their full potential in IE. Although transformers [44] and BERT [45] were introduced in 2017 and 2018, respectively, our literature review includes no articles using these technologies until 2019. This delay in time may reflect the time required for these models to become integrated into clinical research workflows. Surprisingly, rule-based solutions perform better than machine learning [13,22]. One explanation could be that rule-based solutions allow for the implementation of expert knowledge.

XSL•FO
RenderX

The lowest-performing articles in terms of F_1-score do not aim to show the best possible method for extraction, but rather how F_1-scores increase using hierarchical regularization when extracting ICD-O-3 codes [42]. Similarly, the study of Park et al [43] aims to show how to increase the F_1-score, using transfer learning and zero-shot string similarity, when the number of annotated pathology reports is limited.

Multiple reviews have been conducted within the scope of NLP in a clinical context with different aims. The review by Kreimeyer et al [46] aims to identify NLP systems capable of processing clinical free text and generating structured output, thereby compiling a list of NLP solutions in use. The review by Datta et al [47] defines relevant linguistic terms by organizing unstructured clinical text related to cancer into structured data using frame semantics. The review by Bilal et al [48] examines the current state-of-the-art literature on NLP applications in analyzing EHRs and clinical notes for cancer research, quantifying the number of studies for each cancer type and outlining the research challenges and future directions for NLP when analyzing EHRs and clinical notes in cancer research. However, no review has been conducted comparing the performance of NLP models for IE of cancer-related entities from clinical text, a gap relevant to clinical informatics and crucial for improving the accuracy of cancer-related data IE within EHRs. This is the first review to summarize and compare the performance of NLP models for IE of different cancer entities from unstructured text, offering insights for clinical researchers focused on leveraging EHR data for cancer care and research.

Strengths

One strength of our study was its ability to overcome the challenge of comparing low-performing models. By including only articles with 2 or more categories, we can determine the relative performance for each paper while neglecting low-performing models from papers that do not aim to beat state-of-the-art F_1-score. Our review shows how models can be categorized and how the categorizations perform compared to each other through different datasets and extraction entities. The performance differences observed in our included articles highlight the importance of selecting the appropriate NLP model for each health care application. Our categorizations allow all models to be included, even ensemble and hybrid models. Furthermore, our performance calculation uses the best-performing model for each category reported within each included article. This approach allows for the addition of multiple new categories to support the desired level of model performance granularity.

Limitations

A categorization strategy was required to categorize all models. Most models assign into well-defined and distinct categories. However, some could be assigned to multiple categories, notably bidirectional long short-term memory-CRF models. To present intelligible results, the number of categories had to be kept relatively low, neglecting model specificities. Increasing the number of categories would reduce the number of models in that category, making the results too anecdotal. Decreasing the number of categories would increase the number of times each categorization was compared, making the averaged F_1-scores less distinctive. Ideally, we would have wished for multiple studies implementing the same set of models and categorizations to avoid certain categorizations not being compared with every other category and to avoid certain combinations of categorizations occurring only once.

We selected the F_1-score as a metric for performance; precision or recall could also be used. However, extracting specific numbers from the confusion matrix can provide deeper insights. The included studies reported F_1-scores as a measure of performance. Although this is a practical method to generate 1 performance metric, its use has some limitations. In medical IE, one could argue that false negatives are worse than false positives, potentially leading to missed diagnoses or inappropriate treatment decisions, which is not considered in the F_1-score. While metrics such as AUC-ROC, precision-recall tradeoff, or specificity offer complementary insights, their calculation was limited by the inconsistent reporting of the necessary data. Furthermore, given the sensitive nature of EHR data and the need for clinical trust, future research should also prioritize evaluating the interpretability of IE models alongside traditional performance measures to allow clinicians to understand how cancer-related entities are being extracted and validated from EHR data.

Furthermore, our included studies neglected to address the handling of negation and spelling errors. Giorgia et al [49] showed that negations account for 66% of the errors. Another study stated that BERT fails completely to show a generalizable understanding of negation, raising questions about the aptitude of language models to learn this type of meaning [50]. In this study, BTs performed well; one could wish for a general approach to analyze the errors of each model instead of the general performance derived from the confusion matrix. Negation errors pose a significant challenge in EHR data and are critical in oncology, as a misidentified negated symptom or finding can alter clinical interpretation, treatment planning, and patient care.

Perspectives

The field of IE has evolved rapidly, and models, such as LLMs, have been successfully applied in the context of cancer IE, both in terms of model performance and operational efficiency [51]. LLM could allow for enhanced transferability and utility for different IE tasks on unstructured textual data. Using LLMs for IE on unstructured textual data seems feasible because of the variety of available pretrained models in different versions. Some might perform well out of the box or with minor domain-specific fine-tuning [15]. Generally, the evaluation of LLMs is challenging because of the lack of clarity regarding whether a public benchmark dataset has been used for training. However, when using data from EHRs, it is certain that they have not been used for training a public model.

Conclusions

NLP has demonstrated the ability to identify and extract cancer-related entities from unstructured medical textual data. Generally, most of the reviewed models showed excellent

XSL•FO
RenderX

performance in terms of the F_1-score, and more advanced models outperformed less advanced ones. The BT category performed the best, followed by NN. The use of BTs has increased in recent years. Rule-based applications for IE remain competitive in terms of performance in this specific context.

Acknowledgments

This study was supported solely by the institutional resources of the Center for Clinical Data Science at Aalborg University Hospital. We acknowledge the use of Covidence systematic review software (Veritas Health Innovation, Melbourne, Australia) for automatic identification and removal of duplicate articles.

Data Availability

The datasets used and analyzed in this study are available upon reasonable request from the corresponding author.

Authors' Contributions

All authors were involved in the conception and design of the study. SCD contributed to the collection and assembly of data. SCD and CV were involved in data analysis and interpretation. All authors contributed to manuscript writing, and all authors approved the final version of the manuscript.

Abstract

Background: Artificial intelligence (AI) has shown exponential growth and advancements, revolutionizing various fields, including health care. However, domain adaptation remains a significant challenge, as machine learning (ML) models often need to be applied across different health care settings with varying patient demographics and practices. This issue is critical for ensuring effective and equitable AI deployment. Cardiovascular diseases (CVDs), the leading cause of global mortality with 17.9 million annual deaths, encompass conditions like coronary heart disease and hypertension. The increasing availability of medical data, coupled with AI advancements, offers new opportunities for early detection and intervention in cardiovascular events, leveraging AI's capacity to analyze complex datasets and uncover critical patterns.

Objective: This review aims to examine AI methodologies combined with medical data to advance the intelligent monitoring and detection of CVDs, identifying areas for further research to enhance patient outcomes and support early interventions.

Methods: This review follows the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) methodology to ensure a rigorous and transparent literature review process. This structured approach facilitated a comprehensive overview of the current state of research in this field.

Results: Through the methodology used, 64 documents were retrieved, of which 40 documents met the inclusion criteria. The reviewed papers demonstrate advancements in AI and ML for CVD detection, classification, prediction, diagnosis, and patient monitoring. Techniques such as ensemble learning, deep neural networks, and feature selection improve prediction accuracy over traditional methods. ML models predict cardiovascular events and risks, with applications in monitoring via wearable technology. The integration of AI in health care supports early detection, personalized treatment, and risk assessment, possibly improving the management of CVDs.

Conclusions: The study concludes that AI and ML techniques can improve the accuracy of CVD classification, prediction, diagnosis, and monitoring. The integration of multiple data sources and noninvasive methods supports continuous monitoring and early detection. These advancements help enhance CVD management and patient outcomes, indicating the potential for AI to offer more precise and cost-effective solutions in health care.

KEYWORDS

artificial intelligence; machine learning; cardiovascular diseases; cardiovascular events; health care; monitoring; early detection; AI; cardiovascular; literature review; medical data; detect; patient outcomes; neural network; ML model; mobile phone

Introduction

Artificial intelligence (AI) has revolutionized various aspects of our lives, showing exponential growth and advancements. The ubiquity of AI and its influence on nearly every facet of human life, from business and entertainment to technology, has not yet been fully realized in the field of medicine [1]. Despite these strides, machine learning (ML) in health care faces significant challenges, particularly in the realm of domain adaptation, where the goal is to apply ML models developed in one context to different but related health care settings. This is particularly crucial in health care, where the variability in patient demographics, disease prevalence, and health care practices across different regions and populations can affect the performance and reliability of ML models. Addressing these challenges is essential for ensuring that AI-driven technologies can be effectively and equitably applied across diverse health care environments [2].

The increasing availability of medical data, combined with advancements in AI techniques, creates new opportunities for

XSL•FO
RenderX

developing intelligent systems that can assist health professionals in the early detection and rapid intervention of cardiovascular events [3]. For instance, studies like Elvas et al [4] have demonstrated the capability of predictive models to anticipate myocardial ischemia incidents, enabling timely interventions and improving patient outcomes. One key advantage of AI in this context is its ability to analyze large volumes of complex data, uncovering patterns and correlations that might be missed by analysts [5,6]. This capability could be especially significant in the context of cardiology, the specific subject of our study, helping to provide a more comprehensive understanding of a patient's cardiovascular health.

Cardiovascular diseases (CVDs) remain the leading cause of mortality worldwide [7]. Globally, CVDs account for approximately 17.9 million deaths annually, representing 32% of all global deaths [8]. These conditions encompass a range of disorders affecting the heart and blood vessels, including coronary heart disease, rheumatic heart disease, congenital heart defects, and hypertension. The total number of CVD deaths and years of life lost are likely to increase as a result of population growth and aging [9], underscoring the critical need for effective methods to monitor and diagnose these conditions early.

The primary objective of this review is to address these gaps by conducting a comprehensive review of studies focusing on AI methodologies, in conjunction with medical data, that contributed to knowledge and progress in the intelligent monitoring, detection, prediction, and diagnosis of these kinds of diseases. Specially, this review aims to examine and synthesize current research on the application of AI and ML methodologies in CVD management. The study seeks to identify and evaluate various AI-driven approaches, including deep learning (DL) and ensemble methods, that have shown promise in improving the accuracy of CVD classification, risk assessment, and patient monitoring. Additionally, the review aims to highlight the potential of these technologies in enabling diverse treatment strategies, supporting health care professionals' decision-making processes, and ultimately enhancing patient outcomes. By assessing the current state of research, the review also intends to identify challenges, limitations, and areas for further investigation to guide future advancements in AI-driven cardiovascular care.

Despite the comprehensive nature of this review, it is important to acknowledge certain limitations and challenges that affected the search process. The review is confined to papers published between 2020 and 2024, which is a narrow year range, however, no papers were found outside of that range using that selected search query. Additionally, the search was limited to English-language publications, which may have resulted in the omission of valuable research published in other languages. One significant challenge is the variability in study quality across the selected literature. The rapidly evolving nature of AI and ML techniques in health care means that methodologies and reporting standards may vary considerably between studies, potentially affecting the comparability and generalizability of findings. Additionally, the integration of diverse AI methodologies presents a challenge in synthesizing results, as different approaches may have varying levels of interpretability and clinical applicability. The heterogeneity in data sources, sample sizes, and outcome measures across studies may also complicate the process of drawing cohesive conclusions. Furthermore, the field's fast-paced development means that some cutting-edge methodologies might be underrepresented in peer-reviewed literature at the time of this review. These limitations should be considered when interpreting the findings and their implications for clinical practice and future research directions in AI-driven cardiovascular care.

In summary, this literature review highlights the transformative potential of AI in health care, particularly in the domain of CVD. It underscored the significant global impact of CVD and the urgent need for improved methods of monitoring, detection, and early intervention. The review aims to explore how AI and ML techniques, when combined with extensive medical data, can advance our approach to managing cardiovascular health. By examining current methodologies and their practical implications, there were identified areas for further research and development. As health care evolves, incorporating intelligent systems may improve patient outcomes and support early interventions [10]. The potential for AI to transform cardiovascular health care is immense, offering the promise of more accurate diagnoses, personalized treatment plans, and improved patient outcomes.

Methods

The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) methodology assisted the search by providing an organized structure and clear steps. Originally developed for medical research, PRISMA provides evidence-based guidelines to help authors transparently report their review process, methods, and findings [11].

This methodology ensures a rigorous literature review, providing a comprehensive overview of the current state of research on the use of AI in monitoring and detecting cardiovascular events in hospital settings.

The research conducted in May 2024 focused on literature related to the topic in review. The selection process involved developing a targeted search query, specifying the desired paper type, keywords, and subject areas. The search query was as follows:

("Machine Learning" OR "Data Analysis" OR "Artificial Intelligence" OR "AI" OR "Data Analytics") AND ("Cardiovascular events") AND ("Monitoring systems" OR "Early Detection" OR "Alert Systems") AND ("Hospital Data" OR "Medical Data" OR "Clinical Data" OR "Physiological Data") AND PUBYEAR>2017 AND PUBYEAR<2025 AND (LIMIT-TO (SRCTYPE , "j")) AND (LIMIT-TO (SUBJAREA , "COMP") OR LIMIT-TO (SUBJAREA , "ENGI") OR LIMIT-TO (SUBJAREA , "MATE") OR LIMIT-TO (SUBJAREA , "MATH")) AND (LIMIT-TO (DOCTYPE , "ar") OR LIMIT-TO (DOCTYPE , "re"))

The search was first applied on Scopus [12], and then, it was also attempted on the Web of Science website [13]. Textbox 1 illustrates the constructed search query, organized into sections based on keywords (Concepts, Population, Context, and Application). Additionally, specific limitations were defined,

XSL•FO
RenderX

including the publication year, document type, and subject areas. It should be noted that all the papers obtained through this search query were written in English.

Textbox 1. Process of keyword selection

Concepts (7,470,936 documents)

- Machine Learning
- Data Analysis
- Artificial Intelligence
- AI
- Data Analytics

Population (reduced to 23,858 documents)

- Hospital Data
- Medical Data
- Clinical Data
- Physiological Data

Context (reduced to 1601 documents)

- Monitoring systems
- Early Detection
- Alert Systems

Application (reduced to 248 documents)

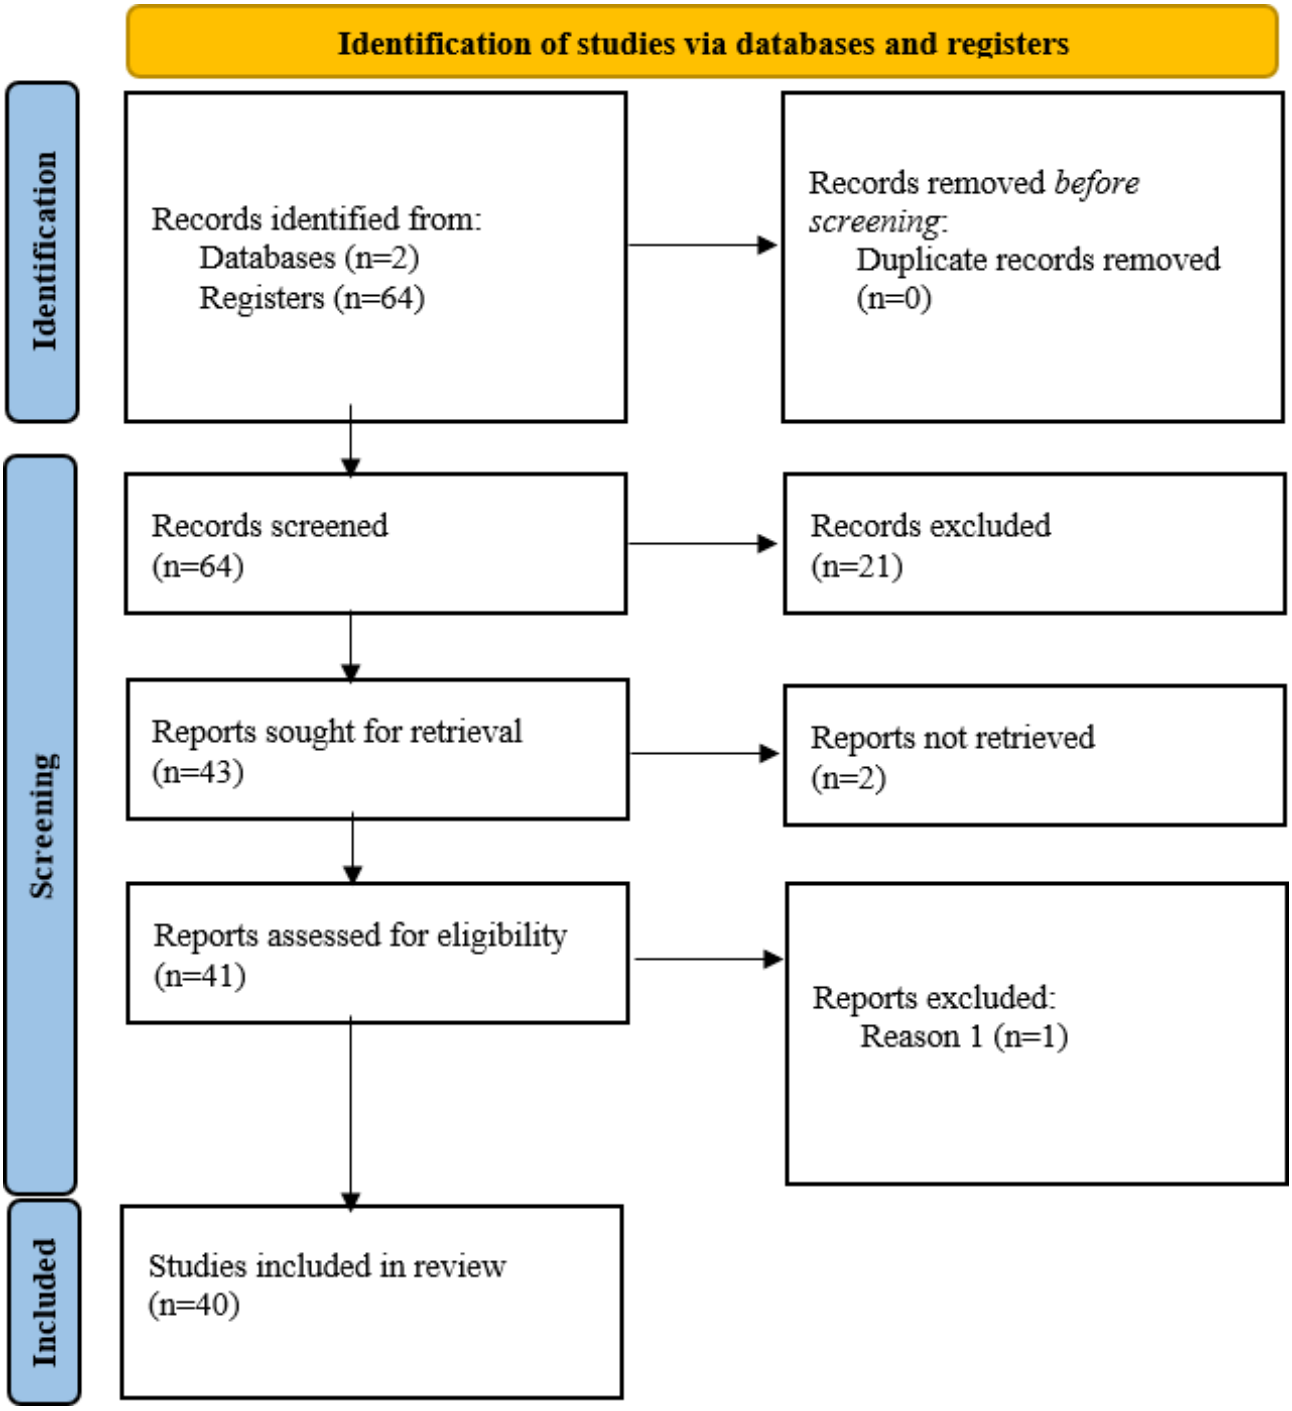
- Cardiovascular events

Limitations (reduced to 64 documents)

- Date: 2017-2024
- Document Type: Article, Reviews
- Source Type: Journal
- Limited to: Computer Science, Mathematics, Engineering

The data publication year was limited to 2017 - 2024, because there were no papers, attending to the other limitations, outside of that range. This may be caused by the need to improve the health care system, combined with technological advances and available data, causing a lot of interest in this area, leading researchers to publish papers as a way of satisfying this need.

The search process yielded a progressive refinement of results, starting from an initial pool of 7,470,936 documents, then 1601 documents, culminating in a final selection of 64 relevant papers, after adding the limitations. This significant reduction reflects the effectiveness of our targeted search strategy and filtering process. The final set of 64 documents represents a focused collection of recent, relevant research in the application of AI to cardiovascular event monitoring and detection.



Results

Overview

All the papers that have been selected came from a selection process detailed in the PRISMA flow diagram (Figure 1).

XSL•FO
RenderX

Figure 1. PRISMA flow diagram with the state-of-the-art results. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

The first step in the process included the removal of duplicated records, and then, a second selection was made based on the title and abstract, where 21 papers did not meet the standards. Essentially, all papers that did not focus on CVDs or events were excluded. After that, the papers that could not be retrieved were removed. In the final step, after analyzing the papers in their entirety, a selection was made, where the papers that were not relevant and that did not meet the established goal would be eliminated. In practice, it meant that any paper that did not have ML applications for the monitoring, detection or diagnosis of cardiovascular events, and diseases were excluded.

As it is shown in Figure 1, 64 documents were retrieved initially, but, after the screening, 40 studies were left in total to include. All the papers selected for this review were published between 2020 and 2024.

The remaining papers selected for inclusion were then subjected to a detailed analysis to extract data. Key themes and concepts were identified through a keyword extraction process, allowing for the categorization of papers into relevant thematic areas. This initial categorization facilitated the identification of common trends across the literature. Subsequently, a deeper analysis was conducted, focusing on the specific methodologies, objectives, results, and conclusions of each study. This in-depth examination enabled a more nuanced understanding of the research landscape, allowing for the identification of recurring approaches, significant findings, and emerging trends in the

XSL•FO
RenderX

field of AI applications for CVD management. The results and discussion chapter were then constructed based on this comprehensive analysis, synthesizing the extracted data to present an overview of the current state of research in this domain.

Outcome Analysis

Overview

Analyzing the application goals keywords in Table 1, the one with the biggest representation was “Early Detection” present in 31 (78%) papers, followed by “Risk Assessment,” present in 14 (35%) of the final papers. On the topics identified in the remaining 40 studies, there was a clear winner approach, as shown in Table 1: “Machine Learning” which appeared in 28 (70%) papers; however, the other techniques referenced were also related to ML, such as “Classification” and “Predictive Analysis.”

Table . Absolute frequency of the identified application goals and identified techniques within the studies included.

		Absolute frequency and percentage (n=40), n (%)
Application goals		
	Alert Systems	2 (5)
	Diagnosis	10 (25)
	Monitoring systems	11 (28)
	Risk Assessment	14 (35)
	Early Detection	31 (78)
Techniques		
	Data Analytics	3 (8)
	AI[a]	9 (23)
	Predictive Analysis	19 (48)
	Classification	24 (60)
	Machine Learning	28 (70)

[a]AI: artificial intelligence.

In Figure 2, we present a visual representation of keyword relationships constructed using Python. Our analysis focused on the existing relationships between keywords within the reviewed papers, specifically in the context of AI and cardiovascular event detection. The keyword relationships revealed in this analysis offer insights into current research trends and potential gaps in the field of AI applications for cardiovascular health.

XSL•FO
RenderX

Figure 2. Keyword network. AI: artificial intelligence.

Key Findings

Frequent Combination

As expected, the most common keyword combination across the papers is "Machine Learning" paired with "Early Detection." This combination appears 22 times, accounting for 57.5% of the papers. This strong association underscores a significant focus on developing predictive models for timely identification of cardiovascular risks. This trend suggests a shift toward more proactive health care strategies, where AI tools could potentially identify subtle indicators of cardiovascular issues before they become clinically apparent.

Additional Relationships

"Classification" correlates significantly with "Early Detection" and "Machine Learning." This could indicate an emphasis on developing nuanced categorization systems for cardiovascular conditions, potentially leading to more personalized treatment approaches.

A weaker relationship between "Predictive Analysis" and the concepts: "Machine Learning," "Early Detection," and "Classification" is also significant. This weaker but notable relationship hints at an emerging, more holistic approach to cardiovascular risk assessment. This could involve integrating diverse data sources and analytical methods for comprehensive, long-term health predictions.

Future Directions

Interestingly, the relative absence of strong connections to "Alert Systems" or specific CVDs suggests areas where research might be less developed, presenting opportunities for future studies.

These insights provide context for understanding the prevailing themes in the literature but also point to potential future directions in AI-driven cardiovascular care. They suggest a trajectory toward more integrated, proactive, and personalized

XSL•FO
RenderX

approaches in clinical practice, where AI tools could significantly enhance early detection, risk stratification, and treatment planning in cardiovascular medicine.

We organized the included references based on the specific topics they address, as outlined in Table 2. Recent years have witnessed significant growth in ML-based models and other innovative approaches, as evidenced by our evaluation of the selected studies.

Table . Papers by topic.

Topics	References	Papers (n=40), n (%)
Early Detection	[3,14-43]	31 (78)
Risk Assessment	[14,16,21,23,24,32,35-37,41,43-46]	14 (35)
Monitoring Systems	[17,24,35,37,39,40,46-50]	11 (28)
Diagnosis	[3,14,20,25,26,44,48,49,51,52]	10 (25)
Alert Systems	[38,50]	2 (5)

Early Detection of CVD

ML Techniques

Recent studies have explored various ML techniques for classifying CVDs. Rani et al [14], Ghasemieh et al [15], Prakash and Karthikeyan [26], and Nijaguna et al [48] present different approaches, each with its own merits:

- Rani et al [14] compared several algorithms, including Naïve Bayes, support vector machine, random forest (RF), and Adaboost. The RF model achieved the best results among these.
- Ghasemieh et al [15] introduced a stacking ensemble learner (SEL) algorithm. In addition to heart-related diagnoses, SEL can be applied for COVID-19-related diagnoses.
- Prakash and Karthikeyan [26] used a more complex Dual Layer Stacking Ensemble (DLSE) classification method. This ensemble approach helps in leveraging the strengths of different models to achieve better performance.
- Nijaguna et al [48] proposed a novel approach using a Selective Opposition strategy based on artificial rabbits optimization algorithm. This novel optimization algorithm is designed to handle the high-dimensional feature space of electrocardiogram (ECG) signals.

The first two studies [14,15] reported accuracy results in the range of 86% - 88%, while the last two [26,48] demonstrated improved performance, achieving accuracy scores above 90%. This progression suggests that more sophisticated ensemble methods and optimization strategies may yield better classification results for CVD.

Another set of papers highlights the promising applications of ML for the prediction of CVD. Theerthagiri and Vidya [21] and Theerthagiri [36] focus on CVD prediction using feature elimination techniques, both achieving accuracy values of 88%. Singh et al [27] compares several traditional ML algorithms for CVD prediction such as decision trees (DT), k-nearest neighbors (KNN), artificial neural networks, and Extreme Gradient Boosting (XGBoost). Among these, XGBoost demonstrated the best performance with an accuracy of 73%. While this accuracy is lower than in some other studies, it is worth noting that the comparison of multiple algorithms provides valuable insights into their relative strengths in CVD prediction.

In a more innovative approach, Safa et al [37] introduces a hybrid clustering–based disease assessment model. This model aims to monitor patients' cardiac and anatomic conditions, predict diseases and associated risks, and use a clustering approach to analyze patient data. The hybrid clustering–based disease assessment model achieved impressive results with prediction accuracy of up to 96% and lower error rates. This high accuracy suggests that hybrid approaches combining clustering with traditional ML techniques may offer significant improvements in CVD prediction.

Several studies focus on predicting and detecting specific cardiovascular conditions, demonstrating the versatility of ML in addressing various aspects of heart health.

Nasarian et al [19], Al-Ssulami et al [30], and Selvaraj et al [33] specifically address coronary artery disease (CAD) prediction and detection. Selvaraj et al [33] combines ML and image processing techniques for CAD prediction and detection. Using three classifiers (RF, gradient boosting tree, and multilayer perceptron [MLP]), it achieved scores higher than 95 in precision, recall, and F_1-score. Nasarian et al [19] introduces a Heterogeneous Hybrid Feature Selection algorithm, combined with the Synthetic Minority Oversampling Technique for data balancing. This approach achieved an accuracy of 80%. Al-Ssulami et al [30] pair a ML model with an augmented dataset approach for early CVD prediction. Using a DT classifier, they achieved 99.2% accuracy with the Cleveland dataset. These exceptionally high accuracy rates suggest that data augmentation could be a powerful tool in improving ML model performance for CVD prediction.

Daliri et al [29] explores a heptagonal reinforcement learning model for predicting sinus and nonsinus arrhythmias. However, the results indicate that the model's performance needs improvement, as the prediction accuracy was suboptimal. This highlights the challenges in applying reinforcement learning to complex medical prediction tasks and suggests areas for future research.

Itzhak et al [35] proposes a prediction model based on temporal abstraction and frequent temporal interval relational sequence patterns to predict acute hypotensive episodes. The approaches are to continuously predict "when" or "whether" an acute

XSL•FO
RenderX

hypertensive episode will occur. The model's performance to each prediction task was:

- "When" prediction: area under the receiver operating characteristic curve of 0.82, area under precision-recall curve of 0.07;
- "Whether" prediction: area under the receiver operating characteristic curve of 0.74, area under precision-recall curve of 0.71.

These results demonstrate the potential of temporal pattern analysis in predicting specific cardiovascular events, though the variation in performance metrics suggests that further refinement may be necessary.

DL Techniques

Recent research has explored various DL approaches for CVD classification and prediction. These studies demonstrate the potential of advanced DL techniques to significantly improve accuracy compared to conventional methods.

Dubey et al [28] and Manur et al [44] aim to classify CVD using different techniques: fuzzy deep convolutional network (FDCN) and a crow search optimization algorithm (CSOA), integrated with DL techniques, respectively. Both approaches significantly improve prediction accuracy compared to conventional classifiers, achieving scores above 95%.

Meanwhile, Nagarajan et al [52] discusses CVD classification through feature selection, using a genetic-based crow search algorithm with deep convolutional neural networks strategy. It reported an accuracy of 88.78% using all original features and 95.34% for extracted features, highlighting the critical role of feature selection and extraction in boosting the performance of DL models for classification tasks.

Abuhaija et al [41] uses various AI algorithms, such as MLP, ZeroR, and Naïve Bayes, to analyze, classify, and predict CVD. The MLP with backpropagation model achieved the highest performance, with an accuracy exceeding 95%. The MLP with backpropagation model proved to be accurate, rapid, and inexpensive medical decision-making. It has handled test datasets robustly and efficiently.

Nuryani et al [17] and Ghavidel et al [42] aim to predict and detect hypertension using convolution neural networks (CNN) and the need for cardiovascular surgery using deep neural networks, respectively. The first study achieved an F_1-score of 98.88, while the second reached a recall of 72%, which may vary depending on the dataset used.

In contrast, Abbas et al [18] uses both ML and DL techniques to identify heart abnormalities. The study uses algorithms such as KNN, RF, XGB, a Machine and Deep Learning–based Stacked Model, and DT for heart disease prediction. Among these, the Machine and Deep Learning–based Stacked Model achieved the highest accuracy, with a score of 94.14%. By gathering and growing more data, in this case, DL techniques better handled the prediction problem and produced better results.

Reviews

Parashar et al [31] explores the current state-of-the-art application of ML in the detection, categorization, and prediction of CVD and respiratory diseases. Key findings include the prevalent use of clinical features such as age, blood pressure (BP), and cholesterol for CVD prediction, and the dominance of CNN for feature selection. Challenges identified include the need for standardized frameworks, data privacy, and algorithm interpretability.

In Rani et al [3], researchers conclude that combining various ML algorithms (such as RF, support vector machine, XGBoost, AdaBoost, deep neural network or CNN, and KNN) with expert cardiologist input on feature prioritization and leveraging unstructured health care data can significantly enhance the accuracy of heart disease prediction systems. Collectively, these studies underscore the transformative potential of AI and ML in improving CVD classification accuracy.

Diagnosis of CVD

Some papers aim specifically at the diagnosis of these kinds of diseases. Al-Absi et al [20] presents a DL approach using the retinal image and dual-energy x-ray absorptiometry to diagnose CVD, achieving an accuracy of 78.3% in distinguishing between patients with CVD and controls. The findings suggest that integrating retinal images with dual-energy x-ray absorptiometry data improves the accuracy of CVD detection, while also highlighting the greater discriminatory power of fat content and bone mineral density over muscle mass and bone areas for CVD diagnosis. Chen et al [38] used self-supervised learning to pretrain generalized laboratory progress model with the aim of detecting CVD, which significantly improves the classification accuracy from 0.63 to 0.90. The results reveal that linear and Piecewise Cubic Hermite Interpolating Polynomial interpolation enhances self-supervised learning performance, by expanding the tolerance for periods of absence. This allows for less frequent patient returns and examinations, reducing travel and medical expenses, and suggests that patients can benefit from diminished frequency of visits and onerous examinations through sustainable estimation methods.

Also, Kakudi et al [25] explores ML methodologies for the diagnosis of metabolic syndrome (MetS). The findings provide valuable insights for researchers and health care practitioners into current trends and developments, suggesting that nonclinical methods could serve as early preventive tools for managing MetS and CVD.

Monitoring Patients

A certain number of publications focus on the use of ECG, BP, and wearable devices for monitoring cardiovascular health. Širaiy et al [39], Charlton et al [40], and Alugubelli et al [46] center around the use of wearable technology for monitoring cardiovascular health. These papers emphasize the role of wearable technology in providing continuous, noninvasive monitoring of cardiovascular parameters, contributing to early detection and management of heart conditions. Lyon et al [22] provides a literature review that describe the clinical applications and main ML methods currently used for ECG analysis, and Agham and Chaskar [49] provides a perspective of ML

XSL•FO
RenderX

approaches using cuffless BP for the generation of predictive models for continuous BP measurement. Pires et al [50] also aims to develop innovative solutions to empower patients with CVD, by providing them with personalized plans for treatment and increasing their ability for self-monitoring.

Varma et al [47] aimed to evaluate the current status of mobile health (mHealth) technologies, including AI-driven tools, in the monitoring and management of heart rhythm disorders. The paper reviewed various mHealth modalities, such as wearable devices, smartphone-based ECG, and photoplethysmography, and discussed their potential in detecting atrial fibrillation and other arrhythmias. The authors highlighted the role of predictive analytics in improving clinical decision-making and patient self-management. Despite the promising applications, the study noted several challenges, including data validation, integration into clinical practice, and cybersecurity concerns. The statement concluded that while mHealth holds significant potential for enhancing CVD management, particularly in arrhythmia detection, further research is needed to overcome operational barriers and optimize its integration into health care systems.

Risk Assessment

The papers presented in this paragraph collectively emphasize the application of advanced ML and AI techniques to improve CVD risk assessment and prediction. Faizal et al [16] and Jamthikar et al [45] highlight the superior performance of AI-based predictive models compared to traditional methods like the Global Registry of Acute Cardiac Events and thrombolysis in myocardial infarction, with AI frameworks incorporating noninvasive data for enhanced accuracy. Groccia et al [23] demonstrates the effectiveness of cost-sensitive models in predicting cardiovascular deterioration in patients with chronic heart failure, stressing the clinical importance of early detection. This last system achieved sensitivity scores of 65% and specificity scores of 55%. Similarly, Bostani et al [32] introduces a novel method combining reinforcement learning and MLPs for early risk detection in athletes, achieving an F_1-measure of 87.4% and a geometric mean of 89.6%. Navarrete et al [43] confirms that RF models perform well in predicting mortality risk in older adults, suggesting practical applications in health care settings. Gunasekaran et al [34] presents an Internet of Health care Things–integrated model that improves accuracy in CVD prediction, enhancing performance and data security. The presented model achieved an impressive accuracy of 97%. These findings collectively underscore the potential of AI and ML in transforming CVD risk prediction and management, providing more accurate, early, and cost-effective solutions.

Baek and Arzani [24] and Kadem et al [51] emphasize the transformative potential of integrating hemodynamic modeling, medical imaging, and ML in understanding cardiovascular anomalies and managing abdominal aortic aneurysms. Both highlight the importance of personalized medicine and data-driven approaches, particularly through physics-based ML models, in improving diagnostic accuracy and risk assessment. They address the need for extensive multisite and multimodal patient studies to validate these tools' benefits, accuracy, and safety. As computational power and data availability increase, these technologies are expected to enhance patient outcomes and reduce health care costs related to CVDs.

Discussion

Principal Findings

The literature review reveals significant advancements in the use of ML and DL techniques for the classification, prediction, and diagnosis of CVD and events. Techniques such as DLSE, FDCN, and CSOA have demonstrated high accuracy, surpassing 95%. Feature selection and elimination methods like Selective Opposition strategy based on artificial rabbits optimization, genetic-based crow search algorithm, and recursive feature elimination (RFE)–based gradient boosting further enhance prediction accuracy.

Some of the studies aim to predict the detection of CVD while others specify their ML algorithms to predict and manage specific conditions such as CAD, arrhythmia, hypertension, MetS, and abdominal aortic aneurysms.

Various studies highlight the importance of integrating multiple data sources and expert input to improve model performance. Wearable technologies and noninvasive methods are emphasized for continuous monitoring and early detection, showing promise in reducing health care costs and patient burden. Additionally, the application of AI in predicting emergency readmissions and the need for cardiovascular surgery underscores its potential to improve patient outcomes. Challenges identified include the need for standardized frameworks, data privacy, and algorithm interpretability.

Multimedia Appendix 1 provides a summary of the various AI methodologies and datasets used in CVD monitoring and prediction. The advantages of ensemble techniques like the SEL and the DLSE method lie in their ability to combine multiple models for improved accuracy, as evidenced by results ranging from 88% to over 95% accuracy. However, their complexity and interpretability present significant challenges that could hinder their adoption in clinical settings. Similarly, techniques like RFE and gradient boosting highlight the importance of feature selection in enhancing model precision, but the imbalanced nature of datasets used in some studies, such as the Nasarian CAD dataset, introduces limitations in the generalizability of results. The current literature often focuses on performance metrics like accuracy, precision, and F_1-score, without offering a robust analysis of the practical limitations of these systems, such as computational cost, scalability, or real-world clinical applicability.

The most frequently used datasets across the reviewed literature include the Cleveland Heart Disease dataset and the Cardiovascular Disease dataset. Some studies leverage datasets from Kaggle, which offer larger, publicly available cardiovascular data that span a variety of CVD conditions. These datasets are valuable for training more generalizable models, but they often demonstrate class imbalances, as seen in studies using RFE and gradient boosting.

Overall, these findings collectively underscore the potential of AI and ML in enhancing CVD risk assessment, prediction, and

XSL•FO
RenderX

management. The application of advanced methodologies such as ensemble learning and optimization strategies offers more accurate and early detection solutions, as evidenced by performance improvements across various datasets. However, the limitations in dataset diversity, model interpretability, and scalability highlight the ongoing need for more comprehensive real-world validations. Additionally, integrating discussions on the specific advantages, disadvantages, and performance measures of existing systems will further strengthen the understanding of their practical applications. Future research should focus on overcoming these challenges to develop more robust, cost-effective, and generalizable AI-driven solutions for cardiovascular health care.

Future Work

The future research prospects, across the studies referenced, suggest promising opportunities for integrating advanced technologies to improve CVD management. Combining multiomics data (genomics, proteomics, etc) with AI and Internet of Things could potentially enhance precision in disease detection, decision-making, and personalized care. Developing hybrid ML models using real-time and large datasets might improve heart disease prediction. Computational techniques for ECG analysis show the potential to uncover new biomarkers and enhance patient risk stratification. Wearable devices and remote monitoring systems could transform patient care by providing continuous, real-time health data. Addressing challenges such as data quality, standardization, and regulatory approval will be necessary to advance these innovations. Additionally, incorporating nonclinical models, evaluating diverse datasets, and leveraging advanced computational resources may be beneficial for developing effective and scalable solutions.

Conclusions

This literature review underscores the transformative potential of AI and ML in revolutionizing cardiovascular health care. Advanced AI-driven methodologies, including DLSE, FDCN, and CSOA, have demonstrated remarkable improvements in the detection, prediction, and management of CVD.

The integration of diverse data sources with these sophisticated algorithms enhances diagnostic accuracy, supports personalized treatment strategies, and enables early intervention efforts. Furthermore, the application of AI in wearable technologies shows great promise for continuous, noninvasive health monitoring, potentially improving patient outcomes while reducing health care costs.

These advancements represent a significant shift toward more proactive and personalized patient care, offering health care professionals powerful tools to support their decision-making processes. The high accuracy demonstrated by AI models in CVD classification and prediction suggests a future where cardiovascular events can be anticipated and prevented with greater precision.

However, the widespread adoption of AI in health care faces several challenges. These include the standardization of frameworks and protocols, ensuring robust data privacy and security measures, enhancing the interpretability and explainability of AI algorithms, validating AI models across diverse patient populations, and addressing ethical considerations in AI-driven health care.

Overcoming these obstacles could be crucial to realizing the full potential of AI-driven technologies in transforming cardiovascular care. Future research should focus on: (1) refining and optimizing AI models for improved accuracy and reliability; (2) integrating real-time data streams to enhance the applicability of AI in clinical settings; (3) conducting large-scale, multicenter studies to validate AI efficacy across different health care systems and patient demographics; (4) developing guidelines and best practices for the ethical implementation of AI in health care; and (5) exploring the synergies between AI and other emerging technologies to create more comprehensive health care solutions.

By addressing these challenges and pursuing these research directions, AI and ML have the potential to revolutionize cardiovascular health care on a global scale. The promise of more accurate, timely, and cost-effective solutions could significantly benefit both patients and health care providers, ultimately leading to improved cardiovascular health outcomes.

As we move forward, it is essential to maintain a balance between technological innovation and ethical considerations, ensuring that the advancements in AI-driven cardiovascular care are accessible, equitable, and centered on improving patient well-being. The integration of these technologies into clinical practice represents a significant step toward more proactive, personalized, and efficient cardiovascular care, aiming to improve global health outcomes.

Abstract

Background: With the rapid development of artificial intelligence (AI) technology, especially generative AI, large language models (LLMs) have shown great potential in the medical field. Through massive medical data training, it can understand complex medical texts and can quickly analyze medical records and provide health counseling and diagnostic advice directly, especially in rare diseases. However, no study has yet compared and extensively discussed the diagnostic performance of LLMs with that of physicians.

Objective: This study systematically reviewed the accuracy of LLMs in clinical diagnosis and provided reference for further clinical application.

Methods: We conducted searches in CNKI (China National Knowledge Infrastructure), VIP Database, SinoMed, PubMed, Web of Science, Embase, and CINAHL (Cumulative Index to Nursing and Allied Health Literature) from January 1, 2017, to the present. A total of 2 reviewers independently screened the literature and extracted relevant information. The risk of bias was assessed using the Prediction Model Risk of Bias Assessment Tool (PROBAST), which evaluates both the risk of bias and the applicability of included studies.

Results: A total of 30 studies involving 19 LLMs and a total of 4762 cases were included. The quality assessment indicated a high risk of bias in the majority of studies, primary cause is known case diagnosis. For the optimal model, the accuracy of the primary diagnosis ranged from 25% to 97.8%, while the triage accuracy ranged from 66.5% to 98%.

Conclusions: LLMs have demonstrated considerable diagnostic capabilities and significant potential for application across various clinical cases. Although their accuracy still falls short of that of clinical professionals, if used cautiously, they have the potential to become one of the best intelligent assistants in the field of human health care.

Introduction

The Google Brain research team has consistently aimed to push the boundaries of recurrent language models and encoder-decoder architectures. In 2017, Vaswani et al [1] introduced a novel and simple network architecture known as the Transformer. This architecture uses a new mechanism called “self-attention,” leading to significant advancements in the development and training of large language models (LLMs). These models possess advanced capabilities beyond extraction or summarization tasks and include natural language generation. Although there is no official definition of LLM, based on the literature [2,3], we define LLM as a model with over a billion parameters, designed for typical artificial intelligence (AI) applications.

Accurate clinical diagnosis is essential for patient treatment outcomes and survival rates. However, even when health care professionals gather extensive information and conduct

XSL•FO
RenderX

numerous observations and tests, absolute diagnostic accuracy cannot be guaranteed. Minimizing diagnostic uncertainty and making the most appropriate treatment decisions remain persistent clinical challenges [4,5]. As of May 2024, the US Food and Drug Administration has approved 882 medical devices that use AI or machine learning assistance. By June 2024, the National Medical Products Administration of China has approved 17 AI-assisted diagnostic devices. In the era of big data in health care, the integration of AI with clinical decision support is a developing trend [6]. Numerous experts and scholars have explored the application of specialized AI and software tools in clinical diagnosis, yet there is limited knowledge about the performance of LLMs in this context. Therefore, this study aims to comprehensively evaluate the performance and accuracy of LLMs in clinical diagnosis, providing references for their clinical application.

Methods

Overview

This systematic review was conducted following the Preferred Reporting Items for Systematic Reviews and Meta-Analysis of Diagnostic Test Accuracy Studies (PRISMA-DTA) statement [7]. Specific details can be found in Checklist 1.

Data Sources

A computer-assisted literature search of PubMed, Web of Science, Embase, CINAHL (Cumulative Index to Nursing and Allied Health Literature), CNKI (China National Knowledge Infrastructure), VIP, and SinoMed databases was performed from January 1, 2017, to the present. Search terms included controlled terms (MeSH [Medical Subject Heading] in PubMed and Emtree in Embase) and free-text terms. The following terms were used (including synonyms and closely related words) as index terms or free-text words: “large language model,” “medicine,” “diagnosis,” and “accuracy.” A search filter was applied to limit the results to humans. Only peer-reviewed cross-sectional studies and cohort studies were included. Multimedia Appendix 1 provides more details of the search strategy and study selection.

Selection Criteria

This review included studies meeting the following criteria: (1) investigated the application of LLMs in the initial diagnosis of human cases, (2) published between January 1, 2017, and the date of the search, (3) study type was either cross-sectional or cohort, (4) a primary source, and (5) written in English or Chinese.

An article was excluded if it (1) was a nonprimary source such as theses, conference papers, etc, (2) did not compare the diagnostic accuracy of clinical professionals in relevant departments with that of LLMs, (3) did not specify the type or scale of the LLM used for diagnosis, (4) did not have LLM independently conduct clinical case diagnoses, (5) was a duplicate publication, and (6) did not provide complete data or the full text could not be obtained.

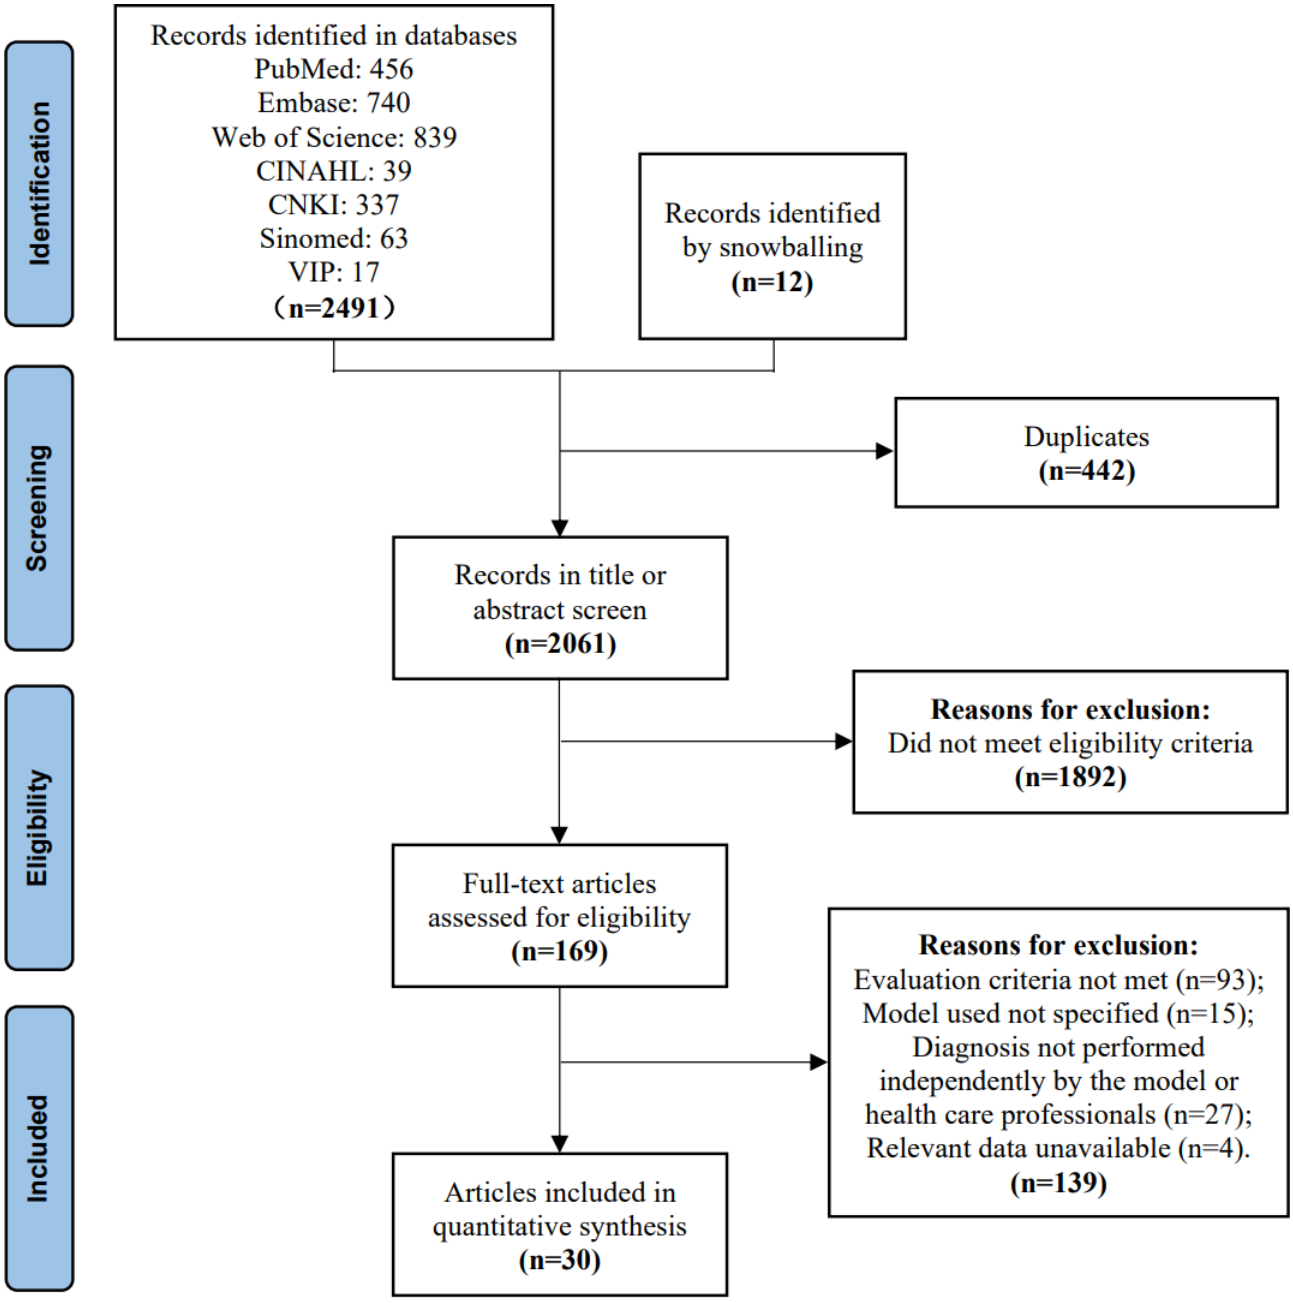
Data Selection and Extraction

A total of 2 reviewers (GS and XC) independently reviewed the full texts of the eligible articles and extracted data. Any disagreements between the reviewers were discussed until a consensus was reached. The detailed characteristics extracted from each included study were: the first author and publication year, the country where the research was conducted, the study type, the study population, the source of cases, sample size, the LLMs used, control groups, and outcome measures.

Quality of Evidence and Risk of Bias

Due to the significant heterogeneity often present in the design and implementation of diagnostic accuracy studies, it is crucial to carefully assess the quality of the included studies. The Prediction Model Risk of Bias Assessment Tool (PROBAST) was used to evaluate the risk of bias and applicability of all included studies [8]. PROBAST assesses risk of bias across 4 domains: study participants, predictors, outcomes, and statistical analysis, while applicability is evaluated through the first 3 domains.

Given the complex structure and vast number of parameters in LLMs, they can be considered a “black box” to some extent, meaning that their internal workings and decision-making processes may not be entirely transparent or easily understood by humans [6]. Consequently, during the quality assessment, certain signal issues were excluded as they were unrelated to generative AI models [9].



Results

Selection of Studies

A total of 2491 studies were found in the databases by 2 researchers independently following the predefined search strategies and data collection methods. An additional 12 articles were identified through reference tracing, bringing the total number of studies screened to 2503. Among these, 169 studies were read in full, resulting in 30 studies that met the inclusion criteria for synthesis. Reasons for exclusion at this stage were recorded and can be found in the flow diagram (see Figure 1).

XSL•FO
RenderX

Figure 1. Flow diagram. Papers identified in databases, title or abstract screened, read full text, and included in the synthesis. Reasons for exclusion are listed. CINAHL: Cumulative Index to Nursing and Allied Health Literature; CNKI: China National Knowledge Infrastructure.

Studies Characteristics

The 30 included studies [10-39] were concentrated within the past 3 years, with 12 published in 2023, 16 in 2024, and 2 in 2025. These studies cover a wide range of countries, primarily from Japan, the United States, and China. A total of 4762 cases were analyzed, involving 19 LLMs. The studies predominantly focused on GPT-3.5 (n=14) and GPT-4 (n=20) versions (OpenAI), extensively applied in assessing clinical diagnostic accuracy. In contrast, fewer studies addressed Google Bard (n=3), Bing (n=3), GPT-4o (n=2), and GPT-4V (n=2). The case diagnoses encompassed various fields, including ophthalmology (n=9), internal medicine (n=6), emergency medicine (n=3), and general medicine (n=3), among others. The control groups included at least 193 clinical professionals, ranging from resident doctors to medical experts with over 30 years of clinical experience, to compare their diagnostic capabilities with those of the LLMs. All included studies used LLMs for data testing purposes only and were not used for real-time diagnosis of clinical patients. Table 1 shows the basic characteristics of the included studies.

Quality of Evidence and Risk of Bias

The included articles were evaluated using the PROBAST tool, with the results presented in Multimedia Appendix 2. Overall, 10/30 (33.3%) studies had a low risk of bias, while 20/30 (66.6%) exhibited a high risk of bias. Regarding applicability, majority of study had low applicability concerns. Due to ethical concerns and patient privacy issues associated with the use of

XSL•FO
RenderX

LLMs in clinical settings, most of the studies consist of retrospective studies with deidentified data and are limited to data testing. A total of 14 studies evaluated the diagnostic accuracy of models using small test sets. In addition, the "black box" nature of LLMs, whose training data are often undisclosed, complicates external evaluation and verification.

LLM Feature Analysis

Although a total of 19 different LLMs were used in the included studies, extracting the LLM with the best diagnostic performance in studies tested with multiple large models simultaneously, we found that the optimal LLM did not belong to the GPT series in only 6 studies. In 80% (24/30) of the studies, the researchers chose to obtain and use the corresponding LLMs directly on the official website by online access, which somewhat lowered the threshold for the use of the LLMs in the medical field and made it more accessible to the public. In total, 18 of the included studies specified the date of access or version of the LLM used. Retrieval-augmented generation (RAG) is a technique that combines information retrieval and generation to enhance task performance by incorporating relevant information into LLMs [40]. RAG was mentioned in 2 of the studies by further training of pretrained models specific to task datasets, and although RAG has been widely used in large model studies, it needs to be strengthened in the medical field. Specific details can be found in Table 2.

Results of Diagnosis

The accuracy of the diagnoses made by the LLMs and the clinical professionals in the studies depends on the "standard answer" mentioned in the literature. The comparison is based on how their answers align with this standard. The "standard answer" in the included studies consists of the final diagnoses recorded in patient medical records or case reports, predetermined answers set by case developers, and diagnoses established by experienced clinical experts in the relevant departments.

Application of LLMs in Clinical Diagnosis

The most common model task was the free text task, which appeared in 19 articles, while only 1 article involved a choice task. English was used for input and output in all but 2 articles: one used Hebrew for prompting, and the other used Chinese to compare model diagnostic performance. In LLM, prompt is an input mode that guides the model to specific tasks or generates specific outputs, typically including elements such as instructions (task descriptions), context (background information), examples, input data, output instructions, and roles [41,42]. When LLMs are used for case diagnosis, the most frequently used elements are commands and input data, which primarily include patient basic information, complaints, medical history, physical examination, and laboratory tests. The output content mainly consists of diagnostic lists or triage recommendations. The diagnostic accuracy of health care professionals in each study was evaluated by investigators or experts in relevant fields.

In studies where multiple LLMs were used to diagnose sample cases, only the data for the model with the best diagnostic performance were recorded. Of these studies, 85% (24/30) reported that the ChatGPT series models demonstrated the best diagnostic performance. Several investigators noted that the diagnostic accuracy of GPT models was comparable with that of physicians and did not show significant differences. Specific details can be found in Multimedia Appendix 3.

Comparison of Diagnostic Accuracy Between LLMs and Health Care Professionals

Pooling the data revealed that 70% (21/30) of the studies used the frequency of correct diagnoses in model responses as the primary evaluation indicator of clinical diagnostic accuracy, excluding other auxiliary indicators. All accuracy results were expressed as percentages. For the optimal model, the accuracy of the primary diagnosis ranged from 25% to 97.8%, while triage accuracy ranged from 66.5% to 98%. In medical practice, the diagnostic agreement criterion is usually set at over 80%. The GPT series LLMs achieved diagnostic accuracy greater than 80% in clinical tasks across 3 studies in ophthalmology, 2 studies in general medicine, and 1 study each in radiology, emergency medicine, and general practice. Among the 7 studies focused on ophthalmic case diagnosis, the diagnostic performance was generally high, with 77.8% (7/9) of the large models showing diagnostic accuracy comparable with that of health care professionals.

In these cases, health care professionals received the same prompting words as the LLMs. In 60% (18/30) of the studies, control group participants were blinded to the true nature and goals of the study until it was completed. The diagnostic accuracy of health care professionals was compared with the outcomes of LLMs. The results showed that in 33.7% (20/30) of the studies, professionals had higher diagnostic accuracy than the models. In 33.3% (10/30) of the studies, the LLMs, specifically ChatGPT, had higher diagnostic accuracy than humans. The specific diagnostic accuracy comparisons are detailed in Table 3.

[j]Frequency of correct diagnosis in the 10 differential diagnoses.

Meta-Analysis

Although this paper synthesizes over 4000 clinical cases, these cases exhibit significant heterogeneity in terms of clinical departments, diagnostic methodologies, and evaluation metrics. Due to these inherent differences, only 18 studies that used primary diagnostic accuracy as the evaluation metric were included in a meta-analysis. The analysis revealed that clinical professionals generally outperformed LLMs in diagnostic accuracy across various conditions, as shown in Figure 2. The *P* value was less than 0.05, and the I^2 value was 77%, indicating significant heterogeneity among the studies. Sensitivity analysis did not significantly improve the heterogeneity. Subgroup analyses by clinical department showed reduced heterogeneity in ophthalmology-related research, yet results still favored the diagnostic accuracy of ophthalmology professionals over LLMs.

XSL•FO
RenderX

Figure 2. Forest plot comparing diagnostic accuracy of large language models (LLMs) and clinical professionals [37,32,25,36,20,23,26,21,35,31,33,22,34,12,30,15,27,19].

Discussion

Principal Findings

In this systematic review, we analyzed the diagnostic accuracy of LLMs compared with clinical professionals, encompassing various LLMs and common medical specialties. Although the results typically indicated superior diagnostic accuracy among professionals, this study compiled the methodologies, functionalities, and outcomes of using LLMs in medical diagnostics. It affirmed the diagnostic capabilities of generic LLMs, providing evidence for their potential as healthcare assistants.

Application of LLMs in Clinical Diagnosis Still in Exploratory Stage

This review includes only peer-reviewed and published literature, so the models examined in the included studies primarily use text-based input and output for diagnostic tasks. However, with the advancement of large models, multimodal capabilities have also been integrated [43]. Some preprint studies [44,45] have explored using GPT-4V, incorporating imaging data into input prompts. Notably, adding images to LLM did not improve diagnostic performance. In a study by Horiuchi et al [44], ChatGPT-4, which relied solely on text prompts, achieved higher diagnostic accuracy compared to GPT-4V, which combined text and images. Without few-shot learning, LLMs may struggle with image recognition and interpretation, sometimes leading to counterproductive outcomes.

Currently, the performance of general LLMs continues to improve, showing strong results in health care question answering, text classification, and clinical concept extraction [46]. However, these studies remain experimental and laboratory-based. Issues such as the interpretability of model responses and medical ethics pose significant challenges to applying these models in real clinical settings. Furthermore, the trust and acceptance of AI models by clinicians directly affect their adoption and implementation. Therefore, education and training programs are crucial for enhancing physicians' AI literacy [47].

Evolution of Artificial Intelligence in Clinical Diagnosis

The evolution of AI in clinical diagnosis has progressed from simple specialized systems to complex deep learning models. Early AI systems were based on fixed rules and expert knowledge bases. While these systems achieved some success in specific tasks, they had limited scalability and flexibility. The advancement of deep learning technologies, particularly the emergence of LLMs, has ushered AI applications in the health care sector into a new era [48,49].

LLM can learn from vast amounts of medical data to autonomously discover and summarize diagnostic rules, significantly enhancing diagnostic accuracy and reliability. The development of RAG technology and fine-tuning techniques has further enabled LLM to acquire advanced domain expertise and effectively perform specialized tasks.

Ethics of Artificial Intelligence in Clinical Diagnosis

Although the pace of artificial intelligence development is swift, its broad implementation in clinical settings continues to encounter numerous obstacles, including concerns over data privacy, accountability, and ethics. Consequently, numerous scholars [50-53] underscore the imperative of utmost caution in using these technologies. Advances in the future will necessitate not only technological innovations but also comprehensive enhancements in legal and ethical frameworks to ensure that AI technology is safely and effectively woven into clinical diagnostic processes. In deploying LLMs within actual clinical workflows, it is crucial to first guarantee the transparency of all used data and secure patients' informed consent. In addition, to tackle potential biases within AI models, periodic audits are advised to identify and amend any discrepancies. Furthermore, to safeguard patient safety and adhere to regulatory demands, medical institutions should work alongside legal and ethical experts to establish stringent guidelines and oversight mechanisms for AI use. For instance,

XSL•FO
RenderX

forming an ethics committee to assess and monitor AI applications could ensure compliance with ethical standards and legal requirements. These targeted measures are essential to surmount existing challenges and foster the successful incorporation of AI technologies in clinical diagnostics.

Application of LLMs in Specific Medical Fields

The application of LLMs in the medical field is gradually expanding, especially in imaging diagnosis, clinical decision support, and personalized treatment planning. Due to their specific needs and challenges, each medical field shows different ways and effects of LLMs' application.

Ophthalmology is one of the pioneers of LLMs' applications. In ophthalmic diagnosis, imaging data such as fundus images, retinal scans are typically complex, but LLMs excel in processing and analyzing these types of data [45,54]. Research has shown that LLMs can identify minor lesions in fundus images and diagnose conditions such as glaucoma and macular degeneration [55,56]. Ophthalmic diagnostics rely not only on imaging but also on additional data such as patients' genetic information and blood sugar levels. In the future, LLMs could integrate these multimodal data to achieve more accurate disease predictions through personalized treatment. Particularly in resource-limited areas, easily accessible LLMs with low usage thresholds could replace some ophthalmologists in preliminary screenings, further providing efficient diagnostic support in remote regions.

There are many internal medicine diseases that require long-term follow-up and monitoring. LLMs can process all historical data of patients simultaneously and updating personalized treatment plans, assisting clinical professionals in making more beneficial decisions [57-59]. In the future, LLMs will be paired with wearable devices to monitor patients' health in real time, predict potential risks through data analysis, and provide early intervention for patients with medical diseases, thereby reducing the incidence and recurrence of the disease.

In the fields of otolaryngology [60,61] and dermatology [62,63], LLMs have been used to analyze imaging data for detecting lesions in respective areas. The latest models now offer voice input features, allowing patients to use the model anytime and anywhere to help in the early detection of speech disorders and vocal cord issues. In the future, integrating voice recognition with physiological data can also assist physicians in more accurately locating lesion areas during otolaryngological surgeries, thus improving treatment efficacy. Furthermore, by combining images of skin lesions with patients' genetic data, LLMs can help predict the risk of dermatological conditions and provide early warnings.

Exploration of the Use of LLMs in Various Clinical Departments

Currently, extensive research in fields such as ophthalmology, internal medicine, and radiology has demonstrated the substantial potential of LLMs in clinical diagnostics and pathological analysis. These models have even been implemented in some hospitals. Many clinical professionals are actively exploring how to integrate these technologies into their daily diagnostic and treatment routines.

However, the application of LLMs in other specialized areas remains limited, and research in these fields appears to be lacking. Several reasons account for this disparity: First, the departments mentioned above primarily focus on diagnostic issues, providing rich training data for large models, especially in terms of imaging and case data. Second, the main challenges these departments face in clinical practice, such as accurate diagnosis and disease prediction, are areas where LLMs can excel. In contrast, other departments such as surgery, although also using imaging data, face complexities in surgical and procedural tasks that hinder the maturity of AI applications. Gynecology has seen some applications of image recognition, but lacks depth in research and sufficient data accumulation, making model training challenging. In addition, real-world factors such as data privacy protection and technology dissemination also restrict the application of large models in certain departments.

Future Directions

The "human-AI collaboration" model involves an initial diagnosis provided by AI, which is then reviewed and confirmed by clinicians. AI's capability to analyze clinical data in real time enables it to offer personalized monitoring plans based on the specific conditions of patients. This continuous tracking of patient health and treatment outcomes helps achieve the goals of personalized medicine and precise diagnosis [64,65]. In addition, AI can provide customized services and recommendations based on user preferences and backgrounds, enhancing user experience and effectiveness. This model combines the rapid processing capabilities of AI with the expert judgment of clinicians, improving the efficiency and reliability of clinical trials. It also enhances data analysis and patient management, offering significant advantages in cost reduction, resource use, and ensuring the reliability of trial results.

Although LLMs are not inherently designed for clinical diagnostic tasks, advancements in technology and data accumulation are expected to improve their performance in clinical settings. Techniques such as large-scale medical literature analysis, specific clinical data training, task-specific fine-tuning, personalized training for particular scenarios, and integration with APIs or other supplementary software tools are anticipated to enhance the diagnostic support and treatment recommendations provided by these models [66,67]. Hybrid models could be developed by combining rule-based clinical decision support systems with the pattern recognition capabilities of LLMs. For example, Vision China 2023 introduced Eye GPT [68], a system that integrates ophthalmic medical knowledge with LLM. This system aims to assist clinicians in disease diagnosis and improve medical efficiency by combining extensive ophthalmic information with powerful computational capabilities. This innovation in integrating large models with specialized clinical fields is expected to play a crucial role in future clinical applications and provide research directions for other medical specialties.

Limitations

This study has several limitations. First, the inclusion criteria restricted the review to studies comparing the diagnostic accuracy of LLMs with that of clinical health care professionals

XSL•FO
RenderX

using case groups. This limitation may affect the comprehensiveness of the review and introduce selection bias. In addition, there is no specialized tool for assessing the risk of bias in literature related to LLMs. Although PROBAST was used to evaluate the quality of the included studies, its focus on diagnostic accuracy may influence the evaluation results. Finally, significant heterogeneity among the studies was observed, with variations in outcome measures potentially related to differences in intervention subjects, prompt inputs, and information modalities. Further exploration of LLM diagnostic performance is needed through large-scale, multicenter, and high-quality cross-sectional and cohort studies.

Conclusions

This systematic review included 20 studies comparing the diagnostic accuracy of LLMs with that of health care professionals, encompassing various generative AI models and medical specialties. The findings indicate that while LLMs still have a long way to go in accurately diagnosing real-world clinical scenarios and currently lack the level of understanding of human experts, they undeniably possess significant potential as health care assistants. With ongoing advancements and optimizations in technology, it is anticipated that LLMs will play an increasingly important role in future clinical diagnostics.

Abstract

Background: Regular exercise recommendations (ERs) and physical activity (PA) are crucial for the prevention and management of chronic diseases. However, creating effective exercise programs demand substantial time and specialized expertise from both medical and sports professionals. Large language models (LLMs), such as ChatGPT, offer a promising solution by helping create personalized ERs. While LLMs show potential, their use in exercise planning remains in its early stages and requires further exploration.

Objectives: This study aims to systematically review and classify the applications of LLMs in ERs and PA. It also seeks to identify existing gaps and provide insights into future research directions for optimizing LLM integration in personalized health interventions.

Methods: A scoping review methodology was used to identify studies related to LLM applications in ERs and PA. Literature searches were conducted in Web of Science, PubMed, IEEE, and arXiv for English language papers published up to March 21, 2024. Keywords included LLMs, chatbots, ERs, PA, fitness plan, and related terms. Two independent reviewers (XL and CH) screened and selected studies based on predefined inclusion criteria. Thematic analysis was used to synthesize findings, which were presented narratively.

Results: An initial search identified 598 papers, of which 1.8% (11/598) of studies were included after screening and applying selection criteria. Of these, ChatGPT-based models were used in 55% (6/11) of the studies. In addition, 73% (8/11) of the studies used expert evaluations and user feedback to assess model usability, and 45% (5/11) of the studies used experimental designs to evaluate LLM interventions in ERs and PA. Key findings indicated that LLMs can generate tailored ERs, save time in clinical practice, and enhance safety by incorporating patient-specific data. They also increased engagement and supported behavior change. This made PA guidance more accessible, especially in remote or underserved communities.

Conclusions: This review highlights the promising applications of LLMs in ERs and PA but emphasizes that they remain a supplement to human expertise. Expert validation is essential to ensure safety and mitigate risks. Future research should prioritize pilot testing, clinician training programs, and large-scale clinical trials to enhance feasibility, transparency, and ethical integration.

KEYWORDS

artificial intelligence; large language model; chatbots; exercise recommendations; physical activity; AI; LLM

Introduction

Background

Personalized, evidence-based exercise programs play a pivotal role in preventing and managing chronic conditions and reducing the risk of sports injuries. In contrast, poorly designed or inappropriate exercise practices can diminish effectiveness or even cause adverse effects [1]. Therefore, formulating scientifically sound and effective exercise recommendations (ERs) is essential to optimize the health benefits of physical activity (PA) while mitigating potential risks. This approach is instrumental in improving chronic disease conditions and

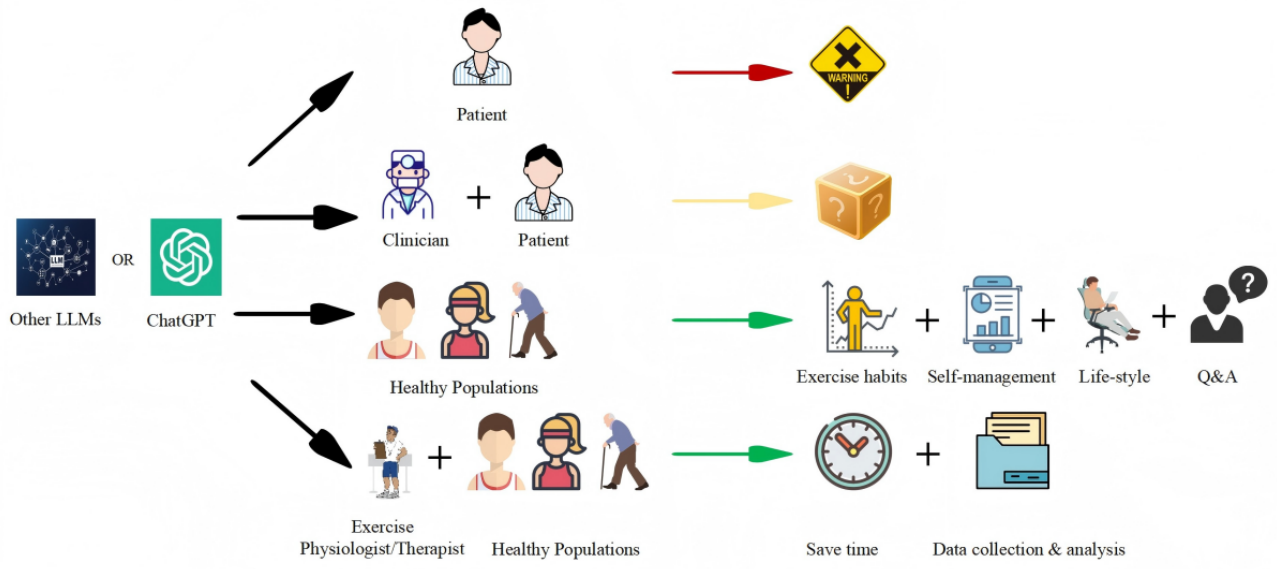
XSL•FO
RenderX

enhancing quality of life [2-4]. However, implementing these recommendations demands significant human resources and time.

Creating effective ERs requires nuanced, interdisciplinary collaboration between medical and sports professionals [5]. Medical experts, drawing on their knowledge of exercise physiology, medicine, and nutrition, consider individual health conditions, medical histories, and medication usage to ensure safety and efficacy. Simultaneously, sports professionals use their theoretical knowledge and practical experience to tailor individualized exercise plans based on skill levels and needs, working alongside medical counterparts to determine optimal recommendations.

Despite these collaborative efforts, the field of ERs has long faced a "black box" challenge, where the underlying mechanisms of exercise interventions are not fully understood, and outcomes are unpredictable [6-8]. Traditional approaches often rely on comprehensive strategies or personal intuition, introducing subjectivity and limitations. The advent of artificial intelligence (AI) in health care, however, offers promising insights into these complexities, enabling precise personalization.

AI's robust data analysis, text generation, and creative capabilities are revolutionizing ERs and PA formulation, steering it toward precision and individualization. Notably, the linguistic understanding and generation abilities of large language models (LLMs), such as those based on transformer neural network architectures, have shown potential in personalized medicine and health management across various domains [9-15].



Numerous studies have successfully tailored LLMs for specific domain tasks [16,17]. Research indicates that using self-supervision or continuing pretraining on domain-specific corpora enhances model performance in downstream tasks [18-20].

Given these developments, health and wellness are poised to be vital areas for AI's future impact. By using advanced AI tools such as LLMs and chatbots, ERs and PA formulation is becoming increasingly scientific and personalized [21]. This not only has the potential to optimize exercise outcomes but may also enhance safety, ushering in a new era in chronic disease prevention and health management.

Objectives

To our knowledge, this paper represents one of the first scoping reviews of the applications of LLMs in the fields of ERs and PA, with 2 primary objectives. First, we aim to summarize and categorize the applications of LLMs used in existing ERs and PA literature to identify trends, synergies, and patterns that could guide future investigations. Second, through our comprehensive review of the literature, we seek to provide valuable insights that can inform and shape the future development of AI technologies in the field of exercise health. By highlighting gaps and opportunities, we aim to assist in directing AI advancements to better meet the needs of personalized exercise and health management. This scoping review is unique not for its focus on health outcomes of interventions but for its emphasis on applying diverse LLM methodologies within the realms of ERs and PA and for providing guidance on future advancements in this interdisciplinary field (Figure 1).

Figure 1. Potential roles and limitations of LLMs in exercise recommendations and physical activity. Direct use for patients is deemed inappropriate, while assisting clinicians requires further validation. LLMs have demonstrated benefits in promoting healthy habits and self-management among the general population. For exercise physiologists and therapists, LLMs enhance efficiency in client management, exercise suggestions, and data analysis. LLMs: large language models; Q&A: question and answer.

The search strategy was designed to address several key research questions guiding this scoping review: (1) What is the current progress in applying LLMs for ERs in the health care field, and how effectively do LLMs support health care professionals in guiding patients toward personalized, evidence-based exercise program? (2) What is the progress of LLM applications in the PA domain for healthy populations, and can these models effectively assist in promoting personalized, evidence-based

XSL•FO
RenderX

exercise program? (3) What methods have current studies used to validate the performance of LLMs, and do these models achieve the competency level of professional practitioners? (4) What challenges have been encountered in applying LLMs for ERs and PA, and what valuable insights do these challenges offer for future updates and iterations of LLM technology?

Methods

Study Design

We followed the scoping review methodology proposed by Arksey and O'Malley, which encompasses (1) identifying research questions, (2) relevant studies, (3) study selection, (4) data charting, and (5) collating, summarizing, and reporting the results. In addition, we adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist to ensure comprehensive reporting.

Search Strategy Development and Study Selection

The search strategy was developed through a collaborative process involving the research team members (XL and CH), who conducted the initial design and refinement of the search terms. The terms were informed by a thorough review of existing literature, discussions among the team members, and the key research questions identified at the outset of the study. These questions focused on the application and efficacy of LLMs in ERs and PA.

To ensure the robustness of the search strategy, we targeted 4 major databases: Web of Science, PubMed, IEEE, and arXiv, using comprehensive search strings that combined terms related to AI, LLMs, and exercise science. The search strategy included combinations of keywords such as "artificial intelligence," "large language model," "exercise recommendations," and "physical activity" to capture a wide range of relevant studies.

While we did not formally consult a librarian or an information scientist, the team members leveraged their collective expertise in medical informatics and exercise science to craft a strategy that was both comprehensive and targeted. The detailed search process, including inclusion and exclusion criteria, is outlined in Table S1 in Multimedia Appendix 1.

Eligibility Criteria

Inclusion Criteria

Non–peer-reviewed and non-English publications or resources were excluded. Studies were included in this review if they met the following criteria:

1. Language: Only those papers that were published in English were considered to ensure consistency and facilitate synthesis across studies.
2. Application of LLMs/Chatbot technologies: Studies that used LLMs or chatbot technologies in the context of ERs, PA guidelines, or fitness interventions were included.
3. Medical and public health context: Papers focusing on applications within medical practice or public health settings related to ERs, PA, or fitness were deemed eligible.
4. Diverse regions and health care contexts: Studies conducted across various geographic regions and health care settings to ensure global applicability and relevance of findings were included.

In addition, studies were considered if the terms "LLMs/Chatbots" and "ERs" or "PA" appeared simultaneously in the title, abstract, or keywords.

For classification purposes, (1) if the study population consisted of patients and the research focused on disease treatment, the study was categorized under ERs; (2) if the study population comprised healthy individuals and the research aimed at enhancing health levels, the study was categorized under PA, and (3) if these specific keywords did not appear but terms such as "fitness plan" or "exercise plan" were present, the study was included after discussion among all reviewers and then appropriately categorized.

Exclusion Criteria

Studies were excluded based on the following criteria:

1. Non–peer-reviewed and non-English publications: Publications that were not peer-reviewed or not published in English were excluded.
2. Nonoriginal research content: Reviews, abstracts, letters, viewpoints, editorials, dissertations, and tutorials were excluded unless they provided original research data.
3. Lack of relevant insights: Studies that did not offer substantial insights into the utilization of LLMs or chatbot technologies in ERs or related fields were excluded.

Data-Charting Process

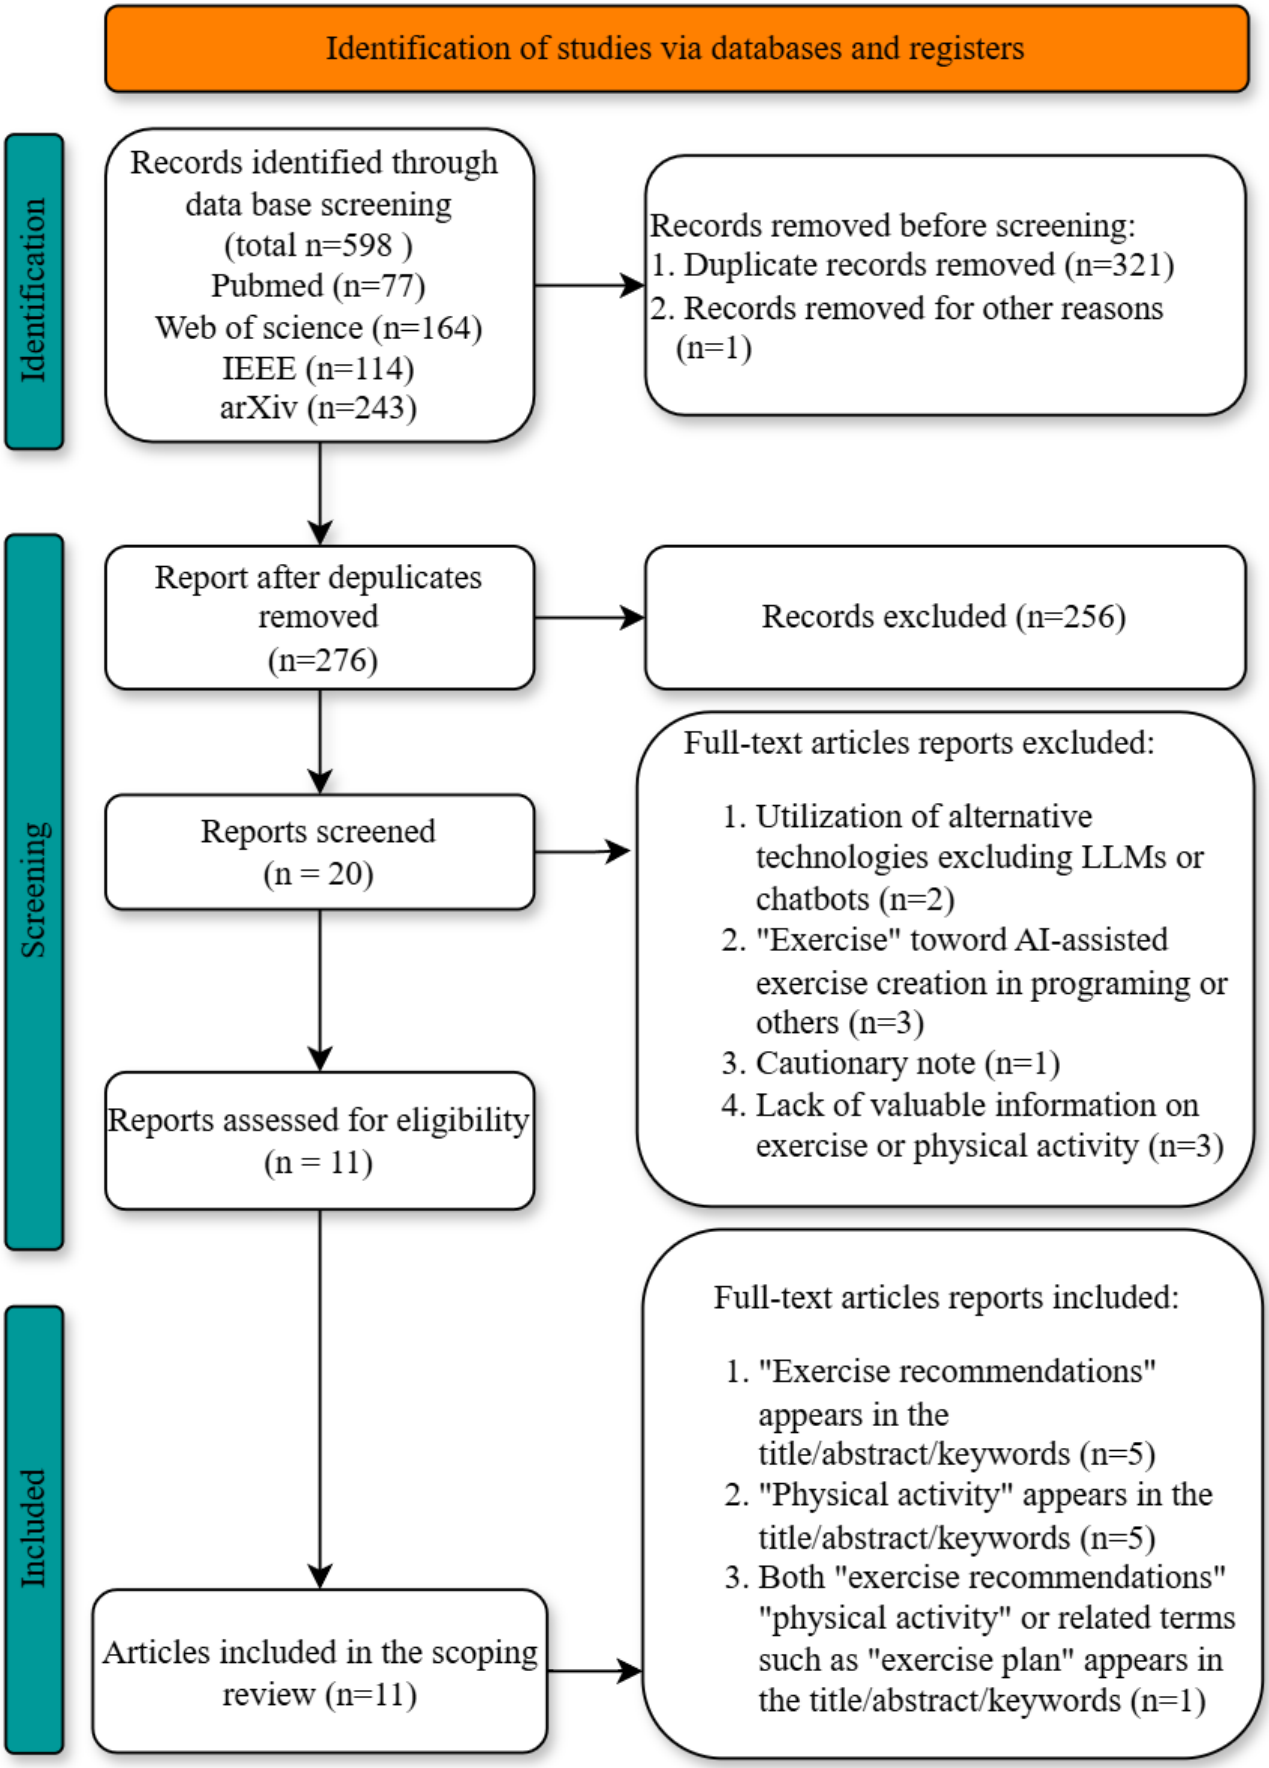
A data-charting form was collaboratively developed by 2 reviewers (XL and CH) to determine which variables to extract. This form comprised six sections: (1) first author and publication date, (2) study design, (3) sample size or datasets, (4) related models, (5) usability testing, and (6) outcomes or contributions. The 2 reviewers (JC and SH) independently charted the data, discussed the results, and continuously updated the data-charting form in an iterative process.

To ensure the quality and relevance of the included papers, 2 reviewers (XL and CH) independently assessed the relevance of the papers to ensure a thorough and unbiased review process. In cases of disagreement, the remaining 4 authors (JC, ZS, YC, and SH) served as arbitrators, and a final decision was made only when consensus was reached among all 6 authors. To enhance consistency among reviewers, all reviewers initially screened the same publications, discussed the results, and amended the screening and data extraction manual before commencing formal screening. Working in pairs, the reviewers sequentially evaluated the titles, keywords, and abstracts of all publications identified in our searches for potentially relevant studies. Disagreements on study selection and data extraction were resolved through consensus and, if necessary, discussion with additional reviewers. This stringent selection process strengthens the validity and reliability of our findings by ensuring that our review is based on high-quality evidence.

XSL•FO
RenderX

Data Items

We abstracted data on paper characteristics (eg, first author, publication date, and study design), engagement characteristics and contextual factors (eg, sample size or datasets, and the specific LLMs or chatbot technologies used), barriers and facilitators to engagement (eg, results from usability testing and user interaction metrics), and results of any formal assessment of engagement (eg, key outcomes, contributions, and the impact of the models on ERs or PA).



Results

Identification of Studies

An initial keyword search identified 598 papers, and after the removal of duplicates, 276 unique papers remained for screening based on their all fields. Of these, 256 papers were considered irrelevant and subsequently excluded from the review, one of the records cannot search full-text paper. After applying the study selection criteria to the remaining 20 papers, a total of 11 studies were included in the review (Figure 2).

Study Characteristics

All the details regarding the study characteristics are comprehensively displayed in Tables 1 and 2.

Table . Main characteristics of 5 reports focused on exercise recommendations in this review.

Author (year)	Study designs	Sample size or datasets	Related models	Usability testing	Outcomes or contribution
Zaleski et al (2024) [22]	Mixed methods study	N/A[a]	ChatGPT (February 2023 version)	Expert evaluations	Moderate comprehensiveness (41.2%) and high accuracy (90.7%).
Dergaa et al (2024) [23]	Simulated patient case study	5 profiles	GPT-4	Expert evaluation	Lack of precision for specific conditions; AI not yet a substitute for expert prescriptions.
Haag (2024) [24]	Experimental comparison	450 JITAIs[b] decisions	GPT-4	User feedback	GPT-4-generated JITAIs rated highest in quality, effectiveness, and emotional impact, surpassing health care professionals and layperson-generated content.
Shin et al (2023) [25]	Exploratory study	18	LLM[c]-infused web interface	Expert evaluations.	AI[e]-generated exercise plans are personalized, actionable, and effective in supporting exercise routines.
Sivarajkumar et al (2023) [26]	Algorithm development and testing	13,605 patient records	Rule-based NLP[d], ChatGPT	F_1-score evaluation against gold standard dataset.	Rule-based NLP had best precision; ChatGPT had high recall and lower precision.

[a]N/A: not applicable.

[b]JITAIs: just-in-time adaptive interventions.

[c]LLM: large language model.

[d]NLP: natural language processing.

[e]AI: artificial intelligence.

XSL•FO
RenderX

Table . Main characteristics of 6 reports focused on physical activity in this review.

Author (year)	Study designs	Sample size or datasets	Related models	Usability testing	Outcomes or contribution
Willms and Liu (2024) [27]	Autoethnographic case study	N/A[a]	ChatGPT-3, Pathverse	Expert evaluations	Efficient content creation; recommended 6-step process for future mHealth[b].
Chowdhury et al (2023) [28]	System development and evaluation	1M+ recipes	Neural network (Chatbot)	Empirical validation	Effective in recommending daily fitness and diet plans; future work aims to enhance personalization and usability.
Vandelanotte et al (2023) [29]	Conceptual framework	N/A	NLP[c], ChatGPT[d]	User feedback	Developed a real-time framework for personalized interventions.
To et al (2021) [30]	Quasi-experimental study	116	Ida (Google Inc)	Self-reported	Significantly increased PA[e] among participants.
Liang et al (2021) [31]	Randomized clinical trial	107 dialogues (7808 sentences)	BERT[f]-based classifier	Expert evaluations and user interaction analysis	Personalized dialogues reduced PA barriers, provided tailored support, and improved motivation for sustained PA behaviors.
Wiratunga et al (2020) [32]	Think-aloud methodology	7 participants	Voice-based chatbot (“FitChat”)	User feedback	Enhanced PA adherence and motivation through personalized, voice-based interactions.

[a]N/A: not applicable.

[b]mHealth: mobile health.

[c]NLP: natural language processing.

[d]GPT: Generative Pre-trained Transformer.

[e]PA: physical activity.

[f]BERT: Bidirectional Encoder Representations from Transformers.

Main Findings

Five of the 11 studies reviewed used experimental designs, which constituted 45% [25,26,28,31,32]. These studies typically assessed the effectiveness of AI-driven interventions in ERs and PA, and ChatGPT-based models were used in 55% (6/11) of studies. In addition, 27% (3/11) of studies were case studies, focusing on real-world applications of chatbots and LLMs, while feasibility and development studies accounted for 27% (3/11) of studies, where prototypes and models were evaluated without full-scale trials [22,30,31].

Sample Size or Datasets

Sample-based research: 5 studies (5/11, 45%) involved direct participant testing to assess the models’ effectiveness. These studies explored how LLMs could provide personalized recommendations for various populations [22-24].

Dataset-based research: 4 studies (4/11, 36%) used large datasets to train or fine-tune models, primarily focusing on improving the models’ functionality in specific use cases such as rehabilitation [26].

Other verification methods: 2 studies (2/11, 18%) used expert-driven or simulation-based evaluations rather than using participant data.

Related Models

In the studies reviewed, ChatGPT-based models were used in 55% (6/11) of studies, with applications ranging from fitness recommendations to disease management. The remaining 45% (5/11) of studies used other LLMs or chatbot technologies, including Bidirectional Encoder Representations from Transformers–based models and specialized AI systems designed for specific interventions.

Usability Testing

Expert evaluation: 6 studies (6/11, 55%) used expert evaluation as the primary method for usability testing. These evaluations typically involved health professionals or exercise specialists assessing the generated content or ERs for accuracy, relevance, and practicality [24,31].

Other methods: In 5 studies (5/11, 45%), alternative methods were used for usability testing, which included the following:

XSL•FO
RenderX

1. User interaction metrics: Studies monitored how participants interacted with AI-generated content, measuring factors such as engagement rates, adherence to ERs, and feedback from end users [22,23].
2. Real-time adaptive feedback: Some studies used just-in-time adaptive interventions, where the usability of the model was assessed based on how well it adapted to real-time changes in participants' PA levels [24].

This mixed approach to usability testing highlights that while expert evaluations are crucial for initial validation, real-world interaction and feedback are also critical for assessing the practical application of the models in promoting ERs and PA.

Outcomes or Contributions

Exercise recommendations: In total, 45% (5/11) of studies focused on generating ERs specifically within the medical domain. These studies revealed several key contributions:

1. Tailored interventions: The use of LLMs such as ChatGPT showed promise in generating personalized ERs based on patient health data and conditions [22-24,26,27]. Studies found improvements in accuracy when addressing clinical rehabilitation needs, particularly for cardiac and orthopedic rehabilitation [22,24].
2. Time saving in clinical practice: The integration of AI-driven ERs was shown to reduce the time needed for health care providers to develop exercise plans, improving efficiency in clinical settings [23].
3. Enhanced safety: By incorporating patient-specific health data, LLMs were able to create recommendations that accounted for safety concerns, especially for populations with chronic conditions [30,31].

Physical activity: In total, 55% (6/11) of studies focused on encouraging PA in healthy or general populations. Key contributions in this area include the following:

1. Increased engagement: LLMs and chatbots were effective at increasing PA levels by providing real-time feedback, adaptive exercise plans, and motivation through interactive features. This was particularly beneficial for populations such as older adults and sedentary individuals [23,30].
2. Behavior change support: AI-driven interventions helped users establish and maintain regular PA routines through personalized just-in-time adaptive interventions, demonstrating a positive impact on long-term behavior changes [24,25,28].
3. Accessibility improvements: Chatbots and AI systems provided low-cost, scalable solutions that increased accessibility to PA recommendations, particularly in remote or underserved communities [28].

Discussion

Principal Findings

The findings suggest that LLMs, such as ChatGPT, can effectively generate customized exercise plans, save health care professionals' time, and enhance user engagement through adaptive, real-time feedback. However, it is crucial to emphasize that LLMs serve as a supplementary tool rather than a replacement for human expertise. Their outputs should always be reviewed and validated by qualified professionals, particularly in clinical settings where incorrect ERs could pose potential health risks [22-24,28]. These advantages are particularly beneficial in settings where access to personalized exercise guidance is limited. However, despite their potential, several key challenges and areas for future improvement have been identified.

Comparison With Prior Work

The rapid advancement of LLMs has significantly impacted medical systems, offering enhanced adaptability and precision compared with traditional approaches. In specialized domains such as orthopedics, spinal disorders, and psychotherapy, LLMs demonstrate greater flexibility but still require refinement to meet professional health care standards [11-15].

Unlike previous static, rule-based systems, LLMs have extended their application to complex clinical scenarios such as cardiac rehabilitation and poststroke recovery [24-26]. Their ability to offer dynamic, real-time interactions marks a significant shift. However, they still fall short of professional-level expertise, particularly in aligning with the detailed exercise prescriptions outlined by American College of Sports Medicine guidelines [22,33].

A notable limitation in existing research is the variability in sample size and dataset quality. While some studies used extensive datasets to enhance model training and generalizability, others were constrained by limited sample sizes, which can hinder the robustness of the findings [24,26,34]. This inconsistency underscores the need for standardized, large-scale datasets to better assess and refine LLMs in ERs and PA contexts.

The current landscape of LLMs also features a variety of models, with many studies predominantly relying on ChatGPT [22-24,26,27]. This model shows strong capabilities in generating personalized ERs but remains supplementary to expert input. Comparatively, other models such as Bidirectional Encoder Representations from Transformers–based systems have been explored, offering unique strengths in specific applications [30]. Future research should explore and refine these models to optimize their use in exercise science, tailoring them to address the nuanced needs of this field [30,31].

Furthermore, usability testing remains a critical component in validating LLMs. While expert evaluations have been the primary method in many studies, incorporating real-world user feedback through interaction metrics and engagement analysis offers deeper insights into the practical use of these models. This dual approach—combining expert review with user-centric testing—ensures that LLMs not only meet theoretical standards but also deliver meaningful outcomes in everyday clinical practice [35].

Building on earlier AI applications, the integration of LLMs with wearable technology holds promise for transforming ERs and PA by delivering real-time, personalized insights. However, generative AI in exercise science still requires fine-tuning and specialized data to fully realize its potential. This underscores the ongoing need for high-quality, diverse data sources and

XSL•FO
RenderX

iterative improvements to enhance the reliability and impact of LLM-driven health interventions [34].

LLMs significantly enhance patient engagement and satisfaction by delivering tailored, interactive, and context-aware health interventions. Through natural language understanding, LLMs such as ChatGPT facilitate real-time, adaptive interactions that make ERs and behavior change strategies more relatable and accessible, fostering deeper connections and prolonged participation in fitness routines [32]. Features such as just-in-time adaptive interventions ensure that guidance is provided at critical moments, reinforcing user commitment and fostering a sense of support while allowing users to dynamically adjust goals and promote sustained behavior changes [27]. Personalization is another key driver of satisfaction, as chatbots such as CHARLIE integrate fitness and diet suggestions into daily routines based on user-specific health data, schedules, and preferences, improving adherence and satisfaction [28]. However, sustaining engagement and satisfaction requires addressing challenges such as data accuracy, equitable access, and algorithmic biases. Transparent communication about data collection, robust validation mechanisms, and regulatory frameworks prioritizing inclusivity and fairness are crucial to maximize the potential of LLM-driven health interventions while ensuring scientifically grounded and emotionally supportive recommendations [29,31].

Transparency of LLM Training Data and Fine-Tuning Approaches

One critical yet underexplored aspect of LLM development in ERs and PA is the lack of transparency regarding training data and fine-tuning methodologies. Most reviewed studies did not specify whether LLMs were trained or fine-tuned on exercise- or health-specific datasets, making it difficult to assess their domain relevance and reliability [22,24]. While some studies used general purpose LLMs, their applicability to exercise science remains uncertain due to potential biases and gaps in specialized knowledge [25,30,31].

To enhance technical rigor and reproducibility, future research should focus on documenting training data sources, improving dataset specificity, and incorporating domain-relevant corpora such as clinical guidelines, sports science literature, and patient-reported exercise data. In addition, developing benchmarking frameworks to systematically evaluate LLM-generated ERs will be essential for ensuring accuracy, safety, and adaptability in health care applications. Greater transparency in dataset composition and model fine-tuning will facilitate better comparisons across studies, enabling the optimization of LLMs for evidence-based exercise prescription.

Limitations of the Study

Despite the valuable insights provided by this scoping review, several limitations should be acknowledged. First, the reviewed studies lacked transparency in data formats, training corpora, and methodologies, making it difficult to assess reproducibility and compare the effectiveness of different LLM implementations. In addition, none of the included studies evaluated the accuracy, safety, or long-term impact of LLMs on behavior change, limiting their clinical applicability. Second, small sample sizes and heterogeneous methodologies reduce the generalizability of findings [30]. Many studies focused on feasibility rather than efficacy, highlighting the need for large-scale, multicenter trials and long-term follow-up studies to validate AI-generated ERs [29]. Third, potential publication bias may have skewed the findings, as studies reporting positive outcomes are more likely to be published than those with neutral or negative results [22]. Future reviews should incorporate preprint archives and unpublished datasets for a more balanced assessment.

Finally, a lack of standardized datasets and evaluation criteria hinders direct comparisons between AI models [25]. Future research should focus on developing benchmark frameworks to ensure consistency and reliability in LLM-driven exercise prescription. Addressing these limitations will improve the transparency, safety, and clinical use of AI-assisted ERs .

Future Directions

Real-World Clinical Trials

Future research should prioritize real-world clinical trials to address the current limitations of LLMs in health care, particularly in ERs and PA. Due to the reliance on synthetic data for training, many LLMs lack the real-world data necessary for optimal performance [9-15]. These trials are crucial for collecting high-quality data, enabling better fine-tuning of LLMs and ensuring that their recommendations are accurate and applicable across diverse populations. In ERs and PA, real-world trials can validate the practical effectiveness of LLMs, assess their generalizability, and ensure that their integration into clinical practice is both feasible and scalable, ultimately enhancing personalized health interventions [35] .

Fine-Tuning Existing Models

Currently, no model matches the expertise of exercise science professionals, largely due to inadequate corpus quality and computational limitations [24,32]. The field of exercise science particularly suffers from a lack of standardized data, with many practitioners relying on personal experience or generalized approaches to develop ERs [36]. While the notion that “one set fixed all” is prevalent, it falls short of delivering truly personalized and scientifically grounded exercise guidance. Therefore, the standardization of data formats and the accumulation of a vast array of high-quality data are essential steps for advancing generative AI’s capabilities in exercise science [37-39].

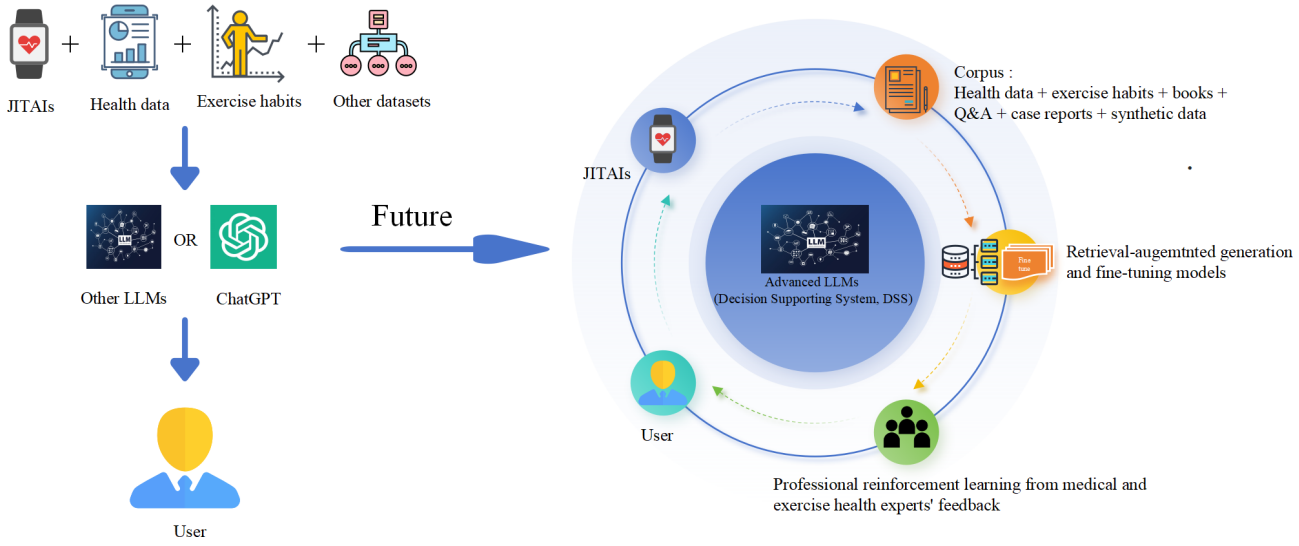
Potential of Retrieval-Augmented Generation

Retrieval-augmented generation (RAG) integrates the real-time retrieval of information with the generative capabilities of LLMs, offering a significant advantage in the domain of ERs and PA [12,28]. This approach ensures that any knowledge gaps in the language model are promptly addressed, reducing the risk of misinformation and enhancing the accuracy of exercise guidance [40]. The effectiveness of RAG is, however, contingent upon the underlying model’s strength, suggesting that fine-tuning a powerful language model in conjunction with RAG could optimize performance [41]. Looking forward, the application of RAG in ERs and PA could extend into broader

XSL•FO
RenderX

health care sectors, potentially revolutionizing personalized medicine and proactive health management by providing data-driven, contextually rich, and adaptive health solutions.

Real-Time Data Collection Via Wearables and Smart Devices: Implementing a Dynamic Feedback Mechanism



The advent of wearable technology and smart devices has opened new horizons for monitoring health and PA in real time [21,22,34]. These devices, ranging from smartwatches and fitness bands to specialized sensors, continuously track physiological and PA data, including heart rate, steps, calories burned, sleep patterns, and advanced metrics such as heart rate variability and oxygen saturation. Their integration into health care enables real-world, individualized health monitoring, offering valuable insights for ERs interventions [22,25,42].

A key feature of this future direction is the establishment of a dynamic feedback loop between users and AI systems . As users engage in prescribed exercises, performance and physiological data are continuously fed into the AI model [43]. This real-time input allows LLMs to adjust recommendations dynamically, enhancing adherence and optimizing exercise effectiveness [24,30].

However, several technical challenges remain. Data accuracy and reliability vary due to sensor inconsistencies, calibration differences, and environmental influences [28]. Standardized validation protocols and AI-driven error correction models are needed to enhance measurement consistency. In addition, device compatibility and interoperability pose integration hurdles, as wearables operate with different data formats and application programing interfaces [32]. Adopting universal data standards, such as Fast Healthcare Interoperability Resources and Open mHealth, could streamline integration across platforms.

Data privacy and security are also critical concerns, given the continuous transmission of personal health information. Compliance with health insurance portability and accountability act, general data protection regulation, and other regulatory frameworks is essential to prevent data breaches and unauthorized access [26]. End-to-end encryption, federated learning, and decentralized storage solutions can enhance security while maintaining user privacy. Addressing these challenges will be key to ensuring the safe and effective deployment of LLMs in personalized exercise interventions (Figure 3).

Figure 3. The current and future applications of LLMs in exercise recommendations. Currently, health data from JITAIs, wearable devices, exercise habits, and various datasets are processed through LLMs such as ChatGPT to provide recommendations to users. Looking forward, advanced LLMs integrated within a Decision Support System (DSS) will use retrieval-augmented generation and fine-tuning techniques based on extensive corpora including health data, exercise habits, literature, Q&A content, case reports, and synthetic data. Enhanced by real-time data collection via wearable devices and continuous professional reinforcement learning from medical and exercise health experts' feedback, this system aims to support personalized recommendations while addressing critical issues such as clinical validation, integration into health care workflows, personal privacy, artificial intelligence bias, and ethical and regulatory considerations. JITAIs: Just-in-Time Adaptive Interventions; LLMs: large language models; Q&A: question and answer.

Expanding Clinical Validation of LLMs

Despite the growing interest in LLM-driven ERs, real-world clinical validation remains limited, with most studies focusing on feasibility rather than long-term efficacy and safety [22]. To bridge this gap, emerging trials are exploring LLM-assisted exercise coaching in rehabilitation [25] and AI-driven personalized exercise plans for metabolic disorders [28].

However, large-scale, multicenter randomized controlled trials are needed to assess their impact on exercise adherence, rehabilitation outcomes, and chronic disease management across diverse populations. Future research should prioritize standardized evaluation metrics, regulatory oversight, and expert-in-the-loop models to ensure safe, effective, and evidence-based integration of LLMs into health care practice.

Integrating LLMs Into Health Care Workflows

Effective integration of LLMs into clinical practice requires interoperability with electronic health records (EHRs) and clinician training [35]. Standardizing LLM-EHR interactions through protocols such as Fast Healthcare Interoperability Resources and HL7 can enable real-time data exchange and personalized exercise prescription delivery [23]. In addition, structured clinician training programs are essential to enhance AI literacy, ensuring that health care providers can interpret,

XSL•FO
RenderX

validate, and oversee LLM-generated recommendations before clinical application [43]. Implementing expert-in-the-loop frameworks, where clinicians supervise AI outputs, will enhance trust, safety, and adoption in real-world health care settings.

Personal Privacy, AI Bias, and Ethical and Regulatory Considerations

Ensuring robust data privacy and security measures is critical in the deployment of LLMs in health care, as secure data management is essential to protect sensitive health information and safeguard users' personal privacy [28,32]. Maintaining patient confidentiality, particularly when using EHRs in precision medicine, remains a persistent challenge that requires systematic attention [25,26]. Addressing AI bias is equally crucial to prevent inequities in rehabilitation plans and ensure fair and inclusive recommendations across diverse demographic groups, especially in the context of ERs and PA. For example, general purpose LLMs may produce exercise suggestions that are overly strenuous for older adults or unsuitable for individuals with chronic conditions, thereby increasing the risk of injury or adverse health outcomes [25,28,30]. Strategies to mitigate bias include implementing advanced detection algorithms, establishing fairness metrics tailored to the exercise and health domains, and using diverse and representative datasets that encompass a wide range of ages, genders, races, and socioeconomic backgrounds. Moreover, fine-tuning LLMs with domain-specific data and incorporating expert insights from exercise physiologists can further tailor recommendations to the unique needs of these populations [22]. Incorporating feedback loops from underrepresented populations further refines model outputs, enhancing the inclusivity and effectiveness of LLM-driven interventions [16,17].

Transparency and ethical accountability play a foundational role in building user trust and fostering the successful adoption of LLMs in health care. Clear communication about data usage practices, system limitations, and decision-making processes is imperative to enhance user confidence, as a lack of transparency may discourage full engagement with AI-driven tools, ultimately reducing their effectiveness [28]. Furthermore, LLMs face significant ethical challenges, including the potential to provide inaccurate or unsafe recommendations, which could result in adverse health outcomes. Integrating expert oversight and providing explicit disclaimers about the limitations of LLM-generated advice are essential safeguards to mitigate such risks [27]. Finally, compliance with evolving regulatory standards is imperative. LLM-based systems must adhere to rigorous requirements for accuracy, reliability, and accountability to align with medical device regulations and ethical norms, ensuring their safe and effective integration into health care practices [29]. This holistic approach to privacy, bias mitigation, transparency, and regulatory compliance will not only enhance the fairness and accuracy of LLM-driven health interventions but also establish a foundation of trust necessary for their widespread acceptance and long-term success.

Conclusions

While LLMs offer promising support in creating exercise plans, they are not yet on par with expert professionals. Their role should be viewed as an adjunct to human expertise, assisting but not replacing health care and fitness professionals. Ensuring expert validation is essential to mitigate risks and optimize patient safety. Future research should prioritize pilot studies to assess the feasibility of LLM-generated ERs and clinician training programs to enhance AI literacy and integration.

Advancing LLM adoption requires large-scale trials, standardized evaluation frameworks, and regulatory oversight to improve transparency and mitigate bias. Leveraging real-time data from wearables can further refine recommendations. With these advancements, LLMs can evolve into a valuable decision support tool, enhancing accessibility and personalization in exercise science while maintaining expert oversight.

Acknowledgments

The authors would like to express their gratitude to the AI tool, ChatGPT-4 developed by OpenAI, for its assistance in refining and structuring the content during the writing process of this paper. The tool provided invaluable support in enhancing the clarity and coherence of the manuscript. This study was supported by National Intelligent Social Governance Experimental Base Project (grant 350201).

Data Availability

This study is a scoping review and does not involve the generation or analysis of new data. All data used in this review were extracted from publicly available papers indexed in Web of Science, PubMed, IEEE, and arXiv. No new datasets were created or analyzed in the course of this research. The studies included in this review can be accessed through their respective journals and databases.

Authors' Contributions

XL participated in conceptualization, literature search, data curation, and writing—original draft; CH participated in conceptualization, literature search, and writing—original draft; QG participated in conceptualization, writing—original draft, and methodology; JC and YL contributed to review and screening of literature, visualization (figures and tables), and writing—review and editing; SH contributed to review and screening of literature and writing—review and editing; YC contributed to visualization (figures and tables) and writing—review and editing; ZS contributed to writing—review and editing—and supervision; and XW and KP contributed to rereview and editing and supervision.

Abstract

Background: Leptospirosis, a zoonotic disease caused by *Leptospira* bacteria, continues to pose significant public health risks, particularly in tropical and subtropical regions.

Objective: This systematic review aimed to evaluate the application of machine learning (ML) and deep learning (DL) techniques in predicting and diagnosing leptospirosis, focusing on the most used algorithms, validation methods, data types, and performance metrics.

Methods: Using Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines, Checklist for Critical Appraisal and Data Extraction for Systematic Reviews of Prediction Modelling Studies (CHARMS), and Prediction model Risk of Bias Assessment Tool (PROBAST) tools, we conducted a comprehensive review of studies applying ML and DL models for leptospirosis detection and prediction, examining algorithm performance, data sources, and validation approaches.

Results: Out of a total of 374 articles screened, 17 studies were included in the qualitative synthesis, representing approximately 4.5% of the initial pool. The review identified frequent use of algorithms such as support vector machines, artificial neural networks, decision trees, and convolutional neural networks (CNNs). Among the included studies, 88% (15/17) used traditional ML methods, and 24% (4/17) used DL techniques. Several models demonstrated high predictive performance, with reported accuracy rates ranging from 80% to 98%, notably with the U-Net CNN achieving 98.02% accuracy. However, public datasets were underused, with only 35% (6/17) of studies incorporating publicly available data sources; the majority (65%, 11/17) relied primarily on private datasets from hospitals, clinical records, or regional surveillance systems.

Conclusions: ML and DL techniques demonstrate potential for improving leptospirosis prediction and diagnosis, but future research should focus on using larger, more diverse datasets, adopting transfer learning strategies, and integrating advanced ensemble and validation techniques to strengthen model accuracy and generalization.

Introduction

Overview of Leptospirosis and Its Diagnosis

Leptospirosis, a zoonotic disease caused by pathogenic *Leptospira* bacteria, is a global public health concern, with an estimated 1.03 million cases and approximately 58,900 deaths annually [1]. The disease is particularly prevalent in tropical and subtropical regions, where environmental factors such as heavy rainfall, poor sanitation, and frequent flooding facilitate bacterial survival and transmission. Although less common, leptospirosis also occurs in temperate regions, including the United States, especially in areas prone to flooding or with high populations of animal carriers like rodents and livestock [1].

In the United States, the Centers for Disease Control and Prevention (CDC) reports approximately 100 - 150 cases annually, with the majority occurring in Puerto Rico and Hawaii due to their specific environmental conditions. Isolated cases in areas like New York City and California highlight the mobility of the disease and its potential for travel-related transmission [1].

Transmission primarily occurs through direct contact with the urine or reproductive fluids of infected animals or exposure to

XSL•FO
RenderX

contaminated water and soil, especially following periods of heavy rainfall [2]. High-risk activities include wading, swimming, or boating in potentially contaminated freshwater. Effective control measures include improving sanitation, controlling rodent populations, and educating at-risk populations. The disease manifests with a broad range of clinical symptoms, from mild flu-like symptoms to severe complications such as Weil's disease, characterized by jaundice, renal failure, pulmonary hemorrhage, and multi-organ dysfunction, which can lead to death if not treated promptly [1].

The diagnosis of leptospirosis is challenging due to the nonspecific nature of its early symptoms, which often overlap with other febrile illnesses. Traditional diagnostic methods include the microscopic agglutination test (MAT), considered the gold standard, and polymerase chain reaction (PCR). MAT is labor-intensive and requires specialized laboratory capabilities, making it less accessible in many endemic regions [2]. PCR, while offering early detection by identifying *Leptospira* DNA in blood or urine, also requires advanced laboratory infrastructure. Rapid diagnostic tests (RDTs) provide quicker results, but their sensitivity and specificity can vary depending on the *Leptospilora* serovars and disease stages, limiting their effectiveness in some settings [2,3].

Machine Learning and Deep Learning in Disease Detection

Machine learning (ML) and deep learning (DL) have emerged as powerful tools in the field of disease detection and management. ML involves training computers to apply past experiences to solve new problems, leveraging algorithms that enable the machine to identify patterns, make predictions, and produce insightful judgments based on data. The increasing availability of computational power and data storage has significantly boosted the application of ML across various fields, including public health. In the context of infectious diseases like leptospirosis, ML can analyze large datasets, including clinical and laboratory data, to identify patterns and relationships that might not be apparent through traditional statistical methods [4-6].

DL, a subset of ML, further enhances these capabilities by using neural networks with multiple layers to automatically extract, analyze, and understand useful information from raw data. Unlike traditional ML techniques that rely on handcrafted features, DL models are capable of automatic feature engineering, which significantly enhances classification performance. DL techniques, driven by neural networks, are known for their accuracy and performance, particularly in complex tasks such as image recognition and analysis [6-8]. For example, convolutional neural networks (CNNs) have been successfully applied to medical imaging, enabling the precise identification and classification of pathogens in microscopy images [9], which is crucial for diseases like leptospirosis.

The application of ML and DL in leptospirosis diagnosis represents a significant advancement over traditional methods. ML algorithms can analyze clinical and laboratory data, including patient symptoms, demographic information, and test results, to predict the likelihood of leptospirosis. This capability is particularly valuable in settings where access to advanced diagnostics is limited, as it allows for earlier and more accurate detection, potentially reducing the time to diagnosis and improving patient outcomes [10].

DL models, particularly CNNs, have shown great promise in analyzing blood and urine samples, medical imaging, and environmental data to predict the presence of *Leptospira* or the likelihood of an outbreak. These models can distinguish *Leptospira* bacteria in microscopy images with high accuracy, reducing the need for skilled microbiologists and improving diagnostic accessibility in low-resource settings [4].

One of the most significant advantages of using ML and DL in leptospirosis diagnosis is their ability to integrate diverse data types—such as clinical, laboratory, and environmental data—into comprehensive predictive models. These models can be used for individual patient diagnosis and public health surveillance, enabling more targeted and timely interventions. For example, predictive models that incorporate climatic and environmental factors, such as rainfall patterns and flooding data, can help identify regions at higher risk for leptospirosis outbreaks, allowing for proactive disease control measures [10].

Despite the significant potential of ML and DL to revolutionize the diagnosis and management of leptospirosis, comprehensive reviews focusing specifically on their application in this area are scarce. Most existing reviews have primarily concentrated on more prevalent conditions such as tuberculosis, malaria, and COVID-19, with minimal attention given to zoonotic diseases like leptospirosis [4,5]. Furthermore, there is a recognized gap in the literature concerning the application of advanced AI techniques in the context of neglected tropical diseases, such as leptospirosis, where the potential for these technologies to improve diagnostic accuracy remains underexplored [6,11]. This gap underscores the need for a focused review that synthesizes current research, identifies the most effective ML and DL models, and evaluates their impact on public health outcomes related to leptospirosis.

The aim of this systematic review is to comprehensively evaluate the application of ML and DL techniques in the prediction and diagnosis of leptospirosis. This review will address the following key research questions:

1. Which ML and DL algorithms are most frequently used in leptospirosis prediction and diagnosis, and how well do they perform?
2. What validation methods are most used in the evaluation of ML and DL models for leptospirosis? and how reliable are these methods?
3. What types of data are most used in ML and DL models for leptospirosis? How does the type of data influence the performance of these models?
4. What are the main challenges and limitations identified in the research studies regarding ML and DL applications in leptospirosis prediction and diagnosis?

XSL•FO
RenderX

Methods

Study Design

We conducted a systematic review following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) checklist [12] (Checklist 1). The Checklist for Critical Appraisal and Data Extraction for Systematic Reviews of Prediction Modelling Studies (CHARMS) was used to frame this review's objectives [13].

Search Strategy

PubMed, IEEE, ACM, and Web of Science databases were searched for articles published from inception till May 29, 2024. Hand-searching of references within included articles was conducted to shortlist other potential articles. Our search strategy used a combination of subject terms related to "machine learning" and "Leptospirosis" (see Multimedia Appendix 1).

Eligibility Criteria

We included full-text English language articles that developed or validated diagnostic or predictive ML models for human leptospirosis. Our review focused specifically on ML and DL methods, including logistic regression, Bayesian learning, and generalized additive models when these were implemented within an ML or DL framework [14].

Several categories of studies were excluded. First, we omitted case reports, case series, letters, corrigenda, editorial commentaries, literature reviews, and meta-analyses. Second, we excluded purely applied statistical methods that were not integrated with ML or DL frameworks, including traditional statistical analyses that did not incorporate ML optimization techniques. Third, non-artificial intelligence methods as well as general artificial intelligence (AI) approaches that could not be classified as either ML or DL (such as rule-based expert systems without learning components or symbolic AI methods) were excluded [14].

The distinction between included and excluded methods was based on whether the approach involved automated learning from data. For instance, while standard logistic regression was excluded, logistic regression implemented with ML techniques like automated feature selection or hyperparameter tuning was included. Similarly, simple threshold-based diagnostic rules were excluded unless they were derived through ML processes. This approach ensured our review focused specifically on applications of ML and DL technologies in leptospirosis diagnosis and prediction.

In this review, diagnostic ML models refer to models that predict the disease status of an individual, while predictive models forecast the probability of future occurrence of the disease in an individual.

Study Selection

A total of 3 independent reviewers (SS, AJ, and BR) conducted the initial search across 4 databases using predefined search terms within the title and abstract, strictly following the inclusion and exclusion criteria. Zotero bibliography software was used to manage the search results by tracking reasons for inclusion and exclusion, grouping records, importing PDFs, and exporting data to Microsoft Excel for extraction. The interrater agreement between the coauthors was evaluated using Cohen's kappa (κ>0.80) [15,16], ensuring a high level of consistency across the reviewers.

To enhance the screening process, we employed ChatGPT-4o (June 2024 version) as a fourth reviewer. This advanced large language model (LLM) was specifically selected for its proven capabilities in biomedical text analysis (OpenAI) and superior handling of technical medical terminology compared to previous versions. We opted to use only this single model to maintain consistency in evaluation criteria and avoid potential variability from multiple LLMs. During implementation, abstracts were systematically input to ChatGPT-4o with standardized prompts mirroring our inclusion and exclusion criteria, and all outputs were automatically logged for verification.

While ChatGPT-4o provided valuable preliminary classifications (achieving 88% initial alignment with human reviewers in our pilot test), we implemented a rigorous 3-stage human verification protocol: (1) initial matching of AI recommendations with human decisions, (2) consensus discussion for discrepancies (κ<0.80), and (3) final unanimous approval. For example, the model initially recommended including 12 statistical modeling studies that were properly excluded after human review. This AI-assisted process reduced initial screening time by 30% while maintaining 100% alignment with final human decisions through our verification protocol, which followed PRISMA-AI guidelines [12] to mitigate potential AI limitations.

We emphasize that ChatGPT-4o served strictly in an advisory capacity, and no studies were included solely based on its recommendation. This approach aligns with emerging best practices for LLM-assisted systematic reviews [17,18], with complete verification records available in our supplementary materials (Multimedia Appendix 2).

Quality Assessment

The articles selected for inclusion were then subjected to a quality assessment using the Prediction model Risk of Bias Assessment Tool (PROBAST) tool [13], which categorizes bias as low, medium, or high (see Multimedia Appendix 3). All authors assessed the quality of their respective parts, starting with a pilot of 5 articles to ensure consistency. The PROBAST tool evaluates risk of bias based on 4 segments—participants, predictors, outcome, and analysis. Each segment's risk of bias was rated as high, medium, low, or unclear. If any domain suggested a high risk of bias, the overall risk of bias for that study was considered high. These studies were not excluded but were analyzed to understand their limitations and impact on the overall findings. The assessment was conducted independently by all authors, ensuring a thorough evaluation process.

Data Extraction

For the extraction process, a standardized form was used to collect data relevant to the review's objectives. This form was adapted from the CHARMS [15] and the Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis

XSL•FO
RenderX

or Diagnosis (TRIPOD) guidelines [19]. The extracted information included publication type, publication year, author, title, country of research, source of data, type of data (public or private), overall number of samples, and data collection methods (see Multimedia Appendix 4).

Additional details were gathered on the ML and DL algorithms used, including whether the models were pretrained or developed from scratch, as well as the use of transfer learning, data augmentation, validation methods, and evaluation metrics. The strength of leptospirosis predictions was documented using performance metrics. Tasks were categorized into segmentation, classification, and object detection, noting the type of classification and any limitations.

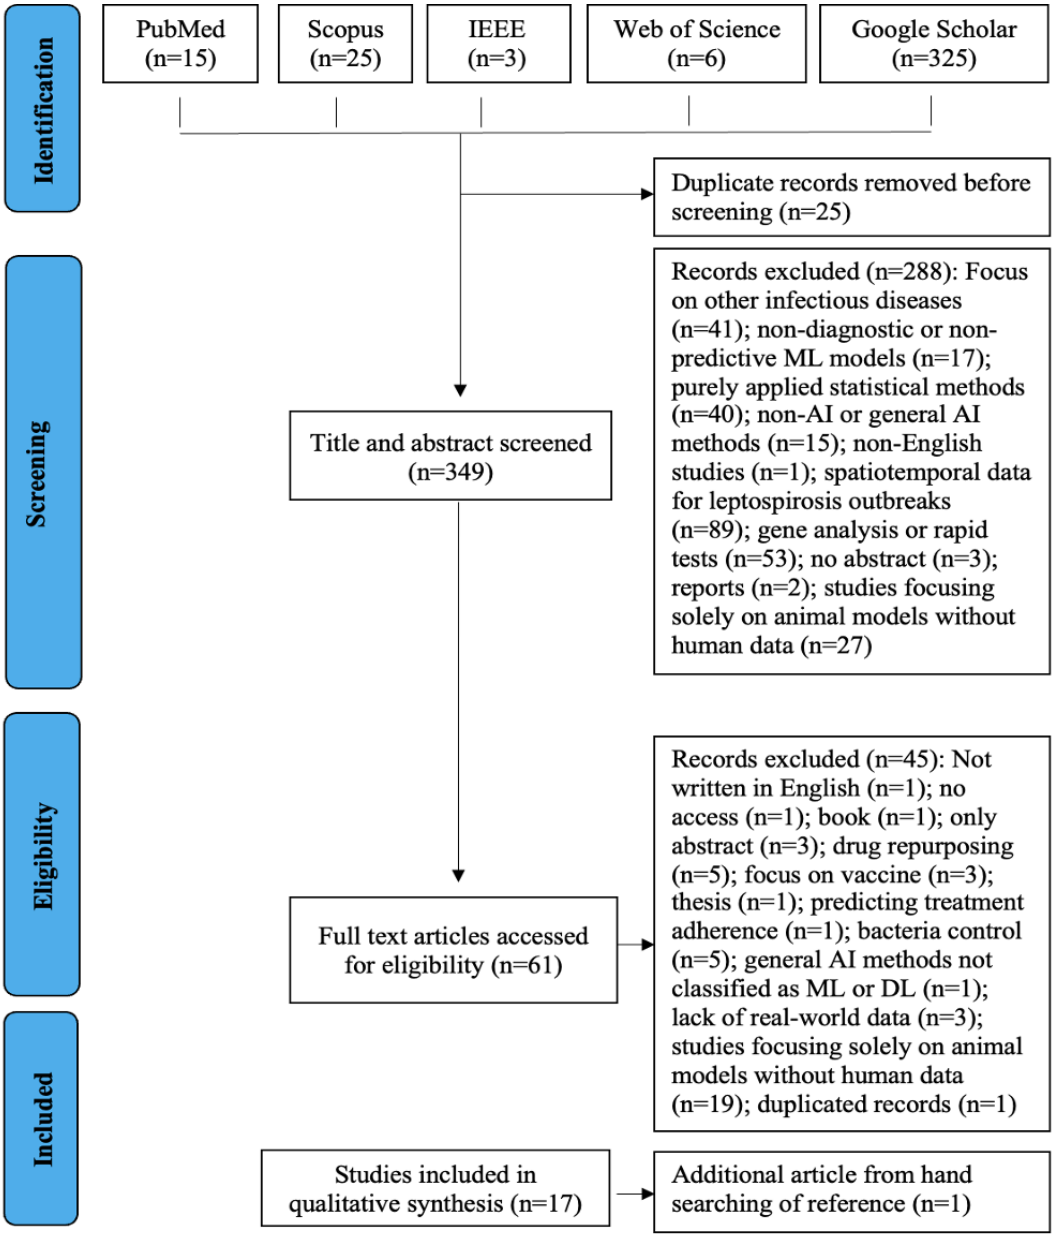
To ensure consistency, reviewers conducted a pilot phase where they independently extracted data from the first 5 articles and compared results, achieving a high agreement (κ=0.98). Afterward, all 17 articles were reviewed, and discrepancies were resolved through discussion. The studies were then rigorously categorized before moving to theme formation. One author (SS) defined the themes, which were reviewed and adjusted by the other authors (AJ and BR) to ensure comprehensive categorization.

Outcomes Assessed

The primary outcomes assessed in this review include the diagnostic and predictive performance of various ML and DL methods for leptospirosis detection, focusing on metrics like accuracy, area under the curve (AUC), sensitivity, and specificity. It also evaluates the applicability and generalizability of these models in health care settings, emphasizing the integration of advanced neural network architectures, transfer learning, and data augmentation to enhance performance.

Data Analysis

We grouped the collected studies into summary tables based on the type of ML and DL models used for leptospirosis detection. R (version 4.3.2; R Foundation for Statistical Computing) was used to perform both descriptive statistical analyses and create visualizations.



Results

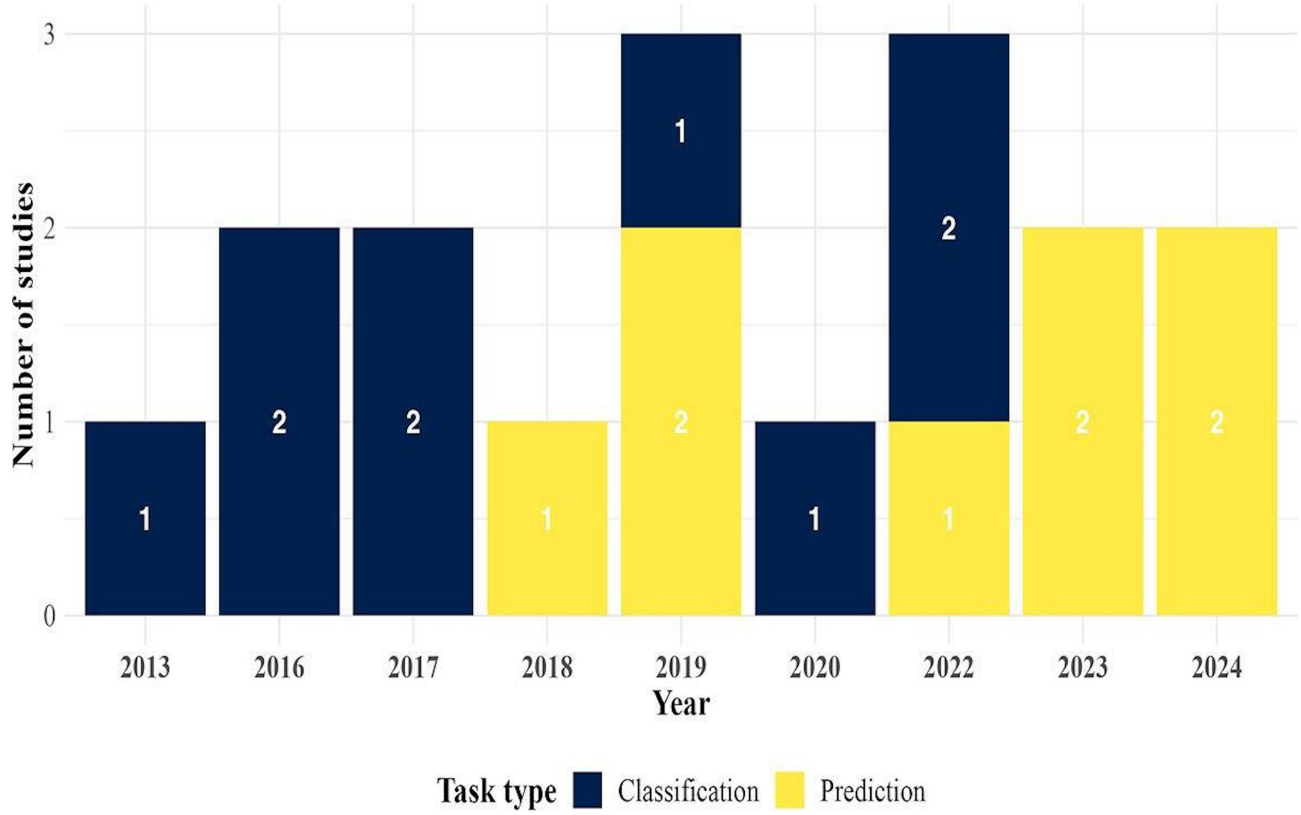
Search and Selection Results

Figure 1 illustrates the process of identifying relevant literature. A comprehensive search across 5 databases yielded a total of 374 articles. After removing 25 duplicate records, 349 unique articles were screened based on their titles and abstracts. Following this initial screening, 61 articles were selected for full-text review. Of these, 45 were excluded for various reasons, including not meeting inclusion criteria or insufficient data for analysis. Ultimately, 16 studies were included in the review, with 1 additional study identified through hand-searching reference lists, bringing the total to 17 studies included in the qualitative synthesis.

XSL•FO
RenderX

Figure 1. Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram illustrating the search and selection process used to identify relevant studies. AI: artificial intelligence; ML: machine learning; DL: deep learning.

Study Description



In this systematic review, we examined 17 studies (n=17) published between 2012 and 2024 that used ML and DL techniques for the prediction and diagnosis of leptospirosis (see Figure 2). Most studies were published in 2019 (n=3, 18%), 2022 (n=3, 18%), and 2023 (n=3, 18%). Brazil was the most common country of research, contributing 4 studies (24%), followed by New Caledonia with 3 studies (18%). Regarding data sources, 6 studies (35%) used health records, 6 studies (35%) used environmental data, and 5 studies (29%) used epidemiological data.

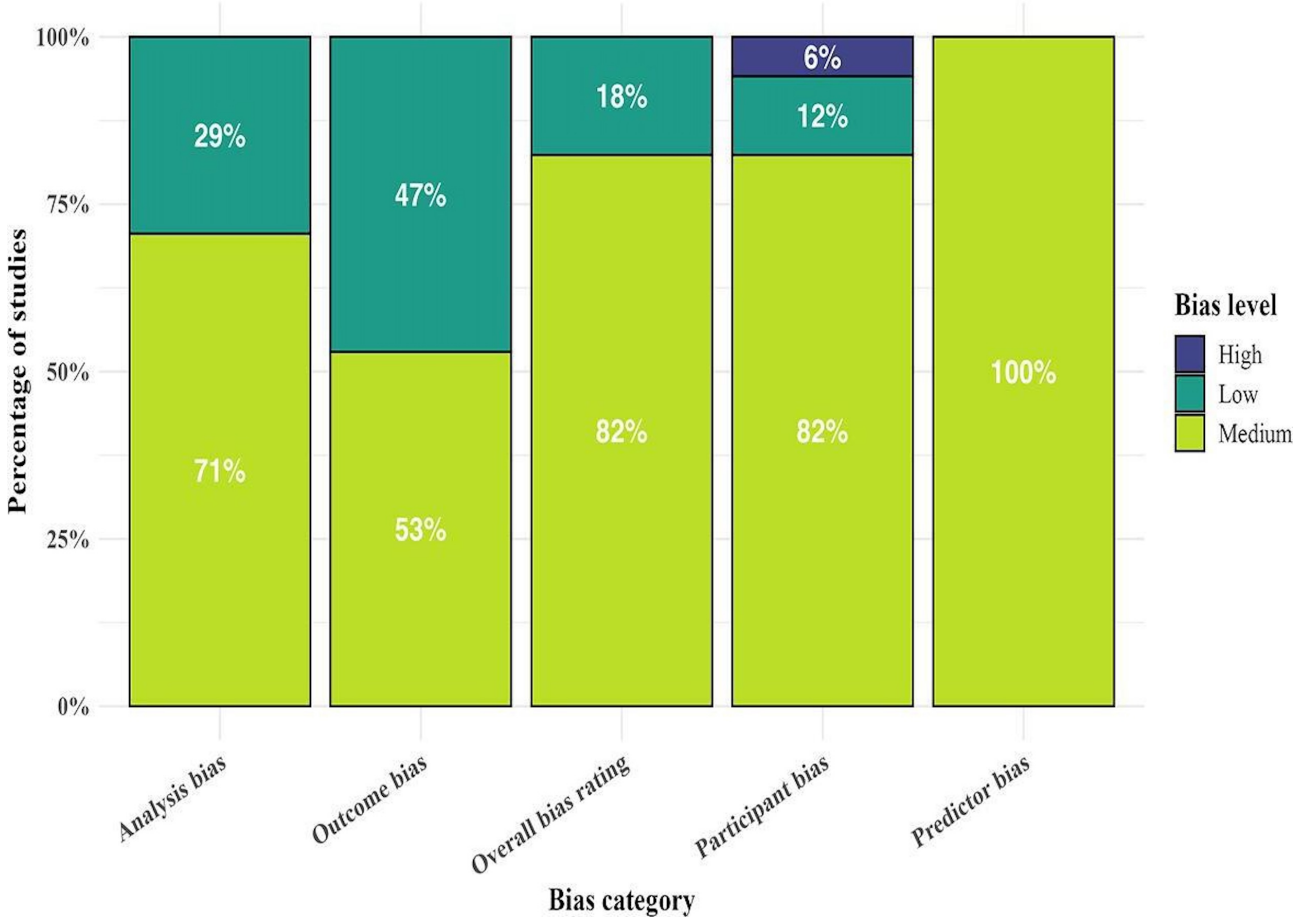
Most studies (11/17, 65%) focused on predictive modeling, while 6/17 studies (35%) concentrated on diagnosis. ML algorithms were overwhelmingly preferred, with 15/17 studies (88%) using techniques such as SVM, decision tree (DT), and random forests. DL algorithms, including CNN and multilayer perceptrons (MLPs), were used in 4/17 studies (24%), and only 1/17 study (6%) combined both ML and DL methods. All studies developed models from scratch without using transfer learning, and only 1/17 study (6%) reported the application of data augmentation techniques.

Regarding model validation, cross-validation methods were most frequently used in 11/17 studies (65%), while holdout validation methods, such as train and test splits, were used in 6/17 studies (35%).

XSL•FO
RenderX

Figure 2. Distribution of studies on machine learning and deep learning applications for leptospirosis diagnosis and prediction by year and task type.

Assessment of Risk of Bias in Machine Learning Models



In assessing the risk of bias across the included 17 studies, most were categorized as having a medium risk across key domains (Figure 3). A total of 14 studies (82%) were rated as having a medium risk of bias related to participant selection, primarily due to the selection of specific regions or populations that may not fully represent broader leptospirosis cases. Examples include studies by [10,20-32]. In addition, 2 studies (12%) [33,34] were rated as low risk, while 1 study (6%) [35] was rated as high risk due to narrower participant selection.

Regarding predictors, 16 studies (94%) demonstrated a medium risk of bias, often because they relied heavily on environmental or clinical data without fully accounting for confounding variables. Only 1 study (6%) [34] was rated as low risk in this domain. For outcome bias, 13 studies (76%) [10,20-27,29,30,34,35] were assessed as low risk, with clear and consistent definitions applied across participants. A total of 4 studies (24%) [28,31-33] exhibited medium risk, mainly due to subjective outcome determinations or a lack of standardized measures.

In the analysis domain, 13 studies (76%) [10,22-33] demonstrated medium risk due to concerns about validation techniques, handling of missing data, and small sample sizes, while 4 studies (24%) [20,21,34,35] were rated as low risk, reflecting stronger analytical methodologies.

XSL•FO
RenderX

Figure 3. Distribution of risk of bias across domains in machine learning and deep learning studies for leptospirosis.

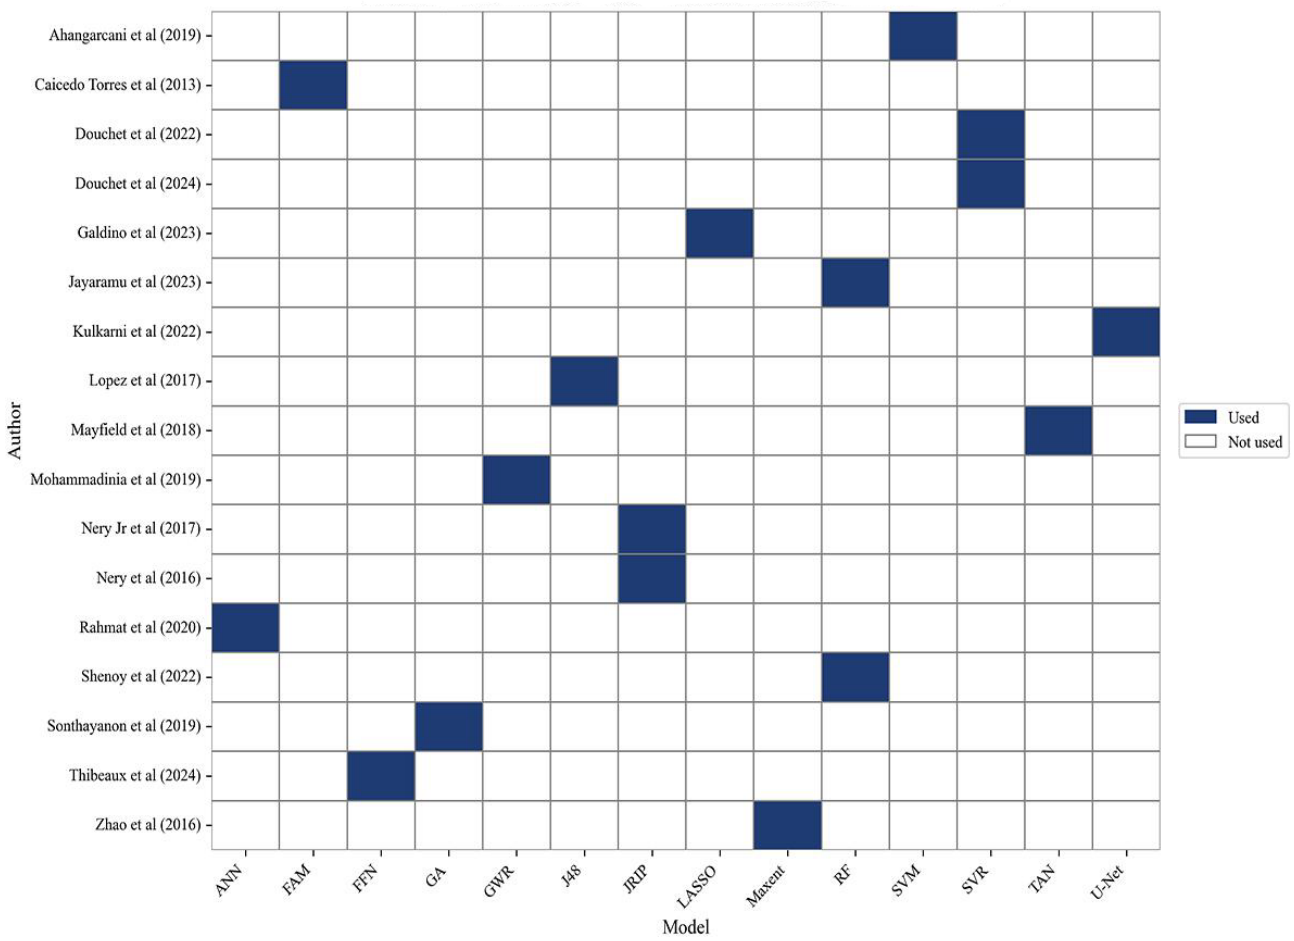
Frequently Used ML and DL Algorithms for Leptospirosis Prediction and Diagnosis

This systematic review considered all ML and DL techniques used in the included studies and examined their applications in either leptospirosis prediction or diagnosis (classification). Figure 4 illustrates the distribution of classifiers across the studies, highlighting the diversity of approaches and the frequency of use of certain models.

For prediction tasks, the most commonly used ML technique was support vector regression (SVR), applied in 2 studies [32,33]. In addition to SVR, several other ML techniques were prominently featured. These included the naïve networks and TAN (tree augmented naive) networks used by Mayfield et al [24] for predictive risk mapping, and the random forest classifier and M1 mixed model used by Jayaramu et al [30] for predictive risk modeling.

Models like LeptoScore and QuickLepto, applied by Galdino et al [10], further illustrate the diversity of approaches taken in predictive modeling. SVM and MLP used in predictive risk modeling by Ahangarcani et al [26], while Mohammadinia et al [27] applied geographically weighted regression, generalized linear models, artificial neural networks (ANNs), and SVM for similar tasks. In addition, feedforward neural networks were used by [31] in prediction tasks, demonstrating the growing role of neural network models in this domain.

For diagnosis (classification) tasks, ANNs were widely used, appearing in studies by [20,28]. FuzzyARTMAP and ARTMAP-IC, both variants of ANN, were also used by [20] to achieve classification. In addition, Bayesian classifiers such as Naïve Bayes were applied by [21,29], further showcasing the diversity of ML techniques in classification tasks.



CNNs were another frequently used DL model for classification. Specifically, U-Net, a variant of CNN, was used by [34] and achieved an impressive accuracy of 98%. Other classifiers, such as k-nearest neighbors (KNNs), DTs (J48), and random forests, were used in multiple studies, with [23,29] demonstrating their efficacy in disease classification.

Performance evaluations showed that many studies combined multiple classifiers. For example [29], applied naïve Bayes, KNN, MLP, J48 decision tree, random forest, multinomial logistic regression, and Adaboost within the same study, with random forest achieving the highest performance at 87% accuracy and 91% sensitivity.

Hybrid approaches combining ML and DL were also present, such as the use of a genetic algorithm combined with both ML and DL techniques in [25], which attained an accuracy of 99%.

RenderX

Figure 4. Heatmap of classifier usage across included studies [10,20-35]. ANN: artificial neural network; DL: deep learning; FAM: fuzzy adaptive resonance theory mapping; FFN: feed forward network; GA: genetic algorithm; GWR: geographically weighted regression; J48: J48 decision tree; JRIP: repeated incremental pruning to produce error reduction; LASSO: least absolute shrinkage and selection operator regression; Maxent: maximum entropy model; ML: machine learning; RF: random forest; SVM: support vector machine; SVR: support vector regression; TAN: tree augmented naïve network; U-Net: U-Net convolutional neural network.

Upon comparing prediction and diagnosis (classification) tasks, it becomes evident that ML models dominated predictive risk mapping studies, while DL models, particularly U-Net, were more frequently used in classification tasks related to disease detection. For risk modeling, techniques like decision trees (J48) and random forest classifiers were commonly applied, with high specificity rates achieved in studies such as those by [21,30].

Interestingly, 50% of the studies (n=8) used more than one algorithm to assess performance, highlighting the importance of comparative evaluations in the field. Supervised-learning algorithms were predominant throughout the studies, with no mention of unsupervised-learning methods, such as K-means, or reinforcement-learning algorithms.

In summary, the most frequent algorithms in prediction tasks were SVR and random forest, while in diagnosis, ANN and U-Net stood out as the most frequently used. Across both types of tasks, the performance metrics indicated high accuracy and sensitivity, showcasing the reliability of ML and DL techniques in leptospirosis research.

Algorithm Performance Metrics

Performance assessment is a crucial process in evaluating ML and DL models. Various metrics are used to measure model performance, including accuracy, sensitivity, specificity, precision, F_1-score, AUC, mean squared error (MSE), *R*-squared (R^2), mean absolute error (MAE), and root mean squared error (RMSE). These metrics are typically evaluated using hidden or unseen examples to assess model generalizability. In the included studies, accuracy was the most frequently reported metric, followed by sensitivity, precision, specificity, and F_1-score. For prediction tasks, MSE, MAE, RMSE, and R^2 were used to assess regression performance.

Tables 1 and 2 demonstrates the widespread use of accuracy rates across various models. The studies examined used accuracy as the primary indicator of performance, although other metrics such as sensitivity and specificity were also highlighted. For instance, the performance of the ANN in the Seremban City dataset reached 80% accuracy, 83% sensitivity, and 75% specificity, while achieving an AUC of 87%. Models such as the Fuzzy ARTMAP applied to other datasets showed lower performance, with accuracy ranging between 60% and 80%, highlighting the variability in effectiveness across different methods.

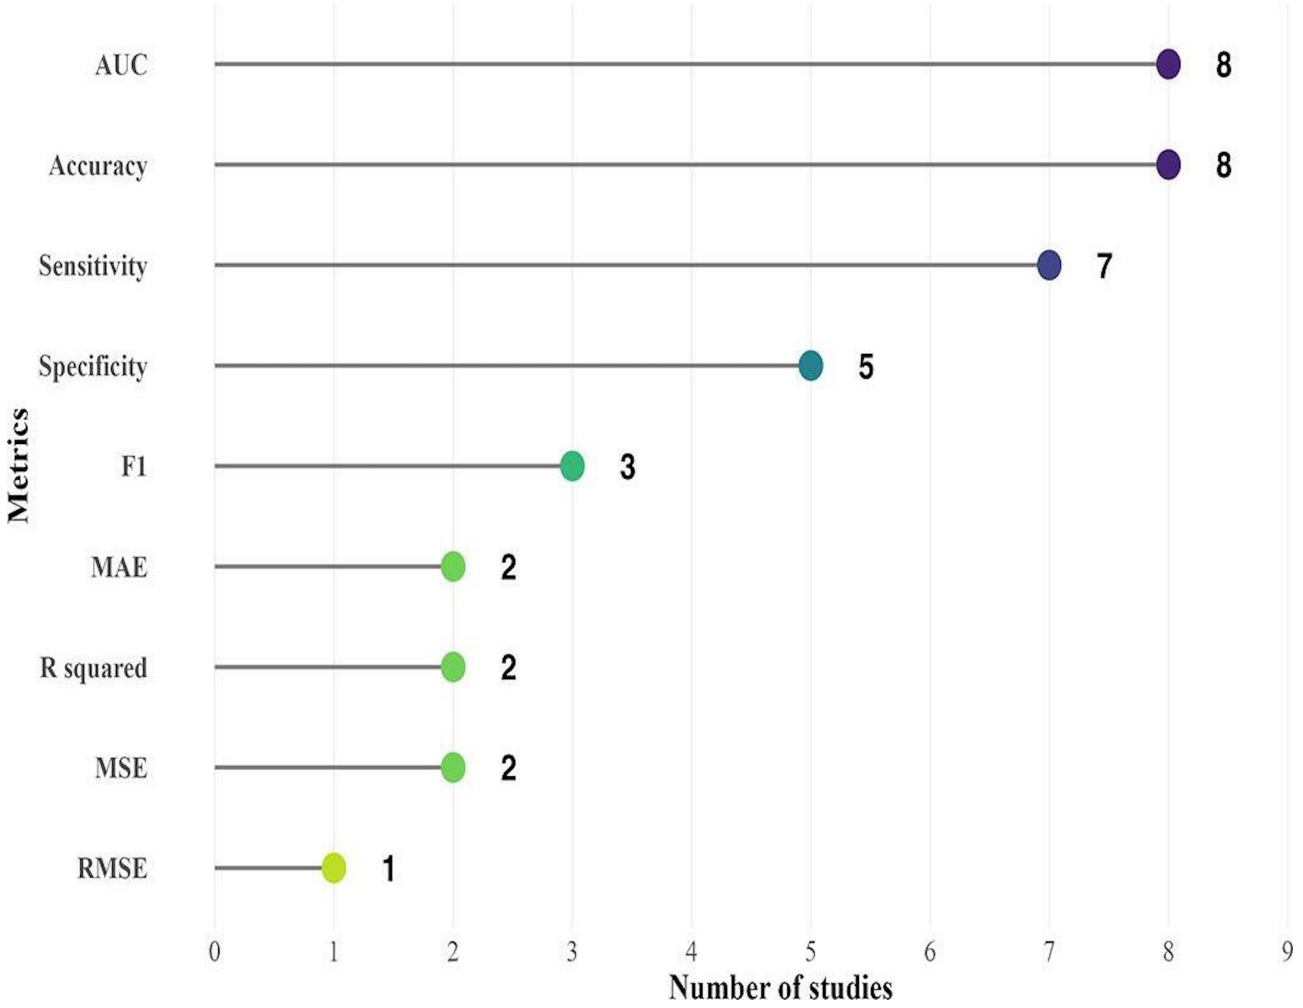
[j]SVM: support vector machine.

[k]GWR: geographically weighted regression.

[l]FFN: feed forward network.

However, as with all model comparisons, it is not possible to directly compare the efficiency of models trained and evaluated on dissimilar datasets. To provide a meaningful evaluation, studies that implemented multiple machine learning methods on the same datasets were carefully selected for comparison. This allows for an accurate ranking of the algorithms based on their mean scores for accuracy, sensitivity, specificity, F_1-score, and other metrics.



In several cases, regression models like SVR were assessed using MSE and R^2 values to gauge prediction performance. For instance, the SVR model in the Reunion Island dataset showed an MAE of 0.75 and an RMSE of 0.44, while other datasets revealed higher error rates, reflecting the challenges in prediction tasks [32].

The study also reveals that deep learning models, particularly those employing architectures like U-Net and CNN, achieved outstanding accuracy rates, with U-Net recording an accuracy of 98% [34]. Random forest models also performed consistently well, particularly in classification tasks, achieving high sensitivity and specificity.

Figure 5 shows the number of studies that reported various performance metrics, highlighting that accuracy and AUC were the most frequently used measures across the reviewed articles. This pattern reflects the widespread reliance on these metrics to evaluate classification performance in leptospirosis-related models. For instance, in one of the best-performing models, a genetic algorithm achieved an accuracy rate of 99%, significantly outperforming other models.

XSL•FO

Datasets and Data Sources

ML and DL studies for leptospirosis prediction and diagnosis rely on diverse datasets with distinct characteristics (see Table 3). Public datasets, typically sourced from government agencies, provide large-scale environmental and epidemiological data ideal for transmission modeling. For instance, the Thai Surveillance System [32] offered monthly rainfall measurements (0 - 450 mm range), soil pH values (4.5 - 8.2), and 30-meter resolution elevation data across 5 Southeast Asian countries from 2003 to 2018, comprising over 15,000 data points.

XSL•FO
RenderX

Table . Comprehensive dataset characteristics of included studies.

Study	Data type (source)	Data categories	Sample size	Temporal resolution	Spatial resolution
Douchet et al [32]	Public (Thai surveillance system)	• Environmental: daily rainfall (mm)[a], soil pH • Climatic: max/min temperatures (°C) • Topographic: elevation (SRTM[b] 30m)	NS[c]	Monthly 2003 - 2018	Regional (5 countries)
Rahmat et al [28]	Public (Malaysia Meteorological Department)	• Meteorological: hourly rainfall (mm), RH[d] (%) • Clinical: PCR-confirmed[e] cases	364 weeks	Weekly 2011 - 2017	District-level (n=12)
Caicedo Torres et al [20]	Private (hospital records)	• Clinical: fever days, liver enzymes (U/L) • Demographic: age, gender, urban/rural	136 patients	Single admission	Hospital catchment
Nery et al [21]	Private (hospital records)	• Clinical: serum creatinine (mg/dL) • Epidemiological: rodent exposure index • Geospatial: residence coordinates	4675 cases	2009 - 2016	Household-level
Nery Jr et al [22]	Private (Gonçalo Moniz Institute [IGM], Federal University of Bahia [UFBA], Yale School of Public Health)	• Clinical: patient records • Epidemiological: risk factors, daily activities	4675 suspected cases (2046 confirmed, 2629 unconfirmed)	Retrospective (hospital and community cohort)	Hospital or community level (Salvador, Brazil)
Shenoy et al [29]	Private (medical records)	• Clinical: jaundice severity scale (0 - 3) • Laboratory: ELISA[f] optical densities • Comorbidities: diabetes status	800 patients	Retrospective 5y	Single tertiary center
Sonthayanon et al [25]	Private (bacterial cultures)	• Genomic: 16S rRNA[g] sequences • Proteomic: MALDI-TOF[h] peaks (2k-20k m/z)	116 isolates	2015 - 2018	Lab-level
Mayfield et al [24]	Private (serosurvey+ GIS[i])	• [j]Serological: MAT titers (1:50-1:6400) • Environmental: livestock density/km² • Village attributes: sanitation index	2152 people	Dry/wet season	GPS coordinates (82 villages)

XSL•FO
RenderX

Study	Data type (source)	Data categories	Sample size	Temporal resolution	Spatial resolution
Jayaramu et al [30]	Private (hydrological stations)	• Streamflow (m^3/s) • Water level (m) • Case reports (weekly)	517 weeks	Daily → weekly	Watershed-level
Galdino et al [10]	Private (hospital EMR[k])	• Vital signs: MAP (mmHg) • Labs: creatinine (µmol/L) • Outcomes: mortality	295 patients	2009 - 2022	3 hospitals
Ahangarcani et al [26]	Mixed (MODIS[l]+ CDC[m])	• Satellite: NDVI[n], LST (°C) • Case reports: district-level • Topography: slope (%)	1863 cases	Monthly 2009 - 2014	District-level
Kulkarni et al [34]	Public (microscopy images)	• Pixels: 256×256 RGB[o] • Annotations: spirochete masks	366 images	N/A	Pixel-level
Lopez et al [23]	Public (SINAN[p] database)	• Case reports: ICD-10[q] coded • Symptoms: 23-item checklist	890 cases	2007 - 2016	State-level
Mohammadinia et al [27]	Public (National Ministry of Health and Treatment of Iran, National Centre of Statistics of Iran, Meteorology Agency of Iran)	• Disease: positive ELISA test results	1186 positive cases (2009 - 2011)	Longitudinal (2009 - 2011)	District-level (Gilan Province, Iran)
Douchet et al [33]	Public (island surveillance)	• Climate: CHIRPS[r] rainfall (mm) • Case counts: ministry reports	Monthly NS	2010 - 2022	Island-level
Thibeaux et al [31]	Private (water monitoring)	• Hydrological: turbidity (NTU)[s] • Microbiological: qPCR[t] (copies/mL) • Weather: 5-min rainfall	226 samples	Event-based	3 km^2 watershed
Zhao et al [35]	Public (China CDC)	• Environmental: river density (km/km^2) • Socioeconomic: nightlight index • Cases: lab-confirmed	2741 cases	Annual 2004 - 2014	County-level

[r]CHIRPS: Climate Hazards Group InfraRed Precipitation with Station data.
[s]NTU: Nephelometric Turbidity Unit.
[t]qPCR: quantitative polymerase chain reaction.

These datasets enabled regional risk prediction but lacked individual patient details. Similarly, Malaysia Meteorological Department records [28] provided 364 weeks of hourly rainfall data (0 - 65mm/hr) and relative humidity (45% - 100%) paired with PCR-confirmed cases across 12 districts, demonstrating how high-resolution temporal data improves ANN-based outbreak forecasting.

Private clinical datasets, while smaller in scale, delivered granular patient-level information crucial for diagnostic accuracy. The Napoleón Franco Pareja Children's Hospital dataset [20] included 136 pediatric cases with detailed clinical parameters: fever duration (1 - 21 d), liver enzyme levels (AST 15 - 980 U/L), and urban/rural residence markers. More extensive Brazilian hospital records [21] encompassed 4675 cases with serial creatinine measurements (0.2 - 9.8 mg/dL) and household GPS coordinates, though missing 12% of lab results. These datasets typically included three key data categories: (1) clinical biomarkers (serum creatinine, MAT titers 1:50-1:6400), (2) demographic information (age, gender in 89% of studies), and (3) epidemiological risk factors (rodent exposure indices).

Advanced studies combined multiple data types to overcome individual limitations. Research in China [35] integrated 2741 CDC case reports with satellite-derived nighttime light indices (0 - 63 DN values) and river density maps (0 - 5.7 km/km²), achieving exceptional predictive performance (AUC 0.95 - 0.96). Hydrological studies in New Caledonia [31] correlated 226 water samples (turbidity 0 - 1,000 NTU, qPCR 10 - 10 copies/mL) with 5-minute rainfall events, demonstrating how microenvironmental data enhances transmission understanding. These multimodal approaches compensated for individual dataset constraints through: (1) temporal complementarity (monthly climate + daily case reports), (2) spatial layering (watershed hydrology+ village coordinates), and (3) clinical-environmental linkages (serum markers + livestock density).

Discussion

Principal Findings

This systematic review of 17 studies (2012 - 2024) shows that while ML and DL techniques achieve promising accuracy (80% - 98%) in leptospirosis prediction and diagnosis, 3 critical limitations hinder clinical translation: (1) reliance on small, private clinical datasets limiting generalizability; (2) inconsistent validation methods, with only 11.8% employing temporal validation despite seasonality; and (3) underuse of advanced techniques like transfer learning (0% adoption) and data augmentation (5.9% adoption).

The most effective algorithms varied by task—SVR and Random Forest for prediction, versus U-Net CNNs for microscopy-based diagnosis—but all models faced challenges related to data quality, sample size, and geographic bias.

Textbox 1 shows the summary of the strengths and limitations identified in ML and DL studies for leptospirosis prediction and diagnosis.

XSL•FO
RenderX

Textbox 1. Summary of strengths and limitations identified in machine learning (ML) and deep learning (DL) studies for leptospirosis prediction and diagnosis.

Strengths:

- High predictive performance (80% - 98% accuracy).
- Variety of ML and DL algorithms applied (eg, random forests, support vector machines, and onvolutional neural networks).
- Integration of clinical and environmental data in some studies.
- Growing research interest and recent publications.

Limitations:

- Small, private datasets limit generalizability.
- Lack of external validation across datasets.
- Underuse of transfer learning and ensemble methods.
- Inconsistent evaluation metrics (accuracy, area under the curve, and sensitivity).

While these methods show strong performance (80% - 98% accuracy in some cases), their real-world applicability remains limited due to dataset constraints, validation inconsistencies, and underuse of advanced techniques such as transfer learning and ensemble learning. Addressing these gaps is essential to improve the robustness and clinical adoption of AI-driven leptospirosis diagnostics.

The most frequently used ML techniques for prediction tasks were SVR and Random Forest, while ANNs and CNNs, particularly U-Net, were commonly applied for diagnosis. This aligns with the increasing popularity of supervised ML methods in disease prediction.

Performance was primarily assessed using metrics such as accuracy, sensitivity, specificity, precision, and F_1-score, although AUC offers a more comprehensive measure of model performance, especially in binary classification tasks. Hybrid methods often produced better outcomes, with Random Forest and U-Net demonstrating strong accuracy and sensitivity in leptospirosis classification tasks. For instance [29], achieved 87% accuracy and 91% sensitivity using Random Forest for diagnosis, suggesting that ensemble techniques could further enhance model performance.

Despite these advancements, there are still limitations in reaching clinician-level accuracy, especially when dealing with smaller datasets or limited training data. Acceptable performance thresholds varied, with some studies using an AUC score of 0.96 or higher as a benchmark, but this was not universally applied. In addition, most studies relied on private, hospital-based datasets, limiting generalizability. The lack of external validation raises concerns about potential bias, emphasizing the need for public datasets and standardized validation protocols to improve cross-study comparability.

Cross-validation was the predominant method for evaluating the models, with k-fold or leave-one-out cross-validation being most common. However, due to the relatively small sample sizes in many studies, the conclusions drawn may not be as robust. Split validation (eg, 80:20 or 70:30 splits) was also used, but inconsistencies across studies hindered direct model comparisons. Future work should prioritize establishing standardized protocols to enhance consistency and reliability in ML and DL evaluations.

One significant finding of this review was the absence of pretrained models. Most studies developed models from scratch, limiting the generalizability and scalability of these models. Transfer learning involves using a pretrained model as a starting point and fine-tuning it for a specific task. It has proven effective in various fields, particularly in image analysis and natural language processing, by significantly improving performance on tasks with limited data.

The lack of transfer learning in these studies suggests a potential area for future research, as it could enhance the performance of DL models in leptospirosis prediction and diagnosis, especially in cases where training data is limited. Similarly, data augmentation, which helps expand training datasets through transformations (eg, rotations, translations, or noise), was only used in 1 study, highlighting a missed opportunity to improve model robustness.

Challenges and Research Gaps in ML and DL Applications for Leptospirosis Prediction and Diagnosis

While ML and DL have significant potential in leptospirosis research, this review also identified key findings that limit their broad application in clinical and public health settings.

Challenge 1: Limited Data Availability and Quality

A major challenge faced by the studies was the limited availability and quality of data. Many datasets, such as the one used in [21], had missing or incomplete data, which reduced the accuracy and generalizability of the models. Small sample sizes were a frequent issue as well, as observed in [20], where a dataset of only 136 patients resulted in high variability in model performance, especially for underrepresented cases like leptospirosis. Retrospective data collection posed further challenges, leading to biases in model training and evaluation, as noted by Shenoy et al [29].

Challenge 2: Generalizability and Regional Bias

Several studies, such as [28,33], identified biases in data collection, such as under- and over-reporting, regional

XSL•FO
RenderX

disparities, and sampling biases, which hindered the broader applicability of the models. In addition, studies like [35] noted issues with the spatial resolution of environmental data, affecting the precision of fine-scale risk mapping. Moreover, the lack of external validation across different regions and datasets, as seen in studies like [10], increased the risk of overfitting and limited the broader applicability of findings.

The review showed inconsistent performance across different ML and DL algorithms. For example, models like SVM, ANN, and CNNs performed well, with accuracy reaching up to 98% [34]. However, advanced DL architectures like ResNet, Inception, and VGG were rarely used [25,33]. Similarly, none of the studies applied transfer learning, a technique that could enhance performance, particularly when data is scarce [10,28,36]. Beyond data related challenges, there are also limitations in the ML and DL techniques currently applied to leptospirosis diagnosis, as discussed next.

Challenge 3: Underuse of Advanced Techniques

Advanced ensemble techniques, such as XGBoost and Adaboost, were notably underused [26]. While Random Forest models and U-Net architectures performed well in specific tasks [29,34], ensemble methods could provide better predictive power when combining ML and DL approaches. The review also highlighted the minimal use of data augmentation techniques, which could help address the small sample size issues observed in many studies [34].

Limitations of This Systematic Review

While this systematic review provides valuable insights, it has certain limitations. The heterogeneity of study designs, dataset sizes, and performance metrics precluded a meta-analysis, limiting our ability to provide a standardized comparison of model performances. In addition, the reliance on published studies may have introduced publication bias, as studies with less favorable results may have remained unpublished. Future systematic reviews should aim to standardize reporting metrics and ensure broader dataset accessibility to improve comparability across studies.

Recommendations for Future Research

Based on these findings, future research in ML and DL applications for leptospirosis should focus on the following areas:

- Integration of advanced DL techniques: future studies should explore the potential of advanced DL architectures, such as ResNet and Inception, which are known to improve predictive performance, especially in image-based analysis.
- Leveraging pretrained models and transfer learning: research should investigate how pretrained models can be fine-tuned for leptospirosis applications, particularly in data-limited scenarios.
- Use of ensemble and hybrid approaches: advanced ensemble techniques like XGBoost and hybrid ML-DL approaches should be explored to improve model accuracy and robustness.
- Broader geographic representation: most studies focused on regions like Southeast Asia and Brazil, with limited research in other high-risk areas like Africa and Central America. Expanding research to these regions will improve model generalizability.

The primary goal moving forward is to aggregate a comprehensive dataset from diverse sources and develop a robust data library to enhance the accuracy and reliability of leptospirosis prediction models. Given the heterogeneity of data features across different studies—ranging from clinical records to environmental data—the focus will be on standardizing and harmonizing these features for better model integration. By consolidating larger and more varied datasets, we aim to improve model generalization and tackle current challenges related to small sample sizes and overfitting. This unified dataset will serve as a foundation for applying advanced techniques, such as transfer learning and ensemble methods, to further enhance the predictive power of ML and DL models in leptospirosis detection.

Conclusion

This systematic review examined ML and DL techniques for leptospirosis prediction and diagnosis by analyzing algorithm performance, evaluation methods, and challenges. While models such as SVM, ANN, decision trees, and CNNs have shown strong predictive power, most studies have relied on private hospital-based datasets, limiting generalizability.

A key reason for the predominance of private datasets is that they often include detailed patient-level clinical information (eg, laboratory values, comorbidities, and symptoms) essential for developing diagnostic models. In contrast, available public datasets mainly provide aggregated epidemiological or environmental data, which, while valuable for outbreak prediction, lack the granular patient-specific features necessary for individual diagnosis. As a result, limited use of public datasets reflects the inherent constraints in the nature and detail of publicly available data, rather than a preference by researchers.

Furthermore, the lack of advanced techniques like transfer learning and ensemble methods remains a concern, along with small sample sizes and inconsistent validation protocols. Overall, while significant progress has been made, there is considerable potential to improve the accuracy and generalizability of leptospirosis prediction models by integrating more comprehensive datasets and adopting advanced AI methodologies in future research.

Authors' Contributions

SS led and conducted this study and contributed to the conceptualization, data extraction, analysis, and manuscript preparation and submission. AJ assisted with all steps, including data extraction, analysis, and manuscript preparation. BR contributed to data extraction, analysis, and provided critical input throughout the study.

Abstract

Background: This review explores the potential of virtual reality (VR) and artificial intelligence (AI) to identify preclinical cognitive markers of Alzheimer disease (AD). By synthesizing recent studies, it aims to advance early diagnostic methods to detect AD before significant symptoms occur.

Objective: Research emphasizes the significance of early detection in AD during the preclinical phase, which does not involve cognitive impairment but nevertheless requires reliable biomarkers. Current biomarkers face challenges, prompting the exploration of cognitive behavior indicators beyond episodic memory.

Methods: Using PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, we searched Scopus, PubMed, and Google Scholar for studies on neuropsychiatric disorders utilizing conversational data.

Results: Following an analysis of 38 selected articles, we highlight verbal episodic memory as a sensitive preclinical AD marker, with supporting evidence from neuroimaging and genetic profiling. Executive functions precede memory decline, while processing speed is a significant correlate. The potential of VR remains underexplored, and AI algorithms offer a multidimensional approach to early neurocognitive disorder diagnosis.

Conclusions: Emerging technologies like VR and AI show promise for preclinical diagnostics, but thorough validation and regulation for clinical safety and efficacy are necessary. Continued technological advancements are expected to enhance early detection and management of AD.

dementia; Alzheimer disease; mild cognitive impairment; virtual reality; artificial intelligence; early detection; qualitative review; literature review; AI

Introduction

Nowadays, widespread access to health care systems and changes in living conditions have resulted in an aging population, leading to an increase in the prevalence of neurocognitive disorders (NCD) [1,2]. This phenomenon will lead to a societal change and place an additional burden on health care systems. Therefore, the main challenge at this time lies in the development of therapeutic measures at the pharmacological level that can prevent or halt the progression of Alzheimer disease (AD). However, so far, it has not been possible to find a pharmacological product that meets the safety and efficacy criteria necessary for large-scale use [3-5].

XSL•FO
RenderX

Conversely, numerous studies have shown that factors such as access to higher education, leading a healthy lifestyle, controlling cardiovascular risk factors, and being socially active can have a preventive effect by delaying the onset of symptoms and disease progression. In this context, it is of vital importance to identify emerging markers of AD that allow a diagnosis to be made in its preclinical stage.

The definition of preclinical AD varies, marked by criteria similarities and differences. It signifies the initial stage in the AD continuum, characterized by an extended asymptomatic phase with evidence of AD pathology, yet lacking cognitive, behavioral, or activities of daily living impairment (Table 1). Duration varies (6-10 years), contingent on onset age, and progression to mild cognitive impairment (MCI) hinges on factors like age, sex, and apolipoprotein E status. The complexity arises from not all those meeting preclinical AD criteria progressing to MCI or AD dementia, adding nuances to the predictive analysis [6].

Table . The AD continuum.[a]

AD continuum	Pathological and anatomical evidence of AD	Behavioral and psychological changes and cognitive impairment	Functional deficit		
IWG-2[b]	Asymptomatic, at risk or presymptomatic	Prodromal	Mild AD dementia	Moderate AD dementia	Severe AD dementia
NIA-AA[c]	Preclinical	MCI[d] (prodromal AD)	AD with mild dementia	AD with moderate dementia	AD with severe dementia
FDA[e]	Stages 1 and 2 (up to 20 years prior to clinical AD)	Stage 3 (episodic memory, executive function, visuospatial function; disease progression to clinical AD	Stages 4-6 (all domains, in a progressive way)		

[a]AD: Alzheimer disease.

[b]IWG: International Working Group.

[c]NIA-AA: National Institute on Aging—Alzheimer's Association.

[d]MCI: mild cognitive impairment.

[e]FDA: Food and Drug Administration.

In this sense then, early biomarkers are crucial for assessing and monitoring AD. These indicators, recommended by the National Institute on Aging and the Alzheimer's Association, include the assessment of extracellular amyloid beta (Aβ) and hyperphosphorylated tau protein (p-tau) in the brain [7,8]. The latest guidelines classify neurodegeneration using biomarkers such as amyloid positron emission tomography, Aβ42 levels, tau protein, and neuroimaging techniques. Incorporating these biomarkers aids in the early detection and understanding of AD, aligning with evolving clinical practices and research efforts [9].

However, these biomarkers are expensive and not widely available in much of the world, and their results are not always consistent with the clinical manifestations of the patient, since even in the presence of positive markers, symptoms may not develop or may develop incompletely, and the time gap between the appearance of these biomarkers and the onset of symptoms has not yet been fully characterized.

Since the 1990s, there has been an increasing number of publications aiming to identify cognitive-behavioral markers of the shift from "normal" cognition (NC) to early symptoms of the disease [10-13]. In most studies, episodic memory appears as the domain that is altered in the first instance, reporting variability ranging from 20 [14] to 2 years prior to symptom onset [3,13,15-17].

More recent studies have explored other domains that could be altered earlier, especially visuospatial function and executive functions; in addition, spatial navigation tasks have appeared as a new domain with characteristics that encompasses the 2 previous ones [18-23]. Some studies have proposed to evaluate functional (such as modifications in expansive activities of daily living, changes in mobility patterns) and behavioral aspects, as well as conduct a more thorough analysis of companion reports, and even subjective memory complaints. However, there is little agreement on how to measure them and which ones exhibit true early marker behavior of the disease [24-26]. At this point, it is important to mention that the vast majority of studies are oriented to the diagnosis of NCD due to AD, with only a handful of studies exploring some characteristics of frontotemporal dementias or NCD associated with Parkinson disease, though these tend to have a much lower quality of evidence than studies for AD [27-32].

The most current approaches have incorporated artificial intelligence (AI) and machine learning (ML) tools with the purpose of developing multivariate models that take advantage of these advanced technologies to integrate neuroimaging results, neuropsychological variables, and biomarkers in the early diagnosis of AD [4,9,33-35]. In this context, the use of virtual reality (VR) environments presents a novel and yet underexplored opportunity. So far, they have mainly been used in therapeutic applications, but their potential in the field of diagnostics remains to be investigated [31,32,36-41].

This study aims to review prevalent neurocognitive markers for the preclinical stages of tauopathies, particularly AD. It also explores recent research on VR applications in this context and

XSL•FO
RenderX

aims to identify the most evidence-supported tests for assessing valuable cognitive domains.

Methods

The steps followed for article selection are based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) methodology [42], as evidenced in recently published literature reviews on similar topics [43,44]. References were obtained from the search for articles in PubMed and Google Scholar. Articles from the last 10 years were included, although we also included 2 articles published more than 10 years ago because of their importance in the field. In the first instance, the terms used for the search were "pre-dementia Alzheimer's disease," "dementia early diagnosis," "dementia early diagnosis financial," "benefits of early diagnosis of Alzheimer's disease cost effectiveness," "benefits of early diagnosis of Alzheimer's disease," and "early diagnosis of Alzheimer's disease." However, the articles obtained with these operators corresponded to those with primary treatment objectives or involving exclusively biological measures in different fluids, development of new neuroimaging modalities, or developments of AI and ML algorithms without including neuropsychological parameters. We opted for the search strategy proposed by Bastin et al [12] using the following keywords: ((memory AND longitudinal AND Alzheimer's disease) AND (prodromal OR conversion OR preclinical)), ((mild cognitive impairment AND (Alzheimer's disease OR dementia) AND neuropsychology AND (prediction OR longitudinal)), and (Alzheimer's disease AND conversion AND neuropsychology).

When using these terms, none of the papers yielded results that included VR tools for diagnosis, so the pattern ((mild cognitive impairment AND (Alzheimer's disease OR dementia) AND neuropsychology AND virtual reality)) was incorporated within the search strategy, finding 13 new papers of which 11 were incorporated, including 2 review papers that are discussed towards the end. Two papers were discarded because they were rehabilitation papers. The terms were used in English for most of the search engines, except for Google Scholar where the same terms were used in Spanish. Articles in both languages were included. As inclusion criteria, we selected those papers that made a longitudinal follow-up or an extensive review either through a systematic review or meta-analysis of the proposed topic. Those papers that could show conversion from NC to MCI or from MCI to dementia were weighted.

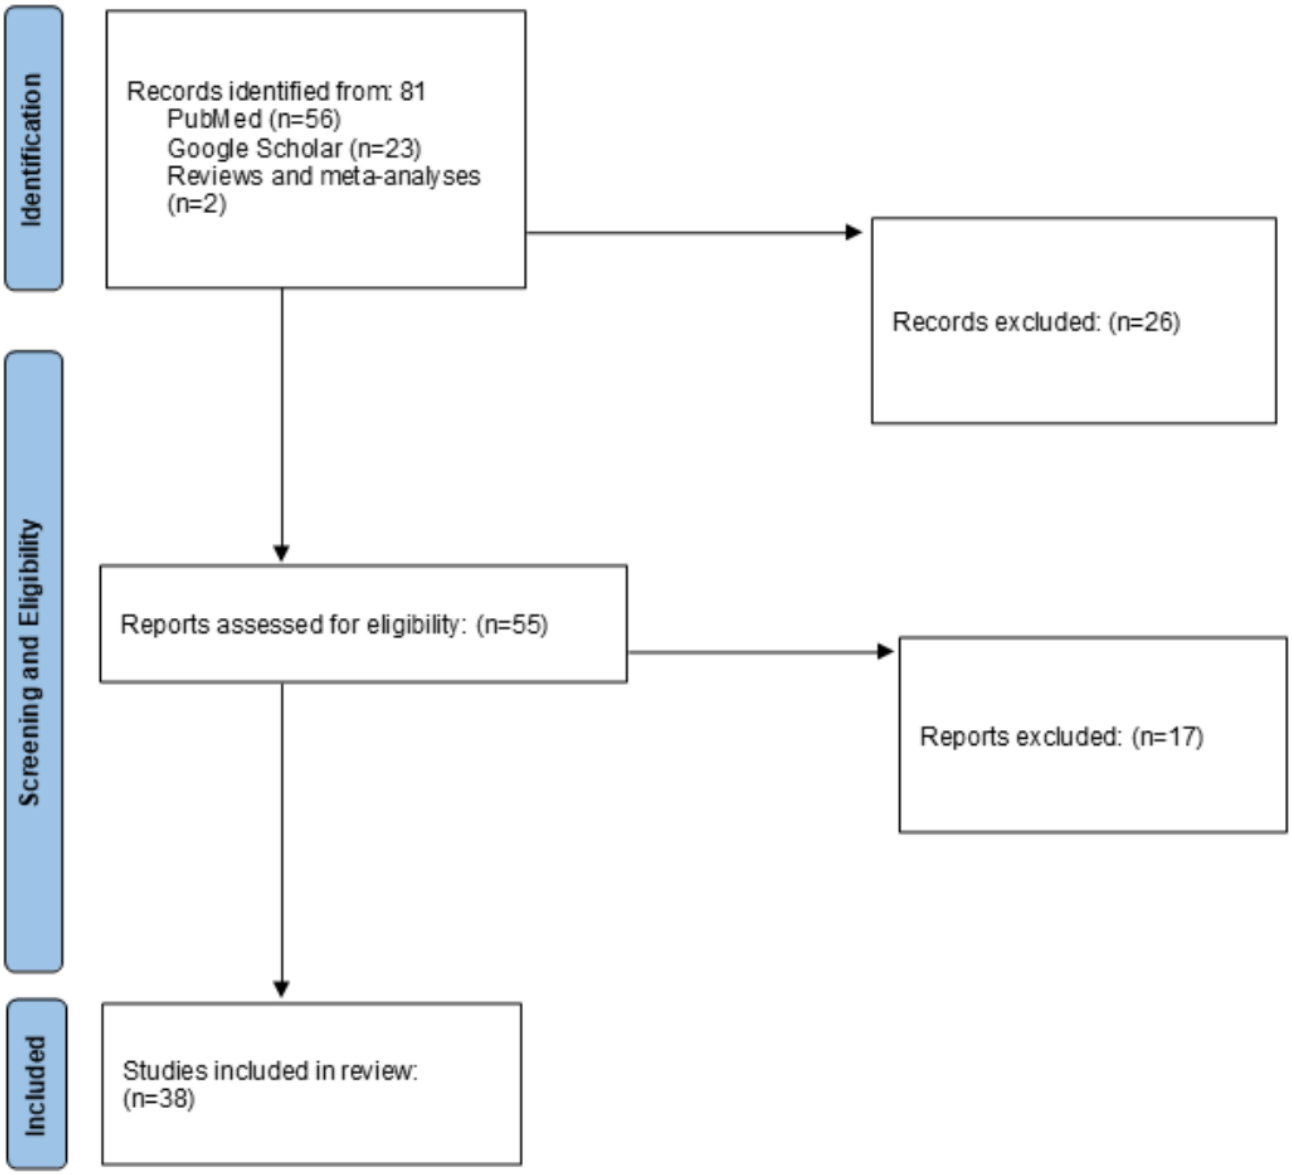
Based on this, 58 articles were selected based on the reading of the abstract. Studies conducted in animals, those that pursued primary treatment objectives, those conducted in patients with depression or other psychiatric/psychological comorbidity, those whose primary objective was to develop an AI algorithm, those that only used markers from blood, cerebrospinal fluid, urine, saliva, or other biological markers, and research theses were excluded. After reading the full text, those papers whose primary objective was the development of diagnostic imaging methods unrelated to neurocognitive variables (mainly related to functional magnetic resonance imaging [MRI], volumetry, cortical thickness) and without development of neurocognitive assessment (the tests used were not reported, they only showed raw scores of screening tests) were eliminated, as well as those papers that did not include a control group (MCI or normal aging or healthy controls).

Moreover, the Mendeley functionalities were used for the purpose of consolidating all references drawn from the various databases consulted. Subsequently, an integrated matching tool was used to identify and eliminate duplicates. In the initial screening phase, a preliminary selection of papers was made based on their relevance to the research question. To conduct this screening, the titles and abstracts of the papers were used to ascertain whether any of the 7 exclusion criteria set out in Table 2 were met. In instances where a decision was not immediately evident, the article was designated as a potential candidate for the subsequent phase.

Table . Summary of the reasons for excluded papers.

Reason for exclusion[a]	Values (n=26+17)
Screening	
Did not report empirical data from human participants	12
Only biological markers (eg, blood, urine, cerebrospinal fluid)	4
Depression or another psychiatric comorbidity	3
Primary target: artificial intelligence algorithm development	5
Thesis	2
Eligibility	
No inclusion of MCI patients or normal aging or controls trials	5
Primary objective in development of diagnostic imaging methods	6
No neuropsychological assessment	6

[a]Reasons for excluding papers during the screening (n=26) and eligibility process (n=17).



Subsequently, the full text of all papers that had been deemed eligible following the screening phase was considered. This was considered to be the most appropriate set of papers on the topic, having overcome the exclusion criteria set out in Table 2.

RenderX

Results

The article selection process is outlined in Figure 1. This narrative outlines key discoveries from selected articles (Table 3 and Table 4)—studies without VR—categorizing the type of work and pinpointing the most early, sensitive, and specific neurocognitive variables according to each paper. Multiple cognitive variables, when presented, are organized by diagnostic profile. The chosen tests for variable measurements are specified. For a more detailed analysis of the reviewed articles, please consult the supplementary material (Multimedia Appendix 1). Moreover, a dedicated section and table are focused on findings related to VR and AI tools utilized for diagnosis (Table 5).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart illustrating the process of selecting eligible publications for inclusion in the literature review.

A large majority of articles present verbal episodic memory measured by different tests (Free and Cued Selective Reminding Test, California Verbal Learning Test, Rey Auditory Verbal Learning Test) as the earliest measure with the best sensitivity and specificity ratio for the detection of the preclinical stage of AD and the most recent works propose to support this measure with different neuroimaging formats, genetic profiling (apolipoprotein E), or markers (Aβ, tau, p-tau) in cerebrospinal fluid [11,12,46,49,50,53,60-62]. Among these papers, the one by Gagliardi's team comparing different neuropsychological tests for the measurement of episodic memory stands out [51].

Harrington and collaborators [45] focused on executive functions using the Stroop test, conducted on individuals without apparent cognitive impairment. They compared those with positive amyloid in cerebrospinal fluid to those without pathology, revealing executive failure preceding memory issues. The study emphasized the absence of standardized protocols for cognitive neural vulnerability in preclinical stages.

The works of Bastin [12] and Gainotti [46] are 2 large review papers that attempted to identify early neuropsychological markers in preclinical and conversion AD, comparing cognitively healthy subjects with and without evidence of pathology. Both papers agreed that episodic memory is the earliest marker, followed by semantic memory, although the protocols used for its assessment differed.

One of the most outstanding articles found in this search is the work of Mistridis et al [63]. The article agrees that verbal episodic memory is an early marker of cognitive impairment, detailing the sequence of decline of various cognitive functions in subjects with NC who progress to MCI. Verbal memory declines about 8 years before MCI, followed by episodic learning, visual memory, and semantic memory about 4 years before MCI. Executive functioning and processing speed declined about 2 years before MCI diagnosis. This suggests that multiple cognitive domains are valuable in assessing preclinical AD.

Another paper that attempted to establish a timeline is that of Soldan et al [47], which used a composite score to evaluate 4 study groups of cognitively unimpaired patients, with the definitions of stage 0 (high Aβ and low tau), stage 1 (low Aβ and low tau), stage 2 (low Aβ and high tau), and suspected non-AD pathology (high Aβ and high tau). The article used linear mixed-effects models to estimate longitudinal cognitive composite scores among individuals in 4 preclinical AD groups. Adjusted for baseline factors, stage 2 individuals showed greater impairment and lower baseline scores compared to others, while stage 0, stage 1, and suspected non-AD pathology groups showed no significant differences. Involving 222 NC adults over 11 years, those in stage 2 (low Aβ, high tau/p-tau) showed markedly lower baseline scores and greater cognitive impairment, suggesting that abnormal amyloid and tau levels are necessary for cognitive differences in NC individuals.

Skills related to visuospatial function, which could prove important in the development of VR environments, were addressed in depth in the work of Caselli et al [14] and Iliardi et al [19]. The first study suggested that visuospatial function deteriorates 20 years before clinical signs of AD, aligning with early pathological changes. It aims to sequence neurocognitive alterations in preclinical stages of AD. The second article addressed the importance of assessing visuospatial working memory, anosognosia, and visuomotor control in patients with MCI, who show worse performance compared to healthy controls and sometimes like patients with dementia. Assessment of visuomotor abilities may help distinguish high-risk AD patients from nonrisk AD patients.

Wadley and colleagues [26] focused on processing speed impact on patient functionality, utilizing an ecological approach integrating neurocognitive and functional variables from professional observations, informant reports, and self-reports. They correlated these with neuroimaging and genetic markers, suggesting processing speed as a stronger correlation of everyday abilities than MRI patterns consistent with AD, and more accessible for measurement. Although neuroimaging demonstrates AD-related neurodegeneration, processing speed captures combined effects, comorbidities, and cognitive reserve, serving as an early marker for functional outcomes.

Among the studies that showed other tools for assessing preclinical stages of NCD that complemented cognitive neural vulnerability, there are studies that incorporate high-resolution electroencephalography measurements [52], olfactory markers [64], auditory [30], retinal thickness measurement by optical coherence tomography [64], use of ML algorithms for speech analysis [9], and home-based sleep studies from specific devices [17]. Some of these works were intended to assess preclinical stages of dementias other than AD, and in the review done by Khan et al in 2020 [9], the proposal of voice analysis in audios and videos allowed for this analysis in several languages. These studies suggest challenges with tests in English, requiring validation for diverse languages and contexts. However, they feature smaller populations, necessitate specific devices, and occur in nonclinical settings.

Literature on the use of VR for early diagnosis of preclinical NCD was limited, unlike its extensive use in cognitive skill training. Papers related to VR for diagnosis or treatment increased from 2008 to 2017, declined until 2020, then started rising again (Table 5).

By 2011, it was confirmed that ego and allocentric memory, linked to the parietal association cortex and medial temporal cortex, could serve as early markers of cognitive decline. VR models, like park or maze navigation, facilitated assessment [23]. Moreover, a Canadian team compared NC subjects with MCI patients using the Montreal Cognitive Assessment, Rivermead Behavioral Memory Test, and a VR test where subjects choose an apartment. The VR test correlated positively with the Montreal Cognitive Assessment, unlike traditional tests, but the sample size was small [39].

The study of Allain et al [24] compares cognitively healthy controls with patients with AD (varying stages, Mini Mental State Examination 18 - 26 points) regarding functionality using a virtual coffee preparation task. Measures include completion time, achievement, and error scores compared with real-world tasks. With 24 patients with AD and 32 controls, the study demonstrates VR's feasibility in studying AD deficits in ecologically valid environments, though limited to a single task.

XSL•FO
RenderX

In 2014, Tarnanas et al [65] conducted research correlating daily living activities assessment in virtual environments with biomarkers like neuropsychological tests, event-related potentials, and MRI. Their study, robust compared to others, suggests VR performance equals biomarkers, attributed to VR's cognitive fidelity and rich behavioral data reflecting early-stage neurocognitive processes.

Zygiuris et al [56] introduced the virtual supermarket, a VR tool for rehabilitation and screening. The article extensively examined its validity with various measures and set cutoff points for a diagnostic algorithm. Several papers corroborate the apparent sensitivity of visuospatial functions in early NCD detection, evaluating ego and allocentric orientation. Morganti [21] compared a paper and VR version of Money's "Road Map" test, noting the virtual version's increased difficulty. They hypothesized that participants solve the traditional version through egocentric spatial transformations, while VR decisions are made based on on-screen interactions. This makes VR tools an interesting alternative, but one that needs to be carefully evaluated to determine what factors influence the results. Similarly, Mohammadi et al [20] used a VR navigation task to distinguish between monodomain and multidomain amnestic MCI, patients with AD, and normal controls, comparing results with traditional neuropsychological tests. They analyzed correct responses and response times in neighborhood and maze environments, establishing distinctive patterns in orientation (ego/allocentric) and visual/verbal memory.

Howett et al [57] published a study correlating entorhinal cortex volume measures, proposed as an early AD marker, with changes in immersive VR tests. They found consistent results with traditional neuropsychological tests, suggesting navigation tasks aid in early AD diagnosis [57]. Within this group, Lecouvey et al [59] utilized VR to evaluate prospective memory through tasks in a virtual city, comparing it with traditional neurocognitive measurements. Results confirmed early prospective memory alterations in AD, suggesting VR as a reliable assessment tool.

Turner's team [37] created a tablet-based tool evaluating real-world task competence in a realistic VR setting, assessing cognition, motor skills, and self-reported cognitive abilities in patients with Parkinson disease.

To conclude, 2 articles in this review elaborated VR protocols to assess neurocognitive domains, revealing the progression from NC to MCI, focusing on memory and visuospatial functions. In 1 study, an Italian team devised a protocol to detect early cognitive signs of conversion in AD, focusing on egocentric and allocentric spatial representations. Previous studies showed alterations, especially in allocentric frames, in patients with amnesia with MCI and AD. Their innovation lies in proposing an intrinsic connection between egocentric/allocentric frames and spatial relations. The results revealed deficits in allocentric coordinated judgments, implying a deviation towards AD in the representation of metric distances [22]. In the other study, Machado et al [58] highlighted the use of VR environments, in particular 3D mazes, as diagnostic tools for MCI or dementia. Their study compares traditional methods with VR environments, combining precalibrated 3D tests with validated 2D neuropsychological assessments, allowing for assessment across several cognitive domains.

Finally, these studies, when paired with advanced AI algorithms, hold promise for early diagnosis. They enable cross-referencing of various variables, enhancing diagnostic accuracy [4,33,34,57,66].

Discussion

Principal Findings

The objective of the Discussion section is to integrate the findings of this literature review and to explore their implications for advancing early diagnostic methods for AD using VR and AI. This section considers the strengths and limitations of current approaches, while also highlighting the potential role of these emerging technologies. Our findings indicate that while verbal episodic memory is a sensitive preclinical marker of AD, other cognitive domains, such as executive function and processing speed, may also serve as valuable early indicators. Furthermore, we examine the significant untapped potential of VR for the assessment of complex cognitive behaviors. VR has the capacity to simulate real-world environments, thereby enabling the evaluation of subtle deficits in cognition that would otherwise be challenging to capture in traditional assessments. AI, with its capacity to analyze multidimensional data, provides a promising approach for integrating biomarkers, cognitive data, and behavioral patterns. Nevertheless, there are considerable obstacles to the clinical implementation of these technologies, particularly in relation to the processes of validation, regulation, and ethical consideration.

The diagnosis of NCD involves advanced pathological definitions based on biomarkers but lacks changes in treatment perspectives. AD remains a paradigm, guiding NCD studies. Although pharmacological treatments are lacking, lifestyle and cardiovascular health modifications may prevent or delay onset, highlighting the importance of early diagnosis for effective intervention.

For more than 30 years, neuropsychological tests have provided the possibility of a more accurate diagnosis and of generating the basis for more specific pharmacological and nonpharmacological treatment plans. However, in recent years, with the advent of biomarkers, the scenario has become more complex [60].

Combining various diagnostic methods like amyloid and tau protein determination in cerebrospinal fluid, positron emission tomography scans with fluorodeoxyglucose or florbetapir, and brain volumetric measurements enhances diagnostic accuracy. However, controversies arise as apparently healthy individuals exhibit positive pathological markers without developing measurable symptoms over extended periods, challenging current diagnostic instruments [6,7,47,67-69].

Incorporating neuropsychological tests into composite diagnostic schemes becomes crucial for reliable conclusions in preclinical disease stages. Verbal episodic memory emerges as the earliest altered neurocognitive domain, followed by visual and semantic memory, despite measurement controversies [3,12-14].

XSL•FO
RenderX

Recent studies suggest executive functions and processing speed alterations as early markers preceding declines in episodic and semantic memory. Improving processing speed through training protocols is vital for maintaining functionality in cognitively demanding tasks like driving and managing finances for individuals with MCI [26,28,31,32,45].

Enhancing diagnostic accuracy for MCI involves indirectly estimating posteromedial parietal cortex function through simple outpatient neuropsychological tasks. Assessing visuomotor abilities in high-risk AD individuals distinguishes conversion probability. Iliardi et al [19] revealed deficits in visuospatial working memory and metamemory as conversion predictors, intricately linked to posteromedial parietal cortex neuronal activity. This innovative approach spans various domains, potentially significantly improving the care and treatment of patients with MCI.

Three recent Spanish review studies focused on identifying cognitive processes assessed via VR and determining commonly used everyday life scenarios in virtual environment design to enhance ecological validity. They noted poor correlation between traditional neuropsychological tests and activities of daily living, prompting the development of technology-based instruments like VR and serious games for evaluation [70-73]. One of these studies reported that 52.3% of works implemented immersive VR, followed by nonimmersive VR (43.2%), and finally semi-immersive VR (4.5%) [70].

VR environments are emerging as new diagnostic tools, but limitations exist. Selected studies were cross-sectional, with few patients evaluated. Gender differences, like navigation strategies in mazes, were noted. Performance in visuospatial tasks is influenced by reference points, instructions, and experimental parameters, highlighting the need for careful consideration in test design [21,24,28,32,56,58].

The translational approach merges animal models and patient evaluations, incorporating complex 3D tasks and standardized neuropsychological tests with automatic analysis, enhancing neuroscience's cognitive function investigations. A clinical module with preconfigured 2D and 3D tasks simplifies routine patient evaluations [58].

Limitations of This Literature Review

However, this literature review on preclinical cognitive markers of AD using VR and AI has several notable limitations. First, many studies were conducted with a limited number of participants, which reduces the generalizability of the findings. This small sample size makes it difficult to draw broad conclusions about the effectiveness of VR and AI for early diagnosis in different populations. Second, there is a lack of psychometric validity in some of the cognitive markers used, which raises concerns about the accuracy and reliability of these tools in assessing preclinical stages of AD. In addition, AI algorithms used in early diagnosis are often subject to bias due to the nature of the training data, potentially leading to biased decision-making that could disproportionately affect certain demographic groups. Ethical considerations also remain a challenge, particularly about privacy, consent, and transparency of AI-driven diagnostic processes. Addressing these limitations is critical to the development of robust, fair, and clinically useful AI- and VR-based tools for early detection of AD.

In conclusion, the integration of VR and AI in AD diagnosis represents a rapidly advancing and promising area in medical and neuropsychological research. Key considerations in this domain may include the following aspects:

- Diagnostic accuracy: The fusion of VR and AI provides an avenue for conducting highly accurate and objective assessments of cognitive functions in general, especially visuospatial functions. These tools can identify nuanced alterations in cognitive performance that traditional assessments frequently struggle to detect.
- Early detection: Detecting AD in its preliminary stages is crucial for early intervention and personalized support. VR and AI technologies can detect early signs of cognitive decline before symptoms manifest in daily activities, facilitating more timely and targeted interventions.
- Personalization: Through AI, VR evaluations can be personalized to match the unique capabilities and requirements of each patient. This enables tests to target specific cognitive areas of deficiency, enhancing diagnostic precision and identifying personalized areas for enhancement.
- Greater immersion: VR offers an immersive environment that replicates real-life scenarios and is ideal for evaluating patients' proficiency in everyday activities like city navigation or shopping. These tasks are challenging to replicate within traditional clinical settings, making VR assessments particularly valuable as they facilitate an ecological and nonintrusive cognitive evaluation of the person.
- Continuous data acquisition: VR and AI facilitate continuous data gathering, enabling precise monitoring of disease advancement and the efficacy of therapeutic measures over time.

Recommendations for Future Research

Further research is needed to improve the effectiveness of VR and AI practices in early diagnosis of AD, particularly by addressing personalization and diagnostic accuracy. One promising direction is to develop VR assessments that can be tailored to each patient's unique abilities and needs, ensuring that cognitive assessments are as individualized and responsive as possible. This personalization could contribute to a more accurate understanding of each patient's cognitive status, thereby improving the sensitivity of early detection. In addition, research should focus on improving diagnostic accuracy by strengthening the psychometric validity of cognitive markers used in VR environments to ensure that these assessments are both reliable and clinically meaningful. In parallel, ongoing efforts are needed to mitigate biases in AI predictions by ensuring that models are trained on diverse datasets that accurately represent the broader population, thereby reducing inequalities in diagnostic outcomes. These future research efforts are essential to refine VR and AI as effective, unbiased, and personalized tools for early detection of AD.

XSL•FO
RenderX

Conclusions

Preclinical diagnosis of NCD remains challenging, with much more exploration needed. Although VR and AI offer benefits, challenges include expensive hardware, rigorous test validation, and results interpretation by trained professionals. Ethical concerns arise from patient data collection in virtual environments, necessitating strict confidentiality measures. Despite these challenges, VR's use in AD diagnosis marks noteworthy progress in health care and NCD research. Continued technological advances will improve early detection and management. It is therefore essential to validate and regulate clinical safety and efficacy, delving into new preclinical cognitive markers. Further research is needed to improve the efficacy of VR and AI practices in the early diagnosis of AD, in particular addressing personalization and diagnostic accuracy.

Abstract

Background: Conversational agents (CAs; chatbots) are systems with the ability to interact with users using natural human dialogue. They are increasingly used to support interactive knowledge discovery of sensitive topics such as mental health topics. While much of the research on CAs for mental health has focused on adult populations, the insights from such research may not apply to CAs for youth.

Objective: This study aimed to comprehensively evaluate the state-of-the-art research on mental health CAs for youth.

Methods: Following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, we identified 39 peer-reviewed studies specific to mental health CAs designed for youth across 4 databases, including ProQuest, Scopus, Web of Science, and PubMed. We conducted a scoping review of the literature to evaluate the characteristics of research on mental health CAs designed for youth, the design and computational considerations of mental health CAs for youth, and the evaluation outcomes reported in the research on mental health CAs for youth.

Results: We found that many mental health CAs (11/39, 28%) were designed as older peers to provide therapeutic or educational content to promote youth mental well-being. All CAs were designed based on expert knowledge, with a few that incorporated inputs from youth. The technical maturity of CAs was in its infancy, focusing on building prototypes with rule-based models to deliver prewritten content, with limited safety features to respond to imminent risk. Research findings suggest that while youth appreciate the 24/7 availability of friendly or empathetic conversation on sensitive topics with CAs, they found the content provided by CAs to be limited. Finally, we found that most (35/39, 90%) of the reviewed studies did not address the ethical aspects of mental health CAs, while youth were concerned about the privacy and confidentiality of their sensitive conversation data.

Conclusions: Our study highlights the need for researchers to continue to work together to align evidence-based research on mental health CAs for youth with lessons learned on how to best deliver these technologies to youth. Our review brings to light mental health CAs needing further development and evaluation. The new trend of large language model–based CAs can make such technologies more feasible. However, the privacy and safety of the systems should be prioritized. Although preliminary evidence shows positive trends in mental health CAs, long-term evaluative research with larger sample sizes and robust research designs is needed to validate their efficacy. More importantly, collaboration between youth and clinical experts is essential from the early design stages through to the final evaluation to develop safe, effective, and youth-centered mental health chatbots. Finally, best practices for risk mitigation and ethical development of CAs with and for youth are needed to promote their mental well-being.

Introduction

Background

Conversational agents (CAs; often called chatbots) are systems with the ability to interact with users using natural human dialogue [1]. Examples of CAs range from customer service chatbots that are available on commercial websites and social media platforms to open-domain, text-based chatbots, such as OpenAI's GPT-4 and Microsoft's Bing, and voice assistants, such as Apple's Siri and Amazon's Alexa. Driven by advances in the underlying language models, CAs enable 2-way interactive communication with the user and have been applied in multiple domains, including health care [2]. Particularly, CAs are seen as an innovative digital medium to communicate information and resources with younger users, given their high digital literacy and familiarity with chat applications [3]. CAs are now increasingly used by youth for interactive knowledge discovery on sensitive topics, including mental health [4].

Youth are in a unique transitional phase between childhood and adulthood. Following the definition provided by the United Nations, in this review, we use the term *youth* to refer to adolescents and young adults aged between 15 and 24 years. Recent reports show that youth are increasingly experiencing mental health issues these days. For instance, from 2009 to 2019, the proportion of high school students reporting persistent feelings of sadness or hopelessness increased by 40%; between 2007 and 2018, suicide rates among youth aged between 10 and 24 years in the United States increased by 57% [5]. However, they are hesitant to seek professional help on mental health topics due to societal views toward the topics themselves and perceived public stigma and embarrassment associated with help seeking in those topics [6]. With the ability for humanlike interactions with the user, mental health CAs have been developed to support their unique informational, educational, and therapeutic needs related to mental health topics.

Existing systematic reviews on mental health CAs shed light on the potential of CAs to provide relevant information and resources via interactive communication. For instance, mental health CAs are used to deliver prewritten therapeutic and training content for people with depression and autism [7]. A systematic review of 13 studies on the outcome of mental health treatment delivered by mental health CAs found reductions in psychological distress after interacting with the mental health CAs [8]. However, another meta-analysis found conflicting results regarding the effect of chatbots on the severity of anxiety and positive and negative affect [9]. A more recent analysis confirmed that CA-based mental health interventions are effective in improving various mental health conditions in the short term, while substantial long-term effects were not observed [10]; artificial intelligence (AI)–based mental health CAs showed a meaningful reduction in symptoms of depression and distress, with no substantial improvement in overall psychological well-being [11]. Consequently, the trends of the clinical effectiveness of mental health CAs in the existing literature are inconclusive.

A scoping review of 37 studies focused on user perceptions toward mental health CAs showed overall positive opinions toward the CAs such as usefulness and ease of use. At the same time, they found conversations with CAs to be shallow, confusing, or brief [12]. There are some systematic reviews on mental health CAs to support people with specific mental health conditions such as substance use disorder [13], depression and anxiety [14], and serious mental illness [15]. For instance, a systematic review of 7 studies involving CAs for assessing serious mental health illness (eg, major depressive disorder and schizophrenia spectrum disorder) found generally positive outcomes regarding CAs' diagnostic quality, therapeutic efficacy, and acceptability. However, they revealed a lack of standardized measures for evaluating CAs and insufficient representation of the pediatric population [15]. As such, reviews on mental health CAs are well established and provide important insights into the benefits and pitfalls of existing research on mental health CAs. However, little work has been done to explore the trends in research on mental health CAs for younger populations such as adolescents and youth.

Recently, Balan et al [16] conducted a scoping review of 25 studies on CAs designed to improve the emotional components of mental health (eg, depression and anxiety) of the young population and found that although usability outcomes are optimistic, the clinical effectiveness of CA-based mental health interventions remains inconclusive. While trends in therapeutic CAs to improve the emotions of young populations were studied, a comprehensive trend in research on mental health CAs with various goals (eg, informational and assessment) or social, behavioral, or cognitive aspects of mental health has not been studied in previous work. In addition, trends in design aspects (eg, CA role and characteristics) and evaluation outcomes beyond efficacy (eg, strength and weaknesses of CAs and ethics) were not addressed in previous work. Therefore, to fill the gap in the literature, we conducted a scoping review of 39 studies that focused on CAs to promote the mental health of youth. In this paper, we address the following research questions (RQs):

- RQ1: What are the characteristics of empirical research on mental health CAs designed for youth?
- RQ2: What are the design and computational considerations for mental health CAs for youth?
- RQ3: What are the evaluation outcomes reported in empirical research on mental health CAs for youth?

Objectives

The objective of this study was to synthesize the current literature on mental health CAs designed for youth to understand the trends in research, the design and computational aspects of the CAs, and the strengths and weaknesses of the current mental health CAs for youth. Following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement guidelines [17], we conducted a comprehensive

XSL•FO
RenderX

review of the existing literature on mental health CAs for youth. We describe this process in the subsequent sections.

Methods

Systematic Literature Search Process

We initially searched the literature with the search string ("conversational agent" OR "chatbot") to explore synonyms of those terms used in the literature. Our initial search informed us of the various alternative terms used to describe CAs or chatbots, which allowed for a more inclusive and thorough search. Our final search string consisted of the following keywords: ("conversational agent" OR "chatbot" OR "virtual agent" OR "virtual assistant" OR "AI assistant" OR "AI bot" OR "social bot") AND (teen OR adolescent OR youth OR young) AND (mental).

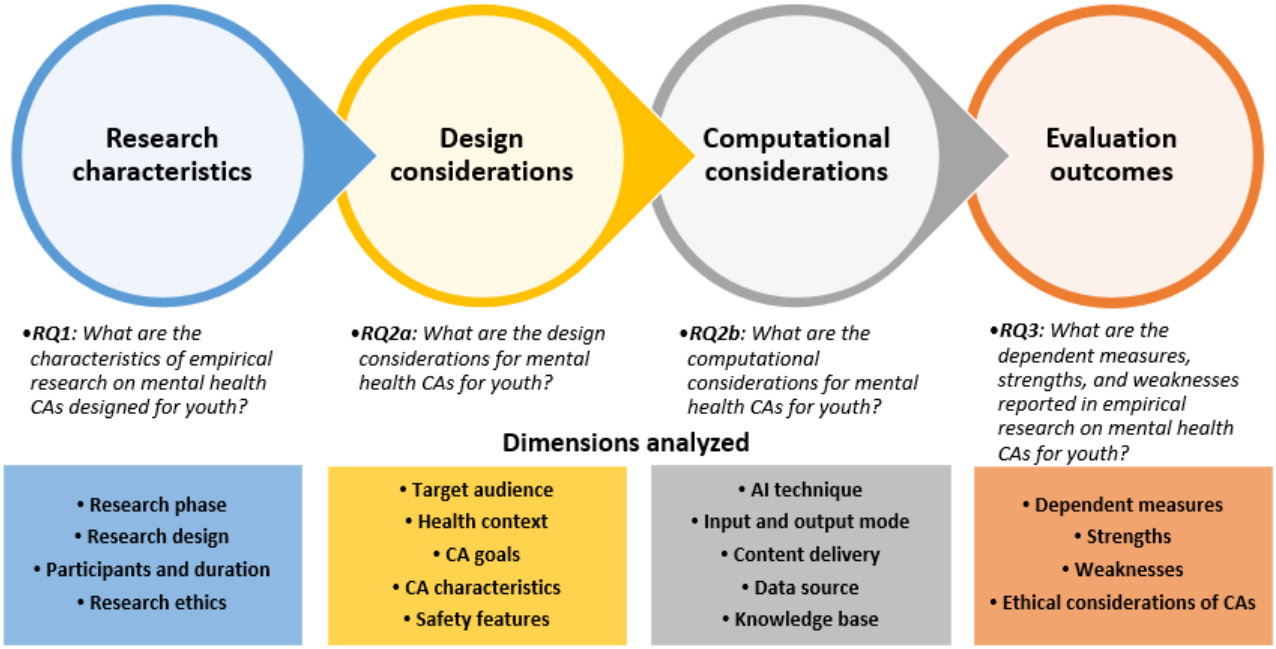
Then, we identified 4 relevant and cross-disciplinary databases that included research on CAs in the health care domain, including ProQuest, Scopus, Web of Science, and PubMed. The same search string was used to retrieve articles across the 4 databases. The searches were limited to journal articles, conference papers, and book chapters written in English. The publication date was not specified. The initial search resulted in retrieving 224 articles from the 4 databases (ie, Web of Science: n=59, ProQuest: n=31, Scopus: n=85, and PubMed: n=49) in February 2024.

Inclusion and Exclusion Criteria

The purpose of this work was to review mental health CAs designed for youth. Therefore, we included full research papers that (1) were peer reviewed (journal articles and refereed conference proceedings were both included); (2) discussed CAs for providing information or resources or support on mental health topics; (3) discussed CAs designed for youth, adolescents, or young adults; (4) described CAs that permitted 2-way interactions that were fully automated (ie, without human mediation); and (5) included empirical results.

We excluded papers that (1) were nonfull or nonreviewed, such as works in progress, extended abstracts, reports, reviews, and meta-analyses; (2) did not include mental health topics (eg, physical health); (3) included forms of 1-way communication and human-mediated communication; (4) did not consider youth population; (5) did not primarily focus on the CAs (eg, explored CAs as one of the features of the mobile health apps); (6) did not focus on natural human dialogue as a primary communication mode for a 2-way interaction (eg, embodied CAs and facial recognition); and (7) were purely theoretical analyses or a review of existing studies.

Data Screening



We first removed the duplicate entries from 224 articles. After removing 94 duplicates, we had 130 unique entries. Screening of articles for inclusion was performed in 2 stages. First, we screened the articles by reviewing titles, abstracts, and keywords. Next, we conducted relevancy coding by reviewing full texts based on the abovementioned criteria. The initial screening using titles and abstracts led to the removal of 54 articles. With the 76 remaining articles, we proceeded with the relevancy coding of the full texts. Through this relevancy coding process, 42 articles were removed, and a set of 34 articles were processed for cross-reference. To identify additional relevant papers that were not identified in our initial search, we cross-referenced the citations of 34 articles. Through this cross-reference process, we identified 5 relevant articles to include in our analysis. After 1 more iteration of the cross-reference process, no additional relevant papers were identified, which suggested that we reached a saturation point. The final number of articles that were included in our literature review was 39.

Data Analysis Approaches

We conducted a thematic analysis to identify major themes and trends in our dataset. We leveraged an iterative approach to our thematic analysis, which involved refining the codes as we gained a deeper understanding of the data. JKP carried out the coding, supported by frequent check-ins with PW for additional expertise on the subject matter. Furthermore, to ensure face validity, VKS quality-checked the coding during the writing of the results. For grounded thematic analysis, we analyzed the papers to identify codes for different dimensions aligning with our RQs. We familiarized ourselves with the literature identified and generated the initial codes. With the initial codes, we coded 20% (8/39) of the dataset and reviewed the codes to ensure that they were representative of our dataset. Once we finalized the codes, we coded the entire dataset. Multiple codes were sometimes assigned to the same paper where necessary. Through the grounded thematic analysis, we identified major dimensions for the characteristics of empirical research on mental health CAs for youth (ie, RQ1), design and computational considerations of mental health CAs for youth (ie, RQ2), and the evaluation outcomes of empirical research on mental health CAs for youth (ie, RQ3). Figure 1 is an overview of the framework, including RQs, dimensions, and codes that were analyzed in this review to understand the trends in research on mental health CAs for youth.

Results

Overview

Overall, we included 39 studies in this scoping review [4,18-55]. Figure 2 presents the data screening process following the PRISMA guidelines (see Multimedia Appendix 1 for the PRISMA Extension for Scoping Reviews checklist). The reviewed studies were published between 2011 and February 2024. Most of the studies (28/39, 72%) were published between 2021 and 2024, with a few published before 2021 (11/39, 28%).

The reviewed studies were conducted in various regions, including the United States (8/39, 20%); New Zealand (5/39, 13%); Australia (4/39, 10%); the United Kingdom, China, and Brazil (3/39, 8% each); Germany, Italy, and Norway (2/39, 5% each); and Argentina, Bangladesh, Belgium, Canada, the Netherlands, the Philippines, and Portugal (1/39, 3% each).

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart for the study.

Characteristics of Empirical Research on Mental Health CAs for Youth

Most of the Empirical Research Involved Development and Summative Evaluation; Less Work Involved Formative Evaluation to Redesign Mental Health CAs With and for Youth

Most of the reviewed studies (36/39, 92%) included summative evaluation, followed by development (29/39, 74%), design (15/39, 38%), and formative evaluation (15/39, 38%; Table 1 and Multimedia Appendix 2 [4,18-55]). All empirical research included an evaluative phase to assess the mental health CAs for youth. Most of the studies included summative evaluation (36/39, 92%) and formative evaluation (15/39, 38%). In 31% (12/39) of the studies, both formative and summative evaluations were conducted. The term formative and summative evaluations originally referred to methodological frameworks for evaluating instructional materials [56]. In human-computer interaction research, summative evaluation is the evaluation of a design after it is nearly complete, often used during field testing. Formative evaluation is conducted during user interface development, often iteratively to achieve the desired usability level [57].

In the formative evaluation work that we reviewed, researchers interacted with youth populations to gain early feedback on the initial CA design through interviews, focus groups, and design workshops [31,32,49]. In most of the studies that included formative evaluation (12/15, 80%), summative evaluations were followed after the iterative design process. For instance, Ludin et al [33] conducted a formative user testing with school guidance counselors, clinicians, and youth to learn about the issues youth faced during the COVID-19 pandemic and lockdowns. The youth's opinions from the formative evaluations were used to inform the ongoing content iteration of the prototypes. Once the prototype was developed, the authors conducted a summative user testing to assess the usability and acceptability of the chatbot with 127 youth participants [33].

[a]CA: conversational agent.

Research on Mental Health CAs Was Conducted With a Small Numbers of Adolescents and Young Adults Without Mental Health Conditions for <4 Weeks

Participant Group

Most of the participants in the reviewed studies were adolescents (16/39, 41%) aged between 12 and 18 years and young adults (14/39, 36%) aged >18 years. In fewer studies, the participants were youth (9/39, 23%) aged between 14 and 25 years. Overall, in a slightly higher proportion of the empirical studies, the participants were general youth (21/39, 54%) compared to at-risk youth (18/39, 46%), such as those who are experiencing depression [51], anxiety [18], body image concerns [23], and alcohol abuse [20].

The Number of Participants

The number of youth participants ranged from a minimum of 3 young adults with autism to explore the acceptability of cognitive behavioral therapy (CBT)–based mental health CA through in-depth interviews [53] to a maximum of 798 adolescents to evaluate the effectiveness and user engagement

XSL•FO
RenderX

through a survey [48]. In most of the research, the number of participants was <100 (28/39, 72%), with few studies having participants between 100 and 200 (6/39, 15%) and >200 (2/39, 5%).

Duration of CA Interaction

Youth participants interacted with mental health CAs for a minimum of 30 minutes [20,25] to a maximum of 16 weeks [47]. In most of the reviewed studies, participants interacted with CAs for <4 weeks (12/39, 31%) or once (6/39, 15%). In fewer studies, participants interacted with CAs for 4 to 8 weeks (5/39, 13%) or 9 to 16 weeks (1/39, 3%). In general, short-term engagement with CAs was for user testing to assess user experience and acceptability. The long-term engagement with CAs was for the experiments to assess the effectiveness of CAs in reducing mental health conditions.

Most of the Research Involved User Testing or Experiments to Evaluate Mental Health CAs

User Testing

The most prevalent research design used in the empirical studies was user testing (18/39, 46%) to assess user engagement and user experience of the CAs. For instance, in a study by Beilharz et al [23], 17 adolescents and 8 parents or caregivers in Australia participated in focus group interviews to evaluate the acceptability, ease of use, and design of the *KIT* prototype, a CA designed to support people with concerns about body image and eating issues. In another study, Gabrielli et al [37] conducted a user test with 21 adolescents over 4 weeks in Italy to assess the user experience and perceived value of content delivered by mental health CAs. Surveys with Likert scale measures and open-ended questions were used to evaluate overall usefulness, ease of use, the value of the content, and suggestions for improvement [37].

Experiment

Another prevalent research design was an experiment (18/39, 46%), which was conducted to explore the effectiveness of CAs in reducing mental health conditions. With the randomized controlled trial design, for instance, young adults who completed active cancer treatment in 5 years were randomly assigned to either immediate access to mental health CA (ie, experimental group) or access to only daily emotion ratings and access to full chatbot content after 4 weeks (ie, control group). After 4 weeks, participants in the experimental group reported an average reduction in anxiety, while the control group reported an increase in anxiety [43]. With noncontrolled experiments, for instance, 105 young adults interacted with the same mental health CAs for 15 days and completed the surveys asking about their mental health conditions (ie, Patient Health Questionnaire [PHQ]) before and after the 15-day intervention period. The comparison of the average survey scores before and after the intervention confirmed that the overall scores decreased after interacting with the mental health chatbot [36].

Research Ethics Such as Institutional Review and Consent Were Addressed in the Majority of Research; However, Only a Few Research Considered Data Privacy and Safety of Youth Participants

In most of the reviewed studies, authors explicitly stated that they acquired participant consent (26/39, 67%) and that the studies were approved by their institutional review board (26/39, 67%). Beyond institutional review and participant consent, which are mandatory in many institutions, in some studies, authors addressed considerations for privacy or confidentiality of youth's digital trace data related to mental health (8/39, 20%). In only a small portion of the reviewed studies (4/39, 10%), the authors provided support to promote the safety of youth participants in empirical research in the mental health context. For instance, in the study by Nicol et al [22], there was safety monitoring provided by the study team by tracking the digital PHQ-9 assessment over 12 weeks. When the PHQ-9 assessment results indicated suicidal ideation, the principal investigator contacted the participant's primary care providers to discuss the next steps regarding the assessment of suicide risk. By the end of the 12-week study, 56% (10/18) of the participants triggered at least 1 alarm to assess for suicidal ideation [22]. In another study by Liu et al [47], participants were informed that professionals would intervene by telephone (ie, mental assistance hotline) when the participants reported that they needed emergency psychological assistance. In 10 papers, research ethics were not mentioned. None of the reviewed papers mentioned risk mitigation plans and mandated reporting or provided critical reflections on best practices for working with youth in the mental health context.

Design Considerations of Mental Health CAs for Youth

Most of the Mental Health CAs Were Designed for Older and General Youth Populations

In most of the studies, the target audience of the CAs were youth or young adults (22/39, 56%), adolescents (12/39, 31%), and college students (6/39, 15%). In most of the studies (27/39, 69%), CAs were designed for general youth populations. In a small proportion of the reviewed studies (12/39, 31%), the CAs were designed for at-risk youth populations (Table 2 and Multimedia Appendix 3 [4,18-55]).

[a]CA: conversational agent.

Within those 12 studies, 5 (41%) studies focused on designing mental health CAs for young adults with depressive symptoms [18,19,29,51,52]. Few studies focused on CAs to promote the mental health of adolescents with type 1 diabetes [26]; adolescents with body image and eating issues [23]; young adults being treated for cancer [43]; youth at risk of HIV and sexually transmitted infections [30]; young adults from immigrant and refugee communities [49]; lesbian, gay, bisexual, transgender, queer, or questioning (LGBTQ+) youth [50]; and young adults with autism [53]. There was a trend in which the number of mental health CAs designed for at-risk youth increased, while the number of CAs for general youth decreased (Figure 3). Overall, most of the mental health CAs were designed for older (22/39, 56%) or general (27/39, 69%) youth populations, with the current trend toward designing CAs for youth who are at risk of mental health conditions.

Figure 3. Target audience of the mental health conversational agents (CAs) by year (n=38).

Mental Health CAs Are Designed to Promote the General Mental Well-Being of Youth as Well as Help Alleviate Mental Health Symptoms of Depression, Anxiety, and Stress

Health Context

Within the studies that focused on mental health CAs for youth, most of the CAs were designed to promote the general mental health or well-being of youth (15/39, 38%; eg, by promoting life skills and resilience), followed by those aimed to reduce depression (12/39, 31%), anxiety (9/39, 23%), and stress (8/39, 20%). There are a few papers that focused on mental health CAs to address the issues of substance use (3/39, 8%; ie, alcohol and drug abuse) [20,28,42], body image (2/39, 5%) [23,48], and phone addiction (1/39, 3%) [21]. Overall, nearly half (19/39, 48%) of the existing research on mental health CAs focused on supporting youth with symptoms of depression, anxiety, and stress.

CA Goals

Most CAs (25/39, 64%) for mental health were designed to help alleviate mental health symptoms such as depression and anxiety, followed by educational or training content (22/39, 56%) to promote mental health and informational support on mental health topics (15/39, 38%). Some mental health CAs were designed to assess mental health symptoms (10/39, 26%) and monitor mental health conditions (2/39, 5%). Two mental

XSL•FO
RenderX

health CAs were designed to promote behavior changes such as reduced screen time [21] and reduced alcohol consumption [41]. Overall, in most of the work, the CAs were designed to help alleviate youth's mental health symptoms or to provide educational intervention to promote youth's mental well-being, while less work has been done on CAs for informational support or the assessment or monitoring of youth's mental health condition.

Mental Health CAs Were Designed to Be Life Coaches or Older Peer Mentors With Friendly and Empathetic Tones, With Few Options to Personalize Agent Characters

CA Role

In 51% (20/39) of the studies, the CA role was mentioned. In many of those studies (11/39, 28%), the mental health CAs were designed as older peers or younger coaches to guide youth with therapeutic modules and provide youth with information to promote mental health. For instance, a mental health CA was designed to be a young person who messages the user once a day. The interaction was designed to be a brief conversation with a friend who checks in and has a helpful tip or an anecdotal story to share to help reduce stress [38]. In other studies, mental health CAs were designed to provide formal health professional–like support (7/39, 18%), for instance, that emulates therapists who encourage patients to explore their problems by asking questions to provide personalized mental health support [52].

CA Characteristics

Meanwhile, most mental health CAs were designed to provide friendly (16/39, 41%) or empathetic (11/39, 28%) responses. For instance, in response to loneliness reflected in users' input, the chatbot replied, "I'm so sorry you're feeling lonely. I guess we all feel a little lonely sometimes," or if participants showed excitement in their input, the chatbot replied, "Yay, always good to hear that!" [18]. In 10% (4/39) of the studies, mental health CAs were designed to be culture specific. For instance, in a study by Ludin et al [33], researchers collaborated with groups of Indigenous and non-Indigenous people (ie, Māori and Pākehā) in New Zealand to cocreate mental health CA called "Aroha," meaning "caring and kind" in their native language. The mental health strategies and activities were designed for and targeted Māori youth and their families [33]. A few mental health CAs were gender specific (3/39, 8%) or designed to provide short and simple answers (2/39, 5%).

CA Characters and Avatars

In most of the studies (33/39, 85%), options to personalize mental health CA characters were not addressed. In a few studies (6/39, 15%), features to support personalization of CA characters were discussed. For instance, for the CA to promote youth resilience, the avatars were designed as older peers with users' choice of gender and ethnicity representative of the target population [32]. In another study, the authors designed the body image CA with an option to choose between male and female versions of the CA avatar [48]. Some studies designed mental health CAs in which users can customize their avatars [52] and app appearance [53]. In 1 study, youth preferred to choose from 3 to 4 characters with variations of gender, avatar, age, and social role (ie, health professional vs younger coach-like) instead of personalizing each aspect separately [19].

The Majority of the Mental Health CAs Did Not Have the Safety Features in Place

Most of the studies (21/39, 54%) did not address the safety features of the designed mental health CAs. In 46% (18/39) of the studies, safety features were discussed, including a reminder that users are interacting with chatbots, not human experts, and chatbots are not replacements for health care providers or places for seeking help (12/39, 31%). There were safety features to provide emergency contact (10/39, 26%), such as crisis hotlines and those that refer to health professionals. In 2 studies, alert features were implemented to notify a trusting adult or providers when a youth was identified as a risk to themselves or others [22,31]. For instance, if trigger words such as self-harm, suicide, death, dead, kill, or die were used by youth, the alert feature to notify adults was activated. The alert recipient is a primary support contact who was identified and confirmed during the initial consent process [31]. Overall, safety features of mental health CAs were discussed in less than half of the reviewed articles (21/39, 54%).

Computational Considerations of Mental Health CAs for Youth

Most of the Mental Health CAs Were Prototypes Built Upon Existing Mobile Chat Apps

Maturity of the Device

In most studies (26/39, 67%), mental health CAs were prototypes. In 18% (7/39) of the studies, CAs were developed as fully functioning systems, and in 20% (8/39) of the studies, researchers evaluated existing systems developed in other studies. In 1 study [24], CAs were explored as concepts without having actual systems (Table 3 and Multimedia Appendix 4 [4,18-55]).

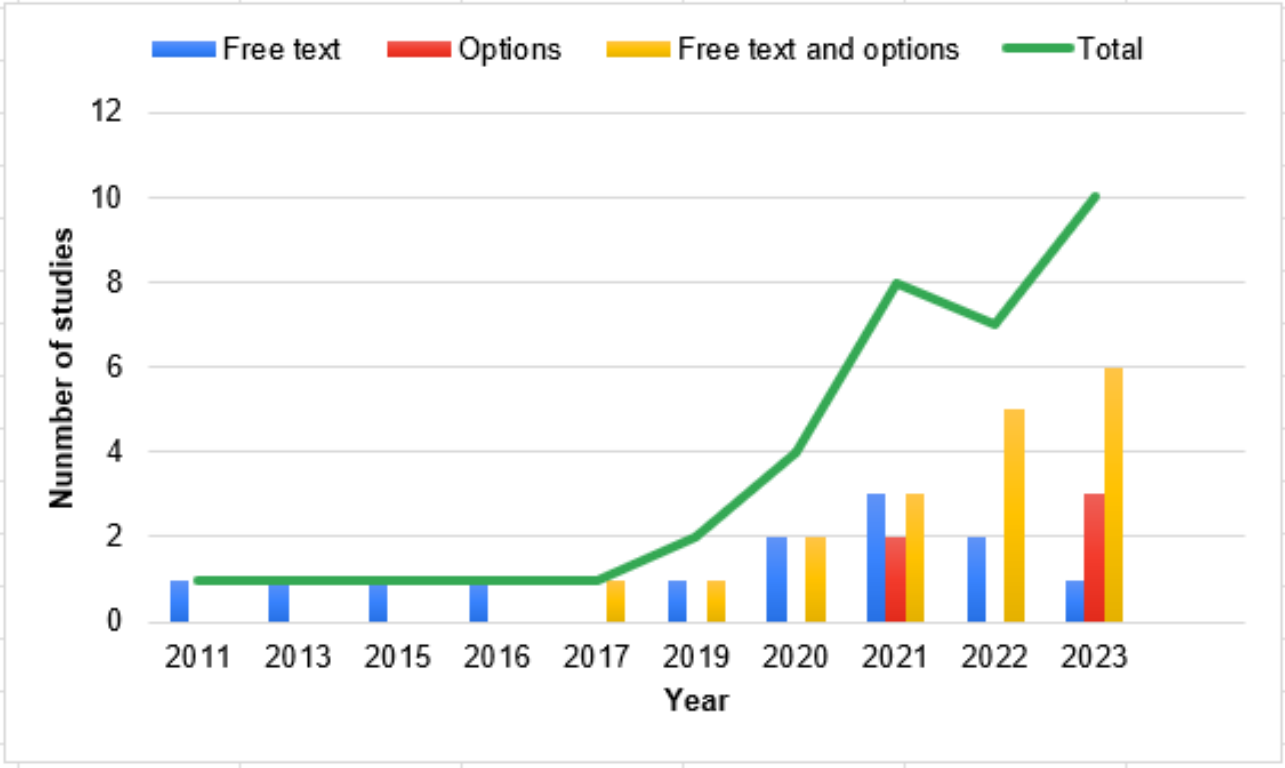
Delivery Channel



Mental health CAs were delivered via diverse channels. Most CAs were delivered through mobile apps (16/39, 41%), followed by web applications (11/39, 28%) and desktop applications (6/39, 15%). In 28% (11/39) of the studies, CAs were made available on >1 channel. In many studies (16/39, 41%), CAs were delivered using existing chat applications such as Facebook Messenger (eg, [32,33,36]), WhatsApp [51], Windows Live Messenger [42], WeChat [47], and Telegram [27].

All CAs Supported Text-Based Input; Most CAs Supported Multimedia Output

Input Modality

In all the reviewed studies (39/39, 100%), mental health CAs supported text as the primary mode of input. In 5% (2/39) of the studies, mental health CAs supported audio input along with textual input [47,51]. For text-based CAs, by extracting keywords related to mental health such as depression and anxiety from user inputs, CAs extract necessary features to develop different classification models or assess their sentiment [46,52]. For voice-based CAs, the key components include the use of automatic speech recognition and natural language understanding to comprehend users' input [47]. Text-based and voice-based chatbots are similar in their design; however, text-based CAs do not include automatic speech recognition components and instead rely on text as the primary modality of input and output. In most of the reviewed studies, CAs supported free text along with quick options (eg, "yes" or "no") as user input (19/39, 49%), rather than free text only (13/39, 33%) or quick options only (5/39, 13%). There was a trend in which the proportion of CAs that supported free text along with quick options as user input increased, while the proportion of CAs that supported free text only as user input decreased over time (Figure 4).

Figure 4. Input mode of the mental health conversational agents (CAs) by year (n=37).

Output Modality

All the CAs (39/39, 100%) supported text as the primary mode of output. In 64% (25/39) of the studies, it was indicated that CAs support multimedia outputs. In addition to textual output, most CAs (21/39, 54%) supported image output in the form of an emoji, moving images in graphics interchange format, infographics, and animated CA avatars. CAs also provided outputs in the forms of video (12/39, 31%), audio (7/39, 18%), and games (6/39, 15%). In many of the reviewed studies (12/39, 31%), CAs supported >2 types of output (eg, text, image, and video).

Many CAs Used Multiple AI Techniques: Free-Textual Inputs Were Processed via Natural Language Processing, While Prewritten Content Was Delivered via Rule-Based Programming

In many studies that we reviewed, the CAs used multiple AI-based computational methods depending on the specific section or feature. Free-textual input from users is processed using natural language processing (NLP), which processes natural language datasets, such as text and voice, using statistical and machine learning models to recognize, understand, and generate text and speech [58]. Accordingly, the AI approaches that were most frequently referred to in the reviewed papers were NLP (19/39, 49%). Meanwhile, quick options are implemented using rule-based methods. Therefore, following the NLP, the second most frequently referenced technique in the reviewed papers was rule-based approaches (15/39, 38%). Mostly, the CAs deliver prewritten conversational lessons via

XSL•FO
RenderX

rule-based programming. However, they use techniques such as NLP at certain points in the tree to determine routing to subsequent conversational nodes (eg, [18,26,38,44,54,55]). For instance, NLP is used to process users' input so that CAs can trigger prewritten therapeutic content [47] or further crises and mental health support services [26] to youth. There were a few papers in which CAs relied solely on decisions made by decision trees or rule-based programs (eg, [23,25,50,51]). With rule-based CAs, once users choose among the given options (eg, yes or no and choosing numbered options), the CAs trigger and provide the most relevant prewritten response. With the CAs that are built solely upon rule-based or decision tree techniques, there is no space for users to type free text to have conversations. None of the mental health CAs we reviewed were built upon generative AI such as large language models (LLMs).

Most Mental Health Content Was Delivered in Flexible Ways, Considering User Preferences and Autonomy

We found 3 types of CA content delivery approaches in the reviewed studies: structured, semistructured, and flexible. In most of the studies (25/39, 64%), mental health CAs implemented a flexible model. With a flexible model, CA contents are delivered depending on users' input or users have options to choose which content to navigate. For instance, CAs first detect stress levels from users' input; then, based on the stress detection result as well as the users' chatting sentence type, the CA chooses an appropriate answer from the knowledge base database [44] or users have options to choose what type of CBT-based therapy they would like to perform [53].

In 20% (8/39) of the reviewed studies, CA content was delivered in a planned and structured way. With the structured models, CA contents are prewritten and automatically delivered to users via rule-based programming for a predefined period (ie, from a few days to a few weeks). For instance, Williams et al [38] designed a mental health CA in which daily conversations and modules are prewritten for 21 days, and the CA guides them through daily activity. Particularly, in half of the papers, the structured CA content was designed to treat mental health conditions of at-risk youth, including adolescent or young adults with depressive symptoms [29,51], youth treated for cancer [43], and adolescents with type 1 diabetes [26].

In a small portion of the reviewed studies (3/39, 8%), CA content was delivered in a semistructured way [32,48,49]. For instance, the mental health CA guided the user through 10 daily sessions that introduced the psychological content modules. The same core psychological concepts (eg, psychoeducation, emotional regulation, and problem-solving) are present for all users, while users can specify their preferences for the content that they feel is most relevant to them [49]. In another study, the mental health content spanning 21 days was structurally designed for users to engage with the CA once a day with a choice of a motivational quote, joke, or an entry into a gratitude journal [32].

Mental Health Content Was Built Upon Evidence-Based Expert Knowledge of Mental Health

In all studies, primary data sources were expert knowledge (39/39, 100%). In almost half of the reviewed studies (19/39, 49%) on mental health CAs, the CA content was developed based on CBT, one of the most extensively studied evidence-based psychotherapy for a wide range of mental health issues such as depression, stress, and general mental well-being [59]. For instance, building upon the principles of CBT, He et al [29] designed 7 modules of mental health CA (ie, cognitive distortions, self-esteem, mindfulness meditation, mental energy, natural connection, self-help, and loneliness) for youth participants to complete 1 module per day during the 1-week intervention period. Besides CBT, mental health CA content was based on positive psychology (7/39, 18%) and other therapeutic content (7/39, 18%), such as interpersonal psychotherapy [19,22], acceptance commitment therapy [23], perceptual control therapy [46,52], self-compassion program [26], and microintervention to improve body image [48]. Some mental health CA content was built upon inputs from school health service experts or counselors (6/39, 15%) and positive answers collected from the web forum [44]. In some studies (4/39, 10%), the source of mental health CA content was not specified.

In summary, we found that most mental health CAs were designed as older peers to provide therapeutic and or educational content to promote youth mental well-being. Most of the CAs were built upon multiple computational methods to flexibly deliver prewritten and evidence-based mental health content. Text was the primary communication mode, with the majority supporting multimedia output. Textbox 1 presents a summary of the key trends in the design and computational aspects of mental health CAs for youth.

XSL•FO
RenderX

Textbox 1. Key trends of the design and computational aspects of mental health conversational agents (CAs) for youth.

Aspects and key trends

- Design
  - Target audience: designed for older and general youth populations
  - Health context and goals: designed to help alleviate mental health symptoms or to promote general mental well-being
  - CA role and characteristics: designed to be life coaches or older peer mentors with friendly and empathetic tones
  - Personalization: personalization of CA characters was not supported in most of the studies
  - Safety features: safety features were discussed in less than half of the studies
- Computational
  - Artificial intelligence technique: multiple computational methods (eg, natural language processing and rule based) depending on the specific features
  - Input modality: all CAs were text based, with a couple of them supporting audio input along with textual input. Most CAs supported free text along with quick options as user input
  - Output modality: all CAs supported text as the primary mode of output, with the majority supporting multimedia outputs
  - Content delivery: CA content was delivered in flexible ways, considering user preferences and autonomy. In some cases, prewritten therapeutic content was delivered in a structured manner
  - Data source: CA content was based on well-established evidence-based expert knowledge

Evaluation Outcomes Reported in Research on Mental Health CAs for Youth

Most Studies Focused on Evaluating the Effectiveness and Acceptability of CAs

Effectiveness

In most of the evaluative research (17/39, 44%), the outcome variable was the effectiveness of mental health CAs (Table 4 and Multimedia Appendix 5 [4,18-55]). In those studies, prevalidated scales such as the PHQ and Generalized Anxiety Disorder Scale were used to measure the mental health conditions of the youth before and after the use of mental health CAs. For instance, to evaluate the effectiveness of mental health CA *Tess*, Klos et al [45] conducted a randomized controlled trial with 181 Argentinian college students. The PHQ-9 [60], a questionnaire comprising 9 items that evaluate the frequency and severity of depressive symptoms, and the Generalized Anxiety Disorder-7 [61], a 7-item scale that evaluates the frequency and severity of anxious thoughts and behaviors, were used to measure the changes in participants' mental health [45].

Table 4. Evaluation outcomes of mental health CAs[a] for youth (N=39).

Dimensions and codes	Value, n (%)	Key trends
Dependent measures		Most studies focused on evaluating the effectiveness and acceptability of CAs
Effectiveness	17 (44)	
Acceptability	17 (44)	
Usability	14 (36)	
User engagement	10 (26)	
Validity or accuracy	2 (5)	
Personalization	1 (3)	
Strengths		Easy access to useful mental health information communicated through friendly, empathetic, and humanlike responses was the major strength of mental health CAs
Accessibility	14 (36)	
Useful content	14 (36)	
Interactivity or engaging	12 (31)	
Anonymity or confidentiality	7 (18)	
Empathetic or friendly responses	6 (15)	
Easy to navigate	4 (10)	
Humanlike interaction	2 (5)	
Nonjudgmental	2 (5)	
Weaknesses		Limited or repetitive content, lack of human language understanding, and robotic responses were the critical weaknesses of mental health CAs
Limited responses or content	13 (33)	
Lack of natural language understanding	8 (21)	
Lack of personalized content	7 (18)	
Non-humanlike traits	7 (18)	
Textual information with jargon	5 (13)	
Inaccurate responses	5 (13)	
Data privacy and confidentiality	5 (13)	
Ethical considerations		Ethical considerations such as privacy, confidentiality, and safety of CAs were addressed in a few studies
Privacy and confidentiality	4 (10)	
Safety	1 (3)	

[a]CA: conversational agent.

Acceptability

Another most evaluated outcome of mental health CAs was acceptability (17/39, 44%). Overall, current mental health CAs were perceived as beneficial and acceptable by not only youth but also health professionals [4]. For instance, semistructured interviews with 3 young adults with autism showed that they considered the mental health chatbot novel and they would be interested in using such systems [53]. In a study by Mariamo et al [24], yes or no questions were associated with a lower likelihood of response compared to multiple-response choice questions and a higher likelihood of response compared to open-ended questions.

Usability

Next, the usability of mental health CAs was evaluated in 36% (14/39) of the studies. For instance, Williams et al [38] engaged with 124 young adults in New Zealand to evaluate mental health CAs with 21-day stress detox modules and found that youth appreciated the interactivity, accessibility, and chatbot design, particularly due to the visualized content as it is engaging. Similarly, a week-long exploratory study with 20 rural-living LGBTQ+ youth confirmed that youth appreciated the colorful design with multimedia content of *REALbot* as well as the conversational flow to first ask users' preferred names [50].

XSL•FO
RenderX

User Engagement

User engagement was also evaluated (10/39, 26%) through analyzing log data of human-CA interaction. For instance, Matheson et al [48] evaluated user engagement with the body image chatbot *Topity*, which was designed to deliver microinterventions for adolescents. The results from randomized controlled trials with 1715 Brazilian adolescents show that 79% of the participants completed the minimum intervention dose of 1 microintervention technique. In addition, most participants chose to receive guidance from a female avatar of Topity, compared to a male avatar [48].

Accuracy and Personalization

In a few studies, the accuracy or validity of mental health assessment (2/39, 5%) as well as personalization (1/39, 3%) were also explored. For instance, a month-long user test showed that the chatbot's stress detection module achieved a precision rate of 78.34% and a recall rate of 76.12% [44]. In terms of personalization of mental health CA, while both experts and youth emphasized the need for autonomy to flexibly choose or change a module instead of a fixed schedule, experts emphasized the importance of planned therapeutic modules in a fixed sequence [19].

Easy Access to Useful Mental Health Information Communicated Through Friendly, Empathetic, and Humanlike Responses Were the Major Strengths of Mental Health CAs

In 67% (26/39) of the reviewed studies, the strengths of current mental health CAs for youth were addressed. The most frequently mentioned strengths of mental health CAs were 24/7 availability (14/39, 36%), followed by useful information and therapeutic content (14/39, 36%) and the ability to have interactive and engaging conversations with CAs (12/39, 31%). In some studies, participants pointed to the strengths of mental health CAs, such as perceived anonymity or confidentiality (7/39, 18%), empathetic and friendly responses generated by CAs (6/39, 15%), and easy to navigate (4/39, 10%). In fewer studies (4/39, 10%), participants liked nonjudgmental responses generated by CAs [23,43] delivered in multimedia output [27,54]. They also liked the sense of caring and support [34,40,41] provided by CAs. Some participants appreciated humanlike interaction with CAs[27,49], perceived CAs as smart and trustworthy friends [37], and sometimes formed connections or friendships with bots [38]. They also liked the availability of personalized support [4,29] delivered by personalized CA avatars [19].

Limited or Repetitive Content, Lack of Human Language Understanding, and Robotic Responses Were the Critical Weaknesses of Mental Health CAs

In 62% (24/39) of the reviewed studies, the weaknesses of the current mental health CAs were addressed. The most frequently addressed limitations in the reviewed studies are limited or repetitive content provided by CAs (13/39, 33%), lack of understanding of human input (8/39, 20%), and lack of personalized content (7/39, 18%). Some of the limitations of mental health CAs were related to non-humanlike traits (7/39, 18%), such as too fast responses generated by CAs [30,41], lack of empathy in their responses [37,39], lack of trust toward nonhuman agents [35], a feeling of loneliness or disconnect when interacting with a bot [38], and CAs being robotic [50,54] and not smart enough [50]. Some youth found CA content with too much textual information with jargon or inaccurate or unclear responses generated by CAs hard to understand (5/39, 13%), while some shared concerns for confidentiality and privacy of sensitive information (5/39, 13%, respectively). In some studies, participants expressed difficulties with the free-text input mode as they found it hard to express their feelings [52] and utterances [20] rather than speak naturally. In a few studies, technical limitations such as overall technical immaturity [29,41] and susceptibility to changes in platform policies and bugs [51,54] were addressed. Some of the potential safety concerns addressed in the reviewed studies were increased screen time [22], overreliance on machines over human support [4,22], risk of missing imminent risk [22,51], and age-appropriateness of CA content [25]. Table 5 shows a summary of the strengths and weaknesses of mental health CAs reported in the reviewed studies.

Table 5. Mapping of the strengths and weaknesses of mental health CAs[a] for youth by dimension.

Dimensions	Strengths	Weaknesses
CA characteristic	Empathetic and friendly responses	Too fast responses without empathy
CA content	Useful information or therapeutic content	Inaccurate or unclear responses
AI[b] technique	Interactive and engaging conversations	Limited or repetitive content and lack of understanding of human input
Input mode	Easy to start a conversation	Difficulties with terming the queries
Output mode	Multimedia output	Too much textual information with jargon
Personalization	Availability of personalized support	Lack of personalized content
Privacy and confidentiality	Perceived anonymity or confidentiality	Concerns for the privacy of sensitive information
Safety	Sense of caring and support via humanlike interaction with CAs	Potential for overreliance on CAs over human support and risk of missing imminent risk

Ethical Considerations Such as Privacy, Confidentiality, and Safety of Mental Health CAs Were Addressed in a Few Studies

Most of the reviewed studies (35/39, 90%) did not address the ethical aspects of mental health CAs. In 10% (4/39) of the included studies, ethical considerations such as privacy, confidentiality, and safety of CAs were addressed [4,22,30,35] as part of their empirical findings. For instance, safety was assessed at 2, 4, 8, and 12 weeks by parents' reports on any hospitalizations or emergency department visits made by their child for depression- or anxiety-related problems. By the end of the 12-week experiment, 1 parent from the intervention group reported that their teen was seen in an emergency department and discharged to home [22], indicating the potential safety concerns and the need for features to ensure the safety of youth. Meanwhile, in 1 study, ethical issues (eg, privacy and confidentiality, efficacy, and safety of CAs) related to mental health CAs were discussed as the primary focus of the study. Through the group discussions with youth aged between 14 and 18 years in the United Kingdom, the authors highlighted youth's concerns about mental health CAs related to their personal information. Their recommendations for designing ethical mental health CAs include (1) providing clear and transparent communication about the systems' privacy arrangement and limitations, (2) informing users of the extent to which the chatbots are evidence based and empirically tested, and (3) ensuring that automated chatbots have systems in place to prevent overreliance and encourage users to seek human support when needed [39]. Overall, more discussion on ethics standards and critical reflections on mental health CAs for the youth is needed.

Discussion

Overview

In this scoping review, we identified 39 studies that focused on CAs designed to support the mental health of youth. In the subsequent sections, we discuss the implications of our findings and outline directions for future research. Finally, we provide recommendations for designing youth-centered, effective, and safe CA systems to support the mental health of youth.

Principal Findings

Mental Health CAs That Can Support Diverse Youth With a Variety of Mental Health Issues Are Needed

In most of the reviewed studies, the target audience of mental health CAs was general youth, with a recent trend toward designing mental health CAs for at-risk youth populations. According to 2021 statistics, growing numbers of youth are at risk of poor mental health outcomes. For instance, nearly half (45%) of LGBTQ+ students seriously considered attempting suicide—far more than heterosexual students [62]. Accordingly, the US Surgeon General set an agenda to prioritize promoting the mental health of at-risk youth populations, such as racial, ethnic, sexual, and gender minority youth; individuals from lower socioeconomic backgrounds; youth with disabilities; youth involved in the juvenile justice system; and other groups [5]. Therefore, future work is needed to design and implement CAs to support the mental health of youth considered vulnerable. In addition, we found that most mental health CAs were designed to reduce symptoms of depression, anxiety, and stress, while only a few were designed to provide support for body image, phone addiction, substance use, and other mental health issues. A recent report shows that youth are increasingly experiencing diverse mental health issues, including attention-deficit/hyperactivity disorder, eating disorders, body image, suicide, and self-harm [5,62,63]. Therefore, mental health CAs that can support youth with a variety of mental health issues are needed.

Multimodal Input and Output Are Needed to Designing Mental Health CAs That Are Inclusive of Youth With Diverse Communication Needs

In terms of user input, all mental health CAs supported textual input, with very few supporting voice-based output. In most of the reviewed studies, mental health CAs supported free text along with quick options as user input, with a few supporting quick options only. Previous research showed that rule-based CAs with quick options are perceived as restricted in offering personalized advice, leading to low trust in the effectiveness of CAs in providing advice on sensitive topics [64]. Therefore, providing options to freely type queries could benefit youth to explore diverse mental health topics. At the same time, it would still be useful to have quick options to choose from or autofill features as some of the health topics are difficult to term the queries from scratch [65]. In addition, as some youth were frustrated by the need to type their utterances rather than speak naturally [20], an option for voice-based input methods could be beneficial for supporting youth with diverse communication needs. When it comes to output mode, in almost two-thirds of studies, mental health CAs provided content in the form of images, audio, video, or games along with textual information. Multimedia content provided by mental and health CAs is important, as evaluative research confirmed that some youth found lengthy texts hard to understand [37,54] and preferred interactive and engaging multimedia content [27]. Hence, along with textual information, providing health information in a multimedia format is needed for designing engaging CAs for youth.

More Advanced AI Technologies (eg, LLMs) Are Needed to Provide Interactive and Engaging Mental Health Support for Youth

Overall, mental health CAs for youth are in their infancy, as many of the systems are developed as prototypes and are being evaluated for improvement. One of the major limitations found in evaluative research was limited content or responses provided by CAs as well as a *lack of personalized content* (eg, [25,27,33,38]). This is because many of the mental health CAs were built upon a rule-based approach in which predefined sets of responses are based on domain-specific knowledge. Early evidence showed that rule-based CAs were seen as *only providing advice about mainstream*, easily accessible information that was already available on the internet [64]. The evaluative studies we reviewed also demonstrated that youth perceived mental health content provided by rule-based CAs to be *repetitive* (eg, [29,31,38,49]). However, many of the existing

XSL•FO
RenderX

research studies implemented rule-based approaches to provide mental health information for youth. Another major technical limitation found in the evaluative research was the lack of human language understanding, followed by inaccurate responses from CAs. Taken together, our findings signify the need for implementing more sophisticated language models in mental health CA development. A recent review study found that CAs enhanced by advanced AI technologies outperformed rule-based CAs in managing psychological distress [11]. Further research is warranted to explore the potential benefits of implementing advanced AI technology (eg, generative AI) in mental health CAs for youth.

Safety Should Be Prioritized When Designing and Implementing Mental Health CAs for Youth

Recent advancements in LLMs are promising in improving the technical immaturity of mental health CAs, with the ability to understand input text written in human language in prompts and generate responses [66]. Early evidence demonstrated the effectiveness of the LLMs in generating coherent and relevant answers to psychological questions [67] or detecting mental health conditions [68]. However, when applying LLMs in mental health CAs for youth, the safety aspects of the information provided by those models should be rigorously considered, given the recent documentation of age-inappropriate and inaccurate content for youth generated by LLMs [69]. Therefore, chatbot development and implementations should undergo a robust validation process to establish a reliable and expert-informed evidence base for safety, particularly with extra care when designing chatbots for youth considered vulnerable (eg, those with mental health conditions). Meanwhile, safety concerns addressed in evaluative research included increased screen time, overreliance on machines over human support, and the risk of missing imminent risk. Although research findings are conflicting, the impact of overreliance on machines and increased screen time on youth's well-being is one of the important safety concerns [70,71]. Therefore, safety features to help track screen time and nudge youth about their CA use could be considered. Safety features to alert mental health professionals for imminent risk (eg, nudges with sophisticated AI tech such as deep learning) could also be critical for mental health CAs.

Long-Term, Large-Scale, and Rigorous Evaluation Is Needed to Ensure the Efficacy and Safety of Mental Health CAs

Overall, most of the empirical research on mental health CAs was conducted with <100 older youth populations in the short term (<4 weeks). This trend was substantial as many of them involved user testing or clinical trials to assess the acceptability and feasibility of the prototypes. Although preliminary evidence shows positive trends in the effectiveness and acceptability of mental health CAs, long-term evaluative research with larger sample sizes and more robust research designs is needed to validate their efficacy before their widespread adoption and use. In addition, we noted a lack of established methods for evaluating the safety of mental health CAs for unintended adverse effects among reviewed studies. This concerning trend was consistent with the mental health CAs for general adults [72]. While empirical research showed that the age-appropriateness of mental health content was one of the weaknesses of mental health CAs [25], none of the reviewed studies evaluated whether the mental health content is developmentally appropriate for youth. Therefore, the accuracy and age-appropriateness of mental health content provided by CAs should be further explored to ensure the efficacy and safety of mental health CAs for youth.

Collaborative Efforts With Youth and Clinical Experts Are Needed to Design Safe, Effective, and Youth-Centered Mental Health CAs

The evaluation outcomes of the reviewed studies raised a few open questions in designing safe, effective, and youth-centered mental health CAs. One key issue is the humanlike traits of CAs; while youth prefer humanlike traits of CAs, existing research documented safety concerns toward the humanness of CAs. For instance, previous research shows that younger youth may lose vital human contact [73] or unintentionally share personal information with CAs [74] if they become too attached to humanlike CAs. Therefore, in some studies we reviewed, CAs were designed with non-humanlike avatars (eg, [23,25,30,34]) or there were safety features to clearly state that the CAs are not human agents (eg, [4,27,33,35,43,47,54]). Consequently, how to balance humanlike and non-humanlike traits of mental health CAs for youth is an important open question to address in collaborative research with youth and clinical experts.

Another open question is on the CA role, as evaluative research showed conflicting perceptions from youth and clinical experts; youth prefer peer- or coach-like roles, while experts were cautious about such roles for clinical purposes [19]. Therefore, careful consideration is needed when designing social roles of mental health CAs for youth taking into account specific health context, purpose, and target audience. In addition, as evaluative research showed, providing an option to choose a preferred CA avatar can help youth feel comfortable when sharing confidential issues on sensitive topics [37]. However, we found that the current empirical research on mental health CAs rarely explored how personalizing the roles and characteristics of mental health CAs impacts the effectiveness or user experience in both positive and negative ways. Therefore, further empirical research with youth and clinical experts is needed to understand how different permutations of CA roles and personalities play a role in supporting youth mental health.

In terms of personalized CA content delivery, we observed a trade-off between flexibility and structured planning in therapeutic content. Experts emphasized that planned modules could make mental health CAs more reliable and the treatment goals more visible; at the same time, they can reduce motivation and user engagement and thus lead to dropout [19]. Therefore, balancing between personalizing therapeutic content flexibly and maintaining a structured program is an open-ended question to address in future research. Finally, in most reviewed studies, the content of mental health CAs was based on well-established evidence-based expert knowledge to safely leverage CA systems. However, to understand the mental health needs of youth, it is equally critical to work with youth from the early

XSL•FO
RenderX

stages of CA design. However, very little work has been done to consider inputs from youth in content generation. Taken together, more collaborative research efforts with youth, caregivers, and domain experts need to be made to address the aforementioned open questions and build effective, safe, and youth-centered mental health CAs.

Ethics Standards and Best Practices to Design and Develop Mental Health CAs for Youth Are Needed

We found a concerning trend in the existing literature on mental health CAs for youth: most of the papers did not address the ethical aspects of mental health CAs. Many of the existing review studies pointed to the lack of ethical considerations in the development of CAs in health care [2,75,76]. While personal health data are collected and processed in mental health CAs, the majority did not provide information regarding security and privacy aspects [76]. As mental health topics are sensitive, particularly for youth [6,30], more discussion on ethics standards and critical reflections on best practices to develop mental health CAs for the youth population is needed. Another concerning trend we found was that the ethical implications and best practices of involving youth considered vulnerable in evaluative research on mental health CAs are rarely discussed. In a 12-week evaluative research study with adolescents with depression and anxiety, more than half of the participants triggered at least 1 alarm for suicidal ideation [22], which signals that safety standards and best practices are pivotal when working with populations considered vulnerable. Hence, further research is needed to establish ethical standards for working with youth, particularly youth considered vulnerable, to ensure that participating in research does not harm already populations considered vulnerable. We summarize the open questions that need to be addressed in future research in Textbox 2.

Textbox 2. Open questions related to mental health conversational agents (CAs) to be addressed in future research.

Open questions

- CA role: How do different CA roles and characteristics impact youth's interaction with mental health CAs?
- CA characteristics: How can we balance humanlike versus non-humanlike traits of mental health CAs for youth?
- CA content: What is the age-appropriate, inclusive, and accurate mental health information for youth?
- Content delivery: What are the effective and safe delivery modes (ie, structured vs flexible) of mental health CA content for youth?
- Safety: How can we design CA features to promote the safety (eg, monitoring imminent risk and screen time) of mental health CAs?
- Data privacy and confidentiality: How can we design artificial intelligence–based systems that ensure privacy and confidentiality of youth data on sensitive topics?
- Research ethics: What are the ethics standards and best practices to design and develop mental health CAs for and with youth?

Design Guidelines

On the basis of our findings and broader implications, we provide the following guidelines for designing youth-centered mental health CAs (Textbox 3).

Textbox 3. Design guidelines for mental health conversational agents (CAs) for youth.

Design guidelines

- CA role and characteristics: The CA role should be carefully designed considering the purpose and primary target audience. Regardless of roles, empathetic and friendly characteristics of mental health CAs are important.
- CA content: CA content should be age-appropriate, inclusive, and accurate. The content should be based on evidence-based expert knowledge along with inputs from youth.
- Artificial intelligence technique: More advanced language models (eg, large language models) are needed to provide diverse, context-aware, and personalized content for youth.
- Input mode: Free-textual inputs with auto-complete or quick options can help youth formulate questions that require domain knowledge. Along with textual input, an option for voice-based input can support youth with diverse communication needs.
- Output mode: Less textual content and more multimedia content can help youth understand mental health information.
- Personalization: It is important to give youth control over the personalization of CA content and avatars. Information on what is being personalized and how it is done should be clear and transparent.
- Safety: It should be clearly communicated to youth that CAs are not human, along with information on the capability and limitations of CAs. Information on confidentiality and data privacy should be clear and transparent. Safety features such as emergency contacts for imminent risk should be provided upfront and available 24/7. Additional safety features to track screen time could help reduce overreliance on CAs and prevent excessive screen time.
- Ethics: Safety standards and critical reflections on best practices to co-design CAs with the youth population are needed.

XSL•FO
RenderX

Strengths, Limitations, and Future Work

This scoping review has several strengths. First, we conducted a comprehensive literature search of multiple databases. We used holistic search terms rather than specific ones to capture the various representations of CAs used in mental health for youth. Second, we analyzed trends in empirical research on mental health CAs for youth as well as design and computational considerations of the mental health CAs studied in empirical research to provide a holistic mapping of the current landscape. Therefore, this study showcased the possible framework of mental health CAs that can be referenced by other researchers in this field.

However, our study has some limitations. First, given the novelty and multidisciplinary nature of the field, some unpublished literature presented at niche conferences and meetings may have been omitted. Second, during the data extraction process, we identified the design and computational approaches of the mental health CAs based on the descriptions reported in the reviewed studies. Hence, some of the design and computational aspects of mental health CAs that were considered yet not reported in the reviewed studies may not have been captured in this paper. As our findings suggest, the maturity of mental health CAs is still in its infancy, and further review with more in-depth analysis is needed as research in the field matures.

Conclusions

CAs are increasingly used by youth for sensitive topics such as mental health. Trends in research on mental health CAs designed for youth have been underexplored. In this review paper, we fill an important gap by synthesizing 39 studies on mental health CAs designed for youth over the last 14 years. Our scoping review highlights that research on mental health CAs is in its infancy, and early evidence shows both strengths and weaknesses in existing systems. We call attention to important open questions that researchers should address to move forward. When designing CAs for youth, a one-size-fits-all approach does not apply. With careful consideration of the health context and needs of specific target groups, mental health CAs can benefit youth. This can be only achieved when engaging with youth from the early design phases to the summative evaluation of the systems. In this regard, we call for further investigation of best practices for risk mitigation strategies and ethical development of CAs with and for youth to promote their mental well-being.

Abstract

Background: Machine learning (ML) and big data analytics are rapidly transforming health care, particularly disease prediction, management, and personalized care. With the increasing availability of real-world data (RWD) from diverse sources, such as electronic health records (EHRs), patient registries, and wearable devices, ML techniques present substantial potential to enhance clinical outcomes. Despite this promise, challenges such as data quality, model transparency, generalizability, and integration into clinical practice persist.

Objective: This systematic review aims to examine the use of ML for analyzing RWD in disease prediction and management, identifying the most commonly used ML methods, prevalent disease types, study designs, and the sources of real-world evidence (RWE). It also explores the strengths and limitations of current practices, offering insights for future improvements.

Methods: A comprehensive search was conducted following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines to identify studies using ML techniques for analyzing RWD in disease prediction and management. The search focused on extracting data regarding the ML algorithms applied; disease categories studied; types of study designs (eg, clinical trials and cohort studies); and the sources of RWE, including EHRs, patient registries, and wearable devices. Studies published between 2014 and 2024 were included to ensure the analysis of the most recent advances in the field.

Results: This review identified 57 studies that met the inclusion criteria, with a total sample size of >150,000 patients. The most frequently applied ML methods were random forest (n=24, 42%), logistic regression (n=21, 37%), and support vector machines (n=18, 32%). These methods were predominantly used for predictive modeling across disease areas, including cardiovascular diseases (n=19, 33%), cancer (n=9, 16%), and neurological disorders (n=6, 11%). RWE was primarily sourced from EHRs, patient registries, and wearable devices. A substantial portion of studies (n=38, 67%) focused on improving clinical decision-making, patient stratification, and treatment optimization. Among these studies, 14 (25%) focused on decision-making; 12 (21%) on health care outcomes, such as quality of life, recovery rates, and adverse events; and 11 (19%) on survival prediction, particularly in oncology and chronic diseases. For example, random forest models for cardiovascular disease prediction demonstrated an area under the curve of 0.85 (95% CI 0.81-0.89), while support vector machine models for cancer prognosis achieved an accuracy of 83% (P=.04). Despite the promising outcomes, many (n=34, 60%) studies faced challenges related to data quality, model interpretability, and ensuring generalizability across diverse patient populations.

Conclusions: This systematic review highlights the significant potential of ML and big data analytics in health care, especially for improving disease prediction and management. However, to fully realize the benefits of these technologies, future research

XSL•FO
RenderX

must focus on addressing the challenges of data quality, enhancing model transparency, and ensuring the broader applicability of ML models across diverse populations and clinical settings.

Introduction

Background

Advances in big data analytics and the growing availability of real-world data (RWD) are transforming health care by enabling new applications of machine learning (ML) to improve health outcomes [1]. Real-world evidence (RWE) generated from diverse data sources, such as electronic health records (EHRs), patient registries, and wearable devices, has become central to informed decision-making in clinical practice [2,3]. When combined with ML, RWD present a promising avenue to enhance disease prediction, personalize patient management, and optimize therapeutic effectiveness. By providing a comprehensive view of patient histories and real-world health outcomes, ML applications in health care can drive actionable insights across various domains, including disease diagnosis, treatment planning, and chronic disease management [4,5]. RWD capture information about patients in naturalistic settings, revealing how health care is delivered and its outcomes. Unlike clinical trials that operate within controlled conditions, RWD offer a more representative view of patient experiences, treatment responses, and health outcomes [6]. The rise of big data technology and data management systems has facilitated the integration of vast, heterogeneous data types, allowing ML algorithms to identify complex patterns within high-dimensional datasets [7,8]. These capabilities allow health care providers to predict health outcomes, identify at-risk populations, and tailor interventions based on individual patient factors, thus making strides toward precision medicine [9].

Despite their potential, ML applications in RWD and big data contexts face several challenges. Data quality remains a primary concern, as RWD often feature inconsistencies, missing values, and a lack of standardization [10]. Unlike the structured data from controlled clinical trials, RWD demand extensive preprocessing, including advanced natural language processing (NLP) methods and imputation techniques, to address data gaps. Such efforts are critical to enhancing ML model reliability and ensuring accurate, meaningful outcomes [11,12]. Biases present another key issue. ML models trained on RWD may inherit biases from the data, often stemming from demographic imbalances or regional health care differences. If left unaddressed, these biases can lead to health care disparities, as ML-driven decisions might inaccurately represent racial and ethnic minority populations or certain patient groups [13]. Incorporating fairness-aware ML algorithms and cross validating models across multiple datasets can mitigate this challenge, although developing equitable ML models remains a high priority [14]. Another significant hurdle is the interpretability of ML models, especially deep neural network (DNN) models, which are known for their “black box” nature. While complex models deliver high accuracy, their opaque decision-making process limits the ability to verify or explain predictions. Model transparency is crucial given the high stakes in health care, where ML-based recommendations can impact lives. Advances in interpretability tools, such as Shapley Additive Explanations and Local Interpretable Model-Agnostic Explanations, have helped enhance model transparency; however, balancing interpretability with performance remains an area of active investigation [15,16].

The integration of ML with RWD poses ethical and regulatory challenges, especially regarding patient privacy, data security, and informed consent. Regulations such as the Health Insurance Portability and Accountability Act in the United States and the General Data Protection Regulation in the European Union impose strict standards for data protection. However, adapting these laws to the context of ML in health care is complex due to the scale and diversity of the data involved [17,18]. Solutions such as deidentification, secure data-sharing protocols, and clear data management strategies have become crucial to ensuring patient confidentiality while maximizing data utility [19]. Ensuring equitable treatment outcomes is another ethical imperative. ML models trained on data predominantly representing certain demographics may perform poorly on underrepresented groups; therefore, addressing these disparities is critical. By incorporating fairness-aware ML models and building representative datasets, health care practitioners can ensure that ML applications benefit all patient groups, regardless of demographics [20]. Regulatory bodies have started developing specific guidelines for the use of ML and RWD in health care. The Food and Drug Administration (FDA), for example, has issued draft guidance on using RWE for regulatory decisions, and the European Medicines Agency (EMA) has also recognized the importance of RWE in evaluating drug safety and efficacy [21]. As ML applications in health care continue to grow, a solid regulatory framework will be necessary to safeguard patient health while supporting technological innovation.

Objectives

The objective of this systematic review is to explore and critically analyze the applications, challenges, and future directions of ML in processing real-world health data and big data across various disease domains. Specifically, this review aims to identify the disease areas where ML with RWD has shown clinical utility; examine the ML algorithms and methodologies applied to big data in health care; and analyze the challenges related to data quality, bias, and model interpretability. In addition, this review addresses the ethical and regulatory frameworks pertinent to the use of ML in health

XSL•FO
RenderX

care, with an emphasis on patient privacy and fairness. Finally, it outlines future research needs and opportunities for innovation in using ML, RWD, and big data for precision medicine and public health.

Methods

Eligibility Criteria

For this systematic review, we focused exclusively on clinical trials and cohort studies that used ML techniques to analyze RWD for disease prediction and management. Studies were included if they met the following criteria: (1) they were randomized controlled trials, pragmatic clinical trials, observational clinical trials, or cohort studies; (2) they involved the application of ML methods (eg, supervised learning, unsupervised learning, and deep learning) to RWD for clinical decision-making, disease prediction, or management of common diseases, such as cardiovascular diseases, diabetes, cancer, and chronic conditions; and (3) they used real-world health data sources, such as EHRs, patient registries, or wearable health devices. Exclusion criteria included trials that did not apply ML techniques or used only data from controlled clinical trials rather than real-world settings.

Information Sources

The following information sources were used to capture the most relevant clinical trials and cohort studies: PubMed, Scopus, and the Cochrane Library. PubMed was specifically targeted for clinical trials and biomedical research, particularly studies published in leading clinical journals. Scopus and the Cochrane Library were also searched to gather clinical trial reports within the health care and ML domains. To ensure comprehensive coverage, Google Scholar was included to identify gray literature, such as theses and reports that were not indexed in traditional databases. These sources were selected to provide a broad overview of clinical trial data and their relevance to ML applications in disease management. In addition, regulatory bodies such as the US FDA and the EMA were consulted to gain insights into clinical trial guidelines and regulatory standards regarding the use of RWD in health care.

Search Strategy

A comprehensive search strategy was developed to identify clinical trials and cohort studies focused on ML applications in RWD. The search query incorporated key terms related to ML (eg, “machine learning,” “deep learning,” and “artificial intelligence”) and clinical trials (eg, “clinical trial,” “randomized controlled trial,” and “pragmatic clinical trial”) along with terms related to disease management (eg, “disease prediction,” and “healthcare outcomes”). For example, the search used the following key terms: (“machine learning” OR “deep learning”) AND (“clinical trial” OR “randomized controlled trial” OR “pragmatic trial” OR “cohort study”) AND (“real-world data” OR “electronic health records” OR “patient registries”). Boolean operators (AND and OR), truncation, and Medical Subject Headings terms were used to refine the search and ensure comprehensive coverage. The search was conducted across multiple databases, including the Cochrane Library, PubMed, and Web of Science, covering the period from January 1, 2014, to December 31, 2024, ensuring that the full range of recent literature was captured. In addition, relevant studies were identified through manual searches of reference lists from key articles and by reviewing clinical trial registries, such as ClinicalTrials.gov, to ensure comprehensive coverage of the clinical trials relevant to ML in disease management. Gray literature was identified by conducting targeted searches in Google Scholar and manually retrieving relevant documents suggested by domain experts. Only English-language publications were included. To enhance transparency and reproducibility, the full search strategy, including specific database queries and search filters, has been provided in Multimedia Appendix 1.

Study Selection

The study selection process was conducted in 2 stages: an initial screening of titles and abstracts by 2 independent reviewers, followed by a full-text review by the same 2 reviewers to ensure consistency and minimize bias. In the first stage, the titles and abstracts of all identified articles were assessed for relevance based on predefined inclusion criteria. Discrepancies between reviewers were resolved through discussion, with a third reviewer consulted when necessary. Studies that met the inclusion criteria proceeded to the second stage, where the full texts were retrieved for further evaluation (Textbox 1).

The evaluation of exclusion criteria was conducted independently by both reviewers, with disagreements resolved through discussion. To maintain transparency, the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram [22,23] was used to document the number of studies at each review stage, including identification, screening, eligibility, and final inclusion. The PRISMA checklist is provided in Multimedia Appendix 2.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria for study selection.

Inclusion criteria

- Study type: clinical trials or cohort studies
- Data source: studies using real-world data, such as electronic health records, patient registries, claims data, or wearable device data
- Machine learning (ML) application: application of ML algorithms for disease prediction or management (eg, supervised, unsupervised, and deep learning models)
- Clinical focus: studies addressing disease prediction, management, monitoring, or outcome prediction in health care
- Outcome reporting: studies reporting ML model performance metrics (eg, accuracy, area under the curve, sensitivity, and specificity) and real-world data sources
- Language: studies published in English
- Publication type: peer-reviewed articles and indexed gray literature

Exclusion criteria

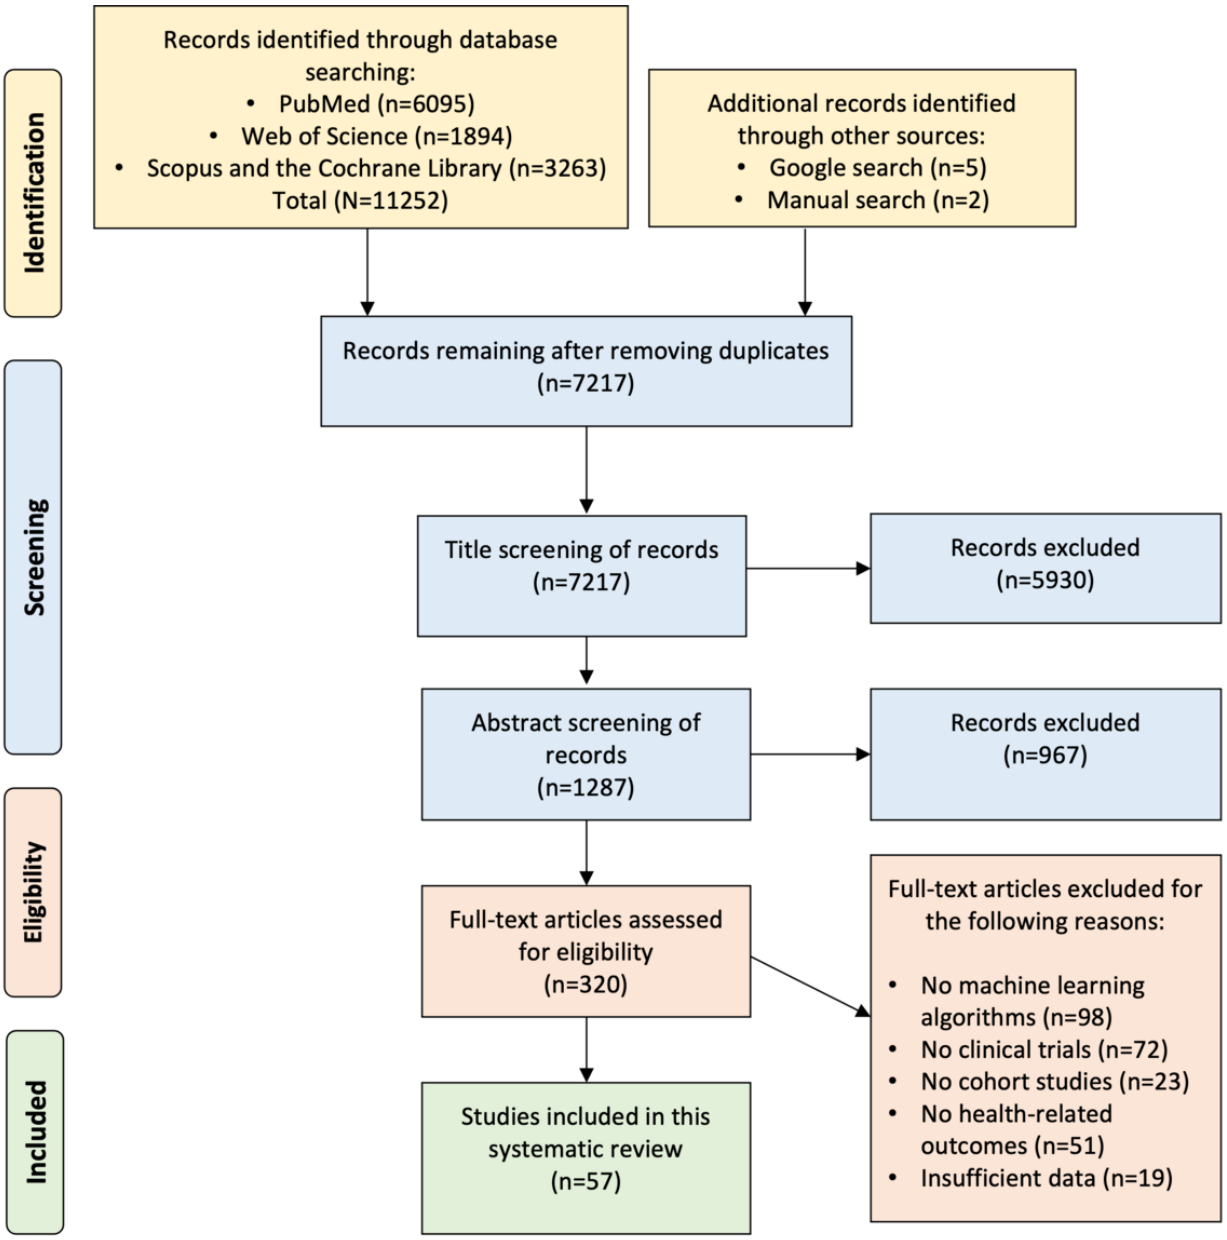
- Study type: case reports, cross-sectional studies, reviews, editorials, letters, and conference abstracts
- Data source: studies using simulated data, animal studies, or laboratory-based data
- ML application: studies using only conventional statistical models (eg, logistic regression and Cox models) or expert systems
- Clinical focus: studies unrelated to clinical decision-making, disease outcomes, or patient management
- Outcome reporting: studies lacking sufficient information on ML model performance or data sources
- Language: non–English-language publications
- Publication type: non–peer-reviewed sources (blogs and social media posts)

Data Extraction

Data extraction was performed independently by 2 reviewers using a standardized form. Key data points extracted from each clinical trial and cohort study included study characteristics (eg, authors, year of publication, and trial design), the specific ML methods used (eg, supervised learning, reinforcement learning, deep learning), disease areas targeted (eg, cardiovascular diseases, diabetes, and cancer), and the types of RWD sources used (eg, EHRs, patient registries, and wearable devices). In addition, we extracted the performance metrics of the ML models used, such as accuracy, sensitivity, specificity, and area under the receiver operating characteristic curve (AUROC), to evaluate their effectiveness in disease prediction and management. Information on the challenges and limitations of applying ML to RWD in clinical trials, such as data quality issues, biases, or model interpretability, was also collected. Any disagreements in data extraction were resolved through discussion. The extracted data were organized systematically to synthesize findings across studies.

Results

Systematic Literature Search and Study Selection Workflow



The systematic literature search was conducted to identify studies applying ML techniques to RWD in clinical trials and cohort studies, with a focus on disease prediction and management. The search covered multiple databases, including PubMed, Scopus, Web of Science, and the Cochrane Library, to capture a broad range of studies from biomedical, clinical, and health care research fields. This search yielded 11,252 records, as illustrated in the PRISMA flow diagram (Figure 1). To ensure comprehensive coverage, an additional 7 records were identified through external sources such as Google searches, manual hand searching of nonindexed journals, gray literature, and other nontraditional academic sources. After removing duplicates, 7217 (64.13%) unique studies remained for screening. The selection process followed a rigorous, multistage workflow. Title screening was first performed to assess relevance based on predefined inclusion criteria. Studies with titles not indicating the application of ML to RWD in clinical or disease management contexts were excluded, resulting in the removal of 5930 (82.17%) records and leaving 1287 (17.83%) studies for abstract screening. During the abstract screening, each abstract was carefully evaluated for inclusion criteria, including the use of ML techniques, relevant RWD sources (eg, EHRs, patient registries, or wearable device data), and relevance to disease prediction or management. This led to the exclusion of 967 (75.13%) studies that did not meet these criteria, most commonly for the following reasons: (1) a lack of ML implementation, with some studies using only conventional statistical approaches such as logistic regression (LR) or decision trees (DTs) without learning-based model development; (2) irrelevance to clinical trials or cohort study frameworks, instead focusing on simulations, animal studies, or nonhuman data sources; (3) absence of disease prediction or management applications, such as papers limited to health care policy, infrastructure, or economic modeling without patient-centered outcomes; and (4) insufficient use of RWD sources, as studies often used synthetic or trial-generated data rather than EHRs, registries, claims databases, or wearable device data. A total of 320 (24.86%) studies proceeded to the full-text review stage. At this stage, articles were assessed in detail to confirm adherence to all inclusion criteria. A total of

XSL•FO
RenderX

263 studies were excluded for specific reasons: 98 (37.3%) lacked ML algorithms (using conventional statistics instead), 72 (27.4%) were unrelated to clinical trial methodologies, 23 (8.7%) did not involve study cohorts, 51 (19.4%) were unrelated to health care outcomes, and 19 (7.2%) lacked sufficient information on ML model performance or data sources. Following this thorough, systematic, and transparent selection process, 57 studies met all eligibility criteria and were included in the final systematic review. These selected studies represented a diverse range of clinical applications, disease areas, ML methodologies, and RWD sources, offering a comprehensive overview of the current role of ML in clinical trials and cohort studies for disease prediction and management.

Table 1 summarizes these studies, while key findings and methodological details are provided in Multimedia Appendix 3 [24-80].

Figure 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram depicting the study selection process from initial identification to final inclusion, detailing the number of records screened, excluded, and ultimately included in this systematic review.

Implementation of ML in RWD for Disease Prediction and Management

ML methods have become integral tools for analyzing RWD for disease prediction and management. These methods analyze complex medical data, helping clinicians make informed decisions for better patient care. Random forest (RF) is one of the most widely used ML methods, appearing in 42% (24/57) of the studies (Table 2). It is an ensemble learning technique that builds multiple DTs and combines their outputs to improve model stability and generalizability [81]. Several reviewed studies reported that RF performed well in handling large datasets with numerous variables, particularly EHRs, which are common medical data sources. Its robustness against overfitting and ability to handle missing data made it a frequently chosen method in clinical applications, where data quality could vary [82,83]. While RF has been widely applied in predictive modeling for disease outcomes, treatment responses, and patient risk assessments, further comparative studies are necessary to directly evaluate its performance against other ML models in real-world health care settings [84]. It is often applied to predict disease outcomes, assess treatment responses, and identify patient risk factors.

Table 2. The frequency of machine learning (ML) methods used in studies included in this review (N=57).

ML method	Studies, n (%)
Random forest	24 (42)
Logistic regression	21 (37)
Support vector machine	18 (32)
Extreme Gradient Boosting	12 (21)
Artificial neural network	11 (19)
Decision tree	9 (16)
Gradient boosting machine	4 (7)
Cox regression	3 (5)
Natural language processing	2 (4)
Deep neural network	2 (4)

LR was a fundamental method used for binary classification tasks and was used in 37% (21/57) of the studies. LR estimates the probability of a particular class, which is essential for predicting binary outcomes, such as the presence or absence of disease. It is a simple yet powerful tool that works well with smaller datasets and provides results that are easy to interpret, making it particularly useful in clinical settings where transparency is crucial [85,86]. LR is commonly used for disease risk prediction, helping clinicians assess the likelihood of a patient developing a condition based on their medical history and other clinical factors. Its interpretability allows for clear communication of results to health care providers, enhancing decision-making [87,88]. Support vector machine (SVM), used in 32% (18/57) of the studies, is known for its ability to handle high-dimensional data, making it suitable for complex medical datasets, including genomic and imaging data. SVM works by finding the optimal hyperplane that separates different classes in the feature space [89-91]. This method is beneficial in clinical settings where the relationship between variables is nonlinear and can be adapted for classification and regression tasks. SVM is applied in disease prediction, particularly when the dataset has many features relative to the number of observations. It is also useful for classifying patients based on genetic or demographic factors, making it a powerful tool for precision medicine [92,93]. Extreme Gradient Boosting (XGBoost) appeared in 21% (12/57) of the studies and is a highly effective method for improving predictive accuracy through boosting. XGBoost builds models sequentially to correct errors made by previous models and uses regularization to prevent overfitting. This method is effective in handling large datasets, common in clinical studies, and where computational efficiency is essential [94,95]. XGBoost is often used for survival analysis and disease outcome prediction, where it can effectively manage the complexity of large datasets and missing data. Its flexibility

XSL•FO
RenderX

allows it to be applied across various disease areas, from cancer prognosis to cardiovascular risk assessment [96,97].

Artificial neural network (ANN) models, used in 19% (11/57) of the studies, are powerful tools for modeling complex, nonlinear relationships in data. With multiple layers of interconnected neurons, an ANN can learn intricate patterns from large datasets. It is widely used in applications that involve unstructured data, such as medical imaging and genetic data, where traditional models might struggle [98,99]. ANN is frequently applied to predict disease progression and response to treatments and identify potential biomarkers. In RWD, an ANN helps identify subtle patterns in complex datasets that simpler models might not capture, such as predicting cancer progression from radiological images [100,101]. DTs, featured in 16% (9/57) of the studies, are straightforward and interpretable models that split data into subsets based on feature values. DT models are highly useful in real-world health care settings, where interpretability is essential for clinical decision-making. They are often applied in clinical decision support systems to guide treatment decisions based on patient data [102,103]. In health care, DTs predict disease outcomes, stratify patients by risk, and recommend treatment plans. Their transparency allows clinicians to understand the decision-making process, which is critical for patient trust and informed consent [104]. Gradient boosting machine (GBM) was used in 7% (4/57) of the studies and is a powerful ensemble method that focuses on correcting errors made by previous models. It is effective in producing highly accurate predictions, particularly in the presence of noisy or incomplete data. GBM is more computationally intensive than other methods, but often outperforms simpler models in accuracy. GBM is particularly useful for predicting disease progression and evaluating treatment efficacy in longitudinal studies, where multiple factors influence outcomes over time [105,106].

NLP, used in 4% (2/57) of the studies, is a subfield of artificial intelligence focused on analyzing unstructured textual data. In health care, NLP extracts relevant information from clinical notes, EHRs, and medical literature. It enables clinicians and researchers to analyze vast amounts of text data to identify trends, predict disease outcomes, and assess treatment effectiveness [107,108]. NLP is crucial in extracting insights from EHRs and other textual data sources. It can help in disease prediction by identifying patterns from patient narratives, diagnostic codes, and clinician notes that would otherwise remain hidden in unstructured formats [109]. Cox Regression, used in 5% (3/57) of the studies, is designed explicitly for survival analysis. It is widely applied in clinical research to model the time of an event, such as the onset of a disease or patient survival. This method is precious for understanding how various predictors affect the risk of an event occurring over time. In RWD, Cox regression is often used in cancer studies and other chronic diseases to predict survival times and assess the impact of different treatment regimens, making it indispensable in clinical trials and outcome-based research [110,111]. DNN models, used in 4% (2/57) of the studies, are a more complex version of ANN with multiple hidden layers. DNN models identify intricate patterns and are increasingly used in health care applications involving large and complex data types, such as medical imaging, genomics, and sensor data. DNN is particularly useful for analyzing high-dimensional data, such as medical images (eg, x-rays and magnetic resonance imaging) or genomic data, where the relationships between variables are complex and nonlinear. It helps identify disease markers and predict outcomes based on these complex datasets [112-114]. The diverse range of ML methods used in RWD for disease prediction and management demonstrates the adaptability of these techniques in clinical practice. From interpretable models such as LR and DTs to more complex methods such as DNN and XGBoost, each ML technique uniquely enhances predictive capabilities. These methods enable health care providers to make more accurate, data-driven decisions, ultimately improving patient outcomes and advancing personalized medicine.

Distribution of Diseases, Study Types, and RWE Sources in ML Applications

The distribution of disease types in studies using ML for disease prediction and management revealed a strong emphasis on cardiovascular diseases, with 19 (33%) of the 57 studies focusing on various conditions within this category (Table 3).

Table 3. Disease categories and the studies included in this review (N=57).

Diseases	Studies, n (%)
Cardiovascular diseases	19 (33)
Cancers and tumors	9 (16)
Neurological diseases	6 (11)
Infectious diseases	5 (9)
Metabolic diseases	5 (9)
Spinal diseases	3 (5)
Gastrointestinal diseases	2 (4)
Ocular diseases	2 (4)
Respiratory diseases	2 (4)
Other diseases	4 (7)

XSL•FO
RenderX

This high representation could be attributed to the multifactorial and complex nature of cardiovascular diseases, which often involve a combination of genetic, environmental, and lifestyle factors. Conditions such as atrial fibrillation, heart transplantation, and peripheral artery disease were prominent in these studies, where advanced ML models were used to enhance predictive accuracy and improve patient management. For instance, studies on heart transplantation and atrial fibrillation highlighted the potential of ML algorithms in survival prediction and early disease detection. A work demonstrated that ensemble models, combining RF, DNN, and adaptive boosting, significantly outperformed traditional LR for predicting 1-year survival rates after orthotopic heart transplantation, with an area under the receiver operating characteristic curve of 0.764 [25]. Meanwhile, another study explored the use of the Future Innovations in Novel Detection for Atrial Fibrillation ML algorithm to identify undiagnosed atrial fibrillation using data from EHRs, aiming to improve early detection and intervention. In addition, studies on peripheral artery disease and atrial fibrillation in older adults underscored the utility of ML models in survival prediction and risk assessment [26]. A study developed a predictive model for amputation-free survival after the revascularization process, with the random survival forest model achieving the highest accuracy in predicting long-term outcomes [28]. Similarly, another study used various ML methods, including DTs and RFs, to predict new-onset atrial fibrillation in older adults, achieving high specificity and performance, particularly with the RF model [32]. Furthermore, the use of ML in acute ischemic stroke, including studies by Sheth et al [30] and Hilbert et al [35], illustrated the growing role of deep learning techniques, such as convolutional neural networks and residual neural networks, in improving diagnostic accuracy and predicting patient outcomes [35]. These advancements in ML could potentially revolutionize clinical decision-making and treatment selection, especially for conditions such as stroke, where rapid and accurate assessment is critical.

A significant (9/57, 16%) portion of studies also targeted cancers and tumors, which were often characterized by their heterogeneity and the need for personalized treatment plans. ML algorithms, such as RF and SVM, enhanced early cancer detection, predicted disease recurrence, and assessed the effectiveness of different treatment protocols, demonstrating great potential in oncology settings. One key area of focus was the prediction of disease outcomes. For instance, a study developed a series of ML models to predict the 5-year survival rate for patients with Ewing sarcoma, a rare type of cancer. Using data from 2332 patients, including various algorithms such as boosted DTs, SVMs, RFs, and neural networks, the study found that the RF method performed best, with impressive sensitivity and specificity. This model is now accessible via a web-based application, providing clinicians a valuable tool for assessing survival probabilities for patients with Ewing sarcoma [36]. Another study used a predictive ML model to improve surgical scheduling in cancer surgeries, specifically for colorectal and gynecologic cancers. The research used gradient boosting and LR techniques to predict surgical durations, reducing operational inefficiencies such as patient wait times and optimizing the use of surgical resources, thereby demonstrating how ML could streamline health care operations while maintaining treatment quality [38]. Furthermore, in survival prediction, a study used an RF model to develop a gene signature that predicted the response of patients with gastric cancer to paclitaxel treatment. Their model, which identified a 19-gene signature, enabled the classification of patients into those who would benefit from the treatment, providing a novel approach to personalized cancer therapy [48].

The studies focusing on neurological diseases, including conditions such as epilepsy, cognitive impairment, and schizophrenia, highlighted the significant impact of ML in improving diagnosis, treatment prediction, and health care outcomes. These studies underscored the potential of ML to personalize patient care and optimize clinical decision-making. For instance, a study investigated the application of NLP embedded in EHR to automate alerts for pediatric patients with epilepsy. This ML-driven clinical decision support system successfully increased referrals for epilepsy surgery, with a marked improvement in presurgical evaluation rates and even higher rates of actual surgery, illustrating how NLP-based interventions could influence health care outcomes by improving referral efficiency and treatment access [24]. Similarly, another study focused on the use of XGBoost, an ML algorithm, to identify older patients in the emergency department at high risk for cognitive impairment. This predictive model, using EHR data, demonstrated high sensitivity and specificity, with the potential to reduce the need for in-person screenings and prioritize patients at high risk. By streamlining screening processes, this approach could enhance the detection of cognitive impairments in older adults, potentially leading to earlier interventions and better management of conditions such as dementia [27]. In schizophrenia, a study developed a nonlinear SVM model to predict treatment outcomes for patients with first-episode psychosis. The model was trained on pretreatment patient-reported data and successfully predicted poor versus good treatment outcomes, thus supporting clinical decision-making in terms of which treatments might be more effective for certain patients and identifying those at risk for nonadherence or poor prognosis [37]. These studies collectively demonstrated how ML methods, such as NLP, XGBoost, and RF, were revolutionizing the management of neurological diseases. By enabling early detection, better prediction of disease outcomes, and more informed decision-making, these tools offered substantial improvements in both clinical and health care settings. Infectious diseases, metabolic diseases, spinal diseases, gastrointestinal diseases, ocular diseases, and respiratory diseases each had a smaller but notable presence in the studies (n≤5). These applications generally focused on disease prediction, early diagnosis, and treatment optimization. ML models such as XGBoost and DNN were used to predict disease onset, assess risks, and improve patient management in these areas.

The data revealed that EHRs were the most frequently used form of RWE, accounting for 68% (39/57) of the studies. EHRs were a rich source of patient data, providing comprehensive records of patient health status, diagnoses, treatments, and outcomes over time. This made EHRs particularly valuable for studies that required large-scale data to identify patterns, trends,

XSL•FO
RenderX

and correlations in real-world clinical settings. The next most commonly used type of RWE was patient registries, which were used in 26% (15/57) of the studies. Patient registries typically collect data on specific patient populations with particular diseases or conditions, allowing for longitudinal tracking of disease progression and treatment outcomes. Wearable devices were the least used form of RWE, accounting for 7% (4/57) of the studies. Wearables were increasingly being used to collect real-time health data, including vital signs and activity levels, which could provide valuable insights into patients' health status outside of clinical environments. This distribution highlighted the dominance of EHR as the primary data source in these studies, reflecting its accessibility and broad applicability in health care research.

Disease prediction emerged as the most widely studied area, represented by 35% (20/57) of the studies. This suggested a strong emphasis on using ML and data analytics to predict the onset, progression, or outcomes of various diseases. The next most studied area was decision-making, with 25% (14/57) of the studies that underscored the growing interest in leveraging data-driven insights to inform clinical decisions and treatment strategies. Health care outcomes, such as quality of life, recovery rates, and adverse events, were the focus of 23% (13/57) of the studies, reflecting the importance of understanding how diseases and treatments affect patients' overall well-being. Survival prediction, accounting for 19% (11/57) of the studies, was another critical area of research, particularly in oncology and chronic diseases, where predicting patient survival and the effectiveness of interventions could guide clinical decision-making. This distribution indicated that disease prediction and decision-making were central to applying RWE in health care, with a significant focus on improving patient outcomes and guiding treatment strategies.

Discussion

Principal Findings

The findings of this study underscore the growing application of ML techniques in RWD for disease prediction and management. The results reveal that ML methods, particularly ensemble models such as RF, play a crucial role in enhancing prediction accuracy and addressing the complexities of large and high-dimensional datasets common in health care. Among the top ML methods used, RF was the most widely used, featured in 42% (24/57) of the studies, showcasing its adaptability to a variety of clinical datasets such as EHRs and patient registries. RF's ability to handle missing data, its resistance to overfitting, and its effectiveness in managing imbalanced datasets made it a powerful tool in predicting disease outcomes [115,116], such as survival rates and complications in cardiovascular diseases and cancer. Regarding disease types, cardiovascular diseases dominated the studies, with 33% (19/57) of the studies dedicated to predicting outcomes related to heart transplantation, atrial fibrillation, and peripheral artery disease. This concentration is likely attributed to the critical need for predictive tools in the early diagnosis and management of these conditions, which account for a significant burden on health care systems globally [117]. ML applications, such as DNN and random survival forests, have been shown to improve the accuracy of survival predictions, assess treatment responses, and enhance patient stratification. In addition, the study highlights the increasing application of ML in predicting conditions such as cancers, neurological disorders, and infectious diseases. These findings align with the broader trend of using RWD to bridge the gap between clinical trials and actual patient care by making predictions based on RWD sources, such as EHRs and wearable devices. As evidenced in the studies reviewed, ML techniques can process vast amounts of medical data from various sources, facilitating early detection, timely intervention, and improved management of chronic conditions. Furthermore, these advancements in ML applications are subject to increasing regulatory oversight. Agencies such as the US FDA and the EMA are actively exploring frameworks for the approval and regulation of ML-driven tools in health care. These regulations aim to ensure ML models' safety, efficacy, and transparency, especially in real-world applications where data variability and model interpretability remain key concerns. As regulatory bodies continue to define standards for using RWD and ML in clinical settings, ensuring compliance with FDA and EMA guidelines will be essential for the broader adoption and integration of these technologies into clinical practice.

Comparison With Prior Work

This systematic review aligns with and extends several recent literature reviews that have explored the application of ML to RWD in health care. Previous studies have highlighted the potential of ML models to transform health care by improving disease prediction and patient management [118,119]. However, our review emphasizes a broader scope by including a wide variety of disease types, from cardiovascular diseases and cancer to neurological and infectious diseases, reflecting the growing versatility of ML tools in clinical settings. A notable comparison can be made with a study that focused on EHRs as the primary data source for ML models, conducted by Miotto et al [120]. While their review identified the challenges associated with EHR-based studies, such as data sparsity and heterogeneity, our study similarly acknowledges these limitations but also expands the discussion to include wearable devices and patient registries as additional data sources. These emerging data sources provide a more complete picture of the patient's health status, significantly improving model performance and enabling better patient monitoring in real-world settings. Another key comparison is with a review that focused on ML's role in health care decision-making and its integration into clinical workflows [121]. While the study by Beam and Kohane [121] explored various ML algorithms in health care, our review places a stronger emphasis on the role of ensemble models, such as RF, and their applicability across diverse health care datasets. One of the key contributions of our review, which sets it apart from previous works, is the focus on regulatory challenges associated with the deployment of ML models in clinical practice. While other reviews have discussed technical aspects of ML, we specifically address the urgent need for clearer regulatory frameworks from authorities such as the FDA and EMA to ensure the safe and effective approval of ML models in health care. This is an area that has received limited attention in previous reviews but is critical as health care systems begin to

XSL•FO
RenderX

rely more heavily on automated systems for clinical decision-making. Overall, this review builds upon the foundations established by previous literature, offering an updated and comprehensive analysis that incorporates new data sources, encompasses a broader range of diseases, and addresses the challenges of regulatory approval and model interpretability in the context of ML in health care.

Limitations

This review has several limitations. First, while a comprehensive search strategy was used, it is possible that some relevant studies were missed, particularly those that did not explicitly use the selected keywords or were indexed in databases not included in this search. In addition, this review was limited to English-language publications, which may have excluded relevant studies published in other languages. Another potential limitation is the application of strict inclusion and exclusion criteria, which, while ensuring the relevance and quality of the included studies, may have led to the omission of some studies that could have provided valuable insights. For example, studies with limited methodological details or those focusing primarily on deep learning applications were often excluded due to insufficient validation or performance comparisons. Future research could consider broader inclusion criteria to capture a wider range of studies. Furthermore, the variability in study designs and data sources posed challenges in synthesizing findings across different studies. The included studies used different types of RWD, ranging from EHRs and patient registries to imaging and wearable sensor data. This heterogeneity complicates direct comparisons and generalizability. Finally, while efforts were made to minimize bias through independent study screening by 2 reviewers, inherent biases in study selection and data extraction may still exist. The reliance on published literature also introduces publication bias, as studies with negative or inconclusive results may be underrepresented. Future work could integrate unpublished data sources or conduct meta-analyses to provide a more comprehensive assessment of ML applications in RWD.

Future Work

While this systematic review aimed for comprehensive coverage by using a broad search strategy across multiple databases and gray literature sources, the large disparity between the number of initially retrieved studies and those meeting the final inclusion criteria highlights an important area for improvement in future research. A more focused, topic-specific keyword strategy, combined with the application of advanced database filters, could increase the precision of future searches by limiting the retrieval of irrelevant studies. In addition, integrating artificial intelligence–assisted search tools and NLP algorithms might further enhance the efficiency of systematic literature reviews by streamlining the identification of eligible studies based on more nuanced criteria. Future reviews may also benefit from targeting more narrowly defined subtopics within the broader field of ML applications in RWD, such as specific disease domains, ML model types, or clinical trial phases. These refinements would likely improve the overall relevance and manageability of retrieved records, ensuring a more efficient screening process and focused synthesis of findings.

Conclusions

In conclusion, this review highlights the transformative potential of integrating ML techniques with RWD in health care, specifically for disease prediction and management. The use of advanced ML models, such as ensemble methods and deep learning, has demonstrated the ability to enhance predictive accuracy, improve patient stratification, and facilitate more personalized and proactive health care. These advancements are poised to significantly impact clinical decision-making, enabling earlier diagnoses, optimized treatment strategies, and efficient resource allocation. However, despite these promising developments, several challenges remain. Issues related to data quality, generalizability across diverse populations, and the interpretability of complex ML models must be addressed to ensure their effective and widespread application. The lack of transparency in some ML algorithms, which often function as “black boxes,” remains a significant barrier to their integration into clinical workflows. Improving the explainability of these models will be crucial in gaining the trust of health care professionals and enhancing the clinical utility of ML predictions. In addition, regulatory frameworks for ML in health care are still evolving, with clear guidelines needed from regulatory bodies such as the FDA and EMA. This will help ensure that ML models meet safety standards and are deployed in clinical settings in a manner that benefits both health care providers and patients. Furthermore, as health care data becomes increasingly heterogeneous, with sources ranging from EHRs to wearable devices and patient registries, strategies for addressing data inconsistencies and ensuring data quality will be essential. Looking ahead, future research should focus on improving the robustness, transparency, and generalizability of ML models, particularly for underrepresented diseases and diverse patient populations. Establishing ethical and regulatory standards for the use of ML in clinical practice will be crucial for fostering public trust and ensuring equitable access to these innovations. Collaboration among clinicians, data scientists, and policy makers will be key to overcoming these challenges, with the ultimate goal of ensuring that ML-driven advancements in health care lead to improved health outcomes, better care delivery, and more equitable health care systems for all.

Multimedia Appendix 2
PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist.
[PDF File (Adobe PDF File), 492 KB - medinform_v13i1e68898_app2.pdf]

Multimedia Appendix 3
A dataset of selected studies, including details such as the year of publication, authors' names, study title, database, diseases or medical conditions, disease category, study type, real-world evidence type, machine learning methods used, and key findings.
[XLSX File (Microsoft Excel File), 41 KB - medinform_v13i1e68898_app3.xlsx]

Abstract

Background: Stroke has a major impact on global health, causing long-term disability and straining health care resources. Generative large language models (gLLMs) have emerged as promising tools to help address these challenges, but their applications and reported performance in stroke care require comprehensive mapping and synthesis.

Objective: The aim of this scoping review was to consolidate a fragmented evidence base and examine the current landscape, shortcomings, and future directions in the design, reporting, and evaluation of gLLM-based interventions in stroke care.

Methods: In this scoping review, which adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines and the Population, Concept, and Context (PCC) framework, we searched 6 major scientific databases in December 2024 for gLLM-based interventions across the stroke care pathway, mapping their key characteristics and outcomes.

Results: A total of 25 studies met the predefined eligibility criteria and were included for analysis. Retrospective designs predominated (n=16, 64%). Key applications of gLLMs included clinical decision-making support (n=10, 40%), administrative assistance (n=9, 36%), direct patient interaction (n=5, 20%), and automated literature review (n=1, 4%). Implementations mainly used generative pretrained transformer models accessed through task-prompted chat interfaces. In total, 5 key challenges were identified from the included studies during the implementation of gLLM-based interventions: ensuring factual alignment, maintaining system robustness, enhancing interpretability, optimizing efficiency, and facilitating clinical adoption.

Conclusions: The application of gLLMs in stroke care, while promising, remains relatively new, with most interventions reflecting early-stage or relatively simple implementations. Against this backdrop, critical gaps in research and clinical translation persist. To support the development of clinically impactful and trustworthy applications, we propose an actionable framework that prioritizes real-world evidence, mandates transparent technical reporting, broadens evaluation beyond output accuracy, strengthens validation of advanced task adaptation strategies, and investigates mechanisms for safe and effective human-gLLM interaction.

Introduction

Background

Stroke represents a leading cause of global morbidity and long-term disability [1], imposing a substantial burden on health care systems through its high incidence and the complex, prolonged care needs of survivors of stroke [2]. The effective management of stroke treatment and rehabilitation is limited by persistent challenges in postacute care, notably fragmented follow-up, insufficient community-based professional support, the heterogeneity of patient requirements, and frequently inadequate health literacy [3]. Despite significant progress in prevention strategies, acute treatments, and rehabilitation technologies, critical gaps persist in providing personalized, continuous, and accessible long-term support for individuals recovering from stroke [4]. These unmet needs highlight a critical opportunity for transformative technological innovation in the delivery and management of stroke care.

The analysis of clinical documentation presents an important strategic avenue for addressing stroke care challenges. Unstructured narratives within electronic health records, including clinical notes, discharge summaries, and other free-text entries, contain rich yet often underused patient information. Systematic analysis of these data can significantly support risk stratification, inform treatment planning, and improve care coordination [5]. This recognition has led to advancements in natural language processing (NLP) techniques designed to extract insights from complex clinical text. Fundamental to many clinical NLP applications are transformer-based models pretrained on extensive biomedical and general-domain corpora. Specifically, encoder-only architectures, which leverage bidirectional encoder representations from transformers and its derivatives, demonstrate proficiency in structured information extraction tasks such as named entity recognition [6] and temporal relation identification [7]. These models typically rely on domain-specific pretraining and task-specific fine-tuning. Nevertheless, they possess inherent limitations related to their generative capabilities and broader generalizability [8], with models often struggling with open-ended clinical reasoning tasks and understanding long contexts, indicating the need for architectures with enhanced generative potential.

Generative large language models (gLLMs), including decoder-only and encoder-decoder architectures (eg, the Llama [9], GPT-4 [10], and bidirectional and auto-regressive transformers [BART] [11] families), represent a significant advancement over previous NLP models. These gLLMs broaden clinical application possibilities by framing diverse tasks within a unified text generation paradigm [8,12]. Key enabling techniques include prompt-based learning, which enables task generalization without parameter updates [13], and inference-time controls (eg, decoding strategies) that modulate output characteristics, which are crucial when access to models is limited [14]. In addition, retrieval-augmented generation (RAG), often integrated with custom medical knowledge bases, enhances factual accuracy and performance for knowledge-intensive clinical applications [15,16]. Together, these advancements present important opportunities for stroke treatment and rehabilitation services [17], potentially improving efficiency through intelligent automation (eg, triage and administration); enhancing patient care through personalization and improved resource access; and accelerating research workflows, including evidence synthesis and writing. Furthermore, the introduction of multimodal functionality, as demonstrated by models such as GPT-4o [18] and the Gemini family [19], marks a pivotal shift in the development of gLLMs. By processing integrated textual, visual, and auditory inputs, these newly introduced models can augment clinical reasoning (eg, in medical image interpretation) and support more effective analysis of real-world, cross-modal patient data, better aligning digital tools with the complexities of stroke care delivery.

Objectives

While digital health technologies provide advancements for stroke care [20], the unique capabilities and rapid evolution of gLLMs require a focused investigation within this specific clinical domain. Current reviews related to digital innovations in stroke care predominantly examine technologies that predate modern gLLMs, such as mobile health platforms [21,22], early conversational agents [23], and conventional machine learning or deep learning frameworks [24-26]. Moreover, although the current literature has reviewed the general clinical utility of gLLMs [17,27-29], there remains a critical gap in systematically reviewing evidence specifically on gLLM-driven interventions applied across the stroke care pathway. To address this critical research gap, this scoping review aimed to map the current landscape of gLLM applications throughout the common stages of the stroke care pathway. Specifically, it identified their uses, implementation characteristics, and reported outcomes and outlined future research directions. The central research question guiding this review was as follows: how, for what purposes, and with what reported outcomes have gLLMs been applied in stroke care? This review used the recommended guide of the Population, Concept, and Context (PCC) framework [30], which is guided by the following subquestions:

1. What study designs are used to evaluate gLLM-driven interventions in stroke care, and what are the key characteristics of the stroke populations involved? (Population or participants)
2. What target tasks, implementation details (ie, tasks, dialogue pattern, input data, and time stamps), evaluation approaches, and outcomes are reported for gLLM-driven interventions in stroke care? (Concept)
3. What cultural settings, specific stroke care stages (ie, prevention, diagnosis, treatment, prognosis, and rehabilitation), and technology adaptation strategies are described in the evaluation of gLLM-driven interventions? (Context)
4. What challenges are reported in implementing gLLMs in stroke care, and what specific directions for future research have been proposed? (Implementation challenges and research directions)

Methods

Study Guidelines and Registration

This review aimed to capture the available knowledge concerning the intersection of stroke care and gLLM technologies. Given the observed heterogeneity and breadth of research in this field, a scoping review methodology was used to summarize the current landscape and challenges associated with gLLM-driven intervention use across the stroke care pathway (ie, prediction, diagnosis, treatment, prognosis, and rehabilitation). The main objective was to address 3 key research questions predefined according to the PCC framework and identify knowledge gaps within this interdisciplinary area. This review was conducted and reported following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [31] (Multimedia Appendix 1) and adhered to the methodological framework of Arksey and O'Malley [32] for scoping reviews. The review protocol was preregistered on the Open Science Framework [33].

Search Strategy

A broad search strategy was considered necessary to capture relevant citations in this relatively novel and rapidly evolving field. The terminology associated with gLLMs currently lacks consensus, requiring the use of diverse search terms. Key terms included in the search were "pretrained language model," "large language model," "natural language processing," and "generative artificial intelligence." Moreover, recognizing the important role of the generative pretrained transformer (GPT) model family in gLLM development, related terms were also incorporated into the search strategy. In addition, given the potential integration of gLLMs within conversational agents, relevant search terms for the latter were included to maximize retrieval breadth.

The search targeted peer-reviewed, full-text original research articles and was executed across 6 major scientific databases: Ovid Embase, PubMed, Scopus, CINAHL Plus with Full Text, Web of Science Core Collection, and IEEE Xplore. All database searches were completed in December 2024, with the last search performed on December 24, 2024. Search strategies were individually tailored to the syntax and indexing of each database. The complete search strategies for all databases are detailed in Multimedia Appendix 2. No restrictions regarding publication date, language, or study type were applied during the initial search phase. Potential selection bias arising from the absence of a standardized technical taxonomy or consensus definition for gLLMs was acknowledged as a limitation in this review. To mitigate this risk, snowballing techniques [34] were systematically used following the initial search. This involved both forward snowballing (ie, examining articles citing the included studies) and backward snowballing (ie, reviewing the reference lists of the included studies). However, this process did not identify any additional studies meeting this review's inclusion criteria.

Inclusion and Exclusion Criteria

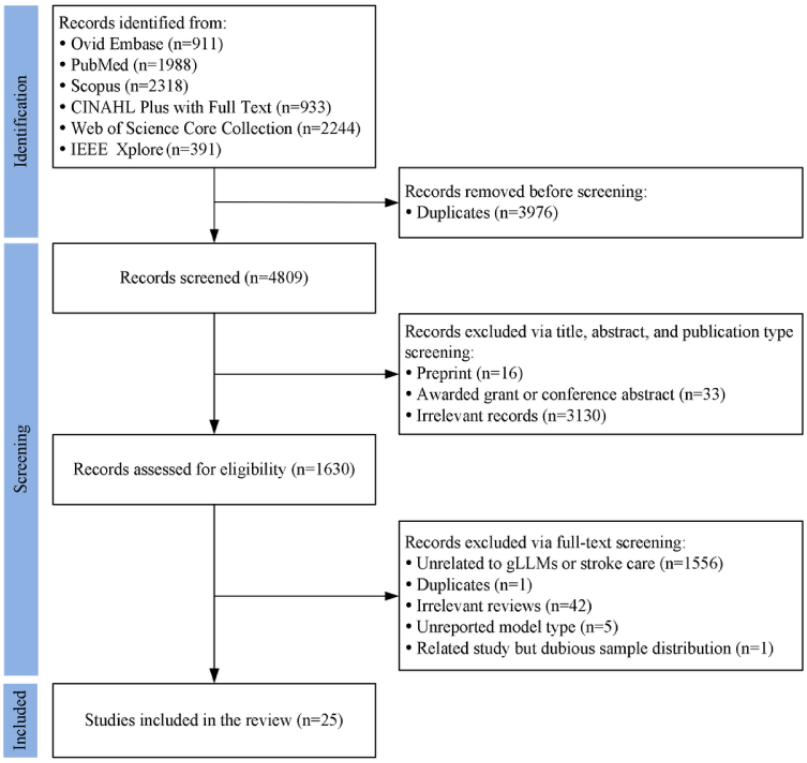
To be eligible for this review, studies had to assess a gLLM-driven intervention relevant to advancing understanding or practice in stroke prediction, diagnosis, treatment, prognosis, or rehabilitation and report at least one metric or qualitative perspective related to the performance evaluation of the specified gLLM intervention. Studies were excluded if they met one or more of the following conditions: they (1) were animal trials or focused exclusively on animal models; (2) did not report any performance outcomes or evaluation pertinent to the gLLM intervention described; (3) were unrelated to the field of stroke care or its advancement; (4) focused exclusively on managing stroke risk factors (eg, diabetes mellitus, hypertension, or atrial fibrillation) without directly addressing stroke management, outcomes, or care processes; (5) had a full text that could not be accessed or obtained; or (6) did not represent original research (ie, were reflection articles, opinion pieces, editorials, letters, conference abstracts without full results, or study protocols).

Study Selection and Data Extraction

Following the literature search, all retrieved records were imported into Zotero Reference Manager (version 7.0.15; Corporation for Digital Scholarship) by one author (XZ), where duplicates were identified and removed. Independent screening of titles, abstracts, keywords, and publication types was then conducted by 2 authors (XZ and WD) to identify potentially eligible studies based on the predefined inclusion criteria. The same 2 authors subsequently reviewed the full texts of these potentially eligible studies to confirm final inclusion and conduct data extraction (Multimedia Appendix 3). Any disagreements regarding study inclusion during either screening phase were resolved through discussion involving a third reviewer (ZL) until consensus was reached. Any unresolved issues encountered during feature extraction were documented as free-text notes; clarification was sought from the original study authors via email correspondence when necessary and feasible. All reviewers possessed relevant expertise in clinical medicine or medical informatics. Data extraction and synthesis activities were conducted in Microsoft Excel (Microsoft Office Long Term Service Channel 2021). Formal interrater agreement metrics were not calculated for the screening or extraction phases. This decision was made because the primary focus of this scoping review was the synthesis of descriptive characteristics, where minor formatting or phrasing differences between reviewers could lead to low numerical agreement despite substantive consensus on the content.

Guided by the PCC framework [35] and its predefined questions, the descriptive characteristics of the included studies were organized into structured tables. To confirm the methodological landscape and current evidence base at this emerging intersection of stroke care and gLLMs, this review commenced with a summary of study features, including publication year distribution and study design types. Then, consistent with the PCC framework, the analysis focused sequentially on (1) population (ie, characteristics relevant to intervention design and implementation, such as sample size, sex and age distributions, stroke phenotypes, and reported comorbidities);

XSL•FO
RenderX



(2) concept (ie, key components describing the processes and outcomes of the gLLM-driven interventions, including the main use categories and specific tasks assigned to gLLMs; input data types used; dialogue patterns and time stamps recorded [where available]; and performance evaluation approaches based on reference standards, evaluative perspectives, and reported metrics); and (3) context, examining the broader cultural, care setting, and technical contexts surrounding the gLLM-driven interventions, including national and sociolinguistic backgrounds, the specific stage within the stroke care pathway addressed, models used, modes of gLLM access used, instruction design strategies, and other technical adaptations. Finally, key implementation challenges associated with applying gLLMs across the stroke care pathway were identified based on reported results and author discussions within the context of the included studies.

Results

Overview

The literature search identified 8785 records across all databases. Of these 8785 records, after the removal of 3976 (45.26%) duplicates, 4809 (54.74%) titles and abstracts were screened for eligibility. This initial screening led to the exclusion of 65.09% (3130/4809) of the records based on relevance and an additional 1.02% (49/4809) due to inappropriate publication types (eg, preprints, awarded grants, and conference abstracts). Consequently, 33.89% (1630/4809) of the articles underwent full-text assessment. During this stage, of the 1630 studies, 1605 (98.47%) were excluded for various reasons, including irrelevance to the application of gLLMs or stroke care context (n=1556, 96.95%), being review articles not meeting the inclusion criteria (n=42, 2.62%), insufficient evidence of gLLM use (n=5, 0.31%), being a duplicate publication identified across different formats (n=1, 0.06%), and unresolved concerns regarding stroke sample composition after author consultation (n=1, 0.06%). Ultimately, 25 studies met the inclusion criteria and were included in this scoping review. Figure 1 presents the detailed PRISMA-ScR flowchart illustrating this study selection process.

Figure 1. Flow diagram of the study selection process based on the PRISMA-ScR guidelines. gLLM: generative large language model.

General Characteristics

Table 1 summarizes the general characteristics of the 25 reviewed articles. A key characteristic was the recent publication time frame, with all included studies published in 2023 or 2024, reflecting the emerging nature of this research domain. With regard to the methodologies used, most studies (16/25, 64%) used retrospective designs analyzing existing data. A few studies (4/25, 16%) adopted prospective designs, typically involving the recruitment of healthy participants or the collection of original data from patients with stroke. There were also some observational studies (4/25, 16%), including one that used gLLMs for literature discovery during systematic review development [36], as well as a single comparative case study [37]. It should be noted that this review identified no randomized controlled trials assessing the clinical efficacy or impact of gLLM-driven interventions in populations of patients with stroke.

[a]IS: ischemic stroke.

[b]AF: atrial fibrillation.

[c]HF: heart failure.

[d]HTN: hypertension.

[e]DM: diabetes mellitus.

[f]DLP: dyslipidemia.

[g]CAD: coronary artery disease.

[h]AC: active cancer.

[i]NIHSS: National Institutes of Health Stroke Scale.

[j]ASPECTS: Alberta Stroke Program Early Computed Tomography Score.

[k]mRS: modified Rankin Scale.

[l]A total of 121 patients had an mRS score of 0 or 1, and 42 had a score of 2 or 3.

[m]NR: not reported.

[n]Description of real patients (n=102).

[o]HS: hemorrhagic stroke.

[p]ESRD: end-stage renal disease.

[q]A total of 100 magnetic resonance and computed tomography images were included, comprising 50 with lesions (25 ischemic stroke, 25 brain hemorrhage) and 50 normal controls (25 matched to each lesion group).

[r]A total of 266 radiological images from patients with acute stroke were included.

[s]A total of 90 participants were included, comprising 30 patients with stroke and 60 healthy controls.

[t]Published case report heterogeneity led to reporting barriers.

[u]MRC: Medical Research Council.

[v]GCS: Glasgow Coma Scale.

[w]K-MMSE: Korean version of the Mini-Mental State Examination.

[x]FAB: Frontal Assessment Battery.

[y]ICH: intracranial hemorrhage.

[z]H&H: Hunt and Hess scale.

[aa]Not applicable.

[ab]SIAS: Stroke Impairment Assessment Set.

[ac]A multicriteria assessment set included quantitative scores and qualitative descriptions.

[ad]In total, 50 annotated electronic health record sections were extracted from the records of 13,605 patients with stroke.

[ae]Parts from triplets, subrelations, and unlabeled text from 3 Chinese stroke-related medical datasets were included.

[af]Description of derivation (n=100).

[ag]CAIS: childhood arterial ischemic stroke.

[ah]PAIS: perinatal arterial ischemic stroke.

[ai]CVST: cerebral venous sinus thrombosis.

[aj]PSOM: Pediatric Stroke Outcome Measure.

[ak]At least 4038 stroke-related hospitalizations of insured beneficiaries were included in the study.

[al]A total of 1050 mechanical thrombectomy reports from patients with acute ischemic stroke were included.

[am]PAD: peripheral arterial disease.

[an]Two questions from the American Stroke Association website were included.

[ao]Three healthy participants were also involved in the test of the generative large language model–based hand exoskeleton controls.

[ap]Did not report whether the 12 participants were patients with stroke.

[aq]Six questions on evidence synthesis during systematic reviews were included.

Distribution of Included Stroke Populations

The first question of this review related to the *population* component of the PCC framework and asked for key characteristics of the stroke populations involved in the gLLM-driven interventions. Specifically, the review examined the characteristics of the stroke populations involved in the included studies. The analysis included sample size, sex distribution, age range, stroke phenotypes, key comorbidities, and reported functional scores as these elements can influence

XSL•FO
RenderX

intervention design and applicability. Notably, 8% (2/25) of the studies did not use patient data (real or simulated); instead, they evaluated the gLLMs using predefined question sets related to stroke care [36,57]. Among the remaining 92% (23/25) of the studies, the level of detail provided for population characteristics varied. A summary of these characteristics, including clarifications obtained via author correspondence, is presented in Table 1.

Reporting of specific population characteristics varied across the 25 studies (see Table 1 for further details). Sample sizes of involved patients were specified in most articles (17/25, 68%), demonstrating considerable range from a single case to 36,922 patients. Data on gender were available in 52% (13/25) of the studies, which indicated that male individuals comprised 56.9% of the aggregate reported sample. A total of 56% (14/25) of the studies provided age metrics (mean or median), which spanned 4.5 years (in a pediatric study) to 76.1 years. Stroke phenotype details were available in 64% (16/25) of the studies, and ischemic stroke (15/25, 60%) was found to be more commonly studied than hemorrhagic stroke (5/25, 20%). Notably, 4% (1/25) of the studies focused exclusively on pediatric patients with stroke. In total, 32% (8/25) of the studies provided information on patient comorbidities, often identified through the main text, appendices, or associated datasets. Commonly reported conditions included hypertension, diabetes mellitus, atrial fibrillation, dyslipidemia, coronary artery disease, heart failure, and active cancer. Furthermore, 36% (9/25) of the studies documented baseline severity or functional outcomes using clinical assessment tools. The most frequently used scales were the National Institutes of Health Stroke Scale and the modified Rankin Scale [38,39,43,55,56]. Other reported instruments included the Glasgow Coma Scale [43,45], Pediatric Stroke Outcome Measure [50], Stroke Impairment Assessment Set [37], intracranial hemorrhage score [45], Hunt and Hess scale [45], Medical Research Council Scale for Muscle Strength [43], Korean version of the Mini-Mental State Examination [43], and Frontal Assessment Battery [43].

Conceptual Considerations for Implementing and Evaluating gLLM-Driven Interventions in Stroke Care

In response to the second subquestion related to the *concept* component of the PCC framework, this review analyzed the target tasks, implementation details (including models, prompts, and data inputs), evaluation strategies, and reported outcomes for gLLM applications in stroke care. In total, 4 key categories of gLLM use were identified, as summarized in Table 2. The main categories focused on supporting health care professionals either through clinical decision-making assistance (10/25, 40%) or administrative workflow automation (9/25, 36%). Other identified applications included direct patient support through interactive online platforms (5/25, 20%) and enabling the discovery of evidence during systematic reviews (1/25, 4%). With regard to the implementation of gLLMs, evaluations mostly involved single-turn dialogues conducted under controlled settings (15/25, 60%), whereas the reporting of intervention time stamps was limited (5/25, 20%). Despite considerable heterogeneity across studies in terms of task objectives, input data sources, evaluation benchmarks, and assessment metrics, common themes and approaches were found within each application category.

XSL•FO
RenderX

Table 2. Summary of the implementation and evaluation of generative large language model–driven interventions in stroke care.

Study	Task objectives	Input data or sources	Dialogue patterns	Reported time stamp	Gold-standard providers or benchmarks	Evaluation perspectives	Evaluation metrics
Clinical decision-making support (n=10)							
Pedro et al [38]	Predict the mRS[a] score at 3 mo after mechanical thrombectomy	Patient H&P[b], neuroimaging, and mechanical thrombectomy procedure notes	Single turn	Yes	Stroke unit clinicians	AGS[c] for true exact and dichotomized mRS scores; bias; comparison with MT-DRAGON	Cohen κ; mean difference and 95% limits of agreement; ND[d]
Chen et al [39]	Make clinical decisions for mechanical thrombectomy	Patient H&P and neuroimaging notes	Single turn	No	Neurology specialists	AGS for mechanical thrombectomy decision; different error analysis	Counts and rate
Strotzer et al [40]	Interpret MRI[e] and CT[f] images and generate free-text reports in stroke cases	MRI and CT images	Single turn	Yes	Radiologists and nonradiologist in training	AGS for free-report items; interrun consistency; AGS for binary pathological findings; impact on nonradiologist	Agreement rate; interrun consistency rate and the Randolph free-marginal κ; accuracy, sensitivity, and specificity; rate (distribution across categories)
Kuzan et al [41]	Interpret DWI[g] and ADC[h] maps in acute stroke cases	DWI and ADC maps	Multiturn	No	Radiologists	AGS for stroke and normal or all-image interpretation	Rate; TP[i], TN[j], FP[k], FN[l], sensitivity, specificity, PPV[m], NPV[n], and accuracy
Fei et al [42]	Evaluate cognitive performance in stroke cases	Patient responses to selected RBMT-II[o], MMSE[p], and MoCA[q] items	Multiturn	No	Rehabilitation physicians	Intermodel and model-physician agreement	Intraclass correlation coefficient and *P* value
Lee et al [43]	Locate lesions based on patient H&P	Patient H&P notes	Single turn	Yes	Location description from original published case report	AGS for trial- and case-based lesion localization; different error analysis	Specificity, sensitivity, precision, and F_1-score; ND
Haim et al [44]	Calculate the NIHSS[r] score and predict the use of tissue plasminogen activator	EMR[s] periods	Single turn	No	Emergency department physicians	Intermodel and model-physician agreement; predictive validity	Cohen κ and *P* value; AUC-ROC[t]
Chen et al [45]	Calculate GCS[u], H&H[v], and ICH[w] scores	Patient neuroexamination notes without scores	Single turn	No	Scores in original neuroexamination notes	AGS for scoring; repeatability; effect of varied case complexity and prompting design	Average error rate and average error magnitude
Blacker et al [46]	Use of SNACC[x] HQRs[y] to answer questions on perioperative stroke and endovascular treatment anesthesia	Patient H&P notes	Multiturn	Yes	Anesthesiologists	HQR identification; correct reference citation; potentially harmful information	ND

XSL•FO
RenderX

Study	Task objectives	Input data or sources	Dialogue patterns	Reported time stamp	Gold-standard providers or benchmarks	Evaluation perspectives	Evaluation metrics
Zhang et al [37]	Generate rehabilitation prescriptions and ICF[z] codes in a stroke case	Patient H&P notes	Multiturn	No	Physical medicine and rehabilitation physicians	Content exhaustiveness and clinical applicability; inference logic	ND
Administrative assistance (n=9)							
Sivarajkumar et al [47]	Extract and categorize physical rehabilitation exercise information from stroke cases	EHR[aa] sections with physical therapy information	Single turn	No	Physical therapy experts	AGS for extracted items	Accuracy, precision, recall, and F_1-score
Guo et al [48]	Extract triples by fine-tuning and integrating a relation classification module	Stroke-related medical text from SEM-RC[ab], CVDEM-RC[ac], and CMeIE[ad]	—[ae]	No	Relevant items from datasets and performance of the CasCLN[af] benchmark models	AGS for total and overlapping triple extraction; performance improvements over baseline models	F_1-score; rate
Lehnen et al [49]	Extract key information for mechanical thrombectomy	Mechanical thrombectomy records	Single turn	No	Interventional neuroradiologists	AGS for extracted items; different error analysis; intermodel extraction performance comparison	Correct rate and Cohen κ; count and rate; correct rate and *P* value
Fiedler et al [50]	Extract IPSS[ag] format information and infer disease severity	Outpatient notes	Multiturn	No	Clinical investigators	AGS for extracted items	Rate
Wang et al [51]	Extract and infer key information for mechanical thrombectomy surgery	Mechanical thrombectomy records	Single turn and multiturn for correct format response	No	Interventional and junior neuroradiologists	AGS for extracted and inferred items; agreement with junior neuroradiologists; processing efficiency	Accuracy, sensitivity, specificity, AUC[ah], and mean squared error; *P* value; average case processing time
Goh et al [52]	Extract stroke audit data	Discharge summaries	Single turn	No	Relevant items from original discharge summaries	AGS for extracted items; model-clinician comparison in AGS; inference error analysis	Counts and rate; ND
Baro et al [53]	Predict stroke hospitalization by fine-tuning and integrating classification layers	Chronological health insurance data with aggregated medical events	—	No	Relevant items from original health insurance data	AGS across time windows using the general fine-tuned models; AGS comparison between general and stroke-specific fine-tuned models	F_1-score, sensitivity, specificity, and AUC
Meddeb et al [54]	Extract key information for mechanical thrombectomy items	Mechanical thrombectomy records	Single turn	No	Radiologists and clinical medical students	AGS for extracted items; efficiency improvement with EITL[ai]	Precision, recall, and F_1-score; average case time savings
Kim et al [55]	Perform data wrangling on a large dataset of patients with stroke	Metadata from the CRCS-K[aj] dataset and neurologist queries	Multiturn	No	Neurologists	Reliability and efficiency of EITL workflow and clinical knowledge alignment	ND
Direct patient interaction (n=5)							

XSL•FO

[ap]PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

gLLM-driven systems categorized as clinical decision-making support were mainly used to analyze clinical documentation to inform medical diagnosis, treatment planning, prognosis estimation, or rehabilitation strategies in stroke care. While textual inputs such as the medical history of patients, neurological examination results, and neuroimaging reports were common, only 8% (2/25) of the studies analyzed computed tomography or magnetic resonance imaging scans directly as

XSL•FO
RenderX

primary input [40,41]. Such gLLM-driven systems were applied across the stroke care pathway, assisting with neurological function scoring during triage (eg, the National Institutes of Health Stroke Scale [44], Glasgow Coma Scale, Hunt & Hess scale, and intracranial hemorrhage score [45]) and supporting diagnosis through direct image interpretation [40,41] or lesion mapping from textual descriptions [43]. In addition, they were used to inform acute intervention decisions, including eligibility for thrombectomy [39] or thrombolysis [44] and anesthesia planning [46]. Moreover, they facilitated rehabilitation through outcome prediction (eg, 3-month modified Rankin Scale [38]), cognitive assessment [42], or generation of personalized rehabilitation plans [37]. Performance evaluation mainly involved clinician assessment or comparison against predefined benchmarks derived from the original clinical records. Additional validation methods often included cross-comparison against the outputs of clinicians or functionally similar tools using identical inputs [38,39,42,44], as well as repeatability checks across multiple models [40,43,45]. Some studies (5/25, 20%) investigated human-computer interaction factors, examining aspects such as the impact on junior clinicians [40] or examining the reasoning processes behind model-generated conclusions [37,39,43,46]. Across these varied approaches, quantitative metrics (eg, accuracy, rate, F_1-score, k value, and P value), particularly those assessing factual accuracy and output consistency, were the primary focus of most evaluations.

gLLM-driven systems categorized as administrative support predominantly focused on alleviating clinician documentation workload and improving the management and use of clinical information. The primary functions involved extracting structured information from clinical text and generating summaries or other abstract representations to facilitate downstream use by other health care workers. These tasks used a variety of clinical data sources, including electronic health records [47], electronic medical records [48], specialized procedural records (eg, thrombectomy reports) [49,51,54], discharge summaries [52], outpatient notes [50], health insurance claim data [53], and stroke registries [55]. Evaluation methods for these administrative tasks were similar to those used for decision support tools. Most often, the alignment of gLLM outputs with gold-standard annotations was measured [47-55], or performance was compared against that of human experts or other specialized systems that were used to analyze identical data [48,49,51-53]. Quantitative metrics were used most frequently during performance assessments [47-54]. Beyond accuracy and alignment, a few studies (3/25, 12%) explicitly evaluated efficiency. For example, 4% (1/25) of the studies reported the average time required for automated data extraction from thrombectomy operative notes [51], whereas another 8% (2/25) demonstrated significant time reductions using expert-in-the-loop (EITL) workflows involving gLLMs for extracting procedural details [54] and processing large-scale registry data [55].

gLLM-driven systems involving direct patient interaction were developed primarily to support personalized out-of-hospital stroke care, reduce patient uncertainty regarding medical information, and promote adherence to preventive and rehabilitative behaviors. The main tasks performed by gLLMs in this regard included (1) answering general stroke-related queries using embedded knowledge [57,58], (2) generating individualized preventive guidance by interpreting patient profiles with relevant literature [56], and (3) translating natural language commands to control upper-limb exoskeleton robots during rehabilitation [59,60]. Consequently, study designs focused on addressing patient needs, either through simulating responses to public-facing queries [57,58] or by developing systems intended specifically for lay users [56,59,60]. Assessment strategies for these systems considered both technical output performance (eg, factual alignment [56-60] and comparative analyses against alternative methods [59,60]) and key patient-centered outcomes. The latter included metrics such as readability [57,58], safety [57], personalized support [57,58], potential for anxiety reduction [56], and overall user experience [60]. As a result, the open-ended and dialogue-driven nature of these systems required diverse evaluation methodologies. These ranged from clinician-led narrative assessments or reviews [56,57,59,60] and independent scoring protocols [57] to user feedback questionnaires [60] and standard quantitative metrics computed by the research teams [58-60].

Only 4% (1/25) of the included studies [36] investigated the application of gLLM systems to support literature review tasks. This study involved asking 6 questions to the gLLM, ranging from general medical knowledge and systematic review methodology inquiries to specific queries about evidence synthesis concerning Actovegin's efficacy for ischemic stroke. A qualitative evaluation of the gLLM-generated answers assessed their correctness and applicability for the review context. The study concluded that all responses generated by the gLLM were unreliable, resulting in their exclusion from the final systematic review conducted by the research team. Table 2 provides a summary of the target tasks, implementation characteristics, and evaluation approaches reported across the included studies.

Contextual Focus on gLLM-Driven Intervention Design in Stroke Care

In response to the third subquestion and the *context* component of the PCC framework, this review examined the settings surrounding the design and implementation of the evaluated gLLM interventions, with further information presented in Table 3. This review considered 3 primary contextual dimensions: cultural, care, and technical settings. Cultural context referred to the study location (country) and relevant national and sociolinguistic backgrounds of the participants (eg, health care professionals, patients, and caregivers). The care dimension referred to the specific phase of the stroke care pathway (ie, prevention, diagnosis, treatment, prognosis, or rehabilitation) targeted by the intervention and associated data sources. The technical dimension involved the diverse adaptation choices evident in intervention development, including approaches used in instruction design (prompt engineering), inference-time parameter configurations, and underlying model-level adaptations.

[c]BART: bidirectional and auto-regressive transformers.

[d]GPT: generative pretrained transformer.

Analysis of the cultural dimension identified the geographic settings for most of the included studies (23/25, 92%). The studies originated from diverse global locations, with the United States (6/25, 24%), China (4/25, 16%), and Germany (3/25, 12%) being the most represented countries. Other studies represented individual contributions from Canada, Australia, Singapore, Japan, South Korea, Turkey, Portugal, Brazil, Indonesia, and Israel. With regard to the care dimension, most gLLM interventions (11/25, 44%) focused on the treatment phase, where systems were typically used to support clinical decisions, integrate therapeutic guidelines, or extract specific treatment data (eg, surgical procedures and medication regimens) from documentation. The diagnostic phase was the second most common focus (9/25, 36%), with applications including lesion localization support, assistance with diagnostic reasoning, and extraction of pertinent diagnostic details from clinical records. Considerably fewer studies focused on stroke prevention (3/25, 12%) or prognosis (3/25, 12%). Prevention-focused interventions mainly aimed to reduce subsequent stroke-related hospitalizations or expand public access to preventive resources. Prognostic applications focused on assisting clinicians primarily by calculating prognostic scores or interpreting relevant information documented within clinical notes.

Regarding the technical dimension, adaptation strategies for the gLLM-driven systems varied across the included studies. These choices often reflected trade-offs between computational cost and task demands, aiming to align model behavior with task-specific constraints while maintaining stable output control. For relatively straightforward tasks, a *plug-and-play* strategy using standard interfaces was frequently adopted. This involved accessing closed-source models using web-based chat interfaces (12/25, 48%) or application programming interface (API) end points (8/25, 32%) without further model customization. As task complexity increased or baseline performance proved inadequate, studies often adopted multiprompt strategies to better guide model behavior. Established methods included zero-shot (20/25, 80%), few-shot (4/25, 16%), and chain-of-thought (1/25, 4%) prompting. Beyond these approaches, specific prompting techniques were used to improve control—role-based prompting assigned domain-specific personas (eg, *You are a neurologist*); format-constrained prompting enforced structured outputs (eg, JSON, CSV, standardized terminologies, and executable code); and context-enhanced prompting incorporated background knowledge, task decomposition steps, or self-reflection instructions to improve response quality.

These prompting strategies were sometimes used alongside inference-time configurations, among which temperature adjustment was the most frequently reported technique (5/25, 20%) for modulating output diversity versus coherence. In a small subset of studies requiring deeper customization (2/25, 8%), locally deployed open-source models underwent model-level adaptations. These included techniques such as

XSL•FO
RenderX

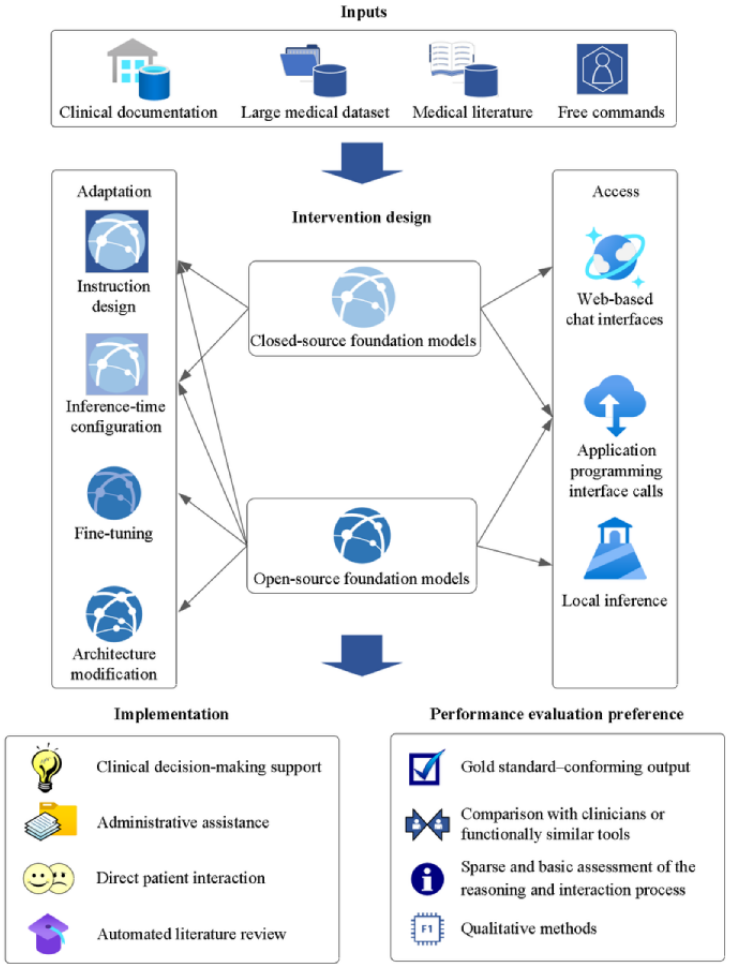
parameter-efficient fine-tuning and architectural modifications to customize the model more closely to the specific clinical application. A variety of gLLM families were used across the included studies. The GPT series (OpenAI) was mainly used in 80% (20/25) of the studies. Other models used in multiple studies included the Mixtral (and its variant, BioMistral) series (Mistral AI; 3/25, 12%), the PaLM 2 (and its successor, Gemini) series (Google DeepMind; 2/25, 8%), the Qwen series (Alibaba Cloud; 2/25, 8%), and the GLM series (Zhipu AI; 2/25, 8%). Models identified in single studies included Llama 3-70B (Meta), BART base and BART-large-Chinese (Fudan NLP Lab), Spark 3 (iFLYTEK), and openCabrita 3B (22h).

Challenges Identified During the Implementation of gLLM-Driven Interventions in Stroke Care

Through a comprehensive review of the findings of the included studies, five key challenges were identified in applying gLLMs across the stroke care pathway: (1) ensuring factual alignment, (2) maintaining system robustness, (3) enhancing model interpretability, (4) optimizing operational efficiency, and (5) facilitating adoption into clinical practice.

Factual alignment was the most frequently discussed concern [36-55,57-60], reflecting persistent difficulties in ensuring consistency among system outputs, established clinical knowledge, and input data. Documented issues included inaccurate or incomplete responses, hallucinated content, and output failures. Several studies (11/25, 44%) noted nondeterministic behavior across repeated runs [41,43,45,51], failure to retrieve pretrained knowledge [36,40,46,57], limited inclusion of up-to-date evidence [37,38], and inconsistencies between the model's reasoning steps and its final outputs [39,43]. Robustness issues were mainly associated with variability in output quality due to changes in input data or instructions. Data-related concerns included difficulty in handling rare or complex cases [38-41,43,45,50,54,55,59,60]; managing human-induced input noise such as incompleteness, ambiguity, or internal contradiction [38-40,44,45,49,51,52,54]; and adapting to distributional discrepancies between training and deployment data [40,41,43,48,57]. Instruction-level fragility was also observed as small prompt modifications led to substantial variations in output [37,40,42,43,46,47,49,50,54,58], demonstrating the sensitivity of gLLM-driven systems to prompt design.

Adoption, interpretability, and efficiency were also deemed potential concerns in applying gLLMs across the stroke care pathway. Adoption-related challenges involved the need for EITL oversight when applying gLLMs [36,37,39-41,44,45,49,50,52,58]; ongoing efforts to integrate gLLMs into clinical workflows [40,42,43,45,50,52,55,57,60]; and unresolved issues related to legal compliance, data privacy, and patient safety [43,50,57]. Interpretability challenges were associated with the opaque and uncontrollable nature of gLLM reasoning [41,43,46,55,57], the limited readability of gLLM responses [57,58], and variations in how individuals understood the same content [46,57]. Efficiency-related concerns included token processing constraints [38,39] and trade-offs between model performance and computational cost [53,59].



Discussion

Principal Findings

This study presented a timely scoping review mapping the intersection of stroke care and gLLMs, providing practical insights into current applications within this rapidly evolving domain. The substantial heterogeneity identified across the included studies, spanning objectives, methodologies, contexts, and outcomes, precluded meta-analysis, confirming the suitability of the chosen scoping review approach. The analysis classified gLLM-driven interventions into 4 key applications, as presented in Table 2. Examination within each category focused on the target tasks assigned to gLLMs, types of input data used, reported dialogue patterns and intervention timing, and performance evaluation methods. The findings of this review demonstrate that existing research has mainly used gLLMs with clinical document inputs for retrospective tasks such as supporting clinical decision-making or extracting data relevant to stroke diagnosis, treatment, prognosis, and rehabilitation. A smaller subset of studies (5/25, 20%) adopted a more patient-centered perspective, either by integrating gLLMs with upper-limb exoskeleton systems to potentially support motor recovery or by applying them to address open-ended patient questions regarding stroke prevention. The single study investigating gLLM use for academic writing support concluded that the outputs were unreliable for practical use, highlighting limitations in that specific application context. Given the breadth of stroke care tasks addressed, considerable diversity in the technical implementation of these gLLM interventions was observed, as shown in Table 3. Common technical approaches involved using GPT-series models, typically accessed through web-based chat interfaces or API calls and guided primarily by task-specific prompt engineering strategies. Moreover, this review identified five critical challenges pertinent to applying gLLMs effectively and safely across the stroke care pathway: (1) ensuring factual alignment, (2) maintaining system robustness, (3) enhancing model interpretability, (4) optimizing operational efficiency, and (5) facilitating adoption into clinical practice. Figure 2 illustrates the current landscape of gLLM-based interventions across the stroke care pathway.

XSL•FO
RenderX

Figure 2. Current landscape of interventions driven by generative large language models in stroke care.

Need for Rigorous Real-World Evidence to Support Clinical Translation

gLLMs represent a novel addition to digital health [14,61,62], creating new avenues for neurological care [17] and offering significant potential to improve stroke prevention and bridge gaps in care access. Despite this promise, the evidence base for gLLMs specifically in stroke care currently relies heavily on retrospective analyses of clinical documentation and experimental studies conducted in simulated settings. This cautious approach likely reflects valid concerns regarding the potential impact of these nascent technologies on patient safety and clinical decision-making [63]. Highlighting the feasibility of real-world assessment in other domains, a recent cluster-randomized trial in China demonstrated that a gLLM-driven chatbot effectively improved parental health literacy concerning human papillomavirus vaccination for adolescent girls [64]. In contrast, most of the stroke care studies included in this review (24/25, 96%) did not involve integrating gLLM-based systems into actual clinical workflows or conducting real-time interactions with patients. Consequently, the real-world effects of these systems on health care delivery efficiency, clinical outcomes, and patient health literacy within the context of stroke care remain largely unverified. This significant evidence gap highlights an urgent need within the stroke research community. Future efforts must prioritize clarifying evidence requirements and systematically generating robust real-world data on the feasibility, safety, clinical impact, and cost-effectiveness of gLLM applications to provide essential support for clinical translation.

Toward Balanced Process and Outcome Evaluation

For stroke care tasks that depend on interaction between human users (eg, health care professionals, administrative staff, or patients and their caregivers) and gLLM-based tools, evaluation needs to extend beyond outcome-oriented performance metrics. Incorporating assessments of model reasoning processes and the dynamics of human-gLLM interaction is critical for providing a complete understanding. While 8% (2/25) of the included studies focused solely on noninteractive tasks, including advanced text representation [48,53], the remaining studies (23/25, 92%) relied on human-gLLM interaction to complete stroke care tasks. Among these, more than half (12/23, 52% of the studies) assessed gLLM performance solely based on how well model outputs aligned with clinical expectations or predefined gold standards without assessing human-gLLM interaction processes or model reasoning behavior. While some of these studies (15/25, 60%) aimed to produce correct responses in single-turn dialogues, this narrow, outcome-focused evaluation perspective is insufficient for interventions that rely on gLLMs' capabilities for open-ended reasoning and interactive engagement [62]. Several studies (11/25, 44%) acknowledged simple process-related metrics in logical coherence, efficiency improvement, and user interaction experience and observed

XSL•FO
RenderX

effects. It is also important to examine how well gLLM-driven tools can identify and collect task-relevant information through multiturn interactions, especially in patient-facing contexts [62]. Fully understanding and ensuring the real-world applicability and safety of gLLM-based systems in health care settings requires broadening performance evaluation frameworks to rigorously include these dynamic processes alongside static outcomes.

Correction of Technical Reporting Deficiencies

Significant issues were raised regarding the normative reporting of gLLM intervention designs within the included studies. A common oversight appeared to be neglecting the fact that different access methods (eg, web-based chat interfaces) may use customized configurations or variants of the same underlying model. This lack of specificity was particularly evident when models were accessed using web chat interfaces. These often used restricted-access [65] or proprietary, fine-tuned, chat-optimized variants [66] (frequently branded as specific products, eg, ChatGPT) that are not directly equivalent to the base models released by developers. Despite researchers' attempts to specify the underlying models, their precise identity often remained ambiguous. As a result, conflating branded chat products with broader foundation model families (eg, ChatGPT with the GPT series) can lead to conceptual confusion and should be avoided in reporting. Furthermore, this review identified instances in which API-based access to closed-source models was inaccurately characterized, for example, as *static version use* or analogous to offline deployment [50]. In reality, such access depends on remote servers where the underlying models can be updated by the provider without explicit version notification, challenging assumptions of both offline use and version stability. Given the rapid iteration cycles common to gLLMs, consistently time-stamping the input and output stages during use could aid researchers in documenting and interpreting the specific model versions or operational states encountered. However, this practice was uncommon in the reviewed literature, with only 20% (5/25) of the studies reporting time-stamped interaction events [38,40,43,46,57]. To maintain analytical rigor amid these reporting ambiguities, this review adopted a strategy of consistently referring to general model series (eg, the GPT-4 family) when exact versions or configurations could not be definitively ascertained from the studies. The observed heterogeneities and frequent lack of precision in technical reporting highlight a critical need for the development and adoption of standardized, transparent guidelines for describing gLLM-driven intervention designs. Such standards are important for ensuring accurate interpretation, enabling reproducibility, and facilitating meaningful cross-study comparability in this advancing field.

Simple and Homogeneous Task Adaptation Strategies

The design and refinement of gLLM-driven interventions specifically for stroke care remain in their nascent stages. Current approaches mainly rely on zero- or few-shot instruction designs, enhanced using techniques such as context augmentation, role-based prompting, or format constraints to guide outputs. While prompt iteration was occasionally used to improve factual alignment [42,46,50], generated outputs still often contained inaccuracies or lacked desired nuance. Similarly, although a small subset of the included studies (2/25, 8%) investigated domain-specific fine-tuning of open-source models for better task adaptability, both prompt engineering and basic fine-tuning strategies appear insufficient for highly complex clinical settings that require integrating robust logical reasoning with precise numerical computation. Emerging architectures such as RAG [55,57] and multiagent systems [52] show promise, mirroring developments in other medical fields [67-69], but their empirical validation within stroke care is currently underexplored. Furthermore, the robustness of gLLM-based stroke care interventions against unexpected inputs or variations remains insufficiently examined. The underlying causes of potential failures were often unexplored due to a lack of proactive and systematic investigation strategies within the reviewed studies.

Underexplored Dual Gap in Human-gLLM Interaction Dynamics

Although intentionally introducing noise or adversarial inputs is a standard method for stress testing and evaluating robustness in machine learning [70], most studies (24/25, 96%) appeared to respond reactively after poor performance was observed, sometimes relying on subjective speculation regarding failure modes rather than rigorous empirical analysis. Systematically analyzing model responses to flawed, edge-case, or adversarial inputs could yield crucial insights into failure mechanisms, thereby informing the development of safer and more reliable gLLMs for stroke care [45,71]. Finally, the rapid iteration cycles and frequent updates of underlying models introduce significant uncertainties regarding the long-term performance, reliability, and transferability of the developed interventions. For example, it remains unclear how effectively interventions initially developed and validated on now deprecated models (eg, early versions of ChatGPT) will function when deployed using substantially updated successor models (such as GPT-4o) [72]. Therefore, this dynamic landscape requires ongoing evaluation, validation, and potentially continuous adaptation strategies for gLLMs intended for clinical use.

While a significant amount of research has focused on gLLM intervention design and technical optimization, how humans interact with such systems within the context of stroke care remains largely underexplored. Although concerns about the *black box* nature of gLLM reasoning processes are frequently discussed, this review suggests that the heterogeneity in users' subjective interpretations of gLLM outputs presents an equally critical yet less examined challenge. There appears to be emerging agreement on the value of EITL frameworks for deploying gLLMs in real-world settings; however, evidence from the included studies shows that clinicians can interpret the exact same generated response quite differently [46,57]. Such variability in human interpretation may significantly influence downstream trust in the system; subsequent clinical decision-making; and, ultimately, patient outcomes in stroke care.

Beyond interpretation variability, safety concerns are extended by potential user behaviors and governance gaps. For example, follow-up reprompting was reportedly used in one study to

XSL•FO
RenderX

bypass built-in safety restrictions designed to prohibit direct radiological image interpretation [40], exposing risks related to both inadequate technology governance and the potential for deliberate misuse by individuals. Moreover, actionable guidelines are urgently needed to address broader safety and ethical concerns, including the legal ambiguities surrounding artificial intelligence–driven interventions and potential conflicts between commercial deployment objectives and established clinical best practices [57].

Consequently, these underexplored dimensions point to a dual gap that limits research and the clinical translation of gLLMs in stroke care. The first gap concerns a limited understanding of optimal gLLM-driven intervention design tailored to specific stroke care tasks, including defining the operational boundaries and failure modes of such systems. The second relates to insufficient investigation into how diverse human users (eg, health care professionals, patients with stroke, and caregivers) actually interact with gLLM-based systems and how these interactions dynamically shape both user understanding and system outputs.

Future Directions

The application of gLLMs in stroke care, while promising, is relatively new, with most current interventions representing early-stage or relatively simple implementations. To enable the responsible and effective integration of such tools into health care settings, the development and adoption of formal, multidimensional frameworks that promote rigorous evaluation and informed oversight are critical. Future studies attempting to bridge the gap between potential and practice would also likely benefit from using mixed methods techniques to gain deeper, more nuanced insights into how gLLMs actually operate across diverse stroke care tasks and how they can be most effectively and safely deployed in complex clinical environments. In light of the considerations raised in this review, several priorities emerge for guiding the safe, successful, and ethical use of gLLMs across relevant stroke care domains, including clinical work, direct patient support, administrative tasks, and academic research.

First, real-world evidence should be prioritized. There is a critical need for reliable prospective strategies guided by clearly defined research questions and evidence priorities to generate robust real-world data. Such studies should focus on the clinical impact, safety, feasibility, and cost-effectiveness of specific gLLMs implemented in stroke care settings.

Second, transparent technical reporting should be mandated. The technical design and implementation details of gLLM-driven systems must be reported with greater precision and completeness. Standardized reporting should include accurate naming of models or specific product versions used, consistent time-stamping of key input and output events during evaluation, and clear descriptions of how the systems are accessed (eg, through chat interfaces, API, or local deployment).

Third, evaluation frameworks should be broadened beyond output accuracy. Existing performance evaluation for gLLMs requires expansion beyond technical metrics. Future frameworks must incorporate rigorous methods for assessing critical aspects of human-gLLM interaction dynamics, model reasoning processes, context appropriateness, usability, and overall user experience.

Fourth, validation of advanced task adaptation strategies should be strengthened. Current task adaptation strategies in stroke-focused gLLM systems remain simplistic and repetitive, relying primarily on prompt design and inference-time controls. These approaches have shown limitations in handling complex tasks. Future research should develop and evaluate emerging methods (eg, multiagent collaboration and RAG), which are being explored for their feasibility in other areas of chronic disease care.

Finally, mechanisms for safe and effective human-gLLM interaction should be investigated. There is a critical need to clarify the behavioral boundaries and failure modes of gLLM-driven interventions tailored to specific stroke care tasks. Equally important is the lack of empirical insight into how diverse users (eg, health care professionals, patients with stroke, and caregivers) interact with these systems in real-world settings. Future research should elucidate how these interactions shape user understanding and dynamically influence system outputs, supporting the development of more responsive, trustworthy, and context-aware gLLM applications in stroke care.

Limitations

This review has several limitations related to its scope and the current state of the literature. First, the decision to exclude preprints and focus solely on peer-reviewed publications, while ensuring a certain quality standard, may have omitted important nascent insights given the rapid technological iteration and common use of preprint platforms for early dissemination in the gLLM field. Second, the substantial heterogeneity identified across the included studies precluded a quantitative synthesis or meta-analysis of gLLM intervention performance. To mitigate this, supplementary details summarizing individual study findings are provided (Multimedia Appendix 4 [36-60]) to give readers further granularity where possible. Despite these limitations and the heterogeneity, most reported gLLM-driven interventions demonstrated encouraging performance on their specifically defined tasks within the study contexts. Lower comparative performance was observed in applications focused on extracting structured clinical data, which may reflect the maturity and optimization of existing methods (eg, rule-based systems, conventional machine learning, and earlier deep learning models) already well suited for these specific tasks. In studies targeting knowledge-intensive tasks (eg, lesion detection, report drafting, and evidence integration), mixed or suboptimal results were often reported, likely attributable more to the specific study design used than to an inherent limitation of gLLMs for such tasks generally. Nevertheless, these findings highlight the need for caution regarding the immediate, large-scale deployment or formal adoption of current gLLM-driven interventions in real-world stroke care settings.

Conclusions

As highlighted throughout this review, current research has yet to establish a coherent, evidence-based foundation addressing robust intervention design, comprehensive multidimensional

XSL•FO
RenderX

evaluation, and effective governance for these rapidly evolving gLLM technologies in stroke care. Consequently, this study contributes by clarifying the current complex research landscape concerning gLLM applications in stroke care, providing an updated review of the strengths and critical gaps in existing investigations, and identifying key priorities and directions for future research design and evaluation.

Acknowledgments

This research was supported by the Fundamental Research Funds for the Central Universities, Huazhong University of Science and Technology (grant 2024JYCXJJ011). The funder had no role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Data Availability

All data generated or analyzed during this study are included in this published article (and Multimedia Appendices 2-4).

Authors' Contributions

XZ, WD, and ZL conceptualized the scoping review and its methodology. XZ conducted the literature search and data charting, prepared the original manuscript draft, and created all figures. XZ, WD, and ZL conducted the study screening. RE, XG, and AM provided significant contributions to the refinement of the analysis and manuscript content. All authors participated in critically revising the manuscript and have read and approved the final version.

Abstract

Background: The use of patient-reported outcome measures (PROMs) as a clinical tool for screening and decision-making has gained widespread interest, with numerous implementation activities across specialties, even though the evidence has not been clear until now.

Objective: The aim of this study was to assess the evidence for using PROMs in clinical practice for patients with diabetes, chronic obstructive pulmonary disease (COPD), heart disease, rheumatoid arthritis (RA), and inflammatory bowel disease (IBD). Additionally, we sought to determine the characteristics of the most effective PROM interventions.

Methods: We conducted a systematic review of published randomized controlled trials (RCTs) on the use of PROMs for clinical purposes, such as systematic PROM assessment alone or with a predefined PROM-based decision-making method. Eligible studies included adult patients (>18 years) with diabetes, COPD, heart disease, RA, or IBD. We excluded studies using PROMs as an outcome measure or otherwise not meeting the inclusion criteria. We searched the PubMed/MEDLINE, CINAHL, EMBASE, and Web of Science databases until February 2023. Two investigators independently screened titles, abstracts, and relevant full texts. Three investigators completed data extraction and risk-of-bias assessment using version 2 of the Cochrane risk-of-bias tool for randomized trials (RoB 2). The data were presented in a narrative synthesis and in summarized form.

Results: The search yielded 21,203 papers, 686 (3.2%) full-text papers were screened, and 56 (8.2%) original studies were included in the review. The studies included patients with heart disease (n=17, 30.4%), COPD (n=13, 23.2%), diabetes (n=10, 17.9%), IBD (n=9, 16.1%), and RA (n=6, 10.7%), as well as patients with mixed diagnoses (n=1, 1.8%). All interventions incorporated systematic PROM assessments. Some interventions additionally used a predefined method for PROM-based decision-making (n=19, 33.9%) or PROM-based dialogue (n=9, 16.1%), while 5 (8.9%) interventions aimed to substitute face-to-face consultations. The predominant mode of PROM administration was over the phone, followed by electronic devices and apps. Endpoints included disease activity, health care use, mortality, mental well-being, quality of life, self-efficacy, self-care, daily functioning, and other outcomes. Six studies with a low risk of bias demonstrated a positive effect or noninferiority of the PROM intervention.

Conclusions: The evidence base for clinical use of PROMs is sparse, with few studies evaluated to have a low or a medium risk of bias. The clinical use of PROMs does not appear superior to usual care in the five included chronic diseases on any

XSL•FO
RenderX

endpoint. To guide further research, we highlighted 6 (10.7%) studies with a low risk of bias and PROM interventions with a positive effect. These were characterized by symptom assessment with predefined cutoffs used for decision and dialogue support.

Introduction

The use of patient-reported outcome measures (PROMs) as endpoints in clinical trials is well established and recommended [1]. Furthermore, PROMs have gained interest as a tool to optimize patient-centered care and other supportive interventions that seek to include patients' preferences and values [2-4]. PROMs are often self-completed questionnaires measuring symptoms, health-related quality of life (HRQoL), personal experience of health care, and health-related behaviors. In routine practice, it has been suggested that PROMs may increase health professionals' awareness of and ability to address patients' concerns [5]. Including PROMs in the electronic health record may trigger relevant clinical actions [6,7] and allow patients and health professionals to observe important trends over time and adjust the health care accordingly [8]. Therefore, questionnaires are continuously implemented in routine health care for systematic PROM assessments, informing clinical decisions and supporting the dialogue between patients and health care professionals (HCPs) [9,10].

Despite the promising aspects of using PROMs to improve health care, efforts to put theory into practice have met several barriers. When implementing PROMs in clinical practice, it is important to know the effectiveness, and this must be evaluated in relation to the time the patient spends completing the PROMs and the resources spent by HCPs. A recent systematic review found that patients may question the relevance and validity of PROMs, lack understanding of purpose, and find the clinical use inconsistent [11]. At the same time, HCPs may be concerned with adding undue burden, cause distress, or impact health care detrimentally if the correct infrastructure is not in place [12]. Furthermore, trials may fail to include the patients most burdened by symptoms [13].

The effectiveness of PROMs in cancer has been reviewed by Graupner et al [14], who demonstrated positive effects on several outcomes, including the HRQoL and survival, but also found included studies lacking power and with a high risk of bias. Although the evidence during acute cancer treatment has been described, the evidence in other noncommunicable diseases is unclear.

To close this gap, this systematic review aimed to address the following question: What is the evidence for using PROMs to improve health care, and what characterizes the most effective interventions? Specifically, the aim of this study was to (1) assess the evidence for using PROMs to improve any endpoint in diabetes, chronic obstructive pulmonary disease (COPD), heart failure (HF), ischemic heart disease, rheumatoid arthritis (RA), and inflammatory bowel disease (IBD) and (2) identify the characteristics of effective interventions that have been evaluated and documented in publications with a low or moderate risk of bias to propose directions for future research.

Methods

Study Design

We conducted this systematic review in accordance with a predefined protocol. The review was reported in line with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement (Multimedia Appendix 1) [15,16]. The review was registered at PROSPERO (International Prospective Register of Systematic Reviews; registration number CRD42021226896; date December 18, 2020).

Eligibility Criteria

Only studies written in English were included. Studies selected for inclusion were found to meet the following PICOS (Population, Intervention, Comparison, Outcomes, and Study Design) framework (Table 1) [15]:

- Population: Eligible studies included adult patients (>18 years) with type 1 or type 2 diabetes, COPD, heart disease (HF or ischemic heart disease), RA, or IBD. These noncommunicable diseases were selected due to a high burden of disease measured by disability-adjusted life-years [17].
- Intervention: Eligible studies described any questionnaire used for assessing patient-reported health conditions in routine clinical practice, where the assessment results were forwarded to an HCP. Acceptable interventions could imply (1) systematic PROM assessment alone without a predefined plan for reacting to the responses, (2) systematic PROM assessment plus predefined PROM-based decision-making, (3) systematic PROM assessment as replacement of face-to-face visits, or (4) systematic PROM assessment implemented to support the dialogue between the HCP and the patient in a clinical health care setting.
- Comparison: Eligible studies described usual care alone or passive usage of PROMs (defined as PROM assessments where results were not forwarded to an HCP).
- Outcome measures: The studies were not restricted to specific outcomes.
- Study design: All randomized controlled trials (RCTs), including cluster RCTs and pilot studies, were included.

[b]COPD: chronic obstructive pulmonary disease.

[c]RA: rheumatoid arthritis.

[d]IBD: inflammatory bowel disease.

[e]PROM: patient-reported outcome measure.

[f]Not applicable.

[g]RCT: randomized controlled trial.

Search Strategy

The research team developed the search strategy. We sought advice from an information expert at the Royal Library to ensure all relevant Medical Subject Headings (MeSH) and filters were addressed. We conducted several pilot searches to capture targeted papers. The underlying principle of the search strategy is delineated in Textbox 1. The specific strategy and search strings are presented in Tables S1-S4 in Multimedia Appendix 2. We systematically searched the following electronic databases for potentially eligible papers: PubMed/MEDLINE, CINAHL, EMBASE, and Web of Science. The initial search was completed on December 18, 2020, for all databases and repeated on February 8, 2023, for PubMed/MEDLINE only (Table S5 in Multimedia Appendix 2).

Textbox 1. Principle for the search strategy.

The search strategy was constructed around three primary components: disease, intervention, and study design.

- Disease: For the disease component, we used Medical Subject Headings (MeSH) terms and conducted searches within the titles and abstracts to identify pertinent diseases.
- Intervention: We specifically searched for patient-reported outcome measures (PROMs) by directly targeting patient-reported outcomes (PROs) and PROMs, along with their synonyms. Additionally, we included synonyms for quality of life, alongside measurement terms. Our preliminary searches revealed that PROMs are frequently administered via telemedicine; thus, we incorporated telemedicine in our search to ensure comprehensiveness.
- Study design: To identify randomized trials, we used Cochrane's validated filter.

Titles and abstracts of the identified papers retrieved from electronic databases and other searches were exported to the systematic review management software Covidence, which was used solely to manage references and remove duplicates. No automated screening was performed in Covidence. Two reviewers independently screened all titles and abstracts according to the eligibility criteria. Full texts were reviewed if eligibility could not be determined by the title and abstract alone or in the case of disagreement. We made the final decision in agreement by going through all the included full texts in the group. The study selection process was reported in a flowchart.

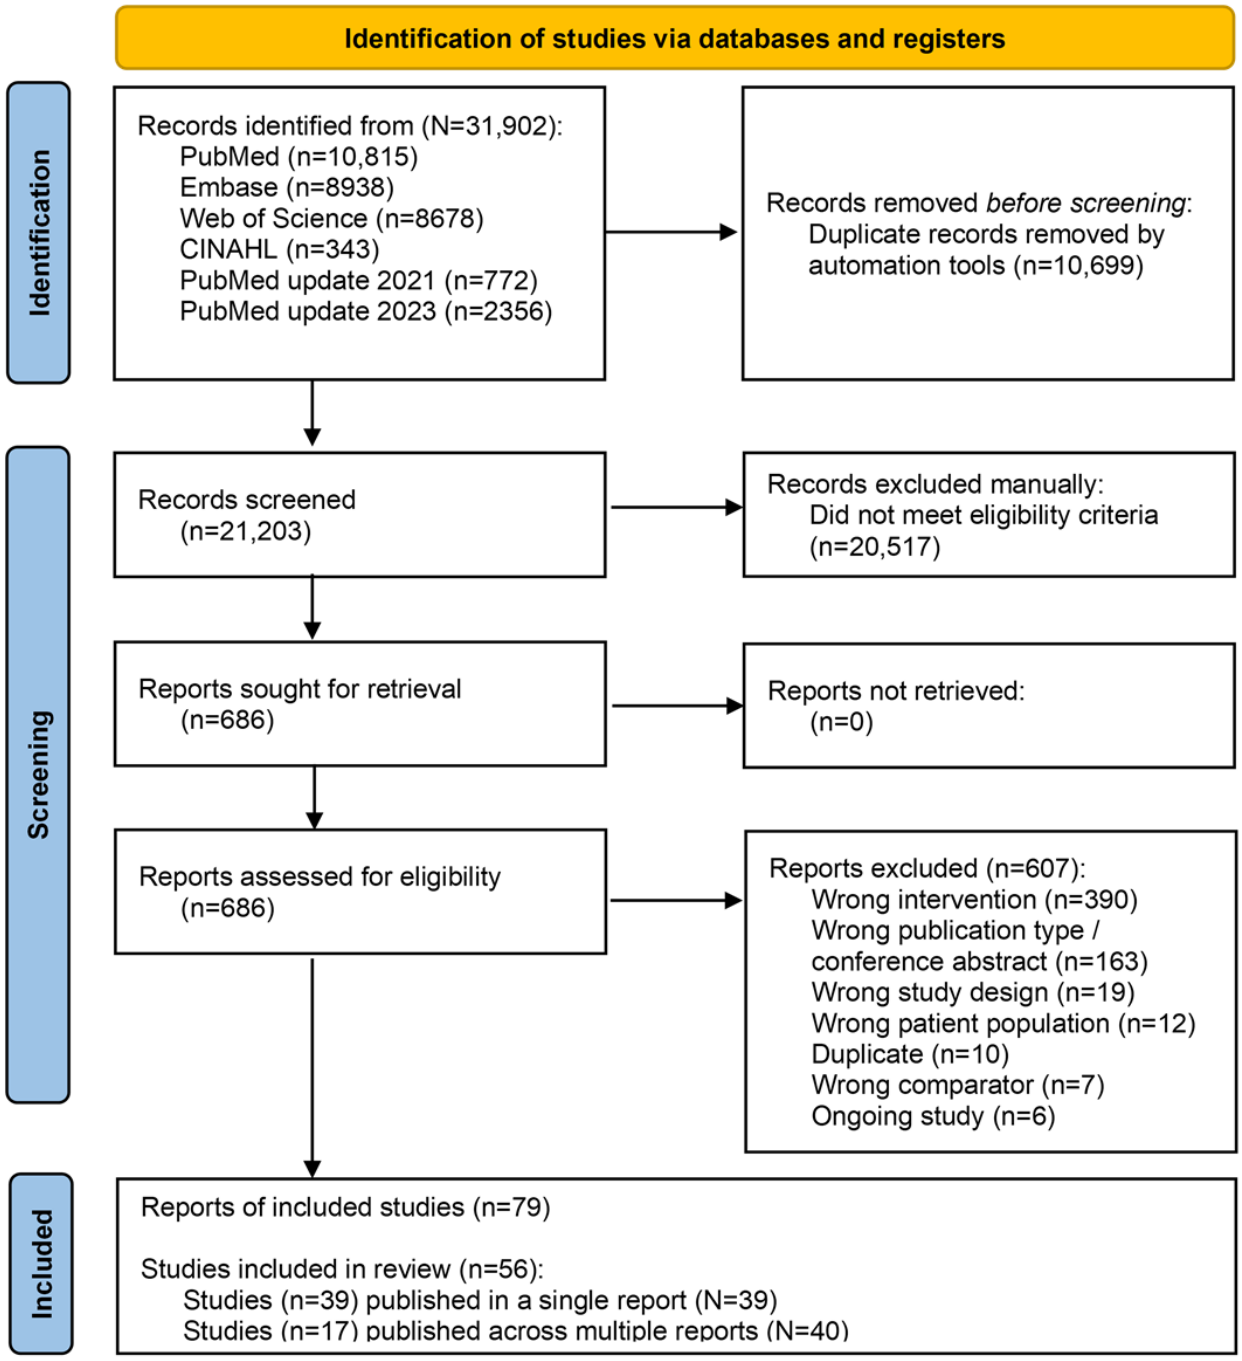
XSL•FO
RenderX

Risk of Bias in Individual Studies

Risk of bias was assessed by one of three of the authors independently using version 2 of the Cochrane risk-of-bias tool for randomized trials (RoB 2) [18]. The assessment was hereafter reviewed by one of the other authors. In the case of discrepancies, the risk-of-bias assessment was agreed on in a joint evaluation. One author also authored one of the included studies and was not involved in the risk-of-bias assessment.

Data Synthesis

Data synthesis followed the synthesis without meta-analysis (SWiM) guidelines [19]. In short, the key characteristics of the studies were extracted and recorded in a predesigned table. If an intervention was reported in 2 or more papers, information about the first author and publication year from all papers were collapsed and reported under the primary publication. We used information from all papers to report the intervention and primary and secondary outcomes. Based on the extracted information, we created a narrative synthesis presenting the characteristics of the studies, the PROM characteristics, and the outcomes. The studies were grouped according to primary outcomes and study populations, and since the outcomes varied in content and type, data were synthesized with vote counting based on direction of effects. To ascertain the characteristics of the most effective PROM interventions, we categorized studies with a low or moderate risk of bias, reporting a positive effect if the intervention group demonstrated a statistically significant superior outcome compared to the control group or reporting noninferiority if the difference between the intervention and control groups was below the noninferiority threshold. The characteristics of these studies were synthesized separately. The PROSPERO protocol included assessment with GRADE (Grading of Recommendations Assessment, Development and Evaluation) [20]; however, this method was discarded because of intervention and outcome heterogeneity, so consistency of effects could not be assessed. More study details are described in Tables S6 and S7 in Multimedia Appendix 2.



Results

Study Details

The search identified 31,902 records. After identification of duplicates, 21,203 (66.5%) papers that were screened at the title/abstract level resulted in 686 (3.2%) potentially eligible papers. Following full-text assessment, 606 (88.3%) reports were excluded, mainly due to wrong interventions and publication types, and 56 trials described in 79 (13%) papers [21-99] were included (see the flowchart in Figure 1). The number of study participants varied widely (range: 17-1653 individuals, median 212.5 individuals). Of the 56 trials, 17 (30.4%) included patients with heart disease, 13 (23.2%) included patients with COPD, 10 (17.9%) included patients with diabetes, 9 (16.1%) included patients with IBD, 6 (10.7%) included patients with RA, and, finally, 1 (1.7%) included patients with mixed diagnoses (heart disease and diabetes).

XSL•FO
RenderX

Figure 1. PRISMA flowchart for the study selection process.

PROM Characteristics

Characteristics of the selected studies and PROMs are summarized in Table 2. Telephonic PROM administration was most common, followed by devices and applications (apps). The weighted mean age among participants receiving a PROM intervention delivered over the phone was 62.9 years (63 years for phone calls and 57.9 years for SMS). The first described use of devices for collection of PROMs was published in 2008. Apps for tablets and smartphones were introduced in 2007 and 2009, respectively. The participants' weighted mean age was higher in interventions that used devices (71 years) than interventions using apps, webpages, or laptops (53.2 years).

[a]RCT: randomized controlled trial.

[b]PROM: patient-reported outcome measure.

[a]COPD: chronic obstructive pulmonary disease.

[d]IBD: inflammatory bowel disease.

[e]RA: rheumatoid arthritis.

[f]HCP: health care professional.

All interventions included systematic PROM assessments, and some additionally included a predefined method for PROM-based decision-making (n=19, 33.9%) [21-39] or PROM-based dialogue (n=9, 16.1%) [40-48], and 5 (8.9%) interventions intended to replace face-to-face visits [49-53]. The PROM interventions used validated scales in 23 (41.1%) of the studies, while specified questions or unspecified questions were used in the remaining interventions. The content of the PROMs varied from symptoms and health status to the HRQoL, health beliefs, and self-care. All interventions included feedback to HCPs as per the inclusion criteria, while 23 (41.1%) also provided feedback to patients [22,27,28,30,32,33,36,37,39,41-43,50,51,54-62]. In 39 (69.6%) of the interventions, predefined cutoff values were used to ensure feedback to the HCPs, 18 (46.2%) of which included alerts. Intervals between PROMs were not always documented but varied widely from a single assessment to collections twice daily. In the 20 (35.7%) interventions where PROMs were collected daily or twice daily, the number of questions varied from 1 to 15. Daily collection was used for COPD (n=9, 16.1%) [28,32,34,35,43,55,63-65], heart disease (n=9, 16.1%) [36,37,57-59,61,66,67], IBD (n=1, 1.8%) [23], and RA (n=1, 1.8%) [68] treatment. The daily PROM collection continued for 3-24 months. Studies only collecting PROMs once or with long intervals between had more comprehensive questionnaires.

Characteristics of the studies and interventions are presented in Tables S6 and S7 in Multimedia Appendix 2.

Outcomes

All trials included more than one outcome. The following review of the results focuses on primary outcomes (Table S8 in Multimedia Appendix 2). Secondary outcomes are listed in Table S9 in Multimedia Appendix 2. Of the 56 trials, 12 (21.4%) had favorable results in the primary outcomes, 3 (5.4%) were noninferior, 6 (10.7%) had more than one primary outcome and mixed results, 6 (10.7%) were feasible, 1 (1.8%) was not feasible, 2 (3.6%) had no group comparison, 24 (42.9%) had no effect, and 2 (3.6%) had negative results by increasing hospital admissions with the intent of reducing them.

Of the 10 (17.9%) studies of patients with diabetes, 1 (10%) concluded noninferiority [53], 1 (10%) focused on feasibility [40], 1 (10%) demonstrated a mixed effect of PROMs [44], and the other 7 (70%) studies showed no effect [30,31,33,45,47,69,99]. For studies of patients with COPD (n=13, 23.2%), there was a positive or partially positive effect in 6 (46.2%); in addition, 2 (66.7%) of 3 feasibility studies were feasible [64,65]. In the 18 (32.1%) studies including patients with heart disease, 5 (27.8%) were positive and 1 (5.6%) intervention was feasible [59]. There was a positive effect of the intervention in 33% of the studies for patients with IBD (n=9, 16.1%), 2 (22.2%) were feasible [23,39], and 1 (11.1%) was noninferior [52]. Half of the studies including patients with RA were positive, and 1 (16.7%) intervention was noninferior [50].

Disease Activity

In 13 (23.2%) studies, disease activity or remission was reported by biomarker thresholds [30,31,44,47,53,60], Boolean remission [92], disease activity indexes [21,22,34,50-52,56], or the time to reach the final dose of medical treatment [37].

None of 5 (8.9%) studies including patients with diabetes reported an effect on glycemic control [30,44,47,60]. However, in an intervention using PROMs to decide routine visits, the hemoglobin A_{1c} (HbA_{1c}) levels were below the predefined noninferiority margin [53]. Biweekly automated telephone management was tested, with no effect on HbA_{1c} [30,31,60]. PROMs used to prioritize visits and facilitate discussion of psychological well-being [44] did not affect measures of HbA_{1c}.

A study of patients with RA receiving PROM-based telehealth with graphical overview and automated decision support was noninferior to usual care [50]. An intervention with frequent PROM monitoring using SMS did not result in Boolean remission of patients with early RA [92].

Common for 5 (8.9%) studies on patients with IBD (n=9, 16.1%), the collected PROMs triggered alerts and action plans customized for intervention patients generated based on the responses. One showed a positive effect [21], another showed noninferiority [52], whereas the others did not show a difference between the intervention group and usual care [22,51,56].

A daily telehealth approach with PROM collection and feedback reduced disease progression in patients with COPD [34]. A similar intervention for patients with HF succeeded in a faster titration of carvedilol compared to usual care [37].

Health Care Use and Mortality

Hospital admission [61], readmission [49,67,72,96,97], time to admission [32,35,54], and outpatient visits [29,84] were outcomes in 11 (19.6%) studies. In addition, 1 (1.8%) study had mortality [89] as an outcome, and 6 (10.7%) studies used a composite of admission and mortality [24,25,36,55,76,91] as

XSL•FO
RenderX

outcomes. Of 16 (28.6%) interventions evaluating the effects of PROMs on hospitalization, 3 (18.8%) reported a positive effect. A multicenter trial successfully reduced a composite endpoint of all-cause mortality and hospitalization for worsening HF in a telephone intervention using PROM to adjust treatment [25]. In contrast, no other PROM intervention studies reported effect on a composite outcome of hospital admission and death in patients with HF [24,36,76,91] or COPD [55].

An effective intervention for reducing the mean number of outpatient visits for patients with IBD included monthly reporting of PROMs into an app for tablets or smartphones with alerts prompting outpatient visits. The system intensified monitoring modules in the case of flares [84].

Two interventions used daily PROMs to generate alerts to prevent admission due to COPD exacerbations [32,35]. No difference was seen when comparing the intervention with usual care [32], whereas the time to hospitalization was shorter when comparing active feedback with passive PROMs [35]. For patients with HF, an underpowered study of daily PROMs indicated a lower mean time to the first HF-related hospitalization [54].

Two interventions using PROMs for systematic PROM assessment alone without a predefined plan for reacting to the responses did not find a reduction in hospitalization [96,97]. An intervention with daily PROMs collected via voice-activated technology had an unexpected increase in the number of hospitalizations and emergency department visits in participants with HF [61]. Two studies resulted in a higher number of readmissions using daily PROMs in patients with COPD [49] and patients with diabetes and HF [72]. A study on RA found that monitoring PROMs could reduce the number of physical visits, while maintaining tight control of disease activity [29].

Mental Well-Being

In patients with diabetes, PROMs have been used to screen for diabetes distress [40], psychological well-being [44], and depression [33,45]. In 2 (50%) studies, participants completed electronic PROMs prior to consultation, which did not show an effect on diabetes distress [40] or the depression score [33]. A favorable effect on mood was reported from an intervention using PROMs on psychological well-being as part of routine outpatient care [44]. In an intervention about self-care behavior and tailored talking points about emotional health, both control and intervention groups continued to have moderate-to-severe depression symptoms [45].

Health-Related Quality of Life

In studies aiming to improve the HRQoL using a PROM intervention (n=10, 17.7%), 2 (20%) studies showed an improvement [41,46], 1 (10%) showed noninferiority [52], 1 (10%) had mixed effects [63], 4 (40%) showed no effect [22,26,56,69], and 2 (20%) showed an unfavorable effect [49,71] compared to usual care. A multicenter trial found a significantly better health status favoring patients with COPD reporting PROMs of general well-being, symptoms, and medications. Alerts were reviewed by HCPs twice weekly, and patients were contacted either via messages or over the phone if any action was needed [63]. Automated telephone-based symptom and side effect monitoring had no effect on the quality of life (QoL) in patients with diabetic peripheral neuropathy [69].

Weekly monitoring of symptoms and medications in patients with IBD did not improve disease-specific QoL [22,56]. However, noninferiority was reported in a similar intervention with quarterly and as-needed PROM monitoring [52]. No effect was documented on quality-adjusted life-years for patients with acute coronary syndrome without a history of depression receiving systematic depression symptoms assessment with or without providing depression treatment compared to usual care [26].

Self-Efficacy, Self-Care, and Daily Functioning

Of 5 (8.9%) studies evaluating the use of PROMs to increase daily functioning [41,99], self-care [43], or self-efficacy [27,57], 4 (80%) showed positive results. In patients with HF, daily PROM collection over the phone increased self-efficacy [57]. Self-efficacy also improved among patients with RA when using PROMs prior to usual consultations with a nurse who provided patient education [27]. Self-care behavior improved in patients with COPD who answered questions on symptoms at least four times a week via a smartphone app that alerted HCPs [43]. Receiving personalized feedback on responding to somatic and psychosocial PROMs improved social participation in patients with IBD [41]. A cluster randomized trial concluded that using PROMs was inconsistent with the nurse-led detection of distress and daily functioning in routine practice [99].

Other Outcomes

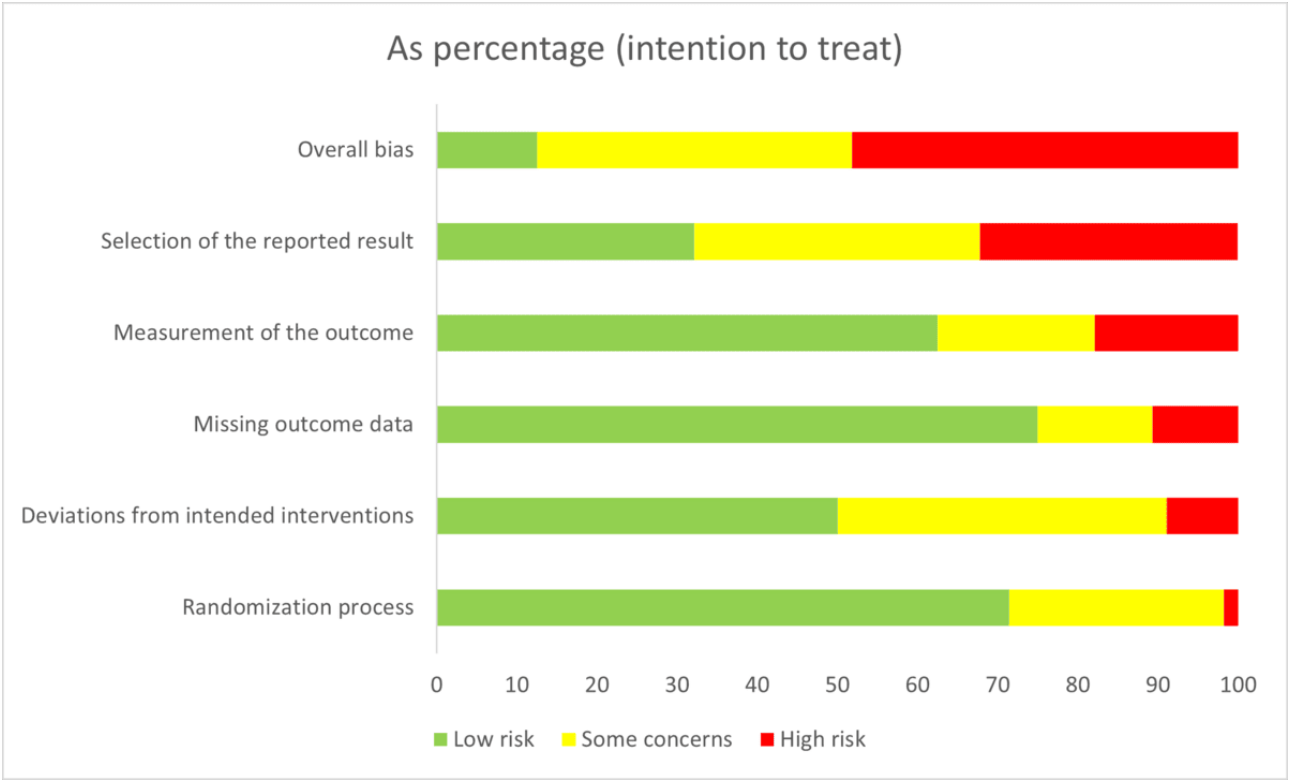
Other outcomes included feasibility [23,49,59,64,65], patient satisfaction [42,62], quality of care [44,48,84], physician-patient interaction [42], and health care costs [21,28]. PROM interventions were considered feasible in 5 (8.9%) studies [23,39,59,64,65], and 1 (1.8%) intervention was considered unfeasible [49]. In 2 (22.2%) interventions for patients with IBD, the intervention was appreciated by compliers, but adherence was low [23,39], and 2 (33.3%) studies of patients with RA found that using PROMs before health care visits has no impact on patient satisfaction [42,62]. Monitoring of phycological well-being in outpatients with diabetes did not change the overall evaluation of the quality of diabetes care [44]. PROMs of psychosocial needs and priorities before routine consultations with a COPD nurse allowed shared decisions about self-management support and increased the quality of care in patients with COPD [48]. Collecting PROMs daily from patients with HF was deemed feasible by the authors, even though number of readmissions was similar in the two groups [59]. A monthly PROM-based self-management system did not enhance patient-reported quality of care [84].

Two studies evaluated cost savings [21,28]. Using daily PROMs of symptoms and medications in the treatment of COPD led to significant cost savings in a telephone intervention [28]. An intervention with proactive symptom monitoring was without a significant difference in median annual IBD-related health care charges [21].

XSL•FO
RenderX

Adverse Events

Several studies indicated adverse events [23,38,39,49,61, 65,71,72,89]. These included 2 (22.2%) studies in patients with heart disease and diabetes, which intended to reduce hospital admissions but increased the number instead [61, 72], and 1 (11.1%) study in which the subgroup analyses indicated increased mortality in women [89]. Adverse events were also observed in secondary outcomes: decreased peak performance and physical activity [65], increased hospital admissions [38], increased medical treatment [39], deterioration in symptoms [71], increased symptoms of depression [23], and higher costs [49].



Characteristics of Effective PROMs

The predefined secondary aim of this systematic review was to describe effective PROM interventions with acceptable quality defined by a low risk of bias or some concerns. Excluding a study [24] that was later debunked by a larger study [89], 6 (10.7%) studies had positive results in the primary endpoint, had positive results in one of two primary endpoints, or were noninferior in replacing face-to-face sessions [25,42,46,50,53,57]. The PROM interventions used multiple administration forms and were focused on symptoms of disease, and 5 (83.3%) of the 6 studies included support for decisions and dialogue [25,42,46,50,53], 4 (66.7%) studies included validated PROMs [42,46,50,53], and 2 (33.3%) included specified questions [25,57]. In addition, 5 (83.3%) of the 6 had 2-week to 6-month intervals between PROM collection [25,42,46,50,53], and 4 (66.7%) of the 6 studies included feedback to patients as well as HCPs, with 3 (75%) having a graphical display of the results [42,46,50]. Furthermore, 2 (33.3%) studies included patients with heart disease [25,57], 2 (33.3%) included patients with RA [42,50], 1 (16.7%) included patients with diabetes [53], and 1 (16.7%) included patients with COPD [46]. Positive effects were achieved in the HRQoL [46], physician-reported interaction [42], self-efficacy [57], a composite endpoint with hospital admissions and death [25], and noninferior RA or diabetes activity when replacing outpatient visits with PROMs [50,53]. These 6 (10.7%) studies had little loss to follow-up, and 5 (83.3%) of the 6 studies had more study consenters than study decliners [25,42,46,50,53].

Risk of Bias

Seven studies were rated with an overall low risk of bias (Figure 2). Among the 22 (39.3%) studies with some concerns regarding risk of bias, concerns relating to the reporting of results were the most frequent (n=13, 59.1%), followed by concerns arising from deviations from the intended intervention (n=10, 45.5%), the randomization process (n=9, 40.9%), the measurement of the outcome (n=5, 22.7%), or missing outcome data (n=5, 22.7%). Nearly half of the studies had a high risk of bias (n=27, 48.2%). No studies had biases in all domains, but 2 (3.6%) studies had high risk in four of five domains [27,38]. The most frequent domain for a high risk of bias was selection of reported results (n=18, 32.1%) led by a lack of prospective descriptions of the trials in registries or protocol papers. Among studies with a low risk of bias or some concerns, 14.3% (4/28) had positive results, while among studies with a high risk of bias, 33.3% (9/27) had positive results. Risk-of-bias evaluation of the individual studies can be found in Table S8 in Multimedia Appendix 2.

Figure 2. Risk of bias across all included studies using RoB 2. RoB 2: version 2 of the Cochrane risk-of-bias tool for randomized trials.

Discussion

Principal Findings

This systematic literature review identified sparse evidence regarding the effectiveness of the clinical use of PROMs in patients with five noncommunicable diseases: diabetes, COPD, heart disease, RA, and IBD. Considering the increase in PROMs' popularity and the fact that we included five highly prevalent and burdensome diseases [100-102], it is notable that the literature search only revealed 56 trials in total, half of which had a high risk of bias. The included RCTs investigated a wide range of outcomes, thus producing a heterogeneous set of data and indicating a lack of consensus on the role of PROMs in clinical practice. Of the 56 RCTs, 12 presented positive results in the primary endpoint, 6 had mixed results in multiple primary endpoints, and 3 were noninferior. Focusing on the 28 RCTs with a low risk of bias or some concerns, 4 resulted in a better primary outcome and 2 demonstrated noninferiority. Successful interventions were characterized by using validated or specific PROMs and had little loss to follow up. They provided feedback to patients as well as HCPs, with 3 interventions incorporating a graphical display of the results.

Comparison With Prior Work

Compared to the results of this review, the results of reviews about acute cancer treatment are summarized as positive [14,103]. However, the majority of the included studies lacked power to detect group differences, and the conclusion of predominantly positive findings may be questioned [14]. The conditions of acute cancer treatment may also differ from those of long-term diseases where patients may have had more time to recognize, to learn self-management of symptoms and side effects, and to seek relevant health care.

Methodological Considerations

This review was conducted with screening by two independent researchers, and discrepancies were handled by including a third researcher in a consensus approach to ensure internal validity. The limited descriptions of interventions posed certain constraints, often lacking detail, which may have affected the external validity of this review. Adopting a more conservative approach of including only pure PROM interventions with no objective measurements at all would have reduced the number of eligible papers and the clinical relevance. Conversely, a less stringent approach, including more interventions where PROMs were one of multiple components, would have reduced focus and confidence in the results. Second, the heterogeneity of the studied PROM interventions and outcomes prevented meta-analyses and permitted only vote counting for data synthesis, which does not allow for differential weights to be allocated to each study.

The proportion of papers included in the review to the original number of studies identified in the search was less than 0.3%. The likely cause was the intervention search words that did not allow for distinction between RCTs using PROMs as endpoints and RCTs using PROMs for intervention. Attempts to reduce the number of papers for screening would have excluded relevant papers, which is why the searches were placed at a high level of sensitivity. In comparison, the systematic review by Graupner et al [14] about PROMs focusing on cancer revealed a quite similar proportion of included studies as 22 of 8341 identified studies were included.

Balancing Person-Centered Care With Evidence-Based Practice

The expectations toward PROMs are underlined by the implementation activities that have preceded robust evidence. Implementation before evaluation demonstrates the dissimilar approach toward PROM interventions to that of drug interventions that would have required robust trials before being released into the market. As demonstrated in this review, adverse effects may also occur in PROM interventions. Furthermore, PROMs require time and resources of HCPs as well as patients, and robust evaluations of PROMs are urgently needed.

PROMs are expected to support a person-centered approach. With 3 noninferiority trials, most trials evaluated superiority in a wide range of endpoints. The range of endpoints underscore the unclear expectations toward PROMs and the difficulty in operationalizing patient-centeredness. Noninferiority trials may be preferable if the purpose of PROMs is to replace face-to-face outpatient visits to compensate for the resources spent on PROM administration and implementation. However, trials to demonstrate noninferiority with a clinically acceptable margin may not be feasible to conduct [104]. Furthermore, most PROM interventions are designed as an addition to usual care, in which case only demonstrated superiority would merit spending resources on PROMs.

Future Directions

The 6 effective PROM interventions may serve as inspiration for further development. They focused on symptoms and were mostly used for systematic PROM assessment, plus a predefined PROM-based decision support method or dialogue support as opposed to systematic PROM assessment alone. This underscores the significance of the organizational structure to ensure consistent monitoring of PROMs and suitable predefined clinical actions. The effective PROM interventions had little loss to follow up and few study decliners, which is a testament to the acceptability of the interventions. A review of patients' reasons for not using digital PROMs has demonstrated the significance of patients' health (patients would forego PROMs if they were too well or too sick) and that it could be burdensome to be confronted with one's poor health and that technical problems, a lack of skills, language problems, and uncertainty about data security could all act as barriers toward the use of digital PROMs [105]. Patients with a moderate symptom burden who use PROMs could be referred to health care services at the expense of the most burdened patients who opt out of using PROMs, thereby increasing health care inequality.

Adding PROMS to usual care does not appear superior; however, replacing specific face-to-face visits with PROMS seems noninferior in patients with diabetes [53], IBD [52], and RA [50]. Noninferiority trials may be more suitable when PROMs are intended to replace face-to-face outpatient visits, thereby offsetting the resources allocated to the administration and implementation of PROMs.

Conclusion

The evidence supporting the clinical use of PROMs in the five chronic diseases included in this study is limited. In these diseases, the clinical application of PROMs does not seem to offer any advantage over standard care in terms of any endpoint. To derive insights from successful research, we highlighted 6 PROM interventions that demonstrated positive effects and exhibited a low risk of bias. These were characterized by symptom assessment with predefined cutoffs used for decision and dialogue support.

Acknowledgments

No generative artificial intelligence tools were used to create the original scientific content of the manuscript. The authors used a generative artificial intelligence tool (Paperpal) to enhance the clarity and readability of the text during manuscript revision. This work was funded by an unrestricted grant from the Capital Region, Denmark (no grant number available). The sponsor played no role in the analysis or interpretation.

Data Availability

All data generated and analyzed during this study are included in this published paper and in Multimedia Appendix 2. The databases created during the data extraction process are available from the corresponding author upon reasonable request.

Authors' Contributions

MV contributed to the protocol, screened papers, assessed the risk of bias, made the final decision to include studies, and took the lead in writing the manuscript. BIO contributed to the protocol, developed the search string, screened papers, assessed the risk of bias, and made the final decision of inclusion of studies. KSB devised the project and the main conceptual ideas, contributed to the protocol, assessed the risk of bias, made the final decision of inclusion of studies, and contributed substantially to the manuscript. KEL supervised the project. All authors provided critical feedback and helped shape the research, analysis, and manuscript. All authors have read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: With the rapid development of artificial intelligence, large language models (LLMs) have shown strong capabilities in natural language understanding, reasoning, and generation, attracting much research interest in applying LLMs to health and medicine. Critical care medicine (CCM) provides diagnosis and treatment for patients with critical illness who often require intensive monitoring and interventions in intensive care units (ICUs). Whether LLMs can be applied to CCM, and whether they can operate as ICU experts in assisting clinical decision-making rather than “stochastic parrots,” remains uncertain.

Objective: This scoping review aims to provide a panoramic portrait of the application of LLMs in CCM, identifying the advantages, challenges, and future potential of LLMs in this field.

Methods: This study was conducted in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines. Literature was searched across 7 databases, including PubMed, Embase, Scopus, Web of Science, CINAHL, IEEE Xplore, and ACM Digital Library, from the first available paper to August 22, 2025.

Results: From an initial 2342 retrieved papers, 41 were selected for final review. LLMs played an important role in CCM through the following 3 main channels: clinical decision support, medical documentation and reporting, and medical education and doctor-patient communication. Compared to traditional artificial intelligence models, LLMs have advantages in handling unstructured data and do not require manual feature engineering. Meanwhile, applying LLMs to CCM has faced challenges, including hallucinations and poor interpretability, sensitivity to prompts, bias and alignment challenges, and privacy and ethical issues.

Conclusions: Although LLMs are not yet ICU experts, they have the potential to become valuable tools in CCM, helping to improve patient outcomes and optimize health care delivery. Future research should enhance model reliability and interpretability, improve model training and deployment scalability, integrate up-to-date medical knowledge, and strengthen privacy and ethical guidelines, paving the way for LLMs to fully realize their impact in critical care.

Introduction

Critical care medicine (CCM), or intensive care medicine, is an essential field dedicated to managing severely ill patients, emphasizing rapid and life-critical decision-making and interventions. CCM deals with patients who have severe conditions and injuries such as acute kidney injury (AKI), sepsis, and acute respiratory distress syndrome (ARDS), potentially leading to a deteriorative state in the intensive care units (ICUs) [1-4]. The incidence of AKI in the ICU could reach over 50% worldwide [5]. Among those who received renal replacement therapy, most of whom were with critical illness in the ICU, the mortality rate was approximately 50% [6,7]. The prevalence of sepsis is around 30% during ICU stay [8]. Sepsis accounted for approximately 11 million deaths, making up about 20% of all global deaths [9]. Recent multicenter epidemiological work shows that the incidence of ARDS in the ICU was between 7.1% and 19% with hospital mortality of 32%-55% [10]. While in resource-limited settings, the ICU mortality of ARDS could be as high as 50% due to the disparities in health care services [11]. Therefore, the special environment of the ICU has imposed higher professional requirements on medical staff. Physicians and nurses in ICUs must manage large amounts of patient data while maintaining high efficiency under high pressure [11,12]. The dynamic and severe nature of critical care demands intelligent decision-support tools to help physicians improve diagnostic accuracy, optimize therapeutic strategies, and facilitate timely clinical decision-making.

Artificial intelligence (AI) technologies, especially generative artificial intelligence (GenAI) models, have developed rapidly in recent years [13,14]. The advent of large language models (LLMs), such as those based on the Transformer architecture [15] and pretrained on extensive text corpora, has marked a substantial advancement in natural language processing (NLP). With billions of parameters, these LLMs have demonstrated remarkable capabilities in understanding and generating human-like text [16]. LLMs have been implemented in various contexts, including answering questions, summarizing texts, and engaging in open-domain conversations [17]. Compared to human practitioners, LLMs have been perceived as more understanding and efficient [18]. Among these LLMs, OpenAI's ChatGPT [16] has become a focal point since its launch in November 2022. OpenAI then introduced upgraded versions of ChatGPT, offering enhanced multimodal capabilities to handle diverse inputs such as text, images, code, and table files. LLMs have revolutionized different fields, including health and medicine [13,14]. A more detailed description of the evolution and applications of LLMs in health and medicine is provided in Note S1 in Multimedia Appendix 1 [19-59].

In the field of CCM, the emergence of LLMs demonstrates its unique potential. Similar to the application of LLMs in informing patients with cancer of diagnosis, treatment methods, and side effects, LLMs in CCM can help make life-or-death decisions after fusing large volumes of patient data in a short time [60]. Physicians in CCM face enormous workloads and pressure, involving LLMs in different clinical decision-making scenarios in CCM will help reduce the workload of physicians and improve health care quality. However, LLMs face challenges when applied in CCM, such as uncertain accuracy and coherence, recency bias, hallucinations, poor interpretability, and ethical issues [61]. Among them, hallucinations are one of the biggest drawbacks of LLMs, which make them act like stochastic parrots [62].

This study aims to review the applications of LLMs in CCM, identifying the advantages, challenges, and future potential of LLMs in this field. Three key research questions were designed to be answered by this review. (1) What is the current status of LLM applications within the critical care setting? (2) What are the recognized advantages and challenges of using LLMs in CCM? (3) What research directions should be taken in the future to promote the application of LLMs in CCM? By addressing the above 3 questions, this review endeavors to provide a clear portrait of and identify the research gaps in the applications of LLMs in CCM, discerning whether they are just stochastic parrots that may mimic human responses based on probability calculation or emerging ICU experts capable of providing timely and highly personalized diagnosis and treatment recommendations. Through this comprehensive review, we aim to outline a roadmap for future research and implementation of LLMs in CCM that could enable them to transform critical care effectively.

Methods

Study Design

This scoping review followed the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [63], and the protocol was registered in the Open Science Framework. We have included a checklist of the PRISMA-ScR guidelines in Table S1 in Multimedia Appendix 1.

Literature Search Strategy

We conducted a literature search across 7 databases, including PubMed, Embase, Scopus, Web of Science, CINAHL, IEEE Xplore, and ACM Digital Library, from the earliest available paper until August 22, 2025. Keywords related to LLMs included "large language model," "LLM," "generative pre-trained transformer," "GPT," "generative artificial intelligence," and "generative AI." For CCM, the keywords included "critical care," "intensive care units," "critical illness," "intensive care," and "ICU." All these terms were combined using the "OR" and "AND" logical operators to ensure the retrieval of literature that addresses both research areas. The detailed search terms for each database are provided in Table S2 in Multimedia Appendix 1.

Study Selection

The study selection in this scoping review was conducted to ensure comprehensive coverage and relevance of the included literature. In the first phase of the study selection, literature was

XSL•FO
RenderX

included based on the following criteria: (1) focusing on LLMs in CCM, including studies that explicitly used or commented on LLMs relevant to the field of CCM, and (2) original research papers from peer-reviewed journals and conferences, perspectives, and letters. Studies were excluded from the review if they met any of the following conditions: (1) irrelevant to LLMs or CCM, including studies that did not focus on applying LLMs within the realm of CCM; (2) conference abstracts, preprint papers, books, patents, editorials, and review papers; and (3) non-English literature. The process for selecting sources of evidence is provided in Note S2 in Multimedia Appendix 1.

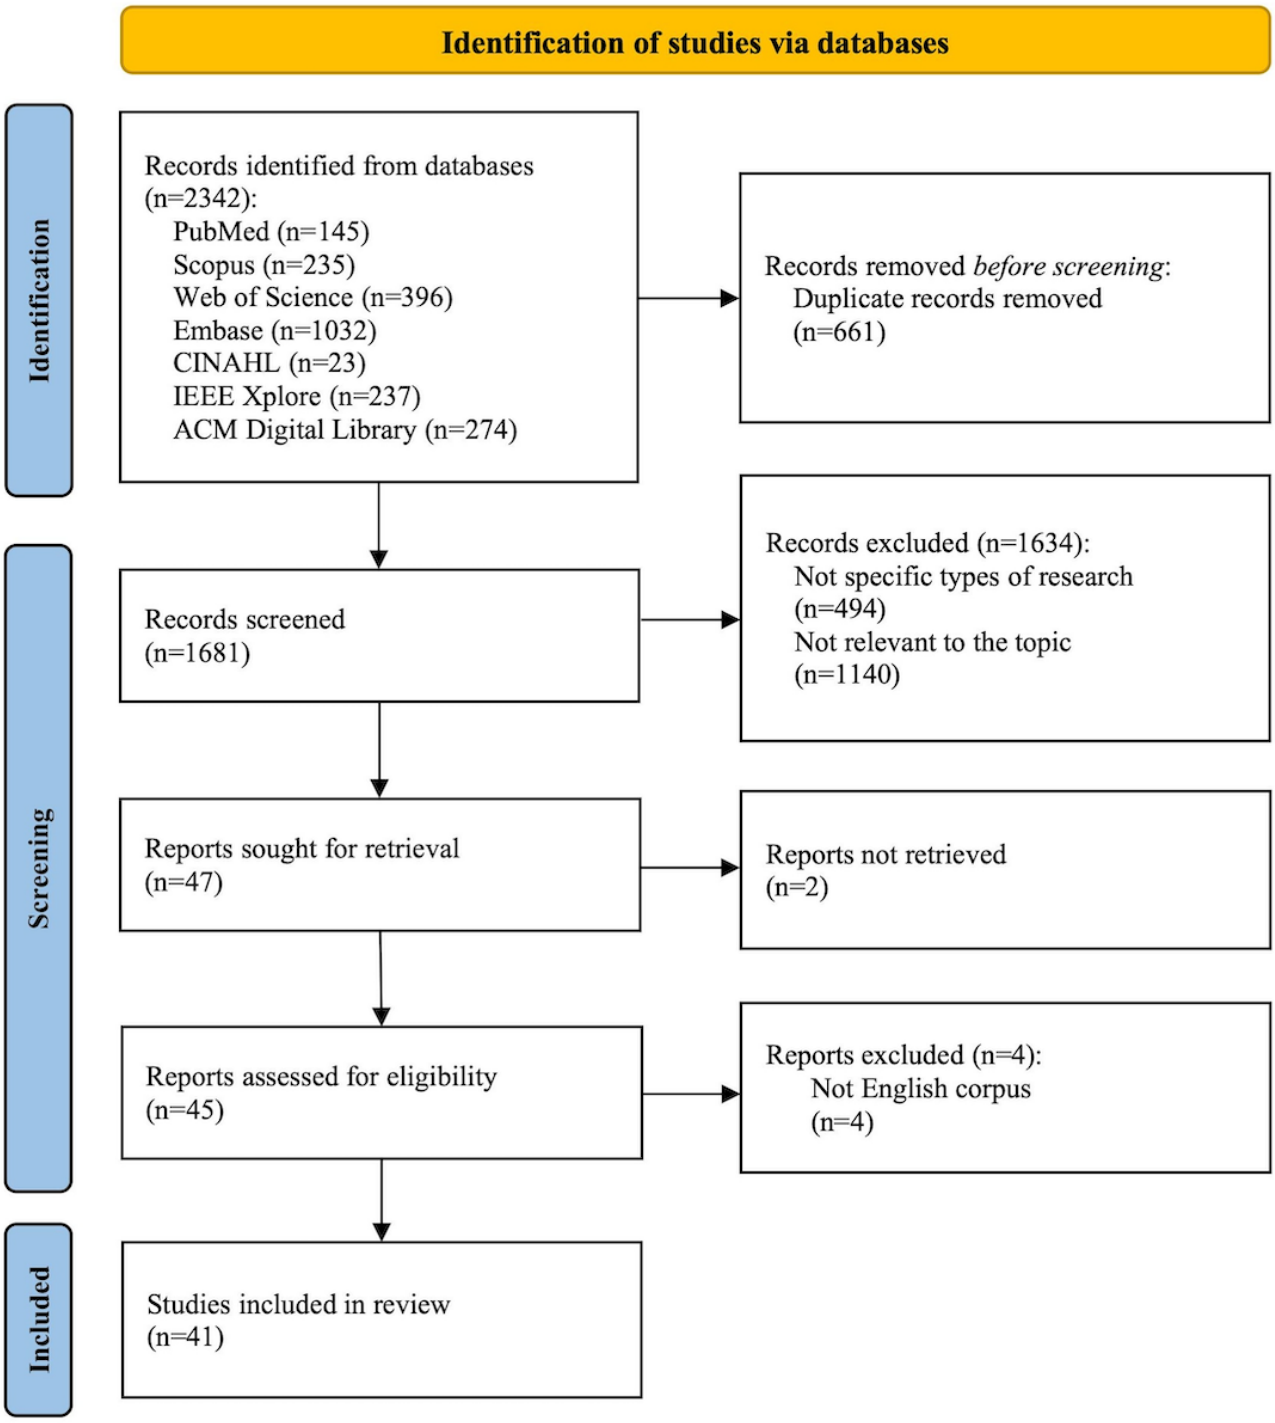
Keyword Co-Occurrence Network Analysis

Keyword co-occurrence network analysis [64] is a bibliometric method to explore the relationships between keywords in academic papers. It involves constructing a network where nodes represent keywords and edges represent the co-occurrence of these keywords within the studied documents. It helps to identify the main research themes, trends, and potential research gaps by analyzing the frequency and patterns of keyword co-occurrences. This study used the VOSviewer (version 1.6.20) software to construct a bibliometric network using the visualization of similarity method [65,66]. The software automatically extracts keywords from a publication's title, abstract, or author-supplied keyword list. The frequency of co-occurrences of 2 keywords is determined by the number of publications in which both keywords appear together in the title, abstract, or keyword list. The visualization of similarity method starts by calculating the similarity between the keywords of publications based on their co-occurrence. Finally, a matrix is constructed to arrange keywords spatially according to their similarities, and it is the basis for multivariate statistical and network analysis.

Risk of Bias and Applicability Assessment

We critically appraised all included studies using the PROBAST-AI (Prediction Model Risk of Bias Assessment Tool-Artificial Intelligence) [67], rating Risk of Bias (RoB) across 4 domains (participants, predictors, outcome, and analysis) and applicability across 3 domains (participants, predictors, and outcome) on a 3-level scale (low, high, and unclear). Full evaluation criteria and rules are provided in Note S3 in Multimedia Appendix 1.

Results



Literature Search Results

This scoping review covered publications in the 7 databases to August 22, 2025, and retrieved 2342 papers initially. The flowchart of the study selection process is presented in Figure 1.

The application of LLMs in CCM is a relatively innovative field, but research is still lacking, and the overall number of papers is relatively small. Finally, 41 papers met all the inclusion criteria and were chosen for this review. Table 1 documents the research contents and publication details of the included studies. The study design and model performance details of the included studies are in Table S3 in Multimedia Appendix 1, where metrics (such as area under the receiver operating characteristic curve and area under the precision-recall curve, and F_1-score) are described, together with the setting, implementation effect on patient outcomes, validation design, and external-validation environment.

Authors	Published year	Article type	Study design	Journal or conference name	Country	Model	Research contents
Savage et al [68]	2023	Original research	Retrospective	*JMIR Medical Informatics*	United States	BioMed-RoBERTa	Developed and validated a language model-based screening tool for optimizing Best Practice Alerts.
Levin et al [17]	2024	Original research	Retrospective	*International Journal of Nursing Studies*	Israel	ChatGPT-4 and Claude-2 (Anthropic PBC)	Compared LLMs[a] to neonatal nurses in clinical decision support for neonatal care.
Pham et al [69]	2024	Original research	Retrospective	*Journal of Medical Internet Research*	United States	ChatGPT-3.5 and ChatGPT-4	Evaluated LLMs in simulations for cardiac arrest and bradycardia based on the American Heart Association's Advanced Cardiovascular Life Support guidelines.
Huespe et al [70]	2023	Observational study	Retrospective	*Critical care explorations*	Argentina	ChatGPT-3.5	Evaluated the capabilities of LLMs in generating the background sections of critical care clinical research questions compared to human researchers.
Si et al [71]	2019	Original research	Retrospective	*Journal of the American Medical Informatics Association*	United States	ELMo and BERT	Applied contextual embeddings to enhance clinical concept extraction from medical texts.
Almazyad et al [72]	2023	Original research	Retrospective	*Cureus*	Saudi Arabia	ChatGPT-4	Used LLMs to enhance expert panel discussions at a medical conference, focusing on pediatric palliative care and ethical decision-making scenarios.
Chung et al [73]	2024	Original research	Retrospective	*JAMA*[b] *surgery*	United States	ChatGPT-4 Turbo	Evaluated the performance of LLMs in perioperative risk stratification and prognostication across various tasks.
Abdullahi et al [74]	2024	Original research	Retrospective	*JMIR Medical Education*	United States	Bard (Google LLC), ChatGPT-3.5, and ChatGPT-4	Assessed the effectiveness of LLMs in diagnosing rare and complex medical conditions, focusing on improving medical education and diagnostic accuracy.
Benboujja et al [75]	2024	Original research	Retrospective	*Frontiers in Public Health*	United States	ChatGPT-4	Developed and applied a multilingual, AI[c]-driven educational curriculum in pediatric care to overcome language barriers in global health care education.
Lu et al [1]	2023	Letter	Retrospective	*Annals of Biomedical Engineering*	China	ChatGPT-3.5 and ChatGPT-4	Explored potential uses of LLMs in intensive care medicine, focusing on knowledge augmentation, device management, clinical decision support, early warning systems, and ICU[d] database establishment.
Madden et al [76]	2023	Letter	Retrospective	*Intensive Care Medicine*	Ireland	ChatGPT-4	Evaluated the effectiveness of LLMs in querying and summarizing unstructured medical notes in the ICU.
Liu et al [77]	2024	Original research	Prospective	*Heliyon*	China	ChatGPT-3.5 and ChatGPT-4	Assessed LLMs in predicting the risk of endotracheal intubation after initiating high-flow oxygen therapy, highlighting potential in decision-making in critical care.
Nolan et al [78]	2024	Original research	Retrospective	*Critical Care Explorations*	United States	ChatGPT-3.5 and BERT	Investigated the use of LLMs in assisting surrogate and proxy decision-making in critical care, focusing on aligning treatment recommendations with patient values.
Shah-Mohammadi and Finkelstein [79]	2024	Original research	Retrospective	*JMIR Medical Informatics*	United States	ChatGPT-3.5	Investigated ChatGPT-3.5's application in extracting substance use information from ICU discharge summaries, highlighting improvements in accuracy with different learning scenarios.

Authors	Published year	Article type	Study design	Journal or conference name	Country	Model	Research contents
Nawab et al [80]	2024	Original research	Retrospective	*Journal of Medical Artificial Intelligence*	United States	ChatGPT-3.5 Turbo	Evaluated ChatGPT-3.5 Turbo's effectiveness in assigning *ICD-10*[e] codes to clinical notes, demonstrating improved accuracy with fine-tuning, particularly in critical care administrative tasks.
Soleimani et al [81]	2024	Original research	Retrospective	*Academic Radiology*	Iran	ChatGPT-3.5 and Claude.ai	Assessed ChatGPT's ability to generate radiology reports using MIMIC-CXR[f] data, with a 3-step prompt guiding report synthesis. Compared outputs to Bart and XLM, showing high similarity to human reports.
Oh et al [82]	2024	Original research	Prospective	*Healthcare Informatics Research*	Korea	ChatGPT-3.5 and ChatGPT-4	Analyzed ChatGPT-3.5-turbo and ChatGPT-4 in predicting sepsis mortality using data from the Korean Sepsis Alliance.
Urquhart et al [83]	2024	Original research	Retrospective	*Intensive Care Medicine Experimental*	Ireland	ChatGPT-3.5, ChatGPT-4, and Llama-2 (Meta)	Evaluated ChatGPT-4, ChatGPT, and Llama 2 for generating ICU discharge summaries, emphasizing event recall and readability.
Pabon et al [84]	2024	Original research	Retrospective	*European Journal of Heart Failure*	United States	ChatGPT-3.5	Explored in-hospital outcomes for heart failure patients with improved ejection fraction. ChatGPT-3.5 was used to extract LVEF[g] data from medical records, but incomplete data detection in some cases required manual review.
Akhondi-Asl et al [85]	2024	Original research	Retrospective	*Pediatric Critical Care Medicine*	United States	Llama-7B, Llama-65B, and BioGPT-Large	Evaluated domain-specific fine-tuned models against general LLMs for generating differential diagnoses in PICU[h] patients. Fine-tuned Llama-7B outperformed larger models, demonstrating the importance of domain-specific training.
Liu et al [86]	2025	Original research	Retrospective	*Clinical Simulation in Nursing*	China	ChatGPT-3.5	Qualitative exploration of ICU novice simulation instructors' experience with ChatGPT in case design, focusing on perceived value, potential applications, and limitations.
Berger et al [87]	2025	Original research	Retrospective	*Journal of Critical Care*	Switzerland	ChatGPT-4o	Qualitative investigation of abbreviation uses in ICU communication, focusing on risks, clinician perceptions, and patient safety implications.
Kurz et al [88]	2025	Original research	Retrospective	*NPJ Digital Medicine*	Germany	DeepSeek, InternVL, and ChatGPT-4o	Comparative benchmarking of LLMs for diagnostic accuracy using medical images plus clinical context in emergency and critical care.
Pham et al [89]	2025	Original research	Retrospective	*Cureus*	Vietnam	ChatGPT-4o	Assessment of ChatGPT-4o's ability to interpret cranial ultrasound images for PVIVH[i] diagnosis in very preterm infants, compared to pediatric radiologists.
Shi et al [90]	2025	Original research	Retrospective	*Journal of Medical Internet Research*	China	SWEDE-HEART-AI, Qwen-2, and Llama-3	Comparison of LLMs for predicting 1-year all-cause mortality post-AMI[j], using structured variables versus discharge note analysis.
Yitzhaki et al [91]	2025	Original research	Retrospective	*Journal of Paediatrics and Child Health*	Israel	ChatGPT-4o	Comparative evaluation of ChatGPT-4 versus PICU specialist in answering open-ended medical education questions sourced from a trainee WhatsApp (WhatsApp LLC) forum.

[r]AKI: acute kidney injury.

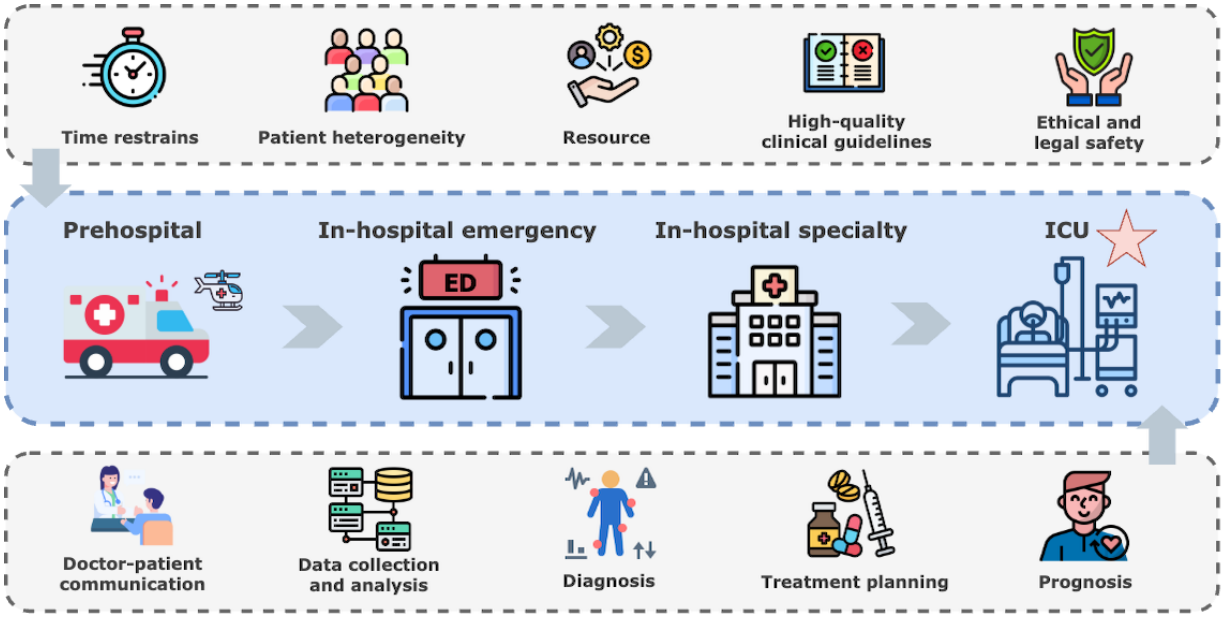
[s]CNN: convolutional neural network.

[t]ARDS: acute respiratory distress syndrome.

[u]ABG: arterial blood gas.

Bibliometric Analysis

This scoping review included a focused selection of 41 papers, providing a global perspective on LLM applications in CCM. This diverse corpus spans several countries, demonstrating widespread research interest in applying LLMs in CCM. The results of keyword co-occurrence network analysis are in Note S4 in Multimedia Appendix 1. Among the 41 papers, only 2 used prospective data, while the other 39 were retrospective studies. The distribution of the selected publications indicates substantial international collaboration and research efforts. We analyzed the countries where each selected paper's first and corresponding authors were based. The authors from the United States took the lead in most studies, followed by authors from China, Ireland, Israel, Korea, etc. It revealed that nearly half of the studies were conducted in the United States, with much fewer contributions from other countries and regions. This indicates a concentration of research activities in applying LLMs in CCM within the United States, potentially reflecting the advanced development and adoption of AI technologies in American critical care settings. Among the LLMs used, ChatGPT-4 appears most frequently, demonstrating its relevance and recent prominence in CCM applications. Other models include ChatGPT-3.5 and models such as Llama, Gemini, Claude, and DeepSeek, highlighting the breadth of generative models explored in the included studies. A minority of studies use domain-adapted or clinical NLP backbones, including BioGPT-Large, BioMed-RoBERTa, BlueBERT, and RespBERT.



Applications of LLMs in CCM

Clinical Decision Support

As illustrated in Figure 2, the primary application of LLMs in CCM is clinical decision support. LLMs can be applied in diagnosis, treatment planning, and prognosis prediction in in-hospital critical care settings.

XSL•FO
RenderX

Figure 2. The process and characteristics of clinical decision support. ED: emergency department; ICU: intensive care unit.

In diagnosis, LLMs demonstrate the potential to aid physicians in making diagnostic decisions. Gandomi et al [107] explored the use of LLMs (Llama 70B and Mistral) in detecting ARDS from radiology reports in the MIMIC-III (Medical Information Mart for Intensive Care-III) database. The study applied LLMs to identify high-probability ARDS cases based on bilateral infiltrates. Akhondi-Asl et al [85] investigated the use of domain-specific fine-tuned models (Llama-7B and BioGPT-Large) against larger general-domain models (Llama-65B) for generating differential diagnoses in pediatric intensive care unit (PICU) patients. They found that fine-tuned Llama-7B outperformed both Llama-65B and BioGPT-Large. Kurz et al [88] benchmarked the diagnostic performance of various vision-language models on a multimodal dataset comprising medical images and associated clinical context in ICU environments. They compared several open-source vision-language models against ChatGPT-4o, finding that while open models achieved accuracy only up to 40.4%, ChatGPT-4o substantially outperformed them with an approximation of 68.1%. Pham et al [89] evaluated the diagnostic utility of ChatGPT-4o in interpreting cranial ultrasound images to detect periventricular-intraventricular hemorrhage among very preterm infants in a neonatal ICU in Vietnam. Comparing ChatGPT-4o's image-based diagnoses against pediatric radiologists, the model achieved moderate performance (area under the curve [AUC]=0.796), with 75% sensitivity and 84.2% specificity, alongside fair-to-good interrater agreement. The study highlights ChatGPT-4o's potential as a supplemental tool for early periventricular-intraventricular hemorrhage screening. Pathak et al [102] developed RespBERT, leveraging BERT-based embedding and transfer learning to automatically identify ARDS from unstructured radiology notes across multiple hospital datasets. Applying the model to notes from 2 independent institutions, RespBERT achieved F_1-scores of 74.5% and 64.2%, demonstrating robust performance across different clinical settings and indicating its potential for ARDS detection in the ICU.

In treatment planning, LLMs show considerable promise in providing personalized treatment recommendations and optimizing clinical pathways for patients with critical illness. Savage et al [68] developed and validated the LLM screening tool to selectively identify patients appropriate for Best Practice Alerts of deep vein thrombosis anticoagulation prophylaxis using the MIMIC-III database. They found that the LLM screening tool improved the precision of Best Practice Alerts, reducing the number of unnecessary alerts by 20% and increasing the applicability of alerts by 14.8%. Pham et al [69] evaluated ChatGPT's performance in treating cardiac arrest and bradycardia simulations in accordance with the American Heart Association's Advanced Cardiovascular Life Support guidelines. Using the 2020 Advanced Cardiovascular Life Support guidelines, ChatGPT's responses to 2 simulation scenarios were assessed for accuracy. They found that ChatGPT had a median accuracy of 69% for cardiac arrest and 42% for bradycardia, with significant variability in its outputs, often missing critical actions, and having incorrect medication information. Nolan et al [78] used LLMs to support critical care decision-making for incapacitated patients. The study simulated scenarios for 50 patients requiring urgent clinical decisions and incorporated patient values captured through various formats, including free-text narratives. The LLMs were tasked with extracting treatments and generating recommendations based on patient profiles. The results showed that LLMs accurately extracted treatments in 88% of cases and received high scores for providing medically plausible and value-aligned recommendations. Williams et al [92] evaluated 4 LLMs (ChatGPT-4, Copilot, Gemini version 1.5, and Meta AI) by medication-related questions based on 6 Society of Critical Care Medicine clinical practice guidelines. Copilot yielded the highest proportion of correct answers, followed by Meta AI, ChatGPT-4, and Gemini, which delivered the most incorrect responses. Despite these capabilities, none of the models consistently matched guideline recommendations, indicating that while clinically promising, AI tools require further development for

XSL•FO
RenderX

reliable use in the ICU. Ucdal et al [99] assessed the performance of Gemini in applying American College of Gastroenterology 2024 guidelines to clinical decisions in acute pancreatitis management. Using MIMIC-III data consisting of 512 patient cases, the study evaluated Gemini's accuracy in determining disease severity, recommending nutritional strategies, and antibiotic use. Gemini achieved 85% accuracy for mild cases, 82% for severe cases, and 78%-85% compliance with guideline-based nutritional and management recommendations, demonstrating solid agreement with scoring systems. This suggests that AI may support consistent, guideline-concordant decision-making in pancreatitis care. Turan et al [104] conducted a prospective observational study comparing ChatGPT-4's interpretation of arterial blood gas results with that of expert anesthesiologists using 400 ICU patient samples. The model demonstrated excellent accuracy for parameters such as pH, oxygenation, sodium, chloride, and hemoglobin, though it struggled with bilirubin. While generally reliable, it occasionally recommended unnecessary bicarbonate therapy, highlighting the promise of ChatGPT-4 as a rapid interpretive aid, but underscoring the necessity of clinician oversight. Yang et al [106] presented a pioneering study that leveraged ChatGPT-4 and a multicenter real-world sepsis dataset (10,544 patients across 3 hospitals in China) to construct a comprehensive sepsis knowledge graph. By combining clinical guidelines, public data, and advanced prompt engineering, they extracted entities and relationships, building a graph with 1894 nodes and 2021 unique connections. ChatGPT-4 achieved a high F_1-score of 76.76 on the study's sepsis-specific dataset and 65.42 under the few-shot condition, surpassing models such as Qwen-2 and Llama-3.

For prognosis prediction, Amacher et al [108] used ChatGPT-4 to predict mortality and poor neurological outcomes at hospital discharge for adult patients who had cardiac arrest. The study involved prompting ChatGPT-4 with 16 prognostic parameters from established post–cardiac arrest scores. The findings showed that ChatGPT-4 achieved an AUC of 0.85 for in-hospital mortality and 0.84 for poor neurological outcomes, comparable to traditional scoring systems. Chung et al [73] used ChatGPT-4 to perform risk stratification and predict postoperative outcomes based on procedure descriptions and preoperative clinical notes from electronic health records (EHRs). They found that ChatGPT-4 achieved F_1-scores of 0.64 for predicting hospital admission, 0.81 for ICU admission, 0.61 for unplanned admission, and 0.86 for predicting hospital mortality. Liu et al [77] conducted a prospective multicenter cohort study using ChatGPT-3.5 and ChatGPT-4 to predict the risk of endotracheal intubation within 48 hours following high-flow nasal cannula oxygen therapy in patients with critical illness. They found that ChatGPT-4 achieved an accuracy comparable to that of specialist physicians, with an AUC of 0.82, which was higher than that of non-specialist physicians (AUC=0.66). Oh et al [82] conducted a study using ChatGPT-3.5-turbo and ChatGPT-4 to predict in-hospital mortality for sepsis patients. The study used clinical data from the Korean Sepsis Alliance database, focusing on ICU admissions and using metrics such as the SOFA (Sequential Organ Failure Assessment) score and lactic acid levels. The findings demonstrated that ChatGPT-4 performed comparably to a gradient boosting machine in predicting short-term mortality, particularly for 7-day outcomes. Shi et al [90] used the MIMIC-IV (Medical Information Mart for Intensive Care-IV) database to compare the performance of 2 LLMs (Qwen-2 and Llama-3) with a specialized artificial neural network (SWEDEHEART-AI) trained on Swedish registry data, in predicting 1-year all-cause mortality among ICU patients with acute myocardial infarction. SWEDEHEART-AI outperformed both LLMs, maintained consistent area under the receiver operating characteristic curve in time-dependent analyses, and demonstrated superior clinical utility and net benefit across risk thresholds, suggesting its stronger reliability for risk stratification. Ding et al [96] proposed a novel framework, cross-modality knowledge learning and extraction, that distills knowledge from LLMs into a predictive model trained on multimodal EHR data in the ICU. By refining clinical text using LLM-generated embeddings and using a cross-modality knowledge distillation approach that combines contrastive and patient-similarity learning losses, cross-modality knowledge learning and extraction significantly improved predictive accuracy for hypertension and heart failure events, demonstrating up to a 4.48% boost over state-of-the-art models using data from the MIMIC-III database. Zhu et al [101] used clinical data from 2 Chinese hospitals and a public South Korean dataset, comprising a total of 2649 older adult patients who underwent surgery, to use LLMs (GPT-4o, ChatGPT-4o mini, Qwen2-7B-Instruct, and Llama3.1-8B-Instruct), comparing their performance against traditional ML models such as XGBoost (Extreme Gradient Boosting) and Random Forest for the task of predicting postoperative AKI. The study enhanced the LLMs' capabilities through prompt engineering techniques such as Medical Chain of Thought and instruction fine-tuning. The results demonstrated that the LLM-based frameworks achieved superior generalization on external datasets while also providing human-readable medical rationales for predictions, significantly improving interpretability and clinical utility compared to traditional ML approaches. Liu et al [103] investigated risk prediction of in-hospital mortality using routinely collected clinical notes in the ICU. It proposes a note-specific hierarchical network that adapts to different note types and benchmarks it against various supervised baselines and 34 instruction-following LLMs under zero-shot and few-shot settings, as well as chain-of-thought prompting. The hierarchical model outperformed both LLMs and supervised baselines, which consistently underperformed in this critical task, highlighting important constraints of LLMs in risk assessment of critical care patients.

Medical Documentation and Reporting

LLMs are making strides in medical documentation and reporting by automating and streamlining these processes. Shah-Mohammadi et al [79] used the ChatGPT-3.5 model to extract substance use information from ICU discharge summaries in the MIMIC-III database, focusing on tobacco, alcohol, and illicit substances. They explored both zero-shot and few-shot prompt learning settings and found that GPT's performance in identifying tobacco, alcohol, and substance use varied depending on the learning scenario. Zero-shot learning achieved high accuracy in recognizing substance use, while

XSL•FO
RenderX

few-shot learning, although lowering accuracy, improved the identification of substance use status, leading to better recall and F_1-scores but lower precision. Nawab et al [80] conducted a study using the ChatGPT-3.5 Turbo to automate the assignment of *ICD-10* codes to clinical notes in the ICU. Their findings demonstrated that fine-tuning the model with a specialized dataset improved its accuracy from 29.7% to 62.6%. Soleimani et al [81] conducted a study using ChatGPT-3.5 to evaluate the performance of radiology report generation. Using data from the MIMIC-CXR (Medical Information Mart for Intensive Care-Chest X-Ray) database, the study explored how ChatGPT, guided by a 3-step prompt, synthesized complete radiology reports. They found that ChatGPT effectively generated comprehensive reports by accurately interpreting both patient characteristics and radiological findings. Urquhart et al [83] used ChatGPT-4, ChatGPT-3.5, and Llama 2 to extract key information from ICU patient text records in an Irish population. The study evaluated the models' ability to generate concise and accurate clinical summaries from unstructured ICU admission notes. The results showed that ChatGPT-4 outperformed the other models in readability, organization, and summarization of clinically significant events, but all models struggled with completeness and narrative coherence. Pabon et al [84] used ChatGPT-3.5 for extracting left ventricular ejection fraction data from medical records in a study involving patients with heart failure with improved ejection fraction. The model achieved 100% accuracy in identifying reported left ventricular ejection fraction values but struggled with a capture completeness of 75%. Si et al [71] explored the impact of ELMo and BERT on clinical concept extraction tasks using data from the MIMIC-III and other clinical corpora. They found that contextual embeddings pretrained on a large clinical corpus outperformed traditional methods. Madden et al [76] used ChatGPT-4 to query and summarize unstructured medical notes in the ICU. They found that while the model could produce concise and useful summaries, it also had significant risks of generating hallucinations. Yang et al [93] developed a platform to facilitate the deployment and extraction of critical care-related big data using LLMs. The system leverages Docker (Docker Inc)–based automated database deployment and visualization tools, along with an ICU-fine-tuned LLM ICU-GPT to generate SQL queries and extract data from complex ICU datasets without requiring programming knowledge. This platform enables clinicians to manage, visualize, and retrieve structured insights from large critical care databases through a user-friendly web interface, reducing the technical barrier to big data research in clinical settings. Walker et al [97] developed CARE-SD, a classifier-based NLP toolkit designed to identify stigmatizing patient labels and doubt markers within ICU clinical notes. By constructing lexicons (127 stigmatizing expressions and 58 doubt markers) using literature-based stems augmented via Word2Vec and ChatGPT-3.5, and training supervised classifiers on annotated samples drawn from 18 million MIMIC-III sentences, the models achieved macro F_1-scores of 0.84 (doubt markers) and 0.79 (stigmatizing labels). This approach supports the detection of linguistic biases in critical care EHRs and could inform interventions to reduce stigmatizing language in health care.

Medical Education and Doctor-Patient Communication

LLMs are used more and more frequently in medical education now. One important area closely connected to LLMs is to generate or answer questions in medical examinations. Workum et al [94] conducted a benchmark study by evaluating 5 LLMs (GPT-4o, ChatGPT-4o-mini, ChatGPT-3.5-turbo, Mistral Large 2407, and Llama 3.1 70B) on 1181 multiple-choice questions from the European Diploma in Intensive Care examination. All models significantly outperformed human physicians, with ChatGPT-4o achieving the highest accuracy of 93.3%. Despite outstanding consistency and performance, models still produced incorrect answers and raised concerns about energy consumption, especially for ChatGPT-4o, highlighting the need for ongoing evaluation before clinical deployment. Yang et al [95] compared the performance and consistency of 5 LLMs (GPT-3.5, ChatGPT-4, Claude 2, Llama2-7B, and Llama2-13B) on a set of 219 multiple-choice questions covering critical care pharmacotherapy for Doctor of Pharmacy students. The study evaluated accuracy, response variance, and the impact of prompt engineering techniques, such as few-shot chain-of-thought prompting, and the use of a custom-trained GPT model. ChatGPT-4 emerged with the highest accuracy (71.6%), chain-of-thought prompting further improved its performance, and the variance in performance differed across models. Notably, customizing models and prompt strategies can enhance LLM reliability in pharmacy education contexts. Chen et al [98] developed and applied a multimodal evaluation framework to assess the performance of widely available machine translation (MT) tools (including DeepL, Gemini, Google Translate, and Microsoft Copilot) in translating critical care educational content from English into Mandarin Chinese, Spanish, and Ukrainian. The study used blinded bilingual clinician ratings (for fluency, adequacy, and meaning), BLEU (bilingual evaluation understudy) scores, and usability assessments to compare MT outputs against professional human translations. The results revealed no single MT tool consistently excelled across languages or metrics, human translation scored best for Chinese, Gemini performed strongest for Spanish, and Microsoft Copilot ranked highest for Ukrainian, highlighting the need for ongoing evaluation of MT tools in critical care education as they rapidly evolve. Wang et al [105] evaluated ChatGPT-4 against the Chinese Health Professional Technical Qualification Examination for Critical Care Medicine, which comprises 600 questions across fundamental knowledge, specialized knowledge, practical skills, and related medical knowledge. ChatGPT-4 achieved an overall success rate of 73.5%, surpassing the 60% passing threshold, with the highest accuracy in fundamental knowledge (81.94%). Notably, performance was significantly better on single-choice versus multiple-choice questions (76.72% vs 51.32%, P<.001), with no difference between case-based and non–case-based formats. The study underscores its potential as a clinical decision support and educational aid, while cautioning on the need for expert oversight due to potential inaccuracies.

Meanwhile, LLMs use information such as clinical guidelines to answer questions and do clinical reasoning from real-world medical scenarios. Levin et al [17] used 2 LLMs, ChatGPT-4 and Claude-2.0, to provide initial assessment and treatment

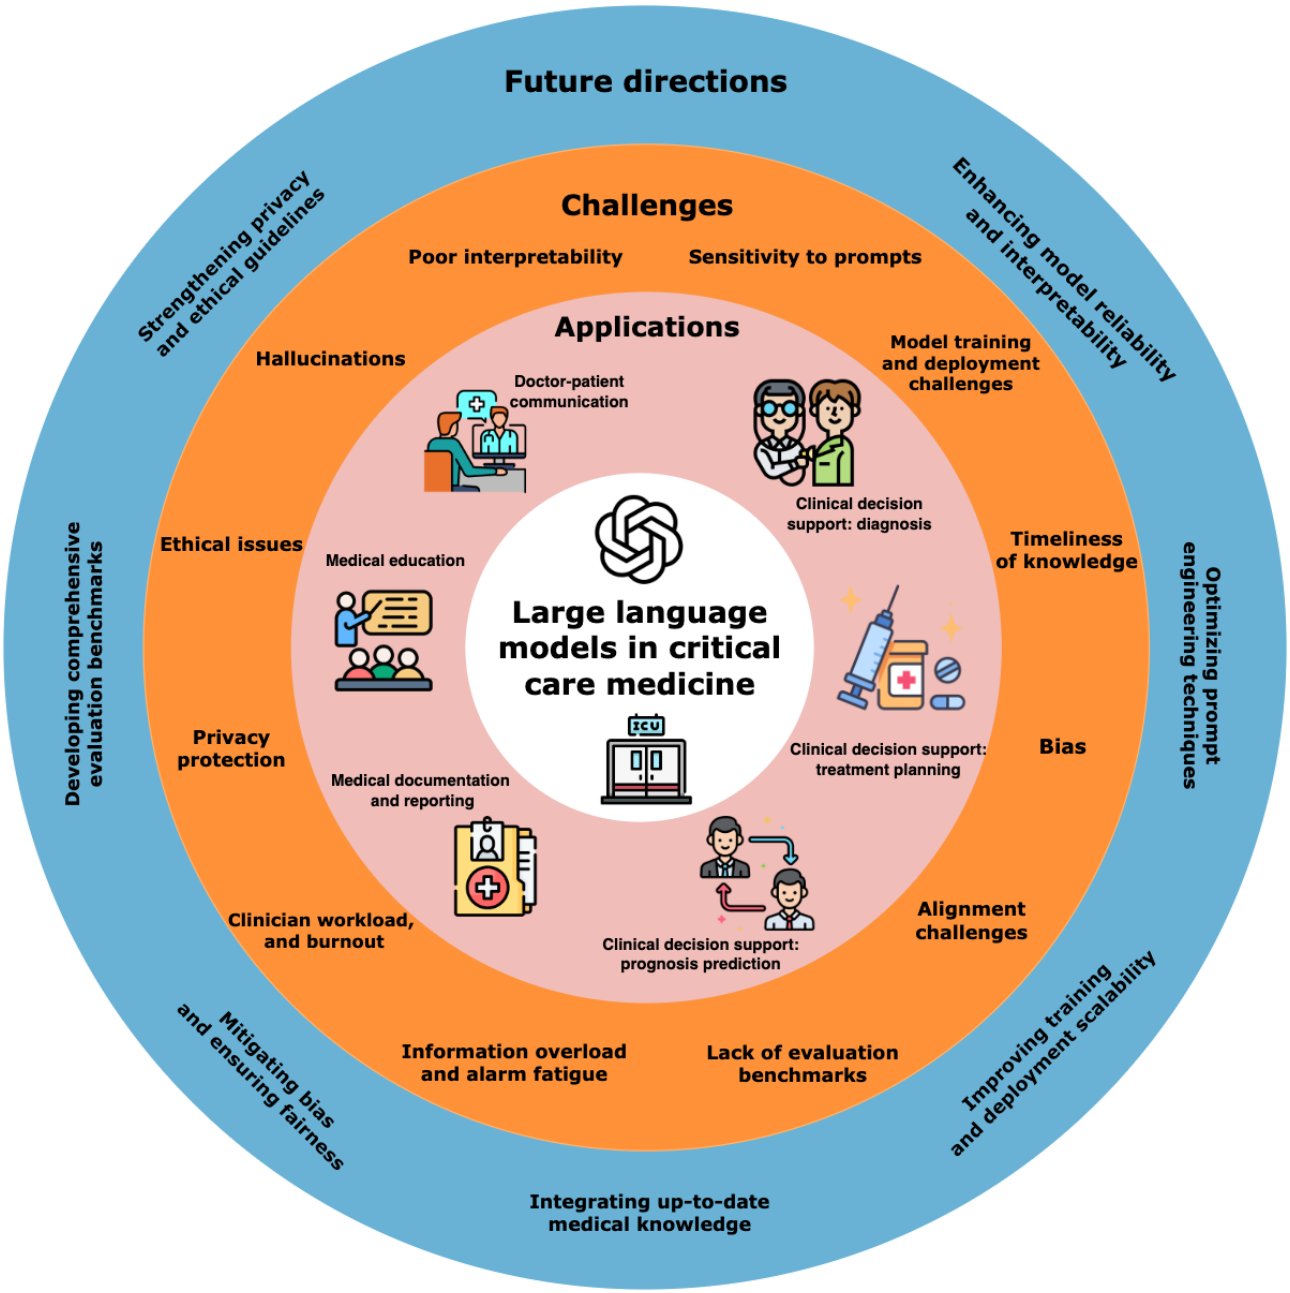
XSL•FO
RenderX

recommendations for patients in neonatal intensive care settings. The results indicated that both models demonstrated clinical reasoning abilities, with Claude-2.0 outperforming ChatGPT-4 in clinical accuracy in providing initial assessments and treatment recommendations, and response speed. Liu et al [86] conducted a qualitative study to explore how novice ICU simulation instructors experience the use of GenAI in case design. Using semistructured interviews with 13 instructors and thematic analysis, the study found that GenAI improved efficiency, provided structured and diverse scenario design, and enhanced learning engagement, especially for beginners. The findings suggest that GenAI can serve as a valuable educational tool in ICU simulation, but must be balanced with instructor-led critical thinking and validated clinical accuracy. Yitzhaki et al [91] used 100 educational questions from a PICU trainee WhatsApp forum to compare ChatGPT-4's performance against pediatric intensive care specialists. Evaluated by 10 PICU experts across multiple tertiary centers, ChatGPT-4's responses were longer and more complete for factual questions, with 60% being preferred for factual knowledge; however, specialists' responses were favored in clinical reasoning (67%), reflecting higher accuracy. Integrated answers were chosen in 37% of evaluations, emphasizing the need for expert oversight when using ChatGPT-4 in PICU education. Balta et al [100] assessed ChatGPT-3.5 versus ChatGPT-4 by having 2 independent intensivists evaluate LLM-generated recommendations to 50 curated core critical care questions from textbooks. ChatGPT-4 delivered significantly higher median appropriateness scores. The study stresses that both models can confidently produce clinically misleading or hallucinated content and thus should be used with caution in the ICU.

LLMs can also be used to overcome language barriers and enhance communication. Benboujja et al [75] developed and evaluated a multilingual, AI-driven curriculum to overcome language barriers in pediatric care. Using ChatGPT-4 for translation, the study created 45 educational video modules in English and Spanish, covering surgical procedures, perioperative care, and patient journeys. Almazyad et al [72] used ChatGPT-4 to enhance expert panel discussions in pediatric palliative care. They found that ChatGPT-4 effectively facilitated discussions on do-not-resuscitate conflicts by summarizing key themes such as communication, collaboration, patient and family-centered care, trust, and ethical considerations. Berger et al [87] conducted a study to investigate the risks associated with the use of abbreviations in critical care communication. By analyzing perspectives from ICU clinicians, the study highlighted how abbreviations, although designed to save time, often introduce ambiguity, misinterpretation, and patient safety risks in high-stakes environments. The findings emphasize that abbreviations can fall short of their intended efficiency, underscoring the importance of clear communication, standardized language, and improved training to minimize preventable errors and improve patient safety in the ICU.

RoB and Applicability Assessment

Across the literature, most studies were judged to have a high RoB in at least 1 RoB domain, most commonly analysis, including reliance on apparent performance without robust internal validation, absent calibration or uncertainty, and risks of temporal or selection leakage, followed by predictors and participants. Outcome definitions were generally aligned with ICU standards, but sometimes lacked blinded ascertainment. Applicability concerns concentrated in predictors (including dependencies on sources not readily available in real-time ICU workflows). Detailed ratings and justifications are presented in Table S4 in Multimedia Appendix 1.



Discussion

Principal Findings

This scoping review provided a comprehensive portrait of the role of LLMs in CCM, identifying the applications, advantages, challenges, and future research directions of this area. With the recent advent of LLMs, medicine has witnessed groundbreaking developments and advancements [109]. Many review papers focus on applying LLMs in health and medicine [110,111]. Particularly, although there are some review papers on AI in CCM [112-114], few review papers focus on the application of LLMs in CCM. From the 2342 papers initially retrieved, 41 of them were selected for final review. An extensive examination of the selected literature revealed that LLMs have shown promise in some main aspects of CCM: clinical decision support, medical documentation and reporting, medical education, and doctor-patient communication. Compared with traditional AI models, LLMs have advantages in processing unstructured data and do not require manual feature engineering. At the same time, applying LLMs to CCM faces numerous challenges, including hallucinations and poor interpretability, sensitivity to prompts, bias and alignment challenges, and privacy and ethical issues. The current applications, together with the challenges and future directions of LLMs in CCM identified by this review, are shown in Figure 3. Our findings highlight the potential of LLMs in critical care practices while also underscoring the need for further research to address corresponding challenges and improve the reliability and applicability of LLMs in the critical care domain.

XSL•FO
RenderX

Figure 3. The main applications, challenges, and future directions of LLMs in CCM. CCM: critical care medicine; LLM: large language model.

The application of LLMs in CCM has demonstrated numerous advantages. Compared to traditional machine learning techniques, using LLM technology in CCM can effectively cause understanding and generate natural language, aiding clinicians in writing patient medical records and diagnostic notes [115-118]. The capabilities of LLMs extend beyond text interpretation and generation. They surpass traditional machine learning methods in handling unstructured data. LLMs can learn directly from extensive patient data without manual feature engineering. Moreover, multimodal LLMs can learn and understand medical images, such as x-rays and CT (computed tomography) scans [110]. In clinical practice, LLMs can extract critical information from a patient's historical medical records and combine it with the latest medical research, aiding physicians in identifying rare diseases or those with early symptoms that are not clearly defined [119]. For medical research, LLMs can assist researchers in summarizing data and information in literature research and providing suggestions for manuscript structure and titles, enhancing the readability and completeness of texts [118]. LLMs have a wide range of knowledge that can provide physicians with a comprehensive analysis of decision-making across different specialties [115].

Challenges

Hallucinations and Poor Interpretability

One of the most critical challenges in applying LLMs in CCM is the occurrence of hallucinations, where the model generates plausible-sounding but factually incorrect information [120,121]. These hallucinations pose risks, where incorrect recommendations can lead to inappropriate diagnoses or treatment plans, potentially endangering ICU patients' lives. Studies have documented examples where LLMs hallucinate during critical care decision-making, raising concerns about their reliability [76,81,122]. Additionally, LLM outputs often

XSL•FO
RenderX

lack transparency, making it difficult for clinicians to understand how specific decisions are reached. This opacity complicates the tracking of decision-making processes, leading to reduced trust in these systems [61,123]. The opaque nature of LLMs further complicates their application, as it becomes challenging to verify the factual basis of their outputs, particularly in the ICU, where patient safety is important. The lack of clarity regarding the sources of information makes LLMs unreliable for autonomous decision-making in CCM [76,81]. Therefore, improving the interpretability and transparency of LLMs remains a critical challenge in their integration into clinical workflows [123,124].

Sensitivity to Prompts and Inconsistent Performance

LLM-generated outputs are highly sensitive to input prompts, and different prompt strategies may affect the model's capabilities and performance [122]. In CCM, where the accuracy of information is essential, this sensitivity can lead to inconsistent results across different clinical scenarios [82,84]. The same LLM might provide different answers to slightly rephrased prompts, requiring clinicians to analyze multiple iterations to ensure accuracy. This lack of consistency raises concerns about the reliability of LLM applications in critical care, especially when time-sensitive decisions must be made. There is no universal prompt strategy that guarantees high performance across all LLMs, which means that clinicians must carefully craft prompts to suit the context of the task [75]. The absence of a one-size-fits-all approach for prompting remains a significant limitation of LLMs in critical care settings [76].

Model Training and Deployment Challenges

Training and deploying LLMs for critical care applications is a resource-intensive process, requiring vast computational power and large, diverse datasets. Public critical care databases, such as MIMIC (Medical Information Mart for Intensive Care) [125,126] and eICU [127], are commonly used for model training. Moreover, hospital regulations and privacy laws often restrict data sharing, complicating the training of models across multiple centers [107]. The deployment of LLMs in real-time ICU settings also requires substantial computational resources, which may not be feasible in all clinical environments, particularly those with constrained infrastructure [68,128,129]. Additionally, compliance with local data privacy regulations in some hospitals can limit the use of LLMs in health care settings [107]. The inability of LLMs to adapt to local computing environments due to privacy concerns further hampers their wide-scale application in critical care [68].

Timeliness of Knowledge and Model Updates

CCM is a rapidly evolving field, with frequent updates to clinical guidelines, treatments, and best practices. LLMs, however, are typically trained on static datasets, limiting their ability to remain up-to-date with the latest medical advancements [19]. This delay in knowledge poses a significant challenge, as outdated information could negatively impact patient outcomes [76,84]. To ensure their continued relevance in clinical practice, LLMs must be regularly updated with the latest medical knowledge. However, this process is computationally expensive and logistically challenging, particularly for large-scale LLMs [84,130]. Therefore, ensuring the timeliness of LLMs' knowledge base is crucial to their successful application in CCM.

Bias and Alignment Challenges

LLMs may unintentionally learn biases from the training data and reproduce them in their outputs, potentially leading to skewed or inappropriate recommendations in critical care. These biases can disproportionately affect specific patient populations, potentially leading to disparities in treatment and care [70,78,131]. In the ICU, biased outputs could result in suboptimal or even harmful decisions. Moreover, aligning LLM behavior with clinical guidelines and ethical standards is also a challenge, as models may not always adhere to best practices when generating recommendations [81,84,132]. Addressing bias and ensuring alignment with clinical guidelines and ethics are essential steps for LLMs to function as reliable tools in critical care [131,133]. Additionally, excessive reliance on AI-generated alerts can lead to "alarm fatigue," where clinicians become desensitized to frequent, nonurgent predictions, potentially missing critical care events [134].

Lack of Evaluation Benchmarks

Currently, there are no universally accepted standards for evaluating the performance of LLMs in critical care settings. Traditional model evaluation primarily focuses on the accuracy of medical question answering, which may not fully reflect the capabilities of LLMs in critical care clinical practice [135]. Across the included literature, model discrimination should not be conflated with clinical benefit. Consistent with current professional guidance and editorials, routine adoption should follow prospective evaluations that consider patient-centered outcomes rather than relying solely on technical metrics. Current benchmarks rarely include patient-relevant end points [136,137]. Without appropriate benchmarks, it is challenging to evaluate the effectiveness of LLMs in critical care or compare different models on an equal standard.

Information Overload and Alarm Fatigue in ICU Workflows

Contemporary ICUs are characterized by a proliferation of bedside devices and dense, multistream monitoring data. Qualitative and narrative evidence suggest that this technological abundance, when poorly integrated, can amplify cognitive load, desensitize clinicians to frequent alarms, and undermine situation awareness and team communication [138]. LLM-enabled systems may help by acting as context-aware filters and data-to-text summarizers that deduplicate near-identical events across monitors, ventilators, or pumps; prioritize alerts using clinical context; and attach traceable rationales for rapid verification [139,140]. However, naïve deployments could also increase burden (eg, secondary notifications and unverifiable rationales), so any use of LLMs should be aligned with human-centered monitoring principles and embedded in sociotechnical workflows rather than added as another layer.

XSL•FO
RenderX

Clinician Workload, Burnout, and Documentation Quality

While LLMs show promise for text generation and knowledge integration, clinical burden and professional burnout are often overlooked dimensions of the ICU setting [141,142]. Hallucinations and lack of interpretability shift the burden from "writing" to "reviewing and evidence verification." Inconsistent sensitivity to prompts and output leads to trial and error for frontline staff [143]. At the deployment level, the ICU's high noise level, multirole collaboration, and rigorous legal review may create new bottlenecks for editing and rework. Furthermore, language biases in generated text and paperwork bloat may compromise team communication and information retrieval efficiency. These factors collectively point to the need for systematic evaluation of clinician burden and burnout beyond model effectiveness.

Privacy and Ethical Concerns

Handling patient data responsibly is a significant concern in critical care, where vast amounts of sensitive information must be processed. Ensuring patient privacy while using LLMs presents both technical and legal challenges. Strict compliance with data protection regulations, such as the General Data Protection Regulation and HIPAA (Health Insurance Portability and Accountability Act), is necessary but can hinder the deployment of LLMs in clinical settings [68,76]. Moreover, the ethical implications of relying on LLMs for life-or-death decisions raise concerns about accountability and the potential over-reliance on AI in medical decision-making [144]. To navigate these issues, health care systems must establish clear guidelines for the responsible use of LLMs, ensuring that patient privacy is upheld and ethical standards are maintained. Addressing these privacy and ethical challenges will be essential for gaining clinician and patient trust in AI systems used in CCM [72].

Future Directions

Enhancing Model Reliability and Interpretability

Improving the reliability and interpretability of LLMs in CCM is critical for their safe integration into real-world clinical workflows. To enhance model reliability, future research should prioritize improving the quality of training data, particularly by incorporating domain-specific knowledge from critical care environments [84,107]. The accuracy and reliability of LLMs can be enhanced by improving training data quality, using ensemble learning, evidential reasoning, implementing adversarial training, and multiagent systems [145-149]. Additionally, the use of methods, such as chain-of-thought reasoning, tree-of-thoughts, and retrieval-augmented generation (RAG), can offer greater interpretability, allowing clinicians to understand how LLMs arrive at specific recommendations [150]. These interpretability techniques would provide clinicians with a clearer rationale for decision-making, thereby building trust in LLM outputs [151,152]. LLM outputs should include provenance-linked evidence and enforce concise, structured formats to curb alert or note bloat and reduce verification burden in human-centered ICU workflows [138]. Further, integrating external knowledge databases such as PubMed through plugins can improve the accuracy of LLM outputs and reduce the risk of hallucinations, particularly in critical care [108].

Optimizing Prompt Engineering Techniques

LLMs are highly sensitive to prompts, and developing robust prompt engineering techniques is essential for improving consistency and reliability in CCM. Recently, advancements such as Medprompt, which combines dynamic few-shot, self-generated chain-of-thought, and choice shuffle ensemble, have demonstrated improved performance in general LLMs, particularly in medical contexts [153]. MedGraphRAG is also a novel graph-based RAG framework designed specifically for the medical domain, enhancing the capabilities of LLMs by generating evidence-based, contextually accurate responses through a hierarchical graph structure, thereby improving transparency and reliability in handling private medical data [154]. These advancements will be particularly useful for critical care environments, where fast and reliable decision-making is essential. Future research should explore the development of prompt engineering strategies to handle complex clinical tasks [74,79].

Improving Model Training and Deployment Scalability

To address LLM training and deployment challenges, scalable model architectures, transfer learning, model pruning, and federated learning approaches can be explored to reduce computational demands and facilitate practical deployment [155]. The emergence of low-powered open-source LLMs running locally could circumvent issues related to data privacy and computational resource constraints [76]. It is crucial to convert medical datasets into easily accessible structured databases and train health care professionals in the ICUs to use LLMs in clinical practice to aid decision-making [108]. Collaboration with hospitals to develop structured medical databases will also aid in better training of LLMs for real-time decision-making in critical care environments [84,107].

Integrating Up-to-Date Medical Knowledge

Using web-based learning systems allows models to update and assimilate the latest medical research and changes in clinical practices on time. Additionally, modular update systems can swiftly integrate new medical discoveries, while expert collaboration ensures the scientific validity and timeliness of model outputs. Moreover, using RAG techniques to connect LLMs with databases in CCM can also address the knowledge timeliness issue to some extent [151,152].

Mitigating Bias and Ensuring Fairness

Bias mitigation should be approached through preprocessing, in-training, intraprocessing, and postprocessing stages [131]. Preprocessing techniques involve modifying model inputs to ensure balanced representations. In-training methods focus on adjusting model parameters to mitigate biases through gradient-based updates. Intraprocessing methods modify inference behavior without further training, while postprocessing techniques correct model outputs to ensure fair treatment across demographic groups. Developing bias detection and dataset augmentation algorithms to review and adjust model outputs regularly can help reduce model bias and ensure fairness in CCM [156].

XSL•FO
RenderX

Developing Comprehensive Evaluation Benchmarks

Recent studies demonstrated that performance varies across different medical tasks, highlighting the need for task-specific evaluations [135,157]. Future efforts should focus on developing more sophisticated evaluation frameworks that go beyond traditional metrics and consider the specific challenges of critical care [68]. For instance, the MIMIC-IV-CDM (Medical Information Mart for Intensive Care-IV-Clinical Decision Making) dataset and evaluation framework, focusing on 2400 real patient cases with acute abdominal pain, offers a new benchmark for evaluating LLMs in clinical decision-making, highlighting the need for more rigorous testing to ensure LLMs meet clinical standards, particularly guidelines [158]. We must standardize clinician-centered metrics, such as time-in-note, click or keystroke counts, handoff completion time, and note quality (accuracy, completeness, consistency, and readability), and report them alongside patient outcomes in prospective, preregistered ICU studies [159]. To establish clinical benefit and safety beyond model accuracy, future studies should use preregistered, prospective designs that prespecify outcomes such as mortality, ventilator-free days, time-to-critical interventions, and ICU length of stay, alongside calibration and uncertainty reporting [136,137]. Future work should explore comparing general LLMs against domain-adapted or fine-tuned LLMs (eg, BioGPT-Large and Llama-Med) on tasks and datasets in CCM. Additionally, collaboration between medical professionals and AI researchers will be necessary to design evaluation metrics that are meaningful, clinically applicable, and capable of guiding LLM improvements [135].

Strengthening Privacy and Ethical Guidelines

Data privacy and ethical guidelines are crucial for ensuring that LLMs are safely integrated into CCM [123,124]. As LLMs handle vast amounts of sensitive patient data, their deployment must comply with strict data protection regulations [76]. Future research should explore synthetic data generation techniques to augment training datasets while protecting patient privacy, allowing for comprehensive model training without compromising confidentiality [76,107]. Moreover, collaboration with policymakers, ethicists, and legal experts is necessary to ensure LLM applications comply with ethical and legal requirements, thus protecting patient privacy and data security [160].

This scoping review may be limited by selection bias due to the literature databases and inclusion criteria, potentially excluding relevant studies in non-English or outside the selected databases. Additionally, the rapid development of LLMs could render the findings quickly outdated, and the broad scope may have limited the depth of analysis for specific LLM applications in CCM.

Conclusions

In conclusion, although LLMs in CCM are not yet ICU experts, they act as more than stochastic parrots. Applying LLMs in CCM presents a transformative potential for enhancing critical care. LLMs are capable of reasoning beyond random generation, and they have demonstrated capabilities to improve diagnostic accuracy, plan optimal treatments, and provide valuable support in prognosis prediction. However, applying LLMs in CCM is still in its early stages, with very few large models specifically designed and fine-tuned for this domain. Future research should focus on enhancing model reliability and interpretability, optimizing prompt engineering techniques, improving training and deployment scalability, integrating up-to-date medical knowledge, mitigating bias and ensuring fairness, developing comprehensive evaluation benchmarks, and strengthening privacy and ethical guidelines. Close collaboration across multiple disciplines, such as medicine, computer science, and data science, may help catalyze the applications of LLMs in CCM. There is some way to go before making LLMs that become true ICU experts. Nevertheless, we are optimistic that LLMs in CCM will become experts in the near future, helping to improve the quality of critical care and the outcomes of patients with critical illness.

Abbreviations

AI: artificial intelligence
AKI: acute kidney injury
ARDS: acute respiratory distress syndrome
AUC: area under the curve
BLEU: bilingual evaluation understudy
CCM: critical care medicine
CT: computed tomography
EHR: electronic health record
GenAI: generative artificial intelligence
HIPAA: Health Insurance Portability and Accountability Act
ICU: intensive care unit
LLM: large language model
MIMIC: Medical Information Mart for Intensive Care
MIMIC-CXR: Medical Information Mart for Intensive Care-Chest X-Ray
MIMIC-III: Medical Information Mart for Intensive Care-III
MIMIC-IV: Medical Information Mart for Intensive Care-IV
MIMIC-IV-CDM: Medical Information Mart for Intensive Care-IV-Clinical Decision Making
MT: machine translation
NLP: natural language processing
PICU: pediatric intensive care unit
PRISMA-ScR: Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews
PROBAST-AI: Prediction Model Risk of Bias Assessment Tool-Artificial Intelligence
RAG: retrieval-augmented generation
RoB: Risk of Bias
SOFA: Sequential Organ Failure Assessment
XGBoost: Extreme Gradient Boosting

Abstract

Background: Liver failure often results in significant coagulation dysfunction, which is a major complication. Artificial liver support systems (ALSS) have been used to ameliorate coagulation parameters, but the dynamic nature of these improvements and the development of predictive models remain insufficiently explored.

Objective: This study aimed to evaluate the effects of ALSS on coagulation function and to develop a dynamic prediction model using machine learning techniques to predict the improvement trends of coagulation parameters.

Methods: A systematic search was conducted in PubMed, Embase, and other databases to identify relevant studies, resulting in 18 studies comprising 1771 patients. A meta-analysis was performed to assess the impact of ALSS on coagulation parameters, including international normalized ratio (INR), prothrombin time (PT), activated partial thromboplastin time (APTT), and fibrinogen levels. In addition, clinical data from the Medical Information Mart for Intensive Care database were used to construct prediction models using logistic regression, extreme gradient boosting, random forest, and long short-term memory networks.

Results: Meta-analysis results showed that ALSS significantly improved INR, PT, APTT, and fibrinogen levels (all $P<.05$), with the treatment efficacy varying by modality. Among the machine learning models, the random forest model demonstrated the best performance, achieving an area under the curve of 92.12%. Dynamic INR was identified as the key predictor for coagulation abnormalities.

Conclusions: This study systematically evaluated the effects of ALSS on coagulation function in patients with liver failure, demonstrating significant improvements in key parameters such as INR, PT, and APTT, with efficacy varying across different treatment modalities. Simultaneously, a machine learning model built using intensive care unit clinical data exhibited strong predictive capability for identifying the risk of coagulation dysfunction, particularly useful in supporting early-stage clinical recognition of high-risk patients and guiding personalized coagulation management strategies. It is important to emphasize that this model is positioned as a dynamic risk alert and assessment tool, intended to assist clinical baseline evaluation and nursing interventions, rather than serving as direct validation of ALSS therapeutic efficacy.

(JMIR Med Inform 2025;13:e76348) doi:10.2196/76348

KEYWORDS

artificial liver support system; liver failure; coagulation function; meta-analysis; machine learning; predictive modeling

Introduction

Liver failure represents a critical clinical condition frequently complicated by severe coagulopathy, which significantly increases bleeding risk [1,2]. The disruption of coagulation homeostasis may lead to life-threatening complications, including gastrointestinal hemorrhage and intracranial bleeding, while potentially triggering disseminated intravascular coagulation that exacerbates multiorgan dysfunction [3,4]. As a crucial therapeutic intervention, the artificial liver support system (ALSS) demonstrates the potential for improving coagulation parameters through its detoxification, synthetic, and metabolic substitution functions [5-8]. However, the

XSL•FO
RenderX

mechanisms underlying ALSS-mediated coagulation improvement remain insufficiently investigated, particularly regarding differential effects among various modalities (eg, plasma exchange [PE] and molecular adsorbent recirculating system [MARS]). Clinical decision-making is further challenged by the lack of reliable dynamic monitoring indicators and predictive tools for optimal treatment timing and duration adjustment [9,10]. Furthermore, the highly individualized nature of coagulation dynamics in patients with liver failure cannot be adequately captured by conventional static tests (eg, prothrombin time [PT] and activated partial thromboplastin time [APTT]) [11-13]. Therefore, a comprehensive investigation of ALSS-induced dynamic coagulation changes and the development of accurate predictive models are clinically imperative for optimizing individualized treatment strategies. Addressing this scientific challenge will directly impact bleeding risk management and overall prognosis in patients with liver failure.

Although several studies have investigated the effects of ALSS on coagulation function in patients with liver failure, most suffer from limitations, such as small sample sizes and single-center designs, which compromise the reliability and generalizability of their findings [14]. More notably, the majority of these studies focus solely on short-term outcomes (eg, changes within 24 hours posttreatment), failing to capture the long-term dynamic evolution of coagulation parameters [15]. Methodologically, conventional statistical analyses (eg, *t* tests and ANOVA) are inadequate for characterizing temporal trends in coagulation indicators, limiting their utility for developing precise predictive models [16-18]. While meta-analyses can synthesize evidence from multiple studies to enhance statistical power [19], no study to date has systematically evaluated the differential effects of ALSS modalities on coagulation function. Advances in machine learning have demonstrated significant potential for medical data mining and predictive modeling [20,21]; however, their application in monitoring coagulation dysfunction in liver failure remains nascent. A critical gap persists in integrating multisource heterogeneous clinical data (eg, electronic health records, laboratory results, and vital signs), as existing studies have yet to leverage the full potential of large-scale public databases like Medical Information Mart for Intensive Care (MIMIC). These methodological limitations hinder clinicians and nurses from accurately predicting and promptly intervening in coagulation function changes among patients with liver failure.

This study uses a multidimensional and multimethod research strategy to achieve 3 key objectives. First, we conduct a systematic review and meta-analysis to comprehensively evaluate the effects of ALSS on coagulation parameters (eg, international normalized ratio [INR], PT, APTT, and fibrinogen) in patients with liver failure, while comparing the efficacy of different treatment modalities. Second, leveraging large-scale clinical data from the MIMIC database, we apply advanced machine learning algorithms to develop a dynamic, time-series predictive model for assessing coagulation function. Third, using interpretability techniques (eg, Shapley Additive Explanations [SHAP] value analysis), we identify key predictive factors influencing coagulation dynamics, providing a theoretical foundation for clinical interventions. From a scientific perspective, this study is the first to elucidate the dynamic mechanisms by which ALSS modulates coagulation function in liver failure, deepening our understanding of coagulopathy in this context and advancing precision medicine in the field. Clinically, our findings offer three major practical applications: (1) an objective, data-driven decision-support tool to optimize individualized ALSS treatment strategies; (2) early detection of coagulation abnormalities, enabling timely interventions to reduce bleeding complications; and (3) improved allocation of nursing resources, enhancing health care efficiency and ultimately patient outcomes. These innovations will significantly elevate the standard of care for patients with liver failure and serve as a methodological reference for research on other organ support therapies.

This study adopts a dual-track integrative strategy, combining meta-analysis with machine learning modeling, aiming to comprehensively elucidate the interventional value of ALSS on coagulation function in patients with liver failure and to uncover the underlying mechanisms of coagulation risk prediction across multiple levels. The meta-analysis, based on 18 clinical studies, systematically evaluated the short-term and long-term improvement effects of different ALSS modalities—including PE, MARS, and double plasma perfusion (PP)—on key coagulation indicators, such as INR, PT, APTT, and fibrinogen. The results confirmed the clinical benefits of ALSS in reducing the risk of coagulation dysfunction and provided an evidence-based foundation for subsequent predictive modeling. However, due to the limited number of patients who received ALSS treatment in the MIMIC database, the training population for the machine learning model focused on a broader cohort of patients with liver failure. The goal was to construct a generalizable and efficient dynamic coagulation risk assessment tool applicable to real-time bedside alerts and optimized resource allocation. We consider this model a “baseline tool” for risk stratification and timing judgment before ALSS initiation in clinical practice, laying a methodological foundation for the development of specialized models based on larger, ALSS-specific datasets in the future. Therefore, this study achieves an organic integration from high-level evidence synthesis to individualized risk prediction, not only enhancing the understanding of the clinical benefits of ALSS but also providing a practical path for the precise implementation of personalized interventional strategies in liver failure management.

Accordingly, the primary aim of this study is to systematically evaluate the short-term and long-term effects of ALSS on coagulation function in patients with liver failure and to further construct a clinically valuable dynamic risk prediction model for coagulation dysfunction. The specific objectives are as follows: (1) to quantify, through systematic review and meta-analysis, the improvement effects of different ALSS modalities (such as PE, MARS, and PP) on major coagulation parameters (INR, PT, APTT, and fibrinogen); (2) to use real-world clinical data from the MIMIC database and apply multiple machine learning algorithms to develop predictive models for early identification of coagulation dysfunction within the next 24 hours; and (3) to integrate model interpretability

XSL•FO
RenderX

techniques (eg, SHAP analysis) to identify key predictive variables associated with changes in coagulation function, thereby providing theoretical support for personalized treatment and nursing interventions. Through this integrated strategy, the study seeks to promote the advancement of precision ALSS therapy and offers a novel pathway for bleeding risk management and prognosis improvement in patients with liver failure.

Methods

Literature Search and Screening

This meta-analysis and systematic review were conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [22]. A comprehensive literature search was performed across multiple databases, including PubMed, Embase, Web of Science, and the Cochrane Library, using a combination of Medical Subject Headings terms and free-text keywords to ensure thoroughness and precision. The search strategy incorporated key terms such as liver failure, artificial liver support (ALS), blood coagulation, and hemostasis, optimized with Boolean operators (AND and OR) to balance sensitivity and specificity (refer to Table S1 in Multimedia Appendix 1 for detailed search queries). To account for variations in database syntax, the search strategy was tailored to each platform. In addition, manual screening of reference lists from included studies was performed to identify potentially eligible articles not captured by the initial database search. To confirm the novelty of this study, a search for registered systematic reviews was conducted in the PROSPERO database.

The screening process was independently carried out by 2 researchers (HW and TH) using EndNote (Clarivate) for reference management. The selection procedure consisted of two phases: (1) initial screening based on titles and abstracts to exclude clearly irrelevant studies, followed by (2) full-text review of potentially eligible articles, with documented reasons for exclusion. Any discrepancies between reviewers were resolved through discussion or adjudication by a third researcher (LR) to ensure objectivity. Interrater agreement was assessed using Cohen κ coefficient to quantify screening consistency. To enhance transparency, the study selection process was visualized using a PRISMA flow diagram, providing a clear and reproducible overview of the screening stages.

Inclusion and Exclusion Criteria

Inclusion criteria consisted of (1) study design: randomized controlled trials, cohort studies, or case-control studies; (2) participants: patients diagnosed with liver failure according to international or national guidelines (eg, Asian Pacific Association for the Study of the Liver, European Association for the Study of the Liver, and American Association for the Study of Liver Diseases); (3) intervention: use of ALSS, including but not limited to PE, double PE, MARS, or continuous blood purification, either alone or in combination with standard therapies (eg, medications or supportive care); (4) outcome reporting: studies must report coagulation parameters at multiple time points; and (5) key outcomes: at least one of the following coagulation-related indicators: PT, APTT, D-dimer, INR, or fibrinogen.

Exclusion criteria included (1) publication type: reviews, conference abstracts, book chapters, or case reports without original data suitable for meta-analysis; (2) language: non-English or non-Chinese publications; and (3) data limitations: studies that did not report changes in coagulation function before and after treatment, reported only single time-point measurements, or provided incomplete or nonextractable data.

Risk of Bias Assessment

This study used the Newcastle-Ottawa scale (NOS) to systematically evaluate the risk of bias in the included studies, ensuring the reliability and scientific validity of the meta-analysis results. The NOS assesses study quality across three domains with a maximum score of 9 points: (1) selection (maximum 4 points)—evaluates whether cases and controls were clearly defined, representative of the target population, and selected using an appropriate study design; (2) comparability (maximum 2 points)—assesses whether key confounding factors were accounted for through matching or statistical adjustment; and (3) outcome or exposure assessment (maximum 3 points)—examines the reliability of outcome or exposure measurement, adequacy of follow-up duration, and handling of attrition. Based on the NOS scores, study quality was categorized as follows: ≥7 points=high quality (low risk of bias); 5-6 points=moderate quality (moderate risk of bias); ≤4 points=low quality (high risk of bias).

Two independent reviewers (HW and TH) conducted bias assessments, with cross-verification of results. Discrepancies were resolved through discussion or adjudication by a third reviewer (LR). The risk of bias was visualized using a risk of bias graph, and a detailed summary was provided in Multimedia Appendix 1. All assessments and graphical representations were generated using Review Manager (RevMan 5.4 [Cochrane Collaboration]).

Data Extraction

The following data were extracted from each included study: (1) study characteristics: first author, publication year, study design (randomized controlled trial, cohort study, or case-control study), country, and journal; (2) participant characteristics: patient type (viral hepatitis-related liver failure), sample size, sex ratio, mean age, baseline disease severity (Child-Pugh score and model for end-stage liver disease score), and coagulation function (PT, APTT, D-dimer, INR, and fibrinogen); (3) methodological features: type of ALS therapy (PE, hemoperfusion, MARS, continuous renal replacement therapy [CRRT]) and treatment protocol (single vs multiple sessions, treatment duration); and (4) outcome measures: the primary outcomes included changes in coagulation parameters (PT, APTT, INR, and fibrinogen before and after treatment). If a study reported multiple follow-up measurements, the longest follow-up data were extracted to assess long-term effects. For missing data, the original authors were contacted for clarification. If unavailable, multiple imputations were applied. Two researchers (LR and TJ) independently extracted all data, with cross-verification to resolve discrepancies; a third researcher (HW) adjudicated unresolved disagreements. The

XSL•FO
RenderX

final dataset was entered into Microsoft Excel and double-checked to ensure accuracy and consistency.

Meta-Analysis Statistical Methods

This study used the "meta" package in R software (version 4.2; R Core Team) to conduct a meta-analysis evaluating the dynamic changes in coagulation function during ALS therapy in patients with liver failure. Heterogeneity across studies was assessed using the I^2 statistic and Q-test. A fixed-effects model was applied when I^2<50% and P>.05, indicating negligible heterogeneity. In cases of significant heterogeneity (I^2≥50% and P≤.05), a random-effects model was used, followed by an exploration of potential heterogeneity sources. The pooled effect size was calculated based on data type: standardized mean difference or mean difference with 95% CIs for continuous variables, and odds ratios or risk ratios with 95% CIs for dichotomous variables. Results were visualized using forest plots to illustrate individual and pooled effect estimates.

To further investigate the key factors influencing coagulation function, we conducted subgroup analyses based on the following variables: type of ALS (PE vs hemoperfusion vs MARS vs CRRT), liver failure classification (acute liver failure [ALF], acute-on-chronic liver failure [ACLF], and chronic liver failure), and etiology of liver failure (viral hepatitis-induced vs cirrhosis-induced liver failure).

To assess the robustness of the findings, a sensitivity analysis was performed using the leave-one-out method, in which each study was systematically excluded before rerunning the meta-analysis. This approach allowed us to evaluate whether any single study disproportionately influenced the overall results. A significant change in the pooled effect size following the exclusion of a particular study would suggest that it was a key driver of the meta-analytic findings.

Publication bias was preliminarily assessed using funnel plots and further examined through Egger linear regression test and Begg test. A statistically significant result (Egger test P<.05) was considered indicative of potential publication bias.

Data Extraction and Cleaning From Public Databases

This study used the MIMIC-IV-3.1 database, released by the Massachusetts Institute of Technology (MIT), which contains clinical data from patients admitted to the intensive care unit (ICU) at Beth Israel Deaconess Medical Center (BIDMC) between 2008 and 2019. Data extraction was performed using Navicat Premium (v15.0.12; PremiumSoft CyberTech Ltd) and structured query language. The inclusion criteria were (1) first-time ICU admission, (2) ICU stay duration exceeding 48 hours, and (3) a diagnosis of liver failure based on *International Classification of Diseases* codes (K704, K7040, K7041, K72, K720, K7200, K7201, K721, K7210, K7211, K729, K7290, K7291, and K9182).

The extracted clinical variables comprised 3 categories: demographic and admission characteristics, vital signs, and laboratory results. Demographic data included age, sex, race, admission time, ICU admission and discharge time, and hospital ID. Vital signs, such as heart rate, respiratory rate, oxygen saturation, body temperature, systolic blood pressure (BP), and diastolic BP, were recorded based on the first measurement after ICU admission. Laboratory tests covered liver and kidney function (alanine aminotransferase, aspartate aminotransferase, total bilirubin [TBIL], creatinine, urea, and albumin), complete blood count (white blood cell count, platelet count, hemoglobin, and hematocrit), inflammatory markers (C-reactive protein), and coagulation parameters, including the INR (PT), partial thromboplastin time (PTT), and functional fibrinogen. All coagulation-related measurements during the ICU stay were extracted for dynamic predictive modeling, whereas static features were derived from the first recorded value after ICU admission. Data cleaning and imputation followed established protocols [23].

The clinical data used in this study were derived from the publicly available MIMIC-IV database (version 4.0), jointly developed by MIT and BIDMC. The database has been approved by the Institutional Review Board of BIDMC and the ethics committee of MIT and is accessible to qualified researchers who have completed the required credentialing course. All authors of this study completed the Collaborative Institutional Training Initiative program data usage training and obtained PhysioNet Credentialed Access to MIMIC. This study strictly adhered to the data usage agreement and did not involve any personally identifiable patient information, thus complying with ethical standards and requiring no additional ethical approval.

Data Cleaning and Missing Value Handling

Before model construction, we conducted systematic cleaning and preprocessing of the raw clinical data from the MIMIC-IV v3.1 database. All data were merged based on the unique patient identifier (subject_id), integrating demographic information, vital signs, laboratory test results, and ICU admission and discharge times across multiple tables. The analysis window was limited to the first 24 hours following ICU admission.

To ensure the stability and interpretability of variables in the model, only candidate features with high sampling frequency and clear clinical relevance were included, and variables with a missing rate greater than 20% were excluded. For features with a missing rate between 5% and 20%, multiple imputation was performed to preserve the covariate structure as much as possible. For features with sporadic missing values, group-level median or mean imputation was applied. Categorical variables such as sex and race, which had low rates of missingness, were imputed using the mode.

For dynamic time-series variables such as INR and PTT, we applied intrasample linear interpolation or forward and backward filling methods to handle missing data. In addition, the number of missing values per variable was included as an auxiliary input feature in the model to reflect potential uncertainty in the data. To eliminate the influence of extreme outliers, we set clinically reasonable cutoff thresholds based on existing literature and expert knowledge, applying percentile truncation or direct exclusion as appropriate.

All numerical variables were standardized using z score normalization before model input to eliminate differences in measurement scale, while categorical variables were converted into dummy variables using one-hot encoding.

XSL•FO
RenderX

Sliding Window Feature Extraction

For each coagulation function record, the collection time (charttime) was treated as the current time point. We then extracted data from the preceding 24-hour window to derive statistical features for 3 key coagulation indicators: INR, PTT, and functional fibrinogen. For each indicator, 6 statistical measures were computed: mean, maximum (max), minimum (min), standard deviation (SD), the most recent value (last), and the slope of the linear regression trend (slope). This process generated a total of 18 time-series dynamic features. To ensure that the extracted features accurately reflected dynamic changes during ICU stays, only valid in-ICU records were included, thereby constructing an ICU-specific dynamic prediction dataset.

Label Construction

This study adopts a 24-hour observation window following the current time point to construct a binary label variable. The label is determined based on clinically established diagnostic thresholds for coagulopathy. A patient is classified as having a "coagulopathy event" (label=1) if any of the following abnormal indicators occur within the observation window: INR>1.5, PTT>60 seconds, or fibrinogen<150 mg/dL. Conversely, if none of these criteria are met, the case is labeled as 0. Records with insufficient laboratory data to determine abnormality are assigned a missing label (label=NaN) and excluded before modeling.

Static Model Construction

The static model incorporates patient features recorded upon ICU admission, including demographic characteristics (eg, sex, age, and race), liver and kidney function metrics, vital signs, and statistical features (mean, maximum, minimum, SD, last recorded value, and slope) of coagulation parameters (INR, PTT, and fibrinogen). The target variable is defined as the occurrence of a coagulation abnormality within 24 hours of the current time point, where an abnormality is identified if any of the following criteria are met: INR>1.5, PTT>60 seconds, or fibrinogen<150 mg/dL. Three supervised learning algorithms—logistic regression (LR), random forest (RF), and extreme gradient boosting (XGBoost)—were used for model development.

To prevent data leakage, the dataset was partitioned into training and testing sets (80:20 ratio) using a group-based hold-out split, ensuring that samples from the same patient (subject ID) were exclusively allocated to either set. During model training, stratified group k-fold cross-validation (5 folds, preserving class balance and group separation) was applied to evaluate performance metrics, including the mean area under the curve (AUC), F_1-score, accuracy, sensitivity, and specificity. Subsequently, the final models were refit on the entire training set and assessed for generalizability on the independent test set.

To prevent information leakage caused by the presence of the same patient in both the training and test sets, we adopted a group-based splitting strategy based on subject ID for static model development. Patients were randomly assigned to the training and test sets in an 80:20 ratio, resulting in 2764 patients (80% of the total 3456) in the training set and 692 patients (20%) in the test set. On the training set, we developed several static models—including LR, RF, and XGBoost—and evaluated their performance using the StratifiedGroupKFold method (5-fold cross-validation with stratification and grouping). This approach ensured robust estimation of average performance metrics, including AUC, F_1-score, accuracy, sensitivity, and specificity. Model-specific parameters are detailed in Table S2 in Multimedia Appendix 1. Based on this, final models were refitted on the entire training set and evaluated on the independent test set to assess their generalizability.

Dynamic Long Short-Term Memory Model Construction

For dynamic modeling, we used a long short-term memory (LSTM) recurrent neural network to analyze the constructed time-series data. Each sample consisted of a sequence of 5 consecutive time points, with each time point represented by sliding-window statistical features. The label indicated whether coagulation dysfunction occurred within 24 hours after the last time point in the sequence. The specific parameters are provided in Table S2 in Multimedia Appendix 1.

Model Evaluation and Visualization

The performance of each model was evaluated on the test set using the following metrics: accuracy, F_1-score, AUC, sensitivity, specificity, and precision. Visual representations included the receiver operating characteristic (ROC) curve, precision-recall (PR) curve, calibration curve, decision curve analysis, and a confusion matrix heatmap. The AUC values were computed with 95% CIs using the bootstrap method.

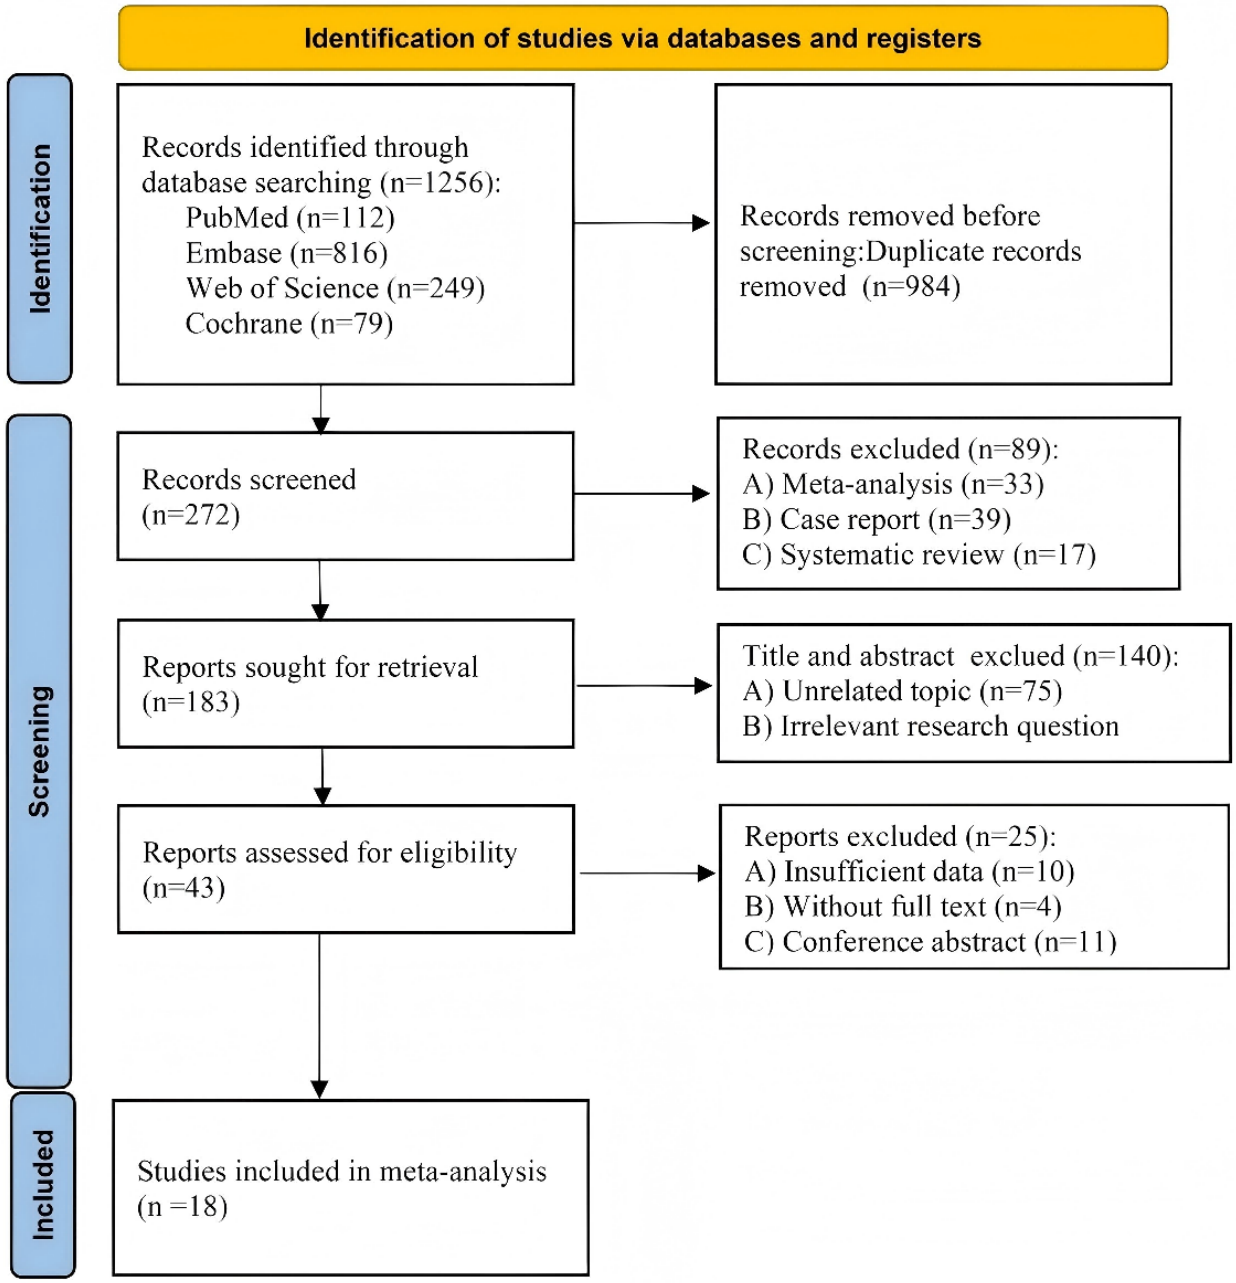
Robustness Validation and Model Interpretation

To enhance model robustness, the static model was further evaluated using 5-fold StratifiedGroupKFold cross-validation. This approach ensured data stratification by subject_id, maintaining label distribution while preventing data leakage. Performance metrics were reported as mean (SD).

Subsequently, model interpretability analysis was conducted using the best-performing RF model. Global feature importance rankings were derived using the Gini index, while SHAP values quantified the average contribution of each variable to model predictions. The most critical clinical predictors were identified and visualized to illustrate their impact on model outputs.

Ethical Considerations

This study does not contain any studies with human participants or animals performed by any of the authors.



Results

Literature Search Results

As illustrated in Figure 1, a total of 1256 studies were retrieved from the database. After removing 263 duplicate records, 993 studies underwent title and abstract screening. Following initial screening, 921 studies that did not meet the inclusion criteria were excluded, leaving 72 studies for full-text evaluation. After a rigorous assessment, an additional 59 studies were excluded due to mismatches in study design, intervention methods, or outcome measures, resulting in 18 studies being included in the systematic review and meta-analysis.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) literature screening flowchart.

All 18 included studies were cohort or case-control designs, examining various ALSS (eg, PE, MARS, and PP). These studies collectively involved 1771 participants and reported changes in coagulation parameters—including INR, PT, APTT, and fibrinogen—before and after treatment. The study populations comprised patients with ALF and ACLF, with etiologies such as viral hepatitis, toxic exposure, infections, and metabolic disorders. The key characteristics of the included studies are summarized in Table 1.

Risk of Bias Assessment

All 18 observational studies included in this meta-analysis were evaluated for risk of bias using the NOS. Among them, 16 studies were rated as high quality (NOS score≥7), indicating robust methodological rigor in case selection, comparability between groups, and exposure assessment. The remaining 2 studies were classified as moderate quality (score=6), primarily due to incomplete follow-up data or unclear exposure assessment methods. No studies were deemed low quality (score≤5).

Overall, the included studies demonstrated high methodological quality, enhancing the reliability of our meta-analysis findings. Detailed NOS scores are presented in Table 2.

Table 2. Risk of bias assessment summary: quality evaluation for each included study using the modified Newcastle-Ottawa scale.

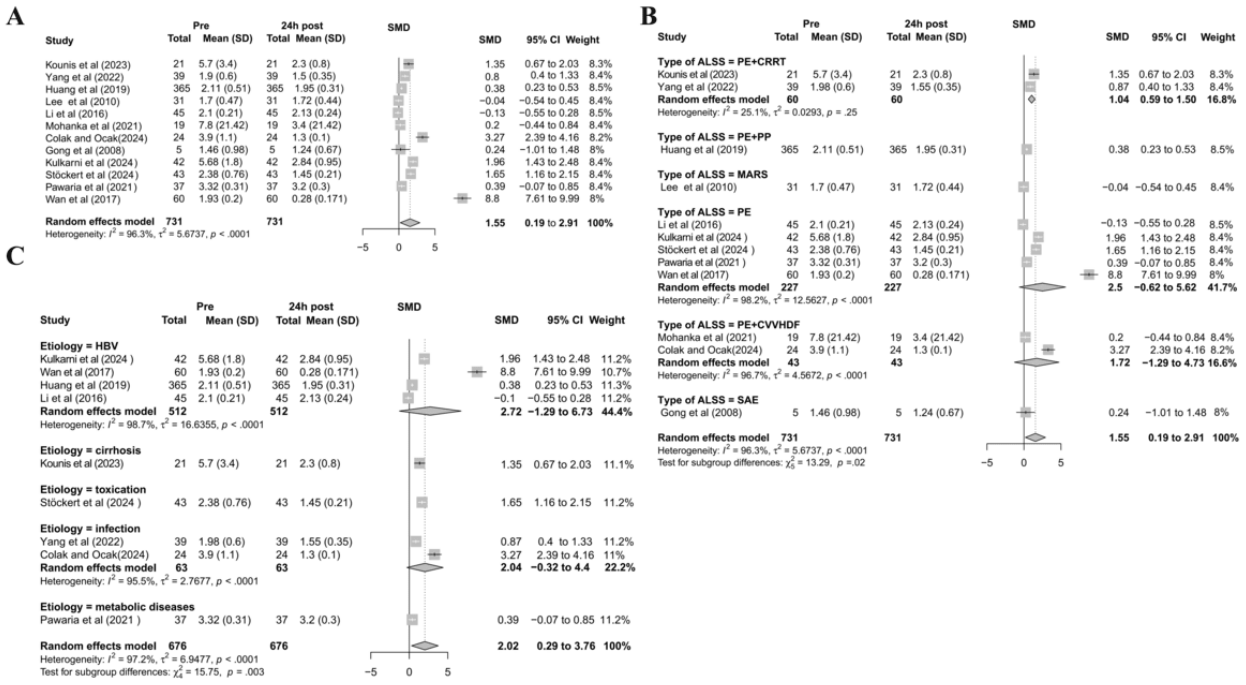
[a]The scoring system ranges from 0 to 9 points. Higher scores indicate better methodological quality.



[b]Not available.

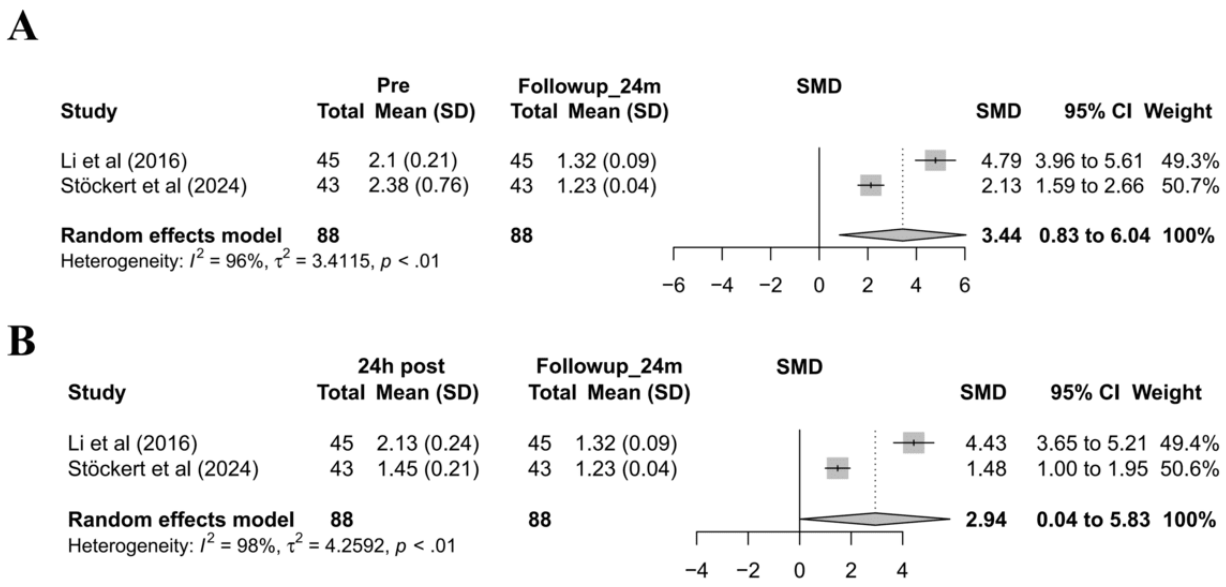
Meta-Analysis Results: INR

A total of 12 studies (encompassing 731 patients) were included to evaluate changes in INR before and 24 hours after ALS treatment. The meta-analysis revealed a significant reduction in INR posttreatment, although with considerable heterogeneity (Figure 2A).

XSL•FO
RenderX

Figure 2. Meta-analysis of the short-term effect of artificial liver support (ALS) on international normalized ratio improvement and its heterogeneity sources. (A) Forest plot comparing international normalized ratio changes within 24 hours before and after ALS treatment; (B) subgroup analysis stratified by ALS modality; (C) subgroup analysis stratified by etiology. ALSS: artificial liver support system; CRRT: continuous renal replacement therapy; CVVHDF: continuous veno-venous hemodiafiltration; HBV: Hepatitis B virus; MARS: molecular adsorbent recirculating system; PE: plasma exchange; PP: plasma perfusion; SAE: severe adverse event; SMD: standardized mean difference [33,35,37-40,44-48,50].

To investigate potential sources of heterogeneity, we conducted 3 subgroup analyses. In the ALS modality subgroup analysis, different treatment modalities exhibited significant variations in INR improvement. PE alone demonstrated the most pronounced reduction in INR, albeit with high heterogeneity. In contrast, the PE+CRRT group showed stable and significant effects alongside markedly reduced heterogeneity (Figure 2B), suggesting that treatment modality may be a key factor influencing efficacy and heterogeneity. The etiology-based subgroup analysis indicated that patients with hepatitis B virus (HBV) or infections exhibited more significant therapeutic effects, whereas those with cirrhosis or metabolic diseases showed smaller or nonsignificant effect sizes. Intergroup differences were statistically significant (Figure 2C), implying that underlying etiology may contribute to variations in INR improvement. The disease-type subgroup analysis revealed that patients with ACLF had greater INR improvement than patients with ALF, although the difference was not statistically significant (Figure S1A in Multimedia Appendix 1).



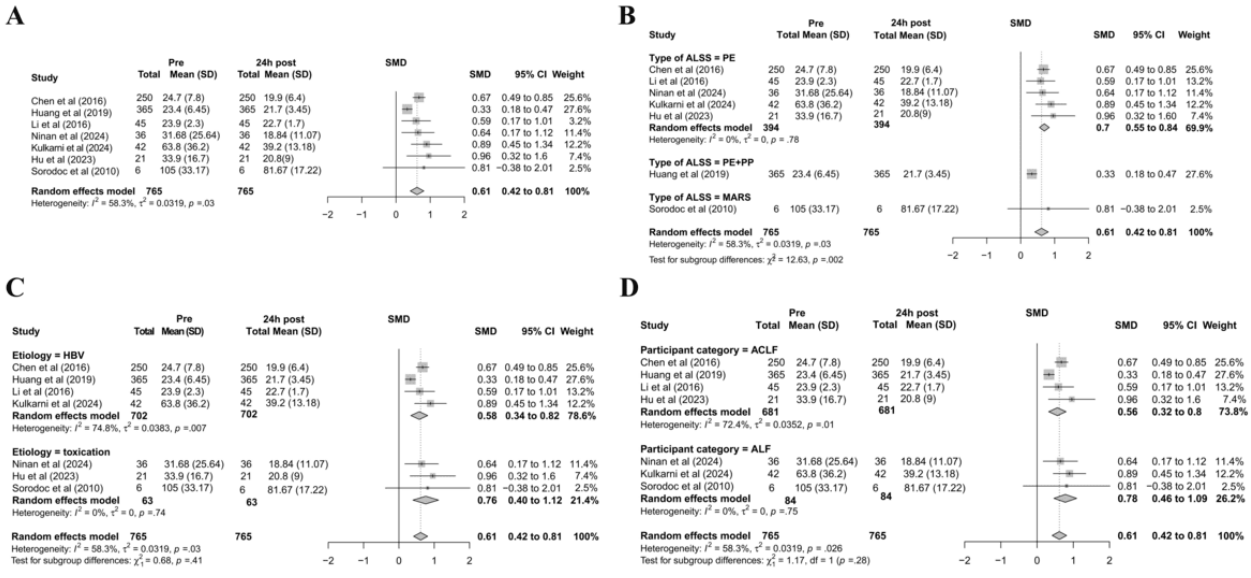
Sensitivity analysis (Figure S1B in Multimedia Appendix 1) demonstrated consistent pooled effect directions and minimal fluctuations in I^2 upon sequential exclusion of individual studies, supporting the robustness of the findings. In addition, the funnel plot exhibited approximate symmetry (Figure S1C in Multimedia Appendix 1), indicating a low likelihood of publication bias and further strengthening the reliability of the conclusions.

In summary, this study demonstrates that ALS significantly improves INR levels in patients with liver failure, with treatment efficacy potentially influenced by therapeutic modality and underlying etiology.

To evaluate long-term coagulation function changes following ALS therapy, we conducted a meta-analysis of 2 studies reporting INR values before treatment and at 24 months posttreatment. The results demonstrated a statistically significant reduction in INR at 24 months compared with baseline, although with considerable heterogeneity (Figure 3A). Furthermore, we compared INR changes between the 24-hour and 24-month time points to assess differences in short-term versus long-term efficacy. The pooled analysis, which included the same 2 studies, revealed that INR remained significantly lower at 24 months than at 24 hours, with statistical significance, suggesting that ALS therapy may have a long-term effect on improving coagulation function (Figure 3B).

XSL•FO
RenderX

Figure 3. Meta-analysis of the effects of artificial liver support (ALS) on international normalized ratio (INR) improvement at different posttreatment time points. (A) Forest plot comparing INR changes between pre-ALS and 24 months post-ALS; (B) forest plot comparing INR changes between 24 hours and 24 months post-ALS. SMD: standardized mean difference [39,47].



Despite moderate heterogeneity, the findings consistently indicate a progressive decline in INR over long-term follow-up, supporting the stability and durability of ALS therapy in enhancing coagulation.

In conclusion, ALS therapy significantly and persistently improves INR levels in patients with liver failure, although its efficacy may be influenced by treatment modalities and underlying etiologies.

Meta-Analysis of PT Levels Before and 24 Hours After Treatment

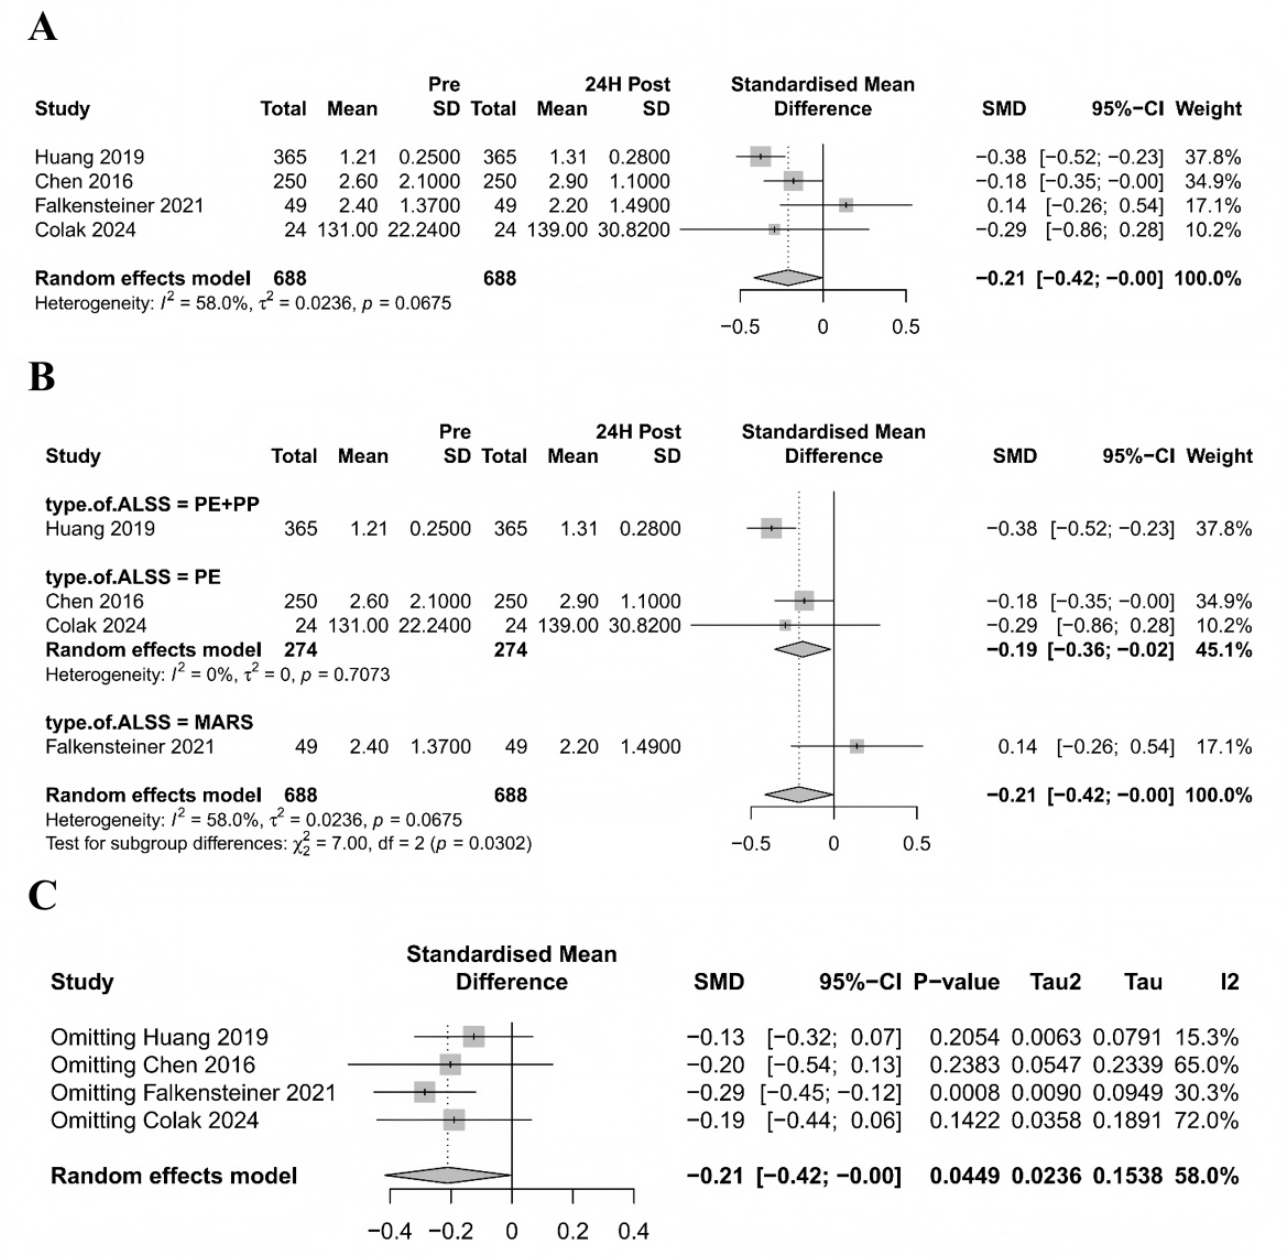
A total of 7 studies (combined sample size=765 patients) were included to evaluate changes in PT 24 hours before and after ALS treatment. The pooled analysis revealed a significant reduction in PT levels posttreatment, with moderate heterogeneity observed (Figure 4A).

Figure 4. Meta-analysis of PT changes before and after artificial liver support (ALS) treatment, with subgroup analyses. (A) Forest plot of PT changes within 24 hours post-ALS versus pre-ALS; (B) subgroup analysis of PT changes by ALS type; (C) subgroup analysis by etiology; (D) subgroup analysis by disease classification. ACLF: acute-on-chronic liver failure; ALF: acute liver failure; ALSS: artificial liver support system; HBV: Hepatitis B virus; MARS: molecular adsorbent recirculating system; PE: plasma exchange; PP: plasma perfusion; SMD: standardized mean difference [34,36,37,39,41,42,46].

Subgroup analysis by ALS type demonstrated statistically significant differences between groups, with the PE subgroup exhibiting no heterogeneity (I^2=0). This suggests that the type of ALS may contribute to heterogeneity and influence the degree of coagulation improvement (Figure 4B). Etiology-based subgroup analysis indicated no significant differences between HBV-related liver failure and toxic liver failure groups, with

XSL•FO
RenderX

the latter subgroup showing no heterogeneity (I^2=0). This implies that etiology may be a source of heterogeneity (Figure 4C). Disease-type subgroup analysis found no significant difference between ACLF and ALF groups (P=.28), with the ALF subgroup displaying no heterogeneity (I^2=0), suggesting disease type as a potential source of heterogeneity (Figure 4D).



Sensitivity analysis demonstrated that the pooled effect size remained stable after the sequential exclusion of individual studies, with no substantial changes in heterogeneity, indicating robust findings (Figure S2A in Multimedia Appendix 1). Funnel plot symmetry suggested no significant publication bias (Figure S2B in Multimedia Appendix 1).

In conclusion, ALS significantly improves PT levels, with treatment type, etiology, and disease classification identified as potential key sources of heterogeneity.

Meta-Analysis of Fibrinogen Levels Before and 24 Hours After Treatment

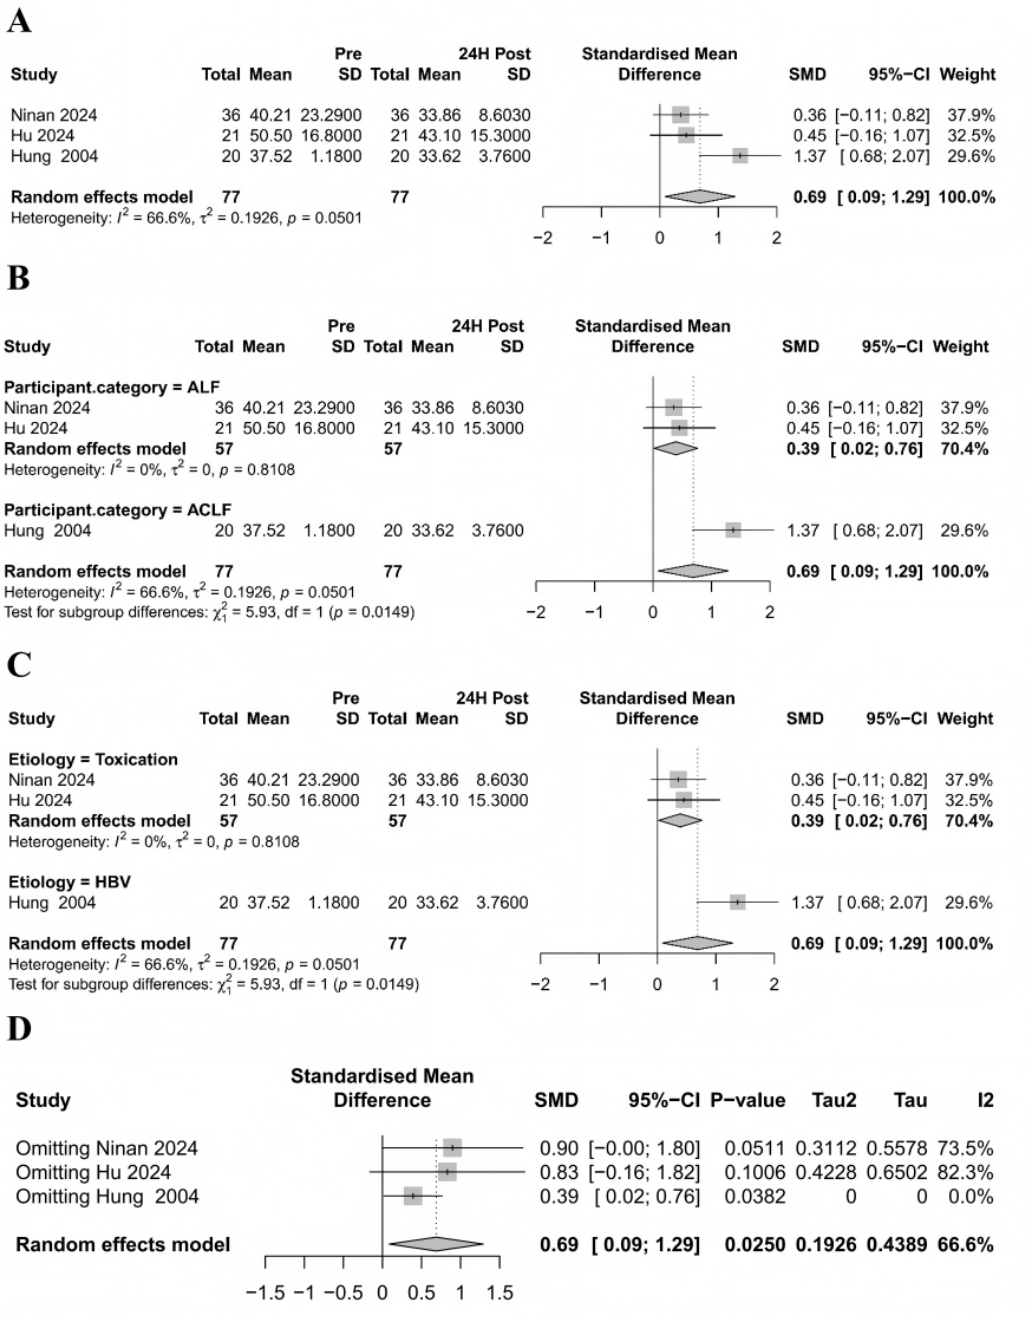
This meta-analysis included 4 studies comprising 688 patients to evaluate changes in fibrinogen levels before and after ALS treatment. The results demonstrated a slight decrease in fibrinogen levels posttreatment, with moderate heterogeneity observed in the overall analysis (Figure 5A).

Figure 5. Meta-analysis of the effect of artificial liver support (ALS) on fibrinogen levels in patients with liver failure. (A) Forest plot of fibrinogen level changes pre- and post-ALS; (B) subgroup analysis by ALS type; (C) sensitivity analysis using the leave-one-out method. ALSS: artificial liver support system; MARS: molecular adsorbent recirculating system; PE: plasma exchange; PP: plasma perfusion; SMD: standardized mean difference [37,42-44].

Subgroup analysis by ALS therapy type revealed that the PE+PP subgroup exhibited the most significant reduction in fibrinogen levels, with statistically significant intergroup differences. Notably, the PE subgroup showed no heterogeneity (I^2=0%)

XSL•FO
RenderX

(Figure 5B), suggesting that treatment type may be a key factor influencing fibrinogen level changes and a potential source of heterogeneity. In contrast, subgroup analyses based on etiology and disease type showed no statistically significant intergroup differences, nor did they substantially alter heterogeneity (Figure S3A-B in Multimedia Appendix 1).



Sensitivity analysis indicated that the exclusion of individual studies only significantly reduced heterogeneity (to 15.3%) upon the removal of Huang et al [28] (Figure 5C), identifying it as a potential source of heterogeneity. Funnel plot analysis demonstrated a generally symmetrical study distribution with no evident publication bias (Figure S3C in Multimedia Appendix 1).

In conclusion, ALS therapy has a limited effect on fibrinogen levels, and the observed heterogeneity may primarily stem from differences in treatment modalities.

Meta-Analysis of APTT Levels Before and 24 Hours After Treatment

A total of 3 studies (comprising 77 patients) were included to evaluate changes in APTT before and after ALS therapy. The meta-analysis revealed a significant reduction in APTT levels posttreatment, though moderate heterogeneity was observed (Figure 6A).

Figure 6. Meta-analysis of the effect of artificial liver support on APTT in patients with liver failure. (A) Forest plot of APTT changes pre- and post–artificial liver support; (B) subgroup analysis by disease type; (C) subgroup analysis by etiology; (D) sensitivity analysis. ACLF: acute-on-chronic liver failure; ALF: acute liver failure; ALSS: artificial liver support system; HBV: Hepatitis B Virus; SMD: standardized mean difference [34,36,49].

XSL•FO
RenderX

To investigate potential sources of heterogeneity, subgroup analyses were performed based on disease type and etiology. The disease-type subgroup analysis demonstrated that patients with ACLF exhibited a greater improvement in APTT than patients with ALF, with a statistically significant intergroup difference. Notably, heterogeneity within the ALF subgroup was 0%, suggesting that disease type may contribute to heterogeneity and influence the degree of coagulation improvement (Figure 6B). The etiology-based subgroup analysis indicated that patients with HBV showed a more pronounced APTT improvement than those with toxic liver injury, with significant intergroup differences and 0% heterogeneity in the toxic etiology subgroup. This further supports etiology as a potential source of heterogeneity and a modifier of coagulation function (Figure 6C).

Sensitivity analysis confirmed the robustness of the pooled effect size after excluding Hung et al [40], with heterogeneity (I^2) decreasing to 0% (Figure 6D). Funnel plot symmetry suggested no significant publication bias (Figure S4 in Multimedia Appendix 1).

In summary, ALS therapy significantly improves APTT levels, with heterogeneity likely attributable to differences in disease type and etiology.

This study demonstrates that ALS therapy significantly enhances multiple coagulation parameters in patients with liver failure, particularly in reducing INR and PT while improving APTT. The long-term improvement in INR suggests long-term therapeutic benefits in coagulation support. Treatment efficacy varies significantly depending on the artificial liver modality (eg, PE, double PE, and MARS), etiology (eg, viral hepatitis vs toxic liver failure), and disease type (ALF vs ACLF), which are key contributors to interstudy heterogeneity. In contrast, improvements in fibrinogen levels were relatively limited, with variability primarily influenced by treatment modality. These findings underscore the importance of individualized coagulation management strategies in ALS therapy, optimizing treatment efficacy while providing evidence-based guidance for coagulation monitoring and clinical care.

Dynamic Coagulation Risk Prediction in Patients With Liver Failure

Based on previous meta-analysis findings, this study confirms that ALS therapy significantly improves coagulation function in patients with liver failure across multiple time points, demonstrating clear dynamic trends in core indicators (INR, PT, APTT, and fibrinogen). However, current clinical practice still lacks individualized predictive tools for coagulation dysfunction, hindering precise intervention and dynamic monitoring. To address this gap, we further integrated clinical data from the MIMIC database to develop a machine learning–based predictive model. By leveraging dynamic coagulation indicators as key features, this model explores predictive pathways for coagulation abnormalities, aiming to provide an intelligent decision-support tool for the early identification of high-risk patients.

A total of 3456 ICU patients with liver failure were included from the MIMIC-IV database based on strict inclusion and exclusion criteria. Patients were stratified by ID and randomly assigned to the training cohort (n=2764) and independent validation cohort (n=692). Table 3 presents the baseline demographic characteristics, vital signs, and laboratory parameters of all patients. Overall, most features were well-balanced between the training and validation sets, with no statistically significant differences. Specifically, there was no significant difference in age distribution between the 2 cohorts (P=.57), with 2262 patients (65.5%) younger than 65 years. A statistically significant difference was observed in sex distribution (P<.001), with a slightly higher proportion of males (2140/3456, 60.9%). Regarding race, White patients accounted for the largest proportion (1942/3456, 56.2%), while the proportion of Asian patients was slightly higher in the validation cohort (P=.02). For laboratory parameters—including liver function markers (alanine aminotransferase, aspartate aminotransferase, TBIL, and alkaline phosphatase), renal function (creatinine and urea), inflammatory marker (C-reactive protein), complete blood count (platelet count, hemoglobin, and hematocrit), coagulation indicators (INR_PT, PTT, and fibrinogen), and vital signs (heart rate, respiratory rate, oxygen saturation, and BP)—the overall distributions between the training and validation sets were consistent. Only hemoglobin (P=.02) and hematocrit (P=.02) showed mild differences, suggesting slight variations in hemoglobin levels among some patients.

In conclusion, the training and validation cohorts exhibited a strong balance in key clinical and laboratory characteristics, supporting their appropriateness for subsequent model development and validation.

Model Discriminatory Power and Performance Evaluation

A comprehensive evaluation of model performance was conducted on an independent test set, incorporating metrics such as ROC curves, PR curves, and calibration curves. The ROC curve analysis revealed that the RF model demonstrated the highest discriminatory power, with an AUC of 0.92 (95% CI 0.91-0.93). The XGBoost and LR models exhibited comparable performance, with AUC values of 0.91 (95% CI 0.90-0.92) and 0.90 (95% CI 0.89-0.91), respectively. In contrast, the LSTM dynamic model showed significantly lower discriminative ability, achieving an AUC of only 0.74 (95% CI 0.72-0.76), suggesting limited generalizability under the current data configuration (Figure 7A).

Figure 7. Performance evaluation of machine learning models in predicting coagulation dysfunction in patients with liver failure. (A) Receiver operating characteristic curves comparing the discriminative ability of logistic regression, random forest, extreme gradient boosting, and long short-term memory models in predicting coagulation abnormalities within 24 hours (test set); (B) PR curves assessing model performance in identifying positive cases under class imbalance; (C) calibration curves evaluating the agreement between predicted probabilities and observed event rates. AP: average precision; AUC: area under the curve; LSTM: long short-term memory; XGBoost: extreme gradient boosting; ROC: receiver operating characteristic.

The PR curve analysis further assessed the models' ability to identify positive cases (ie, predicting coagulation abnormalities within 24 hours). Both RF and XGBoost achieved high average precision (AP) scores of 0.96, maintaining robust precision even

XSL•FO
RenderX

at high recall levels. The LR model exhibited a slightly lower AP (0.95) but remained clinically useful. The LSTM model, however, underperformed with an AP of 0.87, reinforcing its limitations in positive predictive accuracy (Figure 7B).

Calibration curve analysis evaluated the agreement between predicted probabilities and observed outcomes. The LR and RF models demonstrated near-perfect calibration across all risk strata, indicating high reliability. The XGBoost model showed stable calibration in moderate-to-high risk ranges but minor deviations in low-risk regions. In contrast, the LSTM model exhibited substantial fluctuations in low-to-moderate risk ranges, reflecting weaker overall calibration (Figure 7C).

The confusion matrix analysis revealed distinct performance advantages among the models in the classification task. The RF model achieved the best classification performance on the test set, while LR and XGBoost exhibited comparable results, both maintaining a high true positive rate with a low misclassification rate. In contrast, although the LSTM model demonstrated superior sensitivity in identifying positive cases, it showed marked limitations in correctly classifying negative samples, resulting in lower specificity and a higher false-positive rate (Figure S5A in Multimedia Appendix 1). Overall, traditional machine learning models outperformed the LSTM in both accuracy and robustness.

To further evaluate the clinical utility of these models, we conducted decision curve analysis to assess their net benefit across different risk thresholds. The results demonstrated that LR, RF, and XGBoost models consistently outperformed the "treat all" and "treat none" strategies across most threshold ranges, indicating strong potential for clinical decision support. Notably, these models provided greater net benefit in intermediate-risk ranges, suggesting their predictive outcomes could reliably guide individualized interventions (Figure S5B in Multimedia Appendix 1).

In summary, static machine learning models—particularly RF—not only exhibited strong predictive discrimination but also demonstrated better calibration performance than the time-series–based LSTM dynamic model. These findings suggest that static models are more suitable for clinical early-warning applications in predicting coagulation dysfunction risk in patients in ICU with liver failure.

Table 4 summarizes the common performance metrics across all models. Overall, the results demonstrate that the RF model achieves the most robust performance, with an AUC of 92.1%, an F_1-score of 91%, an accuracy of 86.9%, a recall (sensitivity) of 93.3%, a precision of 88.8%, and a specificity of 71.7%.

Based on these findings, we select the RF model as our final risk prediction model.

Table 4. Performance comparison of 4 machine learning algorithms for dynamic coagulation risk prediction.

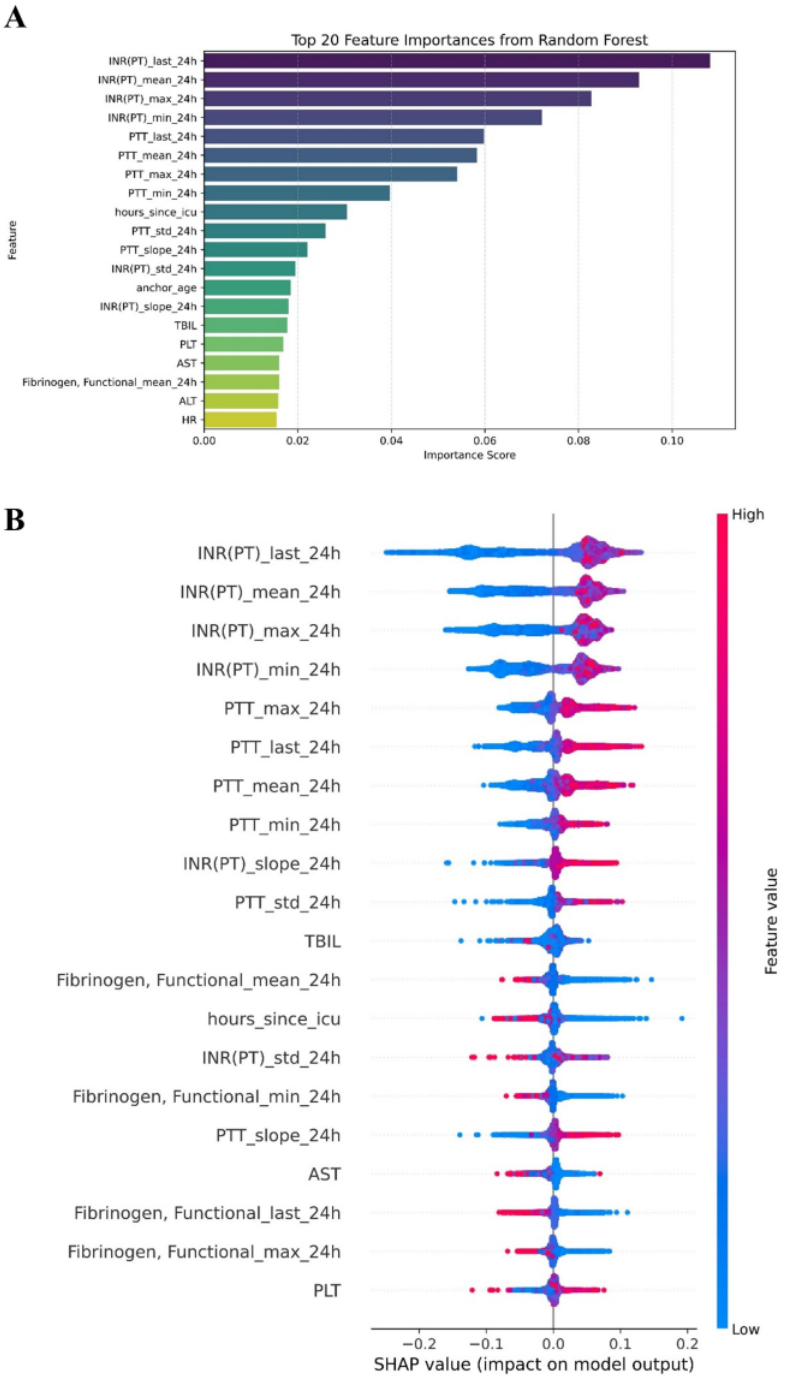
Model	F_1-score (%)	Accuracy (%)	Recall (%)	AUC[a] (%)	Sensitivity (%)	Specificity (%)
LR[b]	89.7	85.1	92.5	90.4	92.5	67.3
RF[c]	91	86.9	93.3	92.1	93.3	71.7
XGBoost[d]	89.7	85.1	92.2	90.9	92.2	68.1
LSTM[e]	82.6	72.2	93.5	75.4	93.5	21

[a]AUC: area under the curve.

[b]LR: logistic regression.

[c]RF: random forest.

[d]XGBoost: extreme gradient boosting.



[e]LSTM: long short-term memory.

Feature Importance and Model Interpretability Analysis

To elucidate the decision-making mechanism of the predictive model, this study conducted a feature importance assessment and interpretability analysis based on the top-performing RF model. As illustrated in Figure 8A, among the dynamic features, multiple INR-related indicators—including INR(PT)_last_24h, INR(PT)_mean_24h, INR(PT)_max_24h, and INR(PT)_min_24h—exhibited the highest importance scores, indicating that INR values play a critical role in predicting coagulation abnormalities within the next 24 hours. PTT-related features (eg, PTT_last_24h, PTT_mean_24h, and PTT_max_24h) also ranked among the top 10, further underscoring the significance of dynamic coagulation time in the model's decision-making process.

XSL•FO
RenderX

Figure 8. Feature importance and interpretability analysis of the random forest model. (A) Bar plot of feature importance scores; (B) SHapley Additive exPlanations summary plot, where red and blue indicate high and low feature values, respectively, and the x-axis represents the directional impact on predictions. “INR (PT)” (labeled per MIMIC database conventions) is standardized as international normalized ratio in this study; “PTT” refers to activated partial thromboplastin time. ALT: alanine aminotransferase; AST: aspartate aminotransferase; HR: heart rate; INR: international normalized ratio; PLT: platelet count; PT: prothrombin time; PTT: partial thromboplastin time; TBIL: total bilirubin.

To enhance model interpretability, we used SHAP for visual explanation of the RF model. The results demonstrated that elevated INR(PT) and PTT values positively contributed to the prediction of coagulation abnormalities, aligning with established clinical pathophysiological mechanisms. In addition, static variables such as hours_since_icu, fibrinogen, TBIL, and anchor_age exhibited moderate predictive importance (Figure 8B).

In summary, the RF model not only demonstrates superior predictive performance but also maintains strong interpretability, effectively identifying key variables associated with coagulation dysfunction. These findings support early clinical identification of high-risk patients.

Discussion

Principal Findings

This study systematically evaluates the dynamic effects of ALS on coagulation function in patients with liver failure by integrating meta-analysis and machine learning modeling based on clinical databases. In addition, it develops an intelligent predictive model for future coagulation abnormalities. The meta-analysis results demonstrate that ALS significantly improves key coagulation parameters, including INR, PT, and APTT, highlighting its critical role in coagulation support for patients with liver failure. These findings align with previous studies [42,43], further reinforcing the evidence-based efficacy of ALS therapy in ameliorating coagulopathy. The maintained reduction in INR during long-term follow-up further underscores the stability and durability of its therapeutic efficacy. Variations in treatment modalities, etiologies, and liver failure subtypes were identified as major sources of heterogeneity in coagulation improvement.

This study adopts a dual-track strategy that integrates high-level evidence synthesis with individualized risk prediction, thereby avoiding the misconception that the meta-analysis and machine learning model are 2 parallel approaches. Specifically, the meta-analysis establishes the overall efficacy and heterogeneity of ALSS in improving coagulation parameters, which provides a rigorous evidence-based rationale for subsequent predictive modeling. Building upon these findings, the machine learning model operationalizes the most clinically relevant indicators—such as INR, PT, and APTT—into a dynamic decision-support tool for real-time risk assessment at the bedside. This methodological pathway transforms population-level evidence into patient-level prediction, thus ensuring both validity and clinical applicability.

Importantly, our results demonstrated that INR was the most significantly improved parameter in the meta-analysis and simultaneously the strongest predictive feature in the machine learning model, underscoring the translational consistency between the 2 components. This alignment exemplifies the synergistic relationship in which meta-analysis informs feature selection and validates the clinical importance of predictors, while the model extends these findings to enable individualized, real-time monitoring. Such integration reflects a broader trend in evidence-based medicine and artificial intelligence, where systematic reviews and meta-analyses provide high-level validity [44], predictive analytics enable dynamic risk assessment [45], and the convergence of these methods enhances clinical decision-making [46,47].

A related study also used MIMIC-IV v3.1 data and applied XGBoost to predict Peripherally Inserted Central Catheter–related thrombosis in patients with sepsis [48]. Compared with that work, our study differs in population (patients with liver failure undergoing ALSS vs patients with sepsis with Peripherally Inserted Central Catheter), target (coagulation abnormalities after ALSS vs catheter-related thrombosis), and methodology (integration of meta-analysis with multiple machine learning models vs single algorithm). Building upon existing literature, this study systematically compares—for the first time—the differential effects of various ALSS (eg, PE, CRRT, and MARS) on coagulation function, thereby addressing a critical research gap and providing new evidence for individualized clinical treatment strategies. These distinctions highlight the novelty and specific contribution of our approach to coagulation risk prediction in the ALSS context. Notably, ALS showed limited efficacy in improving fibrinogen levels, potentially due to differences in fibrinogen clearance efficiency across treatment methods. Subgroup analysis revealed that PE combined with CRRT yielded more consistent coagulation improvements compared with monotherapy, suggesting that hybrid ALS regimens may be more suitable for critically ill patients with severe coagulation dysfunction. In addition, disparities in APTT improvement are primarily influenced by the underlying disease type, underscoring the importance of etiological classification in guiding personalized treatment.

Unlike previous studies that primarily focused on static measurements at single time points [49], this study adopts a dynamic monitoring approach, for the first time, elucidating the evolutionary patterns and predictive value of INR, PT, APTT, and fibrinogen throughout the treatment course. Notably, the dynamic features of INR in the model—including its mean, peak, and trend—demonstrated the highest weighting, confirming its clinical significance as an early warning indicator. This dynamic modeling strategy significantly enhances predictive sensitivity and prospective utility, shifting risk assessment from post hoc evaluation to real-time intervention.

In predictive modeling, this study enhances translational potential by developing a multialgorithm model based on real-world data from MIMIC-IV. Among the tested models, the RF algorithm achieved the highest performance (AUC=92.12%, F_1-score=90.96%) in accurately predicting coagulation abnormalities within 24 hours. Unlike previous studies that primarily relied on single-algorithm approaches such as LR [50], this work systematically compared and integrated multiple machine learning models (including XGBoost and LSTM). Furthermore, SHAP interpretation was used to elucidate feature contributions, improving model transparency and clinical interpretability. The proposed model holds promise as an intelligent clinical decision–support tool in ICU settings, assisting nurses in early identification of high-risk patients for coagulation disorders. By optimizing transfusion strategies, monitoring frequency, and intervention timing, this approach may reduce bleeding-related complications while enhancing the precision and efficiency of coagulation management. Ultimately, this shift from experience-based judgment to data-driven decision-making provides a more reliable foundation for clinical workflows.

In conclusion, ALS significantly improves coagulation parameters (INR, PT, and APTT) in patients with liver failure, while the machine learning model based on dynamic indicators provides accurate risk prediction for coagulation abnormalities. These findings offer valuable support for early intervention and precision management in coagulation care. These results offer strong evidence for implementing earlier and more targeted clinical nursing interventions.

XSL•FO
RenderX

Despite the innovation and clinical utility of this study, several limitations should be acknowledged. First, although this study systematically evaluated the effects of ALSS on coagulation function in patients with liver failure through meta-analysis and developed a dynamic indicator-based coagulation risk prediction model, the constructed predictive model did not specifically target patients who received ALSS treatment. Instead, risk modeling was conducted for the broader population of patients with liver failure. This decision was primarily due to the extremely limited number of ALSS-treated cases identified in the MIMIC-IV database—only 5 patients met the strict inclusion criteria—making the sample size insufficient to meet the basic data requirements for machine learning model development or to ensure model robustness and generalizability. As a compromise, this study focused on the overall liver failure population to explore trends in coagulation function and dynamic risk prediction. This approach provides a foundational reference for future model development based on larger datasets of patients treated for ALSS.

Secondly, although LSTM networks are widely used in clinical prediction due to their temporal modeling capabilities, their predictive performance in this study was significantly inferior to that of static models. This discrepancy primarily stems from the poor temporal resolution of the MIMIC dataset. Laboratory and vital sign data are sparsely sampled, irregular, and discontinuous—particularly for variables such as INR and fibrinogen—making it difficult to construct high-quality time series inputs. In addition, the short length of ICU stays in some patients resulted in insufficient sequence data, further limiting the model's ability to learn time-dependent patterns. In contrast, the RF model, which is based on aggregated features, is less reliant on data continuity and demonstrated superior robustness and generalizability. Therefore, under the constraints of low-frequency and sparse ICU data, static models may offer greater practical value.

To address the limitations of LSTM performance, we attempted to incorporate attention mechanisms to enhance the model's ability to capture critical time points. However, due to the short feature sequences and missing key records, no significant performance improvement over LSTM was observed. In the future, we plan to further evaluate the potential of architectures, such as transformer on higher-quality, multicenter time series data to optimize temporal modeling outcomes.

Furthermore, although the RF model performed well within the MIMIC-IV database, we fully acknowledge that external validation is essential for assessing its generalizability. Given that MIMIC is derived from a single US center and exhibits gender imbalances, the model's applicability to other populations remains uncertain. The current lack of publicly available ALSS-specific, patient-level data limits the feasibility of immediate external validation. We plan to collaborate with regional multicenter hospitals, particularly in Asian populations, to conduct prospective validation studies and improve the model's cross-population adaptability.

In this study, the definition of coagulation dysfunction labels was primarily based on established clinical diagnostic criteria and expert consensus. However, due to the absence of explicitly annotated bleeding events or other coagulation-related outcomes in the MIMIC database, we were unable to validate the correlation between the threshold and actual clinical risk. We acknowledge that future work should incorporate specific clinical outcomes (eg, gastrointestinal bleeding and hemorrhagic shock) to reassess the clinical significance of the risk threshold. Furthermore, considering the complex etiology of liver failure, adopting etiology-specific or dynamically adjusted prediction thresholds may better reflect real-world clinical scenarios and improve model sensitivity and practicality. We have identified this issue as a key direction for future research.

Conclusion

In summary, this study not only provides systematic, evidence-based support for the efficacy of ALSS in improving coagulation function but also constructs a highly discriminative and interpretable risk prediction tool. The findings are of great significance for advancing individualized and intelligent coagulation support therapy and nursing interventions in patients with liver failure. Future efforts should aim to expand the model's applicability by incorporating multicenter data and nursing practice variables, thereby promoting the implementation and refinement of dynamic coagulation monitoring systems and providing data-driven decision support in critical care settings.

Although the RF model demonstrated superior performance in predicting coagulation dysfunction in patients with liver failure, it is currently well-suited for practical use due to its clear structure and transparent feature inputs. Key predictors such as dynamic INR, PTT, and fibrinogen can be visualized through a graphical user interface, allowing clinicians and nursing staff to intuitively assess individual risk and determine optimal intervention timing. In the future, we plan to deploy this model as an open-access web application or integrate it into hospital information systems, enabling rapid clinical access to short-term coagulation risk predictions. This will support intelligent optimization of ALSS treatment pathways and nursing resource allocation. We believe this translational approach will significantly enhance the model's clinical accessibility and practical value.

Funding

This study was supported by Nanchong Science and Technology Bureau City-University Cooperation Special Fund (19SXHZ0058).

Data Availability

All data generated or analyzed during this study are included in this article and/or its supplementary material files. Further enquiries can be directed to the corresponding author.

Abstract

Academic global health informatics (GHI) projects are impactful collaborations between institutions in high-income and low- and middle-income countries (LMICs) and play a crucial role in enhancing health care services and access in LMICs using eHealth practices. Researchers across all involved organizations bring unique expertise to these collaborations. However, these projects often face significant obstacles, including cultural and linguistic barriers, resource limitations, and sustainability issues. The lack of representation from LMIC researchers in knowledge generation and the high costs of open-access publications further complicate efforts to ensure inclusive, accessible, and collaborative scholarship. This viewpoint describes present gaps in the literature on academic GHI collaborations and describes a path forward for future research directions and successful research community development. Key recommendations include centering community-based participatory research, developing post-growth solutions, and creating sustainable funding models. Addressing these challenges is essential for fostering effective, scalable, and equitable GHI interventions that improve global health outcomes.

Introduction

Global health informatics (GHI) is an interdisciplinary subfield of health informatics that aims to use eHealth practices (eg, electronic health records, mobile health [mHealth], telehealth, and technology-enabled learning), including research and innovation in enhancing provision of health care resources, services, including information access in low- and middle-income countries (LMICs). This approach has the potential to improve clinical and population health outcomes for patients in LMICs [1,2]. GHI interventions aim to empower people through context-specific technological solutions to develop innovative solutions that improve health care access and patient outcomes while being locally led and maintained [3].

Academic GHI interventions are research-driven initiatives between higher education institutions (eg, universities and medical schools) with host country governmental agencies, nongovernmental organizations, universities, and community organizations [4,5]. These projects typically have more localized

XSL•FO
RenderX

and regional scope, focusing on specific local issues within a particular community, whether in high-income or low-income settings, systems, or regions; they often address local needs without prioritizing global scalability or broad collaboration. Academic GHI collaborations can include an informatics education training component to build local capacity [6,7]. Finally, a key characteristic of academic GHI projects is that their funding typically comes from governmental agencies or foundations for institutional resources. Knowledge generation through scientific publications and obtaining maintained extramural funding are key differentiating factors between academic collaborations and other GHI interventions.

However, numerous challenges impact the long-term success of academic GHI interventions and collaborations. These include a lack of understanding of the true health care problems, goals, and workflows, "pilotitis" (ie, the lack of scale-up beyond a pilot phase), and insufficient resources or interest amongst communities to maintain interventions independently [8-10]. There is a substantial lack of representation from LMIC researchers in knowledge generation and a scarcity of literature on successful implementation and further operationalization of academic GHI interventions [11,12]. Despite the benefits of open-access publication for knowledge sharing in LMICs, there is a substantial variance in open-access article processing charges, with costs upwards of several thousand US dollars; this limits access to and dissemination of scientific knowledge from researchers in LMICs and globally [13].

While the phenomenon of "pilotitis" remains a recognized challenge in GHI, it does not universally reflect the realities on the ground. In fact, there are numerous examples of successful, long-term implementations of digital health technologies in Africa and Southeast Asia that have benefited from international collaboration while being adapted to local needs.

A leading example is OpenMRS, an open-source electronic medical record system that has been deployed and maintained across multiple countries, including Kenya, Rwanda, Uganda, and Bangladesh [14,15]. These implementations have demonstrated local ownership, strong technical communities, and policy alignment, proving that long-term sustainability is achievable when supported by appropriate governance and capacity building.

Another widely embraced platform is District Health Information Software 2, developed by the University of Oslo and implemented in over 75 countries [16]. It serves as the national health information system (HIS) in countries such as Tanzania, Nepal, and Sri Lanka, enabling robust health data management and public health decision-making at scale. District Health Information Software 2's success is rooted in its open architecture, local customization, and integration into national health strategies.

These examples highlight that international collaboration can indeed support scalable, sustainable innovation, particularly when it promotes local leadership, long-term investment, and codevelopment. Rather than suggesting that pilotitis is a universal outcome, we aim to emphasize the importance of structural enablers and collaboration models that move beyond fragmented, short-term interventions and foster enduring digital health ecosystems.

In this viewpoint, we describe current gaps in the literature on how academic GHI collaborations can be successfully implemented. Our viewpoint also explores a path forward for developing an environment that is conducive to these projects' success, and research priorities for the informatics community to expand academic GHI research. The authors would like to call attention to the use of terms such as "LMICs" throughout this piece. To foster effective global collaboration, respect for the country of origin's culture, customs, and economy is warranted. Such a perspective could place unwarranted stigma or an unequal distribution of power or influence on countries in the southern hemisphere, implying that they are unable to innovate and must remain reliant on high-income countries for solutions to local, country-specific challenges [17,18]. In the absence of alternatives, we continue to use the current nomenclature but recognize it as a limitation and a priority area for developing more inclusive terms.

Expanding the Knowledge Base for Academic GHI Project Implementation

Overview

Although academic GHI interventions are typically implemented locally, they often adopt a more expansive viewpoint by striving to contribute scientific knowledge for solutions to be applied globally. Long-term collaborations across academic institutions and other health care organizations globally are key to technological advancements and ensuring that innovations are scalable and transferable across diverse health contexts [11]. For example, interoperable systems and standards, such as Health Level Seven International, Fast Healthcare Interoperability Resources and Systematized Nomenclature of Medicine–Clinical Terms, are essential to ensuring that health information can easily be exchanged, interpreted, and used across various systems worldwide [19]. Interoperability systems and standards are essential for ensuring secure health information exchange, facilitating data analysis and secondary research use, informing organizational decision-making, and improving patient care.

Despite the critical role of GHI in advancing health care outcomes worldwide, there remains a significant gap in the literature regarding the specific challenges faced during the implementation and scale-up of such projects in LMICs. This has often led to "pilotitis," where systems are designed and implemented yet never scale or report evaluation findings beyond the initial implementation [8,12]. These challenges can be grouped into 3 categories: local context-related, resource-related, and business model-related.

Local Context–Related Challenges

Local context–related challenges encompass cultural and linguistic barriers that can lead to the development of solutions that are not suitable or compatible with the target population. For example, health data may be recorded in different languages, resulting in complicated and potentially erroneous translations, thus challenging data standardization and interoperability.

XSL•FO
RenderX

Similarly, existing medical diagnostic codes, terms, and classifications may not align with existing languages and across countries and cultures. These barriers can result in a lack of user engagement and adoption, ultimately limiting the intervention's effectiveness. These challenges can also include data privacy and security concerns, as well as divergent cultural views and perceptions of diseases and health behaviors, and trust in technology. Understanding and integrating local cultural norms, language requirements, and workflows are crucial for health informatics initiative success [20].

Resource-Related Challenges

Resource-related challenges include technological infrastructure limitations, but extend beyond those and include the availability of a skilled workforce. There is often a shortage of trained professionals (ie, technical and clinical) who can manage and maintain digital health systems, analyze health data, and ensure data security and privacy. This lack of expertise can lead to improper or inappropriate technologies, security vulnerabilities, a lack of data access and use, and unreliable data, which undermine interventions' goals [20]. To increase capacity, additional training of local staff is often necessary, a hidden cost in time and money that may not always be accounted for in grant funding or limited project timelines for academic GHI interventions. Furthermore, even in initiatives that include data science education in their activities, there is a lack of standardization in capacity-building approaches, which is needed to support global and interdisciplinary collaborations and foster strong regional partnerships [21].

Business Model–Related Challenges

Business model–related challenges involve the sustainability and scalability of health informatics projects. Projects often rely on short-term grants or donor funding and lack a long-term financial sustainability plan; this issue is further compounded by challenges faced in communicating return on investment for GHI projects to funders (eg, governments and private donors), particularly given limitations in integrating cost-recovery mechanisms into these projects due to infeasibility or ethical considerations. In addition, vague ownership models for data, systems, and technologies can limit scale-up and integration of smaller-scale informatics project products into national health systems. This issue highlights the need for robust business models that ensure continuous support, funding, and integration of digital health interventions into the broader health system framework [22,23].

In addition, there is limited analysis of how projects navigate these hurdles in real-world settings beyond the pilot stage or the effectiveness of various strategies to overcome these obstacles. While in recent years, there have been some studies on evaluating GHI projects in LMICs [14,24,25], more comprehensive evaluations and reporting on the implementation processes and intervention outcomes at scale are necessary to address these gaps. Such analyses can provide valuable insights into best practices and successful strategies for overcoming the myriad challenges faced in low-resource settings. Studies need to examine these projects' immediate impacts, along with their ability to be integrated into existing health systems, address local community needs, adaptability to changing technological landscapes and health challenges, and capacity to remain relevant and useful over time [26,27]. Centrally positioning LMIC researchers as experts in knowledge generation is imperative, as is acknowledging and mitigating harmful power dynamics between researchers from academic institutions and members of communities in which GHI projects are situated [28,29]. Addressing these gaps is essential for guiding future academic GHI collaborations toward more successful, sustainable, and impactful implementation, thereby contributing to improving global health outcomes.

Developing an Environment That Fosters Success

Global efforts to establish an enabling environment for academic GHI interventions are necessary. In such an environment, stakeholders are invested in GHI projects as a solution to address health care challenges and are prepared to engage in ethical and mutually beneficial informatics projects. As mutually beneficial collaborations, researchers in high-resource settings can benefit greatly from the expertise and interventions proven successful in low-resourced settings. For example, in response to an urgent need for COVID-19 tracking early in the pandemic, the San Francisco Department of Health partnered with Dimagi to use CommCare, an open-sourced tracking application used for 2 decades by community health workers in low-resource settings [30,31]. This partnership led to the successful expansion of the city's COVID-19 response force and scale-up of testing capabilities, forming a generalizable model for other United States jurisdictions [30].

Furthermore, successful academic GHI interventions generally require more input and control from local communities compared to typical commercial HIS seen in the US and other high-income settings. Developing interventions with community buy-in and local ownership is critical to addressing these challenges and should be incorporated into protocols and implementation efforts from a study's inception [24]. For instance, systems must function with limited power, networking, and IT support [32]. Key solutions for developing and implementing successful GHI projects in low-resource settings include flexible coding systems (eg, the Open Concept Lab for OpenMRS [33]) to represent locally important data on diseases, treatments, and social circumstances, such as transport and housing types, along with a focus on open and rigorous evaluation in clinical contexts where informatics solutions are mobilized.

Evaluating and establishing a new program needs to be driven by the equitable involvement of all relevant parties with a mutual and unified understanding of goals and pathways to be achieved. Theories and frameworks regarding technology adoption, sociocultural, user-centered design, and implementation science are important tools to help guide this process [4,34].

While our perspective highlights persistent challenges in GHI academic collaborations, we recognize and seek to build upon the substantial efforts of leading organizations and institutions. International academic partnerships around GHI have played

XSL•FO
RenderX

an important role in strengthening health systems, especially in LMICs.

The World Health Organization has played a critical role in shaping the global digital health agenda through its Global Strategy on Digital Health, the Digital Health Technical Advisory Group, and its coordination of normative frameworks and implementation support mechanisms. The Geneva University Hospitals and the Geneva Digital Health Hub have emerged as key drivers of innovation, knowledge exchange, and capacity building. As a World Health Organization Collaborating Center for eHealth and Telemedicine, Geneva University Hospitals has contributed extensively to advancing digital health solutions for global health challenges. The Geneva Digital Health Hub has further expanded this impact by convening stakeholders across sectors, translating research into policy, and facilitating collaborative digital health projects with a strong emphasis on equity and inclusion.

Other notable examples include the Academic Model Providing Access to Healthcare and the International Training and Education Center for Health at the University of Washington. These collaborations underscore the potential of cross-institutional efforts in driving sustainable health improvements through shared expertise, coleadership, and a better understanding of local contexts. One such partnership that has emerged as a promising model is the collaboration between the Children's Hospital of Philadelphia (CHOP) and the University of Botswana (UB) on GHI research efforts, which is described as a case study in detail.

Case Study: Chop-UB Partnership—a Model for Equitable Global Health Collaboration

The CHOP-UB partnership exemplifies a coleadership model built on mutual respect, shared responsibilities, and the integration of diverse expertise. CHOP brings extensive experience in pediatric health care delivery and clinical research, while UB contributes technical and contextual knowledge critical to health care delivery in Botswana. Specifically, researchers and experts at UB engage in data management and analysis through the eHealth research unit, focusing on ensuring data quality and usability. Their expertise spans digital health technologies, including electronic health records and mHealth applications, as well as compliance with ethical and regulatory frameworks governing data privacy in Botswana.

Key achievements of this collaboration include: the evaluation of health care data collection, sharing, and usage, mapping the flow of health care data, examining clinicians' perspectives on health care data management, and data science capacity development. The CHOP-UB collaboration is focused on building capacity through comprehensive training programs, which are designed and customized for local Botswana health care professionals' needs. These programs emphasized the use of health informatics tools, and the importance of data-driven decision-making in clinical settings. Key factors in this academic GHI partnership's success have been a focus on local context (eg, socioeconomic, cultural, and geographic), use of robust evaluation frameworks [35], focus on long-term outcomes, scalability, and consideration of mitigating barriers to informatics tools adoption, infrastructure deficits, and resistance to change.

A defining characteristic of the partnership has been the commitment to knowledge transfer. There has been a particular focus on knowledge transfer to empower local staff to independently manage and maintain technological advancements, thereby ensuring long-term impact and sustainability. Rather than creating dependency, the programs are designed to empower local health care workers to independently manage and adapt digital tools to meet the evolving needs of the local health system. This approach is critical for ensuring sustainability and meaningful impact. The partnership has adopted a coleadership model where leaders from both CHOP and UB bring skills and expertise ensuring local health care staff are actively involved in capacity building to achieve this knowledge transfer.

Botswana is currently making strides in implementing advanced health informatics solutions to enhance the quality of health care services across facilities. Notable efforts include electronic medical record rollouts, revitalizing primary health care systems, and the development of the health information exchange and the Botswana eHealth Enterprise Architecture. These efforts are geared toward improving patient outcomes, streamlining data management, and facilitating near-real-time clinical decision-making. The CHOP-UB academic partnership's success exemplifies the potential benefit of international collaborations in transforming health care delivery through innovative informatics solutions in low-resource settings [36].

Other stellar examples of collaborative international health informatics efforts include those led by Japan to address infectious diseases prevalent in developing nations through the Global Health Innovative Technology Fund, a public-private partnership [37], and through SATREPS (Science and Technology Research Partnership for Sustainable Development) [38]. In addition, regional partnerships among LMICs (sometimes termed "South-South") in health informatics include those among South and Southeast Asian countries, sub-Saharan African nations [39,40], and Latin American nations [7]. These efforts demonstrate the value of cross-national strengthening of HIS to promote global health outcomes. The 2022 International Medical Informatics Association Yearbook contains the most recent updates on the status of health informatics societies around the world, including Asian, Latin American, and African nations [41,42].

Lessons Learned

This case study offers several important lessons for academic GHI partnerships.

1. Contextual relevance is vital: successful collaborations require a deep understanding of local health system needs, real-life workflows during patient encounters, cultural dynamics, and HIS infrastructure realities. Tailoring solutions to these conditions has the potential to enhance adoption and sustainability.

XSL•FO
RenderX

2. Coleadership builds trust and equity: shared leadership between institutions promotes equitable partnerships and ensures both global and local stakeholders contribute meaningfully to projects and decision-making.
3. Capacity building enables sustainability: investing in local capacity through knowledge transfer and educational initiatives supports sustainable implementation. Intentionally designing knowledge transfer promotes maintenance skills and future innovation of health information technology by local experts and clinical champions.
4. Evaluation strengthens accountability: using robust evaluation frameworks not only measures impact but also guides program adaptation and scalability.
5. Infrastructure and policy alignment are key: tech solutions are more effective when aligned with national strategies and supported by strong policy environments.

Future Research Directions

GHI academic collaborations can undoubtedly draw on HIS technology intervention strengths in high-income settings; however, opportunities to truly meet the needs of diverse global health systems remain. Potential future directions include (1) centering community-based participatory research (CBPR) approaches to colead research with local experts, (2) embracing a post-growth mentality focused on quality of life and equitable distribution of technological benefits (using technology to improve quality and reach of existing health systems rather than solely focusing on growth) to develop GHI interventions, and (3) supporting frameworks for evaluation and scaling that address how to move beyond "pilotitis," and toward sustainable technology implementation and use.

CBPR approaches promote effective, long-term, and equitable collaborations between research teams and community-based organizations with community members representing underserved groups [43]. Fundamentally, the approach centers end-users from marginalized communities in all stages of research, from initial problem-statement generation to design, implementation, and evaluation of solutions. In health informatics research, CBPR applies principles borrowed from health equity and disability rights activism of "Nothing about us without us" and "Center the margins" into studies so that the final health technology product does not widen, maintain, or create novel disparities but instead meets the needs of those most affected by social drivers of health and systemic injustice [44,45].

Throughout this viewpoint, we have pointed to challenges in centering LMIC researchers as experts, power sharing, and building strong community relationships, which can all be addressed by combining CBPR and GHI. For example, incorporating the CBPR conceptual model into GHI research can help center traditional and Indigenous knowledge systems, balance action and research, and prompt colearning and coleadership [46,47]. However, by nature, CBPR has no one-size-fits-all approach and will need to be thoughtfully incorporated into GHI. Specifically, capacity building to ensure that researchers and organizations in LMICs can proactively safeguard themselves against exploitation and co-optive CBPR practices, which can foster beneficial long-term relationships and global partnerships.

One caution against leveraging HI lessons from high-income settings and applying them to LMIC contexts is that a constant search for novel and high-performing yet brittle interventions may not be suitable for lower-resource settings. IT solutions are important in all health environments, but local design input, transparency from large IT companies involved in these projects, and local control are crucial to success in diverse environments and cultures. Moving forward, GHI researchers should look to interventions that emphasize commons-based ownership (eg, of GHI interventions), voluntary simplicity, and learning from the traditional wisdom developed and preserved by many cultures globally [23,27]. Post-growth solutions might necessitate a departure from techno-solutionism, an understanding that technology can facilitate solutions, but truly addressing health inequity will require focusing on structural inequities and local innovation in health care delivery [48].

Finally, given longstanding GHI "pilotitis" issues, future research endeavors should focus on leveraging transient grant funding to develop pilots and then help local organizations sustain long-term research. This may look like assistance and support to receive grants supporting postimplementation monitoring, capacity building to ensure that local community members are well-positioned to continue deriving value from knowledge generated by GHI research (eg, entrepreneurship), as well as ensuring principles, such as commons-based ownership and voluntary simplicity. In addition, advocating for policy change is another important avenue to orient grant organizations toward the importance of long-term monitoring and support of successful GHI interventions.

Conclusions

This viewpoint identified current gaps in the literature on academic GHI implementation and underscored the need for international academic collaborations. A path forward to develop mutually beneficial partnerships and execute projects across the project life cycle phases was outlined, and to circumvent the concept of "pilotitis" was described. The authors propose a call to action to reduce facilitation barriers, strengthen implementation, and GHI knowledge dissemination and translation. This includes developing more appropriate evaluation metrics for GHI interventions outside of publications that encapsulate collaborations' impact. For example, an open register of digital health systems, such as Digital Square [49], with open data on sites, patients, technology end-users, disease coverage, longevity, etc, is an alternative or complementary metric of the scope and success of academic GHI partnerships compared to publications.

Academic institutions working on GHI interventions could collaborate to establish a global community of practice in which health informatics recommended guidelines and standards could be successfully developed, implemented, adopted, and adapted to suit individual resources (ie, human and financial). This will require more funding and support that accounts for realistic timelines given indirect costs and unique challenges to GHI

XSL•FO
RenderX

projects that differentiate them from other health informatics projects in high-income countries. It is critical to reduce barriers to care and implementation through transparent communication, knowledge transfer of lessons learned, and proven techniques to promote sustainable, mutually beneficial GHI academic collaborations. Thus, partnerships between academic institutions and industries spanning diverse countries and geographies are urgently required to address global challenges that transcend national borders without further propagating entrenched inequities [15].

Acknowledgments

The authors would like to acknowledge the members of the Global Health Informatics Working Group of the American Medical Informatics Association for their input on numerous discussions that have led to this viewpoint. Our authors bring extensive knowledge and lived experiences of global health informatics in low- and middle-income countries (LMICs), but a majority of our authors are from academic institutions based in high-income countries. Overall, 3 authors from this paper are originally from LMICs with one still based at an institution in an LMIC. The authors would like to acknowledge the use of umbrella terms, namely LMICs, in this paper. We do not believe that these terms adequately capture the diversity of culture, skills, expertise, and lived experiences of researchers from these settings. However, given the lack of another commonly used terminology, we will use these terms in our viewpoint with the hopes that this creates discourse toward the development of more representative language in the future.

Abstract

In an era where health care is increasingly dependent on digital infrastructure, the resilience of health IT systems has become a cornerstone of patient safety and operational continuity. As cyber threats grow in frequency and sophistication, health care organizations have turned to advanced cybersecurity tools to safeguard their systems. Yet even the most robust defenses can falter. On July 19, 2024, a routine update from a widely used cybersecurity platform triggered a widespread IT disruption. A flawed sensor configuration led to 8647 “blue screen of death” (BSOD) events, with 729 devices requiring manual remediation. What unfolded was not just a technical crisis but a test of organizational agility, collaboration, and resilience. This viewpoint traces the response to that disruption, highlighting the pivotal role of clinical informaticists and the coordinated efforts that enabled a rapid recovery. From the formation of an incident response team to the triage and mitigation of impacted systems, the response was swift and strategic. Clinical informaticists emerged as key players, bridging the gap between technical teams and frontline care providers. They identified workflow disruptions, facilitated communication, and ensured that patient care remained as uninterrupted as possible. Despite the scale of the outage, operations continued with minimal disruption—thanks to early recognition, decisive action, and cross-disciplinary collaboration. This incident underscored the importance of a well-practiced response plan, clear communication channels, and the integration of clinical expertise in technical recovery efforts. As we reflect on this event, several lessons emerge: the need for continuous refinement of incident response strategies, the value of regular training exercises, and the critical role of clinical informatics in navigating digital crises. This paper calls for a renewed commitment to building resilient health IT ecosystems—ones that can withstand disruption and continue to support the delivery of safe, effective care.

Introduction

Cybersecurity and the related disruptions to critical IT systems are a major concern for many organizations due to risks associated with data breaches. This is particularly true in health care organizations due to their unique risk profiles. Health care facilities are high-value targets due to their size, technological dependence, sensitive data, and vulnerability to disruptions [1]. Furthermore, there has been an increase in cyberattacks in recent years, as evidenced by a 93% increase in large breaches reported by the Office for Civil Rights under the Department of Health and Human Services between 2018 and 2022, many involving ransomware attacks [1].

The health care industry continues to deal with a barrage of attacks, with over 1400 cyberattacks globally per week [2]. The range of attack strategies used by threat actors includes social engineering, phishing, distributed denial of service, botnets, zero-day exploits, person-in-the-middle, malware, adware, and ransomware [3]. When hospitals are forced to implement downtime procedures as a result of a successful attack, the average duration is upwards of 24 days, at an average cost of US $10 million [2]. There are additional risks beyond the direct impacts to systems and the operations of the affected organizations. Cyberattacks often result in data breaches that can impact patients receiving care at the affected institutions. In 2024, over 250 million individuals were affected by health care security breaches, with 190 million of those involving a ransomware attack on the Change Healthcare network [4]. Health care entities that endure these kinds of attacks may also incur legal ramifications and reputational damage in addition to the financial impacts [3]. The legal ramifications include violations related to the Health Insurance Portability and Accountability Act (HIPAA), since the presence of any type of

XSL•FO
RenderX

malware on a covered entity's or business associate's computer is considered a security incident under the HIPAA security rule [5]. Compromised patient data can be misused for identity theft, blackmail, and even insurance fraud. Even if the threat actor does not use the information directly, it can still be disseminated on illegal forums, further increasing the risk of misuse [3].

Defense against malicious actors requires continuous vigilance and system hardening against potential attack vectors. The Center for Internet Security publishes best practices called Critical Security Controls (current version, as of this writing, is version 8.1), which detail the steps organizations can take to guard against attacks [6]. CrowdStrike is a leading cybersecurity firm that provides services to many organizations, both inside and outside of the health care sector, to achieve these goals. Among these services is the Falcon platform, which is designed to stop breaches and protect organizations from a variety of cybersecurity threats.

On July 19, 2024, at 04:09 UTC (12:09 AM local time), CrowdStrike released a sensor configuration update to Microsoft Windows systems to maintain the protection mechanisms of the Falcon platform. This update triggered a logic error, which resulted in a system crash and "blue screen of death" (BSOD) on impacted systems. This error was quickly identified by the team at CrowdStrike, and the sensor configuration update was swiftly remediated on July 19, 2024, at 05:27 UTC (1:27 AM local time). The specific machines that were impacted needed to be running the Falcon sensor for Microsoft Windows versions 7.11 and above, be online between July 19, 2024, 04:09 UTC and July 19, 2024, 05:27 UTC, and have downloaded the flawed configuration update during that interval [7].

Importantly, the system failure that occurred in this case was not the result of a cyberattack, but the impacts to critical systems and the recovery strategies used shared similarities with those that would be enacted if systems had been compromised due to a breach. While the underlying cause of the logic error was quickly identified and remediated by CrowdStrike, the downstream impacts to customers were substantial and required a coordinated strategy to mitigate.

Many health care workflows are dependent upon seamless integration of otherwise disparate systems. For example, radiology practices require coordination between imaging devices, a Picture Archiving and Communication System, and the electronic health record (EHR). Each of these components represents an independent point of failure in the event of a major health IT outage, such as the one encountered with the CrowdStrike incident [8]. Considering the time-sensitive nature of significant disruptions in health IT, it is crucial to have clear and effective communication processes, especially in large, geographically dispersed health care systems that rely on health IT infrastructure for patient care and operations.

The CrowdStrike incident highlighted the significant risks associated with workstation downtime, including medication errors, inaccessibility of images and test results, and the need to delay procedures. During the incident, many health care workflows were disrupted due to the inability to access critical patient information on affected workstations (eg, radiology images). In addition, the inability to access lab results on time further compounded the delays in diagnosing and treating patients. Although the EHR itself remained operational, the downtime of numerous workstations could have led to delays in reviewing and acting upon patient information, ultimately impacting the quality of care provided. These risks are well-documented in literature, emphasizing the importance of proactive planning for EHR downtime [9-12].

The primary objective of this viewpoint is to offer real-world insights following a major IT disruption by exploring ECU Health's response to the CrowdStrike incident. In addition, the authors share lessons learned from leveraging a multidisciplinary team across Information Services (IS), including a well-established network of embedded clinical informaticists, to navigate the response efforts. Finally, we describe opportunities for improvement that should help similar organizations address similar challenges in the future.

Background

ECU Health is a rural academic health care system that serves 29 counties in eastern North Carolina. The health care system comprises 9 hospitals spanning in size and scope from a large academic level 1 trauma center to critical access hospitals. Within this network are 185 primary care and specialty clinics in 110 locations, plus other outpatient facilities, home health, hospice, and wellness centers [13]. Together, these ambulatory practices complete over 800,000 visits annually. All ECU Health facilities are served by an enterprise-wide IS division, which oversees all aspects of health IT, including hardware, software (eg, EHR and clinical applications), networking, end-user support (EUS), and cybersecurity.

The clinical informatics team within the IS division, consisting of 19 full-time informaticists and 7 full-time informatics education specialists with diverse clinical and nonclinical expertise, serves as a critical interface between clinical teams, operational leaders, and health IT professionals. These informaticists integrate health care sciences, computer science, and information science to manage and communicate data, information, and knowledge, thereby enhancing patient care, improving health outcomes, and supporting decision-making processes [14,15].

Existing Incident Response Strategy

ECU Health's incident response strategy includes the formation of the incident response team, initial assessment and triage of the situation, and identifying key actions to mitigate impact. When an IS team member is notified of an incident affecting multiple users, the first escalation is to the IT service management team for vetting and validation. The incident is next escalated to the IS executive on call, who determines whether it should be categorized as a Priority 1 (P1)–critical outage. Incidents are categorized according to their urgency and impact, as shown in Table 1. Patient care incidents are prioritized higher than nonpatient care issues. If categorized as a P1, a major incident is created within the enterprise ticket management solution, and the operational executives on call for the impacted facilities are notified. A bridge line (ie, a

XSL•FO
RenderX

dedicated conference call line for coordinating team members) is opened, and command centers are mobilized at the impacted sites. The command center at the medical center serves as the central hub for local hospital operations and as a physical location for the systemwide command center. The systemwide command center is staffed with IS and operational leaders. Regional command centers are staffed with local operational leaders. Each command center's primary roles are to centralize communications, facilitate issue escalation, and disseminate updates as issues are corrected and functionality is restored. Additional bridge lines are opened within IS, including a technical one to problem-solve issues and determine impacted applications.

Table . Impact and urgency matrix used to categorize incidents.

Urgency	Hospital or organization-wide	Multiple users	Single user: patient care	Single user: nonpatient care
Critical	Critical (P1)[a]	Critical (P1)	High (P2)[b]	Medium (P3)[c]
High	Critical (P1)	High (P2)	Medium (P3)	Medium (P3)
Medium	High (P2)	Medium (P3)	Medium (P3)	Low (P4)[d]
Low	Medium (P3)	Low (P4)	Low (P4)	Low (P4)

[a] P1:priority 1.

[b] P2:priority 2.

[c] P3:priority 3.

[d] P4:priority 4.

During the initial assessment and triage phase, the IS command center relies on bridge line communication to determine the scope of impacted applications and incident tracking. All incidents are tracked through the ticket management system. As new incidents are reported, they are tracked as "children" of the "parent" incident if found to be related.

Finally, actions are taken to address the situation, including isolating the impacted systems, communicating with staff and patients, and initiating interventions to correct the underlying problems or implementing short-term alternatives. These measures ensure that the immediate risks are mitigated and that all stakeholders are informed about the ongoing efforts. By isolating the affected systems, further spread of the issue is prevented, while clear communication helps maintain trust and transparency. Timely initial interventions are crucial for stabilizing the situation and providing temporary solutions until a permanent fix can be implemented. This comprehensive approach helps manage the incident effectively and minimizes disruptions to operations.

Timeline of Events, Organizational Impacts, and Remediation Efforts

Following the CrowdStrike update, initial reports of devices receiving the BSOD began on July 19 at 1:30 AM. The sequence of events from the initial BSOD reports to the closure of the systemwide command center approximately 30 hours later is shown in Table 2.

XSL•FO
RenderX

Table . ECU Health event response timeline for the CrowdStrike incident.

Time	Event
Friday, July 19	
12:09 AM	CrowdStrike releases flawed sensor configuration update
1:27 AM	CrowdStrike remediates the flawed sensor configuration update
1:30 AM	Initial reports of workstations and servers receiving the BSOD[a]
1:38 AM	Initial escalation to Information Services (IS) team members
3:40 AM	Escalation to the IS executive on call and then to operational leadership
4:45 AM	Email notification sent to IS staff indicating the BSOD issue had been traced back to the CrowdStrike update
5:30 AM	The systemwide Incident Command Center was opened
6:00 AM-7:00 AM	Clinical informaticists arrive on site at hospital locations prepared for deployment
6:58 AM	Initial notification for IS personnel to report to their closest system hospital
8:20 AM	Systemwide email indicating that command centers had been activated at all system hospitals; users experiencing BSOD are encouraged to reboot their workstations twice; and for issues with ECU Health mobile devices, docking stations were to be unplugged.
10:49 AM	Staff are encouraged to submit incidents into the ticketing system for individual workstations experiencing BSOD unable to be remediated by staff directly
12:29 PM	Health care system staff informed of potential scammers posing as IT professionals attempting to gain access to computers and files
4:32 PM	Command center at the medical center converted from in-person to remote format; all community hospital command centers closed
5:00 PM	The IS meets to recap the day's events and discuss plans for the weekend
Saturday, July 20	
8:18 AM	The medical center closes its command center

[a]BSOD: blue screen of death.

Across the ECU Health enterprise, there are approximately 14,500 end point devices. There were 8647 BSOD events (approximately 60% of devices) on July 19. Most of these workstations were corrected with a reboot once the remediated sensor configuration update was available. Of those that were not corrected with a reboot, 729 devices required hands-on remediation. Approximately 150 workstation thin clients (ie, machines that rely on a central server for processing power and storage) and 100 ground control workstations (ie, centralized systems used to manage, monitor, and control devices for mobile device management) were reimaged to restore them to a functional state.

There are 3000 Windows servers used across the enterprise. Of these, 700 (23%) deliver Citrix applications, including the EHR. Approximately one-third of these devices were impacted by the flawed sensor configuration update. These servers are nonpersistent, meaning they load a golden image (ie, a preconfigured, fully functional template of a computer system and software configuration) each time they are restarted, and temporary data or changes made during the previous session are discarded. There are approximately 100 other persistent servers that provide other services related to the EHR (eg, print servers).

Users working with impacted devices could not access core applications and systems, including the EHR. However, the EHR itself remained operational throughout this incident, and not all workstations were impacted. IS leadership assessed the availability of the EHR throughout the incident to guide recovery efforts. Timing was a significant factor in keeping the EHR operational, as the incident occurred during a low-user volume period, which prevented the whole fleet of servers that deliver the EHR from being engaged and encountering the BSOD conditions.

In the months preceding this incident, the health care system deployed cell phones to clinical staff to support patient care and internal communication. Many of these were not impacted and enabled workflows such as medication administration to proceed even when nearby workstations were unavailable.

Impacted devices were first rebooted. If the issue persisted, an incident was logged to identify it for hands-on support. These devices were then physically accessed by IS personnel. The devices were booted in "Safe Mode" using a BitLocker recovery key, if necessary, and the flawed channel file (C-00000291*) was manually deleted. The device was then rebooted, which enabled the system to start without the BSOD and allowed an update to the channel file to flow across to the machine. These

XSL•FO
RenderX

steps are described in more detail on CrowdStrike's website [16]. Once CrowdStrike released the remediated sensor configuration, nonpersistent servers were corrected with a reboot. For persistent servers, these were recovered using the method described above in this paragraph, which involves booting them into "Safe Mode" and removing the flawed channel file.

Some workstations required remediation using a USB drive to boot the system with Kali Linux (Offensive Security). The IS team members ensured they had adequate privileges to perform actions on the directory that contains the CrowdStrike drivers. The files within were removed, the device was unmounted, and the machine was restarted without the USB drive so that it boots normally. If these options were unsuccessful, the devices were reimaged to restore them to a functional state.

Role of Clinical Informatics in the Recovery Efforts

As soon as clinical informatics became aware of the issue, their first course of action was to call every unit manager (or charge nurse if the unit manager was unavailable) throughout the health care system to make sure they were informed of the situation and that CIs and other IS team members would be on the units helping to troubleshoot and restore the affected devices. During those phone calls, floor staff were encouraged to self-report any machines that were known to be impacted. This was intended to expedite the discovery process, leading to a more rapid resolution. The manager of the clinical informatics team was a key contributor to the ongoing bridge line calls and kept the systemwide incident command center apprised of progress toward remediation of all devices throughout the enterprise. This enabled resources to be focused on priority areas based on the volume of workstations impacted and the propensity for delays in care if not resolved urgently.

The network of CIs was dispatched across the enterprise to their respective sites to augment remediation efforts in coordination with EUS, service desk, and other IS personnel. As a result of the collaborative relationships clinical informaticists have established with clinical operations, CIs became another contact for reporting impacted devices, particularly if there was difficulty accessing or unfamiliarity with reporting incidents. The presence of CIs also instilled a sense of calm in clinical staff, especially during the early phase of the incident. The scale of the outage, both within and outside of the organization, had the potential to create panic due to concerns that this issue was caused by a cyberattack, as expressed by some end users after perusing social media. The CIs were well-positioned to provide accurate information to staff about the nature of the incident as a faulty system update and not a cyberattack. This assuaged their fears and helped ensure staff were able to focus on completing the necessary steps to rectify the situation and bring all systems back to a functional state.

In an effort to avoid duplicate reporting, CIs used sticky notes to label impacted devices as "reported," which helped to limit confusion and focus recovery efforts. The role of CIs in the incident response varied based on diverse needs across sites and included consistent communication, incident reporting, and at-the-elbow support. At-the-elbow support was particularly beneficial because it helped clinicians identify and execute the remediation steps when necessary while ensuring patient care remained uninterrupted.

Key Lessons Learned

Health care organizations are dependent upon technologies to deliver patient care. Considering the scope of this outage, the risk of interruptions that could adversely impact patient care was high. Due to rapid problem recognition and mobilization of IS staff and resources, ECU Health continued operations as usual despite device outages. This speaks to the level of teamwork exhibited throughout the health care system. Even though ECU Health recovered most devices within 24 hours, there are still opportunities to refine its incident response.

Major incidents such as the CrowdStrike outage highlight the importance of having a well-prepared and accessible incident response plan using a framework such as the Hospital Incident Command System [17]. Incident response plans should include clear roles and responsibilities with clarity around decision-making. These plans should also include regular system audits, updates, and reviews to ensure applicability as health care systems continuously change.

Effective and consistent communication during disruptions is paramount. Device outages were first identified around 1:30 AM on July 19th. However, IS leaders were not notified until hours later, representing a missed opportunity for faster mobilization. ECU Health will refine its process for issuing broader alerts based on the event's criticality. In addition, communication challenges were observed related to reliance upon different devices and modalities for call tree escalation. Risks included issues such as battery performance, devices being out of reach, or susceptibility to outage conditions. ECU Health is exploring synchronization of contact numbers with backup redundancy, such as personal devices, to ensure communication capabilities during after-hours incidents.

Dispatching CIs who have established relationships with front-line clinicians allowed for responsive and multimodal support, including at-the-elbow support and virtual troubleshooting. This was invaluable, as it would have been impossible to manage the scale of this outage with the service desk, EUS, and IS teams alone. The effectiveness of this strategy relies on the informal cross-training of clinical informaticists across IS roles during routine operations. Our experience during this major disruption demonstrated that CIs leveraged their skill sets effectively during this crisis and showed the value of cross-training across roles.

In the months leading up to this outage, ECU Health had been deploying Microsoft Teams as the enterprise collaboration and communication platform. This tool was an effective communication method during this event when other tools were unavailable. Video meeting recordings and artificial intelligence–augmented transcription allowed for rapid summaries for team members joining multiple calls simultaneously. Further investigation will be conducted to

XSL•FO
RenderX

determine whether its availability was due to inherent fault tolerance or whether scenarios exist under which it may not be as reliable as it was during this event. More broadly, ECU Health has identified a need for an enterprise-wide alerting system to enable timely communication during emergencies. Minor challenges were encountered related to authentication processes that were required during the outage, indicating a need for better preparedness in handling such challenges in the future.

Changes Going Forward

Overview

Based on the lessons learned from this event, ECU Health is undertaking several initiatives as part of its commitment to a culture of continuous improvement. One of these initiatives involves enhancements to the IS Incident Command Structure. The key roles of the enhanced IS Incident Command Structure are shown in Figure 1, and their core responsibilities are provided in the following subheadings.

Figure 1. Key roles in the Information Services (IS) incident command system, showcasing the central role of the IS incident commander.

XSL•FO
RenderX

IS Incident Commander (Member of the Information Technology Service Management Team)

The IS incident commander will lead the incident response. This individual will coordinate all response workstreams to understand and communicate impacts to the IS executive lead. Other responsibilities include managing tasking for all IS workstreams to ensure proper prioritization of actions, managing shift planning to ensure adequate staffing throughout the incident, and developing situation reports (SITREPs) for proactive communication, which will provide a single source of truth on the impacts of actions taken. This individual will also review the outputs of workstreams and ensure objectives are met in a timely fashion.

IS Executive Lead (Member of the IS Senior Leadership Team)

The IS executive lead will work closely with the IS incident commander and serve as the primary liaison between IS and senior operational leadership. This leader will be an escalation point for any major blockers that cannot be resolved by the response team leaders. Through their interactions with IS personnel and senior operational leadership, they will maintain visibility into the recovery efforts and understand the impacts of these efforts on the wider organization.

Application Lead (IS Manager or Above)

Application leads will be assigned based on the nature of the outage and the impacted applications. Those assigned to these roles will perform an initial triage to understand the impact of the issue, ensure that people with the correct application knowledge and skill sets are engaged, and identify any relevant vendor contracts for escalation and support. As the situation evolves, they will provide updates to the IS incident commander and assist with the production of the SITREPs. They will support and guide the troubleshooting efforts, assist with tasks as necessary, and request additional resources as needs are identified. As workarounds or solutions to the problem are identified, the application lead will be responsible for specifying the testing requirements for the application to ensure successful resolution and to help anticipate potential unintended consequences.

Technical Lead (IS Manager or Above)

Technical leads will be assigned based on the nature of the outage and the impacted systems. Those assigned to these roles will perform an initial triage to understand the impact of the issue, ensure that people with the correct technical skill sets are engaged, and identify any relevant vendor contracts for escalation and support. As the situation evolves, they will provide updates to the IS incident commander and assist with the production of the SITREPs. They will support and guide the troubleshooting efforts, assist with tasks as necessary, and request additional resources as needs are identified. As workarounds or solutions to the problem are identified, the application lead will be responsible for specifying the testing requirements to ensure successful resolution and to help anticipate potential unintended consequences.

Communication Lead (Member of the IT Service Management Team)

The communication lead is responsible for controlling the messaging to staff throughout the enterprise. Examples of this messaging may include unscheduled downtime notices or IS outage communications. They will work with the operations communication team if responsibility for external communication needs to be delegated. Any requests for information will be triaged by this lead, and their response should be consistent with other messaging that is disseminated more broadly within the organization.

Logistics Lead (Supervisor, Manager, or IS Team Member)

The logistics lead is responsible for coordinating and instructing on-site resources and works closely with the application and technical leads to ensure these resources are appropriately prioritizing the work to be done. This lead is responsible for both the human resources and any equipment that is necessary to resolve the incident. This lead receives updates from on-site resources and shares this information with the application and technical leads as appropriate.

Cybersecurity Lead (Manager or Above)

The cybersecurity lead directs activities that are related to incidents stemming from cybersecurity events. This lead participates in the incident response, engages risk management and the legal team as appropriate, and ensures appropriate communication and information collection relevant to the current cybersecurity risk state. In addition to these updates to the IS incident command structure, ECU Health will conduct tabletop exercises and major incident refresher training. Tabletop exercises will involve reviewing example scenarios, and team leads will walk through the actions they would take if the scenario actually takes place. Major incident refresher training will help staff become aware of their responsibilities during these situations so they can confidently act to quickly bring these situations to a successful resolution.

A More Resilient Health Care System

This viewpoint focuses primarily on the ways ECU Health took targeted actions to mitigate an event that could have been catastrophic for the organization. It is equally important to consider opportunities to make the health care system more resilient as a whole. One such proposal would be to shift the culture toward a position of resilience that ensures clinical workflows are carefully considered and changes are thoroughly tested in simulated environments before being implemented to limit the risk of major interruptions [18]. While such a recommendation may be challenging to implement at scale, if successful, this would go a long way toward shoring up confidence and trust in these vendors and demonstrating their commitment to preventing major disruptions in the future.

Major health IT disruptions also highlight important social and economic inequalities that are pervasive in health care. As compared with smaller institutions, larger organizations often have the capital to invest more heavily in cybersecurity prevention measures and the ability to mobilize resources more

XSL•FO
RenderX

quickly when a disruption event occurs [19]. This mismatch can further exacerbate existing disparities in care by causing additional delays in delivery. A truly resilient health care system would ensure that these gaps are closed.

Conclusions

Major IT disruptions have the potential to adversely impact the delivery of patient care services. In addition, the CrowdStrike outage is estimated to have caused US $1.9 billion in losses to the health care industry [20]. This viewpoint emphasizes the critical role clinical informaticists can play in supporting health care organizations in times of crisis. By having a well-defined incident response plan, organizations can mobilize resources quickly to restore services and ensure clinicians have the tools they need to deliver care and mitigate many of the potential financial harms.

Widespread health care IT disruptions in geographically dispersed rural health care systems pose challenges for timely remediation and continuity of clinical operations while ensuring patient safety. Following the CrowdStrike outage in the summer of 2024, ECU Health relied on coordination and collaboration between multiple teams within IS, including a network of clinical informaticists integrated across practice settings. Lessons learned included the need for continuous commitment and refinement of a systemwide approach to incident response plans, clear communication channels with contingency plans if communications are disrupted, and the value of regular training, such as drills or tabletop exercises, for incident response teams. Through the diligence and collaboration of our multidisciplinary teams, IS teams, and CIs, ECU Health demonstrated resilience and adaptability to ensure we are better prepared for future challenges and remain committed to delivering uninterrupted, high-quality patient care.

Acknowledgments

The authors would like to acknowledge Joshua Smith, Wright Barbour, Brian King, and Lynette Timberlake for their contributions in ensuring that this work accurately conveys the actions taken by ECU Health to recover from this event and the plans established for mitigating future disruptions.

Data Availability

Data sharing is not applicable to this article as no datasets were generated or analyzed during the production of this viewpoint.

Authors' Contributions

CRD, CSE, and RJM conceptualized the viewpoint. CRD and CSE drafted the initial manuscript. TT validated the accuracy of the timeline and organizational strategy. KD and MMS validated the role of informaticists in the response. RJM managed the project.

Conflicts of Interest

None declared.

Abstract

Integrating data and information systems into national health strategies is crucial in addressing the growing health care demands. This increase is driven by an aging population and the rising prevalence of chronic diseases. Such systems enable the collection, analysis, and publication of health data and provide critical insights based on data-driven decision-making that support policy decisions, health interventions, and service delivery. Moreover, the systems enhance the capacity for public health surveillance and enable health authorities to monitor health trends, predict disease outbreaks, and effectively manage health crises such as the recent COVID-19 pandemic. This paper highlights the key aspects and characteristics that, according to international references, a well-functioning health information system and data-driven decision-making at the national level should have. We present the outputs in the form of the National Health Data-Sharing Strategy for the Czech Republic, along with successfully implemented case studies across selected domains of its health care system. The Czech National Health Information System has been established as the backbone for centralizing health data. It is a nationwide public administration tool that collects and processes data from the essential registries of public administration bodies, ministries, health services providers, or other persons submitting data to this system. It is the foundation for shaping a health care system that is responsive to patient needs, ensures efficient resource use, and promotes a patient-centered approach. Two examples are given of the tracking of fictitious patient pathways through the health care system. The take-home message of the study is a policy-oriented endorsement of comprehensive, secure, and interoperable health information systems as the basic infrastructure for modern, patient-centered, and data-driven health care. The paper strongly advocates the National Health Information System of the Czech Republic as the primary health database for designing, implementing, and governing such a system in alignment with European and global standards.

(JMIR Med Inform 2025;13:e70066) doi:10.2196/70066

KEYWORDS

information system; health data strategy; data-driven decision support; data interoperability

Introduction

Across Europe, health systems are under increasing pressure to deliver sustainable, efficient, and patient-centered care. The integration of health data and digital infrastructure into national strategies is essential to meet these demands and deliver on European Union (EU) priorities, including the European Health Data Space (EHDS). With its National Health Information System (NHIS), the Czech Republic offers a mature, coherent, and actionable model based on interoperability, standardization, and public trust.

In the context of EU member states' efforts to modernize their health care systems, the Czech NHIS offers a transferable framework for building resilient data ecosystems that citizens trust. This ecosystem covers all segments of the Czech health care system; is structured; and, thanks to its legal alignment with EU standards, is particularly relevant for countries seeking harmonization with new EU regulations such as the General Data Protection Regulation, the Digital Services Act, and the Digital Markets Act.

Robust health information systems (HISs) such as the NHIS enable real-time data sharing, support evidence-based policy decisions, and improve public health surveillance—capabilities

XSL•FO
RenderX

that have proven critical during the COVID-19 pandemic. Furthermore, the Czech system's integration supports goals such as strengthening preventive care, reducing regional inequalities, and improving research capacities. Through the use of advanced data analytics and standardized health data exchange, the Czech NHIS is an example of how national systems can evolve toward more proactive, personalized, and efficient health care, contributing to the European Commission's overarching goal for 2019 - 2025 of creating a unified EHDS. On the basis of extensive surveys conducted in 2023, it is urgent to develop the EHDS framework in consultation with stakeholders. The use of health data scenarios to promote dialogue on technical, legal, and social aspects is crucial in this regard. Using the health data scenarios to establish a good communication channel for discussing the related technical, social, and legal aspects of the EHDS is a crucial step in this process [1].

This viewpoint highlights the Czech Republic's policy-oriented approach to health data strategy and offers practical guidance for EU member states seeking to build modern, data-driven health care systems. The Czech model emphasizes data protection, transparency, and public trust. It calls for legal alignment with EU frameworks, cooperation between different stakeholders, and long-term investment in data literacy and sustainability. Positioned as a case study, it highlights the key elements of effective national HISs—governance, methodology, and technology—while aligning with broader European and global trends. It advocates for a structured yet flexible data infrastructure as the foundation for better health outcomes and public health resilience.

State-of-the-Art Systems and Strategies

Health Information Systems

HISs vary globally in design and capability, evolving in response to technological advances and the increasing role of data in public health. Effective HIS design requires understanding user needs; ensuring data security; and building flexible, scalable systems. A notable approach is the 4-stage ontology-based method, which uses participatory design to capture user knowledge, develop and implement ontologies, and test usability to ensure system effectiveness [2]. HIS design must take into account diverse health care subdomains (eg, hospitals and primary care centers) and stakeholders, ranging from patients to laboratory technicians. National systems often operate as uncoordinated vertical programs, highlighting the need for unified standards [3]. Feature modeling helps map system functionalities, while reference architecture guides domain scoping, modeling, and design through tools such as context and layered diagrams to ensure system-wide coherence and usability across subdomains [4].

Health Data Strategies

Central health data and information system strategies offer several advantages. However, it is essential to balance these advantages with considerations regarding data privacy, security, and ethical use of health information. Making sure that patient data are handled with utmost confidentiality and security is crucial in implementing such systems. Several countries have implemented national strategies for data sharing or opening, recognizing the value of open data in driving innovation, transparency, and improved service delivery, including (but not only) the health care sector. These national strategies make nonsensitive data publicly available for transparency, encouraging innovation and allowing third parties to create value-added services. Some notable examples of organizational, methodological, and technological backgrounds in selected experienced countries are shown in Multimedia Appendix 1 [5-34]. Each mentioned country and region uses data strategies and HISs carefully designed to improve health care delivery, policymaking, and public access to information.

Governance, Methodology, and Infrastructure

Data System

Regarding health data in the Czech Republic, several bodies play a crucial role in the organizational, methodological, and technological backgrounds. These bodies form a robust system based on tangible outputs by being interconnected and sharing the fundamental idea of opening up the NHIS, which can be followed by other EU member states. The close and intensive collaboration with the Digital and Information Agency (DIA), as a leading authority responsible for the digitization of public administration, is an essential support; this agency brings a national perspective and manages the processing and publication of data. Multimedia Appendix 2 documents the current status in the Czech Republic, divided into different areas needed to coordinate the health data agenda sustainably.

Organizations and Initiatives

The Ministry of Health of the Czech Republic [35] oversees health data legislation, manages departmental agendas, and sets priorities for analytical tasks in health policy. The Institute of Health Information and Statistics [36] plays a central role in collecting, analyzing, and presenting health data, while also supporting policymaking, public information, and international cooperation. The DIA [37] supports digital services; data management; standardization; and innovation across public administration, including health care. The Czech Medical Association of Jan Evangelista Purkyně [38] contributes to physician education and acts as a domain guarantor, ensuring accurate interpretation of published NHIS data.

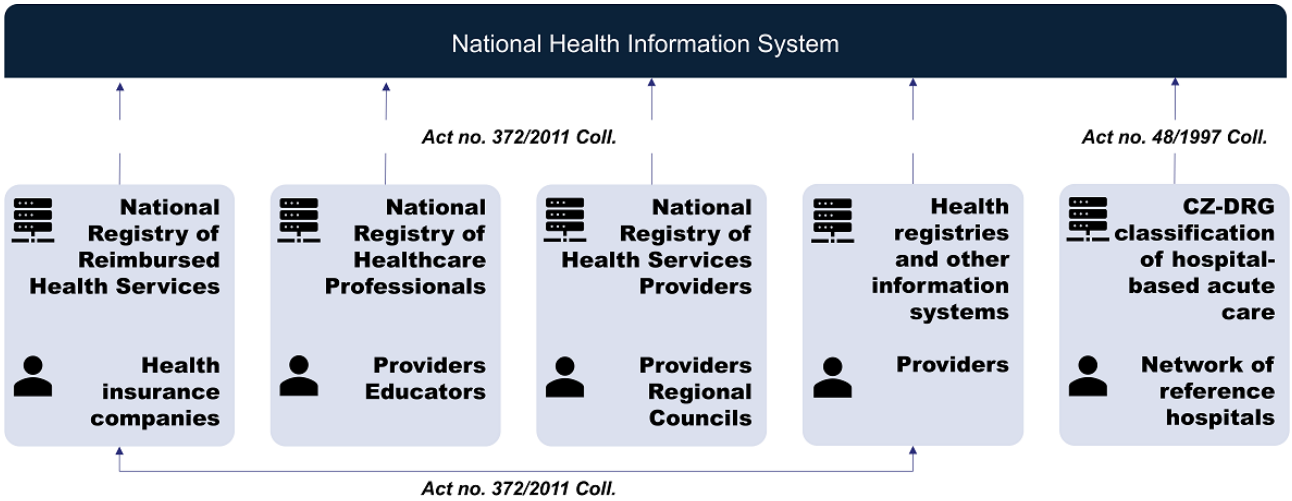
Methodological Frameworks

The methodological background determines the direction of the development of the data agenda in the Czech health care sector. The Strategic Analyses of Health Sector Needs [39] identify key challenges in Czech health care, such as aging populations, rising costs, and workforce shortages. They propose measures to improve access, quality, prevention, infrastructure, digitization, and legislation, while promoting patient empowerment and public health. The National Health Data-Sharing Strategy [40] outlines legal, methodological, and technical frameworks for secure and effective health data sharing across institutions, ensuring protection of personal data and supporting research and health care improvement. It defines

XSL•FO
RenderX

levels of data access, from open datasets to controlled research use.

IT Tools



The Czech NHIS [41] is a central platform that integrates and manages health care data, which enables information sharing among stakeholders and supports health policy, service planning, and public health monitoring with reliable and timely data. NHIS has adopted the following crucial attributes based on the Czech stakeholders' and involved teams' long-term multidisciplinary experience. The National Health Information Portal (NHIP; Multimedia Appendix 3) [42] serves as a central gateway in Czech health care, offering the public, professionals, and institutions reliable, up-to-date information on health, prevention, treatments, and patients' rights. It ensures easy access to essential content and helps users navigate the health care system effectively [43].

Digital Transformation and Data Standardization in eHealth in the Czech Republic

The digital transformation of health care, with NHIS as a core component, depends on broader national developments. The health sector builds on these national structures, extending them with health care–specific attributes and services. Health care providers generate most health data during routine care, while health insurance companies centralize these data for reimbursement. Centralized data collections, especially NHIS, go beyond routine data by adding clinical, standardization, and analytical value, enabling long-term evaluation of health care effectiveness in the Czech Republic.

Primary health care data in the Czech Republic are recorded in various provider systems, which currently lack uniform standards, although all must meet basic legal requirements. Despite the coexistence of old or obsolete and modern information systems, reporting to health insurance companies follows a structured framework. Ongoing reforms, including the EHDS and the national digitization strategy, aim to introduce standardized discharge summaries, imaging, and laboratory reports. These efforts represent a shift toward more unified and quality-assured data management. Figure 1 simplistically shows the origin of the data from the perspective of the basic NHIS components and the entities responsible for entering the data, including their quality.

Figure 1. The basic components and data providers of National Health Information System (NHIS). CZ-DRG: Czech diagnosis-related group.

National Implementation in the Czech Republic

Overview

The NHIS is being developed as the backbone for centralizing health data (Multimedia Appendix 4). It is a nationwide public administration tool that collects and processes data from the essential registries of public administration bodies, ministries, health services providers, or other persons submitting data to this system. NHIS and its infrastructure could serve as an inspiration and potential model for other EU member states. The conditions of management and access to these data are governed by the legislation in force. The following components are essential to the NHIS part:

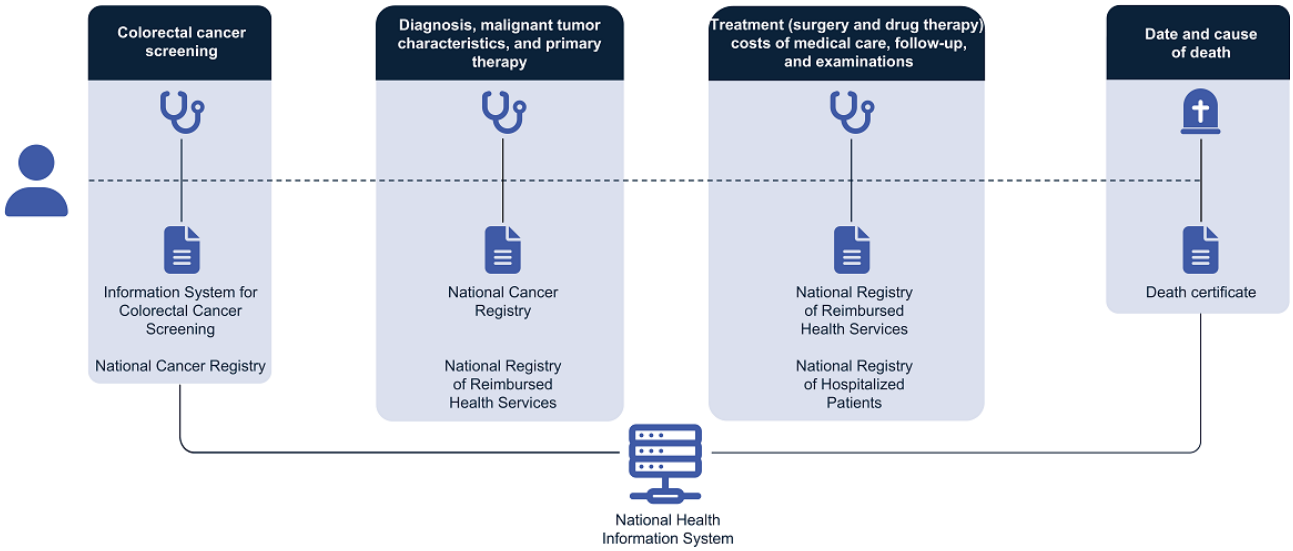
- National Health Registries (National Registry of Hospitalized Patients, National Cancer Registry, National Diabetes Registry, and others)
- National Registry of Reimbursed Health Services and the Czech diagnosis-related group classification system and its reference database
- National Registry of Health Services Providers and National Registry of Healthcare Professionals
- Data from death certificates
- Data from statistical surveys (ie, European Health Interview Survey and European Health Examination Survey)

Patient Pathway Monitoring Through the Health Care System

The following section provides a brief description of a fictitious patient's pathway [44] illustrating how the Czech health care system operates using centrally controlled data recording in the NHIS. The motivation is to describe how these patients go through the various examinations and where corresponding administrative data are recorded.

XSL•FO
RenderX

Colorectal Cancer



A man was diagnosed with colorectal cancer during colorectal cancer screening; more specifically, a malignant neoplasm of the rectum, that is, the C20 diagnosis according to the International Classification of Diseases, 10th Revision. The management of colorectal cancer involves a structured, multidisciplinary approach that follows established clinical pathways, which is briefly described as follows:

1. After the diagnosis of colorectal cancer was confirmed, the patient was referred to specialists (gastroenterologists, oncologists, and surgeons). They conducted further examinations to determine the stage of the disease and suggested the optimal course of treatment.
2. Treatment always depended on the stage and location of the tumor. It might involve surgery, chemotherapy, targeted therapy, immunotherapy, radiotherapy, or a combination of these. Treatment took place in accredited health care facilities specialized in cancer care.
3. Upon the completion of primary treatment, the patient attended regular checkups to detect any recurrence or complications early. This follow-up included regular checkups with specialists and additional examinations if necessary.

The recording of information related to the disease and its treatment in the NHIS (Figure 2) is as follows:

- The Information System for Colorectal Cancer Screening collects data on the screening tests performed, their results, and subsequent diagnostic and therapeutic procedures.
- The National Cancer Registry contains information on all newly diagnosed cancers and includes demographic information about each patient and details of diagnosis, treatment, and outcomes.
- The National Registry of Reimbursed Health Services records information on health care reimbursed through public health insurance (ie, information on the health services provided during the diagnostic process and treatment, medication, the cost of treatment, or data on the health services provider).
- The death certificate sets out basic information about a person's death, such as identification of the deceased, cause of death, any suspected unusual circumstances, and medical examination.

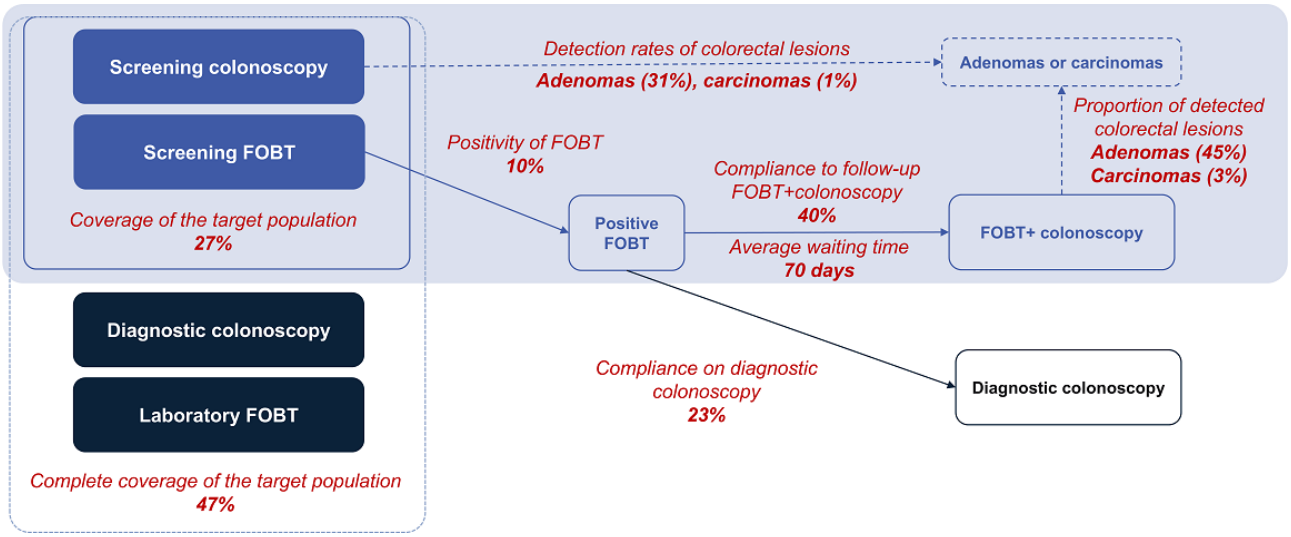


Figure 2. A pathway of a patient with cancer through the health care system.

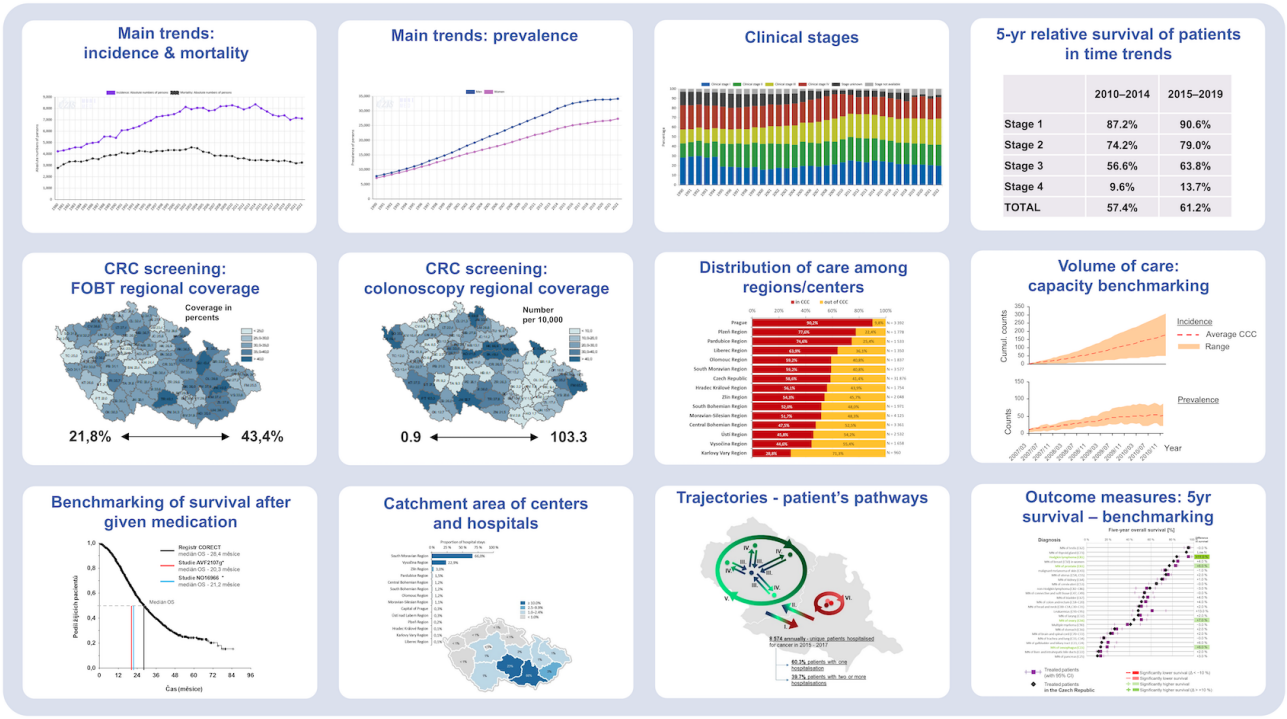
Colorectal cancer screening, introduced in the Czech Republic in 2000, is vital in reducing the population burden [45,46]. Evaluation of the National Colorectal Cancer Screening Program, based on available NHIS data, covers patient trajectories and performance indicators. Figure 3 shows the key performance indicators of the colorectal cancer screening program in the Czech Republic for asymptomatic men and women aged ≥50 years at the population level in 2021. Performance indicators are estimated from several data sources. The target population for the program in 2021 was approximately 4.1 million people. In the same year, around 44,000 preventive colonoscopies were performed (13,000 screening colonoscopies and 31,000 FOBT+ colonoscopies). Other indicators include the positivity rate of the fecal immunochemical test (10%), the average waiting time for colonoscopy (70 d), and detection rates of adenomas (31% - 45%) and carcinomas (1% - 3%). The figure also shows that a certain proportion of the Czech population undergoes other examinations related to the early detection of colorectal lesions, with complete coverage (including both screening and diagnostic examinations) reaching 47% (4.1 million people). These performance indicators for colorectal screening demonstrate the positive impact of the screening program on the population burden. However, it is imperative to continue monitoring the program to improve its quality.



XSL•FO
RenderX

Figure 3. Results of key performance indicators (colonoscopy and fecal occult blood test [FOBT] coverage, FOBT positivity, adherence to colonoscopy recommendations, detection of findings) for colorectal cancer screening at the population level in the Czech Republic in 2021.

The monitoring and evaluation system of colorectal cancer screening is a specific part of the national cancer information system, which aims to monitor and evaluate the entire cancer control continuum (prevention, screening, treatment, survivorship, and end-of-life care) and is, therefore, an essential component of the Czech national cancer control plan. Figure 4 (the full-resolution version is in Multimedia Appendix 5) shows the indicators that enable monitoring of the health care system and benchmarking of the involved health care providers.

Figure 4. Indicators of colorectal cancer management in the Czech Republic (data source: National Cancer Registry [incidence-related parameters] and Czech Statistical Office [mortality-related parameters]). CRC: Colorectal Cancer Screening; FOBT: fecal occult blood test.

Health Data Reporting

Across the mentioned NHIS components, the NHIP team has designed and developed a new data reporting module [47]. It covers various aspects of health care, considering the target audiences for which the tailored views of health data are intended. As of July 7, 2025, a total of 364 data outputs have been published. The individual output formats with a brief description and an example are listed in Multimedia Appendix 6 [48-54]. The release of data reporting represents a significant milestone in sharing health data for the public and professionals. Different data formats are available in one place, depending on the preferences of the data users.

Strategic Framework: Legislation, Publishing Principles, and Target Groups

Overview

Various comprehensive results have been developed based on two crucial documents mentioned in the Methods section: (1)

XSL•FO
RenderX

the strategic analyses of health sector needs and (2) the National Health Data-Sharing Strategy, a guiding methodological pillar fully approved by the Ministry of Health of the Czech Republic. The most central themes included (1) general provisions and compliance with national and international standards, (2) content methodology of health data access, (3) institutionalization and author responsibilities, and (4) data publication and communication channels. The effective management of access to and distribution of centralized data involves numerous steps, including standardizing the primary data from NHIS; ensuring the data are collected, followed up on, and edited efficiently; and ensuring it is published with regular updates while considering user feedback. Centralizing data can impact the entire health care system, which includes tens of thousands of health care providers, their founders, health insurance companies, specialized institutes, and more. Thus, the system must be efficient, secure, user-friendly, and easy to manage.

Legal Background

The full implementation of the NHIS provides a database for centralized data sharing. Its components now have an explicit legislative mandate. Legislation on data collection is essential to protect patient data, ensure data security, and promote transparency in health care processes. The establishment of the NHIS is covered by a legal framework, which is essential in establishing rules for collecting, processing, and sharing health information. Sharing health data between authorized entities contributes significantly to better care coordination, improving the quality of treatment outcomes, and supporting research. Given the sensitivity of health information, compliance with legislation is essential to ensure public trust in health care systems and technology. The legal framework consists of the following list of laws:

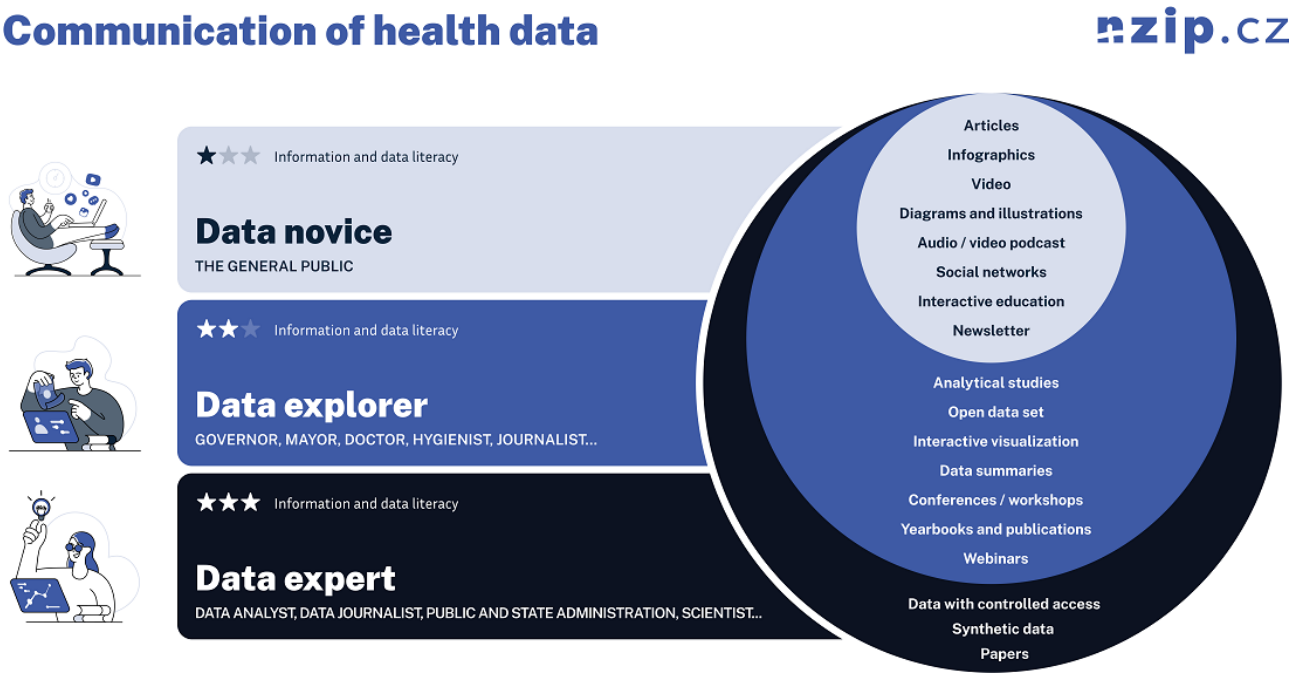
- Act No. 372/2011 Coll., on Health Services and Conditions of Their Provision
- Act No. 325/2021 Coll., on the Digitization of Health Care
- Act No. 89/1995 Coll., on the National Statistical Service
- Act No. 285/2002 Coll., on the Donation, Procurement and Transplantations of Tissues and Organs and on Amendments to Some Acts
- Act No. 258/2000 Coll., on Protection of Public Health and Amendment to Some Related Acts.

NHIS enables a comprehensive and full-fledged analytical evaluation of health services focused on all segments of care, a long-term assessment of patient trajectories in the system, and a representative review of access to care. The already approved (although not yet published) draft regulation on the EHDS will have implications for NHIS both in primary data processing and secondary data use. In primary data management, implementing EHDS can be expected to place greater emphasis on standardizing the content of electronic documentation directly with health service providers and health insurance companies. These processes will increase the information value of data and its usability.

Data Publishing Principles

The NHIS dataset design, preparation, and publishing should respect the algorithm of dataset preparation described in a numbered list below, which always respects several principal rules: (1) individual natural persons must not be identifiable, (2) individual legal persons must not be identifiable unless expressly stated by the law, (3) secondary processing must lead to the pseudonymization of the dataset, (4) the purpose of the dataset publication must correspond to the NHIS purpose, and (5) the standardized process of approval and publishing must be adhered to. The essential requirement of a comprehensive process, which this approach meets, is to ensure the necessary completeness, validity, and overall data quality [45]. The dataset publication consists of six steps describing the critical preparation and implementation phases:

1. Proposal of a dataset concept in the form of a short description, which can be raised by any entity, usually a state institution, a health insurance company, a professional (medical) society, a research institution, or an academic institution.
2. The delivered concept is reviewed from the perspective of data availability, export feasibility, design, and personal data regulations.
3. After approval, a methodology for the dataset processing is proposed (data export from central registries, data preprocessing and cleaning, analytical adjustments, and validation mechanisms).
4. The dataset is generated in an open data standardized format according to the predefined scheme, including an obligatory description with metadata.
5. Reviewing and validating the dataset and its content is a mandatory procedure before publication (a manual approach is always needed, as well as technical control to follow open data standards and best practices).
6. Publication of the final dataset in the data reporting module under the Creative Commons Attribution 4.0 International license (CC-BY-4.0).



These rules allow complete control over methodological, legislative, and technical aspects significantly affecting health data preparation and sharing. At the same time, the processes set up align with the entire ministry's strategic vision, which is based on the principles of evidence-based medicine and data-based decision-making.

Target Group Focus

Effective health communication requires identifying target groups and tailoring messages to their literacy levels regarding health, information, and data. Adapting the complexity of content, language, and format not only increases understanding and engagement but also reduces the risk of misinterpretation. For instance, younger audiences may prefer digital media, while older adults may favor printed materials. Clear communication tailored to a specific audience supports informed decisions and healthier behaviors. Figure 5 illustrates the 3 main target groups according to the expected user input knowledge level, showing the different types of health data outputs.

XSL•FO
RenderX

Figure 5. Communication target group of health data.

A summary of health data use is provided in Table 1, showing the different data formats and the primary (though not exclusive) target users for each format. The motivation is to cover the largest possible group of those interested in health data and to develop health and data literacy in the Czech Republic in the long term through published data.

Discussion

Key Lessons Learned

The Czech Republic's National Health Data-Sharing Strategy, jointly managed by the Ministry of Health, the Institute of Health Information and Statistics, and DIA, highlights several important findings. The centralization of health data through standardized national registries, electronic health records, and real-time reporting tools significantly improves health care efficiency, patient outcomes, and interoperability between health care providers, researchers, and public health authorities. The NHIP forms the backbone of data dissemination and provides interactive visualizations, open datasets, and customized data views for different users.

Privacy and security remain critical, as patient confidentiality and General Data Protection Regulation compliance directly shape data-sharing policies. To address this, the NHIS, which encompasses 61 data agendas (including national registries, prevention programs, and statistical surveys), uses advanced encryption and anonymization techniques, as well as strict access controls that enable authorized yet secure access.

The NHIS is an example of a transformative change in health care methodologies and highlights several key elements:

- Privacy and confidentiality—the protection of patient data is crucial to prevent discrimination and promote public trust and participation in health research.
- Importance for research and public health—data stratified by sex, age, education, and ethnicity are crucial for identifying inequalities and guiding targeted public health interventions (eg, World Health Organization Health Inequality Data Repository and European Cancer Information System).
- Diverse stakeholder concerns—patients, health services providers, and policymakers have different needs and expectations that must be taken into account in the design

XSL•FO
RenderX

of health data systems and the development of policy measures.
- Technological and analytical challenges—advanced technologies and sophisticated analytical methods are essential to effectively manage the complexity and volume of health data.

The digital transformation of health care in the Czech Republic, supported by the aspects mentioned in Methods (subsection: Digital Transformation and Data Standardization in eHealth in the Czech Republic), has been enhanced by new tools currently being developed and tested: a new synthetic data system (a promising innovative tool for data analysis experts to conduct sophisticated analytical studies on NHIS patient data) and artificial intelligence chatbots (which answer questions about health statistics in simple language).

Actionable Recommendations for Other European Countries

The NHIS in the Czech Republic forms the basis for designing a health care system that responds to patients' needs, uses resources efficiently, and pursues a patient-centered approach. When establishing such a robust framework for a specific area, such as health care, EU member states should focus on the following key areas:

- Compliance with regulatory and legal requirements—alignment with local, national, and international health care and legal regulations.
- Data security—protection of sensitive health data and implementation of encryption, user authentication, and access control, including a robust IT infrastructure.
- Data management and validation—ensuring the integrity and accuracy of health data, including automatic and semiautomatic control mechanisms that guarantee valid and correct data.
- Standardization—using health care standards (ie, International Classification of Diseases, 10th Revision or the Czech diagnosis-related group) and uniform lists of values among all related areas (ie, population and demography). A practical example is the shared medical record, which will enable secure access to patients' preventive care and screening data across all health care providers. Its implementation is scheduled for the end of 2025. Another example of planned standardization is the early introduction of structured and standardized discharge reports, imaging reports, and laboratory results as part of the national strategy for the digitalization of health care.
- Multidisciplinary team—appropriate composition of experts with in-depth specialist knowledge (with or without the support of subcontractors), representing all necessary professional groups (data architect, data manager, analyst, developer, web designer, communication expert, language expert, and a representative of an expert medical society) and ensuring regular internal communication.
- Support for leading institutions—all leading representatives and committees of involved stakeholders must be informed and involved in all important decisions.
- Communication and public relations—focus on the actual needs of target groups and clear presentation of data outputs, including the establishment of professional communities through conferences and workshops.
- Data outputs by target groups—provision of outputs tailored to user requirements and preferences (open data, data summaries, infographics, interactive visualizations, and synthetic data).
- User-friendliness, accessibility, and experience—the design and format of the published outputs must comply with user experience or user-friendliness rules and accessibility rules (especially for people with disabilities) and graphical and user-friendly requirements.
- Technological sustainability—minimization of technological debt and continuous development of information systems and portals based on IT trends, user behavior, and needs arising from actual use.
- Financial sustainability—efficient allocation of resources, taking into account development, maintenance, and operating costs, including process optimization, to ensure long-term cost-effectiveness.

Limitations of the Study, Especially With Regard to the Transferability of Findings

This case study examines how health data can be collected, integrated, and published at a national level. Although it is limited to one country, many of the findings are transferable to other countries, depending on the structure of the health care system, the proportion of public health insurance, and the availability of IT data. The main advantages of the Czech health care system in terms of data integration are (1) the high proportion of health services covered by public health insurance and (2) a registry in which data on these health services are centralized. This enables system-wide evaluation and analysis of diagnoses, areas of care, medications, equipment, procedures, and their reimbursement. On the other hand, there are considerable differences in the complexity of data within individual agendas and topics. Although administrative data on health services reimbursed from public health insurance cover the entire spectrum of care, procedures, and medications, clinical information is generally lacking. This is only recorded for selected care segments or diagnosis groups in specialized registries (eg, cancer care, cardiovascular surgery, and blood donation). Given the scope and nature of the data, all interpretations and conclusions drawn from NHIS data should always be made with caution and supported by sound professional knowledge and expertise, taking into account other integrated health data systems. Another significant limitation is the quality of the input data and the lack of motivation on the part of the responsible institutions to enter it correctly and completely into these systems. An example of this is the National Cancer Registry, where incomplete entry of clinical stages is often a major problem.

Conclusions

The integration of data and information systems into the Czech Republic's national health data strategy can transform health care by improving patient outcomes and optimizing resource use, for example, through improved disease surveillance, targeted prevention (eg, colorectal cancer screening), and more efficient health care planning based on integrated patient data.

XSL•FO
RenderX

To reap these benefits, policymakers have created robust interoperable infrastructures that enable real-time decision-making and evidence-based planning. Standardization across the health sector is crucial to ensure seamless communication between stakeholders and prepare for participation in EHDS, which requires legal, technical, and methodological alignment with international frameworks. The Czech Republic's NHIS is an important infrastructure for alignment with the EHDS. Successful integration into the EHDS requires the modernization of the NHIS so that it functions as a system compatible with European standards for the secure sharing and secondary use of health data. With its universal health care model and strong digital infrastructure, the Czech health care system is well positioned to take a leading role in regional efforts to transform digital health care. To fully exploit these advantages and set an example of sustainable data-driven health care governance in Europe, further progress is needed in the areas of infrastructure, harmonization of legislation, and data literacy and awareness among the population.

Acknowledgments

The authors were supported by the following grant projects: (1) systematic education and increasing health literacy through the National Health Information Portal (CZ.03.02.02/00/22_005/0001137), (2) raising awareness via the National Health Information Portal (CZ.03.4.74/0.0/0.0/15_025/0016090), (3) developing models to predict regional health care needs and related economic and personnel indicators (CZ.03.02.02/00/22_046/0002180), (4) strengthening lung cancer screening in Europe, and (5) comprehensive information facilities to improve the quality of cancer screening programs within the National Screening Center (CZ.31.8.0/0.0/0.0/23_075/0008430).

Abstract

The health care industry is currently going through a transformation due to the integration of technologies and the shift toward value-based health care (VBHC). This article explores how digital health solutions play a role in advancing VBHC, highlighting both the challenges and opportunities associated with adopting these technologies. Digital health, which includes mobile health, wearable devices, telehealth, and personalized medicine, shows promise in improving diagnostic accuracy, treatment options, and overall health outcomes. The article delves into the concept of transformation in health care by emphasizing its potential to reform care delivery through data communication, patient engagement, and operational efficiency. Moreover, it examines the principles of VBHC, with a focus on patient outcomes, and emphasizes how digital platforms play a role in treatment among tertiary hospitals by using patient-reported outcome measures. The article discusses challenges that come with implementing VBHC, such as stakeholder engagement and standardization of patient-reported outcome measures. It also highlights the role played by health innovators in facilitating the transition toward VBHC models. Through real-life case examples, this article illustrates how digital platforms have had an impact on efficiencies, patient outcomes, and empowerment. In conclusion, it envisions directions for solutions in VBHC by emphasizing the need for interoperability, standardization, and collaborative efforts among stakeholders to fully realize the potential of digital transformation in health care. This research highlights the impact of digital health in creating a health care system that focuses on providing high-quality, efficient, and patient-centered care.

Introduction

In the last few decades, the health care landscape has undergone changes due to the rapid advancement and integration of technology. This technological progress has transformed how health care is managed, both for individuals and on a scale, by providing insights into patient health and experiences through digital recording and data collection methods.

Nowadays these advancements in technology are collectively known as “digital health.” According to the Food and Drug Administration, digital health encompasses a range of technologies, including mobile health (mHealth), health information technology, wearable devices, telehealth, telemedicine, and personalized medicine [1]. The adoption of health technologies is increasingly common in the health care industry, offering prospects for improved diagnostic accuracy, treatment options, and overall health outcomes [2].

These innovations in health are driving a shift toward a value-based approach [3]. This places patients at the center of care delivery and marks a departure from health care models. However, navigating the complex digital health ecosystem poses challenges for transformations in health care.

Digital Transformation

Digital transformation refers to “a process that aims to improve an entity by triggering significant changes to its properties through combinations of information, computing, communication, and connectivity technologies” [4]. Digital transformation is reforming the modern-day health care system. Propelled by the COVID-19 pandemic, we have witnessed a surge of technology innovation to assure continuity in care delivery [5].

However, in the context of the health industry, digital transformation not only refers to managing clinical data flows

XSL•FO
RenderX

and using advanced technologies but also a wider philosophical framework of business and operation transformation via digital innovations and technologies to increase stakeholder satisfaction. Its aim goes beyond digitizing the organizational environment to facilitate the use of data and leverage the value of data insights for improving clinical governance and performance evaluation, supporting clinical decision-making and operation efficiency, as well as ensuring the highly efficient utilization of health resources [5]. Ultimately, the process of digital transformation for the health care system needs to consider how to increase the quality of care and patient satisfaction via enhancing clinical data communication and patient engagement [6].

The digital transformation of the health care industry has leveraged a range of digital solutions in each part of the patient journey, including patient assessment, treatment, and management. These digital innovations arose out of the need for treatment and patient care, but toward multidimensional well-being and multi-disciplinary health support. The digital transformation enables health care professionals and other stakeholders in the health system to accomplish value-based health care (VBHC) more efficiently and sustainably [7].

Value-Based Health Care

VBHC, defined as a health care activity that highlights value as patient-centric outcomes over the cost invested to treat patients [8,9], is one of the dominant trends in the global health industry [3,10,11]. Due to the high costs and growing inefficiency of health care in many nations, as well as the growing agreement that the existing health care paradigm is essentially unsustainable [12,13], advocating and implementing a VBHC model has become a strategic imperative for many health systems [14,15].

What is value? A definition proposed by the European Commission broadens the interpretation of "value" from a single variable based solely on monetary value in the context of cost-effectiveness to a more inclusive concept. The proposed definition of "value" includes the following four components [16]: (1) allocative "value": equitable distribution of resources across all patient groups; (2) technical "value": achievement of the best possible outcomes with available resources; (3) personal "value": appropriate care to achieve patients' personal goals; and (4) societal "value": contribution of health care to social participation and connectedness.

A system-level model and framework may be necessary to determine "value" within the many components connected by complex processes inside a health care system [17].

Under VBHC, the focus shifts from volumes (the number of physician visits, hospitalizations, procedures, and tests) to outcomes (the patients' prioritized health outcomes, such as an increase in functional independence and quality of life [18]. With a focus on the quality of patient care, the aim is to reduce the time spent in the health care sectors, avoid the development of chronic diseases, and minimize deterioration of medical conditions [18]. VBHC empowers patients and enables caregivers to provide better care at a lower cost, resulting in benefits for all stakeholders: patients, providers, payers, suppliers, and society [18].

Patient-Reported Outcome Measures

An important element of VBHC is measuring outcomes that matter to patients, including their symptoms, functionality, and their satisfaction with their health care experience. This led to the introduction and adoption of patient-centered outcomes assessments, which take into account aspects of cure and survival, as well as recovery and quality of life retained [19,20]. A patient-reported outcome (PRO) is "an outcome reported directly by patients themselves and not interpreted by an observer." PROs bring the "patient's voice" to the care journey and identify conditions or symptoms that matter the most to a patient's daily life and quality of life [21].

To measure PROs, instruments known as patient-reported outcome measures (PROMs) have been developed. These instruments are typically self-reported questionnaires that measure symptom burden, functional status, health-related quality of life, and health-related behaviors such as anxiety [22]. They are generally categorized into 2 groups: general health-related quality of life PROMs and disease-specific PROMs [22]. General PROMs focus on general well-being, mental state, and quality of life across a range of medical conditions [22], whereas disease-specific PROMs capture a combination of symptom severity and impact resulting from a specific condition or treatment [23].

PROMs are an essential part of VBHC because they measure what matters most to patients, and this drives the health care system to take a more holistic and comprehensive view of the physical, mental, and social impacts of illness. Research has found PROMs can be used in different ways to contribute to VBHC, such as enhancing patients' and clinicians' communication for identifying treatment plans; quantifying and monitoring symptoms and illness impact on life; reflecting patients' preference on treatment and care; evaluating the quality of care and improvement of health; facilitating patient adherence and satisfaction with care; and promoting informed utilization of health resources and services [24].

Traditionally, PROMs were administered and distributed on paper throughout a patient's care journey, requiring manual efforts to distribute, collect, and calculate patient scores. This can be a time-consuming and inefficient process, with additional administrative burden for clinical teams. However, web-based software, platforms, and apps are now being used for end-to-end management of PROMs, from automation of distributing, capturing, analyzing, and reporting these data. Features include automatic scoring of PROM data, interpretive dashboards and reports for clinicians, alerts to notify clinical teams of patients' acute needs for symptom management, integration with electronic health records, and notification reminders tailored for patients [25].

One example of a fully digital PROMs system is the Symptom Tracking and Reporting (STAR) system used to assess a patient's functional recovery after radical prostatectomy at Memorial Sloan-Kettering Cancer Center [26]. The web-based

XSL•FO
RenderX

system is used to collect PROMs on urinary function, sexual function, bowel function, and overall quality of life. Patients are automatically emailed a unique link with access to a web-based portal for symptom reporting. Clinicians and patients can view numerical and graphical summaries of patients' reported PROM scores, with prediction models of a patient's future functional status. Tell Us, a web-based system designed for patients with advanced cancer in palliative care, has similar functionalities to STAR, but with the additional ability to trigger real-time alerts to clinical teams when intervention is necessary. The field is growing rapidly [5,27].

Previous studies had confirmed the effect of PROMs on patients in tertiary hospitals [28,29]. A study in a tertiary care center among patients with septoplasty and functional endoscopic sinus surgery found that due to the high response rates, PROMs that use mobile digital patient engagement platforms could effectively monitor postoperative outcomes [30]. Another study in a tertiary care center specialized in skull base diseases also showed that administering digital PROMs seems appropriate for evaluating health-related quality of life in skull base disorders [31].

Research Gaps and Study Aims

In conclusion, the integration of digital transformation, VBHC, and PROMs had been discussed in the previous study [32-34]. However, few studies had ever investigated the specific role and impact of digital health solutions in driving VBHC [5], as well as specific clinical efficiency gains and resource savings from the adoption of digital health technologies [35] and the specific ways and effects of how digital health solutions could be used to personalize treatment [36,37].

Thus, this article aimed to explain the role that digital health solutions played in advancing VBHC. It examined the challenges that came with adopting these technologies and highlighted the work of health startups that were committed to assisting health care organizations in their shift toward value-based care models.

Key Challenges

Although digital transformation facilitates the transition of traditional health models toward VBHC, implementation and adaptation are also needed from the many different stakeholders [38]. A shift in the overall cultural and behavioral environment requires a transition in clinical governance, management, and policy making, which in turn needs the joint contributions of health care professionals, payers, policy makers, caregivers, and, crucially, patients.

One of the key challenges of implementing VBHC in a health system is to facilitate and incentivize stakeholders to commit to capturing and reporting PROs along with clinical outcomes. Taking insights generated from PROs into decision-making processes (eg, care plan development, selection of treatments or therapies) unleashes the power and value of PROs and other patient-generated health data (PGHD), such as objective data captured by wearable devices. However, the applications of PROs and other PGHD into routine patient care will lead to a disruption of the health care governance and clinical practice.

Despite a growing consensus on the utility of PROs in clinical care, most of their applications remain in research or academic initiatives [39]. One major barrier to integrating PROs into clinical practice is the lack of standardization of how PROs are measured [40]. Measurement of PROs can range from unstructured patient diaries to structured clinically validated questionnaires, such as PROMs. More sophisticated questions, such as when to disseminate PROMs to patients, how often to send these PROMs, and what data analysis should be done with the data, are usually raised once the appropriate PROMs are identified for a target patient group. These questions highlight the importance of standardizing the method of PROMs selection and implementation.

Even if there are incentives and standardized PROMs, leadership, resources, and support are needed to encourage current health systems and physicians to change. Introducing an additional workflow of PRO data collection and application may present significant increases in workload for health care providers. This is where a professionally developed and validated digital solution can play its role in the process of digital transformation of the health system toward VBHC. Not only can digital solutions reduce the burden of collecting and using PRO data, but they should also support health care providers in their routine workflow (eg, enabling patient screening, follow-up care, support of self-management, etc), which will further incentivize health care providers to use the platform.

Digital Health Approach

Digital health innovators are at the forefront of advocating for the adoption of VBHC, particularly in addressing the challenges of real-world implementation. Their mission is to assist health care organizations globally in transitioning to a VBHC model by providing tools that promote a patient-centered care approach.

Typically, digital solutions involve cloud-based Software as a Service digital platforms with automated and streamlined digital care pathways, reducing manual and costly processes. Digital care pathways use digital technologies to coordinate the monitoring, engagement, and support of patients throughout their care continuum, consolidating these processes into a unified system that collects, analyzes, and manages PGHD, including PROs and wearable or medical device data. They also deliver educational information to patients and providers.

Moving beyond traditional electronic data capture systems and generic customer relationship management platforms, digital platforms can seamlessly combine clinical and non-clinical data through integration with electronic medical records and clinical workflows. Thus, with a fully configurable, disease and device-agnostic platform, health professionals are equipped with a single, patient-centric system for managing communication, data collection, and analysis, providing real-time actionable information and insights to inform and improve patient care and management. The digital care pathway enhanced access to patient information and accelerated the provision of early specialist care [41]. Previous study had confirmed that digital transmural care pathway was feasible and

XSL•FO
RenderX

beneficial in daily clinical care for patients with lung cancer [42].

For each medical condition and treatment, there are four broad phases in developing value-based digital care pathways: (1) defining schedules, (2) content creation, (3) automated patient engagement, and (4) insight generation. In developing new digital care pathways, they assist health care organizations in identifying areas of digitization that best benefit individual organizations and align with best practice recommendations, such as the frameworks set up by the International Consortium for Health Outcomes Measurement (ICHOM). Every touchpoint within a patient's care journey is digitally transformed and automated from their admission to discharge, including communication sent out to patients, the type and frequency of health data collected, the educational material delivered, and reports to be generated. For each digital interaction, a patient's health data is automatically captured and presented with actionable insights, ensuring providers have access to the right information for delivering high-quality care.

All 4 key components of value (allocative, technical, personal, and societal) can be enhanced through adopting digital health platforms [18]. The digital platform helps in the following ways.

The first is by improving data collection. Digital innovations transform the way data is collected, shared, and analyzed, significantly enhancing clinical decision-making, improving quality of care, and reducing health care costs [43]. The digital platform enables efficient collection of patient-generated data (eg, PROMs) through automation, thus overcoming barriers like time constraints and resource limitations. This leads to a broader scope of data collection beyond clinical data, reducing the time spent administering assessments. A systematic review found that electronic platforms simplified the implementation of PROMs in the lung cancer daily clinic [44].

The second is by enhancing clinical outcomes. To improve clinical health outcomes, both health care providers and patients need access to specific tools for the collection and analysis of patient data: assessment forms, wearables, or medical devices. These specialized tools are being used more and more to identify health risks and support diagnosis, treatment, and monitoring of both health and disease [45]. In this way, health care providers gain a holistic understanding of each patient's unique health status and needs, leading to better-informed diagnosis and treatment decisions.

The third is by improving the performance and standardization of PROMs. Addressing the challenge of standardization in value-based care is crucial. The digital platform aids in implementing a structured and standardized approach to collecting and processing PROMs. A digital platform can allow for detailed measurement of recovery by regularly collecting PROMs, which can be used clinically to support recovery. Using a digital platform makes it possible to automate PROM data collection and characterize recovery across multiple domains, and this approach is likely to be implementable in clinical settings [29]. By adopting digital and automated condition-specific care pathways, health care providers can obtain high-quality data that drive personalization of patient diagnostic and treatment plans and achieve cross-organizational benchmarking for performance and quality of care improvement.

Case Example: Implementation of Digital Platform for PROMs

Patients with lung cancer undergoing chemotherapy commonly experience a range of symptoms that vary in severity, with some indicative of critical oncological emergencies. To monitor patients' symptoms and progress, traditional care processes can take up to 30 minutes, which includes having a nurse practitioner call patients for a weekly check-in, manually noting and transferring this information to an electronic medical record, and then working through required interventions. However, this is a time- and resource-intensive process, inefficient for the management of increasing workloads and patients.

Based on the following reasons, a hospital in Brisbane was selected to work with. First, a tertiary hospital in Brisbane, Australia, was selected as the case study site based on the actual needs and achievements of the hospital in the application of digital health platforms. There was a high demand for the management of postchemotherapy side effects in patients with lung cancer at this hospital, and it was already practically applying the digital platform for monitoring and intervention, which provides a realistic basis for the study. Second, the hospital's challenges in managing postchemotherapy side effects, such as inefficiencies in traditional methods that result in high time and resource costs, make the hospital's real-world problem consistent with the study's goals on how to improve health care efficiencies and patient outcomes through digital health innovations based on PROMs. Working with the hospital, the authors used a digital health platform to monitor and address postchemotherapy side effects in patients with lung cancer. The platform was used to configure a digital care pathway that enabled the automation of the collection and analysis of 12 key posttreatment chemotherapy-related symptoms using PROMs, with real-time alerts when oncological emergencies were reported. This initiative has had positive impacts for both clinical teams and patients: improved clinical efficiencies, patient outcomes, and patient empowerment.

Capturing patient responses allowed clinical teams to effectively analyze patient outcomes, contributing to improved and personalized treatment decisions. Clinical teams have noted significant time and cost savings, with an average reduction of 10 posttreatment phone calls, spanning 20 minutes per call, to identify patients requiring clinical interventions [46]. Improved operational efficiency has allowed the oncology team to handle an increasing workload while maximizing patient outcomes.

Additionally, real-time data on patient conditions improve clinical decision-making and reduce unnecessary hospitalization and travel costs for patients. Clinical teams have noted that employment of the digital health platform has allowed the effective identification of patients suitable for treatments without hospital consultations compared to those requiring a doctor's review. By including patients' voices in the decision-making process, it empowers patients to actively engage in their

XSL•FO
RenderX

treatment plans and feel confident in reporting their outcomes using the digital service.

To conclude, at the hospital in Brisbane, the digital platform enabled clinical process optimization by automating the monitoring and handling of chemotherapy side effects. The use of this digital platform demonstrated that patient care could be significantly more efficient and effective by collecting and analyzing patient data in real time. The digital platform not only reduced the reliance on traditional phone checks but also provided a real-time alert system that quickly identified patients in need of urgent care. This approach highlighted the practical application of digital health solutions in VBHC and their contribution to improving patient outcomes. Meanwhile, the case hospital reduced phone check-in time per patient through the digital platform, reducing the number of calls to be handled from an average of 10 to 0. In addition, the clinical team was able to more efficiently identify and prioritize patients requiring urgent intervention. These improvements not only increased efficiency but also saved significant time and resources, allowing the hospital to handle a larger patient load. This illustrated how digital health tools could help hospitals improve clinical efficiency despite limited resources. Furthermore, the digital platform enabled the hospital's oncology team to provide more personalized care through real-time data analytics that allowed them to adjust treatment plans based on each patient's specific symptoms. This customized approach to treatment helped optimize outcomes for each patient and improve overall quality of care. It illustrated how digital platforms could support VBHC through a personalized approach, enhancing the precision and effectiveness of patient care.

Contribution

This paper could make several important contributions to the field of VBHC and the knowledge base of digital transformation in health care. First, it enhanced understanding of digital health solutions by analyzing the roles of various digital health technologies, including mHealth, wearable devices, telehealth, and personalized medicine. This study clarified how these innovations contributed to the goals of VBHC. It provided a nuanced discussion on how these technologies could improve diagnostic accuracy, expand treatment options, and enhance overall health outcomes. Second, this research identified key challenges in the implementation of VBHC, such as the need for stakeholder engagement and the standardization of PROMs. It provided a detailed discussion of these challenges and proposed potential solutions, thereby offering practical guidance for overcoming barriers to VBHC adoption. Third, this study provided empirical evidence of digital platforms through real-life case studies. This study demonstrated the tangible impacts of digital platforms on health care efficiencies, patient outcomes, and patient empowerment, and the case example offered concrete evidence of how digital health solutions could facilitate the transition to VBHC models and improved care delivery.

Overall, this paper contributed valuable insights into how digital transformation and VBHC could be effectively integrated to create a health care system that prioritizes high-quality, efficient, and patient-centered care.

Future Directions

Digital solutions have played a growing role in the accomplishment of VBHC. In the near future, digital solutions with strong interoperability and accreditation from academic or standardization development bodies (eg, ICHOM) will have their competitive advantages. With the increasing number of digital solutions and systems to be used by a health system, interoperability plays a vital role in determining how easily a digital solution can work across different systems. Working closely with academic or standardization development bodies will ensure digital solutions are more usable and adaptable by health care providers, with measures developed or codeveloped by providers and validated in real-world settings. Due to the lack of standardized regulatory and coding standards with the provision of PROMs, revision and development of policies to support standards for PROMs usage and interoperability need to be better developed for the successful adoption of value-based models. With better regulation and policies in place, this would encourage more funding opportunities for value-based initiatives. While it has been a complex health care process, we have seen the accelerated growth and adaptation enabled by the COVID-19 pandemic [47], with many more untapped needs to be addressed.

Conclusions

The paradigm shift toward VBHC represents not merely a shift in health care delivery metrics but also a fundamental transformation in how health care value is perceived and measured. Central to this transformation is the role of digital technology, which has become a cornerstone in the global pursuit of VBHC.

Digital transformation in health care involves far more than just the adoption of new technologies. It encompasses the standardization of measures to ensure consistency and comparability across different systems and regions. This standardization is crucial for accurately assessing and comparing health care outcomes, which is a fundamental aspect of VBHC. Additionally, innovation in data applications plays a pivotal role. The ability to effectively collect, analyze, and use vast amounts of health data can drive improvements in patient care, enhance operational efficiency, and inform policy decisions.

Engagement with stakeholders is another critical element in this transition. VBHC requires the active participation of all parties involved in health care, including providers, patients, payers, policy makers, and technology developers. Each stakeholder brings unique insights and expertise, contributing to a more holistic approach to health care reform. Collaborative efforts are essential in addressing the challenges and leveraging the opportunities presented by digital transformation.

The execution of digital transformation in health care offers numerous opportunities for stakeholders to work together toward a common goal. This collaboration can lead to the development of innovative solutions, the optimization of resource allocation, and the delivery of care that truly meets the needs and expectations of patients. Moreover, it can ensure that the benefits

XSL•FO
RenderX

of VBHC are realized broadly, leading to tangible improvements in health care outcomes, patient satisfaction, and system sustainability.

In conclusion, the journey toward VBHC is complex and challenging, yet it is filled with immense potential. By embracing digital transformation and fostering collaboration among all stakeholders, the health care sector can achieve a system that not only values quality over quantity but also delivers care that is equitable, efficient, and truly patient-centered. The future of health care lies in harnessing the power of digital innovation to create a system where value and quality are at the forefront of every decision and action.

Abstract

Precision medicine involves a paradigm shift toward personalized data-driven clinical decisions. The concept of a medical “digital twin” has recently become popular to designate digital representations of patients as a support for a wide range of data science applications. However, the concept is ambiguous when it comes to practical implementations. Here, we propose a medical digital twin framework with a data-centric approach. We argue that a single digital representation of patients cannot support all the data uses of digital twins for technical and regulatory reasons. Instead, we propose a data architecture leveraging three main families of digital representations: (1) multimodal dashboards integrating various raw health records at points of care to assist with perception and documentation, (2) virtual patients, which provide nonsensitive data for collective secondary uses, and (3) individual predictions that support clinical decisions. For a given patient, multiple digital representations may be generated according to the different clinical pathways the patient goes through, each tailored to balance the trade-offs associated with the respective intended uses. Therefore, our proposed framework conceives the medical digital twin as a data architecture leveraging several digital representations of patients along clinical pathways.

Introduction

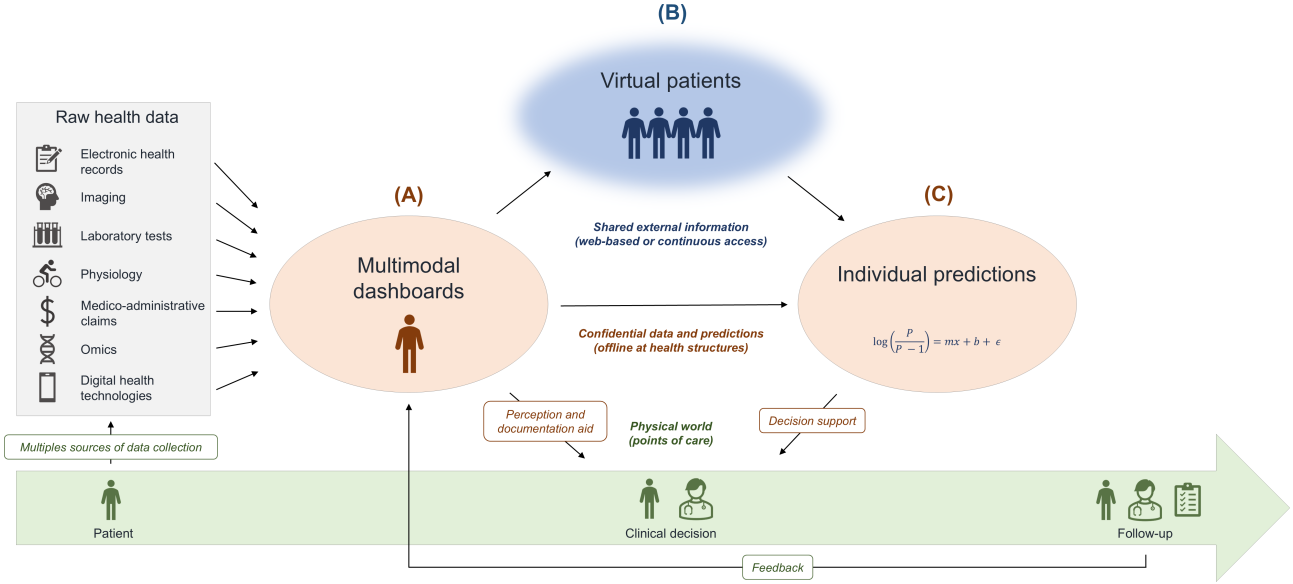
Much has been published about digital twins as a landmark of the digital transition of medicine and as a technology to address the uniqueness of patients in a precision medicine framework [1]. The digital twin concept combines engineering technologies attempting to represent objects digitally while maintaining a continuous connection with the physical object in the real world [2]. The manufacturing industry uses digital twins to model physical assets computationally to optimize procedures along their life cycles such as in silico prototyping, production of regulatory evidence, and predictive maintenance [3]. However, in health care, the term “digital twin” may refer to 2 distinct frameworks. One is industrial and aims at representing medical devices digitally and their physiological environments [4]. The other is medical and aims at representing patients digitally in the context of a medical procedure [5]. As such, medical digital twins embody a paradigm shift in the intentionality of health data, from health records to actionable digital representations of patients supporting various data science applications in health (Figure 1).

XSL•FO
RenderX

Figure 1. Intended data uses related to digital twins in precision medicine. They rely on various ways of representing patients digitally. Each one may be designated as a "digital twin" in the literature, yielding ambiguity.

Representing patients digitally involves 2 major challenges compared to engineering: the complexity of the represented system and the sensitivity of patients' data. As the term "digital twin" gains popularity, confusion arises from its use to designate a wide range of data usage in health [6], summarized in Figure 1. As mentioned, from an industrial viewpoint, it may designate models of medical devices along their product life cycle [7] or patients in a virtual cohort to run in silico trials [8]. From a management viewpoint, it may designate software agents for care coordination during trauma management [9]. In a patient-centric view, it may designate a multi-stakeholder documentation system, enabling health care providers (HCPs) and patients to visualize multimodal data comprehensively [10]. In data management, it may designate the most similar record to a patient found by a matching algorithm in a reference database [11,12]. In modeling, it may designate a biomechanistic model of a body part, such as circulatory systems [13,14] or digital hearts [15]. Such broad usage of the term led to ambiguity about the nature of a medical digital twin in practice.

Here, we propose a framework for the implementation of medical digital twins from a data-centric perspective. We explain why digital representations of patients are limited due to technical and regulatory constraints. We propose three main families of digital representations (Table 1 and Figure 2) and outline their purposes and limitations: (1) multimodal dashboards integrating raw health records at the points of care to assist with perception and documentation; (2) virtual patients, which provide nonsensitive data for collective secondary uses; and (3) individual predictions that support clinical decisions along clinical pathways and medical procedures. We conclude that a single digital representation of patients cannot support a medical digital twin. Instead, we recommend designing data



XSL•FO
RenderX

architectures, leveraging multiple digital representations of the same patient, whose characteristics would be determined by predefined data uses.

Table . Definition of the 3 types of digital representations.

Digital representation	Definition	Purpose	Limits
Multimodal dashboard	Comprehensive visualization of multimodal data	Perception and documentation aid	• Only retrospective • Regulatory obstacles to data sharing
Virtual patient	Computer-generated observations	Collective value	• On-purpose generation • Loss of the connection to the original patient
Individual prediction	Results of predictive analytics and the input preprocessed data	Clinical decision support	• Need of data preprocessing • Typically instantiated once

Figure 2. The proposed medical digital twin framework is a data architecture leveraging 3 main families of digital representations of patients. Patients are encountered at points of care (green timeline). Their data are collected in different records from multiple stakeholders (physicians, nurses, patients, etc) and modalities of investigation. These data are raw materials to be refined into different digital representations with different values. (A) The comprehensive visualization of patient data into multimodal dashboards may provide perception and documentation aid. Such data are strictly personal and confidential (orange). (B) Virtual patients may be generated as proxies of sensitive datasets to share their information content as anonymous data (blue). Careful trade-offs about utility and privacy make them useful for collective secondary uses such as the development of predictive analytics. (C) Individual predictions enrich multimodal dashboards with external information provided by predictive analytics. This data architecture also enhances follow-up by structuring the collection of data during the procedures of the corresponding clinical pathways.

Multimodal Dashboards to Provide Perception and Documentation Aids

Definition and Purpose

The first family of digital representations is the multimodal dashboard. It fetches the raw health records of a patient at the point of care from various data modalities and disparate sources across an institution's information system or a national health system. These sources may be electronic health records (EHRs), imaging, laboratory tests, physiological tests, medico-administrative claims, and more recently, telemedicine through digital health technologies. The latter may include wearable medical devices and web platforms to collect patient-reported outcome measures. The comprehensive collection of these modalities of data into multimodal dashboards aims to provide HCPs with actionable visualizations to aid their perception of a patient's health status and history (Figure 2A).

Capture of Deep Phenotypes

The state-of-the-art digital representation of patients is a set of documents. Typically, general-purpose EHRs (also called "documentation systems") only capture medico-administrative, treatments, or diagnosis codes in a structured fashion. The history and phenotypic details of the patients are captured as text data from documents and clinical notes, despite efforts to encode them into interoperable concepts [16,17]. This limits dashboards to medico-administrative timelines. Specialized EHRs encourage comprehensive structured data collection, also known as deep phenotyping [18]. Their dashboards can thus provide individual timelines relevant to particular diseases, showing trajectories of specialized concepts (eg, a disability rating scale or a specific biomarker) and histories of

XSL•FO
RenderX

disease-modifying treatments. For patients with multiple sclerosis (MS), this is featured by the European Database for Multiple Sclerosis (EDMUS) and Multiple Sclerosis Documentation System 3D (MSDS 3D) [19,20]. The structured data collection about key features of MS diagnosis and follow-up enables them to provide neurologists with summary timelines. The collected data also feed the French and German national MS registries, respectively. Disease registries are currently an invaluable tool for clinical research as they enable retrospective cohort studies to be performed on high-volume databases with specialized concepts that could not be extracted from general-purpose EHRs [21-23]. A limit of the "registry era" is that patients are typically represented only in tabular data. It is a loss of granularity because it requires HCPs to extract the features from raw imaging and signal data. It may also aggregate the information such as representing a clinical phenotype as a 1D disability scale rating. The active data collection yields a problematic amount of missing data, especially during outpatient follow-ups. As such, completion and data quality management by research assistants is usually required.

Navigation of Raw Multimodal Data

Multimodal dashboards aim at fetching data passively and provide innovative interfaces. The MS BioScreen is an iPad (Apple Inc)-based dashboard illustrating the passive integration of the clinical, biological, and raw imaging data relevant to the assessment of patients with MS [24]. This academic software fetched data collected for the EPIC cohort at the University of California, San Francisco. In addition to the specialized individual timeline, neurologists could navigate the different modalities of raw data (imaging, functional tests, genetics, etc) through the touchscreen to obtain a comprehensive view of the patient's status. Likewise, the navigation of 3D reconstructions of imaging data (sometimes called "digital clones" [25]) may support surgery planning through augmented reality [26] or robot-assisted procedures [27]. Current limits of secondary data collection include the lack of interoperability at the scale of national health systems [28]. There are efforts to develop "EHR-agnostic" platforms such as BRIDGE (University of California, San Francisco) [29]. It relies on interoperable standards to first fetch data from multiple sources and then provide customizable clinic-specific dashboards implemented as Substitutable Medical Applications and Reusable Technologies (SMART) on Fast Healthcare Interoperability Resources apps. Efficient and reliable data linkage between the various sources is critical to synchronize the records [30].

Management by Multiple Stakeholders Through Connectivity

Interoperable web-based records promise to enable multiple stakeholders to access dashboards and to contribute to the data collection along with patient follow-up. In a participative approach, patients themselves may visualize their data to support their self-management, as proposed by the open version of the MS BioScreen project [31]. Medical procedures may be continuously monitored by collecting data streams, either during a surgery procedure to give real-time feedback to the operator or along so-called "integrative digital clinical pathways" for outpatients [32]. For instance, data integration from multiple devices has been developed as an agent-based care coordination framework along a clinical pathway of severe trauma management [9]. Process-"digital twins" were developed as web microservices collecting data from the prehospital and in-hospital phases and making it accessible to the different stakeholders through their respective software agents in a multi-agent system environment. In a quality management approach, the data collection about medical procedures through MSDS 3D integrates the concept of digital clinical pathways. Its interface generates dynamically a quality matrix according to the patient's diagnosis and prescriptions [10]. Quality matrices are visual summaries derived from a set of checklists completed by all relevant stakeholders. They later support the optimization of the clinical pathways.

Summary and Limits

Therefore multimodal dashboards would be the perceptive side of the medical digital twin framework and would support the connectivity between the twin and the patient. One patient's data could be displayed by multiple dashboards, each one adapted to the role of each HCP in the relevant clinical pathway. The first limit would be their retrospective nature as external information is needed to give prospective insights and support decisions [33]. The second limit is the regulatory obstacles to sharing patient data, especially for other purposes than the care of the respective patients. Concerns about privacy and consent-restricted secondary uses of patient data have led to regulatory frameworks such as the general data protection regulation in Europe [34]. Patient data are personal, sensitive, and parsimoniously collected from and for the patient. Their collection remains centered on their primary use (ie, personal care), disregarding other secondary uses in research or clinical decision support for other patients. As a consequence, the primary personal and secondary collective uses of data are split (Table 2). The first may be done individually and confidentially. The second relies on the transfer of pseudonymized data between health care and research structures. However, medical practice in a medical digital twin framework would require continuous access to external information through reference data and predictive analytics (Table 2). Data sharing is still underdeveloped in health care because of the loss of usage control and because pseudonymized data only prevents direct reidentification [35].

XSL•FO
RenderX

Table . Key distinctions made by the proposed data architecture.

	Concept 1	Concept 2
Data processing	Data collection (full granularity)	Data preprocessing for a predictive analytic (formatted for specific analytics)
Data exchange and access	Data transfer (restricted exchange between 2 organizations)	Data sharing (continuously accessible data)
Data usage (and values)	Primary (personal care)	Secondary (research and care of others)
Data privacy	Pseudonymized (deidentified)	Anonymized (unlinked to the source patient)
Purpose	Epidemiology (optimize decisions at the populational-level)	Precision medicine (optimize decisions at the individual-level)

Virtual Patients for Collective Uses of Health Data

Definition and Purpose

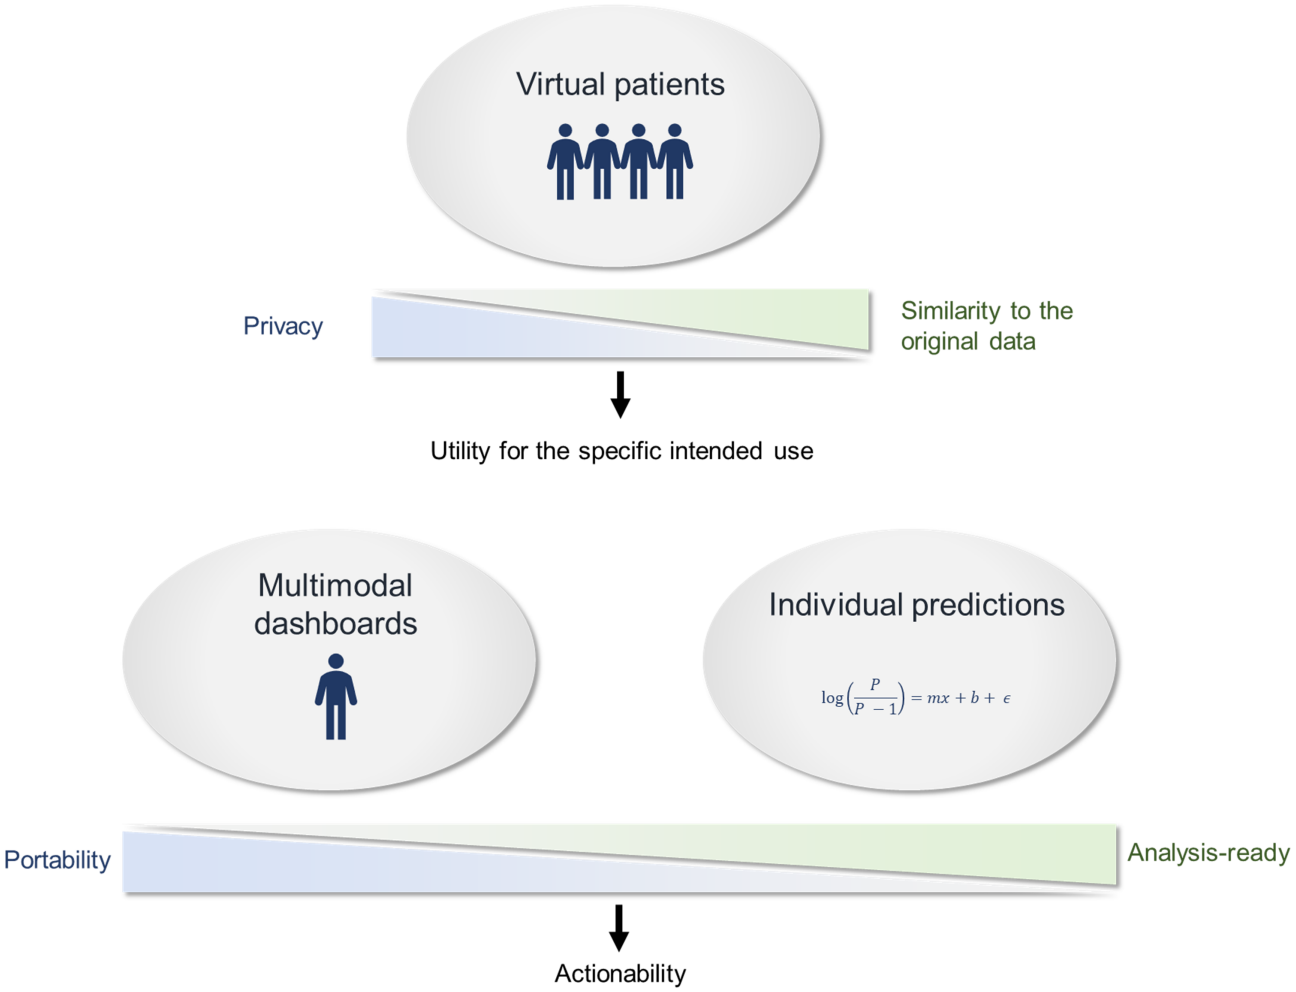
The second family of digital representations is the virtual patient. It is an individual observation in a set of computer-generated observations called "synthetic data" [36]. The generation of synthetic datasets might be arbitrary, random, rule-based, or simulated from statistical or machine-learning models. Synthetic data have recently gained popularity as a technology that could facilitate secondary data uses (Figure 2B) [36,37]. An example of external information supporting medical practices is the use of normative datasets to define reference ranges for quantitative biomarkers or to standardize biomarker values according to a population distribution [38,39]. They may also help interpret qualitative biomarkers such as the pathologic significance of genetic variations. However, precision medicine requires access to data of lower granularity to personalize the assessment of patients. At the scale of a single institution, the MS BioScreen illustrates the personalization of various MS biomarkers' reference ranges according to subgroups of patients with similar profiles [24]. Reference data with individual granularity are also required to develop data-driven predictive analytics. The utility of synthetic datasets stems from (1) the structural similarity (ie, the same level of granularity), (2) the veracity of the information content (ie, the comparison with real data yields the same aggregated results), and (3) indiscernibility (ie, neither experts nor artificial intelligence can distinguish synthetic data from original data).

Potential to Develop Predictive Analytics Through Data Augmentation

Data-driven predictive analytics are developed through machine learning. In cases where high-volume datasets are not available, synthetic data may augment datasets as a workaround for laborious data collection and expert-demanding data labeling [40]. Data augmentation increases the amount of training data either by generating additional slightly modified data points [41] or by using generative artificial intelligence models, such as generative adversarial networks, variational autoencoders, or large language models [42]. For instance, synthetic magnetic resonance imaging (MRI) images with pathologic features of Alzheimer disease may be generated with a variational autoencoder, yielding increased predictive performances of an analytic predicting the diagnosis from the MRI images [43]. The augmentation may also be restricted to data from specific prediction classes to mitigate class imbalance. Synthetic Minority Over-Sampling Technique (SMOTE) is a common technique to do so [44]. In these cases, the utility of synthetic data comes from the gain of predictive performance on an external validation dataset [40,45].

Potential to Produce Evidence Through In Silico Clinical Trials and Cohorts

Synthetic data may accelerate the production of scientific or regulatory evidence through in silico studies, which rely on fully synthetic study populations. The VICTRE (Virtual Imaging Clinical Trials for Regulatory Evaluation) trial illustrates the case when real datasets would be too expensive to create [46]. This in silico cross-sectional study compared the performances of a computational reader to detect breast cancer on 31,055 synthetic full-field mammography versus 27,960 synthetic breast tomosynthesis images. Synthetic cohorts may also be generated with longer follow-ups than what could be available in real datasets. In MS, a study generated a longitudinal synthetic cohort with a discrete event simulation model of MS activity and forecast its evolution with a lifetime horizon, although the treatment of interest (ofatumumab) had only been approved in 2021 [47]. The goal was to simulate its prescription as a first-line therapy against a second-line therapy with various delays. The simulation predicted better long-term benefits of ofatumumab when prescribed as a first-line therapy. Such a synthetic dataset makes statistical inference more interpretable. Instead of analyzing the "black box" of the model itself, it uses the model in a generative fashion to represent the information it captured as a cohort of virtual patients, which can be analyzed classically.



Potential to Share Information Through Anonymization

Since synthetic data are computer-generated, they are not linkable to a person and are thus assumed to be truly anonymous, as opposed to pseudonymized data. Anonymous data are shareable outside the constraints of regulatory frameworks applied to potentially identifying data. However, synthetic data generators typically do not take privacy protection into account. The generative model is indeed a link between the synthetic and the real data as the information content of the sensitive dataset is represented as a new set of individual observations. Concerns are rising about the risk of linkage between a virtual patient and a real patient (ie, membership inference attacks) [48-50]. Some synthetic data generators are first designed as

XSL•FO
RenderX

anonymization techniques, such as the avatars [51]. The avatars take real data as input to generate virtual patients with a probabilistic local model based on the nearest neighbors. The novelty of the method is that it provides privacy metrics to assess that the avatars are no longer identifiable records, even in the case of distance-based membership inference attacks. This privacy-by-design approach to synthetic data generation brings a trade-off [52]. The generation must be destructive enough to protect patients from reidentification while keeping utility for the specific intended use (Figure 3) [37].

Figure 3. The main trade-offs are addressed by the 3 families of digital representation. Real sensitive patient data may be formatted according to interoperable data models to favor data portability for multimodal dashboards or preprocessed for a specific predictive analytic. Virtual patients must balance privacy and similarity to the original data to be valuable proxies of real identifying records.

Summary and Limits

In our medical digital twin framework, we argue that virtual patients could be proxies of sensitive patient data to create collective value by sharing the information contained in sensitive datasets. The generation of synthetic data has to be on purpose to prioritize the variables to be represented in the virtual patients and to set the right trade-off between similarity to the original data and privacy. Specific utility for a given use would imply different generation settings (Table 2 and Figure 3). It could be (1) closed-loop software benchmarking with low-similarity synthetic data, (2) medical education [53] or addressing population-level questions in epidemiology (eg, performing a retrospective cohort study) with an intermediate similarity, or (3) supporting individual decisions in precision medicine with high-similarity synthetic data. Therefore, multiple virtual patients could be generated from the data of a given patient. Yet, the connection to the original patient that would be expected from a medical digital twin would be destroyed in all of them. This prevents virtual patients from supporting personal health care and to support individual predictions.

Individual Predictions to Support Clinical Decisions

Definition and Purpose

The third family of digital representations is individual prediction. Individual predictions are the results of predictive analytics that may use knowledge-based, data visualization, or model-based algorithms [54]. They enable HCPs to assess alternative scenarios to support clinical decisions such as treatment selection, risk factor prevention, or surgery planning (Figure 2C). The individual predictions of most prognosis scores in medicine use population models [55,56], meaning that decisions are optimized on average at the scale of a population. Medical digital twins aim to optimize decisions at the individual level with personalized analyses.

XSL•FO
RenderX

Personalization of the Context of Usage of Predictive Analytics

Prognosis scores and predictive analytics in general are validated in restricted contexts of usage [57]. In a chronic disease such as MS, these contexts may be diagnosis, initial prognosis, treatment selection, assessment of therapeutic response, or assessment of the transition to a secondary progressive phase [54]. Therefore management of 1 patient would require the integration of multiple predictive analytics to support different clinical decisions at different points of care along its clinical pathway. Such an approach is conveyed by the digital twin quality management framework of the MSDS 3D [10]. The structuration of health care into digital clinical pathways eases the description of the tree structure of clinical contexts along the management of chronic diseases. As such, different treatment-specific prognosis scores could be used to assess the probability of a patient to respond to each option. This could be further personalized according to the stage or subtype of the disease.

Personalization of the Analytics to Run Mechanistic Simulations

The most personalized analytics are those modeling the individual. This is the case of organ-level biomechanistic models, such as digital hearts. Their first layer is classically an anatomical mesh of an organ extracted from raw imaging data. The coupling of other modeling layers such as cell and tissue behavior yields an “embodiment” of a generic organ model in each patient’s specific anatomy [5]. Atrial fibrillation (AF) is a case where such modeling is in an early stage of clinical translation [58]. The Optimal Target Identification via the Modeling of Arrhythmogenesis procedure involves a computational model of the left atrium [58,59]. Geometric, fiber orientation, and electrophysiological tissue property layers are simulated to detect the topography of AF re-entrant drivers, including latent ones that electrocardiographic imaging would not detect. It also predicts de novo re-entrant drivers that may later perpetuate arrhythmia according to alternative scenarios of virtual ablation patterns. Thus, the Optimal Target Identification via the Modeling of Arrhythmogenesis procedure integrates the outputs of these simulations to tailor the intervention plan by performing preventive adjuvant ablations of the predicted re-emergent targets [15]. The close-loop of the disease is approached as a multi-scale system and the model enables to simulate emergence phenomena (eg, reentrant drivers) that would not be measurable, or that would occur under various therapeutic scenarios.

Personalization of the Data Use Based on the Matching With Similar Patients

In cases of statistical modeling, predictive analytics may be personalized by fitting the model at query time only on similar patients recorded in a reference database. The model decision boundaries would thus be optimized in the subset of similar patients matching the patient. The selection of similar patients may be distance-based according to a patient-similarity metric. This may imply a digital representation of patients as data points in a latent reduced multidimensional space, using linear or nonlinear dimension-reduction algorithms [60,61]. On the other hand, the selection of similar patients may be filter-based. The MS-VISTA (Nantes University) prototype of the Projections in Multiple Sclerosis project illustrates the querying of groups of similar patients in an MS randomized clinical trial dataset and the computation of a personalized prognosis to support treatment selection [62]. As such, these analytics personalize the use of continuously accessible reference data.

Summary and Limits

Individual predictions in our medical digital twin framework would therefore enrich patient data with external information provided by predictive analytics. Unlike one-size-fits-all population models, the analytic would be personalized according to the patient’s characteristics to yield a patient-specific embodiment of the model. One limit is that each model is typically instantiated once at the point of care corresponding to the respective context of usage. Even organ-level models are typically not maintained in the long run, which would be expected from medical digital twins to remain connected to the patient and support further data collection. Another limit is the need to preprocess patient data to run analytics such as the extraction of an anatomical mesh from a stack of raw images. This may involve feature extraction, feature selection, and feature engineering (eg, longitudinal aggregation, criteria fulfilments, events definition from biomarker trajectories, etc). The preprocessed digital representation of a patient therefore loses portability for other data uses (Figure 3). It may require significant computation costs and be subject to an analytic variability that would make it unfit to support personal care outside the context of usage of the analytic. Therefore, even if the analytics are personalized, a medical digital twin would have to leverage multiple shared predictive analytics, each one informing a limited number of decisions or procedures along a given clinical pathway.

Recommendations

We covered the main digital-twin applications for precision medicine and argued that they cannot all be supported by a single digital representation of a patient due to technical and regulatory constraints. We believe that the clarification of the different digital representations of patients is a foundation for an effective data strategy leveraging various concepts that are currently commonly confounded under the term “digital twins.” We highlighted three main families of digital representations (Figure 2): (1) multimodal dashboards to assist with perception and documentation; (2) virtual patients to facilitate secondary data uses; and (3) individual predictions supporting clinical decisions. For a given patient, multiple digital representations may be generated according to the different clinical pathways the patient goes through, each tailored to balance the trade-offs associated with the respective intended uses (Figure 3).

Therefore the proposed framework conceptualizes the medical digital twin as a data architecture leveraging a multitude of digital representations. It clarifies several distinctions between the characteristics of data usages (Table 2): between data collection and data preprocessing for a predictive analytic, between data transfer and data sharing, between primary personal and secondary collective usages of health data, between

XSL•FO
RenderX

pseudonymized and anonymous data, and between population models and personalized analytics. Raw health records are therefore raw material to be refined into various digital representations of patients to fuel precision medicine. Based on this clarification, we propose 3 strategic recommendations, that would ease data architecture efforts to overcome the limitations of the different families of digital representations (Textbox 1).

Textbox 1. Three recommendations to address the trade-offs of medical digital twin data architectures.

- Medical digital twin data architectures should relate several digital representations of patients, instead of a single all-encompassing representation.
- Intended data uses should be clearly defined to identify the right family of digital representation to use and to set the right trade-off when generating it.
- For collective usages, real sensitive data should be substituted by synthetic data whenever possible.

Discussion

This paper proposes a data-centric approach to clarify the practical digital representations at play in a medical digital twin framework from the intended data uses. It does not cover ethical, property, and usage control issues. Clarification efforts about medical digital twins have already been made from other perspectives. Ethical clarification has been proposed about the benefits and risks of medical digital twins [1], as well as about the conditions for medical digital twins to take on ethically justifiable forms of representation [63]. The scope of digital twin applications in the whole health care sector has been reviewed and led to advocate a global collaboration between stakeholders [6]. Clarifications of the means and objectives of the development of “supermodels” have also been postulated [64]. Efforts are made to develop the concept of medical digital twins in the form of computational modeling platforms [65]. In cardiology, a model-centric framework has been formulated, seeking the synergy between deductive and inductive reasoning, respectively conveyed by mechanistic and statistical models [5]. In MS, the clarification has been proposed in a quality management framework [10].

To highlight the perspectives of our framework, we propose road maps for 3 fictional medical digital twin projects (Table 3). Taking the management of AF as an example [58], the multimodal dashboard would collect and integrate all health data relevant to the patient within the clinical pathway of AF management. Second, synthetic heart MRIs would be used to benchmark generic AF heart models. Third, the patient-specific embodiment of an AF heart model would be used to plan an AF ablation procedure [59]. In epilepsy, the patient history and phenotype could be navigated through an epilepsy-specific dashboard. Synthetic electroencephalogram signals could help develop a seizure forecast model [66] or fit a virtual brain model [67] to the patient to support the planning of the ablation of the epileptogenic zone [68]. In MS, patients could complete symptom diaries on patient portals between the visits. They would be integrated with their imaging and therapeutic history in an MS-specific, ophthalmologist-specific, or rehabilitation-specific dashboard depending on the point of care [69]. Virtual patients generated with the avatars [51] could enable the development of a statistical model detecting transitional states to secondary progressive MS [70]. The subset of virtual patients matching the patient characteristics and planned therapeutic scenario could also be analyzed to support treatment selection [62].

XSL•FO
RenderX

Table . Road maps for fictional medical digital twin projects.

Projects	Multimodal dashboards	Virtual patients	Input and output of predictive analytics
AF[a]	• Patient-centric dashboard with anticoagulant treatment plan • AF-specific dashboard for the cardiologist	Synthetic heart MRI[b] for medical education and to benchmark mechanistic organ-level models	• Virtual heart model for AF ablation planning.
Epilepsy	• Patient-centric dashboard with antiseizure and disease-modifying treatment plans • Epilepsy-specific dashboard tailored to the epileptic disease for the neurologist	Synthetic electroencephalogram signals generated with the virtual brain to train deep learning models	• Seizure prediction model • Virtual brain to plan for the ablation of the epileptic zone
MS[c]	• Patient-centric dashboard with treatment plans and symptoms diaries • Ophtalmologist-specific dashboard tailored to optic neuritis • MS-specific dashboard for the neurologist • MS-specific dashboard for rehabilitation	Synthetic cohort of tabular individual patient data generated with the avatars to fit statistical models	• Statistical model for detection of transitional state to secondary progressive MS • Matching with similar patients to support treatment selection

[a]AF: atrial fibrillation.

[b]MRI: magnetic resonance imaging.

[c]MS: multiple sclerosis.

Conclusion

We propose a medical digital twin framework as a data architecture leveraging several digital representations of patients, instead of a single all-encompassing representation. The generations of digital representations would be determined by the technical and regulatory constraints of the intended data uses as well as their positioning along clinical pathways.

Acknowledgments

We thank Mike Hess, MSc, and Nathalie Virag, PhD, at Medtronic, a medical device company, and Shibeshih Mitiku Belachew, MD, PhD, at Biogen, a biopharmaceutical company, for their interviews, feedback, and proposals that helped conceptualize this viewpoint.

Conflicts of Interest

PAG is the founder of Methodomics (2008) and the cofounder of Big Data Santé (2018). He consults for major pharmaceutical companies, all of which are handled through academic pipelines (AstraZeneca, Biogen, Boston Scientific, Cook, Edimark, Ellipses, Elsevier, Methodomics, Merck, Mérieux, Sanofi-Genzyme, and Octopize). PAG is a volunteer board member at AXA not-for-profit mutual insurance company (2021). He has no prescription activity with either drugs or devices. JDS declares an honorarium and travel grant from Biogen and Merck. SD, GE, TZ, and FS have nothing to disclose.

Abstract

Lishui, a mountainous city in Zhejiang Province, China, is characterized by extensive mountainous terrain and a dispersed population. To address this issue, Lishui has introduced the intelligent mobile clinic service. This model leverages 5G technology and integrates the benefits of mobile clinics and telehealth, tailored to the region's geography and demographic characteristics. The intelligent mobile clinic uses real-time data analysis to deliver medical services effectively to remote mountainous areas. Medical personnel from the intelligent mobile clinic visit villages to provide in-person professional health services and facilitate residents' access to higher-level hospital resources through telehealth. This model has received widespread praise and recognition from residents and has yielded significant outcomes. During 2018-2023, a total of 25,000 visits have been made, benefiting 648,000 individuals. The intelligent mobile clinic provides a valuable reference for enhancing health care access in similar regions.

primary health care; medical resource; telehealth; intelligent mobile clinic; China; remote area

Introduction

The unequal distribution of medical resources is a global issue, particularly in remote areas where access to health care is severely limited.

Telehealth presents an effective solution to address this disparity in health care resources. Its primary aim is to enhance health care access by providing services to individuals who face barriers to obtaining care [1]. Initially, telehealth was employed to treat acute conditions, such as trauma or stroke [2]. As health care demands have risen, telehealth has expanded to include care for military personnel, prisoners, and rural populations [3]. While telehealth has significant potential, its development depends on conditions such as network infrastructure and coverage. Mobile clinics provide an additional solution to the unequal distribution of health care resources. Mobile clinics are mobile health care units, typically modified ambulances, designed to deliver services to both urban and rural communities [4]. This flexible health care model overcomes both time and geographical challenges, bringing medical services directly to remote areas. However, the limited space in the mobile clinic restricts the number of staff and equipment available, making it difficult to meet the diverse health care needs of residents [5].

In Lishui City, Zhejiang Province, China, an innovative integration of telehealth and mobile clinics has resulted in the creation of the intelligent mobile clinic. This model effectively combines the strengths of both telehealth and mobile clinics to address the health care needs of those in mountainous regions.

In this study, we introduce an innovative medical model for improving medical services in remote mountainous areas in Lishui City, Zhejiang Province, China. We will use the application, effectiveness and difficulties of the intelligent mobile clinic model in remote mountainous areas of Lishui City to provide reference experience for other remote areas to improve the uneven medical resources and provide high-quality medical services.

Health Care Inequities and Telehealth Innovations in Rural China

China is a predominantly agricultural country with a large rural population. As of 2022, the rural population in China reached 491.04 million, accounting for 34.78% of the total population [6]. Residents in remote areas face difficulties accessing health care due to factors such as economic constraints, distance, and time limitations [7-9]. For example, they have to spend a whole day seeking medical treatment, and some people may not even know that they are sick until their condition is very serious or has reached an advanced stage [10].

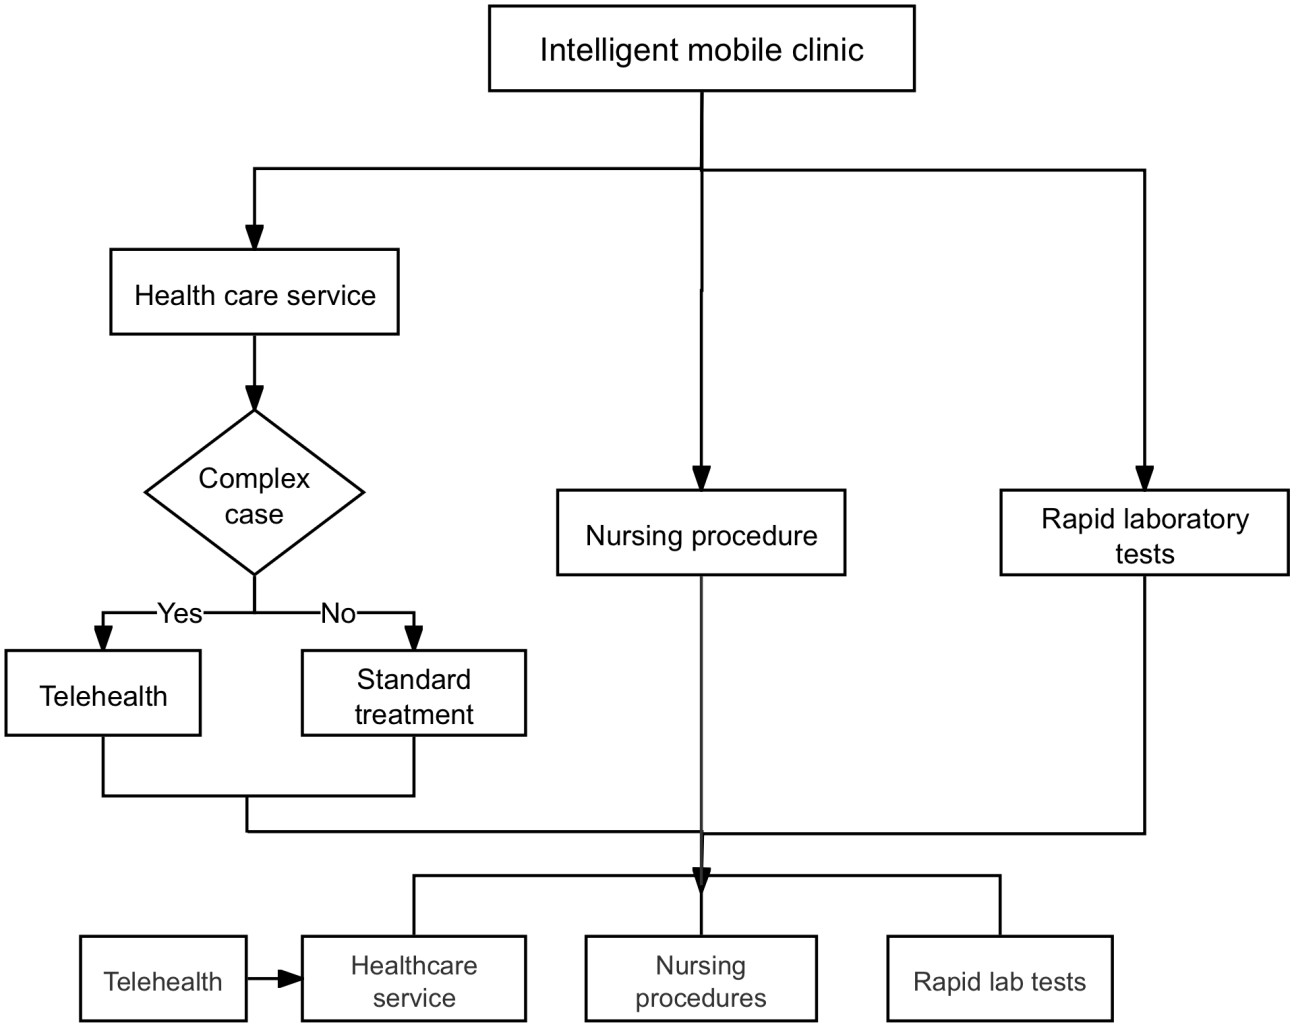
In response, the development of rural health care and medical systems has been the core of the new health care reform launched by China since 2009, which aimed at narrowing the urban-rural and regional disparities [11]. However, despite government efforts to implement medical reforms, there are still issues such as disparity distribution of health resources, a shortage of medical personnel, and inefficiencies in medical services [11,12]. Recognizing these challenges, the Chinese government has introduced various methods. One such method is the use of telehealth. Previous research has confirmed that telehealth can save residents time and costs in seeking medical treatment and promote the management of chronic diseases [13,14]. However, telehealth has not fully filled the health gap in rural areas, mainly due to young people flocking to urban centeres in search of better opportunities. This migration has left rural areas with a population dominated by older persons who face significant challenges in accessing and using e-health resources [15]. Consequently, these barriers prevent elderly residents from fully benefiting from telehealth services, exacerbating the health care disparities between rural and urban areas.

To address these challenges, China has been exploring innovative telehealth models that better suit the country's unique circumstances in recent years.

Intelligent Mobile Clinic in Lishui, China

A notable example is Lishui City, where a new solution has been introduced to address the specific health care needs of its rural population.

Lishui City is located in the mountainous region of southwest Zhejiang Province, where rugged mountains and hills dominate, with mountainous areas covering around 90% of the total land area. The region is home to more than 250 mountain villages, most of which are situated over 80 kilometers from the town center. Despite the local government's efforts to improve health care services, the spread-out population and small village sizes make it difficult for health care to reach every village, failing to meet the basic health care needs of the residents. As a result, residents often face long journeys, taking an entire day to reach a health care facility.



In Lishui's mountainous areas, as is the case in many rural parts of China, the population is largely elderly. These individuals often face additional challenges such as illiteracy, difficulty speaking Mandarin, and an inability to use smartphones or other smart devices. Although telehealth has significant potential to improve health care access, it struggles to address these issues in Lishui's rural context. As a solution, the government of Lishui City has developed the intelligent mobile clinic, which delivers more accessible and effective health care services to the rural population. The intelligent mobile clinic represents an innovative response to the distinct needs of Lishui's residents. The next section will provide a detailed introduction to the intelligent mobile clinic.

The Intelligent Mobile Clinic: An Innovation Solution for Remote Area Health Care

The intelligent mobile clinic offers an innovative solution by combining mobile clinics, telehealth, 5G technology, and big data to tackle the unequal distribution of medical resources in remote areas. This model integrates several advanced technologies to provide high-quality and accessible health care services to people in remote regions (Figure 1).

XSL•FO
RenderX

Figure 1. Flowchart of the intelligent mobile clinic health care service for residents.

The intelligent mobile clinic utilizes modified medical vehicles, equipped with essential diagnostic tools, to deliver health care services to even the most remote mountainous areas. These vehicles provide services such as routine health check-ups and rapid laboratory tests. When the doctor encounters cases that surpass their expertise, the telehealth system connects them with specialists at higher-level hospitals. This real-time consultation enables more accurate diagnoses and effective treatments, even in distant locations.

The roles of 5G and big data are pivotal in supporting the intelligent mobile clinic. 5G technology ensures smooth communication and the real-time transfer of medical data, while big data helps gather and analyze health information to refine services, monitor regional health trends, and improve the distribution of medical resources.

Mobile Clinic Services in the Intelligent Mobile Clinic

The intelligent mobile clinic provides medical services to residents in remote areas. The mobile medical vehicles of the intelligent mobile clinic arrive at mountain villages at fixed times every month to provide medical services to residents.

Doctors provide direct consultations, perform routine tests, diagnose common diseases, and prescribe medication when needed. If a resident's medical needs exceed the available services, doctors can consult experts at senior hospitals through telemedicine systems to ensure that residents receive specialized care. The nurse administers injections and performs dressing changes. Medical technicians perform rapid laboratory tests such as blood pressure monitoring, blood sugar tests, and electrocardiograms to assist in diagnosis. To improve communication with elderly people who are not fluent in Mandarin, the intelligent mobile clinic recruited local volunteers who are fluent in Mandarin and regional dialects. These volunteers play a vital role in maintaining order and helping elderly patients onto medical vehicles. It is worth noting that in order to ensure that patients who are bedridden at home can also enjoy medical care services, doctors provide medical services for patients at home, replace drainage tubes, urine bags, etc.

Telehealth in the Intelligent Mobile Clinic

When medical vehicles are unable to fully meet the health care needs of residents, the intelligent mobile clinic doctors use telemedicine to consult experts in senior hospitals. Through telemedicine devices, doctors can transmit real-time health data to specialists, which ensures that residents have access to vital health care services and receive timely medical attention.

In addition, the 5G network improves the efficiency of telemedicine within the intelligent mobile clinic. It provides a reliable, stable link for online consultations, overcomes

XSL•FO
RenderX

geographical barriers, and gives mountain residents access to the same medical services and resources as urban residents. As a result, the intelligent mobile clinic has significantly improved the accessibility and quality of health care services in remote areas.

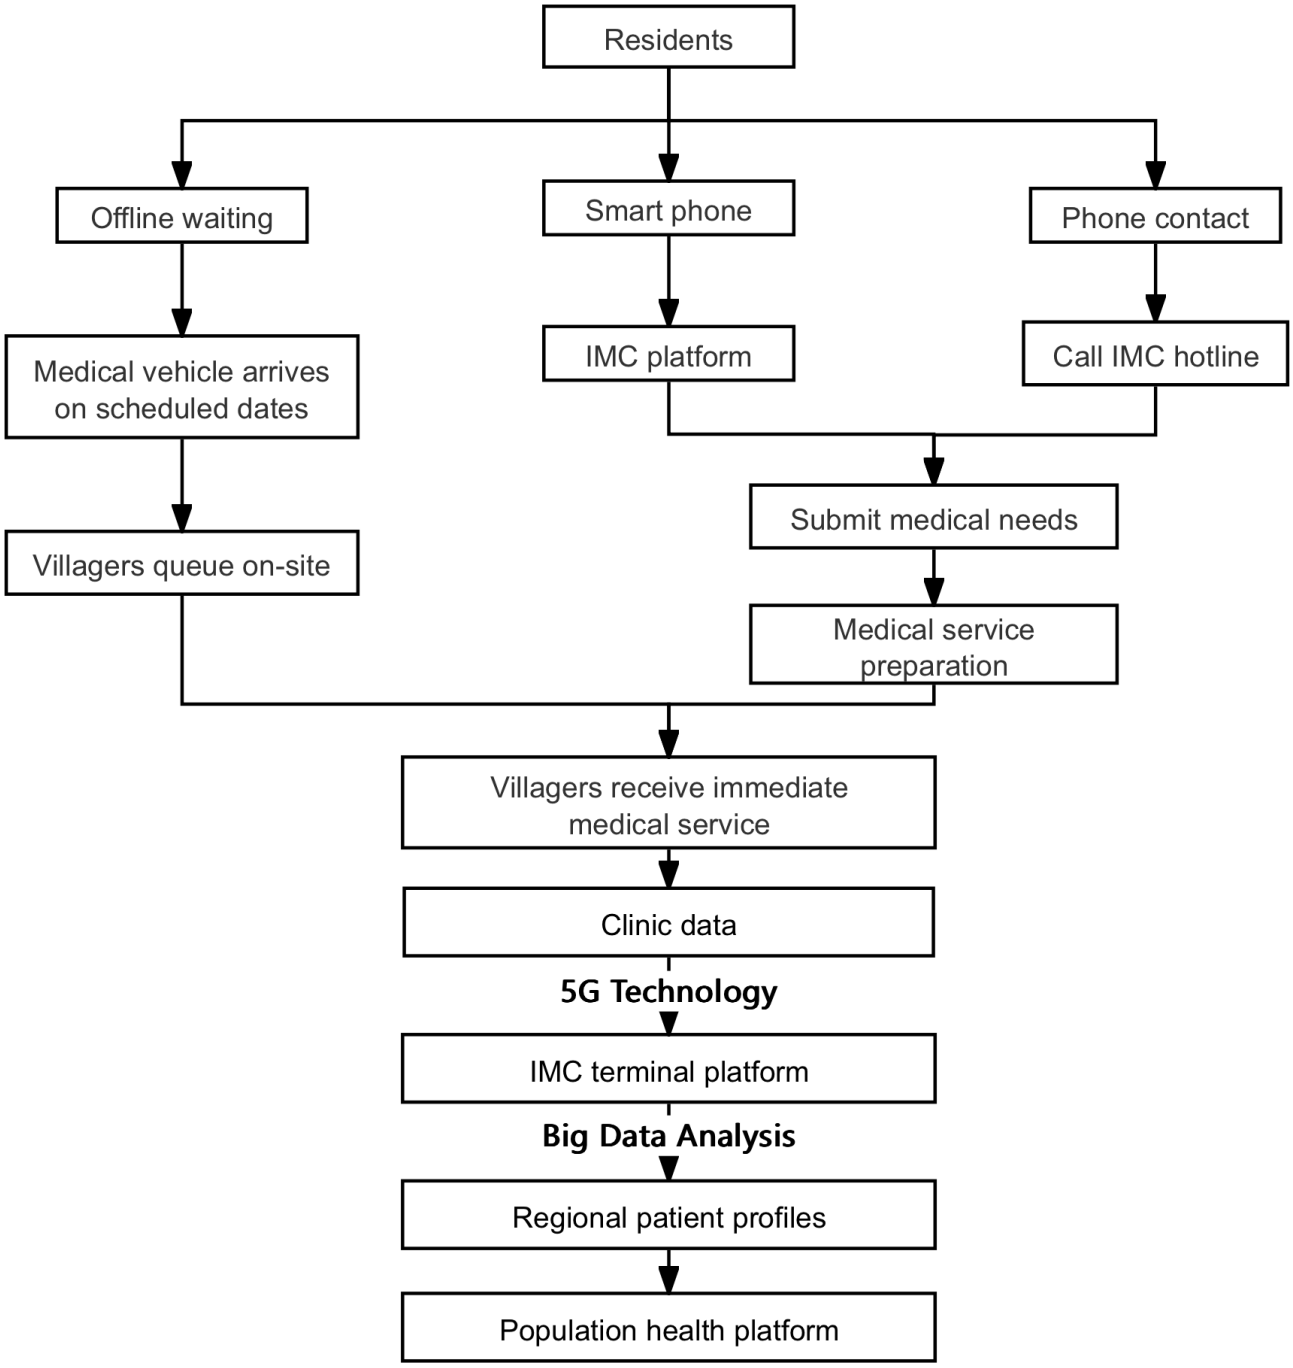
Big Data Support in the Intelligent Mobile Clinic

Big data technology is the key technology for the intelligent mobile clinic to achieve precision medicine. Relying on 5G network technology, the intelligent mobile clinic transmits the relevant data of 50 medical vehicles in real time, including GPS positioning information, diagnosis and treatment records, and disease conditions of patients in various regions to the Lishui Health Information Platform and terminal personnel can form regional health information self-portraits according to the information transmitted by all medical vehicles through big data. It is worth noting that the medical staff on board each medical diagnosis and treatment vehicle can only view the relevant diagnosis and treatment information in their own area of responsibility to protect the privacy of patients.

Extra Functions of the Intelligent Mobile Clinic

The intelligent mobile clinic has taken into account the varied medical needs of villagers, including the delivery of medications to mountainous areas. Due to certain restrictions, the intelligent mobile clinic is not able to carry all types of medicine. When specific medications are needed, the doctor will write a prescription and request confirmation from higher-level doctors via the network. Upon approval, the medication is prepared by the higher-level hospital and sent to the villagers free of charge through express delivery.

Furthermore, to better meet the medical needs of the villagers, the intelligent mobile clinic also functions as a first-line emergency responder. In emergency situations in remote villages, such as bleeding injuries or drowning incidents, villagers can contact the emergency hotline. The dispatcher will then assign the nearest medical vehicle from the local health center to respond based on the villager's location.



Routine Operation and Management

The intelligent mobile clinic collects and addresses the medical needs of the villagers through multiple channels: most villagers line up at the medical site on a fixed date each month. Villagers who have the ability to use mobile phones can access the feedback module by logging into the interface to submit medical requests, while those who do not have access to phones can make requests through the hotline, and the information is entered into the system by staff. Local community hospitals or health centers flexibly adjust the allocation of medical staff and drug supplies based on these real-time data.

In order to achieve efficient service management, the intelligent mobile clinic has created a comprehensive database by integrating vehicle information, medical personnel files, service data, GPS coordinates, and digital maps. The management platform transmits diagnostic records, treatment processes, and vehicle operating status in the diagnosis and treatment vehicle to the terminal platform in real time through 5G technology; and generates regional health information portraits through big data analysis. As regulators, the government and health departments can remotely verify the number of medical personnel, vehicle positioning, and diagnosis and treatment process with the help of monitoring cameras in the diagnosis and treatment vehicle to ensure the quality of service. In the design of the system, the information security mechanism is especially strengthened, and regional data rights management is implemented, that is, doctors in each region can only access the patient information in their jurisdiction, and the privacy security of villagers is protected from the technical level (Figure 2).

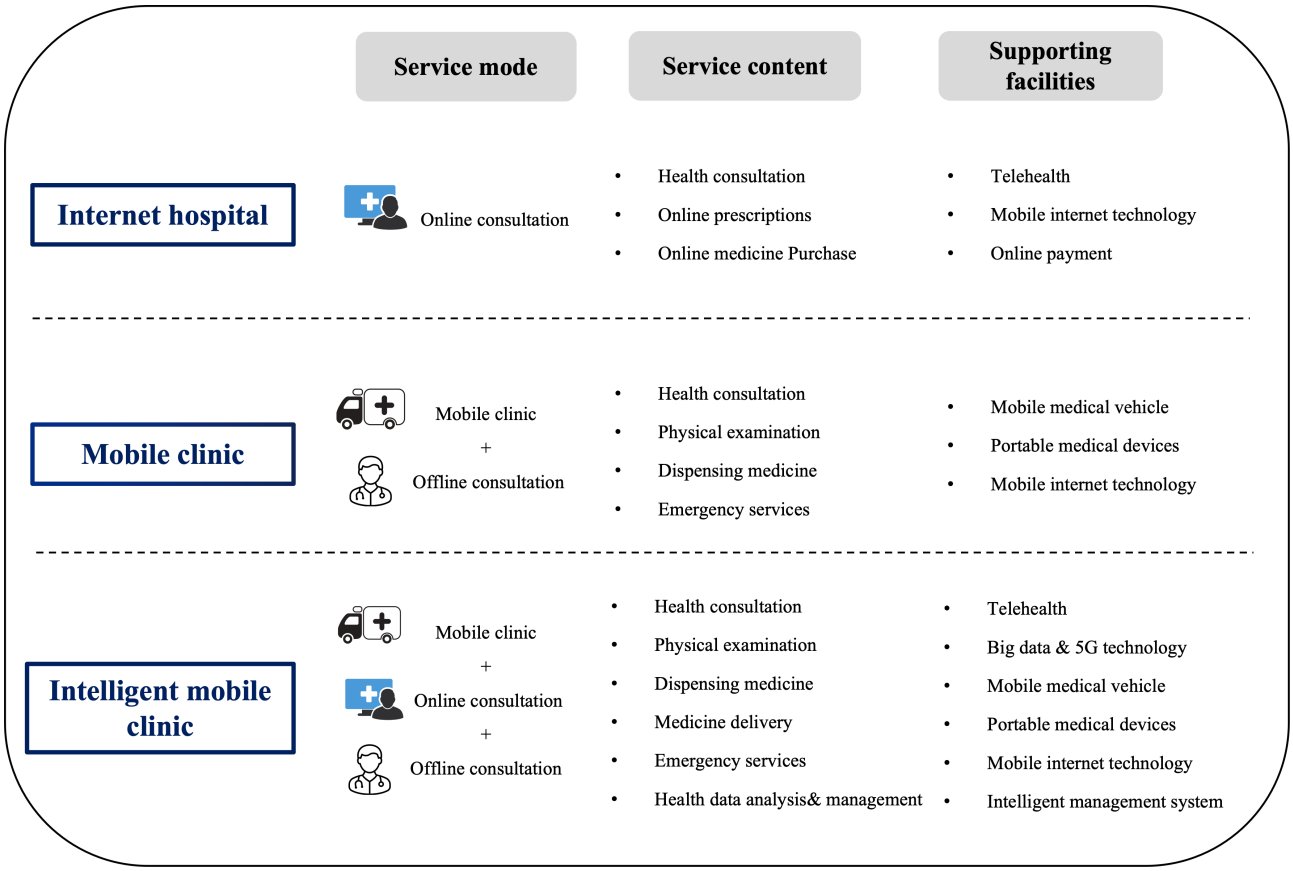
Figure 2. Flowchart of the intelligent mobile clinic (IMC) routine operation and management.

Comparing the Intelligent Mobile Clinic With the Mobile Clinic and Internet Hospitals

Overview

Several models currently exist to provide primary health care services to residents in remote areas. Mobile clinics represent an innovative health care service model that delivers flexible medical services to targeted populations through a customized motor vehicle [16]. Internet hospitals are platforms where registered doctors provide consultations and treatments via the internet, primarily addressing common or chronic health conditions [17]. The rapid development of internet hospitals in China is expected to improve the availability of medical resources and reduce the cost of telehealth services [18].



Despite their benefits, both models have certain limitations. Mobile clinics are restricted by the limited space in medical vehicles, which limits the amount of equipment, medicines, and medical personnel that can be carried on each visit [19]. As a result, in unexpected situations, the medical needs of residents may not be fully met. Internet hospitals services are faced with multiple practical challenges when used for primary medical coverage. First, internet hospitals have high requirements for mobile devices and lack communication equipment in remote mountainous areas [20,21], which makes it difficult for people to effectively enjoy telehealth services [22,23]. Second, the physical isolation between doctors and patients in the remote

XSL•FO
RenderX

diagnosis and treatment mode makes it impossible for doctors to perform basic physical examinations for patients, which may affect the completeness and accuracy of the clinical diagnosis. Third, after using intelligent terminals to complete online consultation, elderly patients also need to go through the drug logistics and distribution link, which increases the time cost compared with traditional medical treatment [24].

In contrast to mobile clinics and internet hospitals, the intelligent mobile clinic integrates the benefits of both online and offline services. Local doctors provide in-person consultations and treatments. When additional expertise is needed, the telehealth system connects them with specialists from higher-level hospitals, offering effective support and guidance. Additionally, the convenience of these services results in high patient satisfaction. This combined approach allows the intelligent mobile clinic to address the limitations of both mobile clinics and internet hospitals, delivering a more comprehensive and accessible health care solution for remote populations (Figure 3).

Figure 3. Comparison of 3 medical models.

To evaluate the real user experience of the intelligent mobile clinic, a telephone follow-up was conducted with residents in January 2024. The research team focused on villagers from Bihu Town, Lishui City, conducting qualitative interviews with them (Table 1). The interviews collected data on basic user characteristics, home addresses, and their evaluations of the intelligent mobile clinic services. The findings reveal that the respondents gave high ratings to the intelligent mobile clinic, highlighting that it significantly meets their health care needs.

XSL•FO
RenderX

Table . Qualitative interviews of the user experience of the intelligent mobile clinic (IMC).

Interviewee #	Age, y	Gender	Disease	Job	Interview content
1	50	Female	Diabetes	Run a grocery store	I have diabetes and need to take my medication regularly. The medical vehicle visits our village, which makes it very convenient for me to get my medication. I can receive it immediately without needing to go to the hospital.
2	52	Male	Disability, hypertension	Farmer	I am disabled and have high blood pressure, so I must take medication every day. Given my condition, I cannot travel to an external hospital by myself. The medical vehicle visits our village once a week, which is very helpful.
3	57	Female	Hypertension, hypothyroidism	Farmer	The IMC is a great help. We live in a rural area with no public transportation, and the medical vehicle comes every week, mainly to visit patients with chronic diseases. For more serious cases, the doctor will refer patients to a higher-level hospital for treatment.
4	56	Female	Hypertension	Farmer	The IMC is well-received by the villagers. They come once a week and bring fresh medicines. Since we do not have a clinic in our village, we have to travel to nearby towns or urban areas for medical care. This has led many people in the village to wait in line for the mobile vehicle to arrive.
5	50	Female	Hyperlipidemia	Farmer	It is far more convenient to see a doctor and get medication, as there is no need to wait in long lines as in traditional hospitals. The outpatient fee at the mobile clinic in the village is just 5 RMB (US $0.7).

Ethical Considerations

This work adheres to ethical guidelines for scholarly commentary. All referenced studies comply with institutional ethics standards. The original research cited in this article was approved by the Zhejiang Chinese Medical University Institutional Review Board (IRB#20250220-1). All the patients

XSL•FO

provided informed consent for use of their data; all the data were de-identified.

Results

From 2018 to the end of 2023, the intelligent mobile clinic had a total of 50 mobile medical vehicles, a total of 18,000 visits, 100 years of travel within the area of 10,000 kilometers, a total of 25,000 village medical services, 33,000 medical personnel, a total of 657,000 services, covering 758 remote villages without medical facilities (Table 2). In addition, the average emergency response time in mountainous areas reduced from 34 minutes to 14 minutes. According to data from the Lishui government, the goal of mountainous residents to have "shorter medical treatment times and the ability to address minor illnesses within the village" has increasingly become a reality.

Table . Characteristics of patients who used the intelligent mobile clinic from 2021 to 2023.

Characteristics, n (%)	2021	2022	2023	Total
Total users	91,287 (10.38)	130,445 (14.84)	656,998 (74.78)	878,730
Number of medical vehicle rounds	2113 (11.60)	5550 (30.47)	10,549 (57.93)	18,212
Number of village visits	4942 (19.11)	5426 (20.98)	15,492 (59.91)	25,860
Number of medical staff	3043 (9.01)	9486 (28.08)	21,257 (62.91)	33,786
Type of medical service				
Diagnosis and treatment	9646 (3.54)	46,465 (17.05)	21,6471 (79.41)	272,582
Traditional Chinese medicine	4765 (4.76)	19,222 (19.20)	76,115 (76.04)	100,102
Prescription	700 (0.35)	36,553 (18.17)	164,591 (81.48)	201,144
Laboratory testing	386 (1.30)	1821 (6.15)	27,386 (92.55)	29,593
Chronic disease follow-up	68,790 (25.71)	26,384 (9.86)	172,435 (64.43)	267,609

Discussion

The emergence of the intelligent mobile clinic has effectively alleviated the unequal distribution of medical resources in remote mountainous areas of Lishui City, and increasing numbers of villagers can get timely treatment. As noted earlier, the population in the remote areas of Lishui is spread across the mountains, making it difficult for residents to access medical resources from urban areas. Building hospitals in these regions would serve only a small portion of the population, potentially resulting in a waste of resources. Additionally, many residents in these mountainous areas are elderly and face challenges such as illiteracy, an inability to speak Mandarin, or limited access to the internet. These factors mean that internet hospitals and mobile clinics may not fully meet their needs. Each region has its own unique circumstances, and local governments must carefully assess these conditions and implement appropriate measures to provide suitable services for residents, such as capsule clinics in Ningbo or internet hospitals in Guangzhou. The intelligent mobile clinic is a new health care service model that integrates the advantages of telehealth and mobile clinics, developed by the local government to address the specific conditions of the area. With the guidance of big data, the intelligent mobile clinic is able to deliver accurate health care services to residents in remote mountainous regions. Medical staff from the intelligent mobile clinic also help elderly residents communicate with specialists through the internet.

Conclusion and Limitations

The intelligent mobile clinic presents an innovative and effective solution for promoting the equal distribution of medical resources in remote areas. By combining the benefits of telehealth and mobile clinics, the intelligent mobile clinic tackles the health care challenges in the mountainous regions of Lishui. The success of the intelligent mobile clinic in Lishui offers a valuable example for addressing similar issues in other remote areas of China and even in countries facing comparable challenges.

Nonetheless, each region must carefully evaluate its specific circumstances and develop suitable approaches to meet the health care needs of its residents, ensuring a balanced distribution of medical resources across various areas.

Acknowledgments

We would like to thank the Lishui Central Hospital for their support of this research. This study was sponsored by National Social Science Foundation of China: "Constructing a Family Medicine Education System with Chinese Characteristics in the Context of Major Public Health Emergencies" (BIA200197).

This research data are provided by the Lishui City Government, Zhejiang Province, China. Due to the confidentiality agreement signed, part of the original data and core steps cannot be shared. All the data in this paper have passed official verification.

Abstract

Artificial intelligence (AI), particularly large language models (LLMs) such as ChatGPT, has rapidly evolved and is reshaping various fields, including clinical medicine. Emergency medicine stands to benefit from AI's capacity for high-volume data processing, workflow optimization, and clinical decision support. However, important challenges exist, ranging from model "hallucinations" and data bias to questions of interpretability, liability, and ethical use in high-stake environments. This updated viewpoint provides a structured overview of AI's current capabilities in emergency medicine, highlights real-world applications, and explores concerns regarding regulatory requirements, safety standards, and transparency (explainable AI). We discuss the potential risks and limitations of LLMs, including their performance in rare or atypical presentations common in the emergency department and potential biases that could disproportionately affect vulnerable populations. We also address the regulatory landscape, particularly the liability for AI-driven decisions, and emphasize the need for clear guidelines and human oversight. Ultimately, AI holds enormous promise for improving patient care and resource management in emergency medicine; however, ensuring safety, fairness, and accountability remains vital.

Introduction

Artificial intelligence (AI), particularly large language models (LLMs) such as OpenAI's ChatGPT, is experiencing rapid growth in adoption, with a user base of tens of millions on a monthly basis [1]. While the United States and China are making significant advancements in AI technology, Europe is experiencing a lag due to challenges in investment and regulatory frameworks [2,3]. This disparity limits the European public's comprehension of AI's potential applications and implications.

In medicine, AI demonstrates exceptional capabilities in processing complex health data [4], advanced medical imaging [5,6], anatomopathology [5], and electrocardiogram interpretation [6]. Furthermore, AI exhibits proficiency in "internship competitions" [7] and has the potential to surpass practitioners in medical diagnoses [8]. AI significantly contributes to medical research by aiding the creation of scientific articles [9] and advancing new therapeutic areas, especially in infectiology [10].

Nevertheless, it is posited that there is an underestimation of the substantial impact of this technology on contemporary and future medicine. Recent advancements in AI, propelled by extensive computational power rather than conceptual innovations, demonstrate that the potential of these systems depends primarily on the accumulation of data, duration of training, and financial resources [11]. This observation suggests that the improvement of AI systems necessitates an increase in high-quality data, extended training periods, and financial investment, rather than relying solely on the ingenuity of researchers.

Emergency medicine is a high-stakes field in which rapid and accurate decision-making is crucial. Overcrowded departments, resource constraints, and time pressure create significant challenges that advanced AI can mitigate. However, the complexity and unpredictability of emergency medicine highlight the importance of safety, liability, and ethical considerations. This paper presents the current applications of AI in emergency medicine, emphasizing both real-world implementations and critical challenges, such as hallucination, bias, and interpretability.

Current AI Capabilities in Emergency Medicine

AI systems, particularly deep learning networks, can be used to identify patterns in large, complex datasets, significantly contributing to medical science by analyzing variables to reliably predict outcomes [12,13]. In emergency departments (EDs), this enables improved triage, patient flow management, and resource allocation in overcrowded settings where resources are limited and time is critical [14-19]. Hospitals are also investigating AI's potential to optimize resource allocation by forecasting bed availability and scheduling staff [20,21]. In one study, an AI tool analyzing historical admission patterns, vital signs, and laboratory data enhanced ED throughput by identifying high-risk patients for earlier admission [22].

Moreover, AI has demonstrated high accuracy in clinical tasks such as the recognition of acute coronary syndromes, recognition of acute appendicitis, and rapid interpretation of imaging for fractures or head injuries [23-30]. These tasks involve pattern recognition in large data streams—vital signs, laboratory results, or imaging scans—and can reduce diagnostic delays. Some EDs have tested AI models for specific conditions, such as early sepsis detection, by monitoring the vital signs and laboratory results [31]. This approach has shown promise in reducing the time to antibiotic administration, although the results vary across different populations.

Conventional clinical decision support systems (CDSSs) have been widely used in health care settings to assist medical professionals in making informed decisions. These systems typically operate on the basis of predefined rules, scoring systems, or algorithms developed by experts in the field. Although effective in many scenarios, these traditional CDSSs have limitations in their ability to adapt to new information or complex, multifaceted clinical situations [32]. In contrast, AI models, particularly LLMs, represent a paradigm shift in clinical decision support. These models leverage vast amounts of data to learn patterns and associations without the need for explicit rule-coding [33,34]. This data-driven approach allows AI models to potentially identify subtle or complex relationships within medical data that may be overlooked by traditional CDSSs or even by human experts [35]. However, it introduces challenges in interpretability as the "reasoning" behind AI outputs may be opaque.

Although these early successes are encouraging, robust prospective trials remain limited. Further evidence from large-scale, peer-reviewed studies is necessary to confirm whether AI-driven solutions consistently improve patient outcomes in emergency care settings.

Challenges and Limitations

A widely documented phenomenon in LLMs is "hallucination," where the model confidently generates inaccurate or fabricated information [36-38]. While all diagnostic tools are susceptible to errors, AI hallucinations can be especially problematic because they are delivered convincingly, making them difficult to spot. In emergency settings, where time constraints are acute, misleading AI outputs can significantly affect patient care. The current research highlights the need for rigorous validation of LLM outputs, particularly when used for direct patient management. Because AI models are trained on large datasets, their performance is strongest for common presentations. Infrequent conditions such as rare genetic disorders or atypical manifestations of common pathologies are prone to misclassification. Moreover, LLMs struggle with rare and atypical cases that are common in emergency medicine, making them less effective in unconventional clinical situations. This limitation arises because LLMs rely on statistical correlations, favoring common cases over unique ones [39]. Additionally, LLMs are not programmed to indicate uncertainty, which increases the risk of misleading information in critical situations [40,41].

Data-driven models of emergency care can significantly improve patient outcomes and operational efficiency. However, their reliance on historical data can perpetuate the existing biases, leading to unequal treatment across diverse patient populations. This is concerning in emergency settings, where rapid decision-making is crucial and biased algorithms can be life-threatening. An AI system trained predominantly on data from one ethnic group might misinterpret the symptoms presented by patients from other backgrounds, resulting in delayed or inappropriate care. A study using an AI-powered dermatological algorithm clearly demonstrated this problem. When applied to Fitzpatrick skin type 6 (dark skin) dermatological conditions, the AI system achieved only 17% diagnostic accuracy compared to 69.9% for Caucasian skin types [42]. Interestingly, AI systems can also be designed to detect limitations when faced with unfamiliar data. Conformal prediction techniques have been shown to flag unreliable predictions when an AI system encounters new data from different laboratories, scanners, or pathology assessments [43]. This approach could help mitigate risks associated with AI systems, such as incorrect diagnoses for patients from underrepresented groups. Diversifying training datasets is critical to ensure that AI models are exposed to a wide range of patient demographics and clinical presentations. Implementing fairness-aware algorithms that consider and adjust for potential biases during decision-making is equally important. Continuous monitoring and auditing of AI system performance across demographic subgroups is essential for identifying and rectifying emerging disparities. This vigilance, combined with regular updates to models and training data, can help ensure that AI-driven emergency care systems serve all patients equally, regardless of their background or socioeconomic status.

Model Interpretability and Explainable AI (XAI)

AI-based triage systems in emergency medicine are powerful and complex tools for optimizing patient care. The "black-box" nature of these algorithms raises ethical concerns in high-stakes emergency settings, where rapid and accurate decision-making is crucial [44]. When an opaque AI system designates a patient as "low priority" without clear justification, it may lead to

XSL•FO
RenderX

prolonged wait times or reduced attention, potentially compromising patient outcomes.

Explainable artificial intelligence (XAI) is important in emergency medicine. Transparent and interpretable AI models are essential to maintain trust, accountability, and safety in emergency care [45]. XAI techniques such as Shapley Additive Explanations or Local Interpretable Model-Agnostic Explanations can provide insights into which variables most influence a model's output, making AI-based recommendations more transparent to health care professionals [46]. This interpretability is crucial in emergency settings, where clinicians must quickly understand and validate AI recommendations.

In the fast-paced environment of emergency medicine, the balance between model performance and explainability is critical. Although complex models may offer superior predictive power, their opacity can hinder clinical trust and integration [47]. Developing AI systems that maintain high accuracy while providing clear explanations for their decisions is an active research area, particularly relevant to emergency care, where trust and clarity are paramount [48].

To address these challenges, transparent and XAI triage mechanisms tailored to emergency medicine are crucial. These systems should provide immediate insights into the decision-making process, allowing health care professionals to quickly understand and validate AI recommendations in time-sensitive situations. Structured override processes must be established to enable rapid human intervention, when necessary, ensuring that algorithmic decisions can be reviewed and adjusted based on clinical judgment and contextual factors.

By prioritizing transparency, explainability, and human oversight in AI-based triage systems for emergency medicine, health care institutions can harness AI benefits, while maintaining fairness, accountability, and public trust. This approach enhances patient care quality, supports clinician confidence, facilitates training, and helps to identify potential failure modes in critical care situations.

The Evolving Regulatory Landscape

Comparative analyses of the European Union, United States, and international regulatory frameworks reveal distinct policy priorities. The European Union's Artificial Intelligence Act and General Data Protection Regulation established a structured, risk-based approach for health care AI, mandating transparency, accountability, and bias prevention [2,49]. The United States relies on sector-specific regulations, notably the Food and Drug Administration's Total Product Life Cycle framework for Software as a Medical Device, prioritizing flexible risk stratification to accommodate continuous AI model updates with weaker postmarket monitoring [50,51]. International bodies, including the United Nations Educational, Scientific and Cultural Organization, the World Health Organization, and the Organisation for Economic Co-operation and Development, have advanced frameworks for ethical AI governance—centering on fairness, transparency, and human oversight—but lack enforceable mechanisms, limiting regulatory convergence across regions [52].

Health care providers face liability concerns when AI-driven recommendations lead to misdiagnoses or suboptimal treatment. The unpredictable nature of AI systems is complex. As legal frameworks evolve, questions arise about responsibility when errors stem from "black-box" AI. Should providers be held accountable for following AI advice? Can liabilities extend to AI developers or institutions? Jurisdictions worldwide are addressing these issues [46,53]. The European Union's proposed Artificial Intelligence Act [2] and the US Food and Drug Administration's guidance on AI in medical devices represent initial steps [50], but specific guidelines for LLM-driven decision support remain limited. The global health care community recognizes the need for rigorous validation and clear risk stratification before integrating AI tools into clinical workflows [54]. Regulatory bodies emphasize robust clinical validation, decision-making traceability, and mechanisms to update AI tools as new data emerge. However, formalized legal precedents for AI liabilities in emergency medicine are still emerging. This lack of established guidelines creates uncertainty for the stakeholders. As AI is integrated into medical practice, stakeholders must collaborate to develop comprehensive frameworks that balance innovation with patient safety and legal protection, addressing transparency, ongoing monitoring, and clear delineation of responsibilities [53,54].

A pressing issue is the global disparity in the adoption of AI regulations. While the European Union has implemented binding legal frameworks and the United States is adapting existing structures to AI technologies, a significant regulatory gap persists in many regions; only 15.2% of countries have enacted AI-specific health care regulations, amplifying concerns over global inequities in AI development and patient safety [55]. Scholars have increasingly advocated hybrid approaches that integrate risk-based innovation enablement with enforceable ethical guardrails to bridge the regulatory divide between EU prescriptive models, US flexible guidelines, and international voluntary standards.

Toward Responsible and Fair AI Implementation

EDs serve diverse patient populations, necessitating a focus on fairness. Institutions employ several strategies to mitigate bias.

First, diversifying the training data ensures representation across demographics, locations, and disease phenotypes. Second, the implementation of fairness-aware algorithms adjusts model parameters to reduce performance disparities. Third, conducting regular audits helps to monitor AI outputs for patterns of discrimination.

While AI offers powerful capabilities, it should complement, rather than replace, clinical judgment. Humans excel in contextual understanding, ethical reasoning, and handling unique cases, whereas AI excels in recognizing patterns in large datasets. A collaborative approach combining AI recommendations with clinician reviews can help to identify errors or biases. Some institutions have established AI oversight committees to evaluate the performance, manage updates, and review near-miss incidents.

XSL•FO
RenderX

To address the risks of AI hallucinations, institutions should implement structured verification processes for AI-suggested diagnoses or treatments. Encouraging AI models to express confidence levels or flag uncertain outputs through uncertainty quantification is beneficial. Additionally, requiring critical decisions prompted by AI to be documented with explanations can increase trust.

AI-driven triage can expedite care, but it also raises questions about distributive justice and patient autonomy. Transparency in how AI models prioritize patients is crucial, and ED staff should retain the authority to override AI-driven triage decisions when necessary.

Future Directions and Conclusion

The integration of AI into emergency medicine holds tremendous potential to revolutionize clinical practice, from optimizing patient flow to aiding in complex diagnoses. However, these powerful tools are associated with significant risks and require careful governance. Ensuring model interpretability through XAI is crucial for building trust and validating clinical applications. Unresolved liability issues necessitate collaboration between health care providers, policy makers, and AI developers to clearly define their responsibilities.

Moving forward, researchers and ED administrators should prioritize several key areas:

1. Comprehensive, multisite validation: large-scale prospective studies should be conducted to assess the real-world impact of AI on patient outcomes and safety.
2. Robust regulatory frameworks: clear guidelines addressing liability, performance monitoring, and transparency requirements should be developed.
3. Bias mitigation: fairness-aware techniques and regular audits should be implemented to ensure equitable treatment across diverse patient populations.
4. Educational initiatives: clinicians, residents, and administrators should be trained to use AI responsibly, critically interpret outputs, and maintain essential diagnostic skills.

The rapid evolution of AI underscores its transformative potential and the need for prudent caution. By implementing appropriate safeguards across the technical, legal, ethical, and educational domains, AI can become a powerful ally in emergency medicine, ultimately enhancing patient care and outcomes.

Acknowledgments

We would like to thank Dr Thibault Viard, Dr Eric Tellier, and Dr Nicolas Peschanski for their help writing this manuscript. There were no sponsors or financial support for this trial.

Authors' Contributions

FA was responsible for the data acquisition, literature review, and writing of this paper. BP was responsible for the data acquisition and literature review.

Conflicts of Interest

None declared.

Abstract

This viewpoint article explores the transformative role of artificial intelligence (AI) in predicting perioperative hypoxemia through the integration of deep learning with multimodal clinical data, including lung imaging, pulmonary function tests, and arterial blood gas (ABG) analysis. Perioperative hypoxemia, defined as arterial oxygen partial pressure <60 mmHg or oxygen saturation <90%, poses significant risks of delayed recovery and organ dysfunction. Traditional diagnostic methods such as radiological imaging and ABG analysis often lack integrated predictive accuracy. AI frameworks, particularly convolutional neural networks and hybrid models like TD-CNNLSTM-LungNet, demonstrate exceptional performance in detecting pulmonary inflammation and stratifying hypoxemia risk, achieving up to 96.57% accuracy in pneumonia subtype differentiation and an area under the curve of 0.96 for postoperative hypoxemia prediction. Multimodal AI systems, such as DeepLung-Predict, unify computed tomography scans, pulmonary function tests, and ABG parameters to enhance predictive precision, surpassing conventional methods by 22%. However, challenges persist, including dataset heterogeneity, model interpretability, and clinical workflow integration. Future directions emphasize multicenter validation, explainable AI frameworks, and pragmatic trials to ensure equitable and reliable deployment. This AI-driven approach not only optimizes resource allocation but also mitigates financial burdens on health care systems by enabling early interventions and reducing intensive care unit admission risks.

KEYWORDS

pneumonia; perioperative; artificial intelligence; hypoxemia; deep learning

Introduction

Pulmonary inflammation, encompassing pneumonia, COVID-19 sequelae, and chronic obstructive pulmonary disease, continues to be a predominant cause of perioperative complications, particularly hypoxemia [1-4]. Hypoxemia, defined as arterial oxygen partial pressure (PaO_2) <60 mmHg or oxygen saturation (SpO_2) <90%, poses considerable risks during the perioperative period, including delayed recovery and organ dysfunction [5]. Traditional diagnostic approaches, such as radiological imaging, pulmonary function tests (PFTs), and arterial blood gas (ABG) analysis, are mutually independent and frequently lack integrated predictive accuracy [6,7]. Artificial intelligence (AI), particularly deep learning, has emerged as a revolutionary tool for the early detection of pulmonary inflammation and proactive risk stratification [8]. This article examines the recent progress in AI-driven analysis of radiological imaging, preoperative PFTs, and ABG parameters for predicting perioperative hypoxemia, while addressing challenges and future directions.

XSL•FO
RenderX

Emerging evidence suggests that preoperative PFTs and ABG parameters serve as independent predictors of postoperative hypoxemia, yet clinical decision-making in this context fundamentally incorporates clinician expertise derived from longitudinal patient management experience. Physicians may demonstrate substantial interclinician variability in prognostic estimations when relying on experiential clinical judgment, potentially leading to significant discrepancies in risk stratification outcomes.

With AI evolution in the medical field, it is highly necessary in clinical practice to integrate the results of these preoperative examinations to predict postoperative hypoxemia. Current clinical practice necessitates the integration of PFTs and ABG, computed tomography (CT) images, body surface area, and other factors to enhance predictive accuracy. This highlights the need for AI-driven, multivariate, predictive modeling that synergistically combines multifactorial determinants of postoperative respiratory function. Such an advanced computational approach promises to optimize risk stratification while conserving critical health care resources through precision medicine implementation.

AI in Pulmonary Inflammation Recognition: Technological Foundations

Deep Learning for Lung Imaging Analysis

Modern AI frameworks have revolutionized the detection and classification of pulmonary inflammation through advanced analysis of radiographs, CT scans, and dynamic ultrasound imaging. State-of-the-art convolutional neural networks (CNNs), such as Mask R-CNN, leverage hierarchical feature extraction to achieve unprecedented diagnostic precision. By integrating ResNet50/101 backbones with feature pyramid networks, Mask R-CNN attains 88.3% classification accuracy (95% CI 86.4-89.8) and 83.13% regression precision (intersection over union ≥0.5) in localizing pneumonia lesions on chest X-rays. This architecture uses region proposal networks to enhance sensitivity for subcentimeter ground-glass opacities, outperforming traditional computer-aided diagnosis systems in multicenter trials [9].

Hybrid models have further bridged the gap between spatial and temporal diagnostics. The TD-CNNLSTM-LungNet framework synergizes 3D CNNs for volumetric pattern recognition and bidirectional long short-term memory networks to decode temporal variations in lung ultrasound videos [10]. Evaluated on 1243 cases, this model achieved 96.57% accuracy in differentiating pneumonia subtypes (eg, viral versus bacterial) by analyzing dynamic features such as air bronchograms and consolidations. Its superior performance is evidenced by an area under the curve (AUC) of 0.983 (95% CI 0.972-0.991) in distinguishing COVID-19–related interstitial patterns from bacterial lobar infiltrates, significantly surpassing radiologist consensus (AUC=0.872, P=.003) [10].

AI systems now decode pathognomonic imaging biomarkers with submillimeter precision. For instance, VGG-Pneumonia v2.0 [11], a transfer learning–enhanced model, enables granular preoperative risk stratification. Attention mechanisms in DenseNet-121/Inception-v3 ensembles [12] have improved early detection of interstitial pneumonia to 91.4% sensitivity (κ=0.86) by mapping septal thickening patterns. Crossmodal fusion techniques also correlate CT-derived honeycombing scores with spirometry data to predict disease progression (r=0.79, P<.001) [13].

Integration of Pulmonary Function Metrics

Preoperative PFTs serve as critical tools for evaluating respiratory reserve and predicting postoperative outcomes in surgical patients. Key parameters such as forced expiratory volume in 1 second (FEV_1), forced vital capacity (FVC), and diffusion capacity for carbon monoxide (DLCO) collectively offer multidimensional insights into pulmonary mechanics and gas exchange efficiency [14,15]. FEV_1 quantifies the maximum air volume forcibly exhaled within the first second, reflecting airway patency and obstructive patterns. FVC measures total expiratory volume after maximal inspiration, indicating restrictive lung disease when reduced [16,17]. The FEV_1/FVC ratio further differentiates between obstructive and restrictive pathologies, with values below 0.7 typically suggesting airflow limitation [15]. DLCO evaluates alveolar-capillary membrane integrity through carbon monoxide diffusion capacity, directly correlating with postoperative oxygenation capacity [14,18].

Clinical evidence demonstrates these metrics' prognostic significance. In cardiac surgery populations, reduced FEV_1 (<70% predicted) and FVC (<80% predicted) independently associate with prolonged mechanical ventilation and increased pulmonary complications [14]. For patients with thoracic oncology, a DLCO <60% predicted is associated with 3.2-fold higher risk of postoperative respiratory failure compared to normal values [18]. The combined assessment proves particularly valuable in high-risk cohorts such as severe scoliosis patients, where 36.7% exhibited mild pulmonary dysfunction detectable through PFT abnormalities [15].

Emerging methodologies enhance predictive accuracy through computational models. Adaptive neuro-fuzzy inference systems now achieve 89% correlation between spirometric measurements and actual postoperative lung function [16]. Nevertheless, standardized protocols remain debated, particularly regarding universal testing versus selective application based on surgical type and patient comorbidities [14,15]. Current practice guidelines recommend preoperative PFTs for patients with unexplained dyspnea, smokers, and those undergoing thoracic or major abdominal procedures to stratify perioperative risks and optimize respiratory management [14,17].

Blood Gas Analysis and Hypoxemia Prediction

ABG parameters—including PaO_2, partial pressure of carbon dioxide, bicarbonate, and the PaO_2/fraction of inspired oxygen ratio—serve as fundamental diagnostic biomarkers for hypoxemia and respiratory insufficiency [19]. Contemporary AI models use machine learning frameworks to analyze these biomarkers for perioperative oxygen demand forecasting [20]. As demonstrated by a multicenter, prospective cohort study, preoperative ABG trends in pH, partial pressure of carbon dioxide, and alveolar-arterial gradients can predict severe

XSL•FO
RenderX

hypoxemia (PaO_2 <50 mmHg) with high accuracy. Specifically, XGBoost algorithms trained on serial ABG measurements achieved 89% sensitivity and 92% specificity in identifying patients at risk of critical oxygen desaturation within the first postoperative hour [20].

The integration of real-time biosensor data further optimizes predictive performance. Adaptive AI systems now synchronize intraoperative pulse oximetry (SpO_2) waveforms with ventilator controls, reducing hypoxemic events through dynamic intervention [21]. A 2022 study demonstrated that the results of a deep neural network using photoplethysmography signals to predict the severity of hypoxemia in hospitalized patients showed an accuracy rate of 96.5% in determining 3 severity categories, with a Cohen κ score of 0.79. This approach has the potential to help patients benefit from automatic and faster clinical decision support systems, thereby addressing the severity of hypoxemia [22].

Multimodal AI Systems for Perioperative Risk Stratification

Fusion of Imaging, Functional, and Biochemical Data

Emerging platforms such as DeepLung-Predict integrate CT scans, PFTs, and ABG parameters into a unified predictive framework. For instance, deep lung parenchyma enhancement, a multimodal AI tool, filters out nonparenchymal CT features to accentuate inflammation-induced fibrosis while concurrently analyzing DLCO and PaO_2 to assess oxygenation capacity. In a 2024 trial, DeepLung-Predict attained an AUC of 0.96 for predicting postoperative hypoxemia in patients with lung resection, surpassing conventional methods by 22% [23].

Dynamic Risk Monitoring

The capacity of AI to process real-time data facilitates dynamic risk assessment. For example, recurrent neural networks undertake the analysis of intraoperative SpO_2, end-tidal carbon dioxide, and ventilator waveforms to predict hypoxemic crises several minutes prior to clinical manifestation [24]. Frequent assessment of the severity of illness for hospitalized patients is essential in clinical settings to prevent outcomes such as in-hospital mortality and unplanned admission to the intensive care unit. Classical severity scores have typically been developed using relatively few patient features. Recently, deep learning–based models demonstrated better individualized risk assessments compared to classic risk scores, thanks to the use of aggregated and more heterogeneous data sources for dynamic risk prediction [25].

Case Study: COVID-19 Recovery and Surgical Planning

Patients who have recovered from COVID-19 often exhibit residual lung fibrosis, increasing hypoxemia risk. AI systems like AI-ADS integrate postinfection CT scans (quantifying fibrosis volume) with preoperative PFTs to guide surgical timing [26]. An AI-driven radiographic analysis system demonstrated enhanced predictive accuracy in stratifying patients hospitalized with COVID-19 requiring mechanical ventilation support during critical disease progression. Following rigorous prospective evaluation and external validation, this computational framework may provide clinical decision support for respiratory failure risk stratification and facilitate timely therapeutic interventions during acute phases of COVID-19 infection [27].

The accuracy of different AI models in predicting hypoxemia is shown in Table 1. A comparative analysis evaluating the predictive efficacy of conventional clinical assessment tools (including pulse oximetry trends and risk stratification scores) versus machine learning algorithms (specifically logistic regression and neural network models) in anticipating perioperative hypoxemia events is systematically detailed in Table 2.

Table 1. Performance comparison of artificial intelligence models in hypoxemia prediction.

Model	Data type	Accuracy (%)	AUC[a]	Key strength
Mask R-CNN	Chest X-rays	88.3	0.91	High lesion localization precision (IoU[b] ≥0.5) in multicenter trials with standardized imaging protocols.
TD-CNNLSTM-LungNet	Lung ultrasound videos	96.57	0.983	Superior spatiotemporal feature analysis validated on 1243 cases across 5 hospital systems.
DeepLung-Predict	CT[c], PFTs[d], and ABG[e]	—[f]	0.96	Multimodal fusion, 22% improvement versus conventional methods in patients with lung resection (n=412) [23].
XGBoost (ABG trends)	Serial ABG metrics	89 (sensitivity)	0.89	Early desaturation prediction (PaO_2[g] <50 mmHg) within 1 h postoperative in cardiac surgery cohort.
Res-SE-ConvNet	Photoplethysmography	96.5	—	Real-time severity categorization (κ=0.79) using ICU[h] biosensors at 125 Hz sampling rate.

[a]AUC: area under the receiver operating characteristic curve.

[b]IoU: intersection over union for lesion localization.

[c]CT: computed tomography.

[d]PFT: pulmonary function test.

[e]ABG: arterial blood gas.

[f]Data not available.

[g]PaO_2: partial pressure of oxygen.

[h]ICU: intensive care unit.

Table 2. Comparative performance of traditional versus artificial intelligence (AI)–driven methods for predicting perioperative hypoxemia.

Parameter	Traditional methods	AI-driven models
Diagnostic modalities	CT[a], PFTs[b], ABG[c] (isolated)	Integrated CT + PFTs + ABG + BSA[d]
Sensitivity (%)	68-75	89-94
Specificity (%)	72-78	91-96
AUC[e]	0.70-0.76	0.89-0.93
Time to diagnosis	24-48 hours	Real-time (<5 minutes)
Key limitations	Subjective interpretation and fragmented data	Requires large, annotated datasets and computational resources

[a]CT: computed tomography.

[b]PFT: pulmonary function test.

[c]ABG: arterial blood gas.

[d]BSA: body surface area.

[e]AUC: area under the receiver operating characteristic curve.

Methodological and Translational Challenges

Dataset Variability and Generalization

While AI models demonstrate high accuracy in controlled settings, their real-world applicability is hindered by dataset heterogeneity. Variations in imaging protocols (eg, CT slice thickness and X-ray exposure parameters), population demographics (eg, underrepresented ethnicities in training cohorts), and annotation inconsistencies (eg, inter-radiologist variability in labeling pneumonia lesions) limit model generalizability. For instance, a 2023 study found that models trained on single-center data experienced a 15%-20% performance drop when validated on external datasets [28]. Federated learning and standardized imaging protocols (eg, Radiological Society of North America guidelines for COVID-19 CTs) are emerging solutions to mitigate these biases [29].

Validation Methods and Generalizability

A 2023 meta-analysis highlighted that AI models trained on narrow datasets experience a median performance drop of 18% (95% CI 14%-22%) when applied to external cohorts, underscoring the risk of overestimating real-world efficacy [28].

Interpretability of AI Systems

The “black box” nature of deep learning models remains a barrier to clinical adoption. While attention maps in CNNs (eg, Grad-CAM visualizations [30]) partially elucidate

XSL•FO
RenderX

decision-making processes, they lack granular pathophysiological correlations. Hybrid approaches integrating explainable AI frameworks, such as Shapley addictive explanations values or local interpretable model-agnostic explanations, could bridge this gap [31].

Integration into Clinical Workflows

Operationalizing AI tools requires addressing infrastructural and human factors. Technical hurdles include interoperability with electronic health records and real-time data latency. Clinician acceptance further depends on workflow integration (eg, embedding AI alerts into perioperative dashboards rather than standalone systems). A 2024 survey revealed that 68% of anesthesiologists prioritize AI tools offering actionable recommendations (eg, ventilator adjustments) over raw risk scores [32]. Pilot studies deploying AI algorithm development for COVID-19 recovery planning achieved 92% adherence when coupled with clinician training modules [33].

Limitations

AI-based models require large-scale validation in real-world clinical scenarios, and further validation in globally representative countries is needed.

Hospital administrators grapple with AI's infrastructural demands. Legacy systems hinder data integration. Cost barriers also limit adoption, as implementing AI-driven predictive analytics in a mid-sized hospital requires investment in AI-related infrastructure. Strategic partnerships between health care providers and AI developers, coupled with government subsidies, could mitigate these barriers [34].

Ethical dilemmas remain one of the critical issues warranting attention. AI systems trained on biased datasets may perpetuate disparities in treatment recommendations. Moreover, data anonymization failures and crossinstitutional data sharing raise privacy risks, as seen in cases where deidentified patient records were reidentified through AI-driven linkage [35]. Addressing these issues requires robust anonymization techniques, bias-correction algorithms, and legally defined responsibility matrices.

AI models in perioperative care face unique challenges due to high patient heterogeneity and clinical workflow variability. Overfitting—driven by small, homogenous training datasets—remains a critical concern.

Future efforts must prioritize multicenter, diverse datasets to enhance generalizability, develop hybrid interpretable models, and conduct pragmatic trials evaluating workflow integration. Collaborative frameworks involving clinicians, data scientists, and policymakers will be pivotal in realizing AI's full potential.

Conclusion

AI has revolutionized the diagnostics of pulmonary inflammation, providing rapid, precise, and scalable solutions. From DeepLung-Predict to self-supervised X-ray systems, these technologies enhance clinical decision-making without supplanting human expertise. Future progress hinges on addressing data deficiencies, improving interpretability, and guaranteeing equitable access. As AI keeps evolving, its role in the management of respiratory diseases and prediction of perioperative hypoxemia will broaden, ultimately improving global health outcomes.

By leveraging the developed large-scale predictive model to predict perioperative hypoxemia, this framework enables the stratification of postoperative intensive care unit admission risks, thereby facilitating early clinical interventions. Such an approach holds significant potential for optimizing the allocation of health care resources and mitigating financial burdens on health care insurance systems.

Abstract

Background: In Spain, the prevalence of heart failure is twice the European average, partly due to inadequate patient management. To address this issue, a standardized care model, the Care Model for Patients with Heart Failure (Modelos Asistenciales de Atención al Paciente con Insuficiencia Cardíaca), was developed. This model emphasizes the importance of sequential visits from hospital discharge until the patient transitions to chronic care to prevent rehospitalization. The standardized care pathway has been implemented in certain areas of the Andalusia Health Service. However, there is uncertainty about whether the region's electronic health record system, Diraya, can effectively support this model. If not properly integrated, it could lead to data inaccuracies and noncompliance with the standardized care pathway.

Objective: This study aimed to explore how to improve Diraya to better support health care professionals in adhering to the transition standardized care model for patients with heart failure as they move from hospital care to chronic care.

Methods: In total, 16 semistructured interviews were conducted with nurses and physicians from both hospital and primary care settings. Thematic analysis was used to analyze the data and recommendations for improvements that were developed based on the findings. These recommendations were further supported by existing literature and validated through additional interviews.

Results: In total, 65 codes, 23 subthemes, and 8 themes were identified. The main themes included optimizing medical data management for enhanced clinical workflow, agreement on standardization and enhancement of the discharge report, enhancing clinical decision support through updated guidelines and automated tools, optimizing interoperability as a solution for better management of patients with heart failure, and encouraging communication based on digital tools and personal connection. In total, 15 improvements were proposed, such as standardizing technology across Andalusia Health Service facilities and offering targeted training programs. These measures aim to enhance interoperability, streamline communication between different health care settings, and reduce the administrative burden for health care professionals.

Conclusions: Diraya currently does not adequately support the transition standardized care model, placing a significant administrative burden on health care professionals, often with ethically concerning implications. To ensure effective implementation of the standardized care model, major updates are necessary for Diraya's clinical information management, system functionality, and organizational structure within the Andalusia Health Service.

Introduction

Heart Failure

Chronic diseases, such as heart failure (HF), pose a significant public health burden, threatening not only population health but also social and economic stability. Consequently, both public health strategies and health care delivery systems must undergo transformative changes [1]. Diagnosing HF requires identifying cardiac dysfunction, often linked to various risk factors [2]. Early detection, timely intervention, and continuous monitoring—from primary care to hospitalization—are crucial in the recovery process [3].

HF was first identified as an emerging epidemic in 1997 [4], and it remains a major health concern today, with a prevalence of approximately 2% among adults in Europe and North America [2,5-7]. In Spain, however, the prevalence is nearly double, with an annual incidence rate of 2.78 per 1000 patients [8].

Managing HF is particularly challenging due to its chronic nature, severe symptoms, and significant impact on patients' quality of life. Furthermore, HF imposes a substantial economic burden, primarily driven by frequent hospitalizations and long-term health care needs [9]. To address these challenges, population health management and integrated care pathways have emerged as effective strategies. These approaches aim to improve health care systems' responsiveness, better meet patient needs and preferences, and enhance efficiency [9]. A key example of such an approach is the standardized care pathway (SCP), which provides structured guidance for the medical treatment of patients with specific clinical conditions, ensuring high-quality care [5]. SCPs offer detailed, standardized treatment plans for patient groups with predictable clinical courses, leading to improved outcomes, more efficient resource use, and enhanced clinical effectiveness—ultimately increasing patient satisfaction [9]. Given its benefits, implementation of an SCP for HF is crucial, as it provides a systematic, evidence-based framework for the comprehensive management and treatment of patients with HF [10].

Spanish National Health System

Overview

The Spanish National Health System (SNHS) encompasses Spain's public health services [11]. It operates under a decentralized model, where autonomous communities are responsible for managing and delivering health services, while the Ministry of Health establishes general guidelines and coordinates national health policies [12].

Within SNHS, HF is the leading cause of hospitalizations among patients aged >65 years, accounting for 5% of all hospital admissions. It is estimated that HF-related hospitalizations will increase by up to 50% over the next 25 years [3]. The economic burden of HF is substantial, costing approximately €2.5 billion (US $2.7 billion) annually, which represents 3.8% of Spain's total health care expenditure [13].

To improve HF management, Spain has implemented a comprehensive continuous care program for patients with HF, which focuses on patient and family education, comprehensive assessment, and continuity of care [14]. Despite these efforts, cardiovascular diseases remain the leading cause of hospitalization and mortality in Spain and effectively managing patients with HF continues to be a challenge [15]. To address this issue, Spain developed a standardized care model known as the Care Model for Patients with HF, (Modelos Asistenciales de Atención al Paciente con Insuficiencia Cardíaca [MAIC]), aimed at improving the quality and coordination of HF care across health care settings [16].

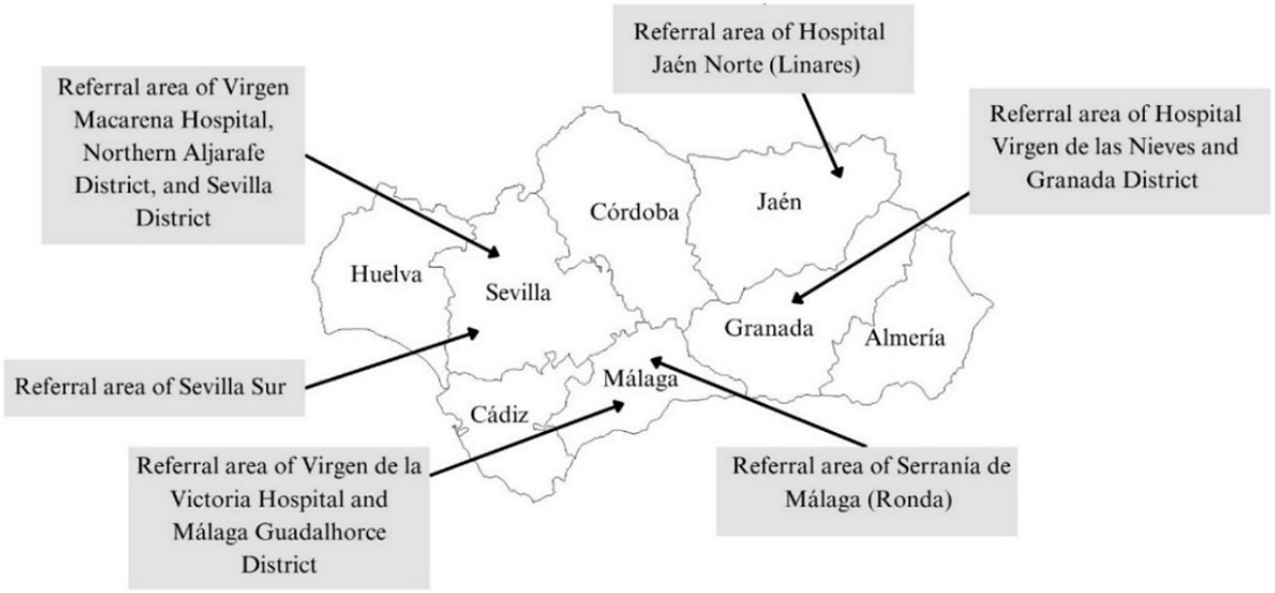
Spanish Care Model for Patients With HF

The Care Model for Patients with HF project is led by several key medical societies in Spain, including the Spanish Society of Cardiology, the Spanish Society of Internal Medicine, the Spanish Society of Primary Care Physicians, the Spanish Society of Family and Community Medicine, the Spanish Society of Healthcare Executives, and the Spanish Society of Hospital Pharmacy, with Antares Consulting and Boehringer Ingelheim as investors [16]. To address challenges in pathology and optimize patient care, these organizations developed a comprehensive document in 2020, synthesizing current literature and interviews with health care professionals (HCPs). This document includes implementation tools, key considerations for HF care as a SCP, and a flowchart detailing the entire patient journey—from hospitalization to chronic treatment and follow-up (Multimedia Appendix 1 [16]).

The transition from hospital discharge to outpatient follow-up is a critical phase for ensuring continuity of care, as it significantly impacts patient prognosis, the risk of decompensation, and the likelihood of hospital readmissions. Figure 1 highlights the main transition SCP (TSCP), which focuses on patient discharge from the hospital to primary care.

After hospital discharge, a hospital nurse (HN) and a cardiologist or internal medicine (C/IM) specialist oversee the patient transition. Within the first 48 to 72 hours, a primary care nurse (PCN) contacts the patient by phone to check their condition. Shortly after, the patient has an in-person visit with both a PCN and a primary care physician (PCP) for further assessment. Finally, 2 to 3 weeks later, the C/IM specialist conducts a follow-up visit, ensuring the patient's transitions to chronic HF care. The standardized care model, MAIC [16]. was implemented during the first semester of 2024 in 5 hospitals and their respective primary care centers in Spain, with 29 additional hospitals in the process of adopting this standardized care model. The implementation follows a 6-8–month timeline during which health care centers are evaluated and monitored for adherence to the care model. The progress tracking covers a year, using process and outcome indicators from health care data to assess improvements.

Andalusia Health Service



The TSCP is currently in operation across several autonomous communities in Spain, including Andalusia. Located in the southern part of the country, Andalusia is the most populous and the second largest autonomous community. The Andalusia Health Service (AHS) is committed to providing accessible, equitable, and high-quality public health care services to its

XSL•FO
RenderX

citizens [17]. The AHS consists of a network of health care services, organized into 15 health areas, which include 5 regional hospitals, 10 specialized hospitals, 19 district hospitals, and 16 high-resolution hospitals [18]. Each health area is structured around a reference hospital and its associated primary care centers, ensuring comprehensive coverage for the population. In terms of HF, approximately 140,000 individuals have been diagnosed with the condition in Andalusia [19].

In December 2023, the AHS initiated the implementation of the SCP in 6 hospitals and their corresponding primary care settings, collectively designated as referral areas, across Andalusia (Figure 1). The goal is to expand this implementation throughout the autonomous community.

Figure 1. Map of Andalusia highlighting each referral area where the standardized care pathway has been implemented. Courtesy of Antares Consulting Company.

The TSCP involves 4 key actors, each playing a crucial role in the process. These actors come from 2 health care settings, hospital and primary care, and represent 2 professions: physicians and nurses. Each participant has distinct responsibilities, performs specific tasks, and receives different training (Table 1). However, their collaboration is crucial to achieving better outcomes for patients with HF.

Table 1. Description of the health care professionals' roles involved in the care of patients with heart failure.

Role	TSCP[a] role description
Cardiologist or internal medicine specialist	• Performs the discharge assessment and a visit after 2-3 wk of the discharge. The main tasks are as follows: manage and assess the discharge report; medication management; communication with primary care, that is, reviewing hospital reports
Hospital nurse	• Performs the nurse assessment for the patient discharge. The main task that is performed is to manage and assess the discharge report.
PCN[b]	• Does the first evaluation after the discharge, via phone call. Then they perform a face-to-face visit. The main tasks that are performed are as follows: educate, check warning signs, and titrate medication (blood test and writing the report, among other); manage upcoming and follow-up visits in the unit; communicate with the hospital, that is, review hospital reports.
PCP[c]	• First medical evaluation after the discharge. This visit must be completed in less than a week. The main tasks are as follows: conduct the initial face-to-face and subsequent follow-up visits after discharge (assessment and medical history among writing the report, among others); manage medication; communicate with the hospital, that is, review hospital reports

Electronic Health Records for HF Practice

To successfully implement an SCP, electronic support, particularly an electronic health record (EHR) system, is essential [20]. The EHR needs to align with the different steps of the SCP and meet the specific needs of HCPs [21]. Diraya, the EHR system used by the AHS, was implemented in 2005 and has undergone multiple updates to adapt to the evolving demands of the health care sector [22].

Diraya consists of various modules that share information across different health care environments and among professionals. These interconnected components ensure that each piece of data are recorded uniquely and can be accessed when needed [22]. For the care of a patient with HF, Diraya uses the following modules in both hospital and primary care settings [23]: (1) the Primary Care Clinical History module allows for the visualization and editing of data, including personal information, health programs, care processes, medical history, allergies, prescriptions, medication orders, medication, work disabilities, and follow-up records by the family doctors; (2) Hospital Clinical History module in hospitals, excluding emergencies, manages care processes associated with clinical profiles from the perspective of hospital care, generating basic and specialized reports; (3) Hospital Clinical Care handles nursing records related to patient care and organizes them into structures reports; (4) Mailbox manages automated notifications to professionals in primary and hospital care, serving as a key communication channel, for example, when a patient with HF is discharged, their PCP receives a notification; and (5) Single Navigator provides access to all reports, regardless of their origin.

The implementation of EHR systems like Diraya enhances health care services by streamlining medical information management. However, a key challenge remains: does Diraya effectively support HCPs in managing care for patients with HF within the SCP?

Aim of the Study

In Spain, patients with HF who are discharged without specific measures face a high risk of readmission within the first month. Optimizing Diraya is imperative to improving care for patients with HF and ensuring better adherence to the SCP. Achieving this requires a comprehensive understanding of the needs of HCPs involved in the transition from hospital to primary care. To our knowledge, no studies have explored the optimization of an EHR system for patients with HF transitions based on HCPs' needs in adhering to an SCP—either within the AHS or in other Spanish regions.

This study aimed to identify ways to improve Diraya to better support HCPs in following the TSCP for patients with HF during the transition from hospital to chronic care. The research focuses on the clinical content, human-computer interaction, technical aspects, and organizational and communication needs in HF care within the EHR and TSCP. In addition, it seeks to provide a list of recommended improvements for Diraya.

Methods

Study Design

The study used a qualitative approach to gain an in-depth understanding of HCPs' needs. Semistructured interviews with open-ended questions were chosen as the data collection method. The sociotechnical system (STS) model [24] served as both the framework and the interview guide for this study. The interviews were analyzed using thematic analysis, combining both deductive and inductive reasoning to thoroughly explore the data. Following the analysis, drafts summarizing the results and highlighting relevant improvements to meet HCPs' needs were created. These results were then verified and validated with a representative from each health care setting. This validation process adhered to the principles of qualitative research methodology, ensuring the reliability and credibility of the data collected.

Study Setting and Participants

The study was conducted across 6 health care areas of AHS where the SCP was in the process of being implemented. The areas were as follows: (1) referral area of Virgen Macarena Hospital, Northern Aljarafe District, and Sevilla District; (2) referral area of Hospital Jaén Norte; (3) referral area of South Sevilla; (4) referral area of Virgen de la Victoria Hospital and Málaga Guadalhorce District; (5) referral area of Serranía de Málaga; and (6) referral area of Hospital Virgen de las Nieves and Granada District.

To ensure the participation of relevant HCPs involved in the TSCP across both health care settings and during the discharge transition, 4 key roles were included: PCPs, PCNs, HNs, and C/IM specialists. Participants were selected using purposive sampling [25], and to expand the participant pool, snowball sampling was also applied [26]. Sampling continued until data saturation was achieved.

Initial contact with potential participants was made via email, with follow-up phone calls or WhatsApp (Meta Platforms) messages when necessary. During these interactions, a concise overview of the study, including its aims and objectives, was provided. Interested participants received an informed consent document, which they were required to sign and return before the interview. Recruitment was facilitated through Antares Consulting [27].

The inclusion criteria required participants to be actively engaged in the care of patient with HF, employed within the AHS, and working in either hospitals or primary care settings as nurses or physicians. The study excluded participants with <3 years of experience and those currently on sick leave. The limited number of participants and the focus on specific areas in Andalusia may limit the generalizability of our study. Future research should include a larger and more diverse participant base. This limitation is discussed further in the Discussion section.

Data Collection

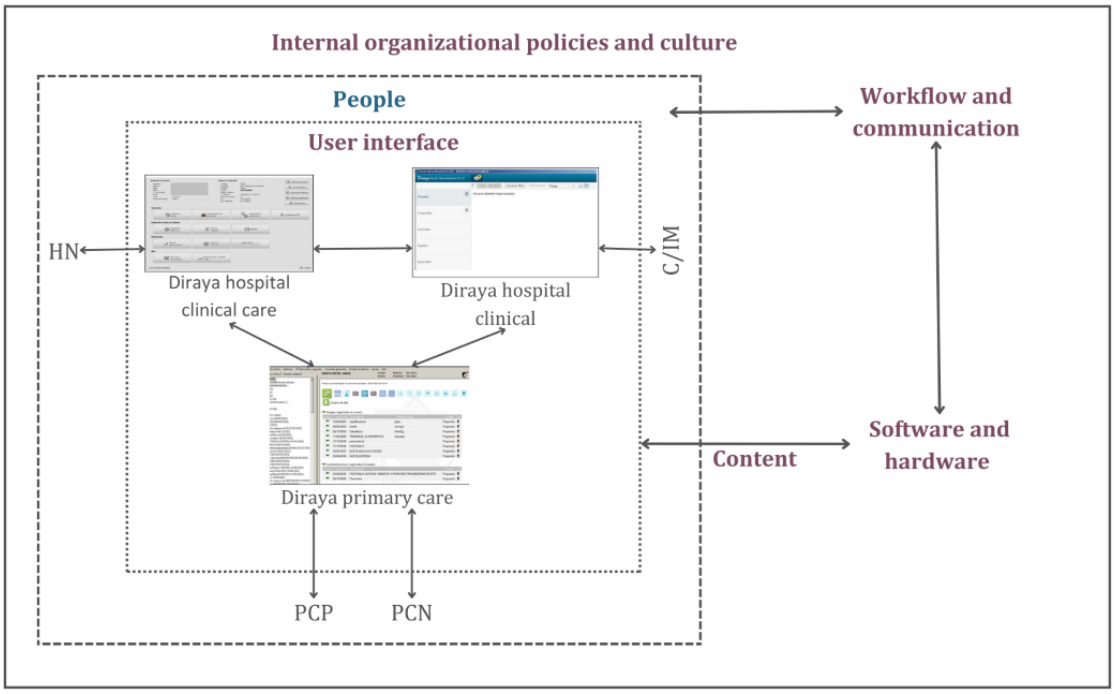
To address the research question, data were collected through interviews guided by the STS model. In addition, the identified

XSL•FO
RenderX

needs and corresponding improvements were verified through follow-up interviews.

Interviews

The interviews were conducted individually, using a semistructured format, with open-ended questions. The process was carried out in 2 phases: the first phase explored the needs of HCPs, while the second phase verified the proposed improvements. For the second phase, 2 participants with different roles were selected from each health care setting.



All interviews were conducted via Microsoft Teams, recorded, and transcribed verbatim using the platform's transcription feature. They were conducted in Spanish, the native language of both the participants and the study's first author (MF). The interviews lasted an average of 30 to 45 minutes.

The STS Model

In the study, the STS model was primarily used to develop the interview guide and analyze the data. It also provided a comprehensive understanding of the TSCP by addressing both its technical and organizational aspects. The STS framework integrates technical components, such as hardware and software, with social needs to ensure an effective human-computer interaction [28]. Within this framework, an STS aligns closely with an EHR, as its effectiveness depends not only on the technological infrastructure but also on how well it integrates with workflows, user needs, and the behaviors of individuals and organizations [28,29]. This perspective is supported by Coiera [30], who highlights that those systems that are reliant on complex human organizational structures, such as health care systems, are particularly well-suited to the STS approach. Moreover, Sittig and Singh [24] argue that models used for explaining technological systems are insufficient in capturing the full range of factors necessary for designing and implementing health care systems.

The STS model defines 8 dimensions [24], 5 of which were used in this study: clinical content, human-computer interface, hardware and software, workflow and communication, and internal organizational policies, procedures, and culture (Figure 2). The dimensions of external rules and regulations, as well as measurement and monitoring, were excluded, as they were less relevant to the 4 key actors in the study, given that clinicians are not directly familiar with these dimensions. The people dimension was also excluded because the direct interactions of HCPs with the system had already been analyzed before the interviews.

Figure 2. Interrelationships among the 6 dimensions of the sociotechnical model. C/IM: cardiologist or internal medicine; HN: hospital nurse; PCN: primary care nurse; PCP: primary care physician.

Data Analysis

The data were analyzed using thematic analysis. After each interview, a preliminary analysis was conducted, followed by a comprehensive analysis at the end of the data collection. Initially, a deductive approach was used to identify the codes based on the 5 dimensions of the STS model. This was then followed by an inductive analysis to explore subthemes and themes in greater depth. As the interviews were conducted in Spanish, all quotes were translated into English. The data were organized in a Microsoft Excel spreadsheet, where the authors (MF and ND) familiarized themselves with the collected data, developed codes, and generated themes based on these codes [31,32]. On the basis of the data analysis, a list of improvements and recommendations was developed.

Ethical Considerations

Although data collection was conducted across 6 health care areas within AHS, the Karolinska Institutet was the principal research institution. The study was carried out in accordance

XSL•FO
RenderX

with the Swedish Ethical Review Act (SFS 2003:460) [33,34]. Since the research did not involve the handling of sensitive personal information as understood by the European General Data Protection Regulation, Regulation (EU) 2016/679 [35], ethics approval was not required. However, ethical requirements still apply. Candidates who expressed interest in participating received an informed consent form before the interview. In addition, participants recruited for the second phase signed an additional consent form. The informed consent form explained the study's objectives, detailed how data would be handled to maintain anonymity, and clarified that the interview would be recorded and immediately transcribed. All participants were informed that their participation was voluntary and that they had the right to withdraw from the study at any time without any consequences. Additionally, no financial compensation was provided to any participants. Participants were given the opportunity to ask questions, and their understanding of the study was confirmed before proceeding. In addition, at the start of each Teams interview, participants provided oral consent before the recording began.

To ensure confidentiality and anonymity, only the study authors (MF and ND) had access to the data. A participant randomization document was created, listing names, demographic data, and participant codes. This document was stored in a password-protected Microsoft Excel database accessible only to the authors (MF and ND). The coded interview data were not linked to participants' names. Antares Consulting, which is collaborating on the SCP implementation with Boehringer Ingelheim, shared nonsensitive and relevant data for the study, including participant contact information. In addition, during the interviews, 2 participants shared their screens to provide a clearer visualization of clinical history. Both participants used a fictitious profile, ensuring that the clinical history data did not belong to a real patient.

Generative Artificial Intelligence Disclosure

In this study, generative artificial intelligence (AI) technologies, such as Grammarly (Grammarly Inc) and OpenAI's ChatGPT (GPT-3.5; OpenAI), were used to help the authors (MF and ND) translate the quotes and documents from Spanish to English. These tools were not used to modify or influence qualitative data or the thematic analysis. The data collected were analyzed in their original form to ensure they accurately reflected participants' responses. The tools were used in the preparation of the manuscript to enhance grammatical accuracy and clarity of the text. After using these tools, the authors (MF and ND) reviewed and edited all AI-generated content to ensure it aligned with the study's objectives and maintained the integrity of the content. The authors (MF and ND) thoroughly reviewed and edited all aspects of grammatical accuracy and textual clarity to ensure alignment with the study's objectives and preserve the integrity of the content, taking full responsibility for the publication's content.

Results

Participants' Demographic Data

Between January 15, 2024, and April 15, 2024, 30 HCPs were contacted, and 53% (n=16) agreed to participate in the study. While the goal was to recruit a balanced representation from each area, half (8/16, 50%) of the participants came from areas 3 and 4, resulting in lower representation from the remaining areas. Regarding professional roles, nurses made up 50% (8/16) of the participants, family doctors accounted for 25% (4/16), and nearly 20% (3/16) were cardiologists. As effective communication between different health care settings is essential for improving the transition of patients with HF to chronic care, an equal number of participants were selected from both primary care and hospital care. The detailed characteristics of the participants are presented in Table 2.

Thematic Analysis

Overview

The results of the thematic analysis are presented in Table 3. The first column identifies the dimension of the STS, and the second and third columns list the subthemes and themes. In total, 65 codes, 23 subthemes, and 8 themes were identified. In addition, a matrix was developed to integrate the results with the actors.

XSL•FO
RenderX

Table 3. An overview of sociotechnical dimensions, subthemes, and themes.

Sociotechnical dimensions and themes	Subthemes
Clinical content	
Optimizing medical data management for enhanced clinical workflow	• Implementation of standardized clinical reports • Reporting management challenges
Agreement on standardization and enhancement of the discharge report	• Enhancement of the discharge nursing report • Summarization of the medical discharge report
Enhancing clinical decision support through updated guidelines and automated tools	• Nursing support to achieve better educational care • Possibility of a medical decision support
Human-computer interaction	
Improving UX[a] and usability for enhanced clinical efficiency and less time-consuming experience	• Need for learnability • Need to improve the visual design • Noneffective iconography • Nonefficiency interaction
Hardware and software computing infrastructure	
Enhancing technical infrastructure to improve HCP[b] efficiency	• Hardware infrastructure limitations • Network connectivity • Technical apparatus issues • Software infrastructure challenges
Optimizing interoperability as a solution for better management of patients with heart failure	• Unification of the EHR[c] modules • Streamlining processes with shared scales
Workflow and communication	
Encourage communication based on digital tools and personal connection	• Inclusion of mailbox as a communication tool in workflow • TSCP[d] implementation workflow on EHR practices • Fostering of effective internal communication • Enhancement of external communication
Internal organizational policies, procedures, and culture	
Cultivating a culture in nursing practice and professional organizational integration	• Willingness to improve the nursing care between primary care and hospital • Training upon joining • Cultivating culture

[a]UX: user experience.

Clinical Content

Overview

Figure 3 illustrates the relationship between the sociotechnical dimension of clinical content, the codes, and subthemes related to the themes—optimizing medical management for enhanced clinical workflow, agreement on standardization and enhancement of the discharge report, and enhancing clinical decision support (CDS) through updated guidelines and automated tools.

XSL•FO
RenderX

Figure 3. A hierarchical structure displaying the sociotechnical dimension, the codes, and the subtheme for themes 1, 2, and 3. CDS: clinical decision support; HF: heart failure.

Theme 1: Optimizing Medical Data Management for Enhanced Clinical Workflow

Primary care professionals, both in nursing and medical roles, are required to report each visit with a document that includes the patient's medical history and relevant examination information. In AHS, after consultations with patients with HF, both PCPs and PCNs must complete the aforementioned report using 1 of the 2 available formats: either a regular clinical report or a report manager. Efficient management of the medical data collected during visits is crucial. Thus, this is facilitated by a protocol-based strategy designed to enhance clinical workflow. This theme explores the outcomes of both formats, addressing their clinical content as well as structural and technical usability aspects, especially in the context of HF practice.

One method of documenting involves using the clinical report, in which the medical history appears at the beginning of the report, followed by details of the physical examination. Nonetheless, variability exists in this format, as participants expressed the need for a standardized version. This approach would ensure consistency in both medical data and clinical content within the reports, particularly during the first visit after discharge. It would also minimize redundant data entry, saving time, and reducing the risks of confusion, misinformation, and errors. However, keeping the medical history up to date remains a challenge, as only physicians are authorized to make updates, and this task depends on their workload and willingness:

> *The medical history data is only updated when completed by the practitioner, leading to occasional information gaps...Sometimes, when a patient visits without a prior diagnosis of HF, I have to review the entire medical history to understand their condition.* [PCN3]

The alternative documentation format is through a report manager, which uses a questionnaire-style format detailing the actions required during a general HF visit. However, participant engagement with this tool is low, only 13% (1/8) of the participants had used it, while 63% (n=5) were unaware of its existence. Aside from increasing awareness of the report manager, the interviews identified several other needs and shortcomings. For example, participants recommended that both data entries and questions remain up to date and relevant, while also being user-friendly and requiring minimal effort to complete:

> *The content sometimes contains inaccuracies or is not aligned with the requirements of the visit...I need the content to be current...some scales that are included are not typically performed in primary care and should only be conducted in the hospital.* [PCP1]

Thus, it was also suggested that each questionnaire's content be specifically tailored to the professional's roles and the type of care they provide. Finally, all clinical content is currently saved as plain text, which limits navigation. Therefore, professionals expressed a preference for a more structured format:

> *When the Report Manager is filled out, the information is directly transferred to the clinical record, where it appears overly condensed and difficult to read. I would prefer the information to be displayed in bullet points, following the same sections as the Report Manager.* [PCP1]

Theme 2: Agreement on Standardization and Enhancement of the Discharge Report

To identify the needs and areas for improvement in the nursing discharge report (NDR), both HN and PCN were asked specific

XSL•FO
RenderX

questions. As HCPs from both settings, their collaboration helped pinpoint which parameters could be optimized.

Focusing first on PCN, they revealed that they never review the NDR because the information appears "copied and pasted" and lacks patient-specific details. Therefore, PCNs used to read the medical discharge report (MDR) instead:

> *Well, I'll tell you that when they discharge a patient, the nurse fills out a form that nobody really reads. Are these responses to a questionnaire about what has happened to the patient? How does he sleep? Does he have any risks? How is his ulcer treated? How is he catheterized? .... I have too many questions that are not provided and others that are unnecessary. If the patient is not catheterized, I don't need to know that he doesn't have a catheter; it's only relevant if he does...* [PCN 3]

Following up with HNs, professionals confirmed that the information received from PCNs is often incomplete. HNs often do not have time to complete the NDR, and if they do, it tends to be very broad and not personalized. They would like to have parameters, such as social risk, patient polypharmacy, fall risk, Barthel scale, edema, weight at discharge, oxygen therapy, dyspnea, and feeding, among other options. This would provide PCNs with a summarized and relevant report of the status of patient with HF. Moreover, it would enhance communication between both health settings:

> *Patient education and management of medication and alarm signs are essential information that must be worked on in both settings. But knowing how these are being addressed and what the patient's status is from PC and in HC is essential so [that] it can be agreed upon and worked on together.* [PCN 3]

In contrast, PCPs commented that the MDR is overly extensive and tedious, requiring a significant amount of time to thoroughly review the details. They suggested that a more concise report, with specific parameters, would be beneficial. This should include key information, such as the confirmation of the initial diagnosis, etiology of the condition, left ventricular ejection fraction data, potassium levels, creatinine levels, and the treatment plan of the patient, including therapies and doses.

Theme 3: Enhancing CDS Through Updated Guidelines and Automated Tools

Although CDS features exist in the current Diraya system, they are limited to nursing professionals. In the Diraya primary care recommendations based on the responses are provided upon completing a questionnaire. Nonetheless, PCNs have expressed concerns regarding the clinical content and functionality of the CDS:

> *It will be nice to have recommendations together with the scale result, the associated risks, and how to manage the patient. I usually remember from experience, but it's harder to recall after some days off.* [PCN3]

In addition, managing medication for patients with HF is crucial for ensuring adherence to treatment and reducing readmissions. PCNs would find it beneficial if medication information included its purpose and use instructions:

> *Sometimes, the treatment involving medication reconciliation causes certain confusions: medications are added without educating the patient. Occasionally, medication is duplicated, and the primary care physician suggests resolving it with the hospital's internal medicine department.* [PCN1]

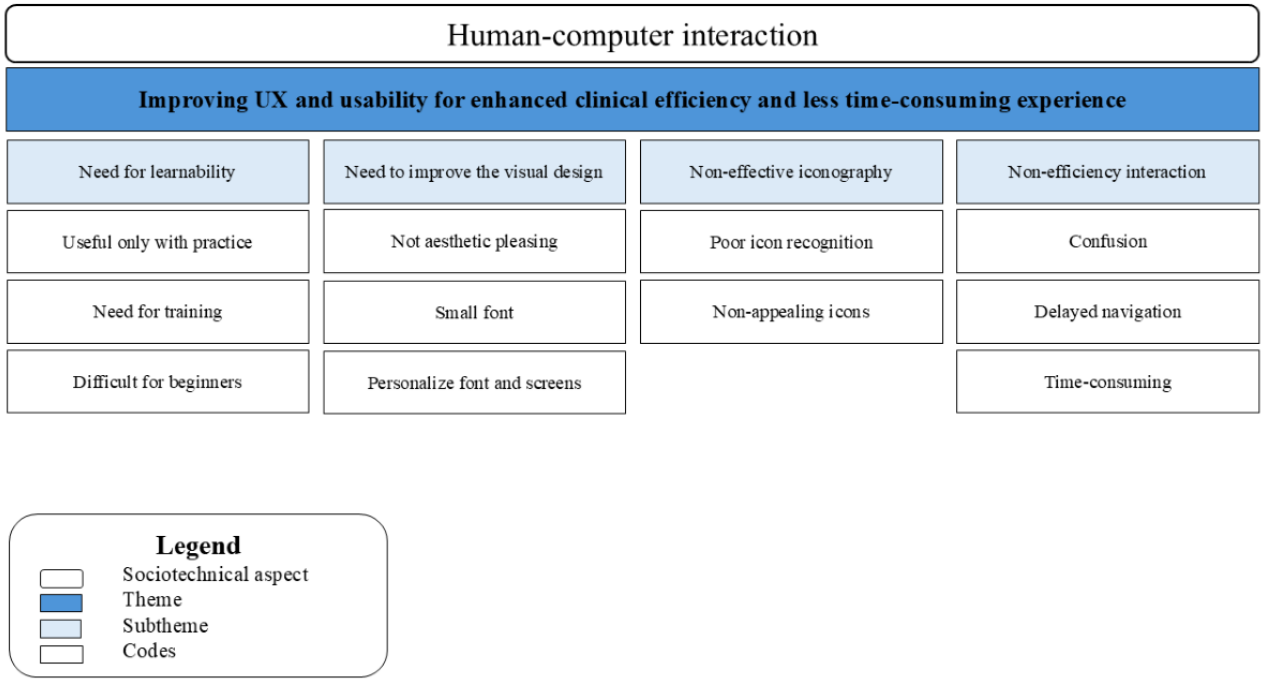
A key component of the TSCP is patient education after hospital discharge through telephone or on-site visits. In addition to providing medication information, it also involves informing patients about their illness, warning signs, and associated risks according to HN and PCNs having a checklist including this information would be helpful:

> *Having a checklist with all the necessary information would ensure nothing is overlooked.* [HN2]

Regarding the report manager, the CDS provides prompts based on questionnaire results. However, these prompts are in free text and do not link directly to actions in the EHR. Automating the CDS to enhance patient management and streamline administrative tasks would be beneficial. In contrast, PCPs do not receive any system-generated recommendations during their visits. Addressing this gap is essential to improving their experience, so feedback and needs were collected:

> *It would be incredible if the system could guide me based on protocols and guidelines for HF patients, such as in scales and patient examinations. This would enable me to make more informed decisions.* [PCP 2]

Finally, it is also important to mention the integration of CDS during the TSCP while the patient is hospitalized. An HN suggested that including recommendations for assessing scales used at the time of discharge would be helpful. Similarly, C/IM specialists mentioned that CDS could provide valuable guidelines and recommendations for patient evaluations during follow-up visits, potentially improving overall care practices.



Human-Computer Interaction

Overview

The interaction among the 4 groups of interface users varied depending on the health care setting and the professional role. PCPs used one module of the interface, while hospital users used 2 different modules, and primary care HCPs only had access to one module. Although these 3 modules differed, participants shared similar needs and insights. Figure 4 illustrates the relationship between the sociotechnical dimension of human-computer interaction, the codes, and subthemes related to the theme—improving user experience (UX) and usability for enhanced clinical efficiency and time-consuming experience.

XSL•FO
RenderX

Figure 4. A hierarchical structure displaying the sociotechnical dimension, the codes, and the subtheme for theme 4. UX: user experience.

Theme 4: Improving UX and Usability for Enhanced Clinical Efficiency and Time-Consuming Experiences

All HCPs agreed that they gradually became proficient in using the EHR for HF care through practice, indicating that the interface is not intuitive. Some found it challenging at first, though 1 PCN mentioned that it became manageable after gaining experience:

> *For me, once learned, its [the EHR] operation was straightforward.* [PCN4]

Professionals also emphasized the need for adjustable font sizes to meet various needs. They suggested that visual enhancements could streamline information retrieval, ultimately improving attention and efficiency.

Moreover, HN explained completing the NDR involves navigating numerous pages, making system interaction cumbersome and the design unappealing. Notably, C/IM specialists reported greater satisfaction with the interface compared to PCPs.

All PCPs commented that the interface icons, particularly those used for medical history, were unclear:

> *For patients with COPD, a lung icon appears; for cervical cancer, there is a figure of a woman; and for HF, a heart icon is used. However, it is not immediately clear whether the icon represents HF. I would use a clearer icon, or better yet, the diagnosis in text form.* [PCP2]

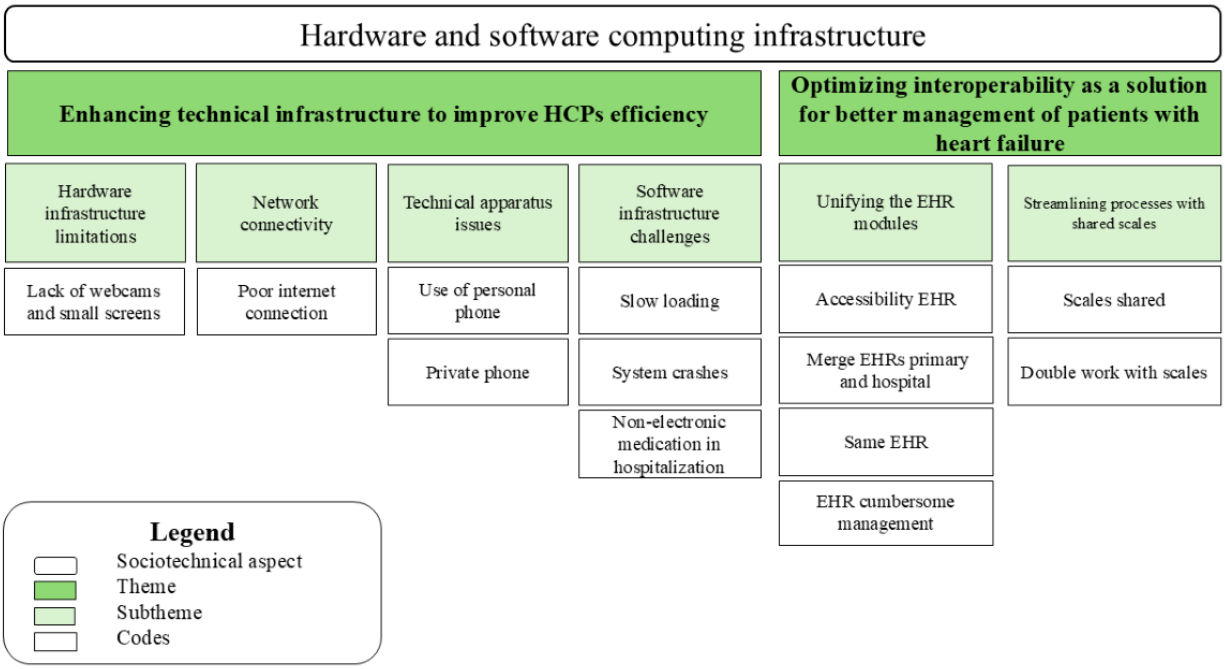
Some (5/8, 63%) participants noted that the icons used throughout the questionnaire were difficult to understand:

> *You need to recognize that one icon represents nursing and another medicine; others stand for medication, vaccine, diagnosis, video call, and more. But with no text in line with the icons, their meanings are unclear.* [PCN 3]

Regarding access to EHRs across different health care settings, hospital participants reported rarely having time to consult the primary care EHR. Conversely, primary care participants often find time, express interest in learning more about hospital data, or value the patient, which motivates them to review the hospital EHR. However, they emphasized the difficulty of doing this regularly or systematically due to time constraints:

> *There is no time and accessing the hospital EHR is time-consuming; it can take up to five minutes to find specific information, which wastes quality time with the patient.* [PCN2]

Therefore, many HCPs choose not to access the data regularly, disrupting communication between professionals.



Hardware and Software Infrastructure

Overview

In this dimension, the findings indicated that the technology used in primary care centers and hospitals was of low quality, resulting in significant delays and extended waiting times. Moreover, interoperability played a vital role in connecting both settings, which was crucial for the effective management of patient care during the discharge transition. Figure 5 illustrates the relationship between the sociotechnical dimension of hardware and software computing infrastructure, the codes, and subthemes related to the themes—improving technical aspects reduces unnecessary task time, thereby enhancing the quality of work; and optimizing interoperability as a solution for better management of patients with HF.

XSL•FO
RenderX

Figure 5. A hierarchical structure displaying the sociotechnical dimension, the codes, and the subtheme for themes 5 and 6. EHR: electronic health record; HCP: health care professional; HF: heart failure.

Theme 5: Improving Technical Aspects Reduces Unnecessary Task Time, Thereby Enhancing the Quality of Work

Most of the participants highlighted the inefficiency of current technology, including hardware, software, and internet connectivity—used in their health care settings. They reported frequent internet outages, especially during rainfall, along with system crashes and slow loading times when using the Diraya system. Participants working in hospitals also faced malfunctioning computers, which caused significant delays in accessing necessary documentation tools:

> *The internet goes down at least three times a week. [C/IM 3])*

Another issue was the use of corporate phones with long and unrecognizable numbers, which affected the availability of PCNs for patient follow-ups within 48 hours to 72 hours after discharge as patients often ignored these numbers:

> *Patients frequently disregard calls from unknown, lengthy numbers, leading to missed follow-up opportunities.... Providing patients with recognizable extension numbers would greatly enhance communication. [PCN 2])*

In addition, some HCPs do not have access to corporate phones, forcing them to use their personal devices for work-related communication. This raises several concerns, such as the traceability of patient interactions and data privacy:

> *I have a friend who works in the cardiology department of another hospital. When I know a patient is from her area, I use WhatsApp to inform her...which means I take work home and there's no traceability for these patient interactions.* [HN 4]

This issue extends even to professionals within the same health care center. Some PCNs mentioned that informal communication methods, such as WhatsApp messages or post-it notes, are used to arrange extra notes for patients with HF after discharge. These practices highlight the need for a more structured and reliable communication system to ensure patient care effectively.

Theme 6: Optimizing Interoperability as a Solution for Better Management of Patients With HF

To provide appropriate care for patients with HF during hospital discharge, it is essential that medical reports are saved and accessible across different health care settings. The single health record allows HCPs to view comprehensive patient reports across facilities. However, many professionals expressed dissatisfaction with its interoperability.

PCPs often struggle to access important clinical discharge reports or test results because they are either not uploaded or incomplete:

> *From the Single Health Record, I often cannot access the discharge report from medicine or nursing...it is either not uploaded, or there are tests that are not included in the report, so I have to review the hospital EHR, which takes a lot of time.* [PCP 2]

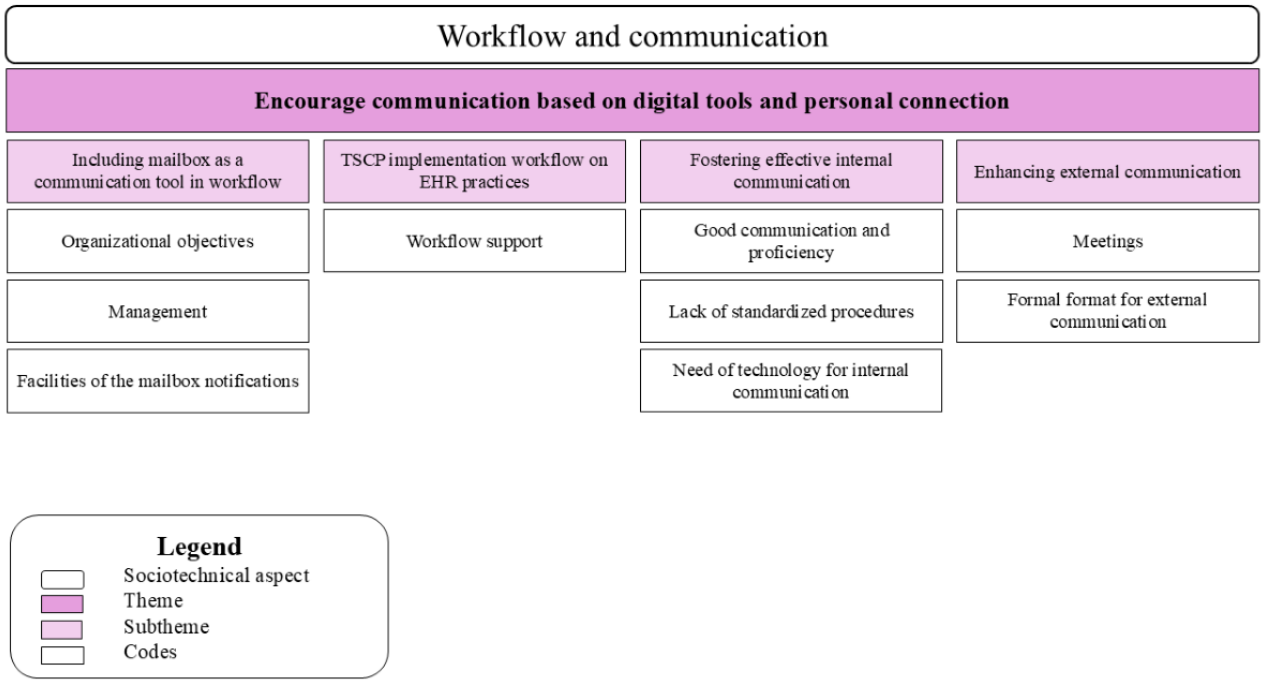
This might be due to a lack of awareness among HCPs regarding the correct process for adding information:

> *For the nursing report to be uploaded correctly, you need to click on an icon, and many times professionals are not aware of this.* [HN2]

Some PCPs mentioned that they access the hospital's single health record only when necessary due to the cumbersome and time-consuming process. Ideally, this should be regular practice to ensure continuity of care. Within hospital settings, C/IM

XSL•FO
RenderX

professionals also echoed this concern, emphasizing the importance of seamless integration between primary care and hospital systems to facilitate smoother patient care transitions:



> *At the time of hospital discharge for heart failure patients, having all the information from primary care is crucial during the initial visit.* [C/IM 4]

Workflow and Communication

Overview

As previously stated, during the interviews, the importance of communication between different settings and professionals was clear, emphasizing its crucial role in ensuring a smooth transition from acute to chronic care. Data analysis showed that communication through EHR can take various forms—internal, external, and both direct and indirect. Internal communication occurs among HCPs within the same health care setting and can be either direct (eg, face-to-face conversations and meetings) or indirect (eg, through the EHR and messages). In contrast, external communication occurs between HCPs from different health care settings and can also be either direct (eg, seminars) or indirect (eg, via the Diraya mailbox or interconsultations). Consequently, participants identified several needs and suggested improvements for these different forms of communication. Figure 6 illustrates the relationship between the sociotechnical dimension of workflow and communication, the codes, and subthemes for the theme—encourage communication based on digital tools.

Figure 6. A hierarchical structure displaying the sociotechnical dimension, the codes, and the subtheme for theme 7. EHR: electronic health record; TSCP: transition standardized care pathway.

Theme 7: Encourage Communication Based on Digital Tools

Regarding internal communication, participants mentioned that it is usually informal yet effective and efficient in most cases. Some centers explained that to communicate with a colleague, they often leave a note, send a WhatsApp message, or speak directly to them. Nonetheless, other participants explained that storing sensitive information in a written note or spoken conversation is not the safest approach for medical care. Moreover, using personal phones to store confidential information is a concern:

> *I usually knock on the door or I leave the information on a post-it.... It would be useful to have an integrated communication and chat system, as currently, we communicate informally.... It would be beneficial if the information were automatically transmitted through the system.* [PCN4]

In contrast, some participants emphasized that certain primary care centers are quite familiar with their current process and feel no technological innovation is necessary. They rely on notes in clinical history for another professional to view, and this approach usually works well:

> *In my opinion, within our field, I would not recommend any technological aid because it could lead to a loss of personalization. As I have the nurse next door, I would not like to have a chat.* [PCP4]

Some PCPs mentioned that they share schedules with PCNs to discuss patients, but these schedules are rarely used.

Within the hospital system, 50% (2/4) HNs indicated that communication with the medical department during hospital discharge needs improvement. A major issue is that, often, when a patient is discharged, the nurse is not informed by the physician, which sometimes causes delays in completing the discharge report for patients with HF:

> *Sometimes, when the patient is discharged, I am not informed. Although communication with colleagues*

XSL•FO
RenderX

> *is good, sometimes the workload causes a noneffective communication.* [HN2]

Regarding communications between HCPs from different medical settings, known as external communications, participants noted that direct communication between physicians from both settings is more established and standardized than communication between nurses across these contexts. However, one participant pointed out:

> *In my center, we maintain a very fluid relationship because I know the head of the cardiology department at the hospital; however, it is informal communication. In other centers or specialties, this type of one-way communication does not exist.* [PCP 3]

Nevertheless, the same participant added:

> *The idea of conducting clinical sessions is excellent and useful, but it requires time and resources that are unavailable.* [PCP 3]

In addition, from the primary care perspective, there is a recognized need to establish a bidirectional communication channel with cardiologists, as information is sometimes lost. From the hospital's medical site, C/IM departments commented that communication is sufficient, with improvements mainly needed in document interoperability. They also pointed out that in some centers, teleconsultations between PCPs and C/IM staff are very successful and efficient.

In contrast, nursing professionals all agreed on the need to enhance direct communication between nursing professionals from both settings. They emphasized the importance of workshops or sessions to standardize patient care and better understand nursing practices across settings:

> *I would like to hold sessions with PCNs to learn about what they do and how I can better emphasize patient care. Sometimes I send them information, but I think they do not consider it important. I would like to meet the PCNs to become more efficient in managing the patient during the transition. For example, educating the patient about medication for HF is very important, and I would like to know how they do it so I can determine what information I need to provide at the time of discharge.* [HN3]

One communication method in place is the mailbox module, which sends notifications to primary care professionals when a patient's status changes, such as when a patient is discharged from the hospital. For patients with HF following the TSCP, when the patient is discharged, both the PCP and PCN receive a notification that includes the patient's name, medical history, and the reason for the previous hospitalization. If no follow-up appointment has been scheduled, the nurse must call the patient within 48 hours to 72 hours and visit them at the primary care center. Even though the protocol was clear, several shortcomings and needs in this communication method were identified during the interviews.

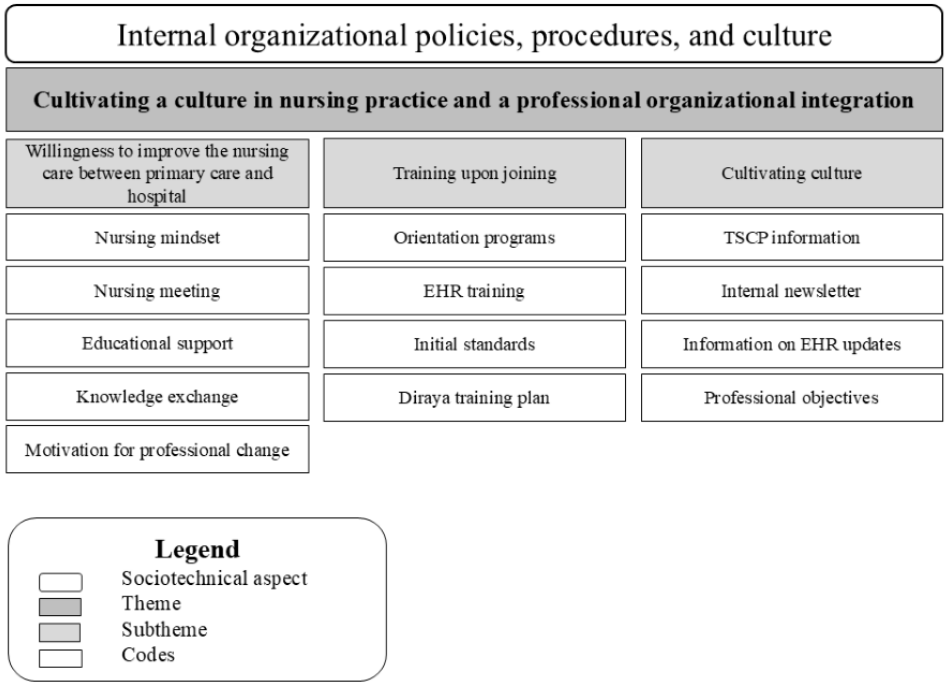
Several PCPs expressed that upon receiving this alert, they need access to more comprehensive patient information:

> *When I receive an alert and the reason for admission is not heart failure but another condition that refers to heart failure, ... I do not call the patient or review the medical history. As a result, this patient is overlooked.... If I had more time and better organizational support, I could handle it more effectively.* [PCN 4]

In contrast, the hospital lacks a Diraya mailbox module, thus discontinuing the communication from primary care. Among professionals, interconsultations through Diraya between physicians at primary care and hospitals are commonly used, which are generally effective according to the participants. However, for nursing staff, such interconsultations are not available. Consequently, nurses have expressed the desire to implement such interconsultations between both settings, when necessary, to enhance the management of patients with HF at discharge.

In primary care, HCPs are accustomed to managing visits for patients with HF. However, when using Diraya, the purpose of each visit often remains unclear. To improve care during the transition to discharge, professionals need to have a clear guide that outlines the specific tasks for each visit. Implementing an HF guide or protocol within the system would streamline these visits, enabling HCPs to effectively adhere to the SCP:

> *I would appreciate having instructions to understand the patient's status and which post-discharge visit they're attending.... All this information is protocolized, but we don't see it; we have to know it by heart.* [PCN2]



Internal Organizational Policies, Procedures, and Culture

Overview

Figure 7 illustrates the relationship among the sociotechnical dimensions of internal organizational policies, procedures, and culture; the codes; and the subthemes for the theme—cultivating a culture in nursing practice and professional organizational integration.

XSL•FO
RenderX

Figure 7. A hierarchical structure displaying the sociotechnical dimension, the codes, and the subtheme for theme 8. EHR: electronic health record; TSCP: transition standardized care pathway.

Theme 8: Cultivating a Culture in Nursing Practice and a Professional Organizational Integration

Nurses were interested in taking on a more empowered role and increasing their involvement in decision-making during the patient transition to a higher level of care:

> *I would like the cardiology specialist nurses to provide us with training, so we can gain more knowledge.* [PCN2]

Indirectly, all of them suggested the importance of collaboration to facilitate cultural change between hospitals and primary care settings:

> *I am very eager to undertake projects to improve patient education for those with HF.... I look forward to meeting the primary care nurses who treat these patients to understand what they do.* [HN4]

Participants reported no organizational dissatisfaction regarding the implementation of the TSCP. However, they identified a potential incentive for HCPs: incorporating TSCP-related tasks into primary care employment objectives. This approach would encourage staff participation and enable verification of each HCP's work.

Some participants expressed the need for structured training on Diraya when starting a new job, recognizing it as crucial for onboarding. However, they noted that HCPs often join on short notice, leaving no time for formal training. Others believed formal training was unnecessary, stating:

> *It's not necessary; you learn on the job. If it's an optional course, no one will take it. What is needed is support during your initial days.* [C/IM2]

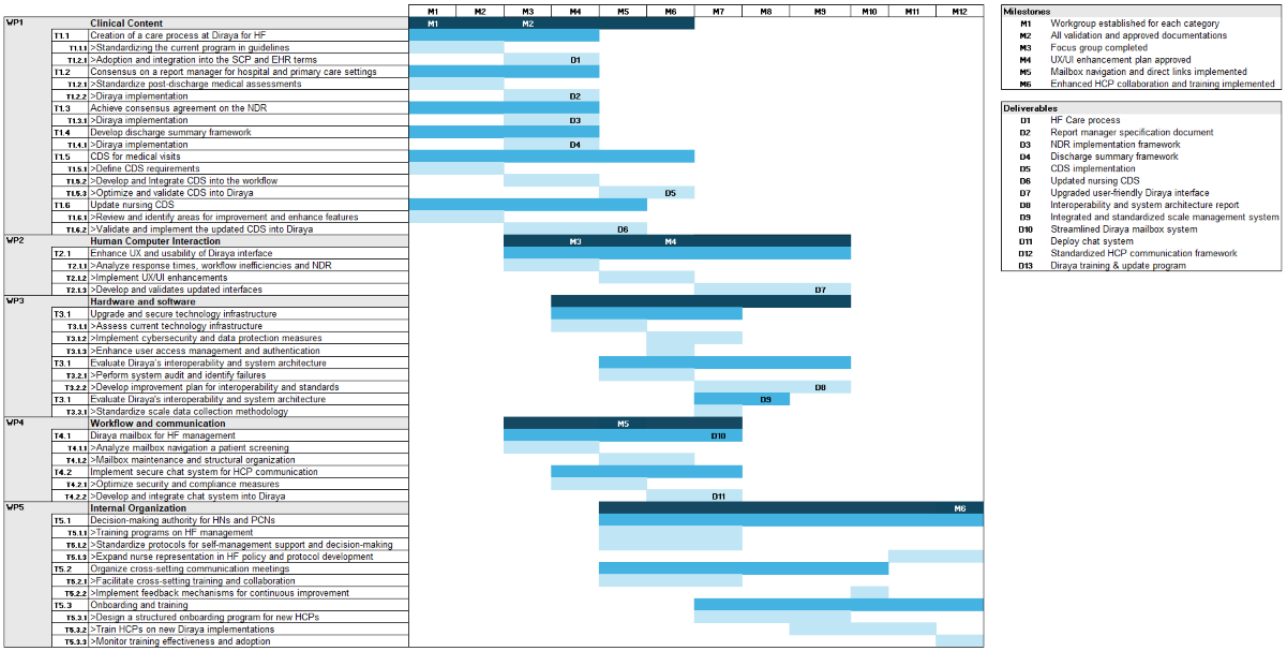
In addition, some professionals mentioned that at AHS, Diraya training sessions are available and can be completed in their free time:

> *At AHS, there are straightforward and accessible Diraya courses, but we have to complete them at home. Ideally, these should be part of work hours or count towards points in the employment pool.* [HN2]

Finally, 3 participants noted that they receive little information about organizational updates, which they consider crucial.

They expressed a desire for managers to keep them better informed about improvements.

Suggestions for Improvements Based on the Results



On the basis of the needs identified in the interviews, several improvements and recommendations have been proposed. These were validated by additional interviews with 2 participants, HN2 and PCP2. A summary of the proposed improvements and suggested actions, linking them to the corresponding key findings in each theme and the HCPs involved in the TSCP, can be found in Multimedia Appendix 2. In addition, each improvement was assigned to a priority scale, which was corroborated by HN2 and PCP2. The priority levels were (1) not important—enhances HCP performance but is not critical for managing patients with HF within the TSCP; (2) important—optimizes HCP workflow and is important for managing patients with HF within the TSCP, though not crucial for its implementation; and (3) urgent—crucial for optimizing HCP workflow and urgently needed for managing patients with HF within the TSCP, as its absence prevents the correct implementation of the TSCP.

XSL•FO
RenderX

Proposed Implementation Plan

Engaging diverse stakeholders, including IT teams, policy makers, and patients, is crucial for the successful optimization and implementation of EHRs and it is also an aspect of the implementation process of the MAIC toolkit. Strategies such as structured communication channels, collaborative platforms, advisory committees, training sessions, and feedback systems can facilitate this engagement. Establishing consistent communication with different stakeholders can identify and address potential barriers during the implementation. In addition, forming committees with representatives from each stakeholder group ensures diverse perspectives are considered. To optimize and implement improvements, incorporating a Gantt chart into the implementation process is recommended. In Figure 8, each work package represents a dimension of the STS, with tasks correlated to the improvements in Multimedia Appendix 2. A 1-year implementation plan is suggested, based on the progression of tasks and subtasks, and should be tailored to the available resources of the health care system. The proposal includes conducting training sessions and regular meetings to align expectations and identify needs. Specific working groups will be established to enhance communication and task execution. In addition, focus groups with end users are proposed to gather feedback and adjust the implementation according to their needs.

Figure 8. Suggestion for a detailed implementation plan. CDS: clinical decision support; EHR: electronic health record; HCP: health care professionals; HF: heart failure; HN: hospital nurse; NDR: nursing discharge report; PCN: primary care nurse; SCP: standardized care pathway; UX/UI: user experience/user interface.

Discussion

Principal Results and Comparison With Previous Work

This study identified the needs of HCPs when implementing the transition standardized care model, MAIC [16], for HF practice within the Diraya system. In addition, it provided recommendations for optimizing the EHR within this context. Notably, the HCPs involved in this study include PCPs, PCNs, HN, and C/IM specialists.

The results showed that the Diraya system does not adequately support the implementation of the TSCP. HCPs are required to complete many unnecessary tasks, ultimately increasing their workload. In addition, these tasks are often ethically inappropriate and add to the administrative burden. The findings also suggested that to implement the TSCP more efficiently, changes and improvements are needed in clinical information within Diraya, the computer system, and the AHS organization.

The first theme, *optimizing medical data management to enhance clinical workflow*, primarily addressed in primary care settings during the initial visits after discharge, suggested the creation of a specific care process for HF in Diraya, as well as achieving a committee consensus on a report manager. The findings highlighted that, as part of the EHR optimization, it is crucial to ensure smooth clinical workflow and personalized data exploration [36]. These 2 improvements, considered high priority, aligned with studies emphasizing the optimization of data management as a key initial requirement [37]. In addition, other studies showed that customizing report managers and care processes for each EHR helps with accurate patient evaluation and effective data analysis. This underscores the need for HCPs to collect and analyze health indicators to better understand the disease state [38,39]. Moreover, customizing the EHR through consensus among various HCPs is consistent with current literature, which underscores the importance of incorporating quality standards in the EHR development through HCP collaboration [21].

As discussed, in the second theme, *agreement on standardization and enhancement of the discharge report* is recommended to create a consensus document for both the NDR and a discharge summary for the MDR. This would improve

XSL•FO
RenderX

communication between health care settings and ensure compliance with the proposed TSCP. The findings highlighted 2 key aspects. First, they identify technological barriers to implementing an automation tool in the EHR system—an essential feature for managing HCPs' workload but also a challenge for the software [40]. Therefore, it is crucial to ensure that the tool is intuitive and user-friendly for HCPs before implementation. Second, the results aligned with studies emphasizing the importance of a nursing care plan during the discharge process to enhance patient care [39].

Regarding the third theme, *enhancing clinical decision support through updated guidelines and automated tools*, it was proposed to implement CDS tools for both medical visits and to update the nursing CDS, including the NDR and the PCN report manager. This would ensure proper compliance with the TSCP during patient visits and provide essential support to HCPs across different health care settings. This recommendation aligns with studies suggesting that effectively integrating CDS tools reduces the cognitive burden on HCPs, enhances clinical decision-making, and leads to better patient outcomes [41]. In addition, research on HF has shown that comprehensive CDS tools significantly reduce hospital readmissions and improve adherence to treatment protocols, such as TSCP [42,43]. Therefore, updating the nursing CDS and implementing CDS tools in medical visits is crucial.

Regarding the fourth theme, *improving UX and usability for enhanced clinical efficiency*, the study highlights how the interface design subtly influences daily procedures and, over time, impacts the workflow of HCPs managing HF practices. To address interface limitations, 2 key recommendations are proposed. The first and most urgent step is to improve the iconography of specific HF-related symbols and the text size. Once this is achieved, the focus should shift to broader improvements across the entire interface to enhance overall usability. These changes are essential, as studies show that complex or poorly designed EHR systems can create stress and pressure on HCPs, negatively affecting their daily work. Enhancing these aspects would directly support HCPs in efficiently performing TSCP-related tasks [44].

The findings from theme 5, *enhancing technical infrastructure to improve HCPs* efficiency, highlighted several critical needs and shortcomings that must be addressed to efficiently implement the TSCP. These include improvements in both hardware and software, network connectivity, and technical equipment. In addition, evaluating the cybersecurity infrastructure is essential, as the system stores sensitive data, and HCPs often resort to using private resources due to issues, such as low connectivity. These findings align with previous research indicating that inadequate technical infrastructure is a major barrier to implementing an SCP in specific health care settings [45].

Regarding theme 6, *optimizing interoperability as a solution for better management of patients with HF*, the need for improved interoperability emerged consistently throughout all interviews. To address this, it is recommended to evaluate the system's current standards and protocols and integrate common assessment scales across health care settings. This would enable better patient monitoring and communication between hospitals and primary care. These findings align with studies emphasizing the importance of sharing documents across different health care settings to improve communication [39].

The interoperability challenges, usability concerns, and workflow inefficiencies in the current EHR system in general are global challenges. The World Health Organization (WHO) emphasizes the need for standardized data exchange and interoperability to ensure seamless health information flow across different systems and regions [46]. They also highlight the importance of user-friendly digital health solutions and the necessity of optimizing digital health tools to support efficient workflow. Several best practices have been established to address these issues. WHO emphasized that digital interventions for health systems should leverage standardized health data exchange formats [47]. For achieving interoperability among systems, standards, such as HL7 Fast Healthcare Interoperability Resources, and terminologies like International Classification of Disease, Systematized Nomenclature of Medicine Clinical Terms, and Logical Observation Identifiers, Names, and Codes are crucial for the seamless integration of EHR systems [48-50]. The WHO Digital Health Guidelines emphasize human-centered design principles to improve EHR usability, ensuring intuitive interfaces and role-specific workflows [47].

Regarding theme 7, *encouraging communication based on digital tools and personal activities*, effective communication is the cornerstone of this study. In an SCP dedicated to discharge and the transition to primary care, clear and efficient communication is essential [51]. Many of the other identified challenges within Diraya are also linked to communication barriers. Research confirms that poor communication is a common issue, and overcoming it requires stronger relationships between HCPs to facilitate referral processes [52]. In addition, studies have shown that electronic communication between primary care and other health care settings is both feasible and beneficial, as it enhances accuracy in information sharing [53]. However, it is crucial to address the privacy concerns surrounding the use of informal communication tools, such as WhatsApp and handwritten notes, particularly regarding data security and compliance with local privacy regulations. Informal communication tools may not provide the necessary safeguards to protect patient information, potentially leading to violation of confidentiality and noncompliance with regulations like the General Data Protection Regulation and the Health Insurance Portability and Accountability Act [54,55]. Ensuring that all communication methods adhere to stringent data security standards is vital to maintaining patient trust and safeguarding sensitive health information. On the basis of the results of this study, the authors (MF and ND) suggested implementing a chat system for internal and external communication among HCPs, ensuring timely mailbox updates, and organizing meetings and training sessions to improve external communication between both settings.

Finally, theme 9, *cultivating a culture in nursing practice and a professional organizational integration*, emphasized the need to strengthen HF care by empowering nurses in their daily work. Suggested strategies include providing seminars, educational programs, and decision-making assessments within the TSCP

XSL•FO
RenderX

tasks. These improvements directly relate to the importance of designing an EHR system that serves both nurses and physicians equally. Current literature supports the idea that nurses must have a significant role in shaping digital tools like EHRs to ensure their smooth integration into patient care workflows. Several studies have demonstrated the positive impact of nurse-led interventions in transitional HF care. Nurse-coordinated transitioning of care significantly reduces readmission rates for patients with HF. Nurse-led transitional care interventions decrease health care use, including all-cause and HF-specific readmissions. These interventions also reduce mortality and improve psychosocial outcomes, such as health-related quality of life and self-care behaviors. In addition, nurse-led transitional care programs improve readmission rates, self-efficacy, functional status, and quality of life among patients with heart disease [56-59].

Nurses bring valuable clinical insights, which are critical for developing technologies that support decision-making and improve care delivery. However, challenges, such as excessive documentation, inefficient workflows, and poor system interoperability, can contribute to nurse burnout and affect care quality. To address these issues, the National Academy of Medicine recommended improvements to EHRs and related technologies to better support nurses and ultimately enhance patient care outcomes [60].

The findings of this study could be applicable to other regions in Spain for managing HF or other chronic conditions requiring coordination between primary care and hospital services. This is particularly relevant as the transition from hospital discharge to primary care in Spain faces significant challenges due to poor interoperability among EHR systems. This fragmentation hinders effective communication and continuity of care across different levels of the health care system. A study [61] highlights that one of the main issues in the SNHS is the lack of interoperability in the EHR systems, which negatively impacts communication between primary and specialized care. For example, in the principality of Asturias, a digital tool has been introduced to assess adherence to HF clinical practice guidelines within internal medicine departments. Hospitals also have a clinical protocol for managing and following up on HF. In addition, the comprehensive continuous care program for patients with HF has been implemented in 5 out of 62 nationwide units. The systems in use include Selene, Millennium, Catalonia primary clinical station, and others, causing a nonunified EHR system [62].

Our findings align with existing research emphasizing the critical role of sociotechnical factors in the successful implementation of EHR systems. By examining both social and technical factors, potential barriers and adoption, the risk of nonadoption or abandonment, and the impact of stakeholders, including patients and HCPs, can be identified [63]. Adhistya et al [64] highlight the critical role of a sociotechnical framework in the implementation of electronic medical records to enhance patient safety. Their research identifies those factors such as user behavior, system design, and the availability of supporting infrastructure influence patient safety outcomes [64].

Limitations of the Study

While the qualitative approach using semistructured interviews and thematic analysis is appropriate, the sample size of 16 participants and the focus on specific areas within Andalusia may limit the generalizability of our findings.

To improve the generalizability of the results, future research should include a more extensive and diverse participant base. This could involve expanding the sample size and including HCPs from various regions and settings, such as rural and urban areas, and different hospital levels. In addition, incorporating perspectives from other stakeholders, such as IT professionals, patients with HF, administrative staff, and pharmacists, would provide a more comprehensive understanding of the challenges and opportunities for EHR optimization. In addition, a dedicated study group on case manager nurses is needed to explore their specific roles within the TSCP in greater detail. Exploring the impact of different socioeconomic and cultural aspects on EHR adoption and use would further enhance the applicability of the findings. Another limitation of this study was time constraints, which allowed for corroboration and validation of findings with only 2 participants, which was insufficient given the initial sample size. Future research addressing this limitation is necessary.

Conclusions

Effective communication is essential for managing patients with HF, as it involves coordination across multiple health care settings, various HCPs, and electronic systems. This requires both technological advancements and improved interpersonal strategies to facilitate efficient document sharing and follow-up calls. Improving the Diraya system's infrastructure, usability, and support tools—along with establishing seminars and an asynchronous chat system—significantly improves the care of patients with HF and adherence to protocols.

Overall, Diraya does not adequately support the TSCP, placing an excessive administrative burden on HCPs. The proposed improvements aim to enhance patient care, reduce hospital readmission rates, and improve overall patient well-being. Achieving these goals will require both technological improvements and the promotion of a collaborative health care culture that strengthens nursing practices and streamlines care transitions between settings.

Acknowledgments

The authors would like to thank Antares Consulting Company for helping recruit the participants. In addition, they would like to thank all participants who participated in this study for their time and valuable insights. The author ND received no specific funding for this work. MF received Erasmus+ Traineeship funding from Karolinska Institutet for this work.

Authors' Contributions

All authors (MF and ND) were involved in the design of the study. Data collection and initial data analysis were performed by MF. The analysis was then reviewed and refined by ND. Both authors (MF and ND) contributed to the subsequent writing and reviewing of the manuscript.

Conflicts of Interest

During this study, MF was employed by Antares Consulting Company.

Abstract

Background: Deep learning has demonstrated significant potential in advancing computer-aided diagnosis for neuropsychiatric disorders, such as migraine, enabling patient-specific diagnosis at an individual level. However, despite the superior accuracy of deep learning models, the interpretability of image classification models remains limited. Their *black-box* nature continues to pose a major obstacle in clinical applications, hindering biomarker discovery and personalized treatment.

Objective: This study aims to investigate explainable artificial intelligence (XAI) techniques combined with multiple functional magnetic resonance imaging (fMRI) indicators to (1) compare their efficacy in migraine classification, (2) identify optimal model-indicator pairings, and (3) evaluate XAI's potential in clinical diagnostics by localizing discriminative brain regions.

Methods: We analyzed resting-state fMRI data from 64 participants, including 21 (33%) patients with migraine without aura, 15 (23%) patients with migraine with aura, and 28 (44%) healthy controls. Three fMRI metrics—amplitude of low-frequency fluctuation, regional homogeneity, and regional functional connectivity strength (RFCS)—were extracted and classified using GoogleNet, ResNet18, and Vision Transformer. For comprehensive model comparison, conventional machine learning methods, including support vector machine and random forest, were also used as benchmarks. Model performance was evaluated through accuracy and area under the curve metrics, while activation heat maps were generated via gradient-weighted class activation mapping for convolutional neural networks and self-attention mechanisms for Vision Transformer.

Results: The GoogleNet model combined with RFCS indicators achieved the best classification performance, with an accuracy of >98.44% and an area under the receiver operating characteristic curve of 0.99 for the test set. In addition, among the 3 indicators, the RFCS indicator improved accuracy by approximately 8% compared with the amplitude of low-frequency fluctuation. Brain activation heat maps generated by XAI technology revealed that the precuneus and cuneus were the most discriminative brain regions, with slight activation also observed in the frontal gyrus.

Conclusions: The use of XAI technology combined with brain region features provides visual explanations for the progression of migraine in patients. Understanding the decision-making process of the network has significant potential for clinical diagnosis of migraines, offering promising applications in enhancing diagnostic accuracy and aiding in the development of new diagnostic techniques.

Introduction

Background

Migraines are a common, incapacitating neurovascular disorder characterized by attacks of severe headaches and autonomic nervous system dysfunction [1,2]. Diagnosing migraines, in general, is a complex task due to the subjective nature of the condition [3]. The symptoms of patients vary greatly, often overlapping with those of other neurological or medical diseases, and the lack of distinct biomarkers or image characteristics also increases diagnostic challenges. Furthermore, migraine with aura (MWA) and migraine without aura (MWoA) are the 2 primary types of migraines [4]. The main challenge in distinguishing between these categories lies in the fact that the warning signs of MWA do not always manifest and vary considerably in duration and severity from person to person [5,6].

In recent years, the study of magnetic resonance imaging (MRI) has greatly advanced our understanding of the neural mechanisms underlying migraines [7], using blood oxygenation level–dependent (BOLD) signals to measure neural activity [8]. Most related findings were obtained by applying mass-univariate analysis techniques to detect group differences and probe the pathogenesis of migraines [9]. Three commonly used indicators—amplitude of low-frequency fluctuation (ALFF), regional homogeneity (ReHo), and regional functional connectivity strength (RFCS)—can effectively help us analyze functional magnetic resonance imaging (fMRI) data because they reflect brain activity characteristics from different perspectives. As a result, these metrics have been widely applied in neuropsychiatric research and have proven valuable in uncovering the neural mechanisms of diseases [10-12]. For example, compared with healthy controls (HCs), patients with migraines have been shown to exhibit significant ALFF variations in the bilateral middle occipital cortex or cuneus and ReHo changes in the prefrontal cortex, orbitofrontal cortex [13], insula [14], and cuneus [15]. Altered functional connectivity (FC) has also been identified between the dorsolateral prefrontal cortex and the dorsal anterior cingulate cortex [16]. However, this analysis lacks a personalized diagnosis for patients in a clinic setting.

Recent studies have highlighted the potential of machine learning in migraine classification; however, challenges such as inconsistent study design and lack of methodological transparency underscore the need for robust frameworks such as deep learning to improve generalization and clinical applicability [17]. Deep learning has been applied to medical data across a variety of fields, allowing for inferences at the level of individual participants and thus solving this problem. Furthermore, it is sensitive to subtle and spatially distributed differences in the brain; excels in automatically extracting intermediate and high-level feature representations from raw data; and identifies the crucial features necessary for accurate classification, which might be undetectable in group comparisons. Ashina et al [18] further emphasized that even though deep learning models demonstrate superior accuracy, their “black box” nature remains a critical barrier to achieving biomarker discovery and personalized treatment. Therefore, developing deep learning frameworks that integrate both high accuracy and interpretability is essential for deciphering the heterogeneous mechanisms of migraine and advancing precision medicine [18].

Objectives

We hypothesize that deep learning models can classify patients with migraine versus HCs using resting-state fMRI (rs-fMRI) data with higher accuracy than traditional methods, while explainable techniques will reveal distinct neurofunctional patterns that align with known migraine-related pathophysiology, thereby bridging the “black box” gap. In this research, we used an array of deep learning architectures, including GoogleNet [19] and ResNet [20], and integrated the self-attention mechanism of the Vision Transformer (ViT) [21] model, alongside various modalities of MRI data for classification purposes. These deep learning architectures each have their own advantages and can extract features from rs-fMRI data from different perspectives. Moreover, these models have been widely applied in medical image analysis and proven effective [22]. We implemented the gradient-weighted class activation mapping (Grad-CAM) [23] technique for convolutional neural networks (CNNs). This method significantly enhances the interpretability of the classification results, thereby increasing the model’s credibility in the context of migraine diagnosis. For the ViT model, we leveraged the attention mechanism to improve interpretability by visualizing attention weights. This allows us to visually identify the regions of the image that the model focuses on when making classification decisions. By using these explainable artificial intelligence (XAI) [24] techniques and visualizing attention maps, we can delineate the approximate locations of the regions of interest via a heat map, thus facilitating the interpretation of the classification results generated by the deep learning models.

Methods

Participants

This study enrolled 64 individuals, categorized into 3 groups: 21 (33%) patients with MWoA, 15 (23%) patients with MWA, and 28 (44%) HC. The patients were recruited from the internal medicine–neurology department of West China Hospital, Sichuan University, and diagnoses were confirmed by neurologists specializing in headache disorders based on the International Classification of Headache Disorders criteria.

Participants were right-handed adults aged 18 to 50 years. They discontinued analgesic medications for ≥2 weeks and other medications for ≥1 month before the study, with no ongoing prophylactic treatment. All patients remained migraine free for at least 72 hours before the brain scan and throughout the 48-hour follow-up period after scanning. Exclusion criteria included for the HCs, and inclusion criteria required no personal or family history of migraine or other headache disorders and no history of neuropsychiatric disorders or neurological impairments. Controls were age matched (±7 y) and sex matched to patients. Exclusion criteria for all groups included MRI contraindications, substance abuse history, and neurodevelopmental disorders. HCs underwent additional

XSL•FO
RenderX

screening via structured clinical interviews to exclude headache disorders.

It is important to note that while the presence of a clinical diagnosis of neuropsychiatric disorders was an exclusion criterion, subclinical levels of depression and anxiety were not. The inclusion of participants with varying degrees of depression and anxiety allowed us to investigate the natural variability of these conditions within the migraine population and HCs. Exclusion criteria for both patient and control groups included the presence of chronic migraines, concurrent pain conditions, history of neuropsychiatric disorders, or any other neurological impairments that could affect the imaging results.

Demographic data (age, sex, and education) and psychometric scores (Hamilton Depression Scale and Hamilton Anxiety Scale) were collected during initial screening using standardized report forms. Psychometric evaluations revealed varied levels of depression and anxiety among the groups, quantified by the Hamilton Depression Scale and Hamilton Anxiety Scale.

Ethical Considerations

The research was approved by the institutional review board of West China Hospital, Sichuan University (2020-666; Figure S1 in Multimedia Appendix 1). All participants provided written informed consent, including explicit permission for secondary data analysis. Participants were informed about the study's purpose, data use, and privacy protections. The consent forms allowed future reuse of anonymized data. All data were deidentified before analysis, with Digital Imaging and Communications in Medicine header information removed using specialized tools. No identifiable facial features or personal metadata were present in any of the presented images.

Statistical Analysis

This study used the Kruskal-Wallis *H* test from the *scipy.stats* package of Python (Python Software Foundation) to analyze the experimental data. This is a nonparametric test used to determine whether there are statistically significant differences in medians among ≥3 independent samples [25].

The specific method involves combining all data from the 3 sample types used in this study and ranking them by value, assigning each data point a corresponding rank. If values are tied, the average rank is calculated. Next, the rank sums (R1, R2, and R3) for each sample group are computed separately. The *H* statistic is then calculated using the Kruskal-Wallis *H* test formula:

where N represents the total sample size across all groups, k represents the number of groups (in this case, k=3), n_i represents the sample size of the i-th group, and R_i represents the rank sum of the i-th group.

Finally, the calculated *H* value is compared with the chi-square distribution with 2 *df*sto obtain the corresponding *P* value. If $P \leq .05$, it indicates that at least 1 of the 3 sample groups has a median significantly different from the others. If $P > .05$, there is insufficient evidence to conclude a significant difference in medians among the 3 sample groups.

Neuroimaging Data Acquisition and Preprocessing

Data acquisition was performed using a 3.0 Tesla MRI system (Trio Tim, Siemens). Participants were instructed to rest with their eyes closed, remain awake, and avoid active thinking. Structural imaging was conducted using a transverse echoplanar imaging sequence with the following parameters: the ratio of repetition time to echo time (TR/TE)=2000/30 ms, flip angle=90°, slice thickness/gap=5/0 mm, field of view =240×240 mm^2, matrix=64×64, and voxel size=3.75×3.75×5 mm^3. The scanning duration for all participants was 6 minutes (360 s), corresponding to 180 time points.

We preprocessed the data using the Graph Theoretical Network Analysis toolbox and Statistical Parametric Mapping. The preprocessing steps included the following:

- The first 10 time points were removed from each functional dataset to account for initial signal instability and participant adaptation, leaving 170 time points (340 s) for subsequent processing
- Slice timing correction and realignment were performed to minimize motion artifacts. Participants with head motion exceeding 2-mm displacement or 2° rotation were excluded. All participants in this study met these motion criteria.
- Spatial normalization was conducted to standard Montreal Neurological Institute space with 3-mm isotropic voxels
- Bandpass filtering (0.01-0.08 Hz) was applied to each voxel's time series to reduce low-frequency drift and high-frequency physiological noise [26]
- Spatial smoothing was conducted using a 4-mm full width at half maximum Gaussian kernel.
- Regression of nuisance covariates was performed to mitigate the influence of nonneuronal signals.

Finally, the ALFF, ReHo, and RFCS were calculated. ALFF serves as a reliable metric of regional intrinsic neuronal activity [27]. Time series from each voxel were converted to the frequency domain via fast Fourier transform to derive the power spectrum. The square root of the power spectrum was then averaged over a predefined frequency range. Within the 0.01 to 0.08 Hz frequency band, ALFF was calculated per voxel using the rs-fMRI Data Analysis Toolkit (REST, Provided by the REST team led by Professor ZANG Yu-Feng, ORCID: 0000-0003-1833-8010) software. To control for interparticipant variability, the ALFF values of individual voxels were normalized by dividing them by the global mean ALFF. ReHo, quantified using the Kendall coefficient of concordance, measures the temporal similarity between a voxel and its immediate neighbors, yielding consistent outcomes in rs-fMRI analyses. In our study, a cubic cluster of 27 voxels was defined for each normalized and resliced image, with the ReHo value of each cluster attributed to the central voxel. Higher ReHo values indicate greater local synchronization of rs-fMRI signals among adjacent voxels. Similar to ALFF normalization, each voxel's ReHo value was divided by the global mean ReHo value per participant. These procedures were carried out using REST software.

XSL•FO
RenderX

The rs-fMRI enables the evaluation of brain function through the measurement of FC among distinct brain regions. To mitigate the impact of regions of interest selection on FC outcomes, we adopted the RFCS approach, which evaluates the average correlation between a given brain region and all others [28]. To calculate resting-state FC, we controlled for the spurious effects of nuisance covariates [29]. The rs-fMRI data were parcellated into 116 regions of interest based on the automated anatomical labeling (AAL) template, yielding 116 FC results for each participant. The RFCS values were subsequently determined using a methodology detailed in a previous study by Jiang et al [30]. The RFCS was defined as follows:

The preprocessed neuroimaging data were managed using the NiBabel library, converting 4D data into 2D matrices suitable for CNNs. Throughout the data conversion process, MRI scans from all 64 participants were processed. Each scan initially produced 33 slices; the first 3 slices were discarded due to potential quality issues, leaving 30 valid slices per participant. Each slice then underwent 3 feature mappings, resulting in a total of 5760 images: 1890 from patients with MWoA, 1350 from patients with MWA, and 2520 from HCs. We ensured that no slices from the same patient appeared in both the training and testing sets to avoid data leakage. To mitigate overfitting, data augmentation techniques, such as cropping, rotating, and flipping of input images, were implemented [31,32]. Further data augmentation, involving random shuffling and resizing to 224×224 pixels, increased the diversity of the dataset. The entire training phase was conducted on a high-performance GPU (Nvidia 4070 Ti with CUDA support), using the PyTorch framework for the implementation of the deep learning model.

Model Validation

For the machine learning applications, we first performed a 5-fold cross-validation to split the participants' data into training and testing sets. Specifically, the entire dataset is first randomly divided into 5 roughly equal parts, a step commonly referred to as folding. Next, 5 iterations are performed. In each iteration, 1 fold is selected as the test set, while the remaining 4 folds are combined to form the training set. The model is trained on the training set and evaluated on the test set, with the evaluation results recorded. After all 5 iterations are completed, the results of the 5 evaluations are averaged to obtain the final model performance assessment. This averaged value provides a more stable and reliable reflection of the model's performance on the data.

In addition, we also used leave-one-out cross-validation (LOOCV) methodology for comparative validation purposes.

Deep Learning Architecture

CNN architectures include several CNN layers that transform an input image step by step, ultimately yielding a class prediction. This study examines some of the most popular CNN architectures used for image recognition tasks, including GoogleNet and ResNet18. In contrast, the ViT is a transformer-based architecture that divides an image into multiple small patches, treating these patches as elements in a sequence, and processes them through the Transformer model. This approach leverages self-attention mechanisms to capture global contextual information within the image. Compared with traditional CNNs, ViT offers greater flexibility and scalability in image processing. The introduction of ViT has brought a new perspective to the field of image recognition, achieving remarkable performance on various benchmark tests. These different models were included to test the impact of network architecture on visualization performance. Results derived from each model were compared, and the best-performing algorithm was used as the basis for visualization.

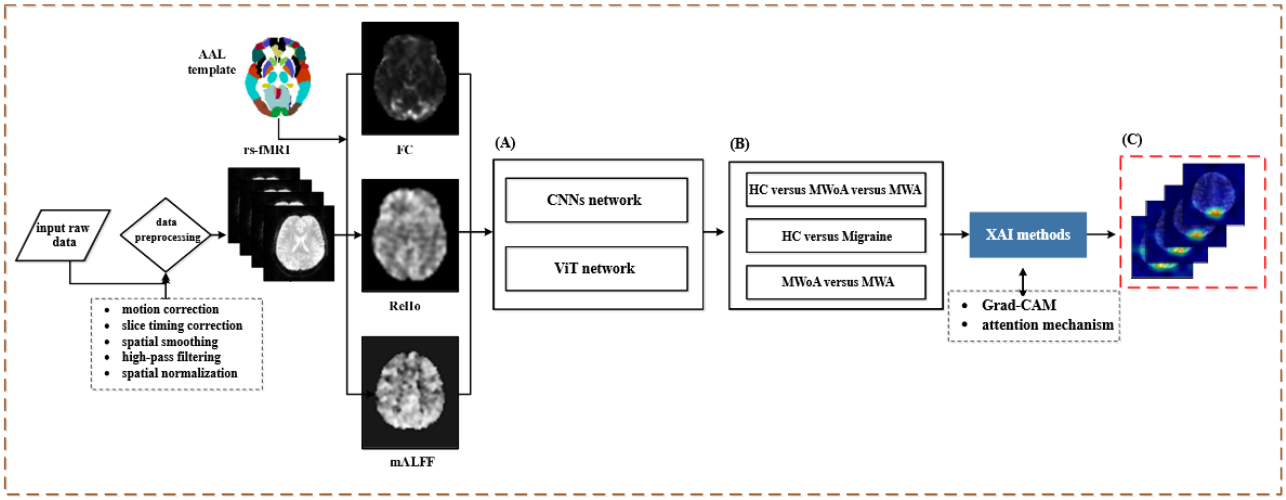
In addition, to provide a more comprehensive performance comparison, we included 2 widely used traditional machine learning methods—support vector machine and random forest—as baseline models, performing 3-class classification directly using features extracted from RFCS.

Transfer Learning

Currently, optimization algorithms such as Stochastic Gradient Descent [33] have significantly improved our training efficiency. To further enhance model performance and reduce training time, we also used transfer learning. Transfer learning increases a model's robustness and accuracy when performing new classification tasks by leveraging knowledge acquired from related tasks, which is particularly beneficial for small training datasets [34]. Initialization weights that have been trained to recognize various items in different images are easier to train than initial random weights, as image recognition primarily involves detecting combinations of edges. The initial weights used in our model included transfer learning weights from the ImageNet competition, derived from images with similar features. In addition, all weights throughout the network were frozen and did not participate in backpropagation, except for those in the last convolutional layer and the fully connected layer. These layers were replaced with new layers exhibiting random weights. By training only the updated layers, we reduced runtime by limiting the number of calculations required in each forward pass iteration. This approach also improved classification performance by simplifying the model and reducing the number of parameters.

XAI Methods

XAI methods are designed to enhance the transparency of machine learning models, enabling a clear understanding of the models' decision-making processes. XAI is particularly well suited for applications that demand a high level of trust and safety. Among the commonly used interpretability techniques are Grad-CAM and the visualization of self-attention mechanisms.



Grad-CAM merges the gradients of target concepts with the final convolutional layer to produce a coarse localization map, highlighting the important regions in an image for the purpose of predicting feature concepts. A previous study by Hao et al [35] has asserted that deeper representations of models allow for the capture of higher-level visual constructs. In addition, convolutional features naturally retain spatial information, which is lost in fully connected layers. As such, we can expect the last

XSL•FO
RenderX

convolutional layer to exhibit the best compromise between high-level semantics and detailed spatial information. Grad-CAM can also be used to represent so-called counterfactual explanations, regions that (if removed) could change the classification results. Neurons in the latter layers of a CNN are mostly used to identify semantic class-specific information in an image (ie, specific structures). In contrast, Grad-CAM uses gradient information passed to the last convolutional layer of the CNN to understand the importance of each neuron for a decision of interest.

The ViT model enhances its ability to capture image features by dividing the image into multiple patches and using the self-attention mechanism [36] in the Transformer architecture. This approach captures the relationships and global contextual information between different regions of the image. By visualizing the attention weights, we can intuitively see which areas of the image the model focuses on when making classification decisions. This visualization of attention maps provides a clear method for understanding the model's decision-making process, thereby improving its interpretability. This enhanced understanding of how the model identifies and distinguishes different categories of images is crucial for increasing the model's transparency and credibility. A flowchart for this process is shown in Figure 1.

Figure 1. A schematic illustration of the proposed classification process. (A) Deep learning models; (B) Output layer; (C) Activation map. AAL: Automated Anatomical Labeling; CNN: convolutional neural network; FC: functional connectivity; Grad-CAM: gradient-weighted class activation mapping; HC: healthy control; mALFF: mean amplitude of low-frequency fluctuation; MWA: migraine with aura; MWoA: migraine without aura; ReHo: regional homogeneity; rs-fMRI: resting-state function magnetic resonance imaging; ViT: Vision Transformer; XAI: explainable artificial intelligence.

Evaluation Criteria

Receiver Operating Characteristic Curve

Prediction model performance was evaluated for the test sets using a receiver operating characteristic (ROC) curve [37]. The area under the curve (AUC) is a quantitative metric assessing the overall performance of a binary classifier without setting a specific threshold. AUC ranges from 0 to 1, where an AUC of 1 indicates perfect classification, and an AUC of 0.5 suggests the model performs no better than random guessing. Values <0.5 are uncommon in practice, as reversing the classification would improve results. Higher AUC values (>0.5) indicate better class separation.

To comprehensively evaluate the classification performance, both AUC and the F_1-score were used as key performance indicators. AUC measures the model's ability to distinguish between classes across all thresholds, making it robust to class imbalance and useful when misclassification costs vary between classes. The F_1-score, defined as the harmonic mean of precision and recall, provides a balanced measure especially suitable for imbalanced datasets where both false positives and false negatives are of concern [38]. The relevant metrics are defined as follows:

where *TP*, *FP*, *TN*, and *FN* represent true positive, false positive, true negative, and false negative, respectively.

Confusion Matrix

An analysis table can be used to summarize prediction results for a classification model and is particularly beneficial for multiclass objects (ie, distinguishing MWoA, MWA, and HC). In this process, decisions for specific data are summarized in a matrix form, using the real category and classification judgments made by the model. A confusion matrix was applied in this study to quantify the consistency between predicted and actual results.

Results

Classification Performance

Table 1 presents the research data, demonstrating that the observed differences in psychometric assessments were not confounded by demographic variables, such as sex, age, or education level.

XSL•FO
RenderX

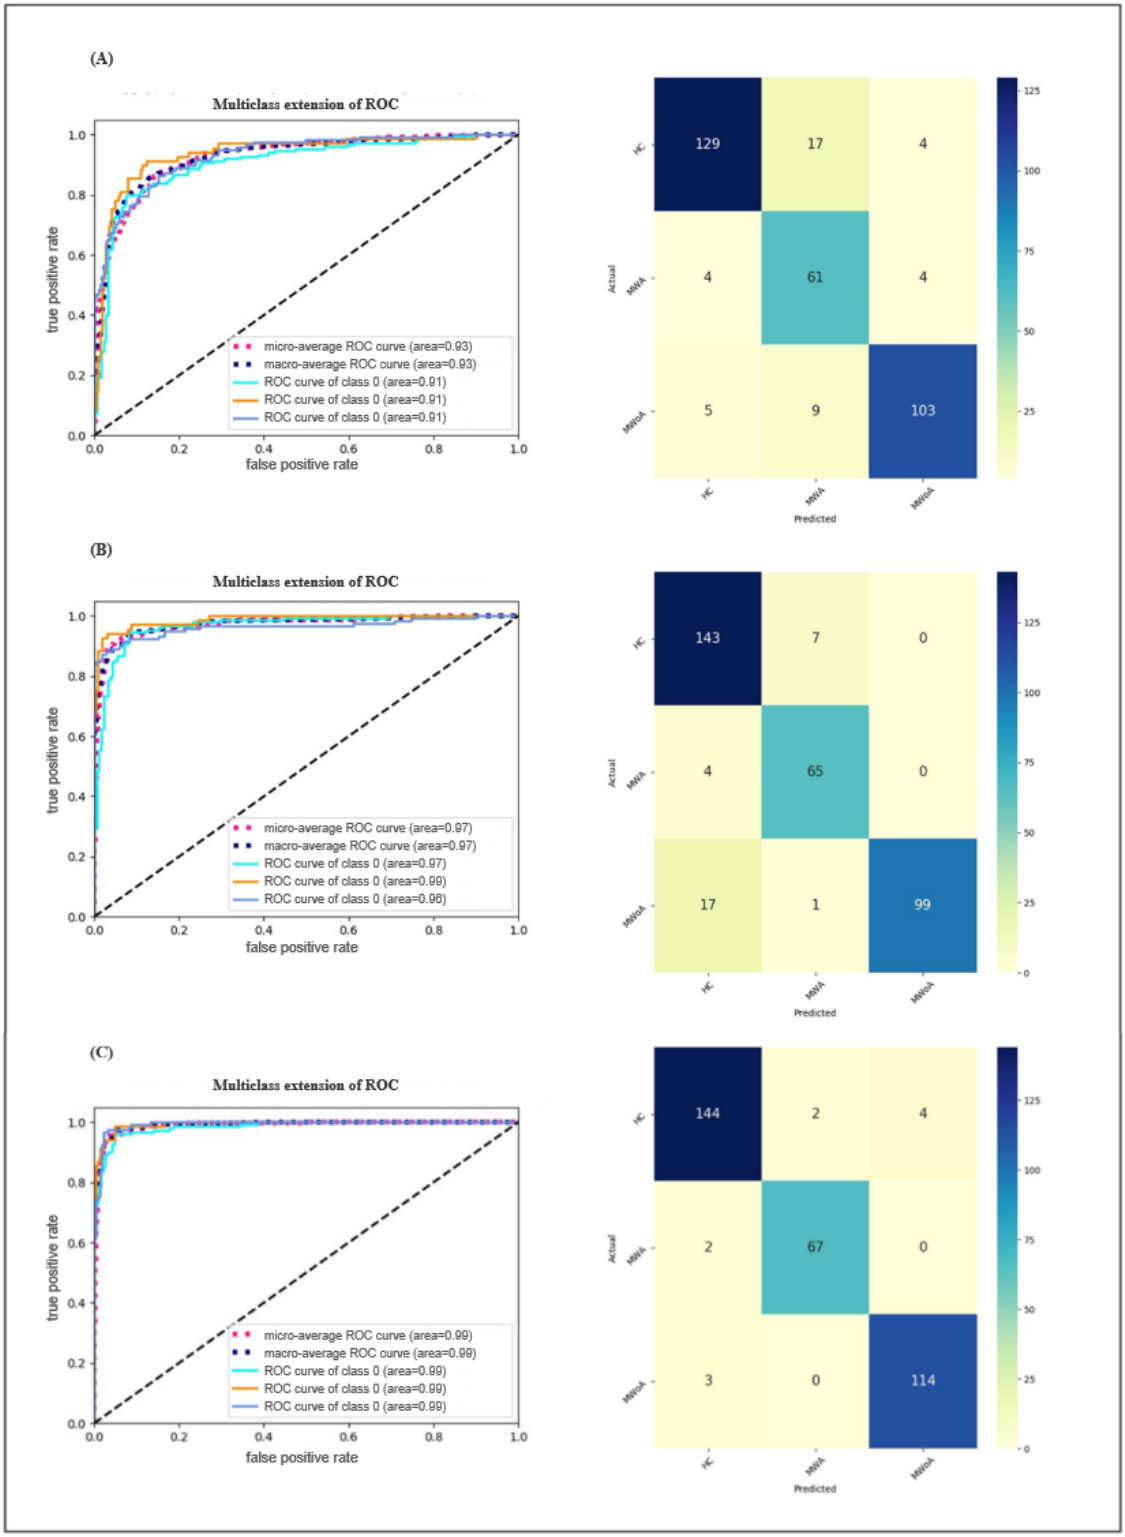
[c]MWA: migraine with aura.

[d]HC: healthy control.

[e]HAMD: Hamilton Depression Scale.



[f]HAMA: Hamilton Anxiety Scale.

Classification performance was tested using deep learning models with different rs-fMRI indicators (ALFF, ReHo, and RFCS). The data were divided into 2 groups before being input to the model: migraine versus HC and MWA versus MWoA. The loss of training and testing data were measured during the training phase. All models exhibited an improved classification accuracy (>84%) when compared with conventional machine learning methods applied to the same data. Our group previously used the LOOCV technique to obtain higher ranking features from the square of a weight vector coefficient, used as a ranking criterion to determine features for training a multicore support vector machine classifier [39].

Confusion matrices and ROC curves were also calculated for each model and used to display the classification results. We found that GoogleNet produced the highest classification accuracy for a given set of indicators, as shown in Figure 2.

XSL•FO
RenderX

Figure 2. Performance classification as determined by various indicators. (A) The ALFF indicator as input to GoogleNet; (B) The ReHp indicator as input to GoogleNet; (C) The RFCS indicator as input to GoogleNet. ALFF: amplitude of low-frequency fluctuation; HC: healthy control; MWA: migraine with aura; MWoA: migraine without aura; ReHo: regional homogeneity; RFCS: regional functional connectivity strength; ROC: receiver operating characteristic curve.

In addition, RFCS achieved the best performance for each classifier among the tested indicators. Therefore, GoogleNet combined with RFCS provided the highest average precision for identifying patients with migraine. In the results, we observed that the use of the ViT-B/16 model did not yield an improvement in accuracy. In fact, compared with the straightforward CNN architecture, the classification outcomes of the ViT model showed a decrease in performance across various MRI modalities. The ultimate accuracy of the models was then determined by averaging the accuracies from 4 distinct trials, as illustrated in Table 2. In addition, we performed LOOCV using the GoogleNet model that achieved the best classification performance, with results available in Table S1 in Multimedia Appendix 1.

Model Visualization

Grad-CAM was used to visualize the GoogleNet model that achieved the best classification performance across various tasks. This process, representing the first time that CNN visualization of migraine classification results has been conducted using different MRI indicators, can be described in several steps. First, backpropagation was performed from the correctly classified images of patients with migraine. The mean gradient in each channel was then determined and multiplied by postactivated values in the feature map. Second, the absolute values of the gradient-weighted feature maps were summed to produce a coarse localization map, which was then thresholded and resized to the original image resolution. This localization map was converted into a heat map by applying a color scale to identify specific brain regions involved in classification tasks.

In this study, 3 MRI indicators—ALFF, ReHo, and RFCS—were registered and spatially mapped onto the AAL template to ensure accurate localization. Using these indicators, we generated heat maps to determine the areas of the brain that contributed most significantly to the classification performance. For example, the ALFFs that produced the most prominent heat maps are shown in Figure 4. Heat maps produced with ReHo and RFCS are shown in Figures 5A and 5B. In addition, we generated heat map results for the ViT model based on its self-attention mechanism. In the self-attention layers, the model calculates the relationship weights between each patch and all other patches in the sequence. By aggregating the attention weight matrices of each patch with others, we obtain the attention distribution of each patch within the image, thus creating the model's heat map (Figure S2B in Multimedia Appendix 1). However, the heat map lacks distinct hot spots, which may be due to the similar attention weights across patches, leading to a uniform attention distribution. This uniformity in the heat map could also explain the reduced classification performance of the model.

Figure 5. Activation heat maps derived from regional homogeneity (ReHo) and regional functional connectivity strength (RFCS) metrics, along with high-resolution activation heat maps based on RFCS, demonstrating the activation patterns across multiple brain regions. (A)Activation heatmaps for multiple slices from an MWA patient (ReHo indicator); (B) Activation heatmaps for multiple slices from an MWA patient (RFCS indicator). (C) Group 1: health control versus migraine (RFCS indicator); (D) Group 2: MWoA versus MWA (RFCS indicator). MWA: migraine with aura; MWoA: migraine without aura.

In addition, to obtain clearer and more intuitive activation maps, we additionally visualized the RFCS indicator activation area on another enlarged and high-definition brain template to achieve more precise localization of brain activity, as shown in Figures 5C and 5D. In Figure 5, group 1 displays the most discriminative activations between HCs and patients with migraine, with red intensity indicating stronger activation, and group 2 highlights the most discriminative activation regions between MWA and MWoA.

Discussion

Principal Findings

This study used the XAI methods to interpret deep learning models' decision-making processes and produce activation heat maps for class-discriminative regions in MRI slices. Various fMRI indicators were included as input data for the classification of migraines by a deep learning model. Results were compared for various MRI indicators (ALFF, ReHo, and RFCS) and different network architectures (GoogleNet, ResNet18, and ViT-B/16). The GoogleNet model combined with RFCS indicators produced the best classification performance (>98.44%). Heat maps confirmed Grad-CAM to be a promising visualization technique for the clinical diagnosis of migraines.

We compared 3 deep learning models based on different fMRI indicators. GoogleNet achieved the best results among the 3 models, producing a performance increase of 2% to 3% (AUC) for each indicator (Table 1). The inception module in GoogleNet could merge receptive fields of different sizes simultaneously with a concatenation filter, which improved classification performance [40]. It was evident in this study that the selection of indicators had a significant effect on classification results, with the RFCS indicator improving accuracy by approximately 8% compared with ALFF. RFCS measures the average correlation between a given brain region and other regions. This was often based on the AAL template-116 brain region [41], which contained important information about the whole brain to enhance accuracy rates. In contrast, ALFF was used to calculate the intensity of brain activity in a single voxel and included far fewer features than RFCS. This result suggested that the improvements in classification were partly the result of

XSL•FO
RenderX

model selection and primarily a consequence of indicator preference. In reviewing the literature, we found that education level was not always directly associated with migraines [42]. Therefore, its ultimate impact on classification performance might be small.

Comparison With Prior Work

A comparison of average localization maps with the AAL template suggested the most discriminative brain regions, for differentiating the migraine and HC groups, to be the cuneus and precuneus. There was also some slight activation present in the frontal gyrus. The most significant areas for distinguishing MWoA from MWA were the frontal gyrus and bilateral cuneus. These findings are in agreement with similar results from other studies. For example, Li et al [43] reported a significant decrease in ALFF in the bilateral middle occipital cortex and cuneus, when compared with HC. In addition, regions exhibiting decreased ALFF in patients with migraine included the bilateral cerebellum posterior lobe, left cerebellum anterior lobe, bilateral orbital cortex, middle frontal gyrus, bilateral occipital lobe, right fusiform gyrus, and bilateral postcentral gyrus [44]. There was no obvious pattern in the HC group, which suggests that pain is somewhat randomly distributed in normal cases.

Similarly, Farago et al [45] studied the low-frequency components of a BOLD signal (0.01-0.08 Hz) in MWoA and MWA groups [45]. Results showed the resting-state amplitude of BOLD fluctuations in the bilateral frontal regions to be higher in patients with MWA than in those with MWoA. This is in agreement with this study, as the cuneus is part of the visual cortex area of the brain [46].

Our study demonstrated the feasibility and clinical relevance of interpretable deep learning techniques in distinguishing between HCs and patients with migraine based on neuroimaging biomarkers. The identified patterns aligned with existing clinical knowledge: the cuneus, involved in visual processing, was associated with migraine as patients often exhibited light sensitivity and photophobia during attacks; the role of the precuneus in self-referential processing and pain modulation might explain the altered FC observed in patients with migraine; and dysregulation in the frontal cortex could be contributed to impaired pain inhibition and cognitive symptoms in chronic migraine [47].

Grad-CAM propagated gradients from the final convolutional layer to the input space, highlighting regions critical for category-specific predictions. The self-attention mechanism was particularly suitable for processing sequential data or data with complex dependencies. In migraine rs-fMRI data analysis, the self-attention mechanism helped the model identify key patterns of FC between different brain regions. In summary, our discovery of abnormal brain regions was supported by abundant literature. By leveraging interpretable models, we not only validated these biologically plausible findings but also provided clinicians with actionable insights. Our method might enhance the convenience of personalized diagnosis or targeted neural regulation therapy in certain scenarios. Therefore, in clinical translation, both methods alleviate the *black box* problem by providing visual explanations (heat maps), enabling clinicians to validate findings against established neurobiological knowledge, thereby increasing trust in model outputs for discovering potential biomarkers.

Limitations

While deep learning–based diagnostic tools have advantages, incorrect decisions can adversely affect patients, leading to misdiagnoses or missed diagnoses. Inaccuracies in our model could result in patients with migraine not receiving timely and appropriate treatment or subject normal participants to unnecessary medical interventions. Therefore, we emphasize the importance of thorough validation before clinical application and suggest using this model as an adjunct rather than the sole diagnostic tool.

Certain limitations existed in this study that should be noted. First, the sample size was relatively small. During the training of the ViT model, overfitting occurred (Figure S2A in Multimedia Appendix 1). For some specific clinical scenarios, a more complex and deeper network does not necessarily yield the best results; instead, it is crucial to select an appropriate model based on the characteristics and scale of the dataset. This was addressed in the study by using data augmentation techniques (ie, rotation, reflection, and cropping in PyTorch) and adding a dropout layer before the fully connected layer to mitigate overfitting. Second, the heat maps exhibited relatively limited resolution, due to a size limit imposed by feature maps in the last convolutional layer. The architecture and class activation map algorithm could be optimized using higher-resolution medical images to produce larger-scale feature maps.

Future Directions

Future research should aim to enhance the model's resolution capabilities, consider other imaging modalities or biological markers, and explore the adversarial attack approach to enrich the data and improve the robustness of the results [48]. In addition, we are also seeking collaborations with similar studies to share datasets, though this process may take time due to the high costs of such data collection. Meanwhile, we are making efforts to acquire data from other hospitals, despite current challenges in obtaining external data. We plan to incorporate multicenter data to evaluate the model's generalizability across different populations and MRI scanners. In addition, we will conduct more in-depth comparisons with neurologists' diagnostic consistency to assess the model's value in assisting clinical diagnosis. As for sex differences, our preliminary analysis did not reveal a significant impact on the model's performance. Nonetheless, given the known variations in migraine prevalence and manifestation between sexes, further research is warranted to explore this aspect in greater detail.

Conclusions

This study has demonstrated that XAI techniques, combined with fMRI-derived FC metrics, can achieve high classification accuracy in distinguishing patients with migraine from HCs while providing interpretable biomarkers. The GoogleNet model paired with RFCS emerged as the optimal framework, achieving exceptional performance (accuracy >98.44%; AUC=0.99) and outperforming conventional machine learning benchmarks. Generating heat maps by identifying the most discriminative

XSL•FO
RenderX

brain regions also confirms that XAI using Grad-CAM is a promising visualization technique.

Acknowledgments

This research was funded by the Sichuan University West China Hospital's horizontal project for the development of a proactive prediction and early warning management system and equipment for venous thromboembolism based on big data and artificial intelligence (project). It was also funded by West China Hospital, Sichuan University's "Development and Application of an Intelligent Decision Support System for Comprehensive VTE Risk Assessment and Prevention-Control Strategies Based on Large Language Models" 135 Project (project).

Data Availability

The datasets generated or analyzed during this study are not publicly available due to hospital institutional review board regulations but are available from the corresponding author on reasonable request. The implementation details and source code are publicly accessible at our GitHub repository [49].

Authors' Contributions

GL conceptualized and designed the study, conducted the research, performed the magnetic resonance imaging analysis, analyzed the data, and wrote the manuscript. LH and HY performed the magnetic resonance imaging analysis and approved the data. GZ conceptualized and designed the study. All authors contributed to editorial revisions, read and approved the final manuscript, participated sufficiently in the work, and agreed to be accountable for all aspects of the study.

Conflicts of Interest

None declared.

Abstract

Background: Death certification provides reliable epidemiological data that are essential for public health decision-making. Implementing an electronic death certificate improves data quality, accuracy, and timeliness. Recognizing its importance, we developed and integrated a mortality management module into the hospital "Le Luxembourg," enhancing mortality data collection and utilization.

Objective: This implementation aimed to improve the completeness and accuracy of mortality data, accelerate the timeliness of death reporting, and facilitate the downstream use of data to inform public health planning and research.

Methods: We began by analyzing the existing infrastructure and organizational setup within the hospital. Through a series of interviews, we identified the needs of all users, enabling the design of a module suited to all levels of operation. We implemented a module comprising multiple functionalities, including certificate editing, validation, storage, mortality statistics generation. It also integrates *ICD-10* coding and follows the World Health Organization (WHO) model, while remaining adapted to the hospital's specific context. To ensure optimal usability, we assembled a project team that included a mortality audit committee. After implementation, all users received training and continuous direct technical support was provided.

Results: We developed a new death certificate model in line with WHO recommendations. Access to the certificate is secured by a unique username and password. To improve data quality, the certification process involves several validation steps: initial recording, which can be modified when the medical section is not completed by a senior physician; pre-validation by the senior physician and final validation by the mortality audit committee. The chain of morbid events is documented using *ICD-10* diagnoses. Beyond the certificate itself, the system also allows for civil registration of the death. Moreover, the module can generate statistics based on multiple criteria. This process takes place with the involvement and active engagement of all stakeholders.

Conclusions: We established a unique, secure, WHO-compliant death certificate model that ensures high-quality, easily exploitable, and well-archived data. The experience of this hospital may serve as a foundation for scaling up this model to other healthcare facilities within the country.

Introduction

Background

Knowledge of the causes of mortality is an integral part of the foundation of public health policies, strategies and programs [1]. Death certification plays a central role in the collection of demographic and epidemiological data worldwide. Not only does it identify the causes of mortality, it is also a fundamental tool for guiding public health policies.

For several years now, high-income countries, notably in Europe and North America, have been deploying electronic death certification systems to improve the efficiency, accuracy and speed of the information collected [2,3]. For example, France introduced such a system in 2007 with the CertDc project to gradually replace traditional paper forms [3]. In Portugal, a

XSL•FO
RenderX

similar system has been in place since 2013, having made a 100% successful transition from paper to electronic certification after 2 years.

The advantages of such a system are multiple. Firstly, digitizing the process eliminates manual transcription errors, but also speeds up data processing, as shown by a French study on the contribution of electronic certification [4].

In Africa, where the civil registry system is still largely dominated by traditional methods, the need for modernization is pressing. The United Nations Economic Commission for Africa (UNECA) report on death registration highlights that of the 46 World Health Organization (WHO) member states in the African region, only 1 can provide high-quality cause-of-death data (Mauritius), and 3 others can provide low- or medium-quality data (ie, South Africa, Seychelles and Zimbabwe) [5]. Nevertheless, we noted a few rare initiatives, such as Burkina Faso's implementation of an electronic death certificate at Bobo University Hospital [6].

On the other hand, Mali like many other African countries, faces similar challenges, notably insufficient coverage of the civil registry system, delays in the transmission of paper death certificates and frequent errors in data collection.

These aspects reduce the quality of national and international mortality statistics and limits their value for health planning and health policy development [7]. Mali is no exception, despite its high maternal, infant, child, infant-child and neonatal mortality rates [8]

In Mali, death certificates vary across health facilities and even within the same hospital. Some services lack a standard form, relying on handwritten notes. This inconsistency limits mortality data availability and accuracy, with records often incomplete, containing only basic details like name, sex, date of death, and a vague diagnosis (eg, cardio-respiratory arrest). Archiving is neither systematic nor organized, and copies are not always retained. Deaths are often tracked by marking "Deceased" or "DCD" in patient registers.

To overcome these problems, we need adapted and harmonized methods and tools that comply with certain norms and standards, and the advantage of using digital tools in our context is no longer in doubt [8-10].

The hospital "Le Luxembourg" in Bamako initiated a system to digitize and integrate the death certificate into its Health Information System (HIS) to improve mortality data management. Despite its technical capacity and nationwide patient intake, it faced challenges similar to other health facilities in collecting and using mortality data. Recording 556 deaths annually, the hospital wants to develop an electronic death certificate for better archiving and data use, as detailed in this implementation report.

Objectives

The implementation aimed to improve the completeness and accuracy of mortality data, accelerate the timeliness of death reporting, and facilitate the downstream use of data to inform public health planning and research.

Methods

Conception and Development

This project was part of a thesis internship, led by a student with support from the Center for Expertise and Research in Telemedicine and E-Health (CERTES), which maintains the HIS. Implemented at the hospital "Le Luxembourg," it involved system analysis, requirement collection, and specifications drafting. Development took three months, carried out by two CERTES developers and the student.

For the successful implementation of the project, a team was established, composed of the head of the public health and medical informatics department of "Le Luxembourg" Hospital, the trainee, the developers of the Cinz@n (HIS), the users represented by doctors (ie, residents, general practitioners, and specialists), nurses from various departments, and the hospital registrar.

All users were involved from the design phase through interviews aimed at understanding their needs. Physicians participated in the validation of the medical component, while administrative staff contributed to the design of the printable certificate. Their involvement facilitated acceptance of the new process.

Analysis of the ongoing certification process and HIS

When a death occurs or is confirmed on arrival, a doctor or resident issues a death certificate in duplicate. One copy is provided to the family for administrative use, while the other serves as proof for body deposit and burial. The deceased's name is recorded in consultation registers or a dedicated logbook, but no cause of death is documented.

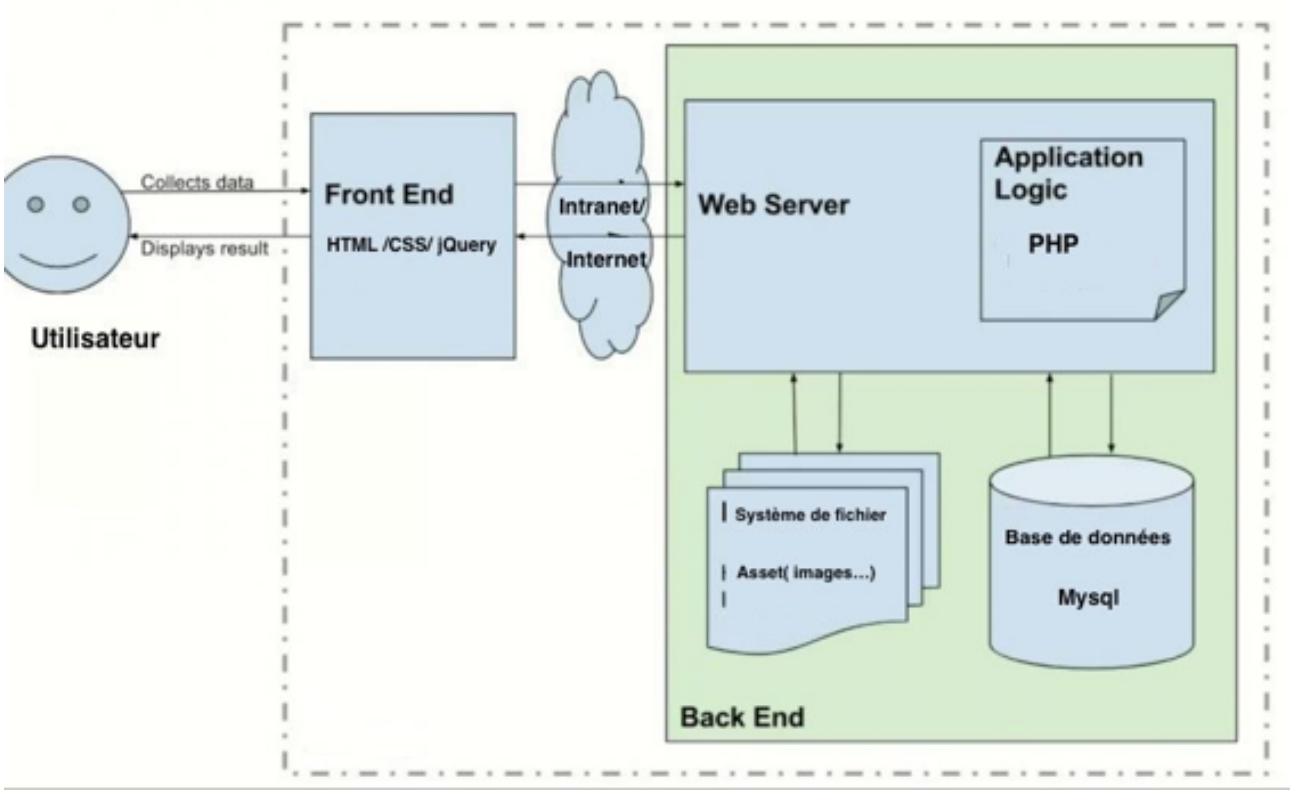
At the end of each month, hospital staff manually count the number of deaths and submit a monthly activity report to the HIS officer, who enters the data into DHIS2, a national HIS. However, this report lacks patient demographics and cause-of-death details.

The hospital operates Cinz@n, a PHP/MySQL-based HIS that integrates patient records, consultations, hospitalization, pharmacy, and related data. However, it does not track death records.

New electronic certification process implemented

A new digital death certification system has been introduced to improve record accuracy and medical data storage. This system ensures that both administrative and medical information are electronically archived in Cinz@n for statistical purposes. The key actors in the certification process are: doctors and residents, nurses, civil registrar and death audit committee.

The module includes the following key functionalities:



- Generation of death certificates: This feature is composed of two main sections:
- An administrative section that records patient identity, hospital details, time of death, and burial information
- A medical section that digitally captures cause-of-death details, comorbidities, and relevant external factors

XSL•FO
RenderX

- Deceased patients list: a searchable registry of all recorded deaths within the facility
- Certificates pending preliminary validation: death certificates awaiting review and approval by a senior physician
- Certificates pending final validation: certificates that have not yet been approved by the audit committee
- Archived certificates: a secure and structured repository of validated death certificates
- Statistical dashboard: aggregated data on mortality trends by sex, age, hospital unit, causes of death, and more
- Configuration panel: allows customization of fields, labels, access rights, and other module parameters

The module architecture is based on that of the HIS "*Cinz@n*" (Figure 1).

Figure 1. Architecture of the HIS "Cinz@n". HIS: Health information system; PHP: Hypertext preprocessor.

In terms of security, the server ensures security by recognizing devices using encrypted authentication, tracking access logs, and deactivating accounts after three failed attempts. A dedicated backup server ensures regular and secure data replication to prevent loss. User access is profile-based, ensuring that each stakeholder (ie, physicians, administrators, civil registry officers) can only access the information relevant to their responsibilities.

The module integrates International Classification of Diseases, Tenth Revision (*ICD-10)* for causes of death, consultations, and comorbidities, while Cinz@n uses the same patient ID and HL7 (Health Level Seven) standards, to facilitate the integration of this module into other systems.

A total of 66 users including 33 doctors, 26 resident doctors, 6 nurses, and 1 midwife, were trained to use the death module and code causes of death. The training consisted of lectures, practical tutorials, and WHO-provided exercises to enhance proficiency.

Budget Report

The project required no additional budget as the hospital already had the necessary infrastructure. The module is maintained internally by the hospital's medical informatics department, with updates managed by a trained technical focal point. With maintenance limited to software support, the solution is sustainable without external funding. Its design also allows for easy deployment in other hospitals using the same HIS.

Ethical Considerations

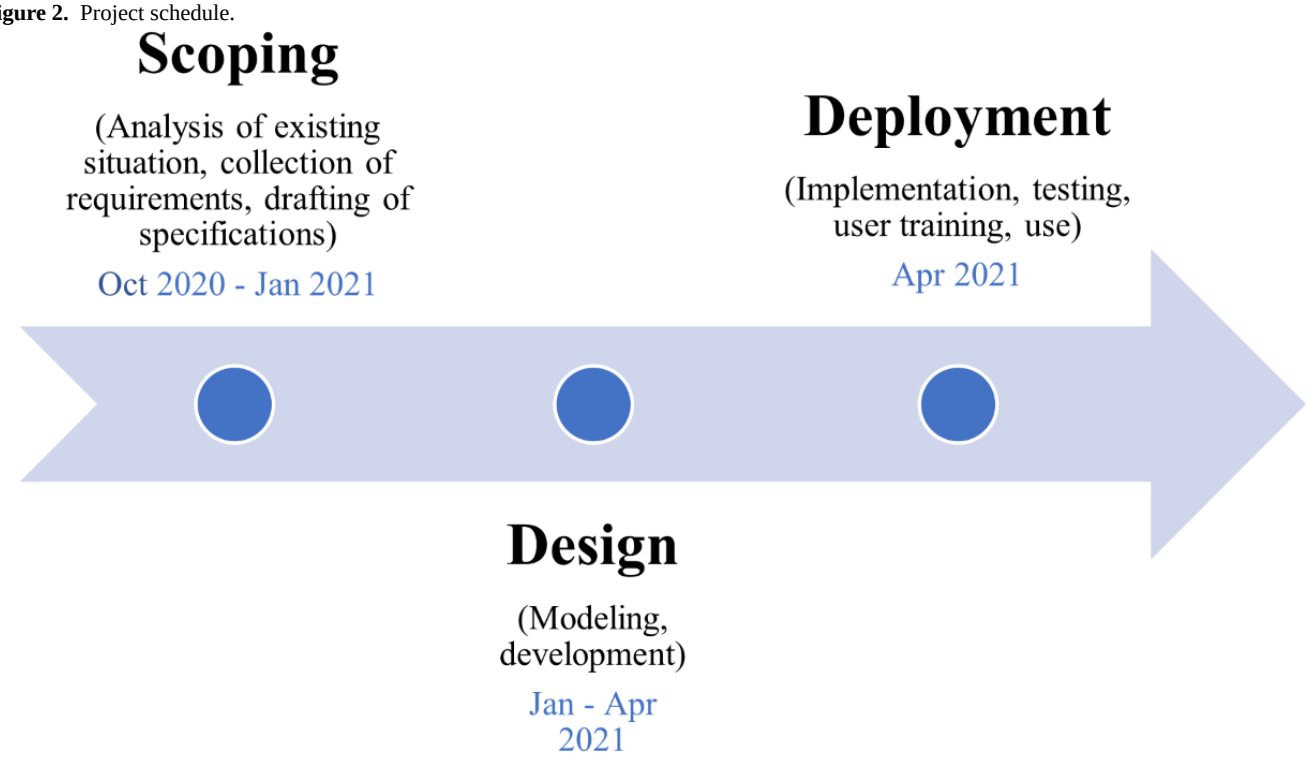
This project, integrated into routine hospital activities, aimed only to digitalize the death certificate and enable the secure storage and structured use of mortality data. No sensitive or identifiable patient information was used, and no direct interaction with patients or their relatives occurred. In accordance with local guidelines, no ethical approval was required. Data confidentiality and security were strictly maintained.

This manuscript complies with the implementation reporting guidelines [11].

Implementation (Results)

Coverage and Stage

After the design and development phases, we implemented a new model of death certificate at the hospital "Le Luxembourg," which included an administrative (Multimedia Appendix 1) and medical (Multimedia Appendix 2) component. This



XSL•FO
RenderX

multifunctional death management module (Multimedia Appendix 3) is now integrated into the HIS. Before implementation, from a methodological standpoint, we adopted an iterative approach, starting with an initial prototype tested in one hospital department, which was then improved through several short cycles, incorporating user feedback at each stage.

User feedback at the end of each training session and two months postimplementation indicated a high level of satisfaction. This was especially attributed to the ease of access to patient information and the automatic generation of certificates.

The project timeline is presented in Figure 2.

Figure 2. Project schedule.

To access the death management module, users require a username and password. Key features include creating death certificates, listing deceased patients, viewing certificates awaiting prevalidation and validation, accessing archived certificates, statistics, and settings.

Users can search for a patient using an ID number, name, or phone number before issuing a death certificate.

The "Establish a Death Certificate" menu integrates both administrative and medical components. Administrative data (Multimedia Appendix 4) are automatically retrieved from the patient's record. The medical section (Multimedia Appendix 5) also pulls relevant information, including reason for admission and comorbidities, with *ICD-10* used for cause-of-death coding.

The validation process follows a structured approach. Automatic alerts remind doctors to correct pending certificates, and pop-ups confirm actions before validation. This validation process ensures data quality, with data being easily obtained and managed from the dedicated menu. Users can filter data and export reports in the Microsoft Excel format for further analysis.

A dedicated interface allows the civil registrar to access the administrative section of the certificate and process official death declarations. By searching the deceased's ID number, the registrar records details of the declarant (ie, relative) before confirming the declaration. Once completed, the entry becomes inactive and validated.

Within three months of implementation, a total of 62 death certificates were recorded. Although the volume appears modest, the key value of the system lies in the structured storage and availability of comprehensive mortality data.

Lessons Learned, Key Success Factors, and Failure

The success of the project was driven by strong leadership, particularly the involvement of key institutional figures such as the heads of the medical informatics department and the medical board. Integrating the module directly into the existing HIS, rather than creating a parallel system, greatly facilitated adoption. Initial resistance from users was overcome through training and support. The inclusion of *ICD-10* coding improved data quality and encouraged broader use of the system. Academic clinicians engaged early, motivated by access to structured data for research. The availability of IT infrastructure also played a critical role. However, limited staff numbers in departments hindered real-time data entry, underscoring the need to consider workforce constraints in future implementations.

Discussion

Principal Findings

Our results emphasize the need to standardize mortality data collection. We developed Mali's first electronic death certificate, aligning with WHO recommendations.

XSL•FO
RenderX

This improvement in data quantity and quality was found by Lefeuvre D et al [12] in a study on the quality of electronic and paper death certificates in France in 2010. Our results highlight challenges such as inconsistent certificates, missing forms, incomplete data, and confidentiality concerns.

The implementation of ICD-10 for coding causes of death improves data reliability and allows international comparability [13].

Reliable mortality data support effective health policies. Accurate coding aids in reducing maternal and child mortality, while the new database improves data archiving and accessibility.

Electronic data storage is undeniably better than traditional storage, optimizing record search and use [14,15]. Our structured approach incorporating an alert system and a multilevel correction and validation process, serves not only to secure data confidentiality but also to elevate the overall data quality, enabling greater precision and accuracy, all of which are part of data quality criteria [16].

Our work introduced many doctors to *ICD-10*, which is not currently part of medical education or patient records in Mali. For civil registrars, digital certificates and automatic searches improved death declarations. The statistics module in Cinz@n enables multicriteria searches and better data analysis.

From an implementation perspective, this work confirmed that successful digital health integration relies on strong institutional leadership, alignment with existing systems, and user engagement. Embedding the module within the current HIS facilitated adoption and minimized resistance, especially when paired with targeted training and ongoing support. The integration of *ICD-10* coding improved data quality and encouraged broader use of the medical record. The involvement of academic clinicians, driven by their need for structured data, further enhanced project ownership. However, limited staffing constrained timely data entry, highlighting the need to consider workforce capacity in similar initiatives. Overall, the project illustrates that a user-centered, standards-based, and system-integrated approach can enhance the adoption and sustainability of digital health tools.

Limitations of Study

One limitation of the project is the absence of a formal long-term evaluation of its impact on the quality of mortality data

Bests Practices and Recommendations

The lessons we have learned are

- The importance of carrying out an analysis of existing user needs as the basis for the success of such a project;
- The advantage of having pre-existing IT infrastructure;
- The academic incentives can strengthen adoption;
- The need for a clear description and definition of the role of each player in the process;
- Setting up a monitoring and steering committee, in our case the death audit committee;
- Training and support for users throughout the implementation process.

Following our work, we recommend:

- Ensuring early involvement of institutional leaders and stakeholders to build trust and alignment
- Prioritizing integration with existing systems to streamline workflows and reduce change management efforts
- Anticipating and addressing workforce constraints by exploring strategies such as task redistribution or automation.
- Investing in tailored user training and post-deployment support to facilitate adoption
- Engaging academic staff by linking system outputs with research and publication opportunities

Acknowledgments

We extend our sincere thanks to everyone who contributed to the success of this project, with special appreciation to the Center for Expertise and Research in Telemedicine and E-Health (CERTES) team for their technical support. We also thank the hospital staff and administration for their valuable assistance. A special acknowledgment goes to Jacky and Michèle Borghini, Janine Guex, Pierre Marie Leibzig, Johan Roelant, and Dr. Sophie Delaigue for proofreading the document and for their generous support throughout the process. We are also deeply grateful to the Journal of Medical Internet Research (JMIR) for granting us a full waiver of the Article Processing Fee, thereby making the publication of this work possible.

All authors declared that they had insufficient funding to support open access publication of this manuscript, including from affiliated organizations or institutions, funding agencies, or other organizations. JMIR Publications provided article processing fee (APF) support for the publication of this article.

Abstract

Background: Increasing adoption of electronic health records (EHRs) enables research on real-world data. In Germany, this has been limited to university hospitals, and data from acute care hospitals below the university level are lacking. To address this, we used established design patterns to build a data platform that aggregates and standardizes pseudonymized EHR data with patients' consent.

Objective: We report on the design and implementation of the research platform, as well as patient participation and lessons learned during the scaling of the platform, to incorporate real-world data (with participant consent) from 77 hospitals into a unified data lake.

Methods: Due to variations in EHR adoption, IT infrastructure, software vendors, interface availability, and regulatory requirements, we used an agile development cycle that involves constant, incremental standardization of data. We implemented a layered lambda infrastructure built on Apache Hadoop. Decentralized connectors ensured data minimization and pseudonymization.

Implementation (Results): We successfully scaled our data model both vertically and horizontally in 77 hospitals. However, we encountered issues during the scaling of real-time data pipelines and IHE (Integrating the Healthcare Enterprise) interfaces. During the first 2 years, patients were asked to consent to secondary data use 1,475,244 times during inpatient admission. We registered 1,023,633 broad instances of consent (consent rate 70.2%).

Conclusions: Patients are generally willing to provide consent for secondary use of their data, but obtaining consent requires considerable effort. Building a research data platform is not an end goal, but rather a necessary step in collecting and standardizing longitudinal data to enable research on real-world data. Through the combination of agile development, phased rollouts, and very high levels of automation, we have been able to achieve fast turnaround times for incorporating user feedback and are constantly improving data quality and standardization.

(JMIR Med Inform 2025;13:e69853) doi:10.2196/69853

KEYWORDS

research platform; secondary data use; data science; Hadoop; broad consent; medical informatics

Introduction

Adoption of electronic health record (EHR) systems has continuously increased in Germany over the past 20 years [1], mainly driven by billing requirements and mandatory digital reporting for quality management. EHR data hold promise for medical quality assurance as well as clinical and health services research [2-4], referred to as secondary data use. However, data silos limit accessibility and hinder cross-institutional analyses.

In 2018, the German Ministry of Health initiated a national health data platform for research on real-world data collected from university hospitals. As part of the German Medical Informatics Initiative, several consortia received funding to develop Health Level Seven (HL7) Fast Healthcare Interoperability Resources (FHIR) models [5], governance processes [6-8], and a broad consent standard for secondary data use [9]. Although European Union and national laws regulate secondary use, consent is typically required to use such data for medical research in Germany [10]. The Helios Hospital

XSL•FO
RenderX

group, operating more than 89 acute care hospitals and 230 outpatient care centers in Germany as of December 2024, has championed voluntary data collection and reporting for quality management, enabling cross-institutional research and peer review [11-14]. Secondary analysis of claims data across our hospital network has already generated insights into admission rates and mortality during the COVID-19 pandemic [15-17]. Existing data centers, network infrastructure, and a unified IT department enable us to build a data platform for secondary data analysis of EHR, quality assurance, and claims datasets in-house.

Methods

Aims and Objective

We describe the design and implementation of a cross-institutional, multidomain data and analytics platform with a modular data model across our organization. While similar platforms have been described for one or a few institutions [18-24], integrating multiple hospitals with differing EHR systems presents unique, yet undocumented challenges [25]. We emphasize highlighting these challenges and presenting our lessons learned for scaling a data platform across diverse software systems, regions, and data domains. Specific research projects are beyond this paper's scope. We used iCHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations) [26] to structure this report.

Requirements Engineering

Upon project initiation, we assembled a cross-functional team comprising research, compliance, project management, and engineering members to ascertain requirements. We considered both data and user perspectives in the design. We conducted an initial high-level data discovery process and interviews with medical, technical, and regulatory subject matter experts. Though unstructured, the interviews helped define key requirements and agile personas (Table 1) to guide development.

Table . Agile personas to guide developing the data platform.

	Persona "Heather"	Persona "Mere"	Persona "Dave"
Function	Health services researcher	Medical researcher	Data engineer/scientist
Background	Epidemiologist with strong statistical background	Physician-scientist with advanced statistical knowledge	Computer scientist
Reasoning	Ensure and improve quality of treatment of patients nationally	Perform and publish peer-reviewed medical research	Advise business users and monitor data quality
Objectives	Facilitate change in processes or standard operating procedures and guidelines	Perform retrospective cohort studies or decide on feasibility of prospective clinical trials	Provide data to users
Example problem	Are antibiotics dosed correctly and routinely monitored during therapy?	Do courses of therapy differ between urban and rural regions?	Does the amount of data correlate to the number of patients who consented to secondary data use?

Infrastructure and Software

Because of regulatory requirements, we implemented an on-premise data platform instead of a cloud-based "platform-as-a-service" solution. Our requirements mandated integration of multiple data types, from tabular data to binary blobs. We selected a lambda architecture based on the Apache Hadoop stack, as discussed by McPadden et al [18], enhanced by Python and R notebooks for rapid analytics [27]. To reduce operational complexity, we used a Hadoop distribution offering cluster configuration, monitoring tools, and vendor support. Our setup operates in fully kerberized mode, requiring authentication for each data operation and generating auditable logs.

We provide three tools to interact with the data lake:

1. Apache Hue with access to Impala-SQL, Hive-SQL, H-Base, and the Hadoop Distributed File System
2. A hosted data science environment with containerized runtimes for Python, R, and custom data applications
3. Hosted BI-Tools for self-service analytics using dashboards

Consent Management

Participation is opt in and requires written consent. This consent is modular, covering broad consent for research on real-world data and contact for clinical trial recruitment. While similar to the Medical Informatics Initiative broad consent, our version excludes modules like biobanking or genetic data, as these domains are rarely available in our hospitals.

We developed a consent management system from scratch to handle modular consent with validity periods. Two interfaces (HL7v2 and REST-API via HTTPS) connect the back end to EHR-integrated front ends, minimizing clicks and avoiding disruptions. Consent information is stored in a multitenant database linked to case number and a validity period. Authorized staff can trigger withdrawals; stored procedures remove expired or withdrawn consent daily to maintain an up-to-date list.

Extract, Transform, Load

Extract, transform, load processes for EHR systems have been described previously [28-30]. This paper details our approach to integrating individual hospitals into a unified data lake. We also outline our data modeling and standardization processes. Figure 1 summarizes the data flow.

EHR adoption levels vary across German hospitals, including within our group, as measured by the electronic medical record adoption model level [31]. For historical reasons, Helios uses EHR systems from different vendors with different subsystems.

XSL•FO
RenderX

Hence, we developed an ingest layer supporting diverse formats and delivery methods.

The connector is a containerized Linux system configurable for single- or multitenant use. Java and Python runtimes filter, minimize, and pseudonymize the data before pushing it to the Hadoop cluster.

XSL•FO
RenderX

Figure 1. Data flows from EHR systems through the CONNECTOR into a data lake. Spark pipelines transform data through a layered structure. XSL•FO
RenderX

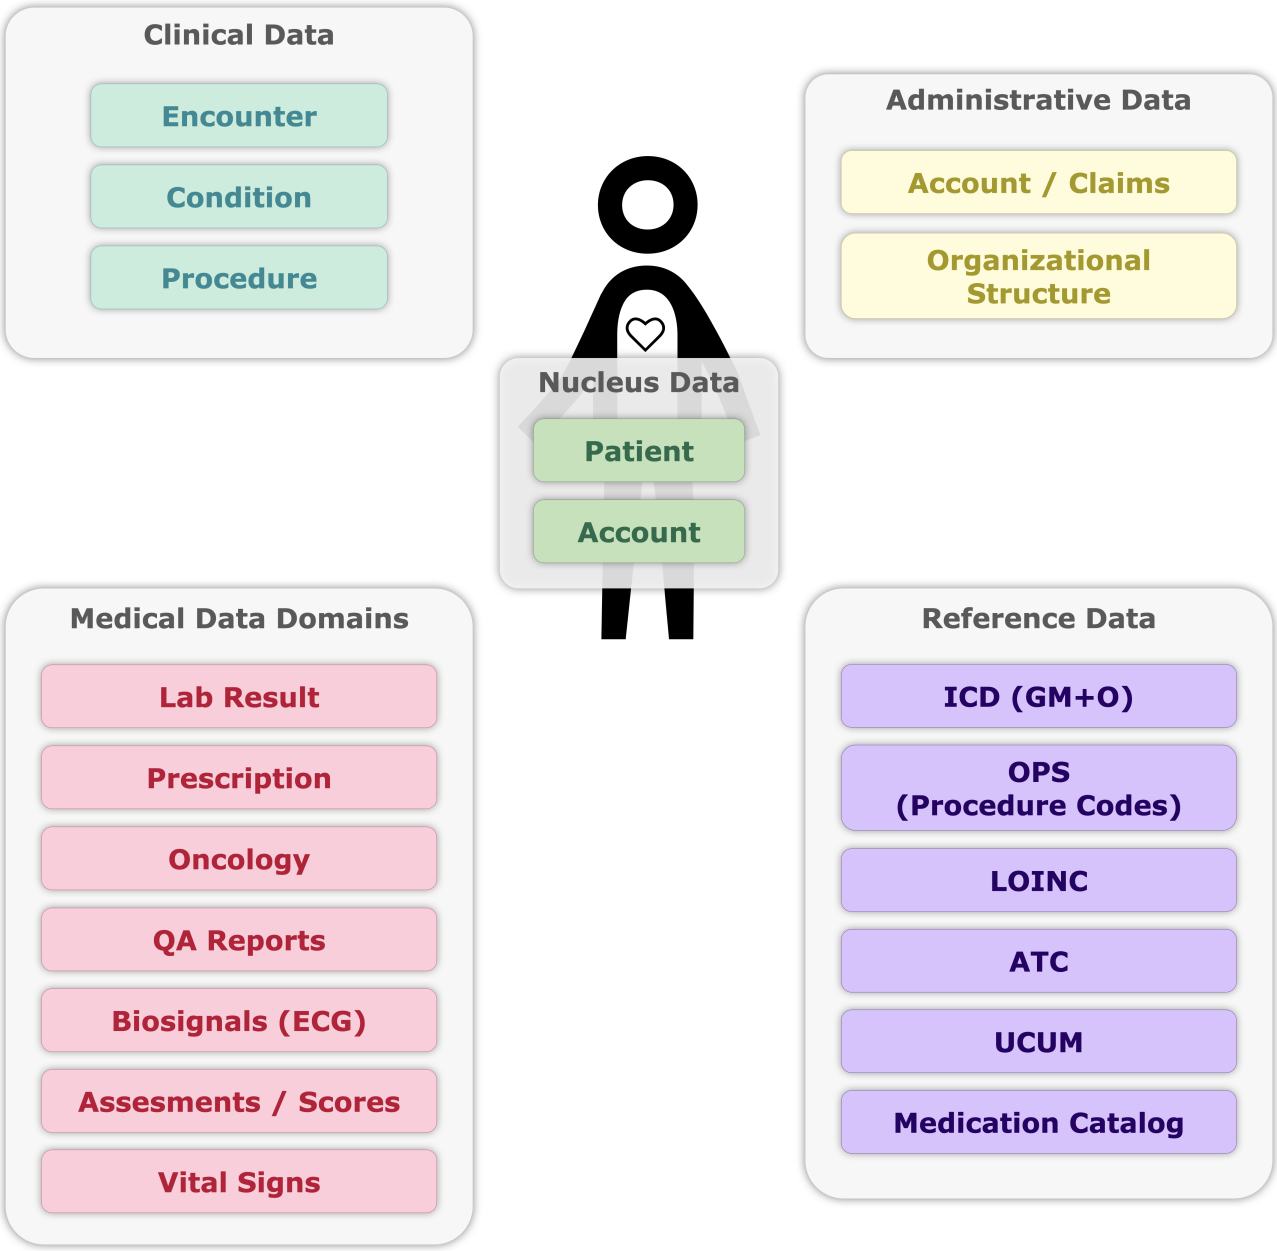
Data Minimization and Pseudonymization

Regulatory requirements mandate that data be minimized to research-relevant information and pseudonymized once they leave the regulatory hospital domain [32].

Preferably, source systems would filter for patient consent, pseudonymize records, and push these to the platform. Some EHR systems allow custom business logic via remote function calls to meet these requirements. FHIR application programming interfaces (APIs) often support minimization through custom profiles that exclude personally identifiable attributes (eg, MedicationAdministration.performer). Systems without API access require vendor support for custom interfaces or queries. Additional minimization and pseudonymization are typically applied within the connector for compliance.

Helios treats patients across inpatient and outpatient settings and across multiple hospitals. To ensure correct longitudinal mapping, we implemented a unique pseudonymous identifier using a dedicated master patient index (MPI). The MPI, based on validated probabilistic criteria [33], consolidates records via the IHE (Integrating the Healthcare Enterprise) protocol (Patient Identifier Cross-referencing [34]) into a unique pseudonymous patient entry. This identifier is transmitted back to the connector to replace the original patient ID. Before granting data access to researchers, we add a second layer of pseudonymization to further reduce reidentification risk across projects [32].

Data Modeling and Transformation



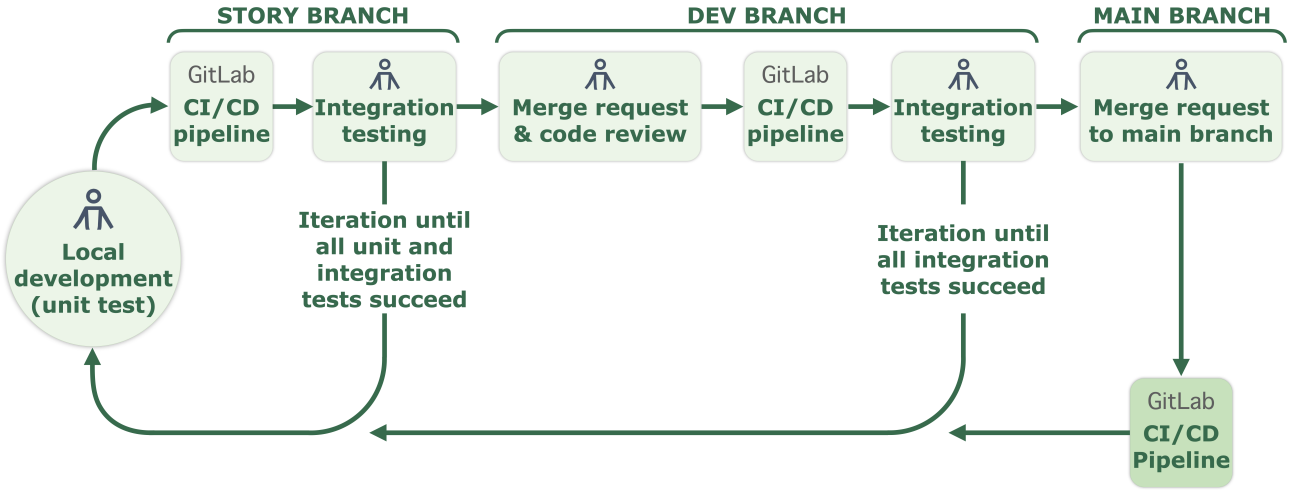
We designed a simple core data model and a four-layer transformation architecture:

1. A raw layer keeps ingested data in append-only store, without relational schema constraints.
2. A transformation layer uses Apache Spark to process raw data in pipelines grouped by source system. Code is continuously deployed via a continuous integration and continuous deployment (CI/CD) pipeline and transforms data into our data model. Transformations run in batches by data source similarity, not by hospital, reducing pipeline complexity.
3. The consumption layer unifies data from different EHR systems into a single EHR core domain, enriches it with semantic information like readable text for codes, and performs data quality and plausibility checks.
4. The data mart layer offers researchers sliced subsets of the consumption layer. Data marts can be stored as checksummed archives to ensure reproducible analyses.

The data model centers on structured data compatible with the HL7 FHIR resources for patients and accounts (Figure 2), enabling representation of inpatient and outpatient visits linked to constant patient objects. Our model closely follows the core dataset of the German Medical Informatics Initiative [35] with deviations for data privacy reasons (eg, reducing birth date to birth year) and data availability (eg, excluding employee data like *requester and performer* in *MedicationRequest* or missing *device* attribute of the *observation*). Two design principles were used: preserving raw data and prioritizing speed over complete standardization. Because most users are experienced in statistics and data analysis, we iteratively refined standardization based on insights from analytical projects. Examples include calculating patient age at admission and converting lab results to international standards like the Unified Code for Units of Measure. Raw values are provided alongside transformed data to maintain trust, though an interactive data lineage is not available.

XSL•FO
RenderX

Figure 2. Data domains. Reference data are used to enrich and standardize data in other data domains and are used mainly for transformation processes. Other data domains contain pseudonymized data from patients who gave consent for secondary data use. ATC: Anatomic Therapeutic Chemical (classification); ECG: electrocardiogram; *ICD*: *International Classification of Diseases*; *ICD GM*: *ICD German Modification*; *ICD O*: *ICD Oncology*; LOINC: Logical Observation Identifiers Names and Codes; OPS: operation and procedure codes (in Germany); QA: quality assurance; UCUM: Unified Code for Units and Measurements.



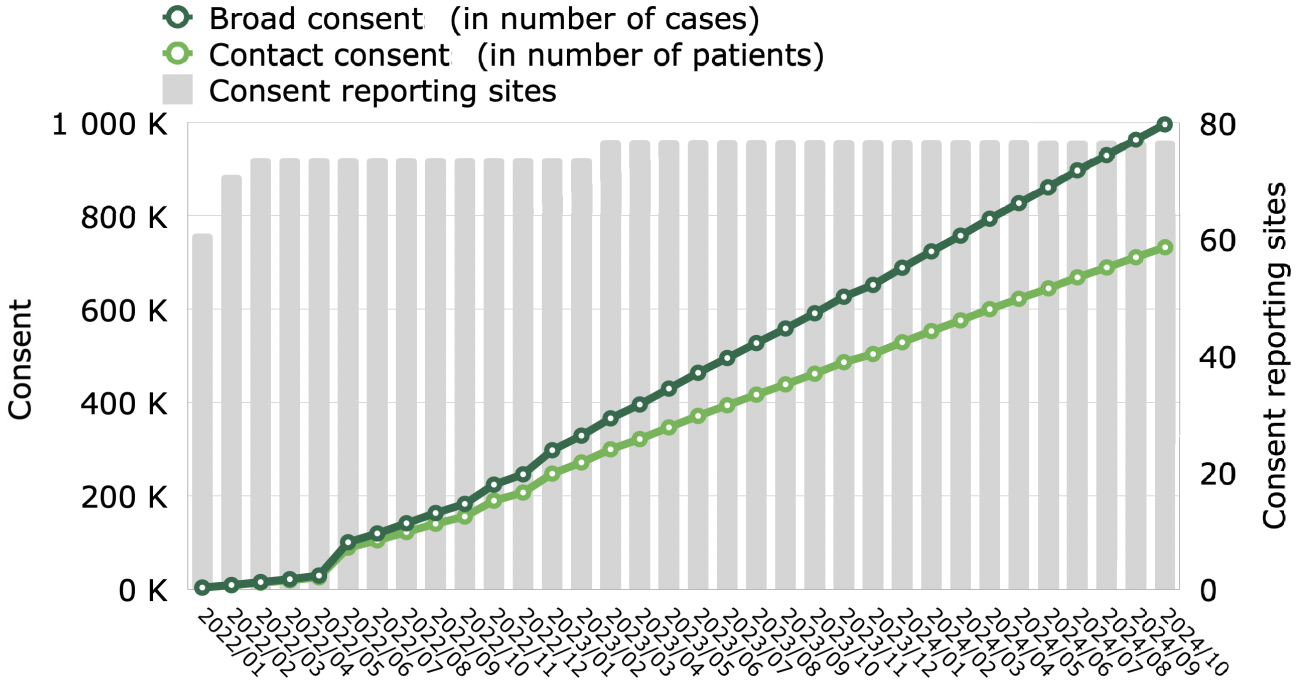
Development Workflow and Process Scheduling

All transformation code is stored in a versioned repository (git), with each feature developed in its own branch, per agile practices. A CI/CD pipeline runs unit and integration tests on each commit using reproducible Docker builds, with a focus on conditional branching. Code is deployed to production only via the CI/CD pipeline (Figure 3) after tests and manual review. Execution and scheduling, including dependencies, are managed via directed acyclic graphs in Apache Airflow. After a successful run, the story owner conducts a user acceptance test before sign-off and archiving of the feature branch.

XSL•FO
RenderX

Figure 3. Agile development workflow using continuous integration and continuous deployment (CI/CD). PySpark code from story branches is tested and evaluated multiple times before it can be merged into production. With each iteration the level of scrutiny increases, from unit tests to integration into tests and manual code review.

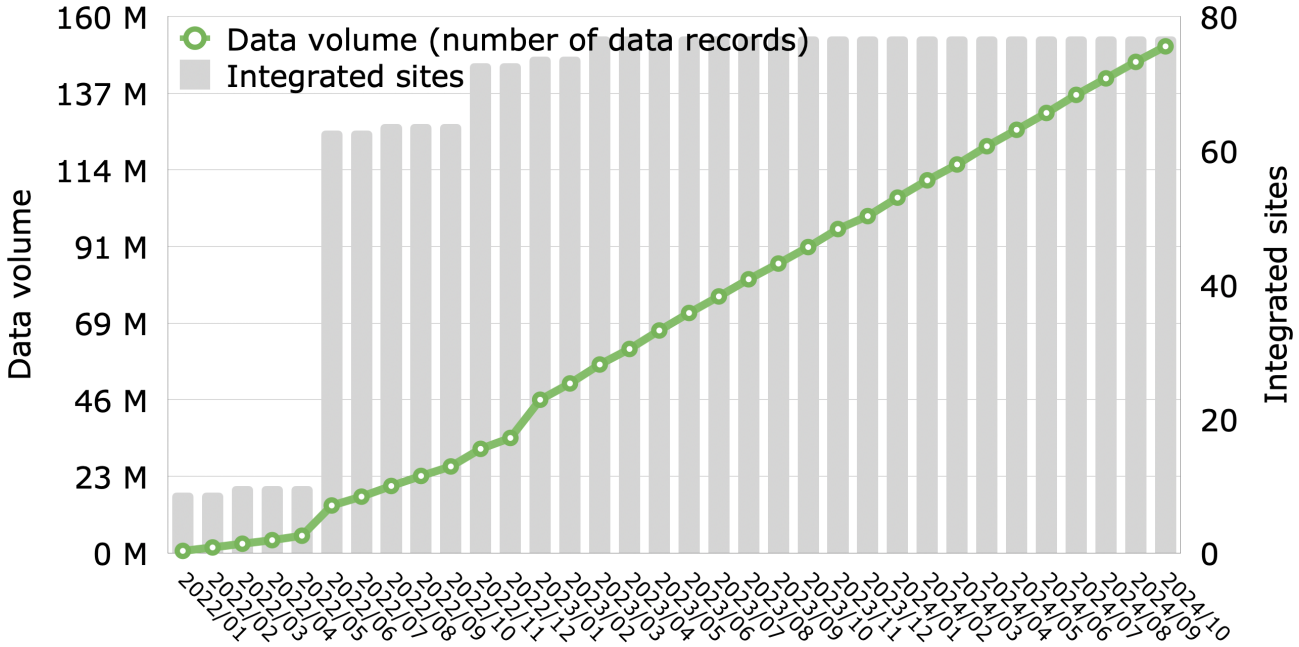
Governance



Data governance follows German guidelines for secondary data analysis [36]. The multidisciplinary Usage and Access Committee (UAC) grants data access per use case, enforced at column and row level by user- or group-based policies in Apache Atlas. Reidentification of patients requires approval from researchers, the ethics committee, and the UAC, typically for clinical trial inclusion, and is performed only at the data-providing hospital, to preserve data sovereignty.

Implementation (Results)

Consent Management



From January 2022 to July 2023, the consent management system was implemented in 77 hospitals (Figure 4 and Figure 5). Ten hospitals were excluded due to their specialization (psychiatric) or incomplete network integration.

Figure 4. Broad consent and contact consent since project launch. Consent infrastructure, as measured by the number of hospitals (sites) reporting consent, was rolled out faster than data infrastructure (see also Figure 5).

XSL•FO
RenderX

Figure 5. Data volume over time, as measured by record counts in the consumption layer in relation to the integrated sites (hospitals), which illustrates a staged rollout and scaling of data infrastructure.

In general, EHR updates occur in cycles within our hospital network. Consent management, which is integrated into the administrative user interface, requires thorough testing before deployment, as updates have to wait until the next cycle. Scaling was rapid: 61 facilities were integrated within the first month and 10 more within the second, and there were a total of 74 within 3 months. Staff received training during the rollout, yet in the initial 6 months, only 40% of patients were asked for consent, with a variation of plus or minus 24% across hospitals. Additional training boosted the rate to 63% by the end of 2023.

Rapid consent integration caused a significant load on the MPI during peak patient admission in the morning. To avoid time-outs, the Patient Identifier Cross-referencing interface was wrapped in an HTTPS API behind a high-availability load balancer.

Over a 24-month period, 1,475,244 patients were asked for consent during admission. In total, we received 1,023,633 instances of broad consent (consent rate: 70.2%), and 732,485 (71.6%) of these also included agreement to be contacted by researchers.

Notably, consent was not uniformly distributed: 714521 (69.8%) of instances stemmed from planned admissions, 217583 (21.3%) from unplanned admissions through the emergency department (ED), and 91529 (8.9%) from outpatient cases in the ED.

Data Volume

After 24 months, the consumption layer held approximately 15.1 billion records (averaging 102 unique medical data points per case), as shown in Figure 5. This amounted to approximately 14.1 terabytes of data as of October 2024. The ingest layer managed on average 1.9 million HL7 messages and 45,378 FHIR bundles per year, per hospital.

Data Modeling and Transformation

An iterative development approach results in frequent, additive changes to the data model, which are difficult to communicate to users. Therefore, we developed an interactive data catalog as a web application that displays the current state of all tables in the Hive Metastore.

We implemented an automated data quality framework to ensure data model conformity, assess data relationships, and detect outliers. This helped identify point-of-care devices reporting lab results in nonstandard units during LOINC (Logical Observation Identifiers Names and Codes) mapping [37].

Since transformations evolve, we implemented data version control [38] to store versioned code and data for reproducibility. It worked very well, but required familiarity with git and command line interfaces.

Lessons Learned

Infrastructure Scaling

The Hadoop ecosystem handles structured, semistructured, and unstructured data. Due to data minimization, data volumes grow more slowly than the compute demand, driven mainly by standardization and data quality checks. Therefore, we added another physical host to the cluster in the first year.

The consent rollout required addressing regulatory compliance, seamless technical integration into patient management systems, and an organizational transition to embed consent into the admission process, which presented unexpected challenges. A stable consent rate of 70% showed strong patient willingness to support research.

Strategies for Scaling the Data Lake

In summary, a 2-phase data integration strategy, starting with a few hospitals, has proven effective. The initial phase facilitates

XSL•FO
RenderX

refinement of interfaces, data modeling, and transformation processes, laying the foundation for seamless integration with a larger number of hospitals during subsequent scaling. Scaling the consent management system prior to data integration also proved beneficial, ensuring a consistent backlog of data for integration into the data lake.

Notably, as our data ingestion interfaces matured, technical integration of new data domains like ICU or cancer registries accelerated. However, full data model integration still requires substantial input from subject matter experts.

Batched Data Scales More Easily Than Streaming Data

Scaling adversely affected our MPI and HL7v2/IHE data ingestion, as these systems rely on an existing communication infrastructure that is not readily scalable. Future real-time data integration will likely shift toward local clinical data repositories for preprocessing, rather than introducing new streaming pipelines with technologies like Apache Kafka.

Interoperability and Standardization

Standardization, even for basic resources, presents difficulties, as transformations impact semantics and may lead to permanent information loss, despite agreement on rules by involved parties (ie, subject matter experts and data engineers).

Divergence in target values across different EHR installations poses risks to information integrity, notably during initial HL7 message processing due to profile limitations excluding certain HL7 "Z-segment" permutations. Consequently, a "raw-data first" policy was implemented to mitigate future data loss, albeit at the expense of increased bandwidth and storage capacity needs. Standardization can also result in decreased precision, particularly when transforming observations that were recorded without adhering to standards like LOINC [37].

Automation

Automation is essential to enhance efficiency, accuracy, and productivity. Versioned code and reproducible builds from the CI/CD pipeline helped to quickly revert changes that turned out to be suboptimal prior to production deployment. We also had substantially more success in onboarding new personnel onto automated, rather than manual, processes. We argue this learning is especially valuable for research institutions, which experience frequent personnel changes among graduate students and postdoctoral researchers.

Unintended Consequences

With 70% of cases in our dataset stemming from planned admissions, ED cases were underrepresented, introducing a selection bias. This disparity compromises the validity of results extrapolated to the ED setting and may distort the performance metrics of predictive models and risk stratification algorithms, possibly resulting in suboptimal outcomes. Thus, meticulous methodological scrutiny, starting in the design phase of each project, is required to mitigate these biases when using this dataset for translational research.

To enhance unbiased subsampling and improve generalizability, we categorized admission criteria for accounts and encounters. Nevertheless, our aim is to seek consent from every patient, irrespective of admission type, ensuring dataset balance. Obviously, in urgent medical situations, obtaining consent may not be feasible for patients who are distressed or have an altered mental state. A potential solution is to separate consent from administrative admission, seeking it during the inpatient stay instead, although this approach would demand extra resources. Unfortunately, vulnerable patient groups (eg, homeless or uninsured patients) will also be underrepresented in our dataset, since most of their interaction with the medical system is through the ED. Ethical implications extend beyond consent collection. The potential for algorithmic bias in medical research based on our dataset must be carefully considered. Researchers using our platform are required to report on the demographic composition of their study populations and explicitly address potential biases in their analyses.

Discussion

We hope to inspire other private hospital networks to build data lakes. Adhering to best practices as defined by national and international research consortia is key to ensure compatibility and to allow for integration with other research consortia in the future. Combining data from academic and nonacademic institutions and health care providers could enable longitudinal analysis of patients across multiple health care sectors, and the German Medical Informatics Initiative has begun branching out into nonacademic health care providers via progress hubs [39].

Our approach centralizes data from all participating hospitals after integration, whereas the German Medical Informatics Initiative operates local data integration centers at every participating hospital or within smaller hospital clusters. Decentralized data repositories provide local autonomy and resilience against system failures but demand infrastructure and personnel investment at every site. A decentralized approach seems ideal for academic institutions because local data expertise can be used for local research projects and education of computer science students as well as physician scientists receiving specialization training. For hospital networks below the level of university medical centers, centralization might be preferable, especially if there are already shared IT resources (infrastructure and personnel) within the network. We acknowledge, however, that our decision to use open source software and implement the platform from scratch was only feasible because our IT organization already runs its own data centers and has developer as well as development operations experience. Nevertheless, the global trend toward platform-as-a-service providers (hyperscalers) for storage and compute tasks poses challenges in recruiting experienced staff for on-premise installations. This presents a pain point for hospital networks: regulatory requirements require on-premise data storage, while most other sectors move to the cloud.

High levels of automation and agile development, characterized by short feature cycles and consistent data quality improvements, are necessary for user satisfaction. However, achieving swift project rollout and overall success necessitates continuous organizational investment and subject matter expert support.

Future developments will involve the extraction of knowledge from unstructured text, and we have collected preliminary

XSL•FO
RenderX

findings on document pseudonymization [40]. Building research data platforms is not a purpose in itself. Meaningful research conducted on these platforms is needed to justify the collection of EHR data, even with patient consent. We are looking forward to research reports beyond the technical level on projects realized with our implementation.

Abstract

Background: Artificial intelligence (AI) algorithms offer an effective solution to alleviate the burden of diabetic retinopathy (DR) screening in public health settings. However, there are challenges in translating diagnostic performance and its application when deployed in real-world conditions.

Objective: This study aimed to assess the technical feasibility of integration and diagnostic performance of validated DR screening (DRS) AI algorithms in real-world outpatient public health settings.

Methods: Prior to integrating an AI algorithm for DR screening, the study involved several steps: (1) Five AI companies, including four from India and one international company, were invited to evaluate their diagnostic performance using low-cost nonmydriatic fundus cameras in public health settings; (2) The AI algorithms were prospectively validated on fundus images from 250 people with diabetes mellitus, captured by a trained optometrist in public health settings in Chandigarh Tricity in North India. The performance evaluation used diagnostic metrics, including sensitivity, specificity, and accuracy, compared to human grader assessments; (3) The AI algorithm with better diagnostic performance was integrated into a low-cost screening camera deployed at a community health center (CHC) in the Moga district of Punjab, India. For AI algorithm analysis, a trained health system optometrist captured nonmydriatic images of 343 patients.

Results: Three web-based AI screening companies agreed to participate, while one declined and one chose to withdraw due to low specificity identified during the interim analysis. The three AI algorithms demonstrated variable diagnostic performance, with sensitivity (60%-80%) and specificity (14%-96%). Upon integration, the better-performing algorithm AI-3 (sensitivity: 68%, specificity: 96, and accuracy: 88·43%) demonstrated high sensitivity of image gradability (99.5%), DR detection (99.6%), and referral DR (79%) at the CHC.

Conclusions: This study highlights the importance of systematic AI validation for responsible clinical integration, demonstrating the potential of DRS to improve health care access in resource-limited public health settings.

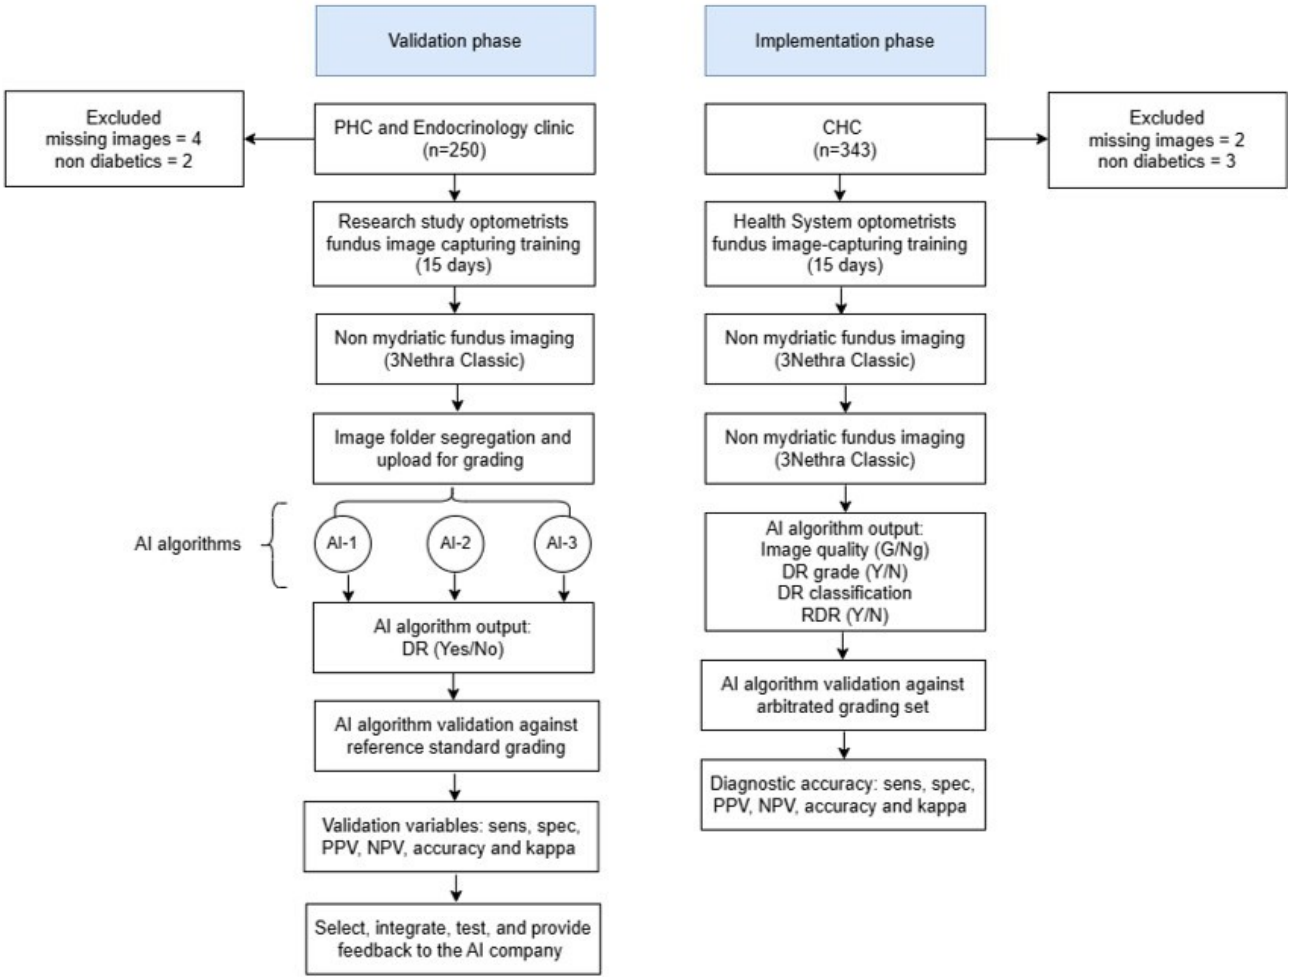
Introduction

The global prevalence of diabetes is growing [1], leading to increased vision loss and blindness associated with it [2]. There is an urgent need for diabetic retinopathy (DR) screening programs to identify vision-threatening DR to enable timely treatment [3,4]. However, this rising prevalence is straining health care systems already struggling to improve care and manage health care costs [4].

Despite its critical role, DR screening (DRS) remains limited in many low-resource settings. Conventional screening with trained human graders is often costly, time-consuming, and challenging to scale [5,6]. The gap between eye care needs and ophthalmologist availability exacerbates public health challenges [7]. In India, DR management faces challenges due to limited screening programs, low public awareness, and poor understanding of routine retinal exams [8]. Artificial intelligence-driven DRS enables faster, more affordable, and efficient screening, especially in underserved areas [9,10]. It allows noneye health professionals to conduct screenings and refer without specialists [11].

AI algorithms have demonstrated performance comparable to or exceeding human experts in DR classification [12,13]. However, concerns exist about their suboptimal performance in real-world settings and across diverse populations [14]. Real-world validation is critical to ensure AI algorithms perform accurately in diverse settings, as disease prevalence, image quality, and patient-related factors may differ from the training dataset [15-17]. Prospective studies are essential for evaluating AI systems in the contexts where they will be deployed [18]. Hence, integrating AI into clinical practice requires alignment with clinical workflows and stronger evidence on its real-world accuracy and user experiences [11,14].

This is the first Indian study to validate multiple commercial AI algorithms for DRS and to assess the feasibility of implementing a validated AI system in public health settings.



Methods

Study Design

The study prospectively validated three DR detection AI algorithms (validation phase) and assessed the technical feasibility of implementing a validated AI algorithm in public health settings (implementation phase). The STARD (Standards for Reporting of Diagnostic Accuracy Studies) checklist [19] was used to report the completeness and transparency of the diagnostic accuracy study and the iCHECK-DH framework to enhance the completeness and transparency of reporting related to the digital health implementation components [20]. Figure 1 summarizes the study design.

XSL•FO
RenderX

Figure 1. Study flow chart. Implementation phase occurred after the completion of the validation phase (ie, not simultaneously). AI: artificial intelligence; CHC: community health center; DR: diabetic retinopathy; PHC: primary health center; PPV: positive predictive value; NPV: negative predictive value; RDR: referable diabetic retinopathy.

Ethical Considerations

The study received approval from the Postgraduate Institute of Medical Education and Research (PGIMER) Institutional Ethics Committee (PGI/IEC/2020/001342) and followed the recommendations of the Declaration of Helsinki. The study was prospectively registered with the Clinical Trials Registry India (CTRI/2022/10/046185). Individuals aged > 30 years with a history of diabetes mellitus were screened for DR, following the National Program for Prevention and Control of Non-Communicable Diseases [21]. Informed consent was obtained, and their routine care remained unchanged. All data used in this study were anonymized prior to analysis, with no personal identifiers retained.

Study Site (Real-World Settings)

Validation was conducted from March to June 2021 at the Department of Endocrinology, PGIMER, Chandigarh, and a Primary Health Center (PHC) in Khizrabad, District Mohali, Punjab. The AI-enabled DRS was implemented between February 2022 and June 2022 at a community health center (CHC) in Badhani Kalan, Moga District, Punjab, India.

Sample Size

Sample sizes (validation=256; implementation=348) were calculated assuming DR prevalence of 17%, nongradable image rates of 18.4% in validation and 30.3% during implementation, 70% sensitivity, 86% specificity, 95% CI, and nonresponse rates of 10% and 15% in validation and implementation, respectively [3,22-25].

AI Algorithms

Based on a scoping review, five AI companies that used cloud-based AI (four Indian, one international) were invited. Before validation, they received the study objectives and camera or image specifications.

Fundus Image Acquisition

Training of Optometrists

Two experienced optometrists were trained for 15 days at the Advanced Eye Centre (AEC) and PHC settings before validation (Table S1 in Multimedia Appendix 1) [26]; two distinct optometrists received similar training for implementation in Moga district. Training covered identifying good-quality images [27] and capturing additional images when needed. They were supervised until proficient in independent data collection and imaging.

XSL•FO
RenderX

Camera

All participants underwent nonmydriatic, two-field (macula and disc-centered), 45° FOV fundus photography using a 3Netra Classic Portable Benchtop Fundus Camera (Forus Health) [26].

Recruitment Process

During validation, participants were recruited through Accredited Social Health Activist (ASHA) workers at PHCs and by research staff in the endocrinology department . The study did not alter patients' routine care during the recruitment process. During implementation, recruitment at the CHC was assisted by a nurse from the medicine clinic.

Darkroom

[To minimize ungradable images from nonmydriatic cameras that are a key challenge for real-world DRS programs, [28]dark rooms with sealed windows and ventilators were set up at PHC Khijrabad and at CHC Badhani Kalan (Figure S1 in Multimedia Appendix 1), with participants seated in the dark for ≥2 minutes to achieve physiological mydriasis before imaging.

Image Grading

Image identifiers were removed, and images remained unprocessed before AI analysis. The research optometrist sorted and uploaded them by eye laterality (ie, right and left eye). AI companies had no direct access; only the uploading optometrist handled the images per the agreement with the companies. A separate, role-based account was created for image upload and grading, accessible only to the optometrist. Audit logs tracked access, and secure file transfer protocols protected the transmission of images and the human grader had similar restricted access. Validation images were not used for training or testing the AI.

AI Grading Protocol

The AI algorithms' screening outcomes were inconsistent in providing DR stages (mild nonproliferative diabetic retinopathy (NPDR)), moderate NPDR, severe NPDR, and proliferative diabetic retinopathy (PDR)), diabetic macular edeme (DME) (yes/no), and referable DR (RDR) (Figure S2 in Multimedia Appendix 1). Hence, the DR grade (yes/no) was chosen to validate the AI algorithms discussed elsewhere [29].

Reference Standard Grading

All AI screening outputs were manually graded by human graders using the International Classification for Diabetic Retinopathy (ICDR) classification system [30]. Images were labeled as "gradable" or "non-gradable," and DR as "present" or "absent." DR was classified as mild, moderate, or severe NPDR and PDR [30]. Microaneurysms that are early signs of DR, indicate mild NPDR [31]. Any DR mentioned above, including moderate NPDR were considered referable DR (RDR) [30]. DME was defined as hard exudates with or without foveal involvement [3]. Images with ≥80% visibility and clear view up to the third vascular branch were considered gradable and assessed for DR [27].

- Validation phase*:* Two masked human graders (HG1 and HG2), a trained optometrist with three years of grading experience, and a retina-trained ophthalmologist with seven years of grading experience, with different institutional affiliations, independently graded all the fundus images. A senior vitreoretinal expert with 25 years of grading experience re-evaluated 224 images from 56 participants (75%) where HG1 and HG2 disagreed on DR presence. A strong level of agreement [32] (κ=0.85) was observed between HG2 and the senior retina specialist; hence, HG2 grading was considered the reference standard (RS) for AI validation.
- Implementation phase*:* All images were independently graded by two masked human graders (HG1 and HG2), who were different from those involved in the validation phase. In cases of disagreement, the grades were reviewed and adjudicated by a senior vitreoretinal specialist with over eight years of experience in grading. The final consensus-based, arbitrated dataset served as the RS and was used for all statistical analyses.

AI Integration and Implementation

The better-performing AI algorithm was integrated into the 3Netra Classic and pilot-tested for two weeks at AEC and District Hospital (DH), Mohali. This phase ensured hardware-software compatibility, assessed internet connectivity, and included dummy tests to validate outputs before implementation. The two-week testing at PGIMER and DH Mohali validated the full AI workflow, identified technical issues, assessed reliability in clinical settings, and highlighted data and reporting bottlenecks.

This feedback led to key refinements, including better internet connectivity, mandatory clinical variables, faster result turnaround, and local data storage on the National Institute of Transforming India (NITI) server for compliance. Final adjustments were implemented at Moga and Mohali sites (Figure S3 in Multimedia Appendix 1). The AI algorithm did not undergo additional training during the implementation period. Testing was conducted by optometrists, supported by a research optometrist, and supervised by the data scientist and principal investigator. The research team coordinated with the AI company to address feedback, and the machine learning scientist assisted with preimplementation adjustments.

Poststudy, a follow-up mechanism was established to ensure continued service delivery (6 mo), with the optometrist monitored for adherence to screening protocols. Notably, the retinal camera and adjustable stand were retained at the CHC rather than being reclaimed as study assets, reinforcing sustainability through local ownership and continuity of service.

Referral Recommendation and Telephonic Follow-Up

Referral were based on cases diagnosed as moderate or more severe, as well as those with DME [30]. Participants requiring follow-up were contacted by phone one month after their DRS appointment to assess compliance, with up to three contact attempts made to gather this information.

Data Analysis

The study data was collected using Research Electronic Data Capture (REDCap) [33]. Deidentified data were downloaded

XSL•FO
RenderX

from REDCap and imported into Stata/IC (version 15.1; StataCorp) [34] for analysis.

The AI platform's sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) were estimated with 95% exact binomial CIs. A *P* value of <·05 was considered significant for all statistical tests. A κ value was calculated monthly during the implementation phase to assess the optometrists learning in image acquisition and the AI algorithm's performance in image quality and DR diagnosis. This measured the agreement between AI and RSs for image quality and DR diagnosis. The folders with missing bilateral or macula-centered images and people without diabetes mellitus were excluded from the analysis. All analyses were conducted on an eye-wise basis.

Results (Implementation)

Three AI algorithm companies Leben Care Health Services, Retinal AI Diagnostic Software, and SigTuple Technologies. Each AI platform was masked from the others and randomly assigned labels such as AI 1, AI 2, and AI 3. One Indian AI algorithm declined participation, and an Food and Drug Administration (FDA)-approved algorithm was excluded due to low specificity in interim analysis. Two Indian AI companies approached during the implementation phase but were not included.

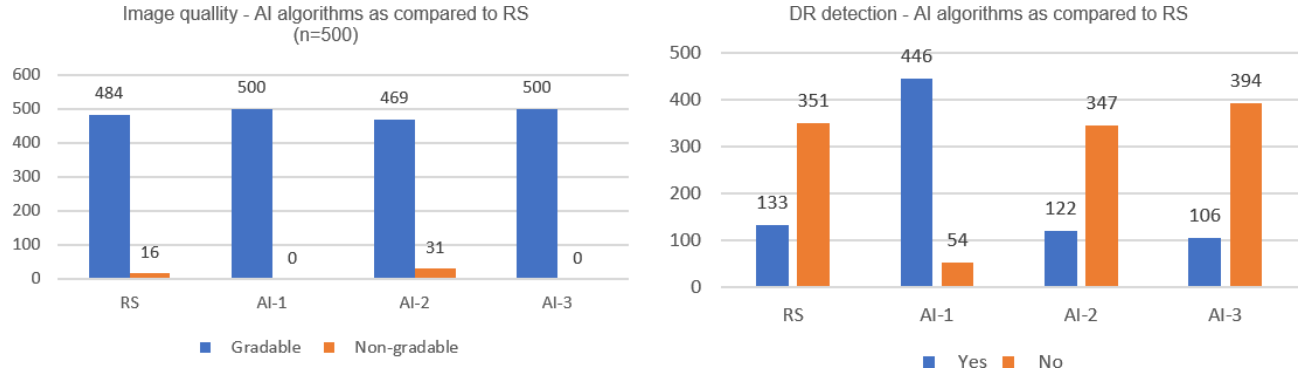
Sociodemographic Details of the Study Participants

Among the 250 participants in the validation phase, 182 were recruited at the PHC Khijrabad and 68 from the endocrinology clinic. The mean age of the participants was 53.5 (SD 7) years in the PHC and 47.2 (SD 4) years in the Endocrinology clinic, respectively. Overall, 87/250 (48.3%) participants in the PHC group were men and 95 (51.7%) were women, and those in the Endocrinology group included 38 (55.8%) men and 30 (44.1%) women. In the implementation phase, 343 participants were recruited. The participants' mean age was 58.48 (SD 10.41) years, with 202/343 (59%) women and 140 (41%) men (Table 1).

Table . Study participants demographic characteristics.

Characteristics	Validation phase (n=250)	Implementation phase (n=343)
Gender n (%)		
Men	121(48.4%)	141 (41)
Women	129(51.6%)	202 (59)
Age (years), mean (SD)	54.4 (13.8)	58.4 (10.4)
Duration of diabetes (years), mean (SD)	7.1 (6.1)	6.2 (5.9)
Education, n (%)		
Illiterate	72(28.8)	135(39.4)
Primary	79(31.6)	125(36.4)
Matriculation	70(28)	63(18.4)
Secondary	14(6.8)	8(2.3)
Graduation and above	15(6)	12(3.5)

Validation Phase



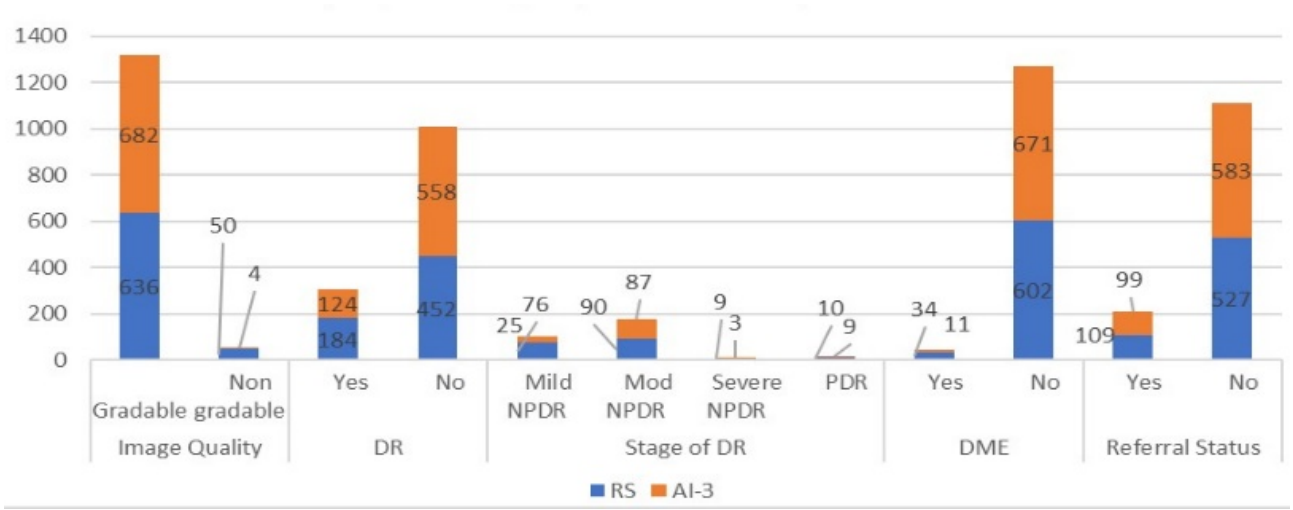
The analysis included 1099 fundus images of 500 eyes from 250 participants. According to the RS, 484 (96·8%) of eyes were gradable, with 16 (3·2%) being ungradable. AI 1, AI 2, and AI 3 achieved excellent gradability (100%, 93.8%, and 100%, respectively). The RS detected DR in 133 (27.48%) of the eyes; AI 1 detected notably more cases of DR in 446 (89.2%) eyes compared with AI 2, 122 (26.22%), and AI 3, 106 (21.2%) (Figure 2).

AI 3 showed the best performance with specificity of detecting DR, 96.01% (93·24 - 97·72); sensitivity, 68.42% (59·71 - 76.05); PPV, 86.67% (78.31 - 92.26); accuracy, 88.43%; and agreement with the RS (κ=0·65) and was selected for implementation (Table S2 in Multimedia Appendix 1). The validation results have been presented elsewhere [29].

Based on our study findings and recommendations from the project technical oversight committee which comprised ophthalmologists, public health experts, academicians, technologists, and research scientists providing technical expertise and strategic direction to evaluate, guide, and strengthen the project's scientific rigor. The AI company was recommended to train its algorithm for DR stages, DME grading, and referral guidelines, incorporating inputs on camera integration, connectivity, and platform functionality. Changes were completed within four months, and implementation began at CHC, with testing images excluded from the final set (Table S3 in Multimedia Appendix 1). Changes were incorporated within four months and implemented at CHC.

XSL•FO
RenderX

Figure 2. Image quality of artificial intelligence (AI) algorithms as compared to the reference standard (RS). DR: diabetic retinopathy.



Implementation Phase

During the implementation phase, 1372 fundus images were captured from 686 eyes of 343 participants. AI-3 exhibited slightly higher image gradability (682, 99.5%) than the RS (336, 92.71%). AI-3 identified 124 (18.2%) of participants with DR, while the RS detected 189 (28.9%). Moderate NPDR was most common (AI-3 at 87 (12.8%) and RS at 90 (14.1%). DME detection was lower for AI-3, 11 (1.6%) than the RS, 34 (5.3%). Referral rates were almost similar, (AI-3: 99; 14.5%) and RS (109, 17.1%) (Figure 3).

Among the 50/686 (7.3%) ungradable eyes graded by HG, 21 (42%) had cataracts, while none labeled as ungradable by AI had cataract. The sensitivity, specificity, PPV, and NPV of AI-3 algorithm for DR detection were 99.6%, 64.7%, 87.4%, and 98.3%, respectively. For DME, specificity, PPV, and NPV were 99.7%, 81.8%, and 96%, respectively. However, sensitivity is relatively low (26.5%); for detecting RDR, sensitivity and specificity were 78.9% and 98.1%. For image gradability, the AI's sensitivity was excellent at 100%, but specificity was low (8%) (Table 2).

Figure 3. Diabetic retinopathy screening outputs of AI as compared to the reference standard at Community Health Center Moga. AI: artificial intelligence; DME: diabetic macular edeme; DR: diabetic retinopathy; PDR: proliferative diabetic retinopathy; NPDR: nonproliferative diabetic retinopathy.

XSL•FO
RenderX

Table . Sensitivity, specificity, PPV[a], NPV[b] of the AI[c] algorithm for various outcome variables with a reference standard.

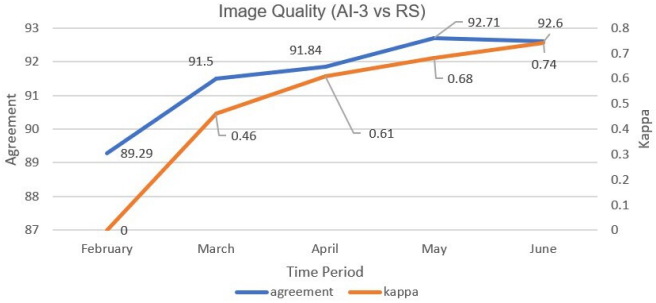
Outcome variables	Image gradability	DR[d] grade	DME[e] grade	RDR[f]
Sensitivity (%)	100	99·6	26·5	78·9
Specificity (%)	8	64·7	99·7	98·1
PPV (%)	93·2	87·4	81·8	89·6
NPV (%)	100	98·3	96	95·7
κ value	0.69	0.72	0.38	0.81

[a]PPV: Positive predictive value.

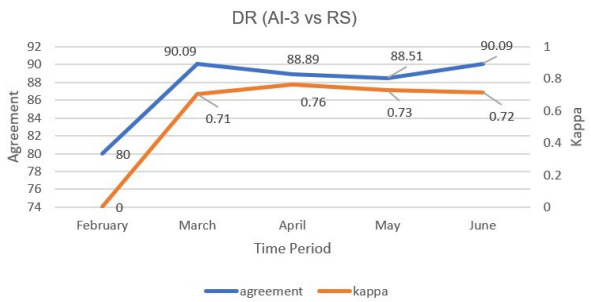
[b]NPV: Negative predictive.

[c]AI: artificial intelligence.

[d]DR: Diabetic retinopathy.



[e]DME: Diabetic macular edeme.



[f]RDR: referable diabetic retinopathy.

κ Statistic Variation Across the Study Period

Figure 4 shows κ variations for image quality and DR grades over 4.5 months when the health system optometrist captured the images. κ values of image quality increased from 0 in February to 0.74 in June, and for DR grade from 0 to 0.71 in June. This steady improvement could be attributed to the enhanced image quality captured by the optometrist over the study period and higher; in DR, this increase can be linked to better image quality and higher detection, with slight dips due to variation in DR severity or case complexity.

Figure 4. Agreement and kappa statistics for image quality and DR grade between AI and reference standard. AI: artificial intelligence; DR: diabetic retinopathy; RS: reference standard.

Participant Referral and Follow-Up

Of 64 referred participants, 28 (43.8%) were contacted; only 9 (14%) adhered to referral advice and visited an ophthalmologist for a review. Of these, 1 received an Optical Coherence Tomography referral, 5 went to facilities without eye care services, 1 received eye drops, 1 was advised antivascular endothelial growth factor injection, 1 left after receiving laser treatment, and 1 had a follow-up visit.

Reasons for nonadherence included harvesting season (n=11), lack of family support (n=2), time constraints (n=2), extended absence from home (n=1), financial dependence on family (n=2), and comorbidities (n=1).

Discussion

Principal Findings

This study is among the first in India to validate multiple AI algorithms for DRS, critically assessing their technical feasibility for integration into real-world public health settings. We evaluated the best-performing AI algorithm using images captured by a skilled research optometrist. This study outlines the Government of India's efforts to foster an ecosystem that ensures the integration of responsible AI technologies before application to end users [35].

In our study, AI system performance during validation varied significantly: sensitivity (59.7%97.74%), specificity (14.25%96.01%), PPV (30.16%86.67%), NPV (85%94.34%), and accuracy (37.19%88.43%). A multicenter study by Lee et al systematically compared seven AI-based DRS algorithms, revealing high NPVs (82.72%93.69%) but widely varying sensitivities (50.98%85.90%) in real-world performance [36]. In pivotal clinical trials for the IDX AI algorithm, the FDA's benchmark for superiority was set at 85% sensitivity and 82.5% specificity [13]. Although AI-3 sensitivity (68.3%) was below the FDA's >85% threshold, it outperformed other AIs in other diagnostic metrics: specificity (96.01%), PPV (86.67%), NPV (88.92%), and accuracy (88.43%). Prospective validation of a DRS algorithm at two Indian tertiary eye care hospitals demonstrated 89% sensitivity and 92% specificity on nonmydriatic images [37].

However, there are challenges in comparing algorithms using published results due to the variations in study methodologies [38]. One challenge is the dependence of an AI algorithm's accuracy on the quality of the retinal images obtained [27]. Our

XSL•FO
RenderX

study included ungradable images in validation, contrasting with many studies that preprocess or exclude lower-quality images in their training data sets [12,13,39-41] (Figure S6 in Multimedia Appendix 1). Excluding these images fails to reflect real-world settings, potentially lowering the algorithm's performance [13,41]. To date, validation studies demonstrate that most AI algorithms using mydriatic fundus images achieve high diagnostic accuracy [42]. In the validation phase, the dark room environment facilitated nonmydriatic conditions, yielding 0% ungradability for AI-1 and AI-3, 6.2% for AI-2, and 3.2% by human grader, contrasting with 1830% in LMIC settings per a systematic review [38,42].

Cataracts are a leading cause of ungradable images [28]. However, no images with cataract or other media opacities were classified as ungradable during implementation, potentially affecting AI-3 specificity (Table 2). Notably, the AI-3 algorithm failed to detect 21 (42%) eyes with cataracts, categorized as gradable. The AI-3 algorithm's sensitivity increased significantly from 68.4% to 99.6%, while specificity decreased from 96% to 64.7% between the validation and implementation phases. The sensitivity likely improved post validation due to algorithm training (Table S2 in Multimedia Appendix 1). The presence of cataracts, affecting media opacity and gradability, likely could have decreased specificity by increasing false positives [43]. After algorithmic training, AI-3 detected DME (Table 2) and sensitivity (26.5%), highlighting the need for improved training to enhance DME sensitivity and subsequently achieve higher RDR sensitivity (78.9%).

Optometrists serve as frontline eye care providers globally and are ideally positioned for task-sharing in DRS. Their integration into DRS and care pathways is well-established in diverse models worldwide, supporting sustainable and scalable eye care delivery [44-46]. In this study, a health system optometrist was trained and engaged in DRS at the CHC, with oversight from the research team. Over the study period, image quality and DR detection improved, reflecting a positive learning curve (Figure 3). These findings highlight the potential of optometrist-led AI-assisted screening in strengthening task-shifting models and expanding access to DR care in resource-limited settings [47-49]. Implementing an opportunistic AI-enabled DRS model holds promise for enhancing detection rates [47]. However, our study's adherence to referral recommendations remains suboptimal, with approximately 14% of participants attending recommended follow-up visits at an eye care facility. Key barriers to referral adherence include awareness gaps, logistical challenges (ie, travel, DR related cost), and persisting health system limitations, including weak referral pathways and poor patient tracking [48]. Personalized approaches, such as phone calls, voicemails, and detailed result letters, are shown to be effective in improving referral adherence [49]. Low referral adherence underscores the need for effective, coordinated referral pathways before introducing new screening models, while recognizing the vital role of teleophthalmology in such systems [47,50].

A notable strength of this study is its real-time implementation, conducted during regular clinics by a health system optometrist within a public health care setting. This marks a significant milestone that is likely to substantially enhance DRS services. The study showed that training and monitoring fundus image quality could significantly improve the effectiveness of the AI-enabled DRS program.

However, several limitations should be considered when interpreting the results. Using a single fundus camera may limit generalizability, as AI performance may vary across camera models and imaging conditions. Additionally, the study relied on a specific AI algorithm, which may not account for variations in other models or evolving AI systems. Setting-specific constraints such as workflow integration and infrastructure availability could also impact scalability. Furthermore, potential biases in real-world data, such as variations in patient demographics, image quality, and disease prevalence, may influence AI performance and limit broader applicability. Integrating DRS was feasible; however, we could monitor the optometrist only for three months poststudy. Regular monitoring is crucial for program sustainability and healthcare provider motivation.

Lessons Learnt

Operational challenges in DRS included limited patient access due to long travel distances, poor transport, and low awareness; inadequate infrastructure; and ergonomic barriers affecting both patients and screeners. Uncontrolled lighting and power issues led to 26% ungradable images. Adaptive measures, such as transport support, ergonomic adjustments, darkroom setups, and equipment reinforcements, raised image gradeability to 95.6% and improved efficiency. Addressing these barriers through infrastructure upgrades, controlled environments, and community facilitation is essential for sustainable DRS in primary health care systems.

In conclusion, this study highlights the essential role of systematic AI validation in integrating technology responsibly into clinical workflows. By demonstrating AI's feasibility for DRS in Indian public health settings, our findings support scalable solutions to improve health care accessibility in resource-constrained contexts across the Global South. However, long-term sustainability and large-scale implementation will require ongoing funding, a robust workforce, and effective policy integration. Further research is needed to evaluate the large-scale deployment of AI-driven screening strategies, examining their clinical effectiveness, cost-effectiveness, and the challenges of implementing them in real-world settings.

Acknowledgments

We extend our gratitude to the Punjab Health Department, Civil Surgeons of Mohali and Moga, Senior Medical Officers of Boothgarh and Badhani Kalan, and the Deputy Commissioner of Moga for their support in conducting this study. The study was funded by the National Institution for Transforming India (NITI) Aayog, the Government of India.
