- Modifying the observation_fact index structure by (1) incorporating elements from the patient and visit dimension tables, and (2) enriching observations with contextual information extracted from the ONT part of the i2b2 data model, stored as facets [50] of the observations. This modification was necessary due to Elasticsearch's lack of support for traditional relational joins.

Finally, the persistence of the observation component of the i2b2 data model in Elasticsearch was evaluated.

Mapping the Native OBSERVATION_FACT Table Structure as the observation_fact Index

The first step involved mapping all the columns of the OBSERVATION_FACT table into an Elasticsearch index. In an Elasticsearch document, mappings define 2 main elements (Table 2):

XSL•FO
RenderX

- The data type of each field in the Elasticsearch index (eg, numeric types such as long or double, text, date, keyword).
- The indexing method for each field. For instance, if a field is assigned the text data type, the mapping specifies the analyzer(s) used to index its content.

Thus, the 2 criteria considered to map OBSERVATION_FACT were:

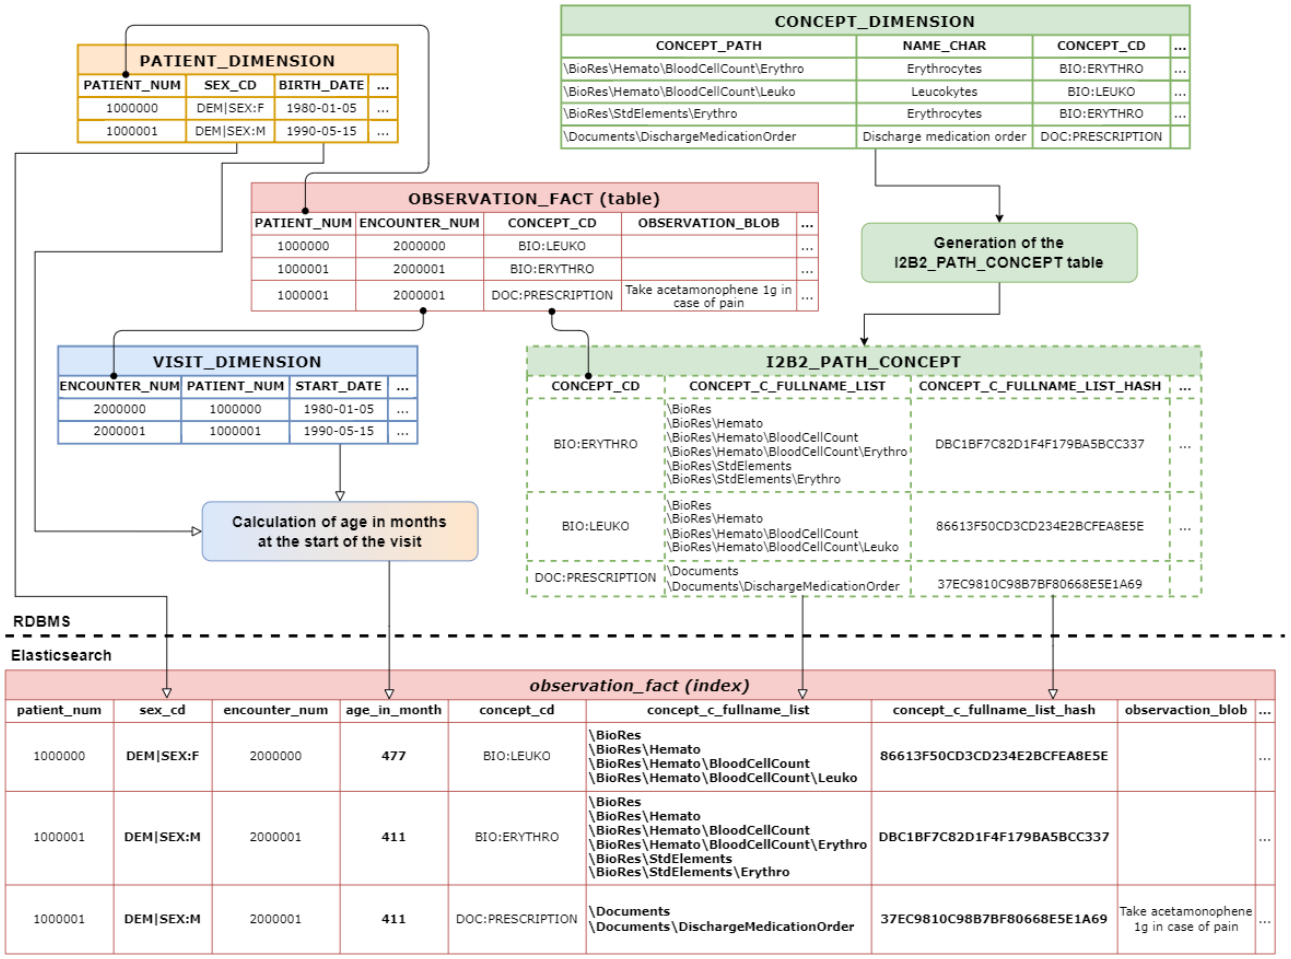
- The need to perform count or aggregation queries on the field. In this case, the Elasticsearch data type used for the field was keyword. In the OBSERVATION_FACT table, the fields used as aggregation criteria or in enumeration queries are fields corresponding to foreign keys in dimension tables:
  - ENCOUNTER_NUM and PATIENT_NUM columns: These are used to count patients or visits, aggregate information by patient or by visit, etc;
  - CONCEPT_CD, MODIFIER_CD, and PROVIDER_ID columns: These are used to count elements by clinical and biological criteria, aggregate information by provider, etc;
  - INSTANCE_NUM column: This corresponds to the key for grouping a principal observation with its modified versions;
  - TVAL_CHAR, VALUEFLAG_CD, and UNITS_CD columns: These are used in the case of numerical observations to specify elements concerning the numerical operator (=, >, ≥, etc), the interpretation in relation to limits, or the unit associated with the numerical result.
- The need to query a field with free-text queries: In this case, the text data type is associated with an analyzer for managing free-text. The column concerned in the OBSERVATION_FACT table corresponds to the OBSERVATION_BLOB column (in OBSERVATION_FACT, the TVAL_CHAR column is also used to store short text. In our implementation, all text [short or long] is stored in OBSERVATION_BLOB).

Table 2. Mapping of the native OBSERVATION_FACT columns to Elasticsearch types.

Column name	Column data type	Elasticsearch field data type	Analyzer
ENCOUNTER_NUM	NUMBER	Keyword	No
PATIENT_NUM	NUMBER	Keyword	No
CONCEPT_CD	VARCHAR2	Keyword	No
PROVIDER_ID	VARCHAR2	Keyword	No
START_DATE	DATE	Date	No
MODIFIER_CD	VARCHAR2	Keyword	No
INSTANCE_NUM	NUMBER	Keyword	No
VALTYPE_CD	VARCHAR2	Keyword	No
TVAL_CHAR	VARCHAR2	Keyword	No
NVAL_NUM	NUMBER	Double	No
VALUEFLAG_CD	VARCHAR2	Keyword	No
QUANTITY_NUM	NUMBER	Double	No
UNITS_CD	VARCHAR2	Keyword	No
END_DATE	DATE	Date	No
LOCATION_CD	VARCHAR2	Keyword	No
OBSERVATION_BLOB	TEXT	Text	Yes
CONFIDENCE_NUM	NUMBER	Double	No
UPDATE_DATE	DATE	Date	No
DOWNLOAD_DATE	DATE	Date	No
IMPORT_DATE	DATE	Date	No
SOURCESYSTEM_CD	VARCHAR2	Keyword	No
UPLOAD_ID	NUMBER	Long	No

Modification of the Structure of the observation_fact Index

As it is not possible to perform joins between indexes in Elasticsearch, 2 types of changes have been made to overcome this limitation (Figure 4):



- Some of the columns describing observations within the PATIENT_DIMENSION and VISIT_DIMENSION tables were added to the observation_fact index. For reasons of parsimony, only PATIENT_DIMENSION.SEX_CD, PATIENT_DIMENSION.BIRTH_DATE, and VISIT_DIMENSION.START_DATE have been integrated

XSL•FO
RenderX

into the observation_fact index. PATIENT_DIMENSION.BIRTH_DATE and VISIT_DIMENSION.START_DATE have not been added as fields, but have been used to calculate the age_in_month_at_start_visit field;;

- To make documents of the observation_fact index accessible through the different hierarchical levels described in the ONT part, all the C_FULLNAME associated with the CONCEPT_PATH (also MODIFIER_PATH and PROVIDER_PATH) have been integrated into the observation_fact index. Additional tables have been added to the ONT part of the i2b2 model to allow the addition, by join, of all the paths (intermediate and final) for each possible value of the OBSERVATION_FACT lookup columns (ie, CONCEPT_CD, MODIFIER_CD, and PROVIDER_ID). The pseudo-code describing the generation of table I2B2_PATH_CONCEPT, for the CONCEPT_CD column, is available in Multimedia Appendix 2. Within the observation_fact index, paths are stored in 3 new fields called c_fullname_concept, c_fullname_modifier, and c_fullname_provider as lists of keywords. As a result, each observation within the observation_index is associated with all the paths (intermediate and full paths) describing all the lookup fields.

Figure 4. Creation of the observation_fact index from the different tables of the Informatics for Integrating Biology & the Bedside (i2b2) model. The table I2B2_PATH_CONCEPT (bordered with dotted line) is created based on CONCEPT_DIMENSION: for each CONCEPT_CD, the table contains the ordered list of CONCEPT_PATH, including all intermediate truncated versions of those paths. The algorithm used for the generation of the I2B2_PATH_CONCEPT table is provided in Multimedia Appendix 2. The relevant data from the PATIENT_DIMENSION, VISIT_DIMENSION, and I2B2_PATH_CONCEPT tables are added into the observation_fact index as a facet. BIRTH_DATE is used with visit START_DATE to compute the age_in_month_at_start_visit facet. The round-tipped arrows represent the joins between the tables. RDBMS: relational database management system.

Evaluation of the Elasticsearch Persistence

The evaluation of the proposed implementation of the main part of the i2b2 data model in Elasticsearch aims to assess:

- The ability to load partial individual data (CRC part) daily. The specific mechanisms used for data loading are described. Loading performance is evaluated in terms of median loading time and the median number of documents loaded per minute.
- The ability to update metadata (ONT part). Similarly, the specific mechanisms implemented to update the metadata elements integrated into the observation_fact index are described. Metadata updating performance is evaluated in terms of median update time and the average number of concept_cd entries that need to be updated each week.

The ability to perform queries on the CDW persisted in Elasticsearch was evaluated. The results of count queries (distinct patients or distinct encounters) were compared between Oracle RDBMS and Elasticsearch implementations for the same

XSL•FO
RenderX

CDW data in terms of result value and execution time (median execution time based on 20 executions). Different types of queries were performed, with criteria evaluated at the patient or encounter level (Table 3):

- Counting queries based on structured data (queries 1 and 2), including a query that returns a small number of patients (≈1500) and a query that returns a large number of patients (≈150,000).
- Counting queries based on structured data combined with a numerical filter (query 3).
- Counting queries based on free-text data (query 4).
- Counting queries based on structured data combined with a temporal filter (query 5).
- Combination of the above criteria in AND/OR Boolean queries, with multiple evaluation orders (eg, [(1) and (2)] vs [(2) and (1)]).

The hardware resources used for data persistence and query computation have been described.

[b]If Oracle RDBMS and Elasticsearch return the same result, a single count is provided. Otherwise, the count obtained with Elasticsearch is presented first, followed by the count obtained with Oracle RDBMS.

Results

Elasticsearch Data Loading

A specific ETL process was developed using Spring Boot [51] to convert data from an RDBMS into Elasticsearch.

Data from PATIENT_DIMENSION and VISIT_DIMENSION were added to the OBSERVATION_FACT table using outer joins in the ETL. For the ONT data, intermediate tables were created to store the ordered list of all CONCEPT_PATH (MODIFIER_PATH and PROVIDER_PATH, respectively) for each CONCEPT_CD (MODIFIER_CD and PROVIDER_ID, respectively). An example for the CONCEPT_CD column is presented in Table 4.

As mentioned above, the data in our OBSERVATION_FACT table are partitioned by data source and year. A similar rolling strategy has been implemented in Elasticsearch, as presented in Multimedia Appendix 3. Consequently, observation_fact consists of multiple indexes, corresponding to the partitions in OBSERVATION_FACT. Each observation_fact index was divided into 3 primary shards (1 per node) to enable parallel queries, with no replicated shards created.

All data from the OBSERVATION_FACT table were loaded into an Elasticsearch cluster, comprising 2,502,063 patients, 20,982,497 visits, and 3,474,264,570 observations. The number of records in the observation_fact indexes matches that in the OBSERVATION_FACT table. Data persistence in Oracle RDBMS requires 1.030 TB for data and 2.640 TB for indexes (including 420 GB for the Oracle RDBMS full-text index). By contrast, data persistence in Elasticsearch requires only 1.635 TB, representing 44% of the disk space needed for Oracle RDBMS.

Table 4. The i2b2[a] PATH_CONCEPT table: a generated metadata table that lists all available C_FULLNAME paths for each CONCEPT_CD described in the ONT[b]. Equivalent tables exist for MODIFIER_CD and PROVIDER_ID.

[b]ONT: ontology management cell.

The duration of data loading in Elasticsearch by source is provided in Table 5. For the full year 2023 (approximately 340,000,000 observations), the median overall data loading time with 10 sources in parallel is 7.41 hours, corresponding to a median indexing rate of 46,546,000 documents per hour. Indexing speed appears to depend on the type of data, with structured numerical data being indexed at a median rate of 171,600 documents per minute—approximately 4 times faster than free-text data, which has a median rate of 48,100 documents per minute. Data loading in Elasticsearch has not been compared with data loading in Oracle DBMS. Indeed, data loading in Oracle RDBMS is heavily influenced by the transformations performed when integrating data from the source information system into the OBSERVATION_FACT table. By contrast, as loading into Elasticsearch is conducted from the OBSERVATION_FACT table, only transformations related to data denormalization are applied during the Elasticsearch loading process.

Table 5. Data loading metrics for the full year 2023 (metrics based on 8 loads).

Source	Observations (n=339,331,147), n	Documents (×1000/minute), median (Q1-Q3)[a]	Loading duration (minutes), median (Q1-Q3)[b,c]
Chemotherapy	478,438	185.3 (132.1-222.8)	2.5 (2.1-4.9)
Forms	77,460,099	181.6 (164.4-188.9)	429.1 (407.3-490.1)
Biology	158,384,678	171.6 (162.4-176.5)	916.4 (893.1-968.3)
Drug prescription/administration	32,736,762	155.6 (148.6-199.3)	204.5 (187.4-214.6)
Nursing care prescription/administration	16,523,635	107.4 (87.2-138.8)	149.2 (113.7-180.2)
Radiology	9,438,970	76.6 (37.8-91.7)	130.8 (79.9-201.4)
Diagnostic (ICD-10[d])	6,690,589	64.6 (57.3-105.7)	105.2 (64.2-116.8)
Localization	6,181,496	59.8 (54.3-79.2)	102.8 (77.6-118.3)
Demographic data	2,142,053	59.6 (55.0-122.6)	34.7 (17.3-37.8)
Nurse notes	12,984,197	58.8 (52.4-66.7)	223.6 (199.0-248.7)
Care prescription/administration	4,930,320	56.5 (30.0-68.6)	86.9 (71.7-162.6)
Free-text notes	6,066,806	48.1 (39.8-78.3)	125.9 (80.2-151.3)
Surgery data	518,998	13.9 (6.5-248.9)	37.4 (2.1-80.3)
Microbiology	3,364,431	13.2 (11.5-17.6)	254.3 (189.7-290.2)
Pathology	678,289	10.7 (7.6-18.8)	65.6 (38.8-89.4)
Other	284,220	4.9 (3.1-190.7)	59.1 (1.5-90.6)
Transfusion	467,166	2.7 (2.1-3.1)	165.3 (152.4-205.4)

[a]Overall: 775.8 (749.2-792.1).

[b]The median loading duration was calculated without considering parallelization. Some sources consist of multiple indexes, such as biology (which comprises 5 indexes) and forms (which comprises 4 indexes). This explains why the maximum median loading duration (916.4 minutes) is higher than the overall median duration (444.8 minutes).

[c]Overall: 444.8 (429.0-461.2).

[d]ICD-10: International Statistical Classification of Diseases and Related Health Problems, 10th Revision.

Elasticsearch Metadata Updating

In the case of a modification in the ONT part, a strategy for updating the observation_fact indexes has been implemented. This strategy is presented and evaluated in Multimedia Appendix 4 [52].

Elasticsearch Querying

The results of queries executed on an Oracle RDBMS engine were compared with those obtained using Elasticsearch. For queries involving joins (AND Boolean queries), the joins were performed at the application layer for both Oracle RDBMS and Elasticsearch. A full-text index was available in the Oracle RDBMS. All necessary indexes for the Oracle RDBMS queries were calculated, and the statistics were up to date. The results and response times were compared between the 2 engines. The Oracle RDBMS (version 19.17) runs as a cluster on 2 servers, each with 80 CPUs and 1 TB of memory. The Elasticsearch database (version 7.17.3) is configured as a 3-node cluster, deployed through Docker, with each node having access to 25 CPUs and 30 GB of memory.

A total of 9 different queries were compared (Table 3). Each query evaluated criteria either at the patient level (nontemporal queries) or at the visit level (temporal queries). To assess execution time, each query was executed 20 times on both engines. The results were identical between the Oracle RDBMS engine and Elasticsearch, except for the full-text query, which returned more results in Elasticsearch due to differences in full-text indexing implementation. Response times were generally lower with Elasticsearch than with Oracle RDBMS, except for the “Pembrolizumab” query, which returned a low number of results. Temporal queries (evaluating criteria within the same encounter) were consistently slower than nontemporal queries on both engines.

Source Code

The ETL between i2b2 RDBMS and i2b2 Elasticsearch was developed using Spring Boot (a Java framework; VMware). The source code of the ETL is available at [53].

Discussion

Principal Findings

To our knowledge, this work is the first to evaluate the technical feasibility and performance of persisting an i2b2 model in an Elasticsearch database. Beyond demonstrating feasibility, the evaluation highlights significant improvements in overall query times and hardware resource requirements, particularly in storage, with a 66% reduction in disk space usage. Additionally, the implementation has been tested on a large volume of data,

XSL•FO
RenderX

demonstrating good scalability. The proposed implementation is currently in production at Bordeaux University Hospital, supporting more than 200 research projects since 2022.

Elasticsearch is designed for very fast searches, prioritizing optimization for speed, high availability, and horizontal scalability. However, this comes at the cost of certain transactional guarantees (ACID) and absolute precision in some operations, such as counts. Specifically, in the event of a failure during the update of a replicated index, the system may restart in an inconsistent state, where data are updated in the primary shard but not across all its replicas. In our context, high availability is not a major concern. We have therefore chosen not to replicate shards across different cluster nodes, avoiding consistency issues in case of failure. Additionally, in the rolling strategy implemented for data loading, a newly created index becomes available for searching only after it has been fully loaded, minimizing the risk of querying incomplete data. To optimize queries, Elasticsearch employs probabilistic counting algorithms (eg, HyperLogLog) for count queries. However, in our context, exact results are essential for this type of query. We have therefore configured Elasticsearch to ensure accuracy, sacrificing some query performance. Despite this, execution times were consistently lower with Elasticsearch than with the RDBMS.

In our implementation, we chose to add the lookup columns from the dimension tables and the paths of CONCEPT_CD (as well as MODIFIER_CD and PROVIDER_ID) as facets of the observation_fact indexes. Combined with fields of the keyword data type, this approach optimizes query times, particularly for enumeration queries, at the expense of indexing time, which is not performed in real time. The disadvantage of this implementation is that data (CRC) and metadata (ONT) are not kept separate, meaning that any modification to the metadata requires reloading or updating the data. To address this issue, we implemented a process for updating metadata within the observation_fact indexes and demonstrated the feasibility of performing these updates without reloading the entire data set.

An alternative implementation would involve maintaining the observation_fact indexes without adding additional fields and instead creating separate indexes for the various dimension tables and the ONT metadata table. Similar to the proposed configuration, joins at the application layer (ie, intersecting patient or encounter lists) would be used to combine results from different indexes for AND Boolean queries. However, this approach presents potential performance challenges. For instance, intersecting gender data (eg, female) stored in the patient_dimension index with a criterion stored in the observation_fact indexes would require loading into memory the list of all patient keys corresponding to women in the CDW—approximately 1.2 million patients in the Bordeaux University Hospital implementation. This issue becomes even more pronounced when handling data from the VISIT_DIMENSION table.

Alternatively, an Elasticsearch implementation could have used nested field data types [54]. These types allow the content of a nested field to be indexed as a separate Lucene document within the main document. This approach would have enabled indexing a patient document containing visit documents as nested data, which in turn would contain observation documents as nested data. However, this implementation would have required reloading all data for a given patient at once, which was incompatible with our goal of reloading recent data daily. Additionally, queries involving nested documents generally perform worse than standard field queries.

In our implementation, we mapped the TVAL_CHAR column of the OBSERVATION_FACT table as a “keyword” in the indexes constituting observation_fact. In the i2b2 data model, the TVAL_CHAR column is used in 2 cases, in conjunction with the content of the VALTYPE_CD column:

- VALTYPE_CD = “T”: The TVAL_CHAR column contains the short text associated with the CONCEPT_CD (eg, a biology comment).
- VALTYPE_CD = “N”: The TVAL_CHAR column contains the mathematical operator associated with the numerical value in the NVAL_NUM column (eg, “E” for “equal,” “NE” for “not equal,” and “L” for “less than”).

In the i2b2 implementation at Bordeaux University Hospital, all free-text data, including short texts, are stored in the OBSERVATION_BLOB column. As a result, the TVAL_CHAR column contains only the mathematical operators for numerical values. In a fully i2b2-compliant implementation, it would be necessary not only to map the TVAL_CHAR column as a keyword but also to associate an analyzer with it. This would enable both full-text search and aggregate queries.

To evaluate query capabilities using the Elasticsearch database, part of the i2b2 query engine was reimplemented. This reimplementation supports multicriteria enumeration queries (ie, “AND,” “OR,” and “NOT” Boolean queries), including numerical data and free-text search, evaluated at the patient or encounter level. However, not all functionalities available in the original i2b2 query engine have been implemented. In particular, the ability to perform queries based on the number of occurrences of observations (eg, identifying patients who have visited the hospital at least three times) or queries that account for temporality between events (eg, patients with hemoglobin measurements within 5 days after colon surgery) has not been implemented. These 2 types of queries are more complex than those already implemented, as they require additional observation aggregation and aggregate filtering steps before results can be aggregated at the patient or event level. However, the organization of the observation_fact indexes proposed here appears to be compatible with executing such queries. Implementing these capabilities could be the focus of future work.

The proposed ETL for loading the Elasticsearch database is based on data already integrated into an i2b2 model persisted in an RDBMS. Beyond enabling a straightforward ETL process from i2b2 RDBMS to i2b2 Elasticsearch, maintaining this relational database appears essential for specific use cases that would not be feasible with Elasticsearch alone (eg, joins with the system containing the source data, preparation of complex data by joining OBSERVATION_FACT to itself). Consequently, while Elasticsearch provides performance

XSL•FO
RenderX

improvements, these must be weighed against the requirement to maintain 2 parallel infrastructures.

Although no i2b2 implementation using a NoSQL database has been described to our knowledge, the literature includes examples of CDWs designed for free-text analysis. OpenMRS [55], an open-source EHR project, features a free-text search module based on Apache Lucene, integrated with Hibernate Search. R-oogle [20], a document-oriented CDW, preindexes free-text data using external terminologies (eg, Medical Subject Headings [MeSH]) and stores them in a Lucene index. Dr. Warehouse [21,56] implements a segmentation approach for free-text documents, breaking them into "propositions" stored in a full-text index within the Oracle RDBMS. These propositions are linked to contextual elements (eg, antecedents, personal and family history, or negation). Doc'EDS [57] provides a phenotyping search engine that integrates both structured and unstructured data, indexed through Apache Lucene. All CDW implementations utilizing NoSQL databases [20,55,57] rely on Apache Lucene's low-level libraries. Elasticsearch, built on Apache Lucene, operates at a higher abstraction level, simplifying deployment and integration. While this limits fine-tuning capabilities for specific indexing needs, it provides significant advantages, such as access to the Kibana [58] visualization engine and query clients available in Java via Spring Boot [59].

Conclusions

This study presents an Elasticsearch-based implementation of the i2b2 data model for phenotyping tasks. By reimplementing part of the i2b2 search engine, the study demonstrates that Elasticsearch provides similar query capabilities while offering faster performance and improved efficiency for free-text searches.

Abstract

Background: Knee cartilage injury (KCI) poses significant challenges in the early clinical diagnosis process, primarily due to its high incidence, the complexity of healing, and the limited sensitivity of initial imaging modalities.

Objective: This study aims to employ magnetic resonance imaging and machine learning methods to enhance the classification accuracy of the classifier for KCI, improve the existing network structure, and demonstrate important clinical application value.

Methods: The proposed methodology is a multidimensional feature cross-level fusion classification network driven by the large separable kernel attention, which enables high-precision hierarchical diagnosis of KCI through deep learning. The network first fuses shallow high-resolution features with deep semantic features via the cross-level fusion module. Then, the large separable kernel attention module is embedded in the YOLOv8 network. This network utilizes the combined optimization of depth-separable and point-by-point convolutions to enhance features at multiple scales, thereby dramatically improving the hierarchical characterization of cartilage damage. Finally, five classifications of knee cartilage injuries are performed by classifiers.

Results: To overcome the limitations of network models trained with single-plane images, this study presents the first hospital-based multidimensional magnetic resonance imaging real dataset for KCI, on which the classification accuracy is 99.7%, the Kappa statistic is 99.6%, the *F*-measure is 99.7%, the sensitivity is 99.7%, and the specificity is 99.9%. The experimental results validate the feasibility of the proposed method.

Conclusions: The experimental outcomes confirm that the proposed methodology not only achieves exceptional performance in classifying knee cartilage injuries but also offers substantial improvements over existing techniques. This underscores its potential for clinical deployment in enhancing diagnostic precision and efficiency.

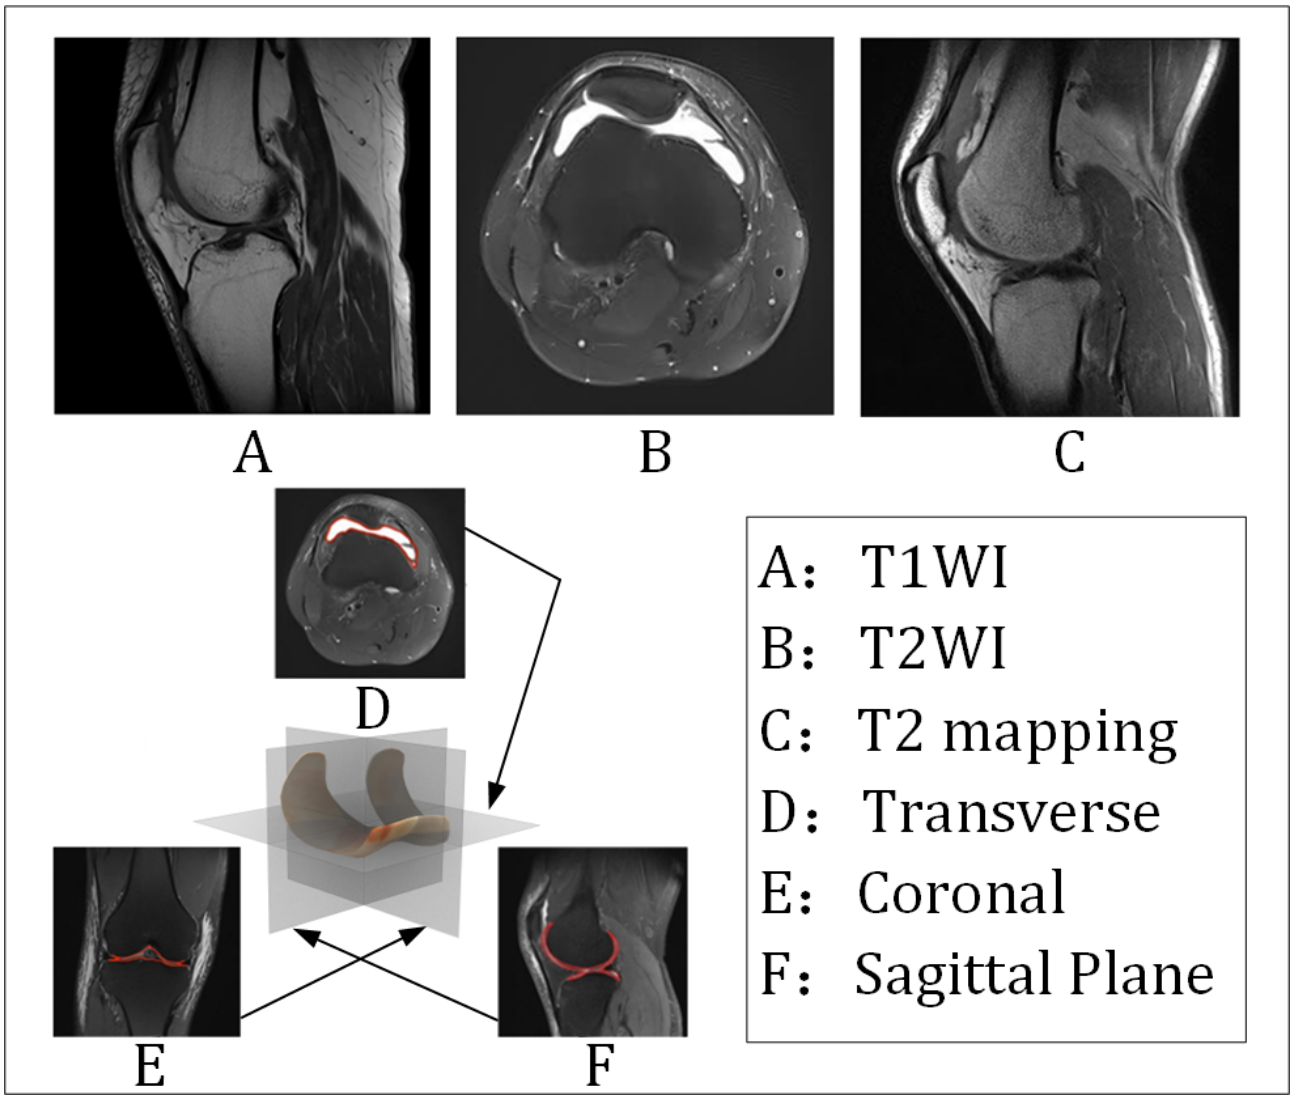
KEYWORDS



knee cartilage injury; multilevel classification; large separable kernel attention; multidimensional feature; cross-level fusion

Introduction

Knee cartilage injury (KCI) is recognized as a prevalent joint disease, with significant challenges posed to diagnosis and treatment by its high incidence and irreversibility [1]. The self-repair capacity of KCI is severely restricted due to the absence of vascularization and innervation. Consequently, the implementation of early and accurate diagnostic strategies has been established as critical for decelerating disease progression [2]. Currently, magnetic resonance imaging (MRI) is the preferred imaging tool for evaluating KCI due to its excellent soft tissue contrast. Clinically, MRI usually uses three orthogonal planes in the sagittal, coronal, and transverse planes for multiangle imaging. The sagittal plane displays the anatomical structures of the patellofemoral joint contact surface, the femoral trochanter groove, and the anterior and posterior corners of the meniscus. This is particularly beneficial for detecting early wear and tear and delamination injuries of the patellar and femoral trochanter cartilage [3]. The coronal plane facilitates observation of the integrity of the medial and lateral tibiofemoral joint surfaces and can visualize changes in cartilage thickness in weight-bearing areas of the tibial plateau and femoral condyles. It can also help identify the correlation between cartilage injury and adjacent bone marrow edema, while the transverse plane can accurately identify focal chondromalacia or fissures in the medial malleolar surface of the patella. Combined with multiplanar imaging, T1-weighted imaging (T1WI) [4], T2-weighted imaging (T2WI) [5], and T2 mapping [6] sequences can reflect KCI from multiple aspects, including structure, water content, and biochemical composition, as shown in Figure 1.

XSL•FO
RenderX

Figure 1. Multisequence and multiplane images of KCI in the retrospective study based on the clinical dataset provided by the Second Affiliated Hospital of Dalian Medical University, China. Multimodal KCI MRI images demonstrate T1WI, T2WI, and T2 mapping sequences across sagittal, coronal, and transverse planes. KCI: Knee cartilage injury; MRI: magnetic resonance imaging; T1WI: T1-weighted imaging; T2WI: T2-weighted imaging.

According to the International Cartilage Repair Society grading criteria [7], KCI is categorized into grades 0 to IV. Grade 0 indicates normal cartilage; Grade I shows surface softening and slight roughness of the cartilage; Grade II involves focal defects with a depth of less than 50% of the cartilage thickness; Grade III has a depth greater than 50% but not reaching the full thickness of the cartilage; and Grade IV represents the end-stage lesion with complete cartilage loss (Multimedia Appendix 1).

The clinical diagnosis of KCI has long depended on the subjective judgment of doctors on MRI images, which has problems such as low efficiency and lack of consistency [8]. With the development of computer vision technology, machine learning-based auxiliary diagnosis methods have gradually become a research hotspot [9].

However, the local receptive field of the fixed convolution kernel limits the capture of global context information. Lightweight models such as SqueezeNet [10] and MobileNet [11] reduce computational complexity through channel pruning and depth separable convolutions; however, they perform poorly when dealing with multisite and multistage cartilage damage. As the KCI area spreads or changes in thickness across multiple sites as the disease progresses, the aforementioned lightweight network models cannot provide optimal classification results. Current studies show that convolutional neural network (CNN) architectures still have insufficient feature representation ability for KCI classification tasks.

Recently, deep learning has made remarkable progress in the field of medical image analysis by virtue of its powerful feature learning ability. Traditional convolutional neural network architectures, such as AlexNet [12], ResNet [13], and GoogLeNet [14], enhance feature representation by increasing the network depth. However, the local receptive field of the fixed convolution kernel limits the capture of global context information. Lightweight models like SqueezeNet and MobileNet reduce computational complexity through channel pruning and depth separable convolutions, but they perform poorly when dealing with multisite and multistage cartilage damage. As the KCI area spreads or changes in thickness across multiple sites as the disease progresses, the aforementioned lightweight network models cannot provide optimal

XSL•FO
RenderX

classification results. Current studies show that CNN architectures still have insufficient feature representation ability for KCI classification tasks.

To address the above limitations, researchers have proposed various improvement schemes. The multilayer convolutional sparse coding framework developed by Abdul et al [15] achieves hierarchical classification of ligament injuries through feature map connectivity modeling but still suffers from feature aliasing in complex lesion scenarios. The sample pyramid local binary pattern combined with K-nearest neighbor classifiers proposed by Demir's [16] team optimizes the shallow texture feature representation, but it is difficult to overcome the interference of background redundant information in medical images. Double Attentive Graph Neural Network (DAGNet) adopts a directed acyclic graph architecture to achieve dynamic feature routing, but its higher computational complexity limits its application in small sample scenes [17]. Lei et al [18] employed convolutional neural network models such as DenseNet121, combined with data augmentation techniques, to achieve automatic classification of pressure ulcer stages. SgmaFuse [19] addresses interpretable breast cancer diagnosis in ultrasound imaging by integrating a spatially guided multilevel alignment mechanism and histological semantic activation vectors to bridge imaging features with pathological patterns. Dai et al [20] proposed a model enabling enhancement of breast cancer detection in mammographic images of dense tissue via a dynamic feature weighting Mamba module and edge-enhanced networks, reinforced by adversarial defense strategies for robustness. Rezk et al [21] developed a classification model that integrates image segmentation, skin tone clustering analysis, and style transfer, effectively enhancing the generalization capability of early skin cancer detection across all skin tones. Dual-stream parallel model based on local centroid optimization (LC-DSPNet) improves feature extraction capability through a localized center-of-mass optimization algorithm and a dual-stream parallel architecture, but it leads to partial loss of key lesion information, which affects the classification accuracy of complex knee cartilage injuries [22]. The improved AlexNet (R-AlexNet) combines the dragonfly optimization algorithm with the regional similarity transformation and achieves the current optimal performance in the task of KCI classification through multimodal feature fusion, but the limitation of its uniplanar dataset influences the model's generalization ability [23]. The YOLO (You Only Look Once) series of algorithms is currently widely recognized in the field of computer vision for its efficient detection speed and excellent accuracy [24]. With the iterative optimization of the algorithms, the YOLO series has been extended from the target detection task to multiple vision task areas such as image classification and instance segmentation [25]. YOLOv8 significantly improves the model training efficiency and detection accuracy by introducing an adaptive learning rate adjustment mechanism and dynamic anchor frame generation technology [26]. Therefore, the YOLOv8 classification model is used as the baseline model in this paper to reduce the calculation complexity while maintaining the high precision classification ability and providing an effective means for the five-level classification of KCI.

Due to the low contrast and small target characteristics of MRI images of knee cartilage injuries, as well as background interference from bones and muscles, the traditional convolution module suffers from the defects of a large number of parameters and limited gradient flow, which make it difficult to effectively capture the fine lesion features, as well as the limitations of a single-plane dataset. For this reason, this paper proposes a multidimensional feature cross-level fusion (MDF-CLF) classification network driven by the large separable kernel attention (LSKA) for KCI, which reduces the computational complexity while maintaining the high-precision classification ability and provides a new solution for the five-level classification of KCI.

In summary, deep learning has shown significant potential in the field of medical image analysis [27], particularly in the automatic classification of knee cartilage, ligament, and meniscus injuries. However, current methods still face several key challenges: (1) single-plane MRI images struggle to fully capture the multidimensional features of KCI; (2) CNNs often lose the deep semantic information of small lesions during feature extraction; (3) the adaptability of multiscale feature fusion strategies is insufficient, limiting the accuracy of grading [28].

To address the above challenges, this paper proposes an MDF-CLF classification network driven by the LSKA. The purposes of this paper are as follows:

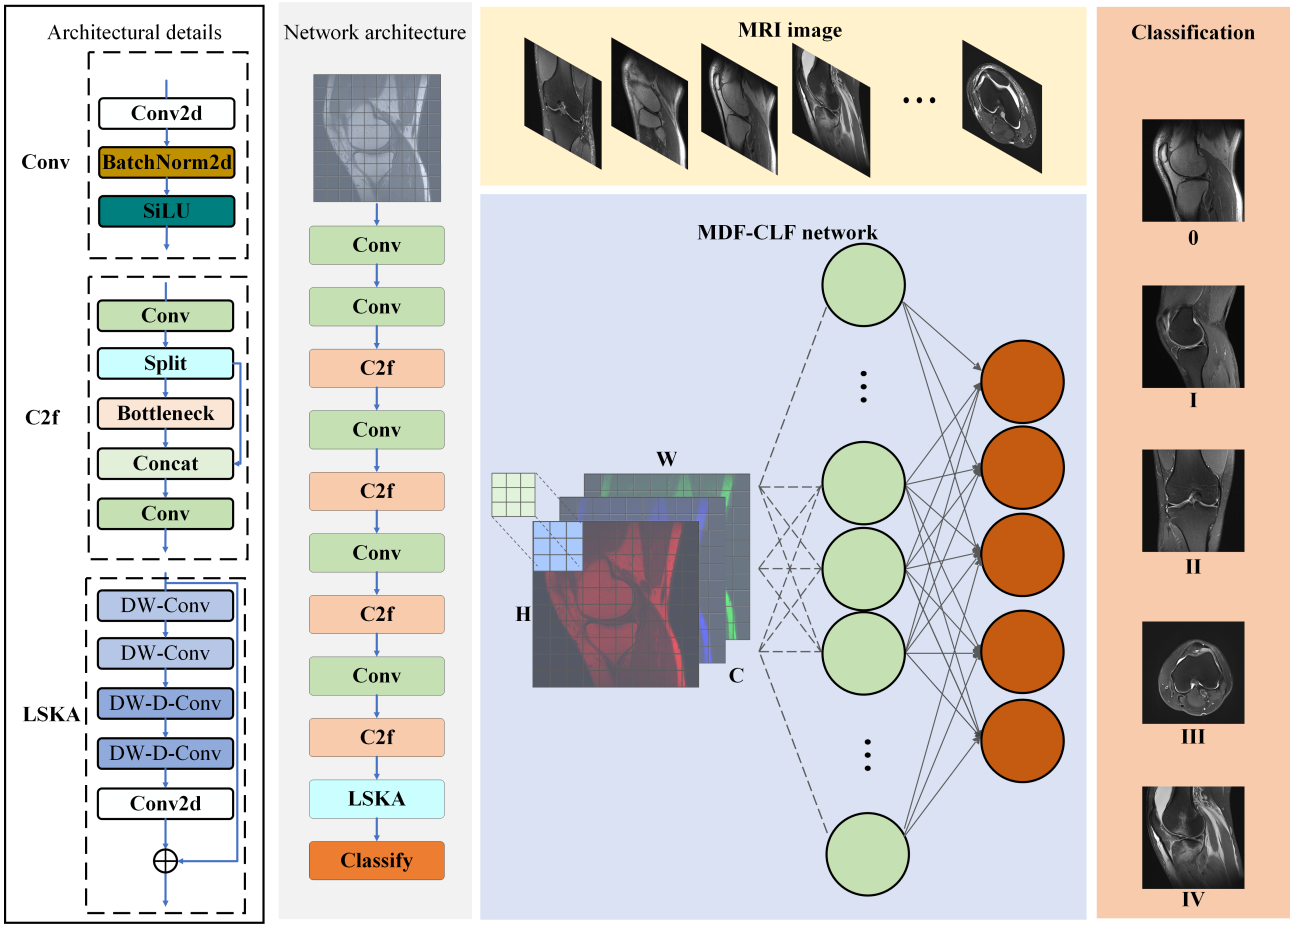
1. The first multidimensional KCI hospital real MRI data set is constructed: This study collaborated with the Second Affiliated Hospital of Dalian Medical University to collect a standard three-plane (sagittal, coronal, and transverse) knee MRI imaging. The T1WI, T2WI, and T2-mapping multiparameter sequences are integrated to create the first multidimensional imaging data set for KCI assessment, addressing the limitations of traditional single-plane medical imaging features.

2. An MDF-CLF network driven by LSKA has been constructed: The LSKA module is embedded into the YOLOv8 network, which integrates spatial feature extraction through deep separable convolution and channel information integration via point-bypoint convolution. This approach enhances multiscale features of KCI areas, effectively improving the feature representation capability for multilevel KCI.

The structure of this paper is organized as follows: Section 2 summarizes the related work; Section 3 introduces the network model proposed in this paper. Section 4 describes the image dataset, model training parameters, and experimental environment and analyzes the experimental results. Finally, Section 5 presents the conclusions and future directions of the algorithm.

Methods

Network Model Architecture



To address the limitations of traditional methods in knee cartilage damage classification, such as insufficient computational efficiency and limited ability to recognize subtle features, this paper proposes an MDF-CLF classification

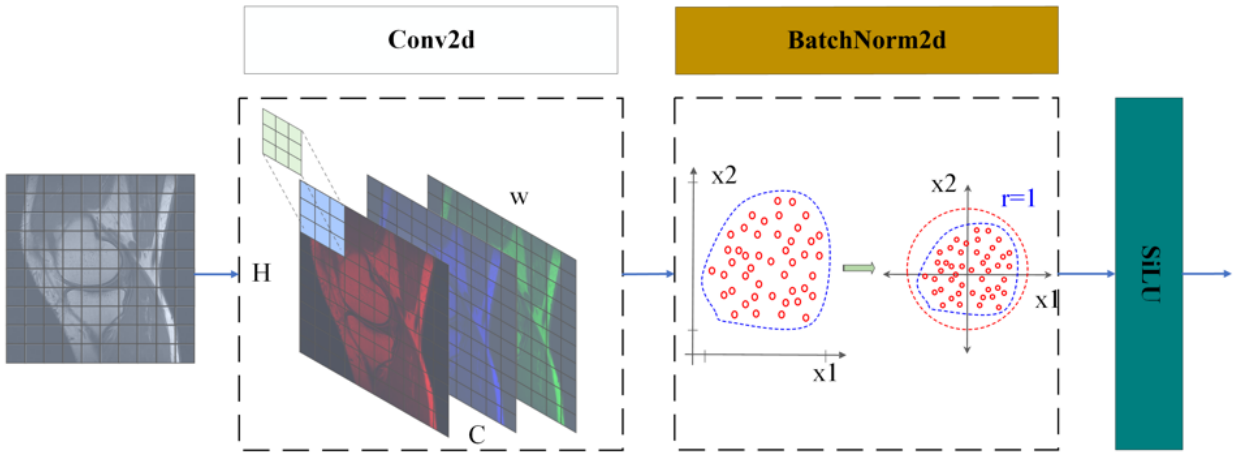
XSL•FO
RenderX

network algorithm driven by LSKA for KCI. The modules in the model proposed in this paper are described as follows.

The algorithm introduces the LSKA module [29] into the backbone of the YOLOv8 framework. It constructs a feature extraction system composed of the Conv module [30], the C2f (Cross-Stage Partial-Connection with 2 convolutions) module [31], and the LSKA module and combines with the head network to realize attention focusing and multiscale feature fusion of the KCI region in MRI images. As shown in Figure 2, the network first inputs multidimensional MRI images of KCI into the feature extraction module. Here, the basic convolutional module uses the three-layer structure of the convolutional layer–batch normalization layer–SiLU (Sigmoid Weighted Linear Unit) activation function for primary feature extraction. It then realizes multilevel feature interaction and attention enhancement through the C2f module and the LSKA module. Finally, it completes the classification of the head network, which in turn effectively improves the accuracy and robustness of the classification of KCI.

Figure 2. Flowchart of the proposed algorithm. Flowchart of the large separable kernel attention (LSKA)–driven multidimensional feature cross-level fusion (MDF-CLF) classification network, integrating LSKA, Cross-Stage Partial-Connection with 2 convolutions (C2f), and Conv modules within a YOLOv8-based framework, for 5-level knee cartilage injury classification using three-plane multimodal magnetic resonance imaging (MRI) images from a retrospective clinical cohort at the Second Affiliated Hospital of Dalian Medical University.

Conv Module



The Conv module is the basic and key component of this model, which consists of the convolution layer, batch normalization layer, and SiLU, as shown in Figure 3. The network model sets the input image as $I \in R^{H\times W\times C}$, where H is the image height, W is the width, C is the number of channels, and the input image size is 640×640×3. The formula for convolution (Conv2d) can be expressed as:

(1)Yi,jp=∑c=0C−1∑m=0N−1∑n=0N−1Ii+m,j+n,cK1m,n,cp+b1p

where i and j are the positions of each pixel point in the feature map, N is the size of the convolution kernel, m and n are both indexes varying in the range of [0, N−1] used to traverse each value in the convolution kernel, and p is the index of the output channel (assuming that the number of convolution kernels is k, then 1≤p≤k). Yi,jp represents the feature map output at channel p, position (i, j) after convolution in the first layer, and Ii+m, j+n, c represents the input image I at channel c, the pixel value at position (i+m, j+n), K1 m,n,c,prepresents the convolution kernel of the first layer, and b1p represents the bias term of channel p in the first layer.

XSL•FO
RenderX

Figure 3. Conv module. Composition schematic of the Conv module integrating convolutional layer, batch normalization layer, and SiLU (Sigmoid Weighted Linear Unit) activation function in the LSKA-driven multidimensional feature cross-level fusion network for five-level classification of KCI based on real MRI data from the Second Affiliated Hospital of Dalian Medical University. KCI: knee cartilage injury; LSKA: large separable kernel attention; MRI: magnetic resonance imaging.

To effectively suppress the internal covariate bias phenomenon during deep neural network training, the model introduces a batch normalization layer (BatchNorm2d). This module normalizes the feature maps output from the convolutional layer. It not only accelerates the convergence rate of the model but also enhances the stability of the training process by stabilizing the activation function input distribution.

Specifically, the normalization process of the BatchNorm2d layer takes the channel dimension as the unit of operation and assumes that the small batch sample capacity is *B*. For the *p*th channel, the normalization is performed for each element Yijp in the feature map Yi,jp:

(2)y^ijp=yijp−μpαp2+ε

where the mean μp=1B·Hout·Wout∑b=1B∑i=1Hout∑j=1Woutyijp, ∈ is a very small positive number, and variance αp2=1B·Hout·Wout∑b=1B∑i=1Hout∑j=1Woutyijl(yijp−μp)2. W_{out} is the width of the output feature map and H_{out} is the height of the output feature map.

To recover the expressive ability lost during the normalization process and to make the model more flexible when learning data features, the module is optimized by introducing learnable scaling factors $\gamma^p \in R$ and level-shifting terms $\beta^p \in R$ into the backpropagation process. These terms are calculated as follows:

(3)yijp,BN=γpy^ijp+βp

To achieve a dynamic balance between model training stability and feature characterization capability, the module combines the probabilistic smoothing property of the sigmoid function with the conditional sparse activation advantage of the rectified linear unit function. This is calculated as follows:

(4)SiLU(x)=x·σ(x)=x1+e−x

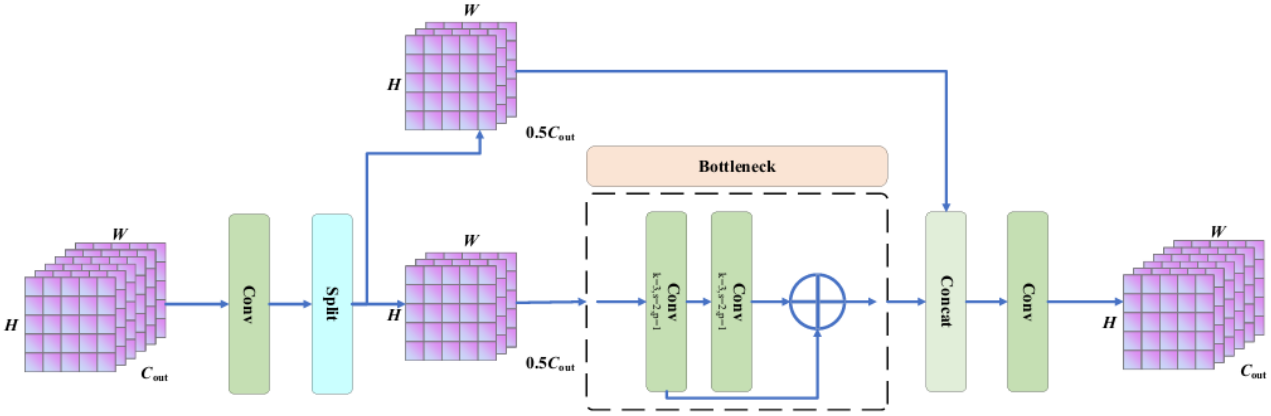
where *x* is the input feature and σ(*x*) is the sigmoid function.

The network architecture proposed in this paper realizes multiscale learning by adopting a hierarchical connection of convolutional modules. This enables the extraction of marginal features of the cartilage and texture features of the subchondral bone edema regions from the shallow network and the extraction of semantic features of KCI categories from the deep network. This allows for the accurate classification of KCI.

C2f Module

To address the contradiction between the attenuation of deep semantic feature information and the small-scale characteristics, this paper introduces a C2f module based on anatomical priors into the proposed network architecture. This module, through a dual-path feature interaction mechanism, provides robust support for the accurate identification of KCI, as shown in Figure 4. The dual-path design of the general-purpose C2f module is strategically adopted here because its inherent operational mechanism aligns effectively with the requirement to capture multiscale features of KCI, ranging from deep structural defects to subtle surface textural changes.

To effectively capture the multiscale damage feature information, it is divided into a semantic enhancement path X_1 and a detail preservation path X_2 by cross-level fusion operation; first, the input feature map is divided into two parts according to the number of channels *C*. The expression of Split is as follows:



(5)(X1,X2)=Split(F,C1,C2)

where $H \times W \times C_{out}$ is the dimension of the input feature map, $C_1 = C_2 = 0.5C_{out}$, and C_{out} is the number of channels in the output. The semantic enhancement X_1 path processes features through Bottleneck units, which are dedicated to capturing the deep semantic information of knee joint deep structural injuries, including subchondral bone cystic lesions, full-thickness cartilage defects, and meniscus-cartilage junction injuries. It enhances the feature representation of such significant structural abnormalities through deep feature extraction, while mitigating gradient vanishing via residual design to improve the model's ability to characterize moderate-to-severe KCI. X_1 path uses the Bottleneck unit for deep extraction of features in the subchondral bone cystic lesion region and mitigates gradient vanishing by

XSL•FO
RenderX

residual design to improve the sensitivity to the cartilage fissure. Concurrently, the detail preservation X_2 path employs a skip connection to circumvent deep processing, thereby preserving high-resolution features essential for early injury identification. This pathway is specifically engineered to capture subtle alterations in the cartilage surface texture at the patellofemoral joint interface, minor abrasions in the meniscal anterior and posterior horns, and superficial cartilage defects within the tibial plateau weight-bearing regions. By mitigating the blurring effects induced by deep downsampling, this architectural choice furnishes critical feature support for precise early-stage KCI detection, enhancing the model's responsiveness to nuanced pathological modifications in these anatomical locales. X_2 path preserves the original feature details and mitigates the blurring of lesion edges caused by deep downsampling. Next, it is output through dual paths, and channel splicing is used to realize multiscale feature fusion.

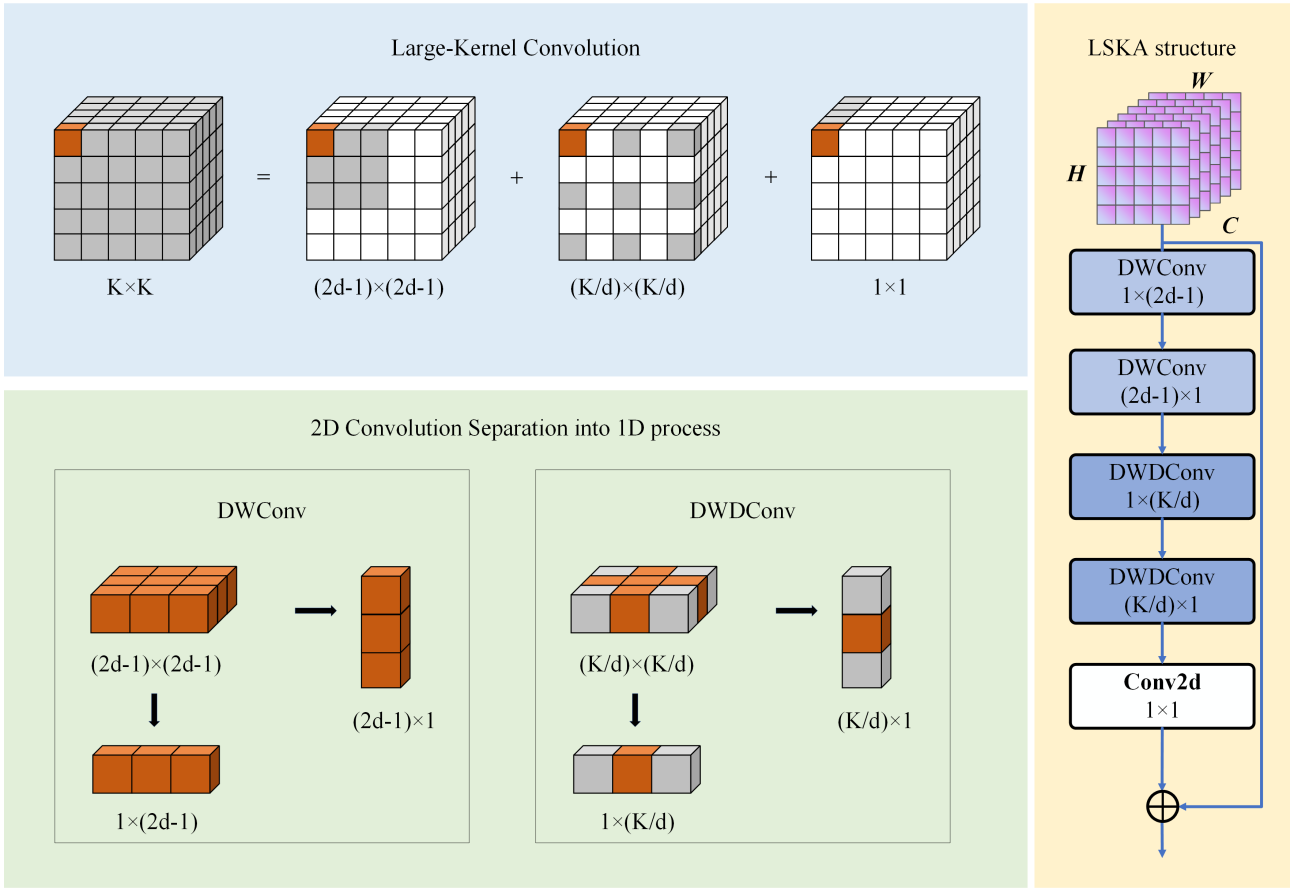
Figure 4. C2f module. Architecture of the C2f module implementing dual-path feature interaction with semantic enhancement path and detail preservation path for multiscale KCI classification in LSKA-driven multidimensional fusion network. C2f: Cross-Stage Partial-Connection with 2 convolutions; KCI: knee cartilage injury; LSKA: large separable kernel attention.

At this time, the number of channels of the feature map becomes $0.5(n+2)C_{out}$ while the height and width remain as $H \times W$, and n=1 is the number of Bottleneck cells. The expression of channel splicing is as follows:

(6)FConcat=Concat(X1out,X2)

where X1out is the output of the X_1 path, and F_{Concat} is the multiscale feature resulting from the splicing of the dual-path channels.

Finally, a 1×1 convolutional layer linearly transforms the number of channels to match the number initially convolved at input time, allowing the subsequent network structure to integrate seamlessly. In the C2f module, anatomical prior knowledge is integrated through a dual-path feature interaction mechanism, which orchestrates channel allocation and feature aggregation. The integration is achieved by leveraging the module's inherent design, whereby the semantic enhancement path is utilized to capture features relevant to advanced, deep lesions, and the detail preservation path is harnessed to retain features essential for early, surface-level abnormalities. The semantic enhancement path extracts deep semantic features of knee cartilage injuries, while the detail preservation path maintains fine-grained features such as cartilage surface textures. Feature fusion is achieved via channel concatenation, enabling effective multiscale integration. Consequently, the C2f module incorporates knee joint anatomical priors through structured feature interaction and dynamic channel adjustment, effectively balancing semantic retention and detailed feature recognition to improve classification accuracy.



LSKA Module

To significantly enhance the cartilage fissure features and effectively improve classification accuracy, this paper introduces an LSKA module into the proposed network architecture. This module improves the sensitivity of long-distance cartilage, ligament, and tissue structures while maintaining computational efficiency through an efficient large kernel decomposition strategy with adaptive feature weighting. The network structure of the LSKA module is shown in Figure 5.

The LSKA decomposes the $k \times k$ convolution into depth convolution (DWConv), dilated depth convolution (DWDConv), and point-by-point convolution (PWConv).

XSL•FO
RenderX

Figure 5. LSKA module structure diagram. Schematic of the LSKA module implementing Large-Kernel decomposition into depthwise convolution, dilated depthwise convolution, and point-by-point convolution for adaptive feature weighting in KCI classification network. KCI: knee cartilage injury; LSKA: large separable kernel attention.

To avoid the exacerbation of parameter redundancy due to the large size of the convolution kernel, DWConv extracts the spatial features independently for each channel and decomposes the traditional 2D depth convolution kernel $k \times k$ into a cascade of the horizontal convolution kernel $(2d - 1) \times 1$ and the vertical convolution kernel $1 \times (2d - 1)$ through the introduction of the dilatation rate d. The intermediate features afterward can be represented as:

$$(7)\bar{Z}C=\sum H,WM1\times(2d-1)C*DW(\sum H,WM(2d-1)\times 1C*DWFC)$$

where *DW denotes the deep convolution operation, M(2d−1)×1C and M1×(2d−1)C are 1D deep convolution kernels in the horizontal and vertical directions, respectively.

To maintain the sensitivity of the long-range structure of cartilage, ligaments, and other tissues, $\bar{Z}c$ processes the intermediate features using dilation depth convolution. This decomposes the traditional 2D convolution kernel into horizontal and vertical 1D convolution kernels 1×[kd] and [kd]×1, respectively, using the dilation rate d. The intermediate feature Z^c after DWConv can be expressed as follows:

$$(8)ZC=\sum H,WM1\times[kd]C*DW(\sum H,WM[kd]\times 1C*DW\bar{Z}C)$$

Besides, to achieve cross-channel information fusion, LSKA uses the 1×1 convolution kernel $M_{1\times 1}$ to highlight the feature channels associated with knee cartilage damage. This kernel performs point-by-point convolution of the intermediate features Z^c, which generates the attention map A^c expression:

$$(9)AC=M1\times 1*PWZC$$

where *PW represents the pointwise convolution operation.

Finally, to enhance the features of the cartilage damage region of the KCI, the adaptive weighted feature map F^c, which is generated by multiplying the attention map and the input feature map F^c element by element via the Hadamard product, can be represented as follows:

$$(10)\bar{F}c=Ac\otimes Fc$$

Where ⊗ means element by element multiplication.

The LSKA module achieves adaptive feature weighting by identifying differences in the importance of cartilage injury-related features in knee joint MRI, dynamically allocating weights based on the contribution of features to injury identification, strengthening the representation of key injury features while suppressing background interference features. This mechanism exhibits significant advantages in distinguishing between mild surface softening and deep lesions; for the former, it can focus on enhancing the feature response of subtle texture changes on the cartilage surface to accurately capture early-stage injuries, while for the latter, it can prioritize strengthening the feature representation of deep cartilage structural abnormalities such as thickness defects and structural disruptions to avoid misjudgment of lesion depth effectively, achieving accurate differentiation between the two types of injuries.

XSL•FO
RenderX

Classify Model

To map the features output by the backbone network to specific KCI categories, the head network module is used in this paper, whose structure consists of a fully connected layer and Softmax activation function.

After the backbone network embedded in the LSKA module processes the data, the feature vector x_c is generated. This vector contains key information, such as soft tissue texture and semantics, from the knee MRI. To transform the high-dimensional features into injury categories, the head network undergoes linear transformation using the fully connected layer. This generates the response values of each injury category using the following mathematical expression:

(11)z=ηxc+b

where η is the weight matrix, *b* is the bias vector, *z* is the output vector of the fully connected layer, and the element η_{ij} in the weight matrix η denotes the extent to which the *j*th input feature contributes to the *i*th KCI output category.

Specifically, after being processed by the backbone network embedded with the LSKA module, a 1D feature vector x_c is generated. This vector encapsulates key information from the knee MRI image, such as cartilage texture and semantic features. To map the high-dimensional features to specific damage categories, the head network utilizes a fully connected layer to perform a linear transformation, producing the response values for each damage category. Upon obtaining the output vector from the fully connected layer, the response value for the *o* knee cartilage damage category, based on the knee cartilage damage MRI image, can be acquired.

Based on the response value for the *o*th knee cartilage damage category from the knee cartilage damage MRI image, the confidence that the predicted knee cartilage damage MRI image belongs to the *o*th knee cartilage damage category is obtained. The formula used is as follows:

(12)y^o=ezo∑o=15ezo

Where $\hat{y}_o$ represents the confidence that the predicted knee cartilage damage MRI image belongs to the *o*th knee cartilage damage category; z_o is the response value for the *o*th knee cartilage damage category based on the knee cartilage damage MRI image; *o* denotes the index of the knee cartilage damage category; and *e* is the base of the natural logarithm. The vector *z* is the output of the fully connected layer, containing the response values for the five knee cartilage damage categories, and z_o is the response value corresponding to one specific category in *z*. The unnormalized class response values output by the fully connected layer cannot be directly used for classification decisions; they need to be transformed into a confidence distribution with probabilistic meaning. To achieve this, the Softmax activation function is applied for normalization.

In the five-class KCI classification task, for the *u*th sample (*u*=1, 2, ..., *U*) in the training set, where *U* is the total number of training samples, the output probability distribution from the LSKA-driven MDF-CLF classification network is denoted as y^u=(y^1u,y^2u…,y^5u)y. The formula for calculating the cross-entropy loss LCEu of a single sample is as follows:

LCEu=−∑o=1Oyoulog (y^ou)

(13)∑o=1Oy^ou=1

LCEu represents the loss value of the *u*th KCI MRI sample; *O* denotes the index of the KCI category; *O* represents the total number of KCI categories. In this study, there are five categories of KCI. you indicates the ground truth label of the *u*th KCI MRI sample, marking the true label value for the *o*th KCI category. y^ou is the predicted probability that the *u*th KCI MRI sample belongs to the *o*th KCI category. In this study, the condition ∑o=15y^ou=1must be satisfied to ensure the rationality and validity of the probability distribution. To prevent individual samples from interfering with the training, the mean loss of all samples in the training set is taken as the optimization objective. That is, the formula for the overall loss value *L* is:

(14)L=1U∑u=1ULCEu=1U∑u=1U(−∑o=1Oyoulog (y^ou))

where *L* represents the overall loss value of the cross-entropy loss function, *u* denotes the index of the KCI MRI sample, and *U* indicates the total number of KCI MRI samples. In this study, through backpropagation, parameters that increase the loss are adjusted along the negative direction of the gradient to mitigate the impact of misclassification, while parameters that decrease the loss are reinforced along the positive direction of the gradient. This process progressively enhances the model's capability to identify low-contrast and small-scale lesion features, thereby achieving accurate classification of the five categories of injuries.

Finally, the parameters that increase the loss are adjusted in the opposite direction of the gradient to reduce the influence of misclassification through backpropagation. The parameters for reducing the loss are strengthened along the positive direction of the gradient, and the recognition ability of the model to low-contrast and small-scale features is gradually improved to realize the accurate classification of five types of damage.

Experimental Environment and Datasets

All the experiments are implemented in PyTorch1.8, with Windows 10 system, Intel(R) Core(TM) with i7-9750H CPU and @ 2.60 GHz processor along with 16.0 GB of RAM, 64-bit Operating System, and NVIDIA GeForce RTX3090.

Besides, this study constructs a dataset based on real hospital data provided by the Second Affiliated Hospital of Dalian Medical University. This dataset comprises multisequence MRI images in three planes, which are sagittal plane, coronal plane, and transverse plane. Specifically, it includes 548 Grade 0 images, 674 Grade I images, 582 Grade II images, 539 Grade III images, and 579 Grade IV images. This dataset comprises 134 patients with KCI and 26 healthy individuals without knee pathology. Following patient-level data partitioning principles, all patients are randomly divided into two groups. Eighty percent of patients' images are included in the training set, while the remaining 20% form a completely independent test set. Examples of images from the dataset are shown in Multimedia Appendix 1. During the acquisition of the multiparameter sequences involved in this study, which are T1WI, T2WI, and

XSL•FO
RenderX

T2-mapping, strict adherence to clinical operating protocols ensures consistent spatiotemporal registration. All sequences are acquired on a 3.0T MRI scanner using identical field of view, matrix, slice thickness, and slice spacing parameters to guarantee spatial pixel correspondence across sequences. Following data acquisition, spatiotemporal registration is validated using anatomical landmarks of the knee joint, which include the anterior and posterior horns of the medial and lateral menisci and the femoral condyles. Additionally, image postprocessing software is employed to match and verify the coordinate points across all sequences, further ensuring consistency in spatiotemporal registration across the multiparameter sequences.

Parameter Setting and Evaluation Index

To ensure the reasonableness of model training and testing, this paper divides the ratio of the dataset into training set and testing set according to 8:2, and the number of training rounds of the model is set to 350 rounds, with an initial learning rate of 0.01. The model with the highest accuracy on the test set is ultimately saved. During the training process, the stochastic gradient descent (SGD) optimizer dynamically adjusts to achieve efficient optimization.

To evaluate the performance of the proposed model, this paper employs several categorical evaluation metrics using accuracy (ACC), sensitivity (SEN), specificity (SPE), *F* measure (*F1*), and Kappa statistic (*K-S*) to assess the model's performance, and these performance metrics are calculated as follows:

(15)ACC=TP+TNTP+TN+FP+FN

(16)SEN=TPTP+FN

(17)SPE=TPTP+FP

(18)F1=2×Sensitivity×SpecificitySensitivity+Specificity

(19)K-S=P0−Pe1−Pe

where $Po = TP + TNTP + TN + FP + FN$, $Pe = (TP+FP)\times(TP+FN) + (FN+TN)\times(FP+TN)(TP+TN+FP+FN)2$. Besides, TP, TN, FP, and FN describe the number of true positives, true negatives, false positives, and false negatives. Here, the closer the values of ACC, SEN, SPE, *F1* , and *K-S* are to 1, the better the model performance. The *K-S* index is used to judge the difference between the degree of agreement of the classifier's classification results and that of random classification.

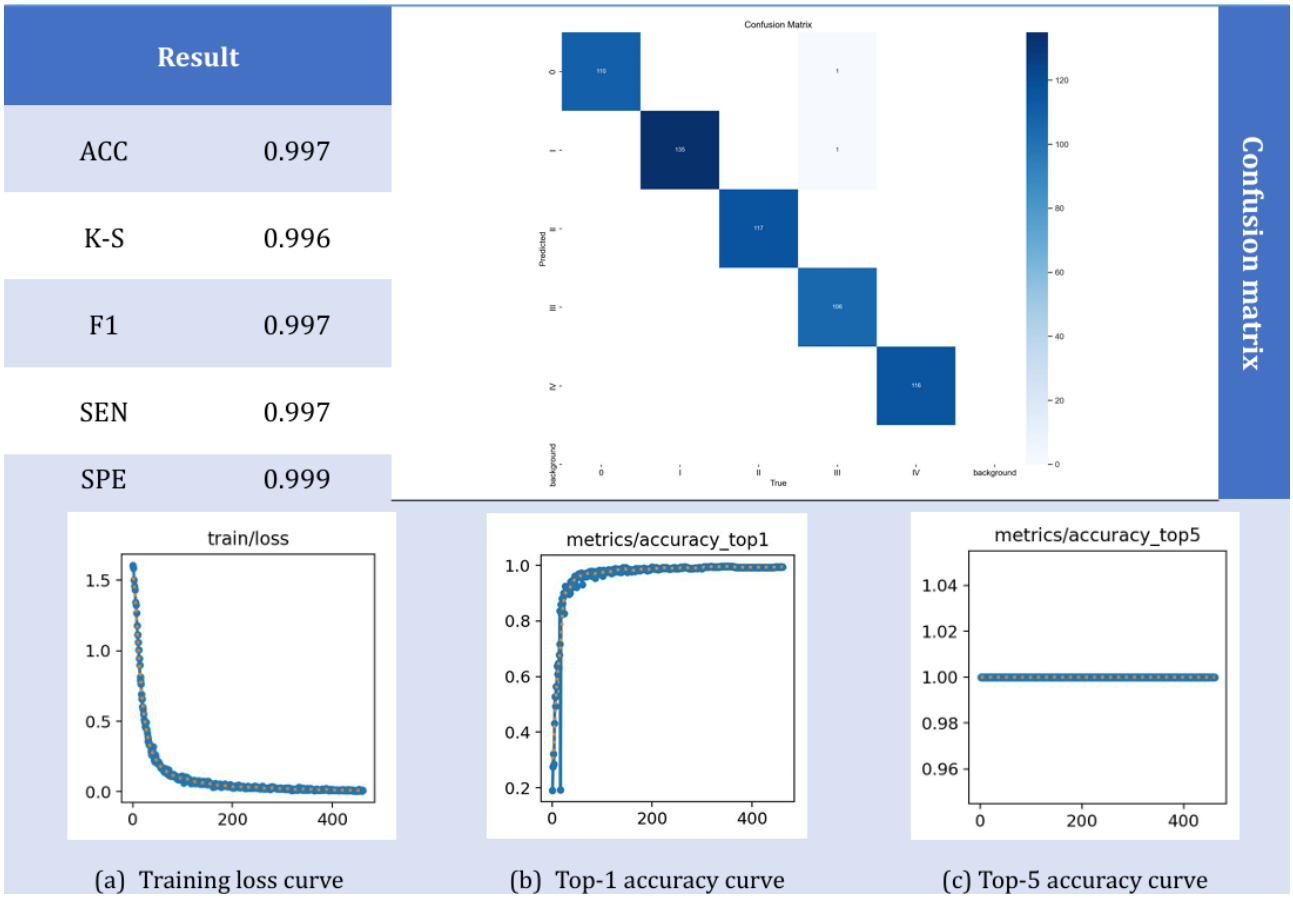
Besides, this paper uses the confusion matrix to evaluate the performance of the classification model. The confusion matrix is a matrix that shows the relationship between the model predictions and the true labels. The rows of the matrix represent the true categories, the columns represent the predicted categories, and the values of the matrix elements indicate the number of samples for which a particular true category is predicted as each predicted category.

Ethical Considerations

This study utilized retrospective and anonymized MRI data. In accordance with Article 32 of the Administrative Regulations on the Ethical Review of Biomedical Research Involving Humans (2023) [32] issued by the National Health Commission of China, ethical review approval is not mandatorily required for research utilizing exclusively deidentified archival data and records, provided that the use of such data does not pose any risk to the human subjects.

All MRI images used in this research are obtained from the Second Affiliated Hospital of Dalian Medical University. Prior to data collection and analysis, all personal identifiers are rigorously removed from the images and associated metadata to ensure complete patient anonymity, thereby mitigating any potential privacy risks. Furthermore, the hospital confirms that informed consent is obtained from all patients at the time of their initial clinical MRI scan. This consent process involved a comprehensive explanation of the nature of the imaging procedure and the potential future use of their deidentified data for research purposes, in line with the hospital's standard operational protocols and in compliance with the Ethical Principles for Medical Research Involving Human Subjects outlined in the Declaration of Helsinki.

The authors hereby declare that the research is conducted in strict adherence to these principles and in compliance with all applicable local, national, and international guidelines and regulations concerning the protection of personal information and human rights, including China's Personal Information Protection Law. The dataset construction and analysis procedures posed no additional physical or psychological risks to the patients involved.



Results

Results and Analysis

The KCI classification algorithm proposed in this paper is tested on the constructed dataset to verify its performance. As shown in Figure 6, the algorithm achieved a classification accuracy of 99.7%, demonstrating its effectiveness. To verify the effectiveness of this algorithm, the following tests are carried out: different data set ratios, different training rounds, and different initial learning rates, as well as comparisons with other algorithms. The detailed data and analysis results are presented in the subsequent experiments.

Performance evaluation of the LSKA-driven multidimensional feature cross-level fusion network for five-grade KCI classification using 3-plane multidimensional KCI MRI dataset from a retrospective clinical cohort at the Second Affiliated Hospital of Dalian Medical University, China: Achieving 99.7% accuracy with comprehensive metrics analysis. ACC: accuracy; F1: *F* measure; K-S: Kappa statistic; SEN: sensitivity; SPE: specificity.

Experiment 1: Analysis of the Proportion Setting of the Dataset

To assess the impact of data partitioning strategy on the model generalization ability, this paper designs multiple sets of ablation experiments in the constructed real hospital dataset and uses 6:4, 7:3, 8:2, and 9:1 partitioning ratios of the training and testing sets for comparative analysis, respectively. As shown in Figure 7, when 8:2 division is used, the model achieves the optimal balanced performance on the independent test set, with a classification accuracy of 99.7% and *F1* of 99.7%, which is significantly better than other ratios.

Figure 7. Experimental results of different proportion data sets. Ablation analysis of dataset partitioning ratios on the generalization performance of the LSKA-driven multidimensional feature cross-level fusion network for 5-grade KCI classification using 3-plane multidimensional KCI MRI dataset from a retrospective clinical cohort at the Second Affiliated Hospital of Dalian Medical University in China with optimal 82 split achieving 99.7% accuracy. Experiment 2: Analysis of the Epoch of Model Training

To observe the performance of the model proposed in this paper under different numbers of training rounds, this paper sets up multiple sets of controlled experiments, which are systematically tested by setting different numbers of training rounds. Under the condition that the ratio of the training set to the validation set is 8:2, the experimental results are shown in Multimedia Appendix 2. The data show that the early stopping mechanism is triggered when the model is trained for 461 rounds. It is worth noting that the accuracy of the network model peaks when the number of training rounds reaches 350. During the training cycle of 1 to 350 epochs, the model's test set accuracy exhibited a steady upward trend, rising from 97.6% at 150 epochs to 99.7% at 350 epochs. When training proceeds to 400 epochs, the accuracy reaches 99.3%, and at 450 epochs, it is 99.5%, with a notable decline in test set accuracy observed. This phenomenon indicates that by 350 epochs, the model had fully learned the general features of the data and did not overfit to local noise in the training set due to overtraining. Meanwhile, the model design and training strategy established a multidimensional system to mitigate overfitting. At the data level, the multimodal T1WI, T2WI, T2 mapping, and multiplanar sagittal, coronal, transverse dataset characteristics effectively reduced the model's dependence on single features, preventing the model from fitting only image noise under a single modality. At the optimizer level, the adopted stochastic gradient descent optimizer enabled dynamic learning rate adjustment, which automatically slowed the parameter update rate in the later training stage and effectively inhibited overfitting caused by aggressive parameter updates that fit local features of the training set. At the model structure level, the C2f module achieved dynamic balance in feature learning depth through dual-path feature interaction, namely the semantic enhancement path and the detail preservation path, further reducing the risk of overfitting.

Experiment 3: Analysis of the Learning Rate for the Model Optimizer

To explore the optimal parameter configuration of the improved algorithm proposed in this paper to achieve the best training effect, this paper adopts the SGD optimizer and systematically carries out comparative experiments under the conditions of different initial learning rates. As shown in Figure 8, the experimental results show that under the premise of using the SGD optimizer, the initial learning rate has a large impact on the model training effect. When the initial learning rate is set to 0.01, the network model shows the optimal performance index in the validation set, which realizes the best training effect under the current experimental conditions and provides a scientific and reasonable basis for setting parameters for subsequent model training.

Figure 8. Experimental results of different learning rates. Analysis of optimizer learning rates in LSKA-driven multidimensional feature cross-level fusion classification network using 3-plane multidimensional KCI MRI dataset from the Second Affiliated Hospital of Dalian Medical University with optimal performance achieved by SGD at initial learning rate 0.01. ACC: accuracy; F1: *F* measure; K-S: Kappa statistic; SEN: sensitivity; SPE: specificity.

[b]DAGNet: Double Attentive Graph Neural Network.

[c]LC-DSPNet: Dual-stream parallel model based on local centroid optimization.

The results show that the algorithm proposed in this paper performs outstandingly in the task of classifying five levels of KCI and outperforms the comparison models in all indicators. Its accuracy rate reaches 0.997, which can correctly determine the injury category, and it is reliable in clinical application and can provide a strong reference for diagnosis. The model features a compact architecture with 1,515,605 parameters. Training efficiency is validated on a single NVIDIA RTX 3090 GPU, where completing 350 epochs takes 5.99 hours, averaging approximately 62 seconds per epoch, demonstrating efficient training capabilities. More critically, the inference speed measured on the same hardware during validation reached 2.5 ms per image, equivalent to a throughput of 400 images per second. These empirical results demonstrate that the model achieves state-of-the-art classification accuracy while maintaining a low computational burden and high inference efficiency, supporting its potential for clinical applications.

Experiment 5: Ablation Analysis of Individual and Combined Imaging Plane Contributions

A comprehensive ablation study is conducted to evaluate the diagnostic value of individual anatomical imaging planes and their combined performance in classifying knee cartilage injuries. The experimental methodology involved a comparative analysis of model performance when trained exclusively on single-plane data in sagittal, coronal, and transverse orientations versus the complete triple-plane combination. The results of our experiments are illustrated in Multimedia Appendix 3. The results demonstrate that the sagittal plane achieved the best single-plane performance with 99.6% accuracy, attributable to its exceptional capability in visualizing critical anatomical structures, such as the patellofemoral joint contact surface and anterior/posterior meniscal horns, which are essential for detecting early-stage cartilage wear and delamination injuries. The coronal plane yielded 99.3% accuracy, effectively capturing tibiofemoral joint integrity and cartilage thickness variations in weight-bearing regions, while the transverse plane achieved 99.1% accuracy, confirming its value in identifying focal chondromalacia and fissures on the medial malleolar surface of the patella. Integration of all three anatomical planes achieved an optimal accuracy of 99.7%, representing a 0.1% improvement over the sagittal-plane-only approach; the multiplane fusion strategy inherently enhances robustness through redundancy. In clinical practice, individual MRI planes may be compromised by artifacts, noise, or acquisition inconsistencies; the fusion strategy mitigates such risks by leveraging complementary information across planes. Additionally, features from the sagittal plane enhance contextual understanding of coronal and transverse data, promoting a more comprehensive feature representation and highlighting the synergistic potential of triple-plane integration.

Discussion

Principal Findings

In response to the growing demand for accurate medical imaging diagnostics, this study focuses on KCI classification by proposing an MDF-CLF network guided by the LSKA mechanism. The network integrates sagittal, coronal, and axial MRI images to construct a 5-class KCI dataset, achieving a final accuracy of 99.7%. The innovative optimization of the YOLOv8 backbone architecture enhances feature extraction capabilities, enabling precise localization of injury regions and identification

XSL•FO
RenderX

of subtle lesion characteristics. The model's performance has been rigorously validated on real-world hospital datasets, demonstrating strong potential for supporting clinical decision-making.

Comparison to Prior Work

Unlike traditional approaches that often rely on single-plane imaging or limited feature integration, our method leverages multimodal MRI data and incorporates an LSKA-based attention mechanism to improve contextual feature capture. While previous studies have utilized deep learning for KCI classification, few have achieved comparable accuracy through multiplane fusion and attention-guided localization. Our model outperforms existing methods in both precision and generalizability, addressing a critical gap in prior work, which often overlooked the integration of cross-plane features and scalable attention mechanisms.

Limitations

This study aims to enhance the classification accuracy of KCI diagnosis by proposing a MDF-CLF classification network driven by LSKA. The method integrates the LSKA module into the YOLOv8 framework, combined with the C2f module and convolutional base modules, achieving multiscale feature enhancement and semantic information extraction from multimodal MRI images. However, although the dataset is derived from real clinical MRI data, all data are acquired from a single medical center using uniform 3.0T MRI scanning equipment and consistent imaging parameters. While this homogeneity ensures internal data consistency, it may constrain the model's generalization capability, potentially leading to performance degradation when applied to heterogeneous data from different centers or equipment. To address this limitation and enhance the model's robustness, future work will employ federated learning techniques to integrate multicenter data. This strategy is expected to significantly improve the model's generalization performance, laying a solid foundation for the broad clinical application of KCI diagnostic models.

Future Directions

Future research will focus on enhancing the algorithm's accuracy and efficiency through lightweight architectural design and cross-domain adaptation, expanding its application to other medical imaging domains such as ocular, pulmonary, and renal diseases, which share analogous challenges in fine-grained classification, and exploring integrated multidisease diagnostic frameworks to broaden the clinical impact and generalizability of the proposed methodology.

Conclusions

This study achieves its initial goal of developing a high-accuracy deep learning model for KCI classification using multimodal MRI fusion and attention mechanisms. The proposed MDF-CLF network not only facilitates precise knee cartilage diagnosis but also provides a transferable framework for other medical imaging classification tasks. By addressing key limitations and outlining clear future directions, this work contributes to advancing automated diagnostic technologies and supports their integration into clinical practice.

Acknowledgments

The author wishes to express sincere gratitude to Vice President Li Yingqiu and Dean Gang Jialin for their invaluable guidance and steadfast support throughout the course of this research. Their expertise and encouragement are instrumental in the completion of this work.

The author is also deeply indebted to Dalian Neusoft University of Information for providing essential institutional backing and resources. Without the university's unwavering support, the successful execution of this study would not have been feasible.

Furthermore, the author gratefully acknowledges the financial assistance provided by the Young Science and Technology Star Project of Dalian, which funded this research.

Abstract

Background: Inflammatory rheumatic diseases (IRDs) affect 5% of the general population, whereas 35% of the population experiences musculoskeletal concerns. IRDs cause early disability, reduced life expectancy, and considerable health care costs. Early diagnosis is essential to prevent long-term damage. Similarly important is the early identification of patients with musculoskeletal concerns without IRDs to prevent unnecessary health care expenses. Of the population referred to the rheumatologist, 60% have noninflammatory musculoskeletal concerns, whereas only 20% of patients with an IRD see a rheumatologist within 3 months of symptom onset. The need for digital predictive (triage) tools for rheumatic and musculoskeletal diseases led to the development of the Frysian Questionnaire for Differentiation of Musculoskeletal Complaints (FRYQ).

Objective: This study aimed to assess whether the FRYQ can distinguish IRD from noninflammatory musculoskeletal concerns in general, and rheumatoid arthritis and fibromyalgia specifically, in newly referred patients.

Methods: The FRYQ is an 87-item tool (20 open-ended and 67 closed-ended questions) used to triage new rheumatology patients at Frisius Medical Center in the Netherlands. We analyzed data from 2 sources: dataset A with 728 outpatient clinic patients and dataset B with 373 patients from the Joint Pain Assessment Scoring Tool study. We built a classifier using Extreme Gradient Boosting to distinguish inflammatory from noninflammatory conditions based on closed-ended questions. Using elastic net regularization, we identified the most informative questions. We evaluated classification using receiver operating characteristic curve analysis and assessed feature importance through Shapley Additive Explanation analysis. To test generalizability, we replicated our analysis on dataset B. Finally, we examined whether the questions of the FRYQ could be used to identify specific conditions beyond the general categories of IRD and non-IRD, specifically for detecting fibromyalgia and rheumatoid arthritis.

Results: Feature selection reduced the questionnaire from 67 to 28 items while maintaining discriminative power. After initial development, the model achieved an area under the receiver operating characteristic curve (AUC-ROC) of 0.72 (95% CI 0.67-0.78) for distinguishing inflammatory from noninflammatory conditions in an external validation set. Using a probability threshold of 0.30, the model achieved 71% sensitivity and 56% specificity on external validation. The FRYQ demonstrated stronger performance in identifying specific diagnoses such as fibromyalgia (AUC-ROC=0.81) and rheumatoid arthritis (AUC-ROC=0.77). Key discriminating features included symptom duration, pain response to movement, and anti-inflammatory medication effectiveness.

Conclusions: The FRYQ effectively distinguishes inflammatory from noninflammatory rheumatic conditions before specialist consultation and shows particular strength in identifying fibromyalgia and rheumatoid arthritis. This tool could improve rheumatology triage by prioritizing referrals with high likelihood of IRD for early rheumatologist evaluation while directing other patients to appropriate alternative resources. Prospective studies are needed to determine the FRYQ's impact on clinical outcomes and health care efficiency.

Introduction

Inflammatory rheumatic diseases (IRDs) affect 5% of the general population in the Netherlands, whereas 35% of the population experience musculoskeletal concerns [1]. Global prevalence of both IRDs and musculoskeletal concerns varies with age and region but is comparable to that in the Netherlands [2]. IRDs can cause early disability, reduced life expectancy, and considerable health care costs.

In the Dutch health care system, as in many European countries, patients with musculoskeletal concerns first consult a general practitioner (GP) before referral to a specialist. To facilitate appropriate and timely care, the Dutch College of General Practitioners (*Nederlands Huisartsen Genootschap*) has developed national guidelines and referral protocols [3], helping ensure that patients receive specialist attention when necessary.

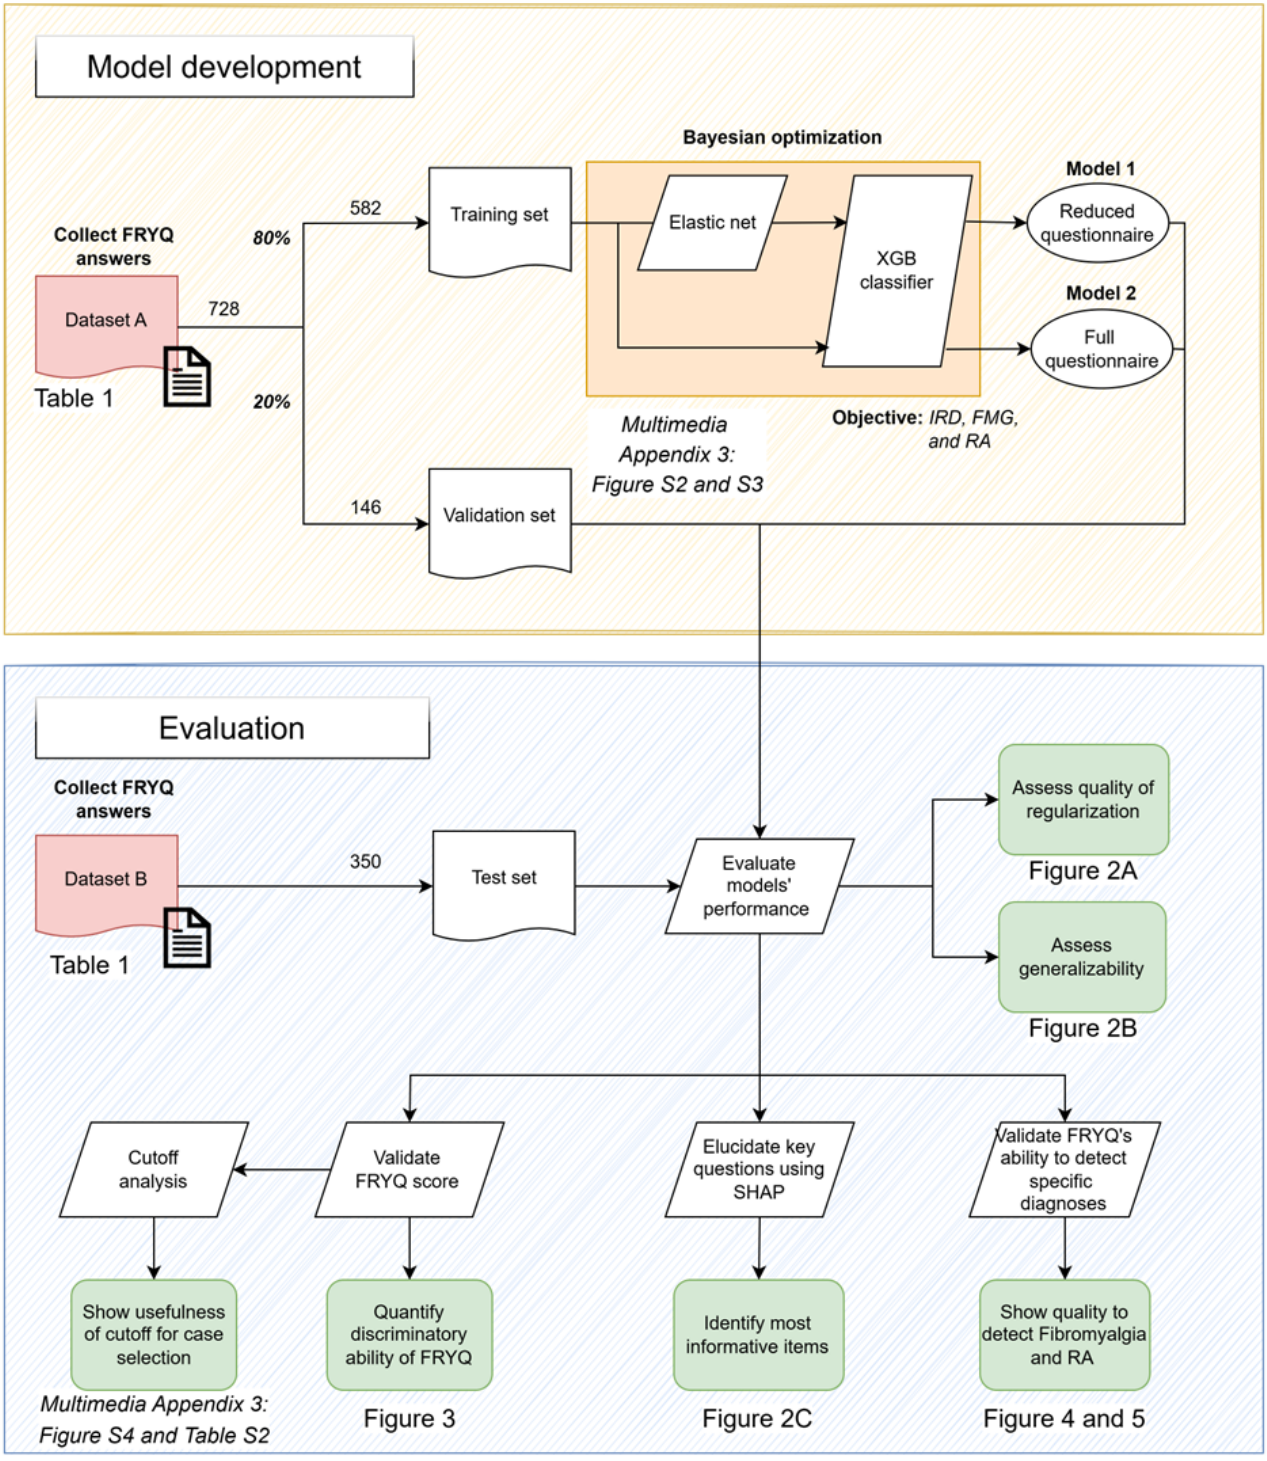
Early diagnosis of rheumatic diseases such as rheumatoid arthritis (RA), ankylosing spondylitis, or psoriatic arthritis by specialists is essential to prevent irreversible damage [4-7]. Similarly important is the early identification of patients with musculoskeletal concerns without IRDs who can be treated in primary care to prevent unnecessary health care expenses. This need is particularly pressing in the Netherlands, which has one of the most expensive health care systems in Europe—ranking third after Austria and Germany [8].

Approximately 109 new patients with musculoskeletal concerns per 1000 people are seen by GPs annually [9]. Of the population referred to a rheumatologist, 60% have noninflammatory musculoskeletal concerns, whereas only 20% of patients with an IRD see a rheumatologist within 3 months of symptom onset [10]. For the target disease, RA, we observe that these patients have to wait—on average—4 weeks from referral to their visit to a rheumatologist [11].

The urgent need for more efficient management of referred patients led to the development of the Frysian Questionnaire for Differentiation of Musculoskeletal Complaints (FRYQ). The FRYQ is an 87-item questionnaire consisting of 20 open-ended and 67 close-ended questions that is used in regular care in the rheumatology outpatient clinic of Frisius Medical Center to triage newly referred patients. It was developed to improve diagnostic speed for referred patients by facilitating early appropriate blood testing.

Our study had three main objectives: (1) evaluate the FRYQ's ability to differentiate IRDs from non-IRDs in newly referred patients using machine learning techniques; (2) identify which questions are most informative for distinguishing inflammatory conditions and develop a streamlined version without losing diagnostic value; and (3) assess whether the FRYQ can be used to identify specific conditions of interest, particularly fibromyalgia and RA, which represent important diagnostic targets in rheumatology practice.

Methods



Study Design and Source of Data

In this study, we conducted a retrospective analysis of newly referred patients to the rheumatology department at Frisius Medical Center, Leeuwarden, the Netherlands (the pipeline is shown in Figure 1). We developed and validated machine learning prediction models to assess the FRYQ's ability to differentiate inflammatory from noninflammatory rheumatic conditions using only preconsultation patient responses. Multimedia Appendix 1 provides the Dutch version of the questionnaire, and Multimedia Appendix 2 provides the translated version in English.

We used two independent cohorts: (1) a development dataset (dataset A), which comprised 728 adult patients who completed the FRYQ between August 2017 and June 2019 as part of routine care, and (2) an external validation dataset (dataset B), which comprised 373 adult patients from the Joint Pain Assessment Scoring Tool (JPAST) study cohort [12] visiting the clinic between January 2023 and March 2024 who completed the FRYQ as an additional research instrument.

Figure 1. Study workflow consisting of two phases: (1) model development, where we built a classifier to detect inflammatory rheumatic diseases (IRDs), fibromyalgia, and rheumatoid arthritis (RA) using only Frysian Questionnaire for Differentiation of Musculoskeletal Complaints (FRYQ) responses+sex based on the data from the first pilot (n=728), and (2) model evaluation, where we deployed the model on unseen data from a different study (n=350) to assess generalizability. FMG: fibromyalgia; SHAP: Shapley Additive Explanations; XGB: Extreme Gradient Boosting.

Ethical Considerations

The FRYQ was developed by the rheumatology clinic at the Frisius Medical Center to assist in prioritizing newly referred patients. The data in dataset A were gathered as part of standard clinical care. Informed consent for the use of anonymized data in research was secured through the opt-out procedure, whereby all patient data were eligible for inclusion unless an individual filed a formal objection. According to Article 1(b) of the Dutch Medical Research Involving Human Subjects Act (Wet medisch-wetenschappelijk onderzoek met mensen [WMO]), ethical review is required only for studies that aim to obtain medical-scientific knowledge and in which participants are subjected to an intervention or are required to follow a behavioral regime [13]. As the FRYQ questionnaire was administered as part of routine care and did not involve any intervention or imposed behavior, the study does not fall under

XSL•FO
RenderX

the scope of the WMO and therefore did not require approval by a medical ethics review committee.

In contrast, dataset B consisted of patients enrolled in the JPAST study, which involved time-consuming study procedures. Therefore, the use of the FRYQ in this dataset was reviewed and approved by the medical ethics committee of the Frisius Medical Center (reference number RTPO-1104) as part of the JPAST study protocol. Since participation in the JPAST study involved procedures beyond standard care, each participant provided written informed consent authorizing the use of their data for research.

For both datasets, patient data security was ensured by assigning each patient a unique sequential identifier through pseudonymization. Data were stored and analyzed in a secure, password-protected database accessible only to authorized personnel. Participants retained the right to opt out of the use of their data for research purposes and did not receive financial compensation for their involvement in this study. All study procedures were conducted in accordance with the principles of the Declaration of Helsinki.

Participants

Eligibility Criteria

All adult patients newly referred to the rheumatology outpatient clinic who completed the FRYQ were eligible. From dataset A, 854 patients were initially invited, with 728 (85.2%) having complete data for analysis. From dataset B, all patients with complete FRYQ responses and diagnosis data were included.

Study Setting

Data collection took place in a nonacademic hospital setting (Frisius Medical Center) during routine clinical care for dataset A and as part of the international JPAST validation study for dataset B.

Outcome

Primary Outcome

The primary outcome was the presence of an IRD versus a noninflammatory musculoskeletal condition (non-IRD) as diagnosed by a rheumatologist after clinical evaluation. This determination represented the clinical ground truth against which the model predictions were evaluated. The outcome was assessed by extracting the final diagnosis from electronic health records.

Secondary Outcomes

Specific diagnoses of fibromyalgia and RA were evaluated as secondary outcomes in additional predictive models.

Predictors (Input Variables)

The primary input variables consisted of responses to the 67 closed-ended questions from the FRYQ supplemented by patient age and sex. The FRYQ is an 87-item tool (including 20 open-ended questions not used in this analysis) designed by rheumatologists for triaging rheumatology patients. Question topics covered pain characteristics and patterns, stiffness symptoms and duration, functional limitations, associated symptoms, comorbid conditions, medication responses, and patient behaviors and characteristics. No laboratory test results or imaging data were included as predictors in the model.

Missing Data

Patients with incomplete demographic and questionnaire data were removed from dataset A (127/862, 14.7%) and dataset B (166/552, 30.1%; Figure S1 in Multimedia Appendix 3). Furthermore, we had some patients with inconsistent diagnostic labels removed from dataset A (7/862, 0.8%) and a few with missing diagnosis information removed from dataset B (36/552, 6.5%).

Model Development

Data Preprocessing

No significant preprocessing was required as the questionnaire items were already structured. Patient sex was included as a binary variable, and patient age was included as a continuous variable.

Feature Selection

We used elastic net regularization to identify the most informative subset of questions from the original 67 closed-ended items. The regularization parameters (alpha and L1 ratio) were optimized using Bayesian methods with a tree-structured Parzen estimator across 1000 iterations [14]. This approach allowed us to reduce dimensionality while retaining predictive power.

Model Specification

We used the Extreme Gradient Boosting technique [15] to build a model for IRD prediction using only the questions selected by the elastic net. Extreme Gradient Boosting was chosen for its ability to capture complex relationships between variables and its robust performance in previous prediction tasks [16]. All machine learning analyses were performed in Python (version 3.6.13; Python Software Foundation).

Model Training

The model was trained on 80% of dataset A. We used Bayesian optimization across 1000 iterations to tune model hyperparameters, optimizing for root mean square logarithmic error to emphasize sensitivity to inflammatory conditions.

Model Performance

Measures of Model Performance

We evaluated model discrimination using the area under the receiver operating characteristic curve (AUC-ROC). Calibration was assessed using calibration plots comparing predicted probabilities with observed outcome frequencies.

Validation

The model was first validated on the reserved 20% of dataset A (internal validation) and then on dataset B (external validation) to assess generalizability. Both the reduced model (with selected features) and the full model (with all 67 questions) were evaluated to assess the impact of feature selection.

XSL•FO
RenderX

Clinical Utility

We conducted threshold analysis to identify an optimal probability cutoff for distinguishing IRD from non-IRD cases in clinical practice, evaluating sensitivity, specificity, positive predictive value, and negative predictive value at various thresholds.

Model Interpretation

To understand feature importance and explain model predictions, we conducted Shapley additive explanation (SHAP) analysis [17]. This approach quantified the contribution of each question to the model output, allowing us to identify which questions were most informative for detecting inflammatory conditions.

Results

Overview

Dataset A comprised 728 patients, of whom 239 (32.8%) were male and 489 (67.2%) were female (Table 1). Nearly half (257/582, 44.2%) of the patients in the training dataset had IRDs. The most common disorders associated with IRD were RA (62/582, 10.7%), gout (45/582, 7.7%), and spondyloarthritis (43/582, 7.4%). Among noninflammatory arthropathies, the most frequent were osteoarthritis (119/582, 20.4%), tendinopathy (92/582, 15.8%), and fibromyalgia (91/582, 15.6%).

The external test dataset B included 350 patients with complete information, comprising 106 (30.3%) male and 244 (69.7%) female individuals. Only 26.6% (93/350) of the patients were diagnosed with an IRD, which was notably lower than those in the training and validation partitions of dataset A (257/582, 44.2% and 67/146, 45.9%, respectively). In contrast, the JPAST data contained a higher proportion of patients with an “other” diagnosis, indicating that this dataset represented a somewhat different patient population.

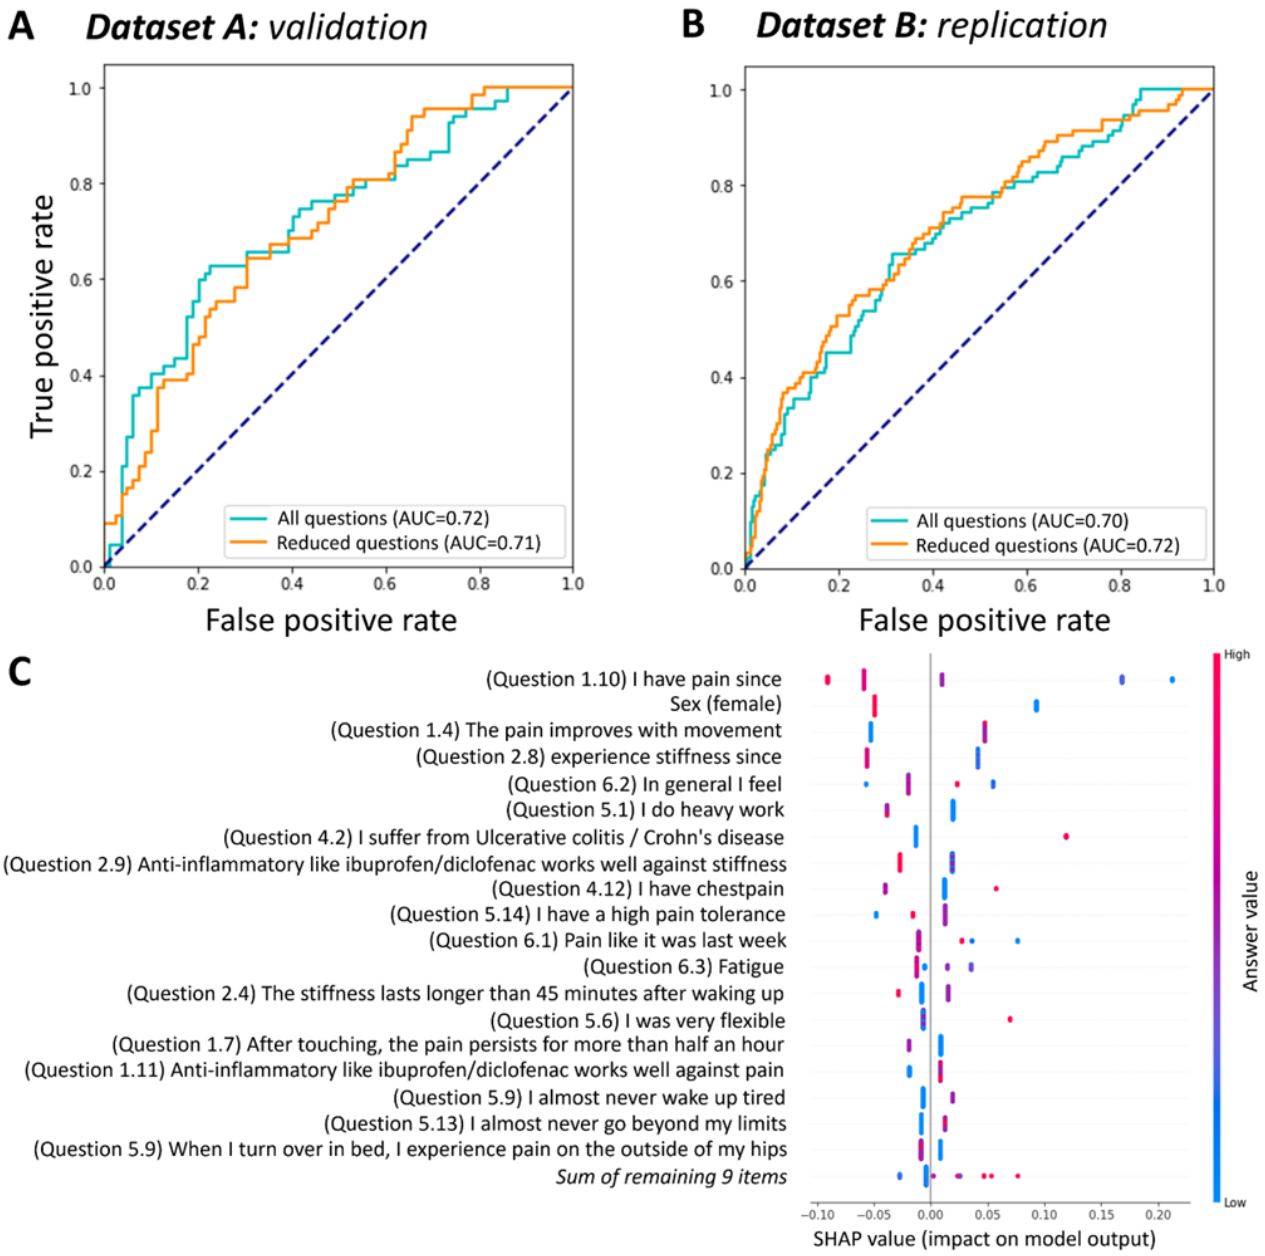
[a]IRD: inflammatory rheumatic disease.

[b]CPPD: calcium pyrophosphate crystal deposition disease.

[c]RMD: rheumatic and musculoskeletal disease.

[d]ANCA: antineutrophil cytoplasmic antibody.

Prediction of IRD



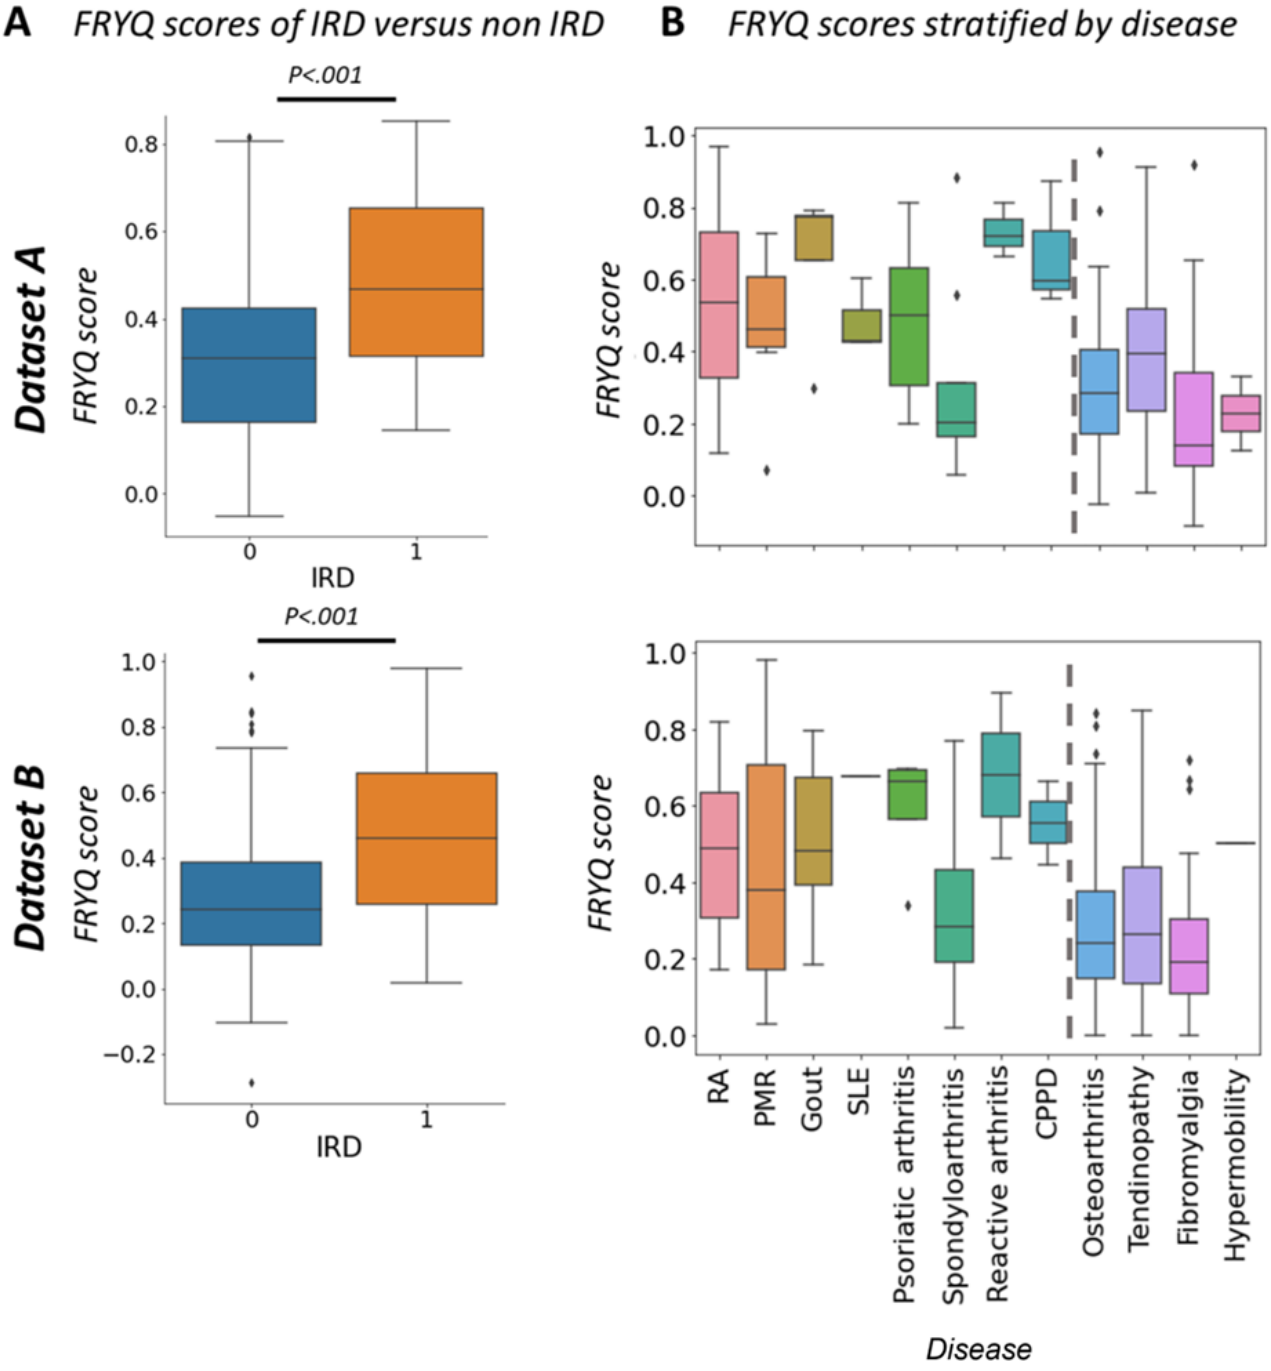
After hyperparameter optimization (α=.07; L1-ratio=0.16; Figures S2 and S3 in Multimedia Appendix 3) and feature selection, our model reduced the 67 closed-ended questions to 28 key items (Table S1 in Multimedia Appendix 3). This streamlined model effectively distinguished IRD from non-IRD across multiple validation steps.

In the development dataset A, the reduced model achieved an AUC-ROC of 0.70 (95% CI 0.67-0.74) in the training set and 0.71 (95% CI 0.64-0.78) in the hold-out validation set, performing comparably to the full model (AUC-ROC of 0.67, 95% CI 0.63-0.72 and 0.72, 95% CI 0.64-0.78, respectively; Figure 2A).

Importantly, when tested in the independent dataset B, the model demonstrated robust generalizability, with an AUC-ROC of 0.72 (95% CI 0.67-0.78) for the reduced model and 0.68 (95% CI 0.63-0.75) for the full model (Figure 2B), confirming the model's stability across different patient populations.

XSL•FO
RenderX

Figure 2. Performance of the inflammatory rheumatic disease classifier: (A) receiver operating characteristic (ROC) curves showing performance before and after regularization in the validation set, (B) ROC curves showing performance before and after regularization in the replication set, and (C) Shapley Additive Explanation (SHAP) analysis results highlighting the impact and direction of the most important features contributing to the classifier's predictions. AUC: area under the curve.



The FRYQ score (model-predicted probability) consistently distinguished IRD patients from non-IRD patients across both datasets (P<.001; Figure 3). In the development set A, the median FRYQ score was 0.47 (IQR 0.31-0.65) for patients with IRD, versus 0.30 (IQR 0.16-0.42) for patients without IRD. Similarly, in replication set B, the median score was 0.46 (IQR 0.26-0.66) for patients with IRD, compared to 0.24 (IQR 0.13-0.39) for patients without IRD. When examining specific conditions, most IRDs exhibited higher scores than non-IRDs, with 2 notable exceptions: spondyloarthritis consistently scored lower among IRDs, whereas tendinopathy scored relatively high (>0.35) among non-IRDs, suggesting areas where diagnostic discrimination was more challenging. Fibromyalgia consistently showed very low scores (<0.2), making it a promising target for specialized detection.

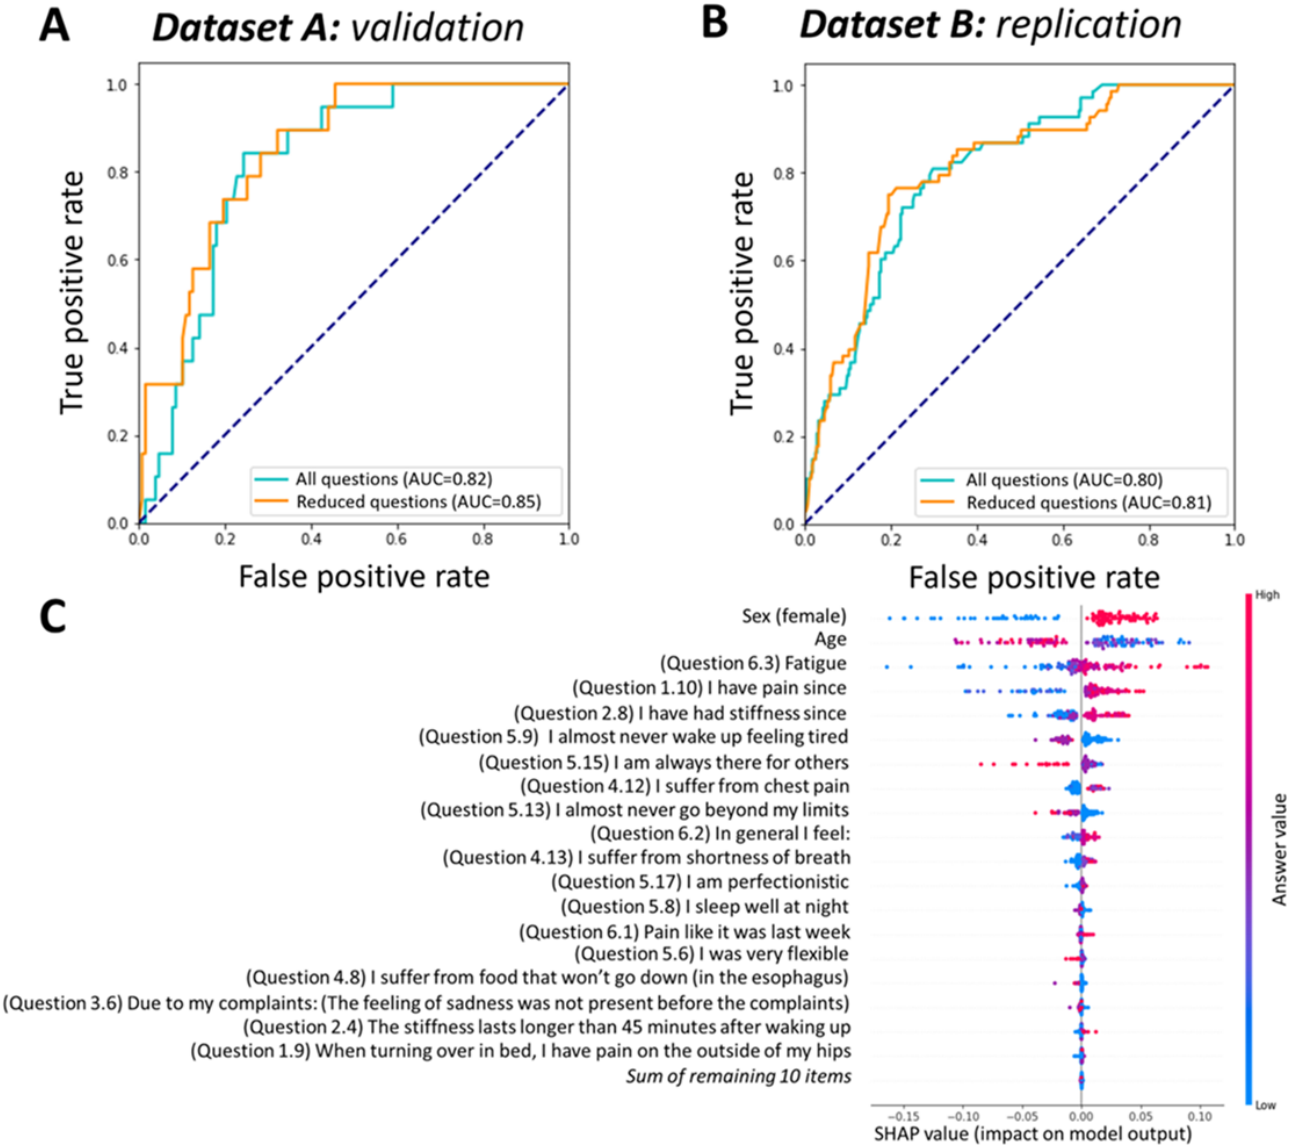
The key features for identifying an IRD in the newly referred population (Figure 2C) were questions related to duration of concerns (questions 1.10 and 2.8), male sex, and decrease of pain upon movement (question 1.4). Moreover, the presence of certain comorbidities influenced the model's assessment. Ulcerative colitis and Crohn disease (question 4.2) showed a positive association with IRDs, whereas chest pain (question 4.12) showed a negative association. Additionally, respondents diagnosed with an IRD more frequently reported that nonsteroidal anti‐inflammatory drugs such as ibuprofen and diclofenac were effective in managing their symptoms (questions 2.9 and 1.11).

XSL•FO
RenderX

Figure 3. Overview of Frysian Questionnaire for Differentiation of Musculoskeletal Complaints (FRYQ) score distributions (A) between inflammatory rheumatic disease (IRD) and non-IRD and (B) more specifically by disease, with IRDs on the left of the dashed line and non-IRDs on the right. The comparison between IRDs and non-IRDs was conducted using a 2-tailed Student *t* test. CPPD: calcium pyrophosphate crystal deposition disease (pseudogout); PMR: polymyalgia rheumatica; RA: rheumatoid arthritis; SLE: systemic lupus erythematosus. **P*<.05; ***P*<.01; ****P*<.001.

Next, we defined the optimal clinical threshold for case selection. On the basis of the training data, we set the cutoff at 0.30 (Figure S4 in Multimedia Appendix 3) as it captured more than three-fourths of IRD cases (sensitivity=0.76) while ensuring that half of the cases without IRDs were excluded (specificity=0.49). This threshold showed similar sensitivity (0.71) and specificity (0.56) in the external validation dataset. The positive predictive value was lower in the external validation dataset (0.39 vs 0.56 in dataset A), attributable to the lower IRD prevalence (93/350, 26.6% vs 257/582, 44.2%; Table S4 in Multimedia Appendix 3).

The calibration curve indicated that the model slightly overestimated IRD probability in the external test dataset (Figure S5 in Multimedia Appendix 3), reflecting the difference in disease prevalence between the training and validation populations. Despite this, the discriminatory ability remained strong, with IRDs consistently receiving higher scores than non-IRDs across both datasets, reinforcing the FRYQ's potential value as a triage tool.



XSL•FO
RenderX

Prediction of Specific Diagnoses: Fibromyalgia and RA

Our analysis extended beyond distinguishing inflammatory from noninflammatory conditions to evaluate the FRYQ's ability to identify specific diagnoses. Patients with fibromyalgia showed particularly distinctive response patterns compared to those with inflammatory conditions (Figure 3), making this a compelling diagnostic target with sufficient representation in our datasets.

The fibromyalgia-specific model demonstrated strong discriminative ability, achieving an AUC-ROC of 0.85 (95% CI 0.78-0.90) in the development dataset and maintaining robust performance in the external validation dataset with an AUC-ROC of 0.81 (95% CI 0.75-0.86; Figure 4). SHAP analysis identified key predictive features for fibromyalgia: female sex, younger to middle age, fatigue (question 6.3), chest pain (question 4.12), extended symptom duration (questions 1.10 and 2.8), and waking up tired (question 5.9). The model effectively differentiated fibromyalgia from RA, although some misclassification occurred with noninflammatory conditions such as hypermobility (Figure 6A in Multimedia Appendix 3).

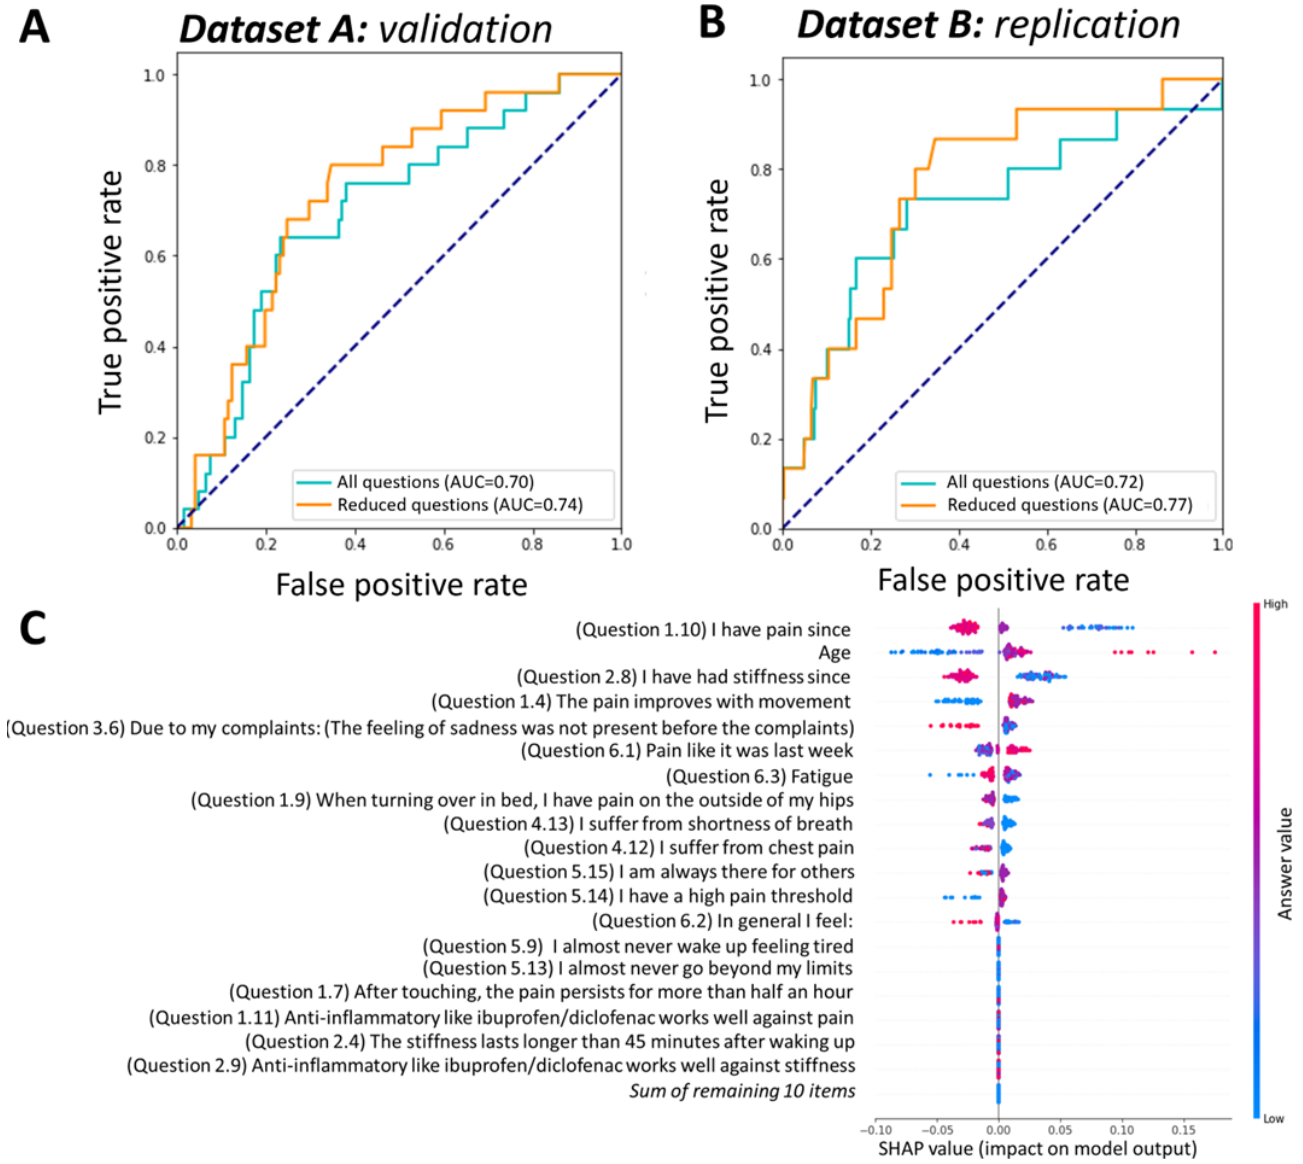


Figure 4. Performance of the fibromyalgia classifier: (A) receiver operating characteristic (ROC) curves showing performance before and after regularization in the validation set, (B) ROC curves showing performance before and after regularization in the replication set, and (C) Shapley Additive Explanation (SHAP) analysis results highlighting the impact and direction of the most important features contributing to the classifier's predictions. AUC: area under the curve.

For RA—a critical target for early rheumatology intervention—our model showed moderate discrimination, with AUC-ROC values of 0.74 (95% CI 0.63-0.83) in the development set and 0.77 (95% CI 0.66-0.86) in the external validation set (Figure 5). Key predictors included shorter disease duration (questions 1.10 and 2.8), pain improvement with movement (question 1.4), recent severe pain (question 6.1), onset at middle age or later, and fewer respiratory or chest symptoms (questions 4.13 and 4.12) or hip concerns (question 1.9). The model's primary challenge was differentiating RA from other IRDs with similar presentations, such as reactive arthritis, polymyalgia rheumatica, and gout (Figure 6B in Multimedia Appendix 3).

Figure 5. Performance of the rheumatoid arthritis classifier: (A) receiver operating characteristic (ROC) curves showing performance before and after regularization in the validation set, (B) ROC curves showing performance before and after regularization in the replication set, and (C) Shapley Additive Explanation (SHAP) analysis results highlighting the impact and direction of the most important features contributing to the classifier's predictions. AUC: area under the curve.

Discussion

Principal Findings

Our results demonstrate that the FRYQ can effectively distinguish between IRDs and noninflammatory musculoskeletal concerns before patients' first rheumatology consultation. The model achieved robust performance, with an AUC-ROC of 0.71 in the development dataset and 0.72 in the external validation dataset, indicating good generalizability. Importantly, we found that a reduced set of just 28 questions from the original 67 closed-ended items maintained equivalent discriminative power, suggesting potential for a more efficient screening tool.

Beyond the primary classification task, our analysis revealed that the FRYQ demonstrates even stronger performance in identifying specific conditions, particularly fibromyalgia (AUC-ROC of 0.85 and 0.81 in the development and replication datasets, respectively). The FRYQ also showed adequate ability to detect RA cases (AUC-ROC of 0.77 in the external validation dataset), although it had more difficulty distinguishing RA from other inflammatory conditions.

These findings have important clinical applications. In settings with limited rheumatology resources, the FRYQ could serve as a triage tool to streamline the large influx of referrals (overreferral) by prioritizing the referred patients with higher probability of inflammatory disease for early specialist intervention. This could result in more efficient allocation of specialist resources, potentially reducing waiting lists for a substantial number of patients with IRD. In light of the anticipated shortage of clinical professionals, it is increasingly important to identify which patients truly need rheumatologists' care versus those who can be managed elsewhere [18].

For example, the FRYQ's ability to identify fibromyalgia among the rheumatology waiting list could help redirect these patients to alternative care providers instead (pain specialists, physiotherapists, or dedicated programs), freeing capacity at the clinic for patients needing rheumatological care. Currently,

XSL•FO
RenderX

rheumatologists spend substantial time on patients they cannot effectively treat as approximately 60% of rheumatology referrals involve noninflammatory conditions (such as fibromyalgia) [10]. This optimized allocation may also offer an additional benefit: the extra capacity created could reduce primary care physicians' reluctance to refer clinically ambiguous cases that would benefit from specialist input.

Finally, the FRYQ could aid clinicians in their decision to request extra laboratory workup. When responses suggest RA, clinicians could order relevant serological markers (anticitrullinated protein antibody, rheumatoid factor, C-reactive protein, and erythrocyte sedimentation rate) before the initial visit, potentially streamlining the diagnostic process and reducing time to treatment for conditions requiring early intervention [4-7].

The clinical threshold of 0.30 that we identified balances sensitivity (capturing 71%-76% of inflammatory cases) with reasonable specificity (49%-56%), making it suitable for initial screening where missing IRD cases would be more concerning than false positives. As reported by Graydon and Thompson [19], primary care physicians and rheumatologists frequently disagree on referral urgency (47%), with rheumatologists upgrading 17% of referrals to urgent status—cases initially overlooked by GPs. This underlines the potential value of applying such a threshold in practice, although adjustments may be required depending on local context, such as disease prevalence and health care setting.

Our findings align with the growing recognition that structured questionnaires can support diagnostic decision-making in rheumatology by systematically capturing and integrating patients' own experiences and symptom descriptions. While over 100 symptom checkers currently exist [20], their adoption has remained limited due to lack of validation or suboptimal diagnostic accuracy [20,21]. Therefore, the availability of a validated tool such as the FRYQ may fulfill a need in the field. As far as we know, this is the first questionnaire developed in the Netherlands for triaging musculoskeletal concerns that has been validated using real-world patient data.

The predictive factors identified in our SHAP analysis align with established clinical knowledge. Pain improvement with movement, shorter morning stiffness duration, and good response to nonsteroidal anti-inflammatory drugs all emerged as important indicators of inflammatory disease [22-24]. The association between inflammatory bowel disease and IRDs supports known connections between these conditions [25]. For fibromyalgia, we observe that patients report sleep problems, persistent pain, and fatigue [26].

Beyond questionnaires, there have been other digital approaches proposed in the literature for improving rheumatology triage. Natural language processing (NLP) of referral letters has shown promising results in studies from the United Kingdom [27] and the Netherlands [28], potentially complementing questionnaire-based methods. Similarly, patient-reported outcomes have been investigated, although Schäfer et al [29] found these to be less effective at distinguishing inflammatory from noninflammatory rheumatic conditions.

Study Limitations

Several limitations of this study should be acknowledged. First, while we validated our model in an external dataset, both cohorts originated from the same medical center, potentially limiting generalizability to different health care settings or patient populations. Second, we observed a rather big difference in prevalence of inflammatory conditions (257/582, 44.2% vs 93/350, 26.6%). This affected the model's calibration in external validation, suggesting the need for recalibration when applying to populations with different disease prevalence.

These prevalence differences likely stem from distinct patient selection mechanisms. Dataset A included patients with prescheduled outpatient appointments who completed the questionnaire during their first visit as part of routine care in Medical Center Leeuwarden (approximately 70% of referrals). In contrast, dataset B comprised volunteers from the JPAST study (approximately 40% of referrals). The time-consuming study procedures of the JPAST study likely led to an overrepresentation of nonurgent (non-IRD) cases among the volunteers.

We should also acknowledge that our model showed moderate discriminative ability (AUC of approximately 0.72) rather than excellent performance. Therefore, it could not reliably distinguish certain conditions such as spondyloarthritis from noninflammatory diseases. Rare inflammatory conditions were also underrepresented.

Crucially, our study was tailored to patients already referred to rheumatologists with the goal of optimizing the time from referral to specialist consultation. This means that the FRYQ cannot be used as a prescreening tool at GP offices. Importantly, it was not designed to exclude patients from care but rather to guide referred patients to the most appropriate care providers and streamline referral pathways.

Future Directions

To definitively establish the FRYQ's clinical utility, we propose conducting a randomized clinical trial in the future to assess whether FRYQ-guided triage leads to faster appropriate treatment, reduced unnecessary appointments, and improved patient satisfaction. Furthermore, our study would benefit from additional replication in other countries to assess how health care system differences affect its effectiveness. Referral rates and treatment protocols vary substantially between countries—for instance, 21% of patients with musculoskeletal conditions are referred to specialists in Spain compared to 11% in the Netherlands and 5% in Sweden [30].

In the future, we also plan to incorporate NLP techniques to leverage open-ended questions as they may capture nuanced symptom descriptions that structured items tend to miss. Modern NLP methods, including large language models, show potential for supporting triage [31] and the identification of rare or unrecognized diseases using free-text data [32,33]. For spondyloarthritis in particular, large language models could be prompted with educational information on axial spondyloarthritis recognition to improve detection.

XSL•FO
RenderX

Finally, we may enhance the questionnaire by incorporating questions on occupational stress given that it is a known predictor of non-IRD [34,35]. Further refinement could also involve integrating FRYQ scores with serological markers and imaging to create a comprehensive multimodal prediction model. This multimodal approach might overcome some limitations of questionnaire-based triage alone, particularly for discerning conditions with overlapping symptomatology (ie, overlapping symptoms of osteoarthritis and early RA [36]).

Conclusions

The FRYQ shows promise in distinguishing inflammatory from noninflammatory rheumatic conditions in newly referred patients, particularly fibromyalgia and RA, before specialist assessment. While not a substitute for clinical judgment, this tool could help optimize the time from referral to specialist consultation by prioritizing cases likely to involve IRDs and guiding others toward alternative care pathways or additional laboratory testing. These potential benefits merit evaluation in prospective implementation studies, especially given the projected shortage of rheumatology professionals.

Acknowledgments

The authors thank all participants of the study for filling out the Frysian Questionnaire for Differentiation of Musculoskeletal Complaints. The authors also want to extend their thanks to the data managers and the outpatient clinic secretariat.

Funding

This study received funding from the Netherlands Organisation for Health Research and Development Clinical Fellowship (40-00703-97-19069), and the SPIDeRR-NL project (Stratification of Patients using advanced Integrative modeling of Data Routinely acquired for diagnosing Rheumatic complaints in the Netherlands), which was granted by the Netherlands Organisation for Health Research and Development Open Competition (activity 09120012110075).

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request. The corresponding code is publicly available on a GitHub repository [37].

Authors' Contributions

FR, AaH, AS, DZ, FW, LH, and RB were responsible for data collection and processing. TDM conducted the machine learning analysis. RK, TDM, RB, and FR interpreted the results. TDM and FR drafted the initial version of the manuscript, which was further developed by RK and RB. All authors reviewed and approved the final version of the manuscript for submission.

Conflicts of Interest

RB has received research grants from Galapagos and Sanofi; has served on the speaker bureau for Galapagos and Janssen; and has received consulting fees from AbbVie, Galapagos, Pfizer, and UCB. All other authors declare no other conflicts of interest.

Abstract

Background: Heart failure (HF) is a public health concern with a wider impact on quality of life and cost of care. One of the major challenges in HF is the higher rate of unplanned readmissions and suboptimal performance of models to predict the readmissions. Hence, in this study, we implemented embeddings-based approaches to generate features for improving model performance.

Objective: The objective of this study was to evaluate and compare the effectiveness of different feature embedding approaches for improving the prediction of unplanned readmissions in patients with heart failure.

Methods: We compared three embedding approaches including *word2vec* on terminology codes and concept unique identifier (CUIs) and BERT on descriptive text of concept with baseline (one hot-encoding). We compared area under the receiver operating characteristic (AUROC) and F_1-scores for the logistic regression, eXtream gradient-boosting (XGBoost) and artificial neural network (ANN) models using these embedding approaches. The model was tested on the heart failure cohort (N=21,031) identified using least restrictive phenotyping methods from MIMIC-IV dataset.

Results: We found that the embedding approaches significantly improved the performance of the prediction models. The XGBoost performed better for all approaches. The *word2vec* embeddings (0.65) trained on the dataset outperformed embeddings from pre-trained BERT model (0.59) using descriptive text.

Conclusions: Embedding methods, particularly *word2vec* trained on electronic health record data, can better discriminate HF readmission cases compared to both one-hot encoding and pre-trained BERT embeddings on concept descriptions making it a viable approach of automation feature selection. The observed AUROC improvement (0.65 vs 0.54) may support more effective risk stratification and targeted clinical interventions.

Introduction

Heart Failure (HF) is a major and growing public health concern, affecting around 3% of the adult population of high-income countries, with increasing prevalence in low and middle-income countries [1,2]. It is estimated that 56.2 million people worldwide are affected by HF [2]. HF is also associated with high rates of unplanned readmissions, which strain the health care system and diminish patient quality of life. The 1-year readmission rate is as high as 53% globally and 59% in the United States [3]. Given the significant burden imposed by readmissions, healthcare providers strive to identify patients with HF at risk for readmission. Several predictive models have been developed for this purpose, including traditional statistical models and machine learning models. However, their predictive performance remains suboptimal in real-world applications, with area under the receiver operating characteristic curve (AUROC) of 0.6 when using electronic health record (EHR) data [4].

Medical codes such as International Classification of Diseases (ICD) codes, procedure codes, and medication identifiers vary in structure and granularity, introducing complexity and high dimensionality into the data. These high-dimensional spaces make it difficult to extract meaningful patterns for prediction. Natural language processing and embedding techniques such as word2vec and BERT offer a promising approach to address these challenges by transforming discrete medical codes into continuous vector representations. These embeddings capture

XSL•FO
RenderX

semantic relationships between medical codes, enabling models to understand the similarities and differences between related diagnoses and procedures [5,6]. Several studies have demonstrated that embedding methods may improve the performance of predictive models in healthcare by reducing dimensionality while preserving relevant clinical information [6,7].

To address these challenges, our study, investigates the utility of EHR embedding techniques and their performance in the prediction of 30-day hospital readmissions among patients with HF, leveraging the open data available in MIMIC-IV dataset. The 30-day readmission metric is widely used in healthcare policy and quality assessment. In the United States, the Center of Medicare and Medicaid Services includes this metric in the Hospital Readmissions Reduction Program, which penalizes hospital excess readmissions [8]. As such, accurate prediction of 30-day readmissions risk has direct implications for hospital reimbursement and patient care planning.

We compared two embedding approaches: (1) *word2vec* embeddings trained on terminology codes and Unified Medical Language System (UMLS) Concept Unique Identifier (CUIs) and (2) BERT embeddings derived from concept descriptors. We hypothesize that embeddings derived from structured medical codes capture patient-level clinical patterns more effectively than embeddings generated from descriptive text. This is because code-based embeddings reflect co-occurrence and usage patterns in real clinical settings, while text-based embeddings may lack the specificity and contextual relevance needed for structured prediction tasks.

Word2vec is a widely used embedding technique used to represent words (or codes) in a vector space, trained using shallow neural networks on text corpora [9], In the clinical domain, word2vec has been successfully used to embed medical concepts from EHR data [10-12]. In contrast, BERT is a transformer-based language model that generates contextualized embeddings by capturing the position and surrounding context of each word [13]. BERT and its biomedical adaptations such as BioBERT and BioClinicalBERT have shown promise for a range of tasks in biomedical and clinical domains [14-17]. Among these, BioBERT is pretrained on PubMed abstracts, while BioClinicalBERT extends it with clinical narratives from MIMIC. Lee et al [6] demonstrated that textual descriptions of ICD codes can be effectively used for semantic-preserving vector representations.

While BERT provides contextualized embeddings that excel in natural language understanding, its effectiveness in representing brief and structured medical concept descriptions remain uncertain. In contrast, word2vec, trained on real-world sequences of medical codes, may better capture clinically relevant co-occurrence patterns. In this study, we aim to empirically evaluate whether code-based embeddings (eg, word2vec on medical codes) outperform text-based embeddings (eg, BERT on concept descriptions) in predicting 30-day hospital readmissions, given the structured nature of EHR data.

Methods

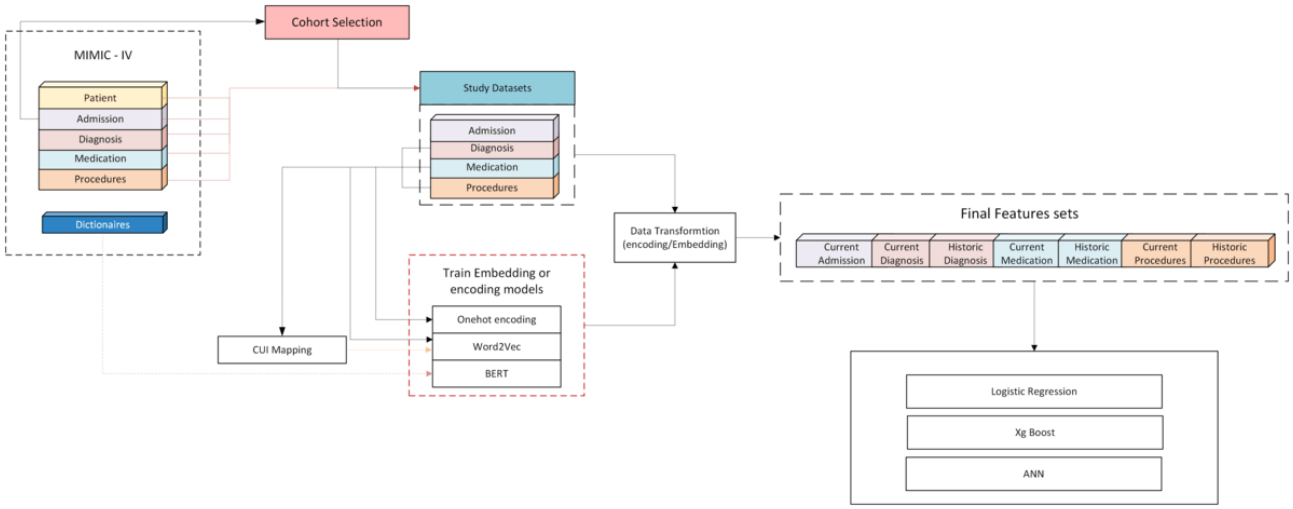
Study design

For this study, we used Medical Information Mart for Intensive Care (MIMIC)-IV version 2.2, a publicly available dataset released in January 2023. The MIMIC-IV dataset contains comprehensive, de-identified EHR data for patients admitted to the Beth Israel Deaconess Medical Center between 2008 and 2019. The dataset includes 299,712 patients and 431,231 hospital admissions [18]. Diagnoses are coded using the ICD, with both 9th and 10th Clinical Modification (CM) revisions. Procedures are recorded using both *ICD*-9 and *ICD*-10 Procedure Coding System codes. Medications are recorded with the National Drug Code (NDC) along with the Drug name, route, strength, etc. To develop predictive models for HF readmission, we used data from the hospital module capturing demographic information, diagnosis, medication and procedure codes.

We identified patients with HF using the least restrictive phenotyping method, which defines HF-positive cases as any patient with at least one relevant *ICD*-9 or *ICD*-10 code for HF [19]. We included HF-positive patients only for this study. 30-day readmission was defined as any subsequent admission occurring within 30 days of discharge, regardless of the reason for readmission. Patients were excluded from the cohort if they died (n=1475), or the length of stay was less than one day (n=1740) at the indexed admission. The exclusion criteria were applied because patients who died during the index admission were not at risk for readmission, and the definition of ‘inpatient’ becomes ambiguous for patients with hospital stay of less than one day. Admission occurring after the index admission were also excluded, as our objective was to predict readmission following the index HF hospitalization.

Data preprocessing was structured into three main components: admissions, clinical data extraction, and embedding preparation:

1. Admissions: Admissions were categorized as indexed, historic, and future admissions. Indexed admissions were defined as the first hospitalization with a diagnosis of HF. All the admissions prior to indexed admissions were classified historic admission and any subsequent hospitalizations as future admissions. We only developed models for predicting readmission after the index admissions. We included age at admission, length of stay and gender from indexed admissions as features.
2. Clinical Data extraction: We extracted diagnoses, procedures, and medications from structured data for selected cohorts. These were split into current if date of record corresponds to the index admission and historic if it precedes the indexed admissions. We applied different encoding or embedding methods to these extracted data. We applied one-hot encoding for baseline. The embeddings approaches applied are described below. The current and historic data are combined with indexed admission features to create the final features sets (Figure 1).
3. Embedding: We applied three embedding approaches to the feature matrix to capture the semantic representations in the data, to output a new feature matrix.



XSL•FO
RenderX

a. Word2Vec on Terminology Codes: ICD codes were concatenated with their version (ICD-9 or ICD-10) to form unique identifiers that account for overlapping codes between the two versions. For medications, we used NDC codes, excluding drugs that lacked NDC identifiers. Each unique code (diagnosis, procedure, or medication) was treated as a word, and the list of codes for each patient encounter was considered as a document. The word2vec model was trained using the skip-gram with negative sampling (SGNS) algorithm. The subset of training dataset was used to finetune parameters for word2vec (please refer to Table S1 in Multimedia Appendix 1 and Figure 1). Based on the finetuning experiments, we selected the context window size of 10, resulting in 200-dimensional embedding vectors. Separate *word2Vec* models were trained for diagnoses, procedures, and medications.

b. Word2Vec on UMLS CUIs: To map ICD and procedure codes to UMLS CUIs, we implemented a hybrid code and string-matching approach. First, codes were matched directly to UMLS using a code-matching algorithm. For unmapped code, we truncated the first three characters and attempted matching again. If multiple CUIs were returned, we selected the most generic code. For Medications, NDC codes were matched and for unmapped codes, we used a string search from the drug name. These mapped CUIs were then treated as 'word' and trained in the same manner as recorded medical codes using Word2Vec.

c. BERT on Descriptive Text: For each medical code, we utilized its long-form descriptor to generate embeddings using pre-trained BERT models. We used BioClinicalBERT, which is specialized for clinical texts, to generate context-aware embeddings from the long descriptions provided in the MIMIC-IV datasets. For medication, as long descriptions were not available, we created one by concatenating multiple columns (drug, prod_strength, dose_val_rx, dose_unit_rx, form_val_disp, form_unit_disp and route) from the prescriptions table for example - "Docusate Sodium 100 mg Tablet 100 mg 1 Tab 2.0 Oral." This approach captures semantic meaning and context-specific nuances that are often lost when only the codes are used.

Figure 1. Graphical summary of the Study. CUI: Concept Unique Identifiers ; MIMIC-IV: Medical Information Mart for Intensive Care - IV (Database).

We developed multiple machine-learning models to predict 30-day readmissions. The embeddings generated from each approach were used as input features for these models. We trained and evaluated three machine learning algorithm—logistic regression, and eXtream gradient-boosting (XGBoost) and artificial neural network (ANN). A feedforward ANN consisting of three fully connected layers with Tanh activation and dropout for regularization with progressively reduced dimensionality and outputs a probability via a final sigmoid activation was implemented. Like *word2vec* parameters finetuning, we run multiple experiments with a combination of different parameters and oversampling of minor classes using Synthetic Minority Oversampling Technique (SMOTE). Model performance was assessed using standard metrics such as Area under the receiver operating characteristic curve (AUROC), and F_1-score. (please refer to supplement file in Multimedia Appendix 1 for the link to the source code).

Ethical Considerations

The study used the MIMIC dataset, which contains deidentified health-related data and is publicly available through PhysioNet platform. Access to the dataset requires completion of the "Data or Specimen Only Research" course and acceptance of the data use agreement. The institutional review board at Mass General Brigham determined that the project does not meet the criteria for human subject research, as the dataset used does not contain any identifiable patient information. Since this study used an open dataset available in the public domain that was published by another research group, informed consent and opt-out procedures were managed by the original investigators. Therefore, no direct consent or interaction with participants was required for this study.

XSL•FO
RenderX

Results

A total of 21,031 patients were included in the study with 3933 (19%) experiencing a 30-day readmission. This cohort was randomly split into training with 14721 patients (70%), test with 3155 patients (15%), and validation with 3155 patients (15%) sets (Figure 2). The average age at indexed admission was 73 years, the mean number of admissions was 2, the mean number of ICD codes used was 25 and the mean length of stay is 8 days. The number of admissions (P<.001, t-statistic=10.83), number of ICD codes (P<.001, t-statistic=12.71), and length of stay (P<.001, t-statistic=10.41) are higher among patients with 30-day readmission, and there is no significant difference in age at index admission (P=.40, t-statistic=−0.851) and the number of male versus female (P=.63, odds ratio =1.017). This is true in all splits of datasets as well (Table 1). The rate of 30-day readmission was 19% in the Cohort, 19% in the Train dataset, 17% in the test set, and 19% in the validate set.

Figure 2. Flow diagram study cohort selection. *The total number of unique excluded patients accounts for 86 individuals who met both exclusion criteria.

We used one-hot encoding as baselines, which yielded AUROC scores of 0.54 and F_1-scores ranging from 0.24 to 0.26 across validation and test sets. The embedding-based approaches consistently outperformed the baseline across all models. Logistic regression, XGBoost, and ANN models achieved AUROCs ranging from 0.59 to 0.64, 0.59 to 0.65 and 0.59 to 0.64, respectively. Among the embedding strategies, BERT embeddings from descriptive text performed worst, while the best AUROC (0.65) was achieved using *word2vec* on CUIs with XGBoost. F1 scores varied modestly, ranging from 0.32 - 0.37 (validation) and 0.29 - 0.34(test) (Table 2). The best logistic regression results were obtained using L2 regularization with C of 0.01 for both *word2vec* and BERT embeddings. For XGBoost, optimal performance was achieved with max depth of 3 and learning rate of 0.01. For ANN models, a learning rate of 0.001, dropout rate of 0.3, and hidden size of 384 yield the best outcomes across most experiments. Logistic regression and XGBoost performed better without oversampling, whereas the ANN showed improved performance when training set was oversampled to address class imbalance (please refer to Table S2 in Multimedia Appendix 1).

Table . Best results of different experiments by model.

Experiments and models	AUROC[a] validation	F_1 validation	AUROC test	F_1 test
Baseline				
Logistic regression	0.54	0.26	0.54	0.25
XGBoost[b]	0.54	0.25	0.54	0.25
ANN[c,d]	0.54	0.24	0.54	0.24
Word2vec on terminology code				
Logistic regression	0.64	0.37	0.64	0.34

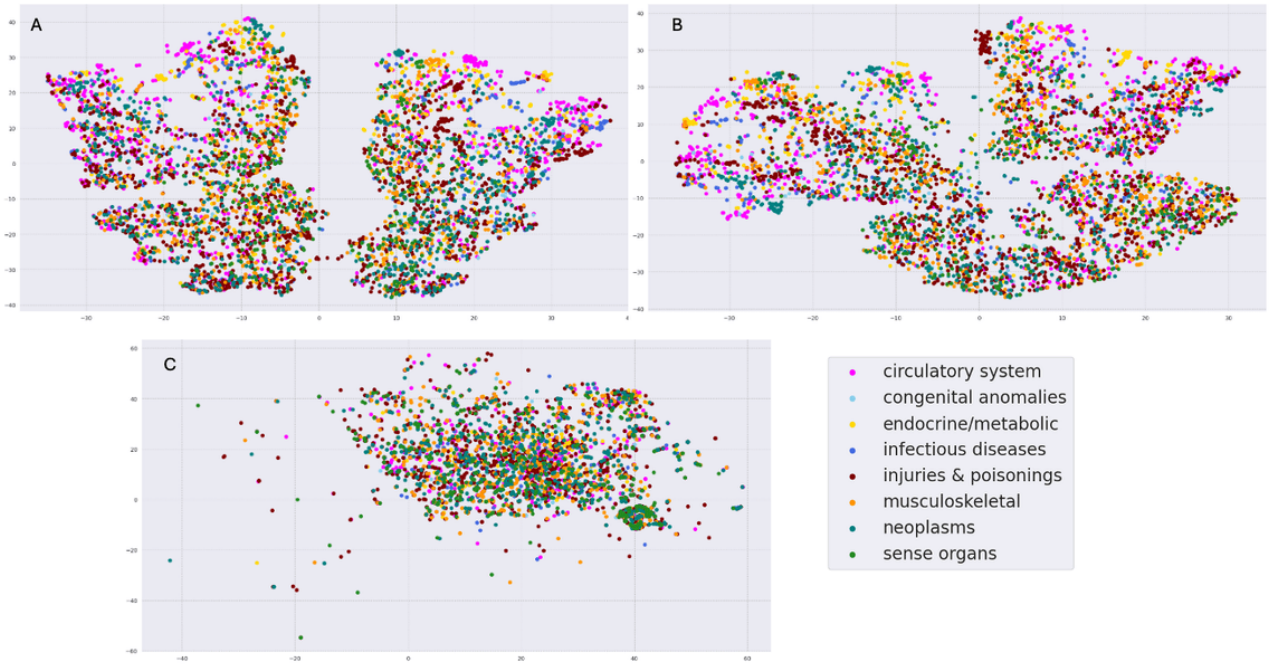
Discussion

Principal Findings



The study presents the systematic comparison of embedding techniques for predicting 30-day heart failure readmission using EHR data. Our analysis of 21,031 heart failure admission from MIMIC-IV dataset demonstrates that the use of *word2vec* embedding trained on the patient data achieved superior performance compared to traditional one-hot-encoding and pretrained language model (BERT).

The *word2vec* on CUIs with XGBoost had AUROC of 0.65, which is substantial improvement of 0.11 over the one-hot-encoding baseline, and modest improvement of 0.06 over pre-trained BioClincial_BERT model. The corresponding F_1-score improvement of 0.10 and 0.04, respectively demonstrates enhanced performance of the word2vec approach.

We investigated the performance gains for word-2-vec using dimensionality reduction analysis. A t-distributed stochastic neighbor embedding (Figure 3) revealed that word2vec embeddings facilitated more coherent clustering of diagnostically related codes, implying superior capture of clinically relevant semantic relationships.

XSL•FO
RenderX

Figure 3. T – SNE plot of diagnosis code embeddings with encoded categories.

A – Word2vec embeddings from Recorded ICD Code; B – Word2vec embedding from CUIs maps; C - embedding obtained using BERT over Descriptors of recorded code.

Overall our findings align with literature in data-driven approaches for readmission prediction [3,7,20,21], while revealing important improvements that can be obtained by using embeddings. However our results were inferior compared to previous studies that utilized expert-crafted features, where the AUROC scores exceeding 0.8 [22,23]. For instance, Pishgar et al [22] reported AUROC of 0.70 using features selected as the event logs with ANNs, and Ben-Assuli et al [23] achieved 0.88 using mix of ML algorithm and expert-selected features with XGBoost. This performance differential highlights the trade-off between automated feature engineering and use of human-experts for feature selection. This is consistent with findings across other clinical areas, where domain expertise has been shown to significantly enhance predictive performance.

Notably, our results suggest that dataset-specific word2vec embeddings may outperform sophisticated pre-trained language models. This is likely because approaches that directly model co-occurrence patterns within the target dataset may capture more task-specific signal as compared to models trained on broader textual corpora.

Overall our study fills a significant gap in the literature by offering a systematic evaluation of embeddings strategies, thereby providing evidence-based guidance for selecting the appropriate embedding method for clinical prediction tasks.

The study has several limitations. Patient encounters were modeled as static collection of medical codes without considering temporal patterns. The study did not evaluate the portability of the models as the dataset is limited to a single institution. Our evaluation focused on traditional machine learning approaches (logistic regression, XGBoost, and ANN), which may not fully exploit the representational capacity of embedding methods. Future research should explore temporal sequence modeling with transformer-based architectures, graph-based representation learning, and multimodal data to capture richer clinical context. Validation across multiple institutions and diverse population is essential to demonstrate portability.

Conclusion

In conclusion, this study demonstrated that embedding techniques, particularly word2vec trained on study dataset is a viable automated approach for heart failure readmission prediction. Further studies are required to investigate if task-specific representation learning may be more effective than use of general-purpose models for specific clinical applications.

Acknowledgments

We extend our thanks to the developers of open-source tools and frameworks, including word2vec, BioClinical_BERT which greatly facilitated the embedding generation and analysis in our study.

Abstract

Background: The burden of paralytic ileus (PI) in the intensive care unit remains high, and the Charlson Comorbidity Index (CCI) is strongly associated with the prognosis of several acute and chronic diseases. However, evidence specifically evaluating the prognostic value of CCI in intensive care unit patients with PI remains limited.

Objective: This study aimed to investigate the association between CCI and clinical prognosis in critically ill patients with PI.

Methods: In this study, data were extracted from the Medical Information Mart for Intensive Care IV (version 2.2), a large, publicly available critical care database, and used to determine the optimal cut-off value of CCI for predicting mortality in patients with PI using the receiver operating characteristic curves, and the association between CCI and mortality was evaluated using Cox regression and restricted cubic spline analysis. A machine learning (ML) prediction model was then constructed to predict hospital mortality by combining CCI and other clinical characteristics.

Results: The study included 863 patients with PI (age: median 65.4, IQR 54.6 - 75.5 y; male: 575/863, 66.6%). The receiver operating characteristic curve identified an optimal cut-off value of 4.5 for CCI. The multivariate Cox regression analysis showed that compared to the lowest CCI quartile, patients with elevated CCI levels were more likely to have elevated hospital (Q4: hazard ratio [HR] 2.447, 95% CI 1.210 - 4.951), 28-day (Q4: HR 3.891, 95% CI 1.956 - 7.740), and 90-day (Q4: HR 3.994, 95% CI 2.224 - 7.173) all-cause mortality were significantly associated with elevated CCI levels; however, the association with ICU mortality (Q4: HR 1.892, 95% CI 0.653 - 5.480) was weak. Among the 11 ML models, the light gradient boosting machine model performed best, with internal validation results showing an area under the curve of 0.811, a geometric mean of 0.670, and an F_1-score of 0.895.

Conclusions: The CCI is an important predictor of hospital, 28-day, and 90-day all-cause mortality in critically ill patients with PI, and the optimal threshold is 4.5. ML models, including the CCI, show high accuracy in predicting hospital mortality, and the CCI occupies an important position in the model. This suggests that the CCI helps to identify high-risk patients, supports clinical decision-making, and improves prognosis.

KEYWORDS

Charlson Comorbidity Index; paralytic ileus; MIMIC-IV database; all-cause mortality; machine learning

Introduction

Background

Paralytic ileus (PI) is a common functional intestinal obstruction due to decreased or loss of intestinal motility, with etiological factors including electrolyte imbalance, severe infection, substance abuse, and abdominal surgery [1,2]. The global incidence is approximately 1 - 5 cases per 100,000 people, with a higher incidence in women but a higher mortality rate in men [3]. The overall mortality rate for PI is 5% - 6%, but this increases to 10% - 20% in the intensive care unit (ICU) patients [1,4]. Patients with PI are often associated with chronic diseases or comorbidities such as diabetes, neurological diseases, systemic sclerosis, and malignant cancer, and the cumulative burden of these underlying diseases may have a significant impact on mortality [5-8]. Given the high morbidity and

XSL•FO
RenderX

mortality associated with PI, it is important to accurately identify high-risk patients and assess their prognostic risk.

The Charlson Comorbidity Index (CCI) is a widely used scoring system that quantifies the burden of chronic comorbidities (eg, diabetes, malignant cancer, and connective tissue disorders) and evaluates their impact on overall prognosis, thereby providing an estimate of mortality risk [9,10]. It has demonstrated significant prognostic value across a variety of clinical scenarios, including older patients, critically ill populations, and cancer cohorts [11-14], and has been validated in settings such as chronic granulocytic leukemia [15], the assessment of postoperative complications [16], and fracture risk prediction [17]. These findings highlight the use of the CCI in capturing the cumulative effect of chronic disease burden on patient outcomes. In critically ill patients with PI, comorbidities such as cardiovascular disease, diabetes, and chronic kidney disease are common and may substantially influence prognosis, making the CCI particularly relevant for this cohort [1,4]. Moreover, unlike scoring systems such as Sequential Organ Failure Assessment (SOFA) or Acute Physiology and Chronic Health Evaluation that primarily reflect acute illness severity, the CCI captures the cumulative impact of chronic conditions on outcomes, thereby complementing conventional acute severity scores [9]. However, evidence specifically evaluating the prognostic value of the CCI in ICU patients with PI remains limited.

Objective

With the rapid development of big data and machine learning (ML), mortality prediction models based on electronic health records have become a research focus, as ML can capture complex associations in high-dimensional data and often outperform traditional methods [18-20]. Recently, explainable ML approaches have been applied in critical care, with several studies using the Medical Information Mart for Intensive Care (MIMIC) database to develop interpretable mortality prediction models that enhance clinical applicability [21,22]. For instance, a deep-learning model for mortality prediction based on MIMIC used neural networks with Shapley Additive Explanations (SHAP) analysis to predict outcomes in ICU patients with PI [23]. Building on these advances, the primary objective of this study was to evaluate the association between CCI and all-cause mortality, including hospital, ICU, 28-day, and 90-day mortality, in ICU patients with PI. The exploratory objective was to assess the feasibility of incorporating CCI into ML models for mortality prediction in this population.

Methods

Study Participants

This is a retrospective cohort study. The Massachusetts Institute of Technology and Beth Israel Deaconess Medical Center (BIDMC) collaborated to develop the MIMIC-IV electronic database (version 2.2), which was used for this study [24]. The database contains information on more than 50,000 patients who received ICU care at BIDMC between 2008 and 2019. The database provides a wide range of clinical data and has been used extensively in critical care medicine research [25-27]. Detailed information about the database, including access instructions, is available at PhysioNet [28]. The institutional review board (IRB) of BIDMC waived informed consent and allowed sharing of research resources because all data were deidentified. Therefore, this study did not require additional informed consent (2001-P-001699/14; 0403000206). To comply with the regulations, the author, HF, obtained a Cooperative Institutional Training Initiative license (certification: 61863057) and the necessary permission to use the MIMIC-IV database.

Adult patients who were first admitted to the hospital with a diagnosis of PI according to the International Classification of Diseases (ICD-9: 560.1 and ICD-10: 56.0) were included in this study. Individual patient consent was not required due to the anonymized nature of patient health information in this database. Exclusion criteria included: (1) patients who stayed in the ICU for <6 hours; (2) multiple ICU admissions for which only data from the first admission were extracted; and (3) patients who lacked information on CCI. Finally, a total of 863 patients were included in this study and divided into 4 groups according to the quartiles of CCI.

Patient Characteristics

Data collection involved the use of structured query language and PostgreSQL (version 16.3.7; PostgreSQL Global Development Group) to extract baseline patient characteristics. The following data were obtained: (1) demographic information includes sex, age, and race; (2) comorbidities identified according to ICD-9 or ICD-10: congestive heart failure, renal disease, malignant cancer, sepsis, diabetes, and hypertension; (3) mean vital signs include respiratory rate (RR), mean blood pressure (MBP), heart rate, and oxygen; (4) laboratory parameters include white blood cell (WBC) count, red blood cell distribution width (RDW), platelets, hemoglobin, anion gap, blood urea nitrogen (BUN), creatinine, total calcium, chloride, sodium, and potassium; (5) severity scores include Simplified Acute Physiology Score II (SAPS II), Oxford Acute Severity of Illness Score (OASIS), Acute Physiology Score III (APS III), SOFA score, and CCI; and (6) therapeutic agents include ondansetron and neostigmine. All laboratory variables were obtained from the first 24 hours after the patient's admission to the ICU. Follow-up began on the date of ICU admission and ended on the date of death. Variables with more than 10% missing values were excluded to mitigate potential bias [29]. The proportions of missing values for variables are shown in Figure S1A in Multimedia Appendix 1, and variables with less than 10% missing values were interpolated using the random forest interpolation method implemented in the *missForest* package of the R software (R Foundation for Statistical Computing) [30]. In the ML section, the patients with PI were divided into a 70% training cohort and a 30% test cohort.

Clinical Outcome

The primary outcome of this study was all-cause hospital mortality, and secondary outcomes were ICU mortality and mortality at 28 and 90 days after ICU admission. In addition, the primary objective of the ML modeling was all-cause hospital mortality.

XSL•FO
RenderX

Statistical Analysis

The normality of continuous variables was assessed using the Kolmogorov-Smirnov test. Continuous variables that followed a normal distribution were analyzed using the 2-tailed *t* test or ANOVA, and those that were not normally distributed were analyzed using the Mann-Whitney *U* test or the Kruskal-Wallis test. Categorical variables were compared by the chi-square test. The CCI was categorized into 4 quartiles, Kaplan-Meier survival analysis was used to assess differences in mortality between groups, and log-rank tests were used to compare differences between groups. The optimal cut-off value for CCI was determined by receiver operating characteristic (ROC) curve analysis using the Youden index maximization method. Variance inflation factor (VIF) was used to assess multicollinearity between variables, and variables with a VIF>5 were removed (Figure S1B in Multimedia Appendix 1).

Cox regression analysis was used to assess the association between CCI and hospital mortality, ICU mortality, as well as 28- and 90-day mortality, with model 1 including only CCI and model 2 including age and sex as correction variables. Model 3 was developed based on clinical expertise, a previous study by Zhao et al [4], and the results of feature importance selection from the least absolute shrinkage and selection operator (LASSO) algorithm. The following variables were included: sex, age, CHF, renal disease, malignant cancer, sepsis, diabetes, hypertension, RR, SpO_2 , WBC, RDW, platelets, anion gap, BUN, creatinine, SAPS II, OASIS, APS III, and SOFA. In addition, restricted cubic spline (RCS) analyses were performed to explore the potential nonlinear relationship between CCI levels and hospital, ICU, and 28- and 90-day all-cause mortality rates. The CCI was used as a continuous or ordinal variable entered into the model (the first quartile of CCI served as the reference group). *P* values for trends were calculated using IQRs. Further stratified analyses were performed according to sex, age (≤65 and >65 y), CHF, malignant cancer, sepsis, and diabetes to determine the consistency of the prognostic value of CCI for the primary outcome. Likelihood ratio tests were used to examine the interaction between CCI and the variables used for stratification. A 2-sided $P<.05$ was considered statistically significant.

To test the robustness of the results of the primary analysis, several sensitivity analyses were performed. First, patients who died within 3 days of ICU admission were excluded to assess whether these patients had a significant impact on the primary outcome. Second, patients were grouped according to the optimal cut-off value of the CCI to test the stability of the main results by different CCI groupings. Finally, a stratified analysis of SOFA scores was performed: patients were divided into 3 groups based on their 24-hour SOFA scores after ICU admission: low (first 1/3 quartile), intermediate (1st or 3rd to 2nd or 3rd quartile), and high (last 1/3 quartile). This grouping method helps to further validate the effect of different SOFA score groups on the association between CCI and mortality.

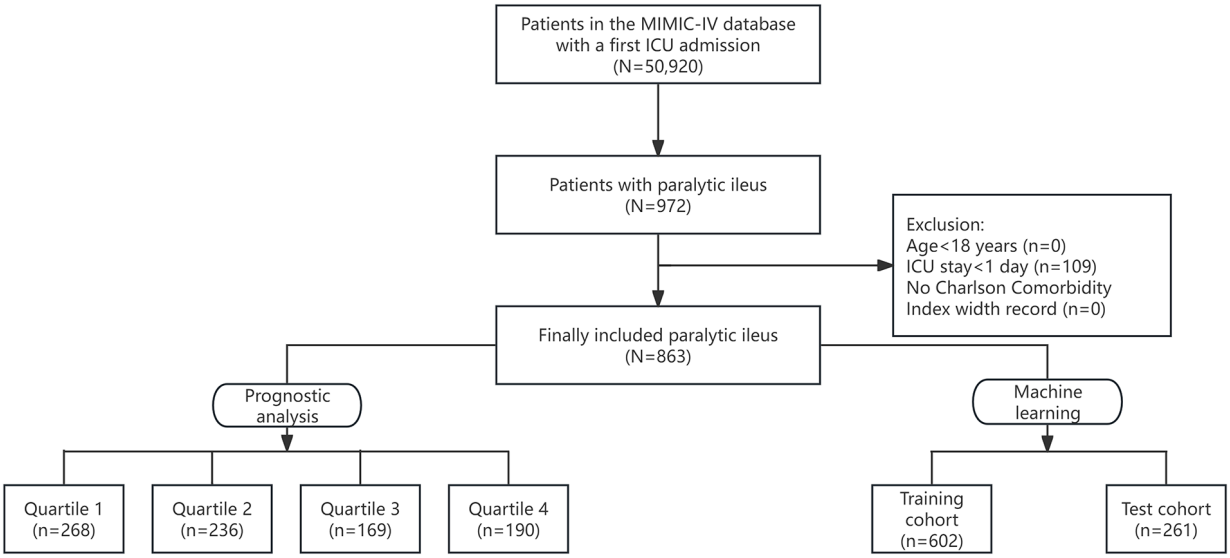
In addition, an ML model was constructed to predict all-cause hospital mortality in patients with PI using a binary classification approach. First, the correlation between variables was assessed using a Pearson correlation test, and those with coefficients >0.5 were excluded to reduce multicollinearity. Continuous variables were standardized and categorical variables were encoded. Feature selection was performed using LASSO regression and 3 ML algorithms, and the top 10 features were identified. These features were then tested again for Pearson correlation and VIFs before being incorporated into 11 common ML algorithms (eg, light gradient boosting machine [LightGBM], random forest, and extreme gradient boosting). The dataset was divided into a training and internal validation cohort in a 7:3 ratio. Model training and evaluation were performed using 10-fold cross-validation (repeatedcv, repeats =1) to reduce the risk of overfitting. Hyperparameter tuning was conducted with a random search strategy in R using the trainControl function, and the optimal parameters are shown in Table S1 in Multimedia Appendix 1. Model performance was compared with SOFA and SAPS II scores using ROC curves and multiple metrics, including AUC, accuracy, sensitivity, specificity, F_1-score, geometric mean, precision, and recall. For the best-performing ML models, Shapley Additive Explanations (SHAP) were used to assess feature importance and generate partial dependence plots. Finally, a web-based prediction platform was developed based on the best-performing models to improve clinical accessibility.

All statistical analyses were performed using SPSS (version 23.0; IBM Corp), R (version 4.3.2), and Python (version 3.11.1; Python Software Foundation).

Ethical Considerations

This study was a retrospective observational cohort study using the publicly available MIMIC-IV database (version 2.2), which contains deidentified patient data. The IRB of BIDMC waived the requirement for informed consent, as all data in the MIMIC-IV database are deidentified. The use of the database for this research was approved by the IRB of BIDMC. To comply with relevant regulations, the author, HF, obtained a Collaborative Institutional Training Initiative certification (61863057) and the necessary permissions to access and use the MIMIC-IV database. All procedures involving human subjects in this study adhered to the ethical standards of the institutional and national research councils as well as the 1964 Declaration of Helsinki and its subsequent amendments or equivalent ethical standards. As this study used the publicly available MIMIC-IV data, no participants were directly involved and no compensation was provided.

Results



Baseline Characteristics

After screening the data of patients with PI in the MIMIC IV database, 863 patients who met the inclusion criteria were included in this study and divided into 4 groups according to the quartiles of CCI (Figure 1). Table 1 shows the baseline characteristics of critically ill patients with PI stratified by CCI quartiles. Patients were divided into 4 groups based on their CCI level on admission (quartile 1: 0 - 3; quartile 2: 3 - 5; quartile 3: 5 - 7; and quartile 4: 7 - 14). The median CCI values for each quartile in each group were 2 (IQR 1 - 3), 4.5 (IQR 4 - 5), 6 (IQR 6 - 7), and 9 (IQR 8 - 10), respectively. The

XSL•FO
RenderX

median age of the enrolled patients was 65.4 (IQR 54.6 - 75.5) years, of which 575 (66.6%) were male. The median CCI for all participants was 5 (IQR 3 - 7). Compared to the lower group, patients in the highest CCI quartile generally had higher age, RDW, anion gap, BUN, creatinine, SAPS II, OASIS, APS III, SOFA, lower MBP, heart rate, hemoglobin, higher CHF, renal disease, malignant cancer, diabetes prevalence, and lower hypertension prevalence. Hospital mortality, ICU mortality, 28-day mortality, and 90-day mortality were 157 (18.2%), 76 (9%), 171 (19.8%), and 233 (27%), respectively. As the Q4 group was better associated with all-cause mortality, the differences between Q4 and Q1-Q3 were further compared. The analysis showed that different grouping methods gave similar results (Table S2 in Multimedia Appendix 1).

[a]Continuous data are presented as median (IQR), whereas categorical data are presented as n (%), Q1 (0 - 3), Q2 (3–5), Q3 (5–7), Q4 (7–14).

[b]CHF: congestive heart failure.

[c]RR: respiratory rate.

[d]MBP: mean blood pressure.

[e]SpO_2: saturation of peripheral oxygen.

[f] WBC: white blood cell.

[g]RDW, red blood cell distribution width.

[h] BUN: blood urea nitrogen.

[i] SAPS II: Simplified Acute Physiological Score II.

[j]OASIS: Oxford Acute Severity of Illness Score.

[k]APS III: Acute Physiology Score III.

[l] SOFA: Sequential Organ Failure Assessment.

[m]LOS: length of stay.

Table 2 shows the differences in baseline characteristics between survivors and nonsurvivors during hospitalization. Patients in the nonsurvivor group were more likely to have higher RR, heart rate, RDW, anion gap, BUN, creatinine, SAPS II, OASIS, APS III, SOFA, CCI, higher prevalence of CHF, sepsis, lower prevalence of hypertension, lower SpO_2, platelets, hemoglobin, calcium, lower ondansetron, and neostigmine use. CCI values were significantly higher in the nonsurvivors than in the survivors (6 vs 5; $P<.001$). Figure S1 in Multimedia Appendix 1 shows the distribution of CCIs stratified by mortality status for inpatient deaths, ICU deaths, 28-day deaths, and 90-day deaths (Figure S2 in Multimedia Appendix 1).

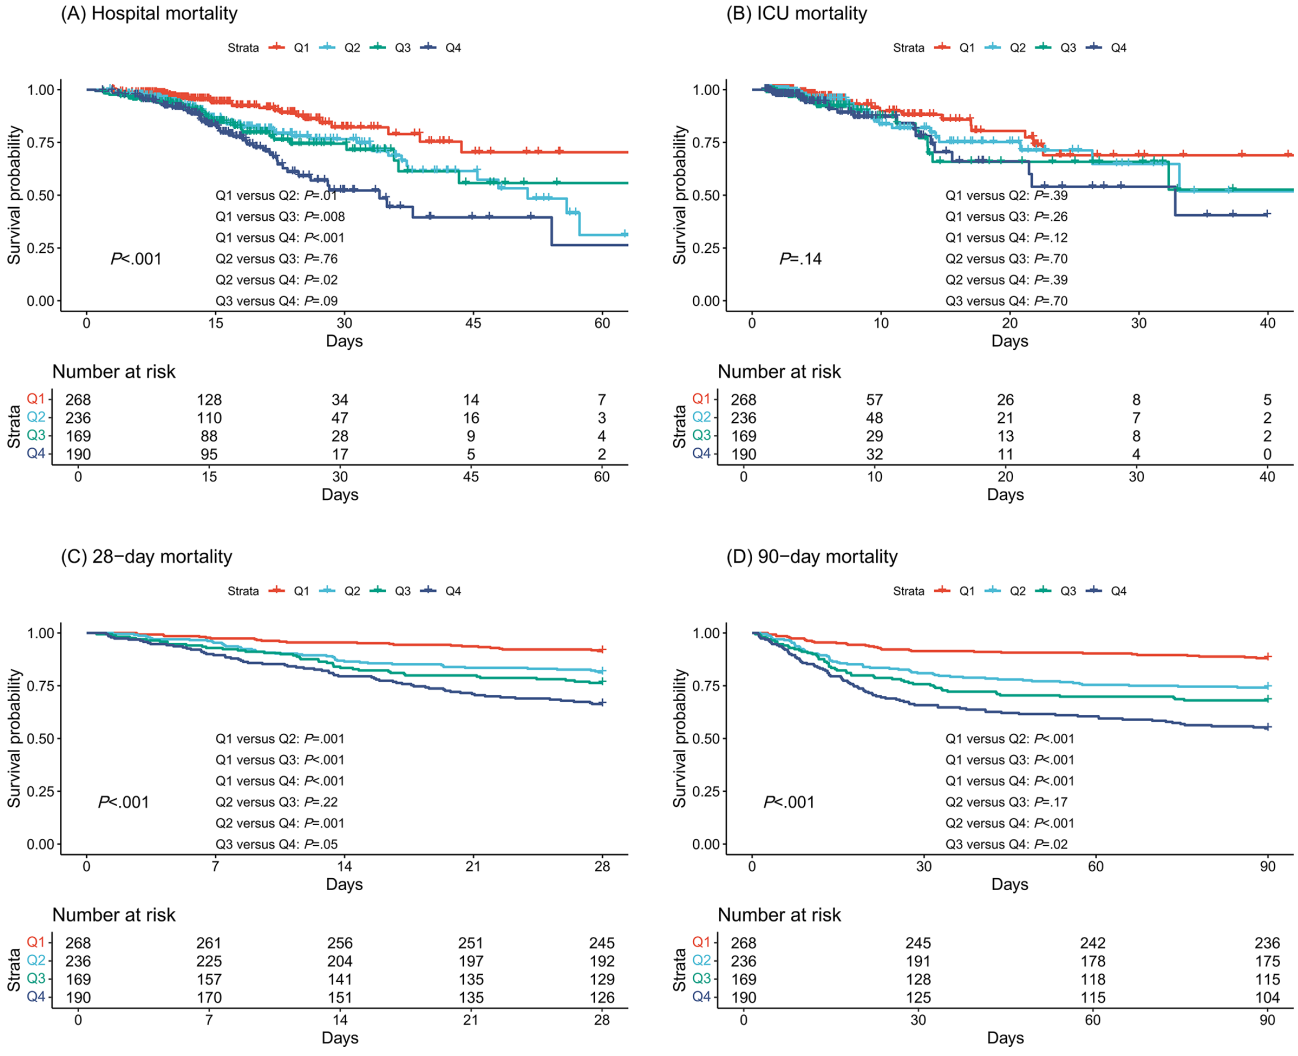
[k]APS III: Acute Physiology Score III.



[l]SOFA: Sequential Organ Failure Assessment.

[m]CCI: Charlson Comorbidity Index.

Primary Outcomes

Kaplan-Meier survival analyses showed that patients with higher CCI scores had a significantly higher risk of hospital, 28-day, and 90-day all-cause mortality (Figure 2). ROC curve analyses assessed the clinical efficacy of the CCI (Figure S3 in Multimedia Appendix 1) and showed that the AUCs of the CCIs were all greater than 0.5, which to some extent discriminated patients who died in hospital, ICU, 28-day, and 90-day from those who did not (AUC for hospital deaths: 0.631, odds ratio [OR] 1.17, 95% CI 1.10 - 1.24, *P*<.001; AUC for ICU deaths: 0.58, OR 1.10, 95% CI 1.02 - 1.20, *P*=.02; 28-day death AUC: 0.678, OR 1.24, 95% CI 1.17 - 1.32, *P*<.001; 90-day ICU death AUC: 0.687, OR 1.27, 95% CI 1.20 - 1.34, *P*<.001). The optimal CCI cut-off for hospital, ICU, 28-day, and 90-day death was 4.5.

Figure 2. Kaplan-Meier survival curves for all-cause hospital, intensive care unit (ICU), 28-day, and 90-day mortality in ICU patients with paralytic ileus. Charlson Comorbidity Index quartiles were defined as Q1 (0 - 3), Q2 (3–5), Q3 (5–7), and Q4 (7–14). Panels show cumulative probability of all-cause mortality at (A) hospital, (B) ICU, (C) 28-day, and (D) 90-day follow-up.

XSL•FO
RenderX

Cox regression analysis was used to assess the association between CCI and in-hospital mortality. The results showed that when CCI was a continuous variable, CCI was a significant risk factor in the unadjusted model (hazard ratio [HR] 1.159, 95% CI 1.099 - 1.222; *P*<.001), the partially adjusted model (HR 1.158, 95% CI 1.088 - 1.233; *P*<.001), and the fully adjusted model (HR 1.204, 95% CI 1.099 - 1.319; *P*<.001). When CCI was the ordinal variable, patients in higher quartiles of CCI were significantly associated with a higher risk of in-hospital death compared with participants in the lowest quartile in all 3 established Cox regression analysis models: unadjusted model (HR 3.124, 95% CI 1.945 - 5.017; *P*<.001), partially adjusted model (HR 2.950, 95% CI 1.708 - 5.097; *P*<.001), and fully adjusted model (HR 2.447, 95% CI 1.210 - 4.951; *P*=.01) and showed an increasing trend with increasing CCI (Table 3 and Figure 3A). Similar results were observed in multivariate Cox regression analyses for 28-day mortality (Table 3 and Figure 3) and 90-day mortality (Table S3 in Multimedia Appendix 1; Figure 3), but less favorable results were observed in multivariate Cox regression analyses for CCI and ICU mortality (Table S3 in Multimedia Appendix 1; Figure 3). In addition, the use of an RCS regression model showed a linear increase in the risk of hospital, ICU, 28-day, and 90-day mortality with increasing CCI (nonlinear *P* values of .73, .87, .64, and .29, respectively; Figure 3).

XSL•FO
RenderX

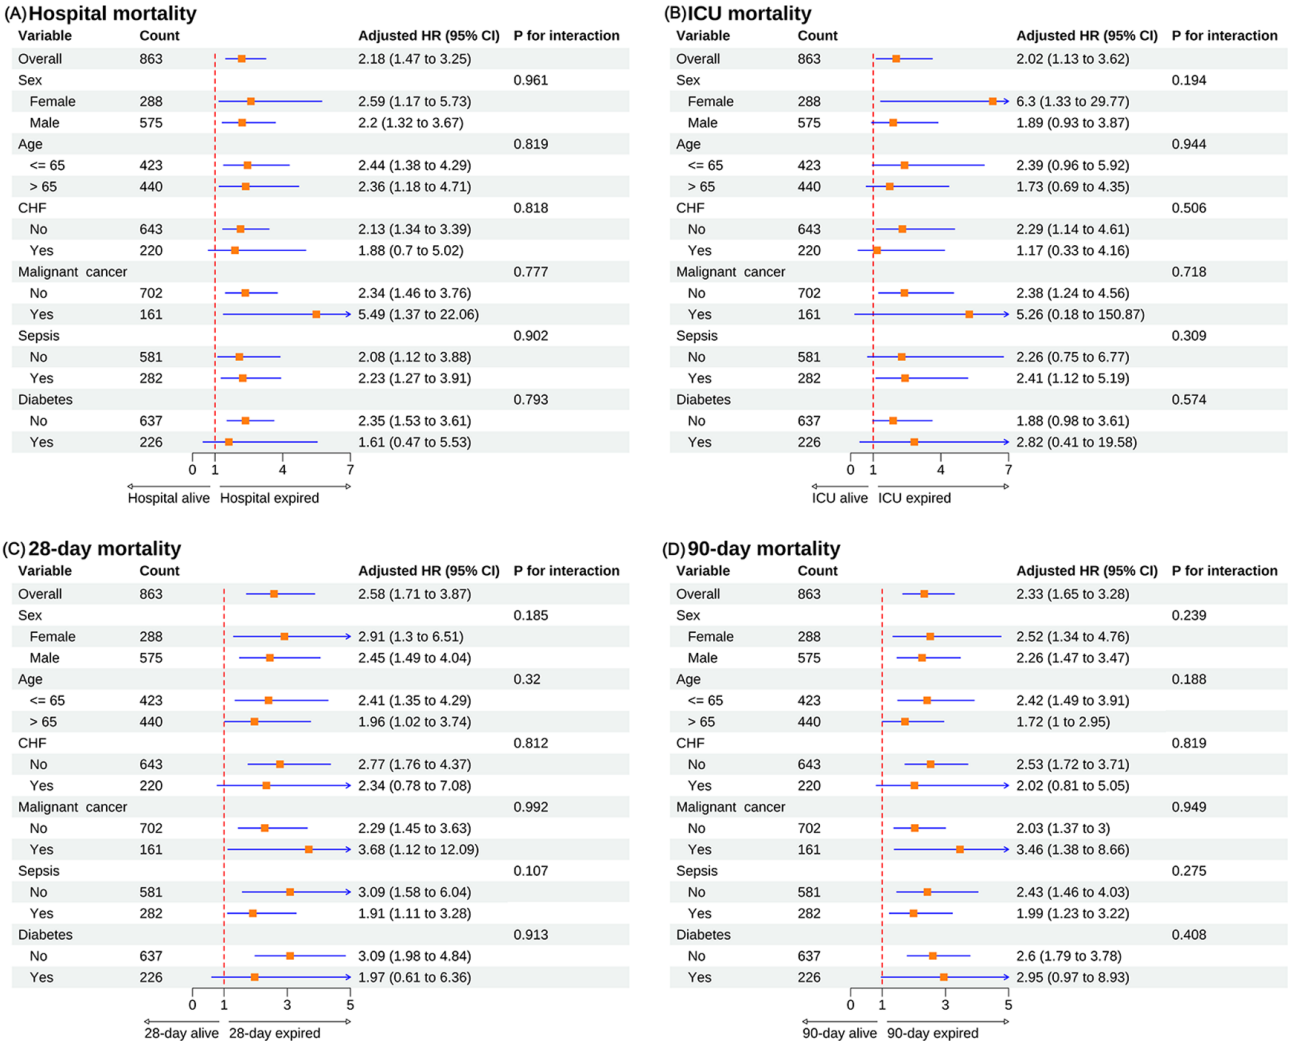
Figure 3. Hazard ratios (HRs) and restricted cubic spline curves for all-cause mortality from Charlson Comorbidity Index (CCI) after adjustment for confounders. All models were adjusted for multiple confounders, including sex, age, congestive heart failure (CHF), renal disease, sepsis, hypertension, diabetes, white blood cell count, red blood cell distribution width, anion gap, creatinine, and CCI. The bar graph shows the HRs for all-cause mortality between different CCI quartiles, with the CIs for each group. The first quartile of CCI is the reference group to which the other quartiles are compared. The central thick solid line represents the estimated HR after adjustment, the shaded area represents the CIs, and the horizontal dashed line represents the HR of 1.0. The vertical dashed line corresponds to the CCI value where the HR is 1.0. (**A**) Hospital mortality: the vertical dashed line corresponds to a CCI value of 3.65. (**B**) Intensive care unit (ICU) mortality: the vertical dashed line corresponds to a CCI value of 2.68. (**C**) 28-day mortality: the vertical dashed line corresponds to a CCI value of 4.47. (**D**) 90-day mortality: the vertical dashed line corresponds to a CCI value of 4.39.



Subgroup Analysis

Subgroup analyses by sex, age, CHF, malignancy, sepsis, and diabetes showed no interaction (all interactions $P>.05$), that is, the association between CCI and the risk of all-cause hospital mortality did not change with changes in the stratification variables of sex, age, CHF, malignant cancer, sepsis, and diabetes levels (Figure 4).

XSL•FO
RenderX

Figure 4. Subgroup analyses of the association between Charlson Comorbidity Index (CCI) and all-cause mortality in intensive care unit (ICU) patients with paralytic ileus. (A) Hospital mortality. (**B**) ICU mortality. (**C**) 28-day mortality. (**D**) 90-day mortality. CHF: congestive heart failure; HR: hazard ratio.

Sensitivity Analysis

Table S4 in Multimedia Appendix 1 shows that the association between CCI and mortality outcomes in patients with PI remained stable and similar after excluding patients who died within 3 days of ICU admission.

Table S5 in Multimedia Appendix 1 shows that the sample was divided into groups of ≤4.5 and >4.5 based on the optimal cut-off value for CCI. The results show that regardless of the grouping method used, the conclusions obtained are consistent with the results of the main analysis.

A further sensitivity analysis of the SOFA score for the 3 groups was performed. The analysis showed that for the different subgroups of SOFA scores, consistent associations were observed between CCI in the higher quartiles and mortality from PI, supporting the stability of the findings (Table S6 in Multimedia Appendix 1).

Feature Preselection for ML Models

Baseline characteristics of patients in the training and test cohorts are shown in Table S7 in Multimedia Appendix 1. Figure S4 in Multimedia Appendix 1 shows the heatmaps of all variables for which correlations are provided. Because BUN and creatinine (r=0.69), SAPS II and APS III (r=0.69) or OASIS (r=0.68), OASIS and APS III (r=0.62), age and CCI (r=0.59), and chloride and sodium (r=0.66), BUN, SAPS II, OASIS, age, and chloride were excluded in the next step. In the training queue, the 3 ML algorithms with default parameters and the LASSO algorithm preselected the 10 features used to construct the model (Figure S5 in Multimedia Appendix 1), with CCI ranking in the top 10 in each algorithm. Importantly, there is no strong correlation or multicollinearity between the selected features (Figure S6 in Multimedia Appendix 1).

ML Model Construction and Evaluation

The best hyperparameters were determined after inputting the selected features into the 11 ML models. Then, Figure 5A is the confusion matrix of the LightGBM model, and the ROC curves (Figure 5B) and other metrics (Figure 5C) were evaluated among all the ML models. LightGBM was considered the best model, outperforming other ML models including random forest and extreme gradient boosting model. This is because the internal validation results show that it has the highest AUC (0.811), F_1-score (0.895), and geometric mean (0.670) and outperforms both the traditional SOFA score and the APS III score (Table 4).

Visualization of Feature Importance

The corresponding SHAP values for each feature in the internal validation cohort of the LightGBM model were calculated and ranked (Figures 5D and 5E), and CCI ranked third in significance compared to the other predictor variables. The SHAP dependence plot of the CCI (Figure 5F) showed that increased CCI was associated with an increased risk of hospital death in patients with PI.

Web-Based Forecasting Platform

To improve the usability of the LightGBM model, it has been embedded in a user-friendly website for external users and practitioners to validate or make predictions [31]. This prototype website allows users to input clinical variables such as APS III, SOFA, Charlson Comorbidity Index, and laboratory parameters (platelet, RDW, creatinine, and others) to estimate mortality risk in patients with PI. It is intended solely for research demonstration, does not replace clinical judgment, and does not store any protected health information. For example, Figure S7A in Multimedia Appendix 1 illustrates the case of a patient with PI aged 48 years with the characteristics shown. The final output probability of hospital all-cause mortality is 0.68, indicating a high risk status. This website also allows you to view and download this patient's SHAP force plot, as shown in Figure S7B in Multimedia Appendix 1.

Discussion

Principal Findings

This study analyzed the association between CCI and clinical outcomes in a US cohort of critically ill patients with PI, with the following key findings:

1. Higher levels of CCI were significantly associated with hospital, 28-day, and 90-day all-cause mortality in patients with PI. Even after correction for confounders, CCI remained strongly correlated with these mortality indicators, with a trend towards a linear relationship. Our study suggests that the critical value of 4.5 for CCI levels provides a potential reference for mortality risk stratification, helping clinicians to identify high-risk patients who require closer monitoring.
2. A LightGBM model was developed combining CCI and other clinical variables beyond the traditional critical illness score, and the results showed that CCI had a higher weight and contribution in the model. Overall, this study highlights the critical role of CCI in risk stratification of mortality in critically ill patients with PI, helping to optimize clinical management strategies.

CCI affects the prognosis of patients with PI through several interrelated biological mechanisms. First, CCI reflects a patient's chronic disease burden, including conditions such as diabetes, neurological disorders, and malignant cancer, all of which increase all-cause mortality [5,6,8]. Chronic disease states are associated with persistent low-grade systemic inflammation, which can lead to endothelial dysfunction, oxidative stress, and vasoactive imbalances, which in turn exacerbate gut microcirculatory disturbances [32-34]. In addition, patients with high CCI often have suppressed immune function, as evidenced by decreased monocyte human leukocyte antigen–DR isotype expression, T-cell dysfunction, and prolonged immune paralysis, making them more susceptible to infectious complications [35,36]. The development of infection and sepsis can further exacerbate intestinal dysbiosis [37], leading to a vicious cycle of gut flora translocation and toxin release [38]. Dysbiosis may also affect the function of the enteric nervous system through abnormalities in short-chain fatty acid metabolism, thereby prolonging the course of PI [39-41]. In addition, patients with a higher CCI usually have a poor nutritional status, as evidenced by hypoproteinemia, muscle wasting, and inadequate metabolic reserve [42-44]. These factors may lead to reduced contractile function of the intestinal smooth muscle, delaying recovery of bowel function in PI and increasing the risk of death [45,46]. Taken together, CCI affects several key pathophysiological aspects of patients with PI, including chronic inflammation, immunosuppression, impaired intestinal barrier function, and malnutrition. The interaction of these mechanisms may explain why CCI is an important predictor of mortality in patients with PI and emphasizes the need for early detection and targeted intervention.

This study found that higher CCI was significantly associated with hospital, 28-day, and 90-day all-cause mortality in patients with PI, highlighting the importance of CCI in predicting the prognosis of critically ill patients. Patients with PI are often accompanied by a variety of comorbidities, such as diabetes mellitus and malignant cancer [5,8], and CCI, as a standardized measure of comorbidity burden, is effective in reflecting the systemic health status of the patient and in revealing the potential impact of comorbidities [9,10]. An international multicenter and subgroup bias assessment study showed that the risk of death in elderly critically ill patients increased with elevated CCI, emphasizing the profound prognostic impact of comorbidity accumulation [11]. In addition, this study also found that the critical value of CCI was 4.5 for hospital death, 28-day death, and 90-day death, a finding that further supports the important role of CCI in the prognostic assessment of patients with PI. There is no literature on the clinical value of CCI as a prognostic assessment tool for patients with PI, and this study is the first to explore and present this important finding. Compared with a single physiological parameter or laboratory index, CCI can provide more comprehensive information to the clinic by comprehensively assessing multidimensional health status, which may help in fine risk stratification and individualized treatment.

However, Cox regression analyses showed that patients with elevated CCI scores were associated with suboptimal ICU all-cause mortality outcomes after adjustment for confounders, while Kaplan-Meier survival analyses indicated that higher CCI scores were not significantly correlated with ICU mortality in patients with PI. This may be explained by the predominant role of acute care factors, such as the extent of organ failure, the intensity of systemic inflammation, and the severity of infection, which often outweigh the prognostic contribution of chronic disease burden in critically ill patients. For instance, prospective studies have demonstrated that inflammatory markers are associated with delirium, coma, and increased mortality risk [47], and multicenter cohort studies have further

XSL•FO
RenderX

shown that inflammation and organ dysfunction are key determinants of 90-day mortality in acute respiratory distress syndrome [48]. In addition, intensive interventions commonly administered in the ICU, including mechanical ventilation, hemodynamic support, and renal replacement therapy, may mitigate the short-term impact of chronic comorbidities on mortality outcomes [49-51]. Thus, although the CCI remains a valuable tool for assessing chronic disease burden and predicting outcomes in hospitalized patients, its prognostic effect in ICU settings may be attenuated by acute care factors or interventions. Moreover, the relatively small sample size and low ICU mortality rate in this study may have limited statistical power. Future research should expand sample size and incorporate additional acute clinical indicators (eg, inflammatory markers and organ dysfunction scores) to further clarify the association between CCI and ICU mortality.

RCS regression analysis in this study showed that the level of CCI was significantly and linearly related to hospital mortality, ICU mortality, and 28- and 90-day mortality. Specifically, the threshold for hospital mortality was 3.65, the threshold for ICU mortality was 2.68, and the thresholds for 28-day and 90-day mortality were 4.47 and 4.39, respectively. These results suggest that lower CCI values (eg, thresholds for hospital and ICU mortality) indicate that the acute course of illness may be the primary risk factor for death, whereas higher thresholds reflect the importance of chronic disease burden in long-term prognosis. Chronic diseases, such as diabetes and malignant cancer, may have little impact on patient survival in the short term, but over time they progressively affect the patient's immune system, organ function, and overall health [52,53], and may increase the risk of patient death in acute conditions, such as PI. Thus, the impact of chronic disease burden on prognosis was more pronounced during the 28- and 90-day observation periods, and long-term patient survival was closely linked to effective management of comorbidities. The results highlight the need to closely monitor and adjust patients' CCI levels in clinical practice to optimize their short- and long-term prognosis.

Subgroup analyses showed no significant differences between subgroups (sex, age, CHF, malignant cancer, sepsis, and diabetes) in the effect of CCI on hospital, ICU, and 28-day and 90-day mortality. CCI levels have been shown to be strongly associated with poor prognosis in patients with CHF and malignant cancer [54,55]. Gadre et al [56] concluded that CCI ≥2 is a high-risk factor for readmission after sepsis hospitalization and may serve as an important indicator of poor prognosis in sepsis. These findings highlight the potential of CCI in a wide range of patient populations. Notably, in the sensitivity analysis of this study, the association between CCI and mortality outcomes in patients with PI remained stable and similar after excluding patients who died within 3 days of ICU admission. In addition, based on the optimal cut-off value of 4.5 for CCI grouping, the results obtained were consistent with the results of the primary analysis, further validating the reliability of CCI for predicting mortality. Finally, 3-group sensitivity analyses on SOFA scores were performed, and consistent associations between CCI and mortality were observed in the higher quartiles, supporting the stability and consistency of the findings. These sensitivity analyses demonstrate the strong robustness of CCI in predicting mortality in patients with PI under different subgroups and assumptions.

This study successfully developed and validated an ML model incorporating CCI for predicting hospital mortality in patients with PI. A total of 10 features were selected by a combination of LASSO and other ML algorithms, of which CCI ranked high in all algorithms, indicating the importance of CCI in predicting hospital mortality. This is similar to previous studies, many of which have demonstrated the importance of CCI in predicting mortality in a variety of patient populations, particularly critically ill patients [11,54,55]. This result is also consistent with the results of our previous Cox regression analysis. The performance of the ML model, SOFA [57] and APS III score [58], was evaluated by several metrics such as confusion matrix, ROC curve, and F_1-score. It was found that the LightGBM algorithm outperformed other ML models, traditional SOFA and APS III scoring systems, achieving an AUC of 0.811 and an F_1-score of 0.895, demonstrating its excellent predictive ability. These results are consistent with a growing body of literature showing that LightGBM has significant advantages in clinical prediction tasks, for example, Chen et al [20] concluded that LightGBM models outperform ML models such as random forest and support vector machines in predicting mortality in critically ill patients with atrial fibrillation. Feature importance analysis further highlighted the critical role of CCI in predicting mortality. SHAP value analysis, an interpretable ML technique, revealed that increasing CCI was associated with a higher risk of death in patients with PI, a finding consistent with the known association between comorbidities and patient prognosis [11,59]. The biased dependency plot also confirmed that increasing CCI values were associated with an increased risk of all-cause hospital mortality, further confirming its clinical relevance. Interpretable ML provides a more transparent model decision process and helps clinicians better understand the impact of features on predicted outcomes [60,61]. Razo et al [23] constructed a predictive model using deep learning and obtained an AUC of 0.887. However, because the predictive goal of this model is different from that of our study, it is not possible to directly compare the performance of the 2 models.

Strengths and Limitations

This study has several important strengths. First, it provides validation that elevated CCI is an independent risk factor for short- and long-term mortality in critically ill patients with PI in a large US cohort. While prior studies have applied ML approaches to predict mortality in this population using the MIMIC database [23], our work extends these efforts by systematically evaluating the prognostic value of comorbidity burden as captured by the CCI. Second, this study methodologically advances by integrating CCI into a LightGBM-based ML framework and combining it with SHAP interpretability analysis. Finally, in practical terms, this web-based platform can be applied at the time of ICU admission to rapidly identify patients with PI at high risk of mortality, thereby supporting early triage, intensified monitoring, and timely interventions. By providing individualized risk estimates together with SHAP-based explanations, the tool not only enhances transparency of the prediction process but also

XSL•FO
RenderX

facilitates communication between clinicians and patients' families. Importantly, the model is designed to complement, rather than replace, physician judgment, and thus may serve as a practical decision-support tool within routine ICU workflows.

However, this study has some limitations. First, although a higher CCI was significantly associated with hospital, 28-day, and 90-day all-cause mortality in patients with PI, as a composite scoring tool, CCI still did not cover all clinical factors that may affect prognosis, such as B-type natriuretic peptide level, etiology of PI, individual patient differences, nutritional status, and cause of death. These factors not included in the analysis may have a significant impact on the risk of death, thus introducing a potential confounding bias. Second, given the retrospective design of this study, we could only identify associations between variables and not infer causality. Although there was a significant association between CCI and all-cause mortality, this does not mean that CCI was the direct cause of death. Third, CCI is mainly based on patients' past medical history and does not take into account dynamic changes during the course of the disease, which may lead to limitations in capturing the complexity of the disease and the comprehensiveness of prognostic assessment. Fourth, although the ML-based LightGBM model performed well in internal validation, the absence of external validation using independent datasets (eg, eICU or non-US cohorts) limits its generalizability to broader populations. Fifth, given the multiple disease states and comorbidities of patients with PI, the model may be overly dependent on certain specific variables, ignoring complex interactions that may affect prognosis. Although multiple characteristics were included, the interactions between disease progression and comorbidities may not have been adequately considered. Future studies should improve the modeling of interactions between variables and dynamic factors to improve the accuracy of prognosis prediction. Sixth, although mortality was used as the primary end point in this study, considering the complexity of the prognosis of patients with PI, a single mortality indicator may not be able to comprehensively assess the health status and quality of life of patients. Therefore, future studies should explore more dimensional prognostic indicators, such as functional recovery, quality of life, and long-term survival, to provide a more comprehensive prognostic assessment. In conclusion, although CCI and ML-based models show promise in predicting mortality in critically ill patients with PI, their limitations need to be fully recognized in practical applications and combined with external validation data and dynamic clinical information to improve their clinical use and accuracy.

Conclusions

This study demonstrated that higher CCI levels were strongly associated with hospital, 28-day, and 90-day all-cause mortality in patients with PI and were valuable in mortality risk stratification. Monitoring CCI levels in patients with PI in the ICU may be useful for early identification of high-risk patients and optimization of treatment strategies.

Acknowledgments

The authors gratefully acknowledge the use of the Medical Information Mart for Intensive Care IV database for this study. The authors extend their appreciation to the Massachusetts Institute of Technology Laboratory for Computational Physiology and the dedicated staff involved in the development and maintenance of this invaluable resource. The authors would also like to express their sincere gratitude to Song Wu from the Department of Statistics, Anhui University of Chinese Medicine, for his invaluable guidance and support throughout this research. This work was supported by the National Natural Science Foundation of China (grant 82174160), and the Anhui Province "14th Five-Year" Clinical Key Specialty Construction Recommendation Plan in Traditional Chinese Medicine Surgery (WWYM [2022] 105).

Data Availability

Data used in this study are publicly available from Medical Information Mart for Intensive Care IV

Abstract

Background: Kidney cancer remains a significant challenge in oncology, with accurate prognostic assessment being crucial for postoperative management. While radiomics has shown promise in cancer prognosis, there is limited research on comprehensive models that effectively integrate radiomic features with clinical parameters for kidney cancer survival prediction.

Objective: This study aimed to develop and validate a comprehensive computed tomography (CT) radiomics-based nomogram for predicting overall survival in postoperative patients with kidney cancer by integrating radiomic features with clinical parameters.

Methods: Radiomic features were extracted from regions of interest in CT images of 207 postoperative patients with kidney cancer. The eigenvalue data of all radiomic features were processed using *z* score standardization and the R software package *GLMNet*. We integrated survival time, survival status, and radiomic features and screened these features using the least absolute shrinkage and selection operator–Cox regression method. We conducted 10-fold cross-validation to obtain an optimal model of 5 radiomic features. Multivariate Cox regression hazard models were established to analyze patients' overall survival. The predictive ability of the nomogram (receiver operating characteristic curve and calibration curve) was evaluated using bootstrap resampling validation. Patients were divided into high- and low-risk groups based on the radiomic risk score cutoff value, and the Kaplan-Meier method was conducted to identify established models' forecasting ability. Five radiomic features were screened for predictive model construction.

Results: This retrospective analysis was conducted from April 2024 to July 2024 using data from The Cancer Imaging Archive public database. The final cohort included 207 patients (3 excluded from the initial 210) who underwent nephrectomy for kidney cancer. The median follow-up time was 33 (IQR 11-47) months. The receiver operating characteristic curve and area under the curve showed that the predictive model performed well. The calibration curve of nomogram and radiomic features in the cohort study set indicated an overall net benefit. Kaplan-Meier curves indicated that overall survival time was dramatically shorter in the high-risk group.

Conclusions: Our radiomics nomogram successfully integrates CT-derived radiomic features with clinical variables for kidney cancer survival prediction, demonstrating good prognostic capability and offering a noninvasive, quantitative tool for personalized postoperative management and clinical decision-making.

Introduction

Background

Kidney cancer is the most common malignant cancer of the urinary system, and nephrectomy is the standard treatment for locoregional kidney cancer [1]. Progress has been achieved through multiple optional methods of surgical resection and systemic therapies for kidney cancer [2]. However, overall survival (OS) and prognosis, especially if the cancer is detected at an advanced stage, remain unsatisfactory if the cancer is not treated optimally because of its high invasiveness, high mortality, and resistance to chemoradiotherapy [2,3]. Furthermore, the incidence of kidney cancer has been reported to have steadily increased in recent years [4-6]. The ability to predict the prognosis preoperatively and noninvasively is vital; however, patients who undergo nephrectomy still lack specific radiomic markers because of the complexity of disease progression and high heterogeneity. Radiomic markers that can facilitate predicting and monitoring the prognosis with good accuracy are urgently needed, after which a personalized strategy for clinical treatment needs to be provided. However, there remains limited research on comprehensive prognostic models that effectively integrate radiomic features with clinical parameters for kidney cancer survival prediction [7].

Radiomics is a rapidly developing field in which medical images are transformed into available radiological data and allows for efficacy monitoring, prognosis surveillance, microenvironment evaluation, and biological behavior assessment through quantitatively extracting features and facilitating in-depth characterization of tumor phenotypes beyond imaging interpretation [8-10]. Clinically, the postoperative prognosis of patients with cancer is frequently evaluated using the tumor-node-metastasis (TNM) classification system [11]. Recently, there has been an increasing focus on the application of computed tomography (CT) radiomics in kidney cancer, which has satisfactory potential in terms of lesion characterization, histological grade, and assessment of response to treatment [12-14]. Nevertheless, the correlation between radiomic features and the prognosis of patients with kidney cancer remains unclear, and further research is required to provide references for the clinical setting.

Objectives

To address this need, we developed a comprehensive radiomics-based nomogram that combines CT-derived features with clinical parameters for survival prediction in postoperative patients with kidney cancer. This integrated approach provides a practical tool for prognostic assessment and clinical decision-making.

Methods

Patient Selection and Clinical Data Collection

Data from 210 patients with kidney cancer were obtained from The Cancer Imaging Archive (TCIA) database [15]. Inclusion criteria were (1) pathologically confirmed kidney cancer, (2) having undergone nephrectomy, (3) available contrast-enhanced CT imaging data, and (4) complete survival follow-up data. Exclusion criteria were patients with an OS of 0 days (n=3). Our final cohort comprised 207 patients. Clinical characteristics collected included demographic data (age and gender), smoking history, comorbidities, tumor characteristics (pathology TNM stage, tumor histologic subtype, and tumor International Society of Urological Pathology grade), surgical parameters, and survival outcomes (vital status and survival time). To identify independent risk factors of OS, univariate and multivariate Cox regression analyses were conducted using the *survival* and *forest plot* packages in R (R Foundation for Statistical Computing).

Radiomic Datasets and Feature Extraction

Image Preprocessing

CT images were preprocessed using wavelet-based methods. Before feature extraction, all images were resampled according to a voxel size of $1 \times 1 \times 1$ mm^3 to ensure standardized spatial resolution across the dataset.

Region of Interest Definition

Presegmented regions of interest, including gross tumor volume (GTV) and healthy kidney regions, were obtained from the TCIA database annotations. All regions of interest were visually inspected for quality and anatomical accuracy to ensure appropriate boundaries for radiomic analysis.

Feature Extraction

Feature extraction was based on the 3D Slicer platform and was conducted using the PyRadiomics package [16]. A total of 851 radiomic features were extracted from the GTV and healthy kidney regions, including shape features (volume, surface area, and sphericity), first-order statistical features (mean, variance, skewness, and kurtosis), and texture features (gray-level dependence matrix [GLDM], gray-level co-occurrence matrix, neighboring gray tone difference matrix, gray-level size zone matrix, and gray level run length matrix). Wavelet-transformed features from different frequency decompositions were also extracted. The eigenvalue data of all radiomic features were processed using *z* score standardization to ensure comparability across different feature scales [17].

Feature Selection and Model Development

Feature Selection Rationale and Methodology

Least absolute shrinkage and selection operator (LASSO) regression was chosen for feature selection due to several advantages: (1) it effectively handles high-dimensional data with small sample sizes, which is common in radiomics studies; (2) it performs automatic feature selection by shrinking coefficients of less important features to 0; (3) it reduces overfitting risk through L1 regularization; and (4) it has been widely validated in survival analysis and radiomics research.

LASSO-Cox regression analysis was conducted using the *glmnet* package in R. We integrated survival time, survival status, and radiomic features from all 207 patients. The optimal regularization parameter (λ) was determined through 10-fold cross-validation using the minimum cross-validated partial likelihood deviance as the selection criterion. Features with nonzero coefficients at the optimal λ were selected for model construction.

XSL•FO
RenderX

Risk Score Construction and Stratification

A radiomic risk score was constructed using the linear combination of selected features weighted by their LASSO regression coefficients. The optimal cutoff value for risk stratification was determined using time-dependent receiver operating characteristic (ROC) curve analysis. Patients were then classified into high- and low-risk groups using this cutoff value.

Statistical Analysis and Model Validation

Model Development and Nomogram Construction

Univariate and multivariate Cox regression analyses were conducted on the entire cohort to identify independent prognostic factors using the *survival* and *forestplot* packages in R. Clinical variables with $P<.10$ in univariate analysis were included in multivariate analysis along with the radiomic risk score. A nomogram was constructed using the *rms* package incorporating significant variables from multivariate analysis.

Model Performance Evaluation

Model performance was assessed using multiple metrics following established methodologies for machine learning–based cancer prediction studies [18]: discrimination (time-dependent ROC curves and area under the curve [AUC] at 1, 2, 4, and 6 years using the *survivalROC* package), calibration (calibration plots comparing predicted vs observed survival probabilities), clinical utility (decision curve analysis to evaluate clinical net benefit), and risk stratification (Kaplan-Meier survival curves with the log rank test to compare survival differences between risk groups) [19,20].

Validation Strategy

Given the presegmented nature of the TCIA dataset, we used bootstrap resampling for model validation. The 10-fold cross-validation was specifically used during the LASSO regression phase to determine the optimal regularization parameter (λ) for feature selection. For final model validation, we performed 1000 bootstrap iterations on the entire cohort (N=207) to assess model stability and obtain CIs for performance metrics.

Statistical Software and Significance

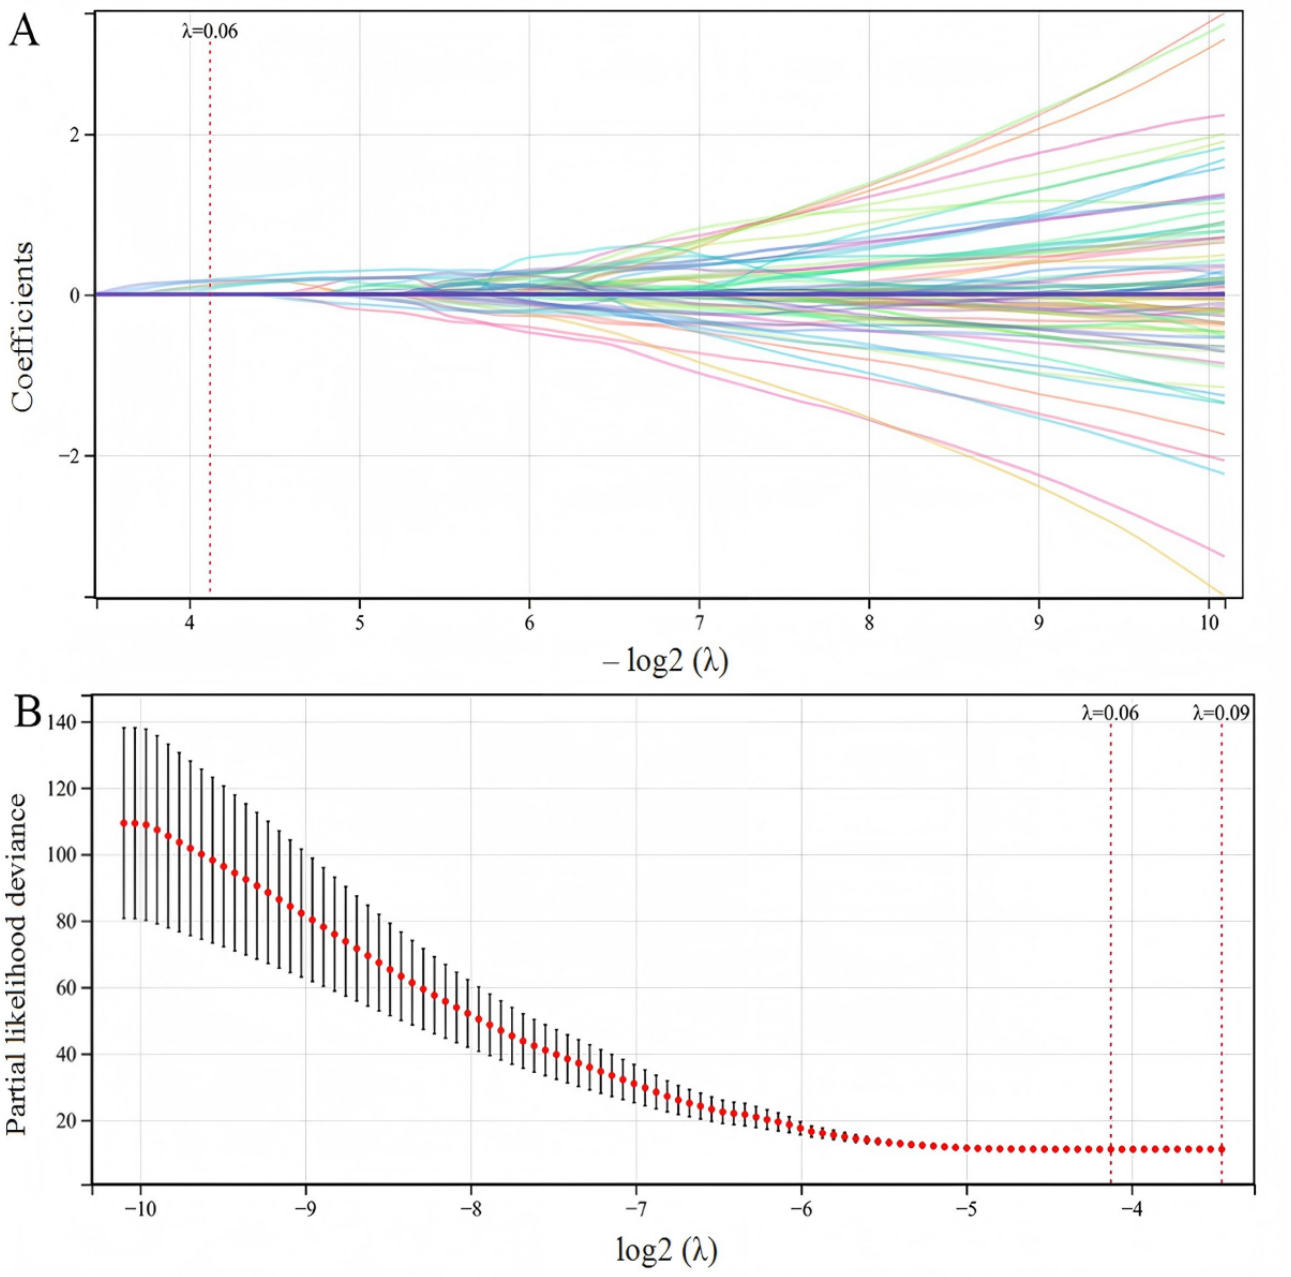
All analyses were conducted using the R software (version 3.6.3). A 2-sided $P<.05$ was considered statistically significant. Missing data were handled using complete case analysis.

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee of Jiangxi Cancer Hospital & Institute (2024ky057). As this study used publicly available databases, all data in this study have been anonymized or de-identified, so written informed consent from patients was not obtained.

Results

Clinical Data



This retrospective analysis was conducted from April 2024 to July 2024 using data from the TCIA public database. The final cohort included 207 patients (3 excluded from the initial 210) who underwent nephrectomy for kidney cancer. This study comprised 58.5% (121/207) male and 41.5% (86/207) female patients. The median follow-up time was 33 (range 1 - 102; IQR 11-47) months at the time of analysis.

Radiomic Feature Variable Selection

Five radiomic features were selected through LASSO-Cox regression analysis for OS prediction (Figure 1). The radiomic features included the following: kurtosis of first-order wavelet-LLH (H: high-frequency band; L: low-frequency band; GTV; feature 1), large-area high gray-level emphasis of the gray-level size zone matrix of wavelet-LHL (GTV; feature 2), dependence nonuniformity of GLDM of wavelet-HHL (healthy kidney; feature 3), long-run low gray-level emphasis of gray-level run length matrix of wavelet-LHL (GTV; feature 4), and large-dependence low gray-level emphasis of GLDM of wavelet-LLL (GTV; feature 5). The 5 selected radiomic features represent different aspects of tumor and tissue characteristics that may have clinical relevance. Texture features such as gray-level emphasis and dependence measures reflect tissue heterogeneity and organizational patterns, which may correlate with tumor biological behavior and aggressiveness. The inclusion of features from both tumor regions (GTV) and healthy kidney tissue suggests that both local tumor characteristics and the impact on surrounding normal tissue contribute to prognostic assessment. These features collectively capture quantitative imaging biomarkers that complement traditional clinical prognostic factors.

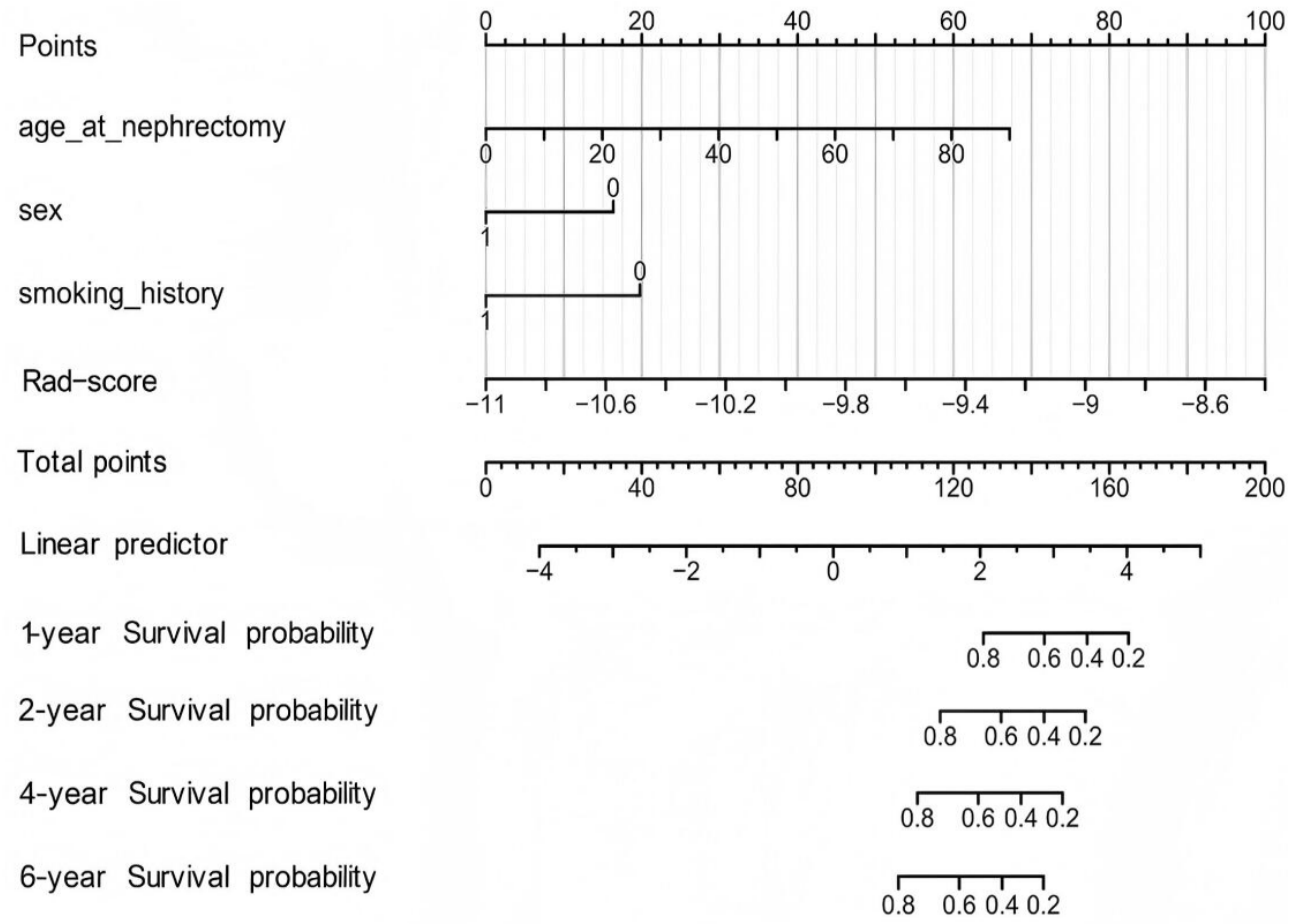
Table . Features 1 to 5, corresponding to different parameters for radiomics.

Feature number	CT[a] radiomics
1	Kurtosis of first-order wavelet-LLH (GTV[b])
2	Large-area high gray-level emphasis of GLSZM[c] of wavelet-LHL (GTV)
3	Dependence nonuniformity of GLDM[d] of wavelet-HHL (healthy kidney)
4	Long-run low gray-level emphasis of GLRLM[e] of wavelet-LHL (GTV)
5	Large-dependence low gray-level emphasis of GLDM of wavelet-LLL (GTV)

[a]CT: computed tomography.

[b]GTV: gross tumor volume.

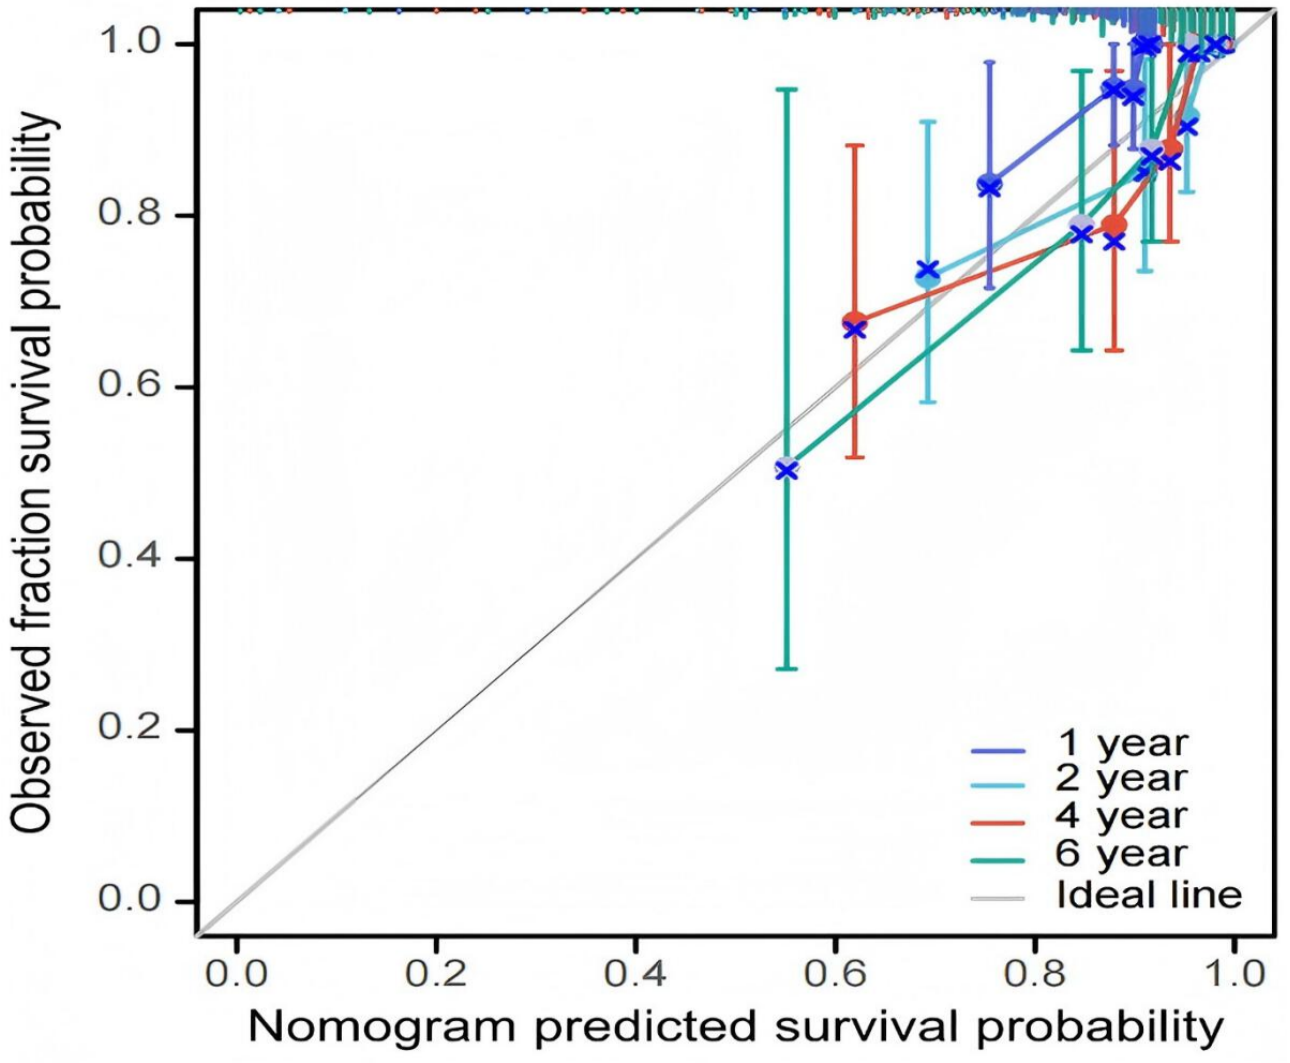
[c]GLSZM: gray-level size zone matrix.



[d]GLDM: gray-level dependence matrix.

[e]GLRLM: gray-level run length matrix.

Establishment of Nomograms and Prediction Performance of the Nomogram Models



As shown in Figure 2, based on identified radiomic features, after integrating the data on survival time, survival status, and 5 features, we established a nomogram using the Cox method to assess the prognostic significance of these features in 207 patients. As shown in Figure 3, all calibration curves showed good results for the study samples.

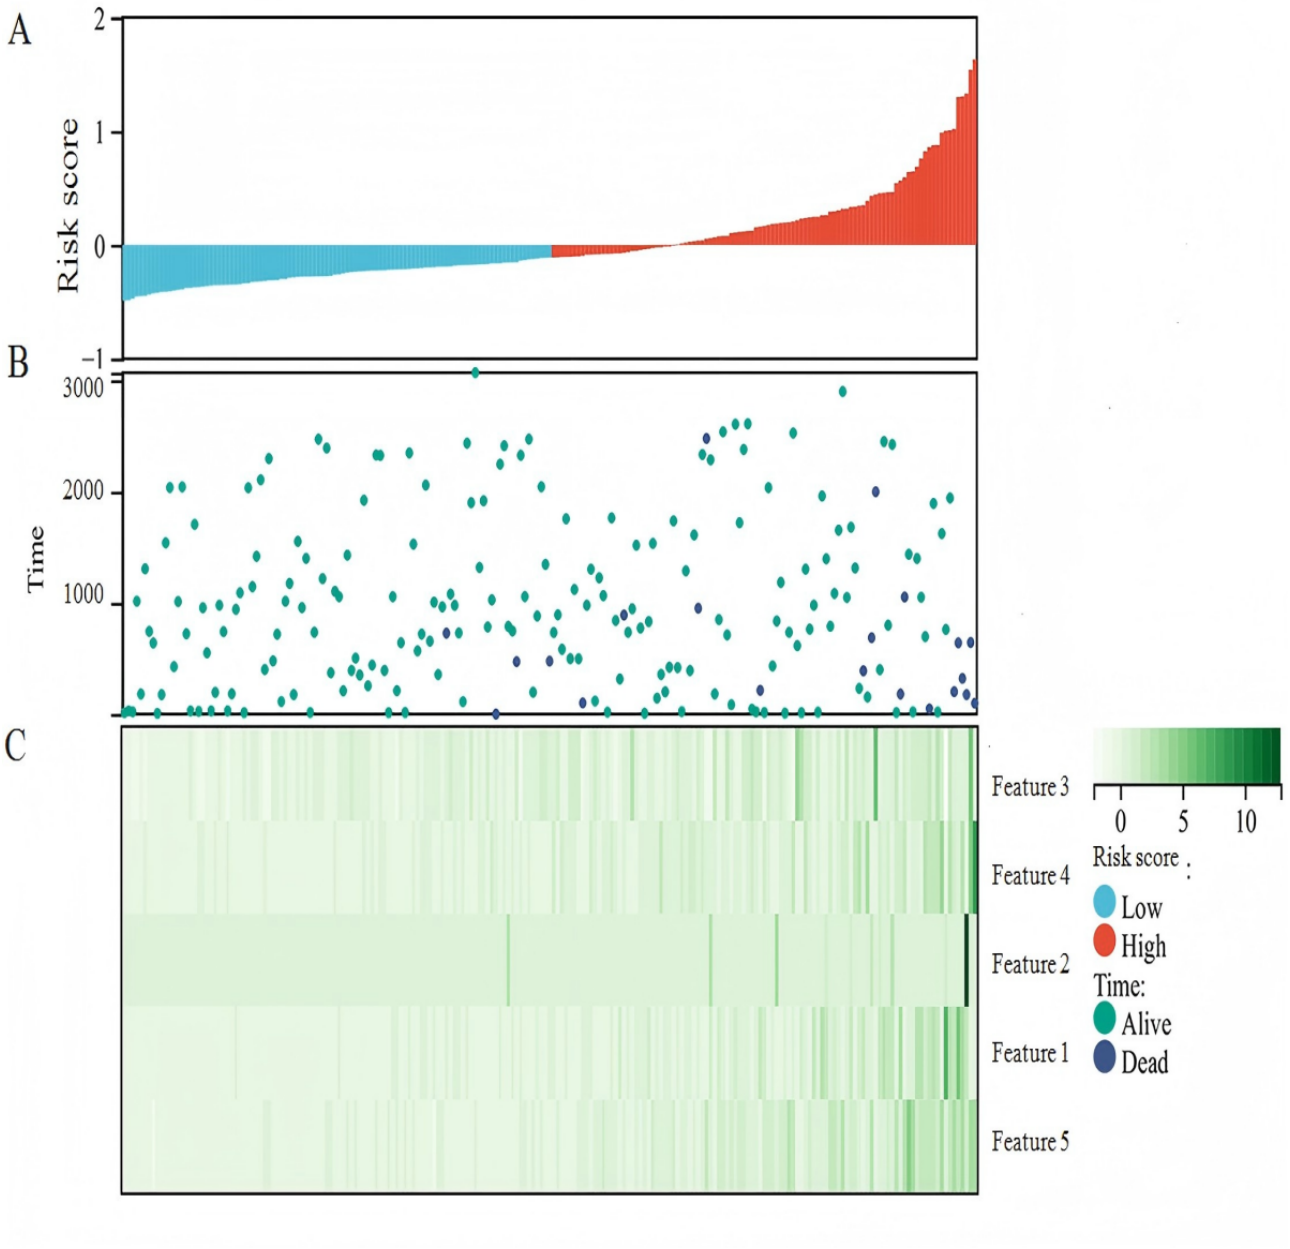
Figure 2. Nomogram prediction for 1-, 2-, 4-, and 6-year survival for patients with kidney cancer (entire cohort: N=207). Rad-score: radiomic risk score.

XSL•FO
RenderX

Figure 3. Kidney cancer overall survival nomogram calibration plots (entire cohort: N=207).

Model Validation Results

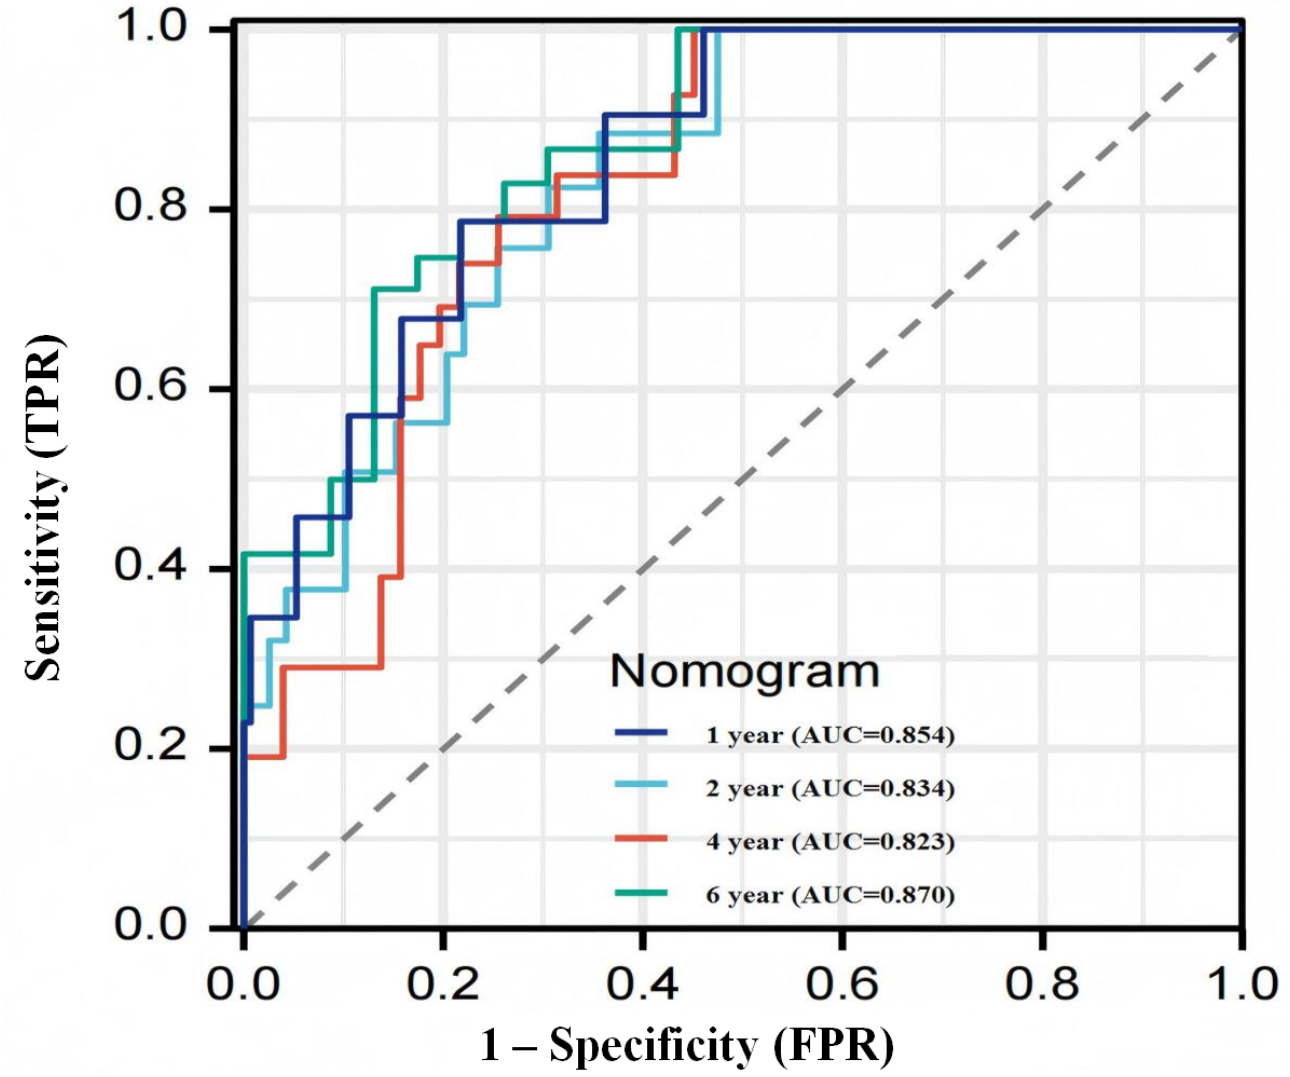
Bootstrap validation using 1000 iterations demonstrated robust model performance. The bootstrap-corrected AUC values were 0.80 (SD 0.03) for 1-year survival prediction, 0.77 (SD 0.04) for 2-year survival prediction, 0.74 (SD 0.04) for 4-year survival prediction, and 0.71 (SD 0.05) for 6-year survival prediction. The optimism-corrected concordance index was 0.73 (95% CI 0.68-0.78), indicating minimal overfitting.



Association Between Radiomic Features and Survival Prognosis

As shown in Figure 4, we analyzed the relationship between risk scores and patient outcomes across the entire cohort. The visualization clearly demonstrates that patients with higher risk scores experienced shorter survival times and higher mortality rates, as expected. The heat map pattern shows how the 5 radiomic features (features 1-5) collectively contribute to risk stratification, with distinct expression patterns between high-risk and low-risk patient groups. This risk score–based stratification effectively separates patients into clinically meaningful survival groups.

As shown in Figure 5, we used the time-varying ROC curve and AUC as the criteria for evaluating the nomogram. Figure 5 shows AUC of the model combining clinical features, and the radar score shows good performance.



XSL•FO
RenderX

Figure 4. Risk stratification visualization showing the relationship between radiomic risk score and patient survival outcomes (entire cohort: N=207). The upper panel displays the distribution of risk scores ranked by patient survival time. The middle panel shows survival time for each patient. The lower panel illustrates the expression patterns of the 5 selected radiomic features (features 1-5) contributing to the risk score calculation. Color coding indicates patient survival status and risk group classification (high-risk vs low-risk groups based on the optimal cutoff value).

Kaplan-Meier Survival Analysis

As shown in Figure 6, we divided the patients into low-risk and high-risk groups based on their radiomic characteristics. The cutoff value was 0.154921. The log rank test method was used to evaluate the significance of the prognostic difference between the groups, and a significant prognostic difference was observed (P<.001).

Discussion

Principal Findings

On the basis of publicly available data from the TCIA database, this study developed and validated prognostic nomogram models for patients with kidney cancer, and the results showed that our nomogram was advantageous for predicting patient prognosis. The nomogram could be useful for postoperative evaluation of patients with kidney cancer and development of individualized treatment plans. ROC and calibration curve results showed that the nomogram performed well in terms of noninvasive prediction of survival in patients with kidney cancer. The nomogram visually showed how to numerically quantify each factor for predicting survival in patients with kidney cancer. On the basis of our results, we observed good performance in terms of our radiomics characterization and the predict nomogram, suggesting that our model can be used to effectively predict the prognosis of patients with kidney cancer and create a robust decision-making framework for clinicians.

Comparison With Previous Work

The incidence of kidney cancer has been steadily increasing over recent decades, although the reasons for this remain unclear [1]. The annual incidence of kidney cancer has been increasing in both men and women [21]. However, patients with the same type of kidney tumors might have different prognoses owing to the complex internal structure and high heterogeneity within tumors. Complete resection or percutaneous core histopathology biopsy remains a standard invasive method for assessing prognostic indicators (ie, histological classification, grades, and stages) of kidney cancer to guide further treatment [21,22]. An objective and noninvasive approach is needed to evaluate and predict the clinical outcomes of patients with kidney cancer. CT plays a vital role in the diagnosis and prognosis of renal disease as it is noninvasive and convenient, especially compared with biopsy, surgery, and immunohistochemistry. Biopsy is not always necessary because imaging is a highly accurate method for characterizing renal malignancy [23]. Radiomics, which is a commonly used method to extract characteristics in terms of mass data from each medical image, can provide tumor characteristics and functions at both macroscopic and micromolecular levels [24]. Recently, several studies have explored the biological progress of kidney cancer via the

XSL•FO
RenderX

construction of radiomic models using CT images. Feng et al [25] and Kocak et al [26] showed that CT radiomics has the potential to predict the *BRCA1*-associated protein 1 mutation status in patients with kidney cancer. Ghosh et al [27] provided a radiomics-genetics pipeline that extracted 3D intratumor heterogeneity features from contrast-enhanced CT images and explored associations between features and gene mutation status. In 2001, a nomogram used to predict the 5-year survival of patients with kidney cancer was reported by Kattan et al [28]. The nomogram incorporated 4 factors: symptoms, histological subtype, tumor size, and TNM stage (1997 version) [28]. In 2018, Zhang et al [29] developed a nomogram specifically to assess the prognosis of patients with renal clear cell carcinoma postoperatively based on clinical data from 35,151 patients. However, several studies addressing the roles of immune profiles have encountered various uncertainties and have used constructed classification models to preoperatively identify pathological grades for patients with kidney cancer using machine learning–based CT radiomics with noninvasion [30-32]. Some studies have also shown the significance of CT radiomics in distinguishing kidney cancer from other renal mass diseases. Yang et al [33] developed various machine learning–based classification models to differentiate renal angiomyolipoma and kidney cancer, which performed well. Coy et al [34] reported the utility of machine learning in differentiating kidney cancer from oncocytoma on routine CT images using their models, which were able to accurately predict renal lesion histology on imaging. Meng et al [35] proposed a CT-based radiomic method to distinguish sarcoma from kidney cancer, with a good diagnostic performance. This is the first study to provide a predictive nomogram showing that radiomics can be used independently to predict prognosis in patients with kidney cancer. Our results indicated that our model could be a pivotal tool for the prognostic surveillance of kidney cancer.

Clinical Implications

Risk stratification with specific risk scores using a radiomic signature was accurately performed, and the predictive nomogram, which comprehensively integrated radiomic and clinical signatures, could effectively predict outcomes for patients with kidney cancer and facilitate decision-making for clinicians. The noninvasive nature of this approach makes it particularly valuable for routine clinical application, potentially reducing the need for invasive procedures while providing accurate prognostic information [36]. In clinical practice, the radiomics nomogram could be integrated into routine postoperative imaging review to guide surveillance intensity and treatment decisions. High-risk patients might benefit from more frequent monitoring or earlier intervention discussions, whereas low-risk patients could have less intensive follow-up schedules. The scoring system could be incorporated into existing hospital information systems using automated feature extraction, requiring minimal workflow changes for clinical staff.

Methodological Considerations

Our analytical approach evolved during the course of this study. Initially, we planned to use a traditional 70:30 train-test split for model development and validation. However, when we examined the TCIA dataset more carefully, we found that the presegmented images and the relatively small sample size (N=207) would result in insufficient power for robust model validation using a holdout approach, particularly for survival outcomes at multiple time points.

Therefore, we modified our approach to use the entire cohort (N=207) for model development, with bootstrap resampling for internal validation. This is a well-established alternative when sample sizes are limited, as recommended in radiomics guidelines [37]. Bootstrap validation provides robust performance estimates and CIs while maximizing the use of available data. Our results indicate acceptable model performance without significant overfitting.

This methodological adaptation underscores the importance of flexibility when working with real-world datasets and the need for transparent reporting of analytical decisions in radiomics research.

Limitations

This study had several limitations that should be acknowledged. First, our conclusions were based on data obtained from public databases, which inevitably have limitations due to patient selection characteristics and data availability constraints. To mitigate this limitation, we applied rigorous inclusion and exclusion criteria and standardized image preprocessing protocols. However, this may still affect the generalizability of our results. Future studies should incorporate multi-institutional datasets with standardized imaging protocols to improve data quality and external validity. Second, our study sample size was relatively small (207 patients with kidney cancer), which was insufficient for robust model development and validation. This limitation may affect the performance and efficiency of the predictive signatures and limit the statistical power of our analysis. Future research should aim to include larger, multicenter prospective cohorts to validate this predictive model and improve its reliability. Third, TNM staging was not selected as a clinical feature related to OS in this study because patients with hepatocellular carcinoma with portal vein tumor thrombosis are classified as being in the late clinical stage, which makes it challenging to predict OS using clinical staging as all patients have similar staging information. This may limit the comprehensive evaluation of traditional prognostic factors. Future studies should explore methods to better integrate staging information with radiomic features. Fourth, our model only explored tumor regions using imaging. To our knowledge, peripheral tumors provide biological information for prognosis monitoring, but we did not investigate peritumoral regions that might contain valuable prognostic information. Future research should explore the integration of peritumoral radiomic features to enhance predictive performance. Fifth, the TCIA dataset may introduce selection bias as cases were contributed by specific institutions with potentially different patient populations and referral patterns. In addition, heterogeneous CT imaging protocols across contributing institutions (scanner types, reconstruction algorithms, and contrast protocols) present challenges for radiomic feature standardization and reproducibility. These factors limit the direct clinical applicability of our model, requiring validation and potential

XSL•FO
RenderX

recalibration for different imaging protocols and patient populations before clinical implementation.

Future Directions

To advance radiomics-based prognostic modeling in kidney cancer, several key research directions should be prioritized. First, multicenter prospective validation studies using standardized imaging protocols are essential to establish the generalizability and clinical applicability of radiomics models across different institutions and patient populations. These studies should include larger collaborative cohorts (>500 patients) to improve statistical power and model reliability. Second, radiomics research should expand beyond tumor regions to systematically investigate peritumoral features and explore integration with clinical biomarkers to enhance predictive performance. In addition, focused investigation of patient subgroups, particularly those with shorter survival periods who may benefit most from accurate prognostic prediction, represents an important research priority. Finally, the development of automated radiomics workflows and real-time clinical decision support systems will be crucial for translating research findings into routine clinical practice and facilitating widespread adoption of radiomics-based prognostic tools [38,39].

Conclusions

We developed a triphasic contrast-enhanced CT–based radiomics nomogram that combined clinical factors and radiomic features. This nomogram demonstrated favorable predictive efficacy for differentiating kidney cancer postoperative outcomes. The model, combining CT-extracted radiomic features, showed good potential for evaluating OS in patients treated with nephrectomy and may facilitate clinical management and prognostic evaluation of postoperative patients with kidney cancer. As a noninvasive and quantitative method, the radiomics nomogram represents a promising tool for personalized medicine in kidney cancer management.

Data Availability

The datasets generated or analyzed during this study are available in The Cancer Imaging Archive database repository [15].

Authors' Contributions

QZ, YL, and HZ guarantee the integrity of this study. HZ, GH, and HP undertook the literature search. QZ and HZ were responsible for statistical analyses and manuscript editing. QZ, YL, and HZ are considered co–corresponding authors. All authors were involved in the study concepts, study design, data acquisition, data analysis and interpretation, manuscript drafting, manuscript revision for important intellectual content, approval of the final version of the submitted manuscript, agreement to ensure that any questions related to the work are appropriately resolved, and clinical studies. Author QZ is the co-corresponding author of this paper, affiliated with The Third People's Hospital of Jingdezhen, The Third People's Hospital of Jingdezhen affiliated to Nanchang Medical College, and can be reached at 394035513@qq.com. Author HZ is also the co-corresponding author of this paper, affiliated with Jiangxi Cancer Hospital & Institute, Jiangxi Clinical Research Center for Cancer, The Second Affiliated Hospital of Nanchang Medical College, and can be reached at 1761580890@qq.com.

Abstract

Background: Depression is a critical psychological disorder necessitating urgent assessment and treatment, given its strong association with increased suicide risk (SR). Effective management hinges on promptly identifying individuals with high depression severity (DS) and SR. While machine learning and deep learning have advanced the identification of DS and SR, research focusing on both aspects simultaneously remains limited and requires further refinement.

Objective: This study aimed to evaluate whether our proposed methods, which integrate multitask learning (MTL), multimodal learning, and transfer learning, enhance the efficacy of deep learning models in the joint classification of DS and SR.

Methods: This study proposed a multitask framework employing a multimodal fusion strategy for pretrained audio and text embeddings to concurrently assess DS and SR. Data encompassing Chinese audio recordings and clinical questionnaire scores from 100 patients with depression and 100 healthy controls were used. Preprocessed audio and text data were transformed into pretrained embeddings and integrated using concatenation and hard parameter sharing. Single-task learning (STL) models (DS and SR tasks) were evaluated with different embeddings and further compared with the MTL models.

Results: The STL models demonstrated exceptional DS prediction (area under the curve [AUC]=0.878) using wav2vec 2.0 combined with ERNIE-health, and SR prediction (AUC=0.876) using HuBERT combined with ERNIE-health. The MTL models significantly improved SR prediction over DS prediction, achieving the highest DS classification (AUC=0.887) with wav2vec 2.0 combined with ERNIE-health, and SR classification (AUC=0.883) with HuBERT combined with ERNIE-health.

Conclusions: The findings of this study underscore the effectiveness of the proposed MTL models using specific pretrained audio and text embeddings in enhancing model performance. However, we advocate for cautious implementation of MTL to mitigate potential negative transfer effects. Our research presents a method that is both promising and effective, offering an objective approach for accurate clinical decision support in the parallel diagnosis of DS and SR.

Introduction

Background

In its pervasive embrace, depression, an ever-expanding mental malady, reaches across the globe, leaving its mark on approximately 280 million lives [1]. Neglecting proper care of patients with depression can lead to dire consequences, as research has shown that individuals with this condition face a staggering 20-fold higher risk of suicide than the general population [2,3], exposing a troubling link between depression and suicide [4-6].

XSL•FO
RenderX

In clinical practice, regular and comprehensive assessments of depression severity (DS) and suicide risk (SR) remain challenging due to time and resource constraints [7,8]. Traditional evaluations often rely on subjective and infrequent self-reports from patients or caregivers, which are susceptible to recall bias, cognitive limitations, and social stigma [9,10]. These issues are particularly acute in high-volume settings, where limited consultation time may hinder the timely identification of critical warning signs related to mental health deterioration or suicidal ideation.

Machine learning has demonstrated strong potential in predicting DS and SR, using text and audio data (eg, [11,12]). Text-based approaches have extracted clinically meaningful insights from medical narratives [13,14], while speech analysis has improved predictive accuracy by identifying vocal biomarkers linked to depression and suicide, such as reduced intensity, slower tempo, and increased hesitation [15-17]. These advances have driven the development of multimodal learning (MML) frameworks for mental health prediction. Although effective in detecting depression [18,19], applications of MML to SR prediction remain limited—likely due to the scarcity of high-quality annotated data in this sensitive domain [20,21].

Given the frequent co-occurrence of depression and suicide in clinical populations [22-24], SR prediction is inherently linked to depression assessment. This conceptual interdependence highlights the potential of multitask learning (MTL) for simultaneously modeling related mental health outcomes. Benton et al [25] demonstrated the utility of MTL by jointly predicting SR and other psychiatric conditions using social media data. With the rapid advancement of deep learning, transfer learning (TL) has also emerged as a promising strategy to address data scarcity, with recent studies showing that fine-tuning pretrained models on downstream mental health tasks can significantly enhance predictive performance (eg, [26,27]).

However, the current literature reveals several gaps. First, data source diversity remains limited, with most studies relying on datasets from English-speaking populations (eg, [28,29]). In addition, many analyses are based on social media platforms (eg, [25,30]) or public datasets (eg, [27,31]), which often lack clinical relevance. Second, most SR prediction studies have underutilized TL for audio processing, despite its successful application in related domains such as speech emotion recognition [32,33]. Third, although the comorbidity and shared clinical features of DS and SR are well documented [22-24], few studies have applied MTL to model these outcomes jointly. While recent advances in MML and MTL have shown promise in mental health prediction, few studies have jointly modeled DS and SR using clinically grounded, non-English data. Furthermore, the potential of TL to improve model generalizability across tasks and modalities remains underexplored in Chinese-language clinical contexts. These gaps motivate this study's unified framework, which integrates MML, MTL, and TL to support scalable and efficient mental health screening in real-world clinical settings for Chinese-speaking populations.

The key contributions of this work are three-fold: (1) the development of the first integrated framework that combines MML, MTL, and TL for the joint prediction of DS and SR in Chinese contexts; (2) empirical validation of MML approaches compared to single modality baselines in a non-English clinical setting; and (3) demonstration of the effectiveness of MTL in modeling related mental health constructs. By addressing linguistic, cultural, and resource-specific challenges, this framework supports scalable and efficient screening in high-volume clinical environments, addressing an urgent need in early mental health assessments and targeted interventions.

Related Work

Research on predictive models in mental health has traditionally adopted single-task approaches, predicting either depression or suicide independently [34-38]. These studies have primarily relied on text, audio, or other features, such as structured electronic health records [39] and social media images [40], to build predictive models. Recent advancements in text processing technologies have facilitated a shift from conventional hand-crafted features toward sophisticated automated feature learning approaches, exemplified by the heterogeneous graph convolutional network of Wang et al [14]. Concurrently, speech-based analyses have gained prominence for their capacity to capture nuanced vocal markers indicative of mental health conditions [11,15].

MTL has emerged as a promising framework for mental health assessment, as summarized in Table 1, aligning with the clinical observation that psychiatric conditions often co-occur and share common underlying mechanisms [22-24]. By jointly learning related tasks, MTL facilitates representation sharing and information transfer, thereby mitigating data sparsity and overfitting issues [41-43]. Benton et al [25] pioneered the use of deep neural networks to simultaneously predict depression and SR using Twitter data.

et al [31], for example, demonstrated enhanced depression prediction accuracy using long short-term memory models trained on combined textual and acoustic features from the DAIC-WOZ (distress analysis interview corpus-Wizard of Oz) dataset. Additionally, TL has also been increasingly adopted in these frameworks to address the challenge of limited labeled data. Teng et al [26] applied depression detection with sentiment assistance through deep neural networks and TL techniques on the AVEC (audio/visual emotion challenge) 2019 DDS Challenge and CMU-MOSEI (CMU multimodal opinion sentiment and emotion intensity) datasets. Similarly, Yang et al [27] used MTL with a BERT-based model to incorporate time-perspective cues for suicidal ideation detection on the CEASE dataset.

Despite these advances, key limitations persist. First, most studies rely on English-language data. Furthermore, text-based models are often trained on social media content [25,30,45], while audio models rely on public datasets [26-29,31,44,46] that may lack relevance to real-world clinical scenarios, thereby potentially limiting their applicability. Second, most SR prediction models are still trained from scratch, with only a few studies (eg, [27]) leveraging TL to enhance model performance. Most critically, empirical research exploring MTL's effectiveness for simultaneously predicting both DS and SR remains scarce. To our knowledge, only Benton et al [25] have conducted similar research, though their work was conducted exclusively in English on social media data.

To address these gaps, this study introduces a unified MML, MTL, and TL framework for the simultaneous prediction of DS and SR using Chinese-language data collected in clinical settings. This approach facilitates the development of culturally and linguistically tailored predictive models for Chinese-speaking populations. Moreover, by incorporating TL, the proposed framework retains knowledge acquired from source tasks, enabling efficient adaptation to downstream applications.

Methods

Ethical Considerations

This study received approval from the Institutional Review Board of Taichung Veterans General Hospital (approval number: SE21183B).

Every participant was required to complete and sign a participant consent form before their involvement. This form outlined the purpose and procedures of the study, potential risks and benefits, confidentiality measures, and voluntary participation rights. The completion of this form indicated their informed and voluntary consent to partake in the study. In the section of the participant consent form dedicated to "consent to participate," participants were explicitly informed about the inclusion of a clause seeking their agreement to employ their personal data, information, or research outcomes for publication purposes. By completing and signing the participant consent form, participants signified their understanding and acceptance of the terms outlined, thereby granting their "consent for publication." This agreement encompassed the use of their anonymized data and contributions in academic papers, reports, presentations, or other forms of scholarly dissemination.

Study Population

We collected a Chinese chief complaint dataset, which includes data from 100 patients with depression from a regional hospital in southern Taiwan, along with 100 age- and sex-matched nondepressed counterparts selected at random, resulting in a total of 200 cases. To verify the matching process, we conducted tests. The chi-square test for gender in relation to the prevalence of the condition was not significant (P=.88). Similarly, the t test for age in relation to the prevalence of the condition was not significant (P=.60).

Each case in the dataset includes personal data, an audio recording describing the current situation, transcripts, and clinical questionnaire results. The audio recordings were acquired by instructing participants as follows: "Please take a minute to elucidate your recent emotions, life circumstances, and other states." Subsequently, participants initiated the recording of their spoken expressions. Based on the questionnaire results, we conducted 2 specific clinical assessments: Hamilton Depression Rating Scale-17 (HAMD-17) [47] and SAD PERSONS scale [48]. DS was categorized into 3 levels: no depression (HAMD-17 score of 0 - 7; sample size of 106), low/moderate depression (HAMD-17 score of 8-16/17-23; sample size of 21), and high depression (HAMD-17 score of ≥24; sample size of 73). SR was classified into 2 levels: low risk (SAD PERSONS score of 0 - 3; sample size of 110) and moderate/high risk (SAD PERSONS score of 4-7/8-10; sample size of 90).

The demographic data for both groups can be found in Tables 2 and 3. In the 3 DS groups, there were statistically significant differences between the 2 study groups regarding age (P=.048), educational level (P<.001), occupation (P=.01), and marriage (P=.001). In terms of educational level, the HAMD-17≤7 group exhibited higher levels compared to the 8<HAMD-17≤23 and HAMD-17≥24 groups, and the proportion of individuals employed was also higher in the HAMD-17≤7 group than in the 8<HAMD-17≤23 and HAMD-17≥24 groups (64/97, 66% vs 13/30, 43% and 33/73, 45%). In terms of marital status, the HAMD-17≤7 group had a higher proportion of married individuals and a lower proportion of divorced individuals. In the 2 SR groups, there were statistically significant differences between the 2 study groups regarding educational level (P<.001), occupation (P=.02), and marriage (P<.001). In terms of educational level, the SAD PERSONS≤3 group exhibited higher levels compared to the SAD PERSONS≥4 group. In terms of occupation, the proportion of individuals was also higher in the SAD PERSONS≤3 group than in the SAD PERSONS≥4 group (69/110, 62.7% vs 41/90, 45.6%). In terms of marital status, the SAD PERSONS≥4 group had a higher proportion of unmarried individuals.

Proposed Framework

The framework comprises 3 components: feature extraction, multimodal fusion, and MTL architecture, which are discussed sequentially in the following sections (Figure 1). First, audio and text data undergo processing by pretrained models to extract their embeddings. Second, the embeddings obtained from the previous step are fused using a modality fusion layer. The resulting fused representations are then fed into a fully connected (FC) network to project them into lower-dimensional vectors. Lastly, these representations are shared between the 2 classification tasks (DS and SR) and are input into 2 task-specific layers implemented as multilayer perceptron classifiers to generate output probabilities separately. The details of the 3 components are presented below.

Figure 1. Overview of our proposed framework. FC: fully connected.

First, considering the small sample size in our study and recognizing the potential of TL in predicting DS and SR, we used 4 advanced pretrained models for feature extraction: wav2vec 2.0 and HuBERT for audio analysis [49,50], and Longformer and ERNIE-health for text analysis [51,52]. Each method has distinct advantages, rendering them especially suitable for our research objectives, as elaborated upon in the following sections.

- wav2vec 2.0: It is developed by Facebook AI Research, uses a multilayer convolutional neural network (CNN) for audio encoding, and is supplemented by latent representation masking and contextualization through a Transformer network trained with contrastive learning methods [49]. This self-supervised model excels with minimal labeled data, consistently surpassing state-of-the-art models, as demonstrated in the tasks of depression detection [52] and emotion recognition [53].
- HuBERT: It extends self-supervised learning to audio data, using a CNN for encoding and a BERT encoder for contextualization, enhanced by masked prediction and cluster refinement [50]. HuBERT has demonstrated superior performance in audio classification tasks for detecting depression [54] and assessing cognitive function [55].
- Longformer: It stands out as a transformer-based language model designed to capture extended dependencies using sliding window and global attention mechanisms [51]. This design enables Longformer to effectively integrate local and global information while mitigating challenges associated with traditional attention mechanisms.
- ERNIE-health: It is a Chinese biomedical language model tailored for biomedical text processing, enhancing tokenization and comprehension of biomedical content through in-domain text [56]. ERNIE-health consistently outperforms other models across various biomedical tasks [57], underscoring its effectiveness in this domain.

Second, these pretrained models were used to generate audio embeddings, xa, and text embeddings, xt, by feeding the preprocessed audio recordings and transcripts as their inputs. To combine the information from text and audio modalities, we adopted the early fusion approach by concatenating the audio embedding (xa) and text embedding (xt) into a single vector (x), using Eq. (1). This fusion strategy, also known as feature-level fusion, is characterized by its simplicity, its computational efficiency, and the potential to capture intricate interactive details. We adopted this approach due to its aforementioned advantages and its ability to circumvent the risk of information overlap or cancellation inherent in more complex operations such as addition, deduction, inner product, and outer product. This approach has been widely used in prior studies on audio-text fusion, consistently yielding improved accuracy [58-60].

(1)x=xa⊕xt

Lastly, our proposed framework adopted the hard parameter sharing scheme for MTL of DS and SR classification using deep learning. This scheme involves a shared encoder with multiple task-specific decoding heads [46]. This MTL technique enables our framework to learn multiple related tasks simultaneously while improving the generalization performance. In our framework, an FC network acts as the shared encoder, and dense layers act as the task-specific heads. The FC network f learns a condensed representation x` from the fused input x, as shown in Eq. (2). Subsequently, a softmax function is applied to 2 task-specific dense layers, gd and gs, to transform x` into output

XSL•FO
RenderX

probabilities for DS classification (Eq. (3)) and SR classification (Eq. (4)), respectively.

(2)x`=fx

(3)y^d=Softmax(gd(x′))

(4)y^s=Softmax(gs(x′))

In the context of an MTL model, the design of loss functions for multiple objectives is crucial. Instead of using weighted sum of loss functions, which can be influenced by weights and time-consuming to determine, we adopted the automatic weighted loss approach introduced by [47]. This method considers the homoscedastic uncertainty of each task and derives appropriate weights based on task uncertainties. Tasks with higher uncertainties are assigned lower weights, allowing the model to effectively learn across tasks in a more balanced manner.

For the loss calculation, our proposed method involves a 2-stage approach. In the first stage, we compute task-specific losses, Ld and Ls, for DS and SR tasks, respectively, using cross entropy, as described in Eq. (5) (C represents the number of labels in the corresponding task). In the second stage, the total loss, Ltotal, is determined using the automatic weighted loss method proposed by [47], as depicted in Eq. (6). The goal is to minimize the total loss, enhancing the model's performance in DS and SR classification tasks, which can enable effective learning from the data and accurate predictions for both tasks.

(5)L=−∑i=1Cyi·log (y^i)

(6)Ltotal=12σd2Ld+12σs2Ls+log σd2+log (σs2)

Implementation Details

We implemented our approach using PyTorch [61] and the Transformers library from Hugging Face [62]. Pretrained models were loaded by specifying the model version string in the application programming interface. Refer to Table S1 in Multimedia Appendix 1 for details of the Chinese versions of the 4 models selected for this study.

To extract features from the audio and text modalities, we configured several parameters. The audio features were generated with a sampling rate of 16,000 and a duration of 6.25 seconds, resulting in a 100,000-dimensional feature. For the text modality, transcripts were tokenized into a fixed length of 512 tokens, with truncation or padding applied if necessary. The audio features were then transformed into 1024-dimensional embeddings, while the tokenized text inputs were represented as 768-dimensional embeddings.

To prevent overfitting during training, batch normalization and rectified linear unit activation were applied to linear layers that did not act as classifiers. A batch size of 8 was used, and the models were trained for 20 epochs with an early stopping patience of 3. Cross-entropy was used to calculate the loss for single-task learning (STL), while automatic weighted loss was used for MTL. The AdamW optimizer was used for optimizing the losses. The parameter details for each model, including the modality used (single or multiple) and the learning architecture adopted (single task or multitask), are presented in Table 4.

Table . Parameter settings.

Parameter	SMSTL[a]	MMSTL[b]	SMMTL[c]	MMMTL[d]
Epochs	20	20	20	20
Early stopping patience	3	3	3	3
Batch size	8	8	8	8
Learning rate	0.0005	0.0005	0.0005	0.0005
Warmup ratio	0.3	0.35	0.35	0.25
Dropout probability	0.2	0.1	0.1	0.1

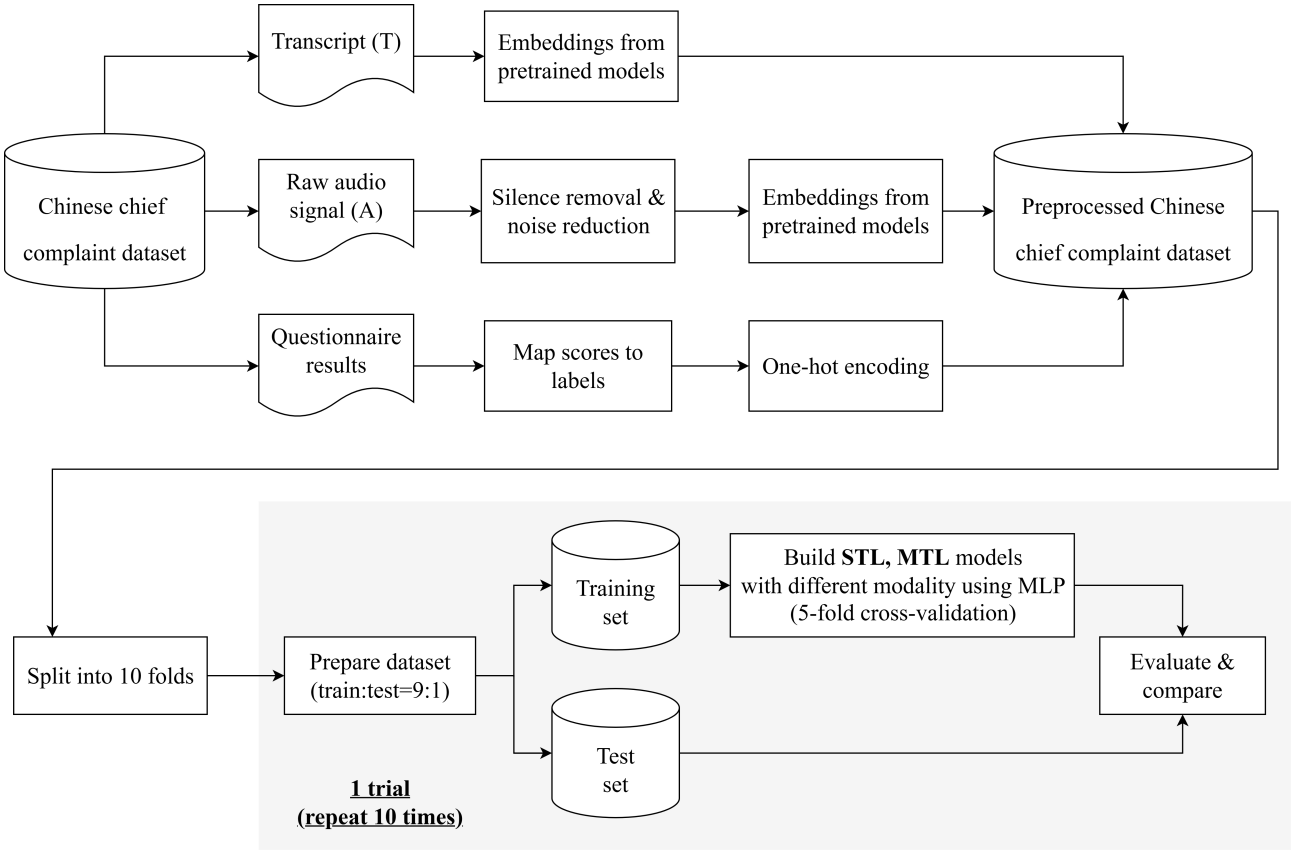
[a]SMSTL: single modality with single-task learning.

[b]MMSTL: multimodal with single-task learning.

[c]SMMTL: single modality with multitask learning.

[d]MMMTL: multimodal with multitask learning.

Experimental Evaluation



Our proposed framework is built using the 3 data types in the dataset: audio recordings, transcripts, and questionnaire results, as shown in the flow diagram in Figure 2.

During preprocessing, the audio data underwent 3 steps: removal of file-edge silence, denoising using Podcastle [63], and feature extraction. We used Podcastle's Magic Dust AI technology for its advanced denoising capabilities, which integrate spectral filtering, adaptive noise cancellation, and machine learning algorithms [64]. Specifically, we used the "noise reduction" mode to automatically detect and suppress nonstationary background noises, such as coughs, sniffles, and microphone taps, while preserving speech clarity and signal integrity [65]. This step minimized noise-related distortions prior to feature extraction and analysis.

Feature extraction was then applied to both audio and text data using pretrained models, yielding their respective embeddings as described earlier. The processed dataset was partitioned into 10 subsets for cross-validation, with 1 subset used for testing and the remaining 9 for training in each fold. Final performance metrics were averaged across all 10 trials. In parallel, questionnaire responses were one-hot encoded to represent discrete class labels, serving as the output variables for prediction.

XSL•FO
RenderX

Figure 2. Flow diagram. MLP: multilayer perceptron; MTL: multitask learning; STL: single-task learning.

Our study consisted of 3 experiments. In experiments 1 and 2, we built STL models for DS and SR tasks, using different combinations of embeddings. The primary aim was to identify the best pretrained models for extracting text and audio embeddings in each task and assess the advantages of using multimodal data compared to unimodal data for each task. In experiment 3, we developed several MTL models with hard parameter sharing to combine information from both tasks. The performance of these MTL models was then compared to the STL models from experiments 1 and 2, providing insights into the potential benefits of MTL for the 2 tasks.

Performance Measure

To assess the effectiveness of our classification models, we used a range of standard metrics, including accuracy, recall, precision, specificity, F_1-score, and area under the curve (AUC). These metrics were derived from the confusion matrix, with AUC serving as the primary metric for comprehensive performance evaluation. In cases where the difference in AUC between models was not significant, we also considered other metrics, such as accuracy, F_1-score, and recall, to ensure a thorough assessment of model performance.

In the SR prediction task, the positive class (eg, “at risk”) encompassed individuals with a moderate or high risk of suicide, as detailed earlier. In contrast, for the DS prediction task, the models’ performance across all classes (eg, none, low/moderate, and high) was evaluated using the macro-average approach, rather than focusing solely on a specific positive class.

Results

Experiment 1: STL Models for DS Prediction

In experiment 1, we aimed to find the best STL model for DS classification by using various pretrained embeddings to differentiate between the 3 severity levels. These models employed a multilayer perceptron classifier for classification and were categorized into audio-only, text-only, and combined audio and text modalities based on the embeddings used. The classification performance of these DS prediction models on each metric is presented in Figure 3.

XSL•FO
RenderX

Regarding DS prediction models, we obtained several findings (Figure 3). First, the results demonstrated that most embeddings, except those of the audio modality, performed well in terms of AUC, with scores exceeding 0.8. In the audio modality, the wav2vec 2.0 embedding outperformed the HuBERT embedding. In the text modality, the ERNIE-health embedding demonstrated superior performance in terms of AUC (0.877), accuracy (0.780), recall (0.609), and specificity (0.868), indicating its effectiveness in capturing specific aspects of DS in textual data. Second, combining embeddings from different modalities led to improvements across all metrics for most embeddings. Notably, the addition of the ERNIE-health embedding to the HuBERT embedding resulted in a substantial performance boost, with an 11.5% increase in AUC and up to 27.79% improvement in precision. Third, our comprehensive evaluation of multiple metrics showed that the multimodal models outperformed the single-modality models, except for the combination that included the HuBERT embedding, which may impair the ability of text embeddings. Lastly, among all the embeddings analyzed, the wav2vec 2.0+ERNIE-health and wav2vec 2.0+Longformer embeddings achieved the highest AUC scores of 0.878 and 0.873, respectively.

Experiment 2: STL Models for SR Prediction

In experiment 2, our objective was to identify the best STL model for SR classification by using different pretrained embeddings. Similar to experiment 1, multilayer perceptron classifiers were used to analyze the embeddings from different modalities. The evaluation results of these embeddings for SR classification are presented in Figure 3.

Based on the data presented in Figure 3, regarding SR prediction models, several findings were obtained. First, the results demonstrated that most embeddings achieved AUC values greater than 0.8, except for audio modality embeddings and the Longformer embedding. In the audio modality, the HuBERT embedding outperformed the wav2vec 2.0 embedding on most metrics, except for precision and specificity. This suggests that the HuBERT embedding may be a better choice for overall SR classification, while the wav2vec 2.0 embedding may be more effective in correctly identifying individuals who are not at risk of suicide. In the text modality, the ERNIE-health embedding outperformed the Longformer embedding, obtaining higher values on all metrics, indicating that the ERNIE-health embedding is more effective for SR classification. Second, combining embeddings from different modalities consistently improved AUC, precision, and specificity. Specifically, incorporating multimodal embeddings led to significant performance improvements, with increased AUC (2.28% to 15.60%), precision (3.32% to 20.81%), and specificity (2.73% to 10.19%) across all single-modality models, indicating improved accuracy in identifying nonrisk individuals. Third,

XSL•FO
RenderX

the HuBERT+ERNIE-health embedding achieved the highest performance in terms of AUC (0.876) among all embeddings.

Experiment 3: MTL Models for DS and SR Predictions

In experiment 3, we aimed to explore the potential of MTL models in improving DS and SR predictions by leveraging shared information between the 2 tasks. Figure 4 provides a comprehensive summary of the performance metrics, and the subsequent content further discusses the results of experiments 1 and 2 for comparison.

Figure 4. Performance comparison of multitask learning models for depression severity (DS) and suicide risk (SR) prediction. Performance metrics are presented as a heatmap, where color gradients reflect the relative magnitude of values, ranging from red (lower values) to green (higher values). A: audio only; A+T: combined audio and text; ACC: accuracy; AUC: area under the curve; E: ERNIE-health; F_1: F_1-score; H: HuBERT; L: Longformer; P: precision; R: recall; S: specificity; T: text only; W: wav2vec 2.0.

		H+L	0.821	0.720	0.697	0.697	0.706	0.733

From Figures 3 and 4, we found that all models, except the ones using the wav2vec 2.0+Longformer embedding, demonstrated an increase in AUC ranging from 0.25% to 3.88% with MTL, indicating the potential of MTL in enhancing performance for DS. Additionally, we observed that when adopting MTL for SR prediction, all models, except for the wav2vec 2.0+ERNIE-health and HuBERT+Longformer embeddings, demonstrated an increase in AUC ranging from 0.96% to 10.18%. On the other hand, what stands out is that when applying the MTL framework, there was a consistent enhancement in accuracy, F_1-score, and recall among the combined audio and text models, including the aforementioned 2 models using the wav2vec 2.0+ERNIE-health and HuBERT+Longformer embeddings. These findings suggest that combined audio and text embeddings are well-suited for the MTL approach, although they may increase false positives while better identifying individuals at risk for suicide.

Discussion

Principal Findings

This study proposes a multitask framework that integrates a multimodal fusion strategy using pretrained audio and text embeddings to concurrently assess DS and SR. The efficacy of the proposed method has been validated using real-world clinical data.

Some of the significant findings of this study are as follows. First, we introduced and investigated renowned pretrained models for their effectiveness in audio and text classification tasks. The findings demonstrated that the ERNIE-health text modality embedding, specifically trained on a medical corpus, consistently outperformed the Longformer text modality embedding in both STL models (for DS prediction and SR prediction) and MTL models. On the other hand, the wav2vec 2.0 audio modality embedding performed better than the

XSL•FO
RenderX

HuBERT embedding in STL models for DS prediction and MTL models for both tasks, but performed worse than the HuBERT embedding in STL models for SR prediction.

Second, our results underscore the effectiveness of multimodal approaches over single-modality ones in classifying DS and SR in the majority of cases. Even straightforward fusion techniques, such as concatenation, improve performance by integrating richer information, consistent with previous research [30,31,66]. This implies that the combination of audio and text embeddings provides a more comprehensive representation of the underlying phenomena than using each modality independently.

Third, the results indicated that the performance of text modality models significantly surpassed that of audio modality models, except in MTL models using the Longformer embedding for SR prediction. Several potential explanations can be considered for this observation. Despite preprocessing efforts to reduce noise, the audio modality model remains susceptible to variations in speaker accents or weaker emotional expressiveness [67], which can adversely affect the model's performance. In contrast, text data are not influenced by such variations. Additionally, techniques for processing and embedding text data are highly advanced, such as ERNIE-health, which can contribute to the superior performance of most text modality models. This demonstrates that ERNIE-health can effectively bridge the gap between pretraining goals and downstream tasks [56]. Conversely, processing and feature extraction for audio data in our dataset may not be as efficient as for text embeddings. Furthermore, research indicates that suicidal tendencies and depressive symptoms are explicitly conveyed through syntactic and semantic patterns in text, which are efficiently captured by text embeddings [68]. On the contrary, extracting and interpreting these signals from audio data are inherently more complex and less robust.

Fourth, our findings demonstrated that the proposed MTL framework, using specific pretrained audio and text embeddings, significantly enhanced the classification performance for DS and SR. Considering the common class imbalance in clinical datasets, we selected AUC as our primary evaluation metric to provide a reliable and clinically meaningful representation of model performance [69,70]. However, our experiments also revealed that not all models benefited from its use, with 3 multimodal models showing no improvement in AUC (Table 5). Interestingly, MTL improved the performance of all single-modality models on both tasks. However, among the 4 multimodal models, only 1 (ie, using the HuBERT+ERNIE-health embeddings) exhibited improvement in AUC for both tasks when using MTL. The remaining 3 models demonstrated mixed results, with 1 task showing improvement, and the others experiencing a drop in performance. This highlights the phenomenon of negative transfer [71], suggesting that transferred knowledge may not always have a positive impact on other tasks, even if they share similarities [71].

[b]MTL: multitask learning.

[c]AUC: area under the curve.

[d]Highest AUC values for each task.

Finally, our study revealed that MTL models led to more substantial improvements in the SR prediction task compared to the DS prediction task, with all multimodal MTL models demonstrating higher recall than their STL counterparts in predicting SR. These findings may be attributed to several aspects. On one hand, the SR prediction task may involve information or patterns different from those in the DS prediction task. For instance, text modalities might convey clearer linguistic patterns, such as specific word choices, pronoun usage, and negative terms [17], which could be more predictive of SR than DS. However, MTL allows models to share learned representations across tasks. If the features relevant to the SR prediction task benefit from certain text or audio modality representations, these features may also aid the DS task, even if the latter shows less improvement. On the other hand, the prediction of DS may be more influenced by sample variability [72,73], whereas the prediction of SR might exhibit stronger commonalities across samples. These findings further underscore the value of MTL, as it enables the model to address such differences through shared representations, thereby enhancing prediction accuracy.

To contextualize our work within current state-of-the-art techniques, we compared our multitask framework with recent studies on depression and suicide prediction, as summarized in Table S2 in Multimedia Appendix 1. Our proposed MTL model, which integrates audio and text modalities with pretrained embeddings, achieved competitive performance (DS: AUC=0.91; accuracy=0.81; F_1-score=0.69 with wav2vec 2.0+ERNIE-health; SR: AUC=0.90; accuracy=0.78; F_1-score=0.77 with HuBERT+ERNIE-health), outperforming several prominent MTL models. These include models by Benton et al [25] (depression: AUC=0.77; suicide: AUC=0.83), Ghosh et al [46] (depression: accuracy=0.74), and Yang et al

XSL•FO
RenderX

[27] (suicide: accuracy=0.74). While Buddhitha and Inkpen [29] reported slightly higher performance for suicide prediction (AUC=0.88; accuracy=0.84), their approach relied on Reddit posts rather than clinical data.

Our study also outperformed all single-task depression prediction studies presented in Table S2 in Multimedia Appendix 1, which predominantly used binary classification (ie, depressed vs nondepressed). In contrast, our multitask framework enabled a more nuanced assessment by explicitly predicting the severity of depressive symptoms rather than merely classifying their presence or absence. Although some single-task suicide prediction models reported higher metrics, including models by Chen et al [38] (F_1-score=0.76), Tsui et al [39] (AUC=0.93), and Bouktif et al [36] (accuracy=0.94), they used substantially larger datasets (1284 subjects, 45,238 patients, and 3,48,110 posts, respectively) and focused exclusively on single-task prediction. Similarly, Ramírez-Cifuentes et al [40] achieved an AUC of 0.94 for suicide prediction using social media data, which suffered from known limitations, including self-presentation biases, language ambiguities, and an inability to detect offline SR [30].

Our study uniquely applied MTL to simultaneously predict DS and SR using multimodal data from clinical interviews. Unlike prior work that focused on single tasks or unimodal inputs, often derived from electronic health records or social media, our approach captured direct clinical interactions, yielding more authentic behavioral signals. Comparative analyses demonstrated that our model effectively predicted both DS and SR, offering clear advantages over existing methods for this clinically important objective.

Theoretical Implications

This study makes substantial contributions to existing literature from 2 main perspectives. First, this study delineated the efficacy of integrating MML, MTL, and TL in simultaneously identifying DS and SR, thereby advancing the understanding of depression and suicide detection. While existing research, such as [25], has explored the impact and importance of MTL in DS and SR prediction, studies have predominantly focused on social media contexts. Limited research has evaluated the effectiveness of MTL in clinical settings. This study addressed this gap through empirical experiments using real-world clinical datasets, demonstrating that the proposed multimodal multitask approach, integrating pretrained embeddings, is applicable to clinical settings.

Furthermore, our findings underscore that MTL generally enhances model performance, consistent with prior literature (eg, [25,45,46]), highlighting the benefits of knowledge sharing across domains [25]. However, our experiments also revealed instances of negative transfer [71], emphasizing the importance of selecting optimal MTL strategies based on embeddings, tasks, and application scenarios. Moreover, further thoughtful evaluation should consider balancing the costs associated with false positives and false negatives, using more comprehensive metrics.

Second, we discussed and presented a comparison of popular pretrained models (Longformer and ERNIE-health for text modality, and wav2vec 2.0 and HuBERT for audio modality) to evaluate their effectiveness with clinical data, providing a valuable addition to the existing literature on depression and suicide prediction research. Our findings revealed that ERNIE-health outperformed Longformer in text modality embedding, and wav2vec 2.0 generally surpassed HuBERT, although there were instances where the reverse was true. This underscores the necessity of judicious pretrained model selection and thorough testing for clinical applicability in the future. Nevertheless, we still affirm the efficacy of TL, as even single-task and single-modality models exhibited commendable performance, although our dataset included only 200 samples.

Practical Implications

This study has several important practical implications. First, the persistent challenge of data scarcity has limited progress in both academic research and clinical practice. Through techniques like MML, TL, and MTL, we propose promising solutions. Second, by integrating multimodal data from speech and text and applying TL methods, our approach can facilitate clinical diagnosis with objective and quantitative measurements. This enables a rapid, efficient, and cost-effective assessment of DS and SR based solely on patients' verbal disclosures to health care providers. Third, the effectiveness of our method suggests a promising avenue for automated SR detection through the development of innovative tools, thereby making a significant contribution to early suicide prevention efforts.

Limitations and Future Research

This study has certain limitations that warrant further research. First, our dataset of 200 participants (100 patients with depression and 100 healthy individuals) represents a significant limitation that severely constrains the generalizability of our findings to broader populations. Despite implementing cross-validation techniques, this small sample size introduces considerable risks of overfitting, where the model may capture dataset-specific characteristics rather than robust, generalizable patterns for DS and SR detection. This limitation necessitates external validation with larger, more diverse cohorts from different clinical settings and demographic backgrounds to establish the true clinical utility and robustness of our proposed method. The incorporation of larger external datasets is therefore essential to not only enhance robustness but also refine and validate our approach across varied populations.

Furthermore, addressing data imbalance has emerged as a critical challenge in accurately identifying and classifying depression cases across varying severity levels. Our comprehensive analysis revealed significant performance disparities among "none," "low/moderate," and "high" severity subcategories, with particularly pronounced difficulties in classifying "low/moderate" severity cases (Table S3 in Multimedia Appendix 1). This variability underscores the intricate complexity of developing a robust diagnostic approach capable of consistently discerning nuanced variations in DS. Future research should, therefore, focus on advancing MTL strategies that integrate multimodal feature representations with targeted sampling techniques and refined weighting mechanisms to enhance the robustness of model predictive performance across varying severity levels of depression.

XSL•FO
RenderX

Furthermore, the exploration of diverse fusion strategies and weight adjustments in MTL, along with the investigation of various pretrained models, warrants further investigation to potentially enhance model performance in future studies. However, while our implementation was straightforward, our primary objective was to develop a computationally efficient and effective method that prioritizes resource efficiency. Finally, exploring the applicability of these techniques to a broader spectrum of mental health disorders is essential. This includes leveraging MML and MTL approaches to integrate information across different disorders, thereby expanding the scope of potential applications in mental health diagnostics.

Conclusion

Early detection and accurate diagnosis are crucial for implementing timely interventions and alleviating the societal and economic burdens associated with mental health conditions. This study proposes an effective approach to improving model performance by integrating MTL, MML, and TL for concurrent depression and suicide detection. Our empirical findings, obtained by fine-tuning MTL models on clinical datasets, provide compelling evidence for the effectiveness of integrating MTL, MML, and TL methods in addressing mental health tasks. However, we advocate for cautious MTL implementation to mitigate potential negative transfer effects. Additionally, we recommend careful consideration for the selection of pretrained models and rigorous validation to ensure their clinical applicability. Our proposed methods offer a promising pathway for future research and clinical applications in mental health diagnostics.

Abstract

Background: Delayed extubation after general anesthesia increases complications and can lead to longer hospital stays and higher mortality. Current risk assessments often rely on subjective judgment or simple tools, whereas machine learning offers potential for real-time evaluation, though research is limited and typically uses single-algorithm models.

Objective: The aims of this study were to identify risk factors for delayed extubation after general anesthesia in the sample and to construct a risk prediction model for delayed extubation in this population.

Methods: Data from 4779 patients admitted to the postanesthesia care unit between September 2023 and May 2024 were used to develop prediction models for delayed extubation using k-nearest neighbor, decision tree, extreme gradient boosting, random forest, a light gradient boosting machine, and an artificial neural network. Model performance was assessed by calculating the area under the receiver operating characteristic curve, sensitivity, specificity, accuracy, F_1-score, and Brier score. Calibration performance was evaluated using calibration curves generated with 100-bin quantile calibration and Loess smoothing to provide bias-corrected and smoothed visual assessment. Additionally, the Hosmer-Lemeshow goodness-of-fit test was performed to quantitatively evaluate calibration, with P values >.05 indicating good calibration.

Results: Among the 6 models evaluated, the extreme gradient boosting model demonstrated the best performance, with an area under the receiver operating characteristic curve of 0.750 (95% CI 0.703 - 0.796), a sensitivity of 0.734 (95% CI 0.635 - 0.827), and a specificity of 0.647 (95% CI 0.623 - 0.673). The model calibration was acceptable, with a Brier score of 0.0505 and a nonsignificant Hosmer-Lemeshow goodness-of-fit test (χ^2_6=7.3; P=.287), indicating good calibration. Shapley additive explanations were used to rank feature importance.

Conclusions: These machine learning models enable early identification of delayed extubation risk, supporting personalized clinical decisions and optimizing postanesthesia care unit resource allocation.

KEYWORDS

delayed extubation; general anesthesia; postanesthesia care unit; machine learning algorithms; XGBoost; extreme gradient boosting

Introduction

Background

Extubation is a critical step in the recovery process following general anesthesia. More than 20% of major airway management–related complications occur immediately before or after extubation, with severe consequences such as hypoxia and mortality [1,2]. Prolonged intubation offers no benefit; delayed extubation may adversely affect the patient's cardiovascular and respiratory systems, resulting in complications such as ventilator-associated pneumonia, pulmonary fibrosis, ventilator dependency, and arrhythmias [3]. Delayed extubation after general anesthesia not only reduces the efficiency of the transition from the postanesthesia care unit (PACU) to the ward but also slows functional recovery, exacerbates physiological and psychological stress responses, and diminishes the quality of the patient's resuscitation period.

XSL•FO
RenderX

This increases the mental and economic burden on the patient and family and raises the incidence of medical disputes [4].

Screening and predicting patients with a high risk for delayed extubation is crucial for optimizing PACU operations and patient care. Several demographic features have been identified as significant predictors, including advanced age [5,6] and the presence of comorbidities such as chronic obstructive pulmonary disease (COPD), cardiovascular diseases, and diabetes [7]. Additionally, a high BMI has been linked to increased respiratory complications, potentially prolonging the need for ventilatory support [8,9]. Furthermore, the nature of the surgical procedure itself significantly influences the likelihood of delayed extubation. Complex and prolonged surgeries, particularly those involving the thoracic or cardiovascular systems, can lead to increased physiologic stress and a higher risk of postoperative complications that may necessitate extended intubation [10]. Significant hemorrhage can result in hemodynamic instability, which can affect the patient's ability to maintain adequate oxygenation and ventilation postoperatively [11-13]. In clinical practice, extubation following general anesthesia is predominantly executed by medical and nursing professionals within the PACU. However, current research provides limited information on the impact of nursing-related monitoring and management variables within the PACU on the extubation time.

There are increasing studies on building machine learning predictive models for delayed extubation. Previous studies have suggested that machine learning algorithms, including extreme gradient boosting (XGBoost), gradient boosting machine, and artificial neural networks, have advantages in constructing predictive models for delayed extubation in the intensive care unit [14,15]. However, for postoperative delayed extubation, most studies used logistic regression for developing a nomogram model or a single machine learning algorithm for constructing a predictive model [9]. Fewer studies use multiple machine learning algorithms to build a postoperative delayed extubation prediction model following general anesthesia in the PACU.

Therefore, this study aimed to explore perioperative features, including monitoring and management variables in the PACU, associated with delayed extubation after general anesthesia and to develop prediction models for delayed extubation using machine learning algorithms. It is hypothesized that machine learning models incorporating PACU monitoring and management variables can be developed to predict delayed extubation, enabling early assessment and prevention of this adverse event following general anesthesia.

Delayed extubation after general anesthesia is a common postoperative complication associated with increased adverse events, such as prolonged hospital stays, higher intensive care needs, and elevated mortality rates. Identifying patients with high risk and optimizing recovery care is crucial. Current risk assessments often rely on subjective judgment or simplistic tools, which may overlook the complex patient profiles and intraoperative dynamics. Machine learning, with its robust data mining and predictive capabilities, offers real-time evaluation and intervention potential. However, research specifically addressing delayed extubation remains limited, with most studies relying on traditional single-algorithm models.

Aims

The aims of this study were to identify the risk factors for delayed extubation after general anesthesia in the sample and to construct a risk prediction model for delayed extubation in this population.

Methods

Machine Learning Model Selection

The data extracted from electronic medical records in this retrospective cohort study can be used to substantially predict the risk of delayed extubation after general anesthesia. In line with our research objectives, we selected 6 predictive modeling methods for analysis: random forest (RF), XGBoost, k-nearest neighbor (KNN), decision tree, light gradient boosting machine (LightGBM), and artificial neural networks.

Data Collection

Patient consent was waived due to the retrospective nature of the study. Patients transferred to the PACU after general anesthesia at Shenshan Medical Center in Shanwei, China, from September 2023 to May 2024 were retrospectively enrolled.

Variables

Demographic information included sex, age, American Society of Anesthesiologists (ASA) classification, BMI, smoke history, and comorbidities (including cerebral infarction and COPD).

Preoperative examinations included red blood cell distribution width; alanine and aspartate aminotransferase levels; serum sodium concentration, serum concentrations of sodium, potassium, calcium, hemoglobin, and creatinine; and chest x-ray findings. Preoperative examinations were performed within 7 days preoperatively, and the latest result was included in case the same test was conducted multiple times.

Surgery-related parameters included intraoperative infusion volume, intraoperative blood loss, duration of surgery, case condition (usual, urgent, difficult, and critical), site, and level of surgery. Intraoperative infusions were determined by the anesthesiologist based on the patient's intraoperative vital signs, urine output, or hemodynamic monitoring.

PACU monitoring and management indicators included tympanic temperature following PACU admission, time to extubation in PACU, and the sufentanil administered before extubation in the PACU. The supplemental dose of sufentanil was administered at 0.1 μg/kg per dose, with adjustments made based on the patient's specific resuscitation process and the severity of postoperative pain.

Study Population and Data Extraction

Eligibility Criteria

The inclusion criteria were patients who underwent tracheal intubation under general anesthesia and were transferred to the PACU postoperatively. The exclusion criteria were as follows: (1) extubation before admission to the anesthesia recovery room, (2) preoperative coma, (3) presence of severe mental illness or psychiatric disorders, and (4) missing data exceeding 30% of the required information. Patients' demographic information,

XSL•FO
RenderX

comorbidities, preoperative examinations, surgery-related parameters, and PACU monitoring and management indicators were retrieved from the institutional database.

Anesthesia Method

No premedication was used for any patients. Induction was administered by intravenous injection of sufentanil (0.3 - 0.5 μg/kg), propofol (1.5 - 2.5 mg/kg), and rocuronium (0.6 mg/kg). Alternatively, mivacurium (0.07 - 0.25 mg/kg) or cisatracurium (0.2 mg/kg) was used for muscle relaxation. After achieving the appropriate anesthesia depth and muscle relaxation, intubation was performed for mechanical ventilation (Tidal Volume 6 - 8 ml/kg, Respiratory Rate 10 - 12 breaths/min). Intraoperative parameters were managed, and patients were transferred to the PACU within 5 minutes after surgery.

Data Analysis

Statistical analyses were performed using Python (version 3.12.4; Python Software Foundation). Variables with ≥30% missing data were excluded from the analysis, while those with <30% missing data were imputed using the KNN classification algorithm. Continuous variables were assessed for normality and compared using the independent 2-tailed *t* test or the Mann-Whitney *U* test, as appropriate. Categorical variables were compared using the chi-square test or the Fisher exact test, depending on expected cell counts. All statistical tests were 2-sided, and a *P* value <.05 was considered statistically significant.

Feature selection was conducted on the training set using the least absolute shrinkage and selection operator (LASSO) to identify the most predictive variables. During the evaluation phase, a threshold optimization strategy was applied to determine clinically meaningful cut-off points. Specifically, thresholds were selected under dual constraints, requiring both sensitivity and specificity to be ≥0.60, to ensure that the model achieved a balance between correctly identifying positive cases and minimizing false positives. When no threshold met these dual criteria, the Youden index was used as an alternative to identify the optimal threshold. This approach ensured that the final model outputs had practical applicability for clinical risk stratification.

Model discrimination performance was evaluated in the test set by calculating the area under the receiver operating characteristic curve (AUROC), alongside sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV). CIs for these metrics were estimated using 1000 bootstrap resampling iterations to enhance the robustness of performance assessment.

Calibration performance was evaluated using calibration curves generated with 100-bin quantile calibration and LOESS smoothing; in the LOESS procedure, the parameter frac=0.3 indicates that 30% of the data were used for each local fit to control the degree of smoothing. The Hosmer-Lemeshow goodness-of-fit test was also performed to quantitatively assess calibration, with *P* values >.05 indicating good calibration.

Data Processing and Feature Selection

Delayed extubation after general anesthesia has been defined as the removal of the tracheal tube 60 minutes or more after general anesthesia [16]. This study defined delayed extubation as removal of the tracheal tube over the same time frame following PACU admission, while removal in less than 60 minutes was categorized as nondelayed extubation.

Continuous variables were presented as mean with SD or median with IQR according to normality for the variables. Categorical variables were expressed as frequencies with percentages. Missing values were filled in using the KNN classification algorithm, which estimates missing values based on the values of patients with similar features. Patients ultimately enrolled in this study were randomized in a 7:3 ratio into primary and test cohorts. We used the optimal thresholds from receiver operating characteristic (ROC) curve analysis to convert continuous variables, such as intraoperative infusion volume and duration of surgery from the training set, into categorical variables [17].

The LASSO was used to identify key features associated with delayed extubation after general anesthesia for the construction of the machine learning models. The machine learning algorithms used in this study included KNN, decision tree, XGBoost, RF, LightGBM, and artificial neural networks. To enhance model performance, parameter tuning was conducted on the training set using a 10-fold cross-validation approach.

Model Evaluation

The AUROC, sensitivity, specificity, PPV, NPV, accuracy, and F_1-score were chosen as primary metrics for model evaluation. To enhance the robustness of performance assessment, 1000 bootstrap resampling iterations were performed to estimate the CIs for these metrics. Model calibration was evaluated using calibration curves generated with 100-bin quantile calibration and Loess smoothing (frac=0.3) to provide bias-corrected and smoothed visual assessment, and the Hosmer-Lemeshow goodness-of-fit test was performed to quantitatively assess calibration, with *P* values >.05 indicating good calibration. Additionally, Brier scores were calculated to assess overall calibration accuracy.

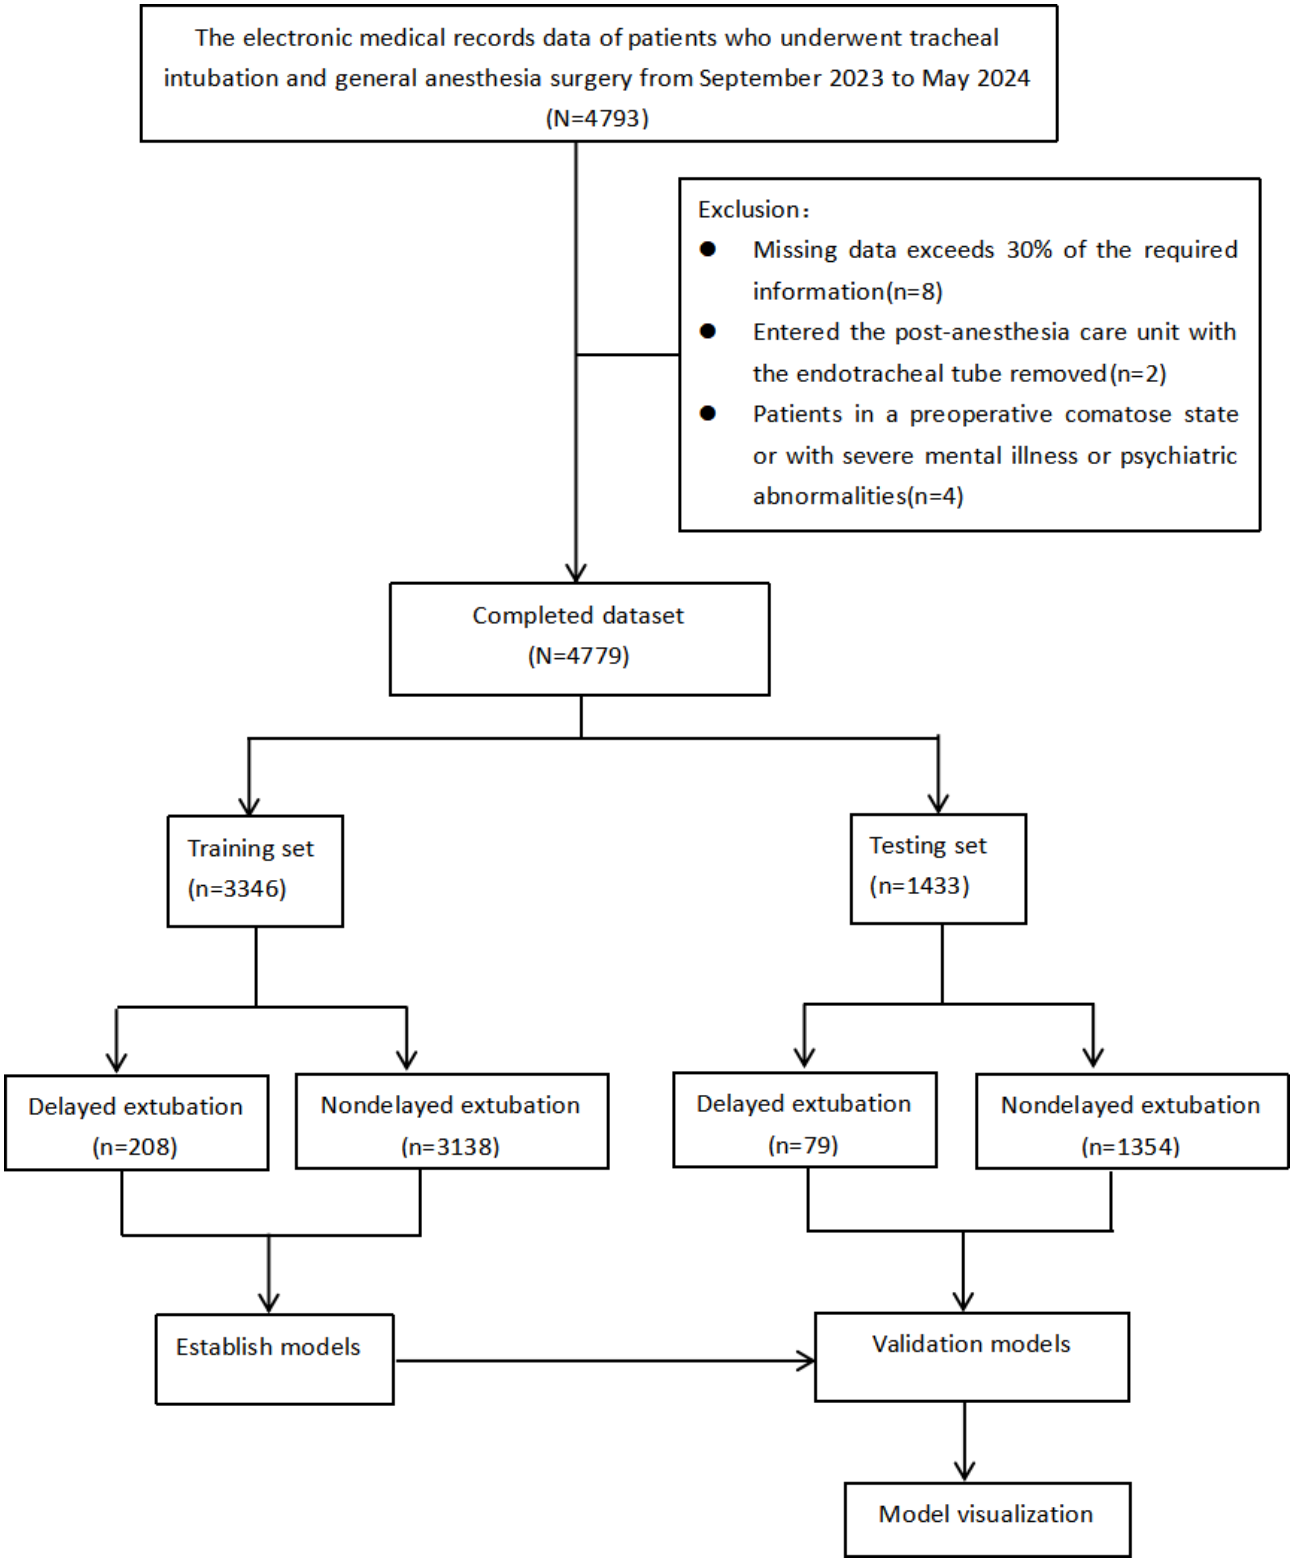
Ethical Considerations

This study was approved by the institutional review board of Shenshan Medical Center, Memorial Hospital of Sun Yat-sen University (2024-SSKY-113-01). The trial was registered in the Chinese Clinical Trial Registry (ChiCTR2400090247). Because this was a retrospective study using deidentified clinical data and posed minimal risk to participants, the institutional review board waived the requirement for informed consent. Participant privacy and data confidentiality were strictly protected; all data were anonymized before analysis and used only for research purposes. No financial compensation was provided to participants.

Results

A total of 4793 patients were initially included in the study. On the basis of the exclusion criteria, 8 (0.16%) patients were excluded due to having more than 30% missing data, 2 (0.04%)

XSL•FO
RenderX



patients were excluded because their tracheal tube had been removed before admission to the PACU, and 4 (0.08%) patients were excluded due to preoperative unconsciousness or severe psychiatric disorders. Therefore, 4779 patients were finally enrolled in the analysis, of whom 6% (287/4793) experienced delayed extubation, defined as extubation time of 60 minutes or more after admission to the PACU, and 93.72% (4492/4793) of patients did not experience delayed extubation. The dataset was randomly divided into primary and test cohorts in a 7:3 ratio, resulting in 70.01% (3346/4779) of patients being placed in the primary cohort and 29.99% (1433/4779) being placed in the test cohort. In the primary cohort, 6.21% (208/3346) of patients were assigned to the delayed extubation group and 93.78% (3138/3346) of patients were assigned to the nondelayed extubation group. The patient recruitment flowchart is shown in Figure 1.

No statistically significant differences were found in the univariate comparisons between the primary and test cohorts (Multimedia Appendix 1). The optimal parameter (λ) in the LASSO model was selected using 10-fold cross-validation. Dashed lines were drawn at the optimal value using the minimum criterion. A vertical line was drawn at the value chosen by 10-fold cross-validation, where the optimal λ resulted in 13 nonzero coefficient features (Figure 2). LASSO regression generated 13 nonzero coefficient variables at the value of λ (minimum)=0.0037 for building a machine learning prediction model, including age, sex, BMI, ASA classification, cerebral stroke history, intraoperative infusion volume, duration of surgery, history of COPD, case condition, surgical site, surgical level, tympanic temperature following PACU admission, and sufentanil administered before extubation in the PACU.

On the basis of the test cohort, ROC (Figure 3) was drawn for different machine learning prediction models (KNN, decision tree, XGBoost, RF, LightGBM, and artificial neural networks). The XGBoost model demonstrated the highest overall performance among all models tested. In the test cohort, the XGBoost model achieved an AUROC of 0.750 (95% CI 0.703 - 0.796), a sensitivity of 0.734 (95% CI 0.634 - 0.827), a specificity of 0.647 (95%CI 0.622 - 0.673), a PPV of 0.108 (95% CI 0.083 - 0.134), a NPV of 0.976 (95%CI 0.966 - 0.985; Table 1), an F_1-score of 0.188, and accuracy of 0.652 (Table 2). The Brier score was 0.0505, indicating a low mean squared difference between predicted probabilities and actual outcomes and suggesting good model calibration (Table 2).

ANN[f]	0.669	0.174	0.0503	4.27 (6)	.64

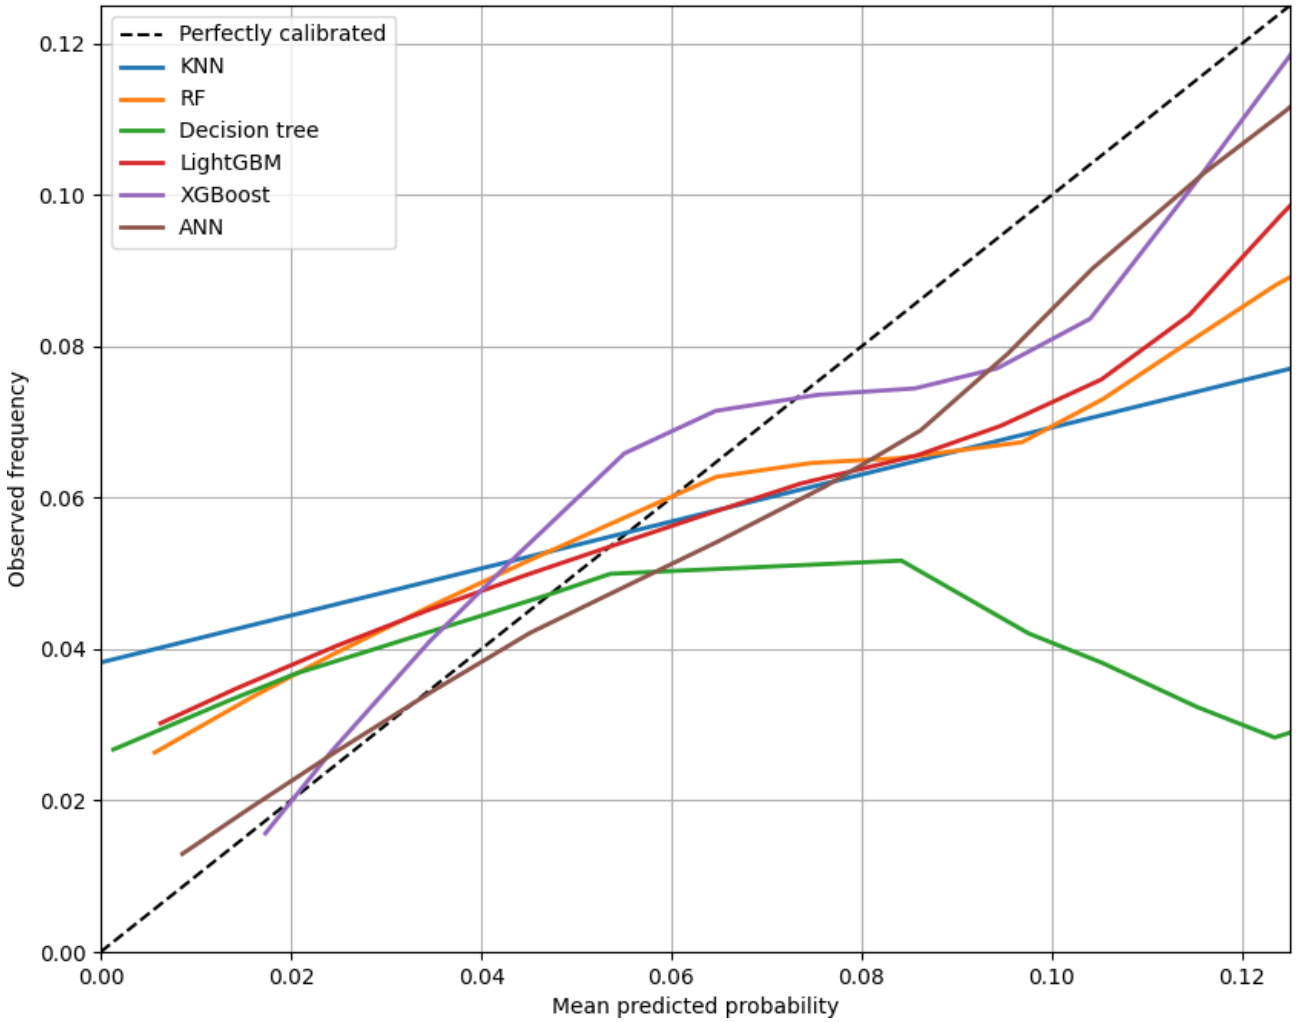
[a]KNN: k-nearest neighbor.

[b]RF: random forest.

[c]DT: decision tree.

[d]LightGBM: light gradient boosting machine.

[e]XGBoost: extreme gradient boosting.



[f]ANN: artificial neural network.

The calibration curve (Figure 4) showed good agreement between predicted probabilities and observed outcomes for the XGBoost model, with a Hosmer-Lemeshow goodness-of-fit test χ^2_6=7.38 and *P*=.287 (Table 2), indicating no significant lack of fit. These results suggest that the XGBoost model may serve as a reliable tool for predicting the risk of delayed extubation following general anesthesia in the PACU.

Similar trends were observed in the other models tested, although their overall discrimination performance and calibration were lower compared to XGBoost (Table 1 and Figure 3).

Figure 4. Calibration curve. ANN: artificial neural network; KNN: k-nearest neighbor; LightGBM: light gradient boosting machine; RF: random forest; XGBoost: extreme gradient boosting.

Given the difficulty clinical practitioners face in interpreting unexplained predictive models, this study used the Shapley additive explanations (SHAP) method to elucidate the XGBoost model by calculating the contribution of each feature variable to the predicted outcome (Figure 5). The variables showing the contribution to delayed extubation after general anesthesia in the SHAP plot of the XGBoost model were as follows: age, BMI, ASA classification, tympanic temperature following PACU admission, sex, intraoperative infusion volume, duration of surgery, surgical site, surgical level, case condition, cerebral stroke history, sufentanil administered before extubation in the PACU, and history of COPD (Figure 6).

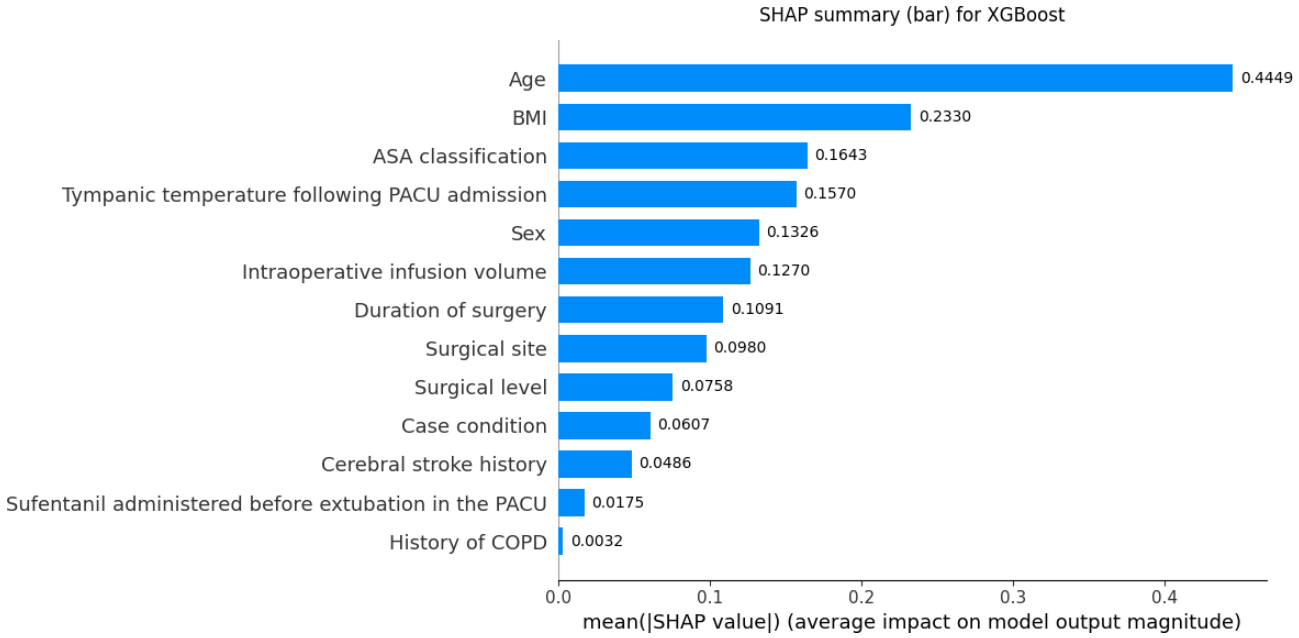
Figure 5. Bar chart of Shapley additive explanations (SHAP) for important features in the extreme gradient boosting (XGBoost) model. ASA: American Society of Anesthesiologists; COPD: chronic obstructive pulmonary disease; PACU: postanesthesia care unit.



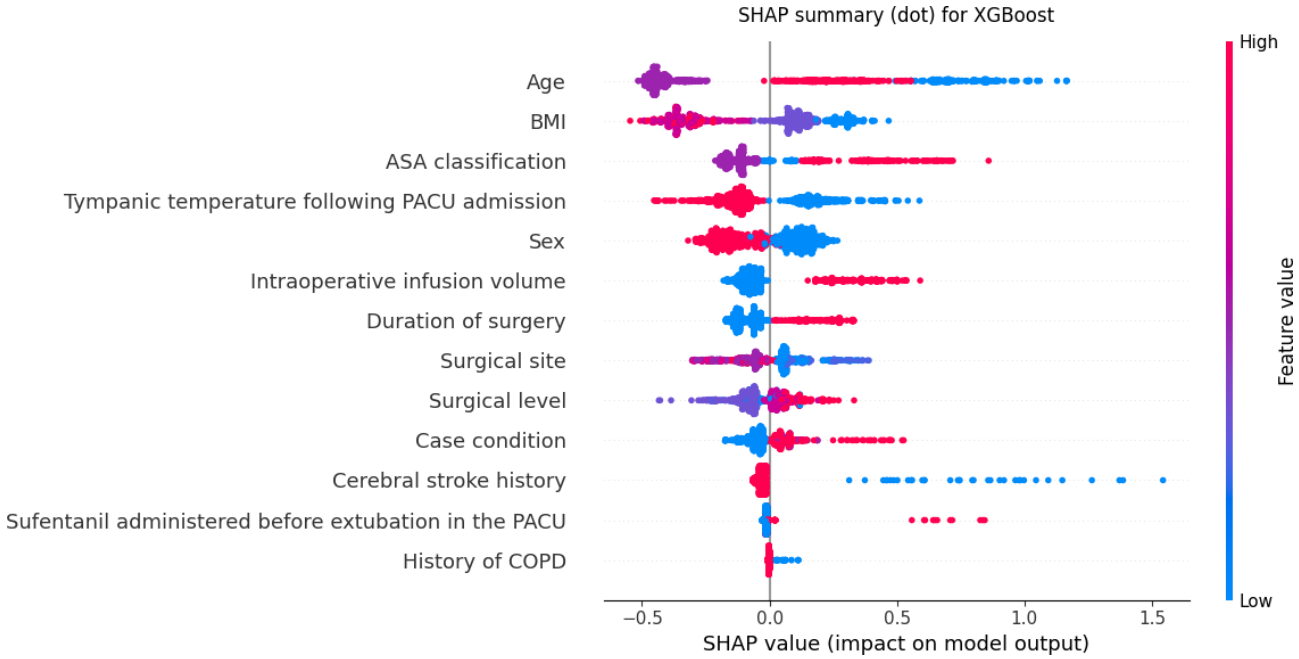


Figure 6. Global Shapley additive explanations (SHAP) summary for the extreme gradient boosting (XGBoost) model. Positive SHAP values increase the predicted probability of delayed extubation. Point color encodes the numeric feature code listed in Multimedia Appendix 2. Risk directions should be interpreted from SHAP values together with the coding scheme. ASA: American Society of Anesthesiologists; COPD: chronic obstructive pulmonary disease; PACU: postanesthesia care unit.

Discussion

Principal Findings

This study collected perioperative assessment and management data, including nursing management indicators in the PACU, and attempted to construct predictive models for delayed extubation in the PACU using various machine learning algorithms. The results showed that the XGBoost-based model achieved the highest predictive performance. The SHAP interpretation in the XGBoost model identified features with high predictive value, providing a basis for early risk assessment of delayed extubation and optimal nursing intervention strategies within the PACU.

The SHAP summary plot demonstrated that age, BMI, ASA classification, and tympanic temperature were the top 4 features in predicting delayed extubation risk. Age showed the strongest positive contribution to model predictions, indicating that patients aged ≥65 years were more likely to experience delayed extubation. This finding aligns with previous studies showing that older patients are at higher risk for delayed extubation due to decreased respiratory reserve, altered drug metabolism, and delayed muscle strength recovery [18,19]. PACU nurses should

XSL•FO
RenderX

implement individualized monitoring and interventions for older adults or patients at risk of respiratory dysfunction (eg, obesity, obstructive sleep apnea, and COPD), including close monitoring of respiratory rate, oxygen saturation, and partial pressure of end-tidal carbon dioxide to detect hypoventilation, hypoxemia, or airway obstruction early, as well as extending awakening time to ensure full consciousness and respiratory recovery before extubation [20,21]. Diaphragm ultrasound can effectively assess diaphragmatic thickness, thickening fraction, and mobility, reflecting diaphragm contractility, and is a powerful tool to predict the recovery of spontaneous breathing and extubation success [22]. In the PACU, particularly for older patients or those with impaired respiratory function (eg, COPD or chronic respiratory failure), diaphragmatic function assessment helps nurses determine whether the patient has sufficient respiratory drive and muscle strength to maintain ventilation after extubation [23]. If the thickening fraction is <20% or diaphragmatic movement is significantly reduced, it indicates diaphragmatic dysfunction and suggests that the patient may not yet be ready for extubation [24]. Conversely, normal diaphragmatic movement indicates good respiratory muscle recovery and extubation safety, reducing reintubation risks.

BMI was the second most important predictor. SHAP interpretation showed that underweight (BMI <18.5 kg/m²) contributed more to delayed extubation predictions than obesity. This contrasts with most studies focusing on obesity as a risk factor for delayed extubation. Previous studies indicated that patients with obesity have impaired lung function, characterized by decreased lung compliance and reduced functional residual capacity, which is further exacerbated by general anesthesia and mechanical ventilation, leading to delayed recovery of spontaneous breathing and increased risk of extubation delay [25,26]. However, patients who are underweight may also experience delayed extubation due to potential mechanisms such as malnutrition-induced respiratory muscle weakness, reduced adipose tissue affecting the distribution volume and metabolism of lipophilic anesthetics, and poor overall recovery capacity [27]. Therefore, preoperative nutritional risk screening (eg, Nutritional Risk Screening 2002 or Patient Generated Subjective Global Assessment) should be routinely performed to identify potential malnutrition [28]. During PACU recovery, nurses should closely assess muscle strength recovery, including respiratory and limb muscle strength, to evaluate readiness for extubation. Patients with respiratory muscle weakness, hypoventilation, or delayed awakening may require prolonged mechanical ventilation support to ensure sufficient respiratory capacity and consciousness before extubation, thus ensuring safety and reducing postoperative complications. ASA classification also contributed significantly to the model, with patients classified as ASA III or above having a higher likelihood of delayed extubation, suggesting that baseline comorbidities and overall health status play crucial roles in postoperative recovery [29]. PACU nurses should integrate comprehensive preoperative functional assessments with ASA classification to develop graded nursing plans, optimize resource allocation, and strengthen cardiopulmonary monitoring and support [30]. Tympanic temperature was also an important predictor, with lower temperatures associated with increased risk of delayed extubation. Previous studies have shown that hypothermia reduces hepatic and renal blood flow, slowing anesthetic drug metabolism and clearance and prolonging awakening and spontaneous breathing recovery [18,31]. PACU nurses should measure tympanic temperature immediately upon admission and initiate active warming using forced-air warming blankets and prewarmed infusions if the temperature is <36 °C. Temperature should be remeasured every 15 minutes during anesthesia recovery to ensure a stable warming trend, and a standardized hypothermia management protocol should be implemented to ensure continuity of care [32].

Furthermore, intraoperative infusion volume ≥1135 ml, anesthesia duration ≥230.5 minutes, neurosurgery, and higher surgical levels contributed moderately to predictions, suggesting that intraoperative fluid management, anesthesia duration, and surgical complexity should be comprehensively considered to optimize extubation timing. Increased intraoperative fluid volume may lead to interstitial fluid retention, edema, and decreased lung compliance, adversely affecting respiratory function and delaying recovery of spontaneous breathing and readiness for extubation [33]. Previous studies have shown that excessive fluid management is associated with increased risk of postoperative pulmonary complications [34]; thus, rational intraoperative fluid management is essential to avoid volume overload.

Finally, although a history of cerebral infarction, additional sufentanil administration in the PACU, and COPD showed relatively low SHAP contributions, they remain clinically important predictors. A history of cerebral infarction indicates potential central nervous system dysfunction, including altered consciousness, impaired swallowing, and weakened cough reflex, increasing extubation risks [35,36]. Previous studies have shown that individuals who have sustained a stroke are prone to delayed extubation and insufficient airway protection due to intracranial pressure changes, impaired autonomic regulation, and reduced respiratory center control [37,38]. Additional sufentanil administration in the PACU reflects increased postoperative analgesic requirements. While sufentanil is a potent lipophilic μ-opioid receptor agonist providing excellent analgesia, high doses may suppress respiratory drive and delay spontaneous breathing recovery [39]. Therefore, postoperative analgesia should aim to achieve effective pain control while minimizing the risk of respiratory depression. For older patients or those with compromised respiratory function, sufentanil dosing should follow recommended ranges (0.1 - 0.5 μg/kg), with close monitoring of respiratory status and consciousness to ensure effective analgesia without prolonging extubation time [40]. Patients with COPD are prone to airway secretion retention, ventilation-perfusion mismatch, and weakened respiratory effort due to abnormal airway function and increased resistance. They may experience respiratory muscle fatigue and hypoxemia after extubation, necessitating reintubation. PACU staff typically delay extubation until oxygenation improves, necessitating careful assessment of respiratory function recovery and extubation timing, thus increasing the risk of delayed extubation [41].

Strengths and Limitations

This study found that among all models compared, XGBoost achieved the best performance. Previous models were mainly developed based on logistic regression and presented as nomograms [9]. However, XGBoost outperforms logistic regression in capturing complex nonlinear interactions among variables, resulting in higher predictive accuracy. Compared with other machine learning algorithms, XGBoost offers advantages such as superior performance with high-dimensional sparse data, built-in LASSO and ridge regularization, cross-validation to prevent overfitting and enhance generalizability, and native handling of missing data without prior imputation [29].

This study also had limitations. First, as a retrospective study, it was subject to unavoidable biases and lacked external validation. Additionally, some variables potentially affecting extubation time were not included, and only patients with ASA ≤ III were enrolled, limiting generalizability. Future multicenter prospective studies with larger samples are needed to develop and validate delayed extubation prediction models in the PACU. Furthermore, despite the obvious class imbalance in this study, no resampling techniques (eg, Synthetic Minority Over-sampling Technique) or class weighting strategies were used during model training. To reduce the risk of majority class bias, we incorporated a threshold adjustment mechanism in the evaluation stage by imposing dual constraints on sensitivity and specificity (eg, sensitivity ≥0.60 and specificity ≥0.60) to select clinically meaningful thresholds. Although this post hoc adjustment does not address imbalance during training, it partially mitigates the majority class overfitting. Future studies will incorporate integrated balancing strategies to further improve model robustness and generalizability.

Conclusions

The machine learning–based predictive model for delayed extubation risk after general anesthesia has significant clinical implications. It allows for early identification of patients with high risk, enabling personalized management and timely interventions to reduce complications. PACU nurses can consider integrating the model into routine postoperative care, especially in PACU settings, to improve decision-making and optimize resource allocation.

Abstract

Background: Although an increasing number of bedside medical devices are equipped with wireless connections for reliable notifications, many nonnetworked devices remain effective at detecting abnormal patient conditions and alerting medical staff through auditory alarms. Staff members, however, can miss these notifications, especially when in distant areas or other private rooms. In contrast, the signal-to-noise ratio of alarm systems for medical devices in the neonatal intensive care unit is 0 dB or higher. A feasible system for automatic sound identification with high accuracy is needed to prevent alarm sounds from being missed by the staff.

Objective: The purpose of this study was to design a method for classifying multiple alarm sounds collected with a monaural microphone in a noisy environment.

Methods: Features of 7 alarm sounds were extracted using a mel filter bank and incorporated into a classifier using convolutional and recurrent neural networks. To estimate its clinical usefulness, the classifier was evaluated with mixtures of up to 7 alarm sounds and hospital ward noise.

Results: The proposed convolutional recurrent neural network model was evaluated using a simulation dataset of 7 alarm sounds mixed with hospital ward noise. At a signal-to-noise ratio of 0 dB, the best-performing model (convolutional neural network 3+bidirectional gate recurrent unit) achieved an event-based F_1-score of 0.967, with a precision of 0.944 and a recall of 0.991. When the venous foot pump class was excluded, the classwise recall of the classifier ranged from 0.990 to 1.000.

Conclusions: The proposed classifier was found to be highly accurate in detecting alarm sounds. Although the performance of the proposed classifier in a clinical environment can be improved, the classifier could be incorporated into an alarm sound detection system. The classifier, combined with network connectivity, could improve the notification of abnormal status detected by unconnected medical devices.

KEYWORDS

sound event detection; deep learning; alarm sound; polyphonic sound; notifications

Introduction

Background

While an increasing number of bedside medical devices, such as syringe pumps, have wireless connections that enable reliable data transmission to hospital information systems, many nonnetworked devices are still used in general hospital wards. Although dongles connected to the external output terminal of these devices may allow wireless connections [1,2], most devices are not equipped with external output terminals. Instead, these devices use auditory alert signals (alarm sounds) to notify medical staff of abnormal conditions. Medical staff members may not hear these alarms, especially when they are in distant areas or other private rooms. Between 2010 and 2015, the Japan Council for Quality Health Care reported 173 accidents and other incidents, including 23 cases of unnoticed alarms [3]. The report included the following comments about environmental factors:

> *There are many blind spots due to the facility's structure.*

XSL•FO
RenderX

> *When I entered a patient's room, I could not hear alarm sounds from another room.*
>
> *The alarm sound did not reach the staff because the room was far from the nurse station.*
>
> *The staff could not hear the alarm in the farthest private room in the ICU.*
>
> *The recording room was structured so that the alarm sound could not be heard.*

These findings indicate the need for reliable alarm notification to ensure patient safety. Alarm sounds emitted by medical devices are regulated by the International Organization for Standardization and the International Electrotechnical Commission (ISO/IEC) 60601-1-8. This standard specifies the melodies and lengths of alarm sounds to reduce the risk of misunderstanding, confusion, and omission of alarm sounds from various medical devices, even when these sounds overlap and reverberate. This standard prescribes that the sounds should be organized based on the priority of corresponding abnormal situations, with alarm sounds for different situations varying in melody and length. Thus, sound event detection (SED) is expected to identify every kind of abnormal situation detected by medical devices [4-8]. The standard also defines visual alarm signals, but monitoring the signals of multiple devices with cameras is not feasible without blind spots.

As SED can be implemented using a single (monaural) microphone, it was selected as the approach to detect alarm status. Clinical application of SED requires robustness against noise because environmental noise in hospital wards is generally substantial. SEDs with deep learning have been found to be sufficiently robust against noise [9,10].

This study proposes a deep learning–based method for classifying patient abnormalities detected by medical devices with polyphonic alarm sounds collected with a monaural microphone. The ability of the classifier to identify abnormal states of these devices was evaluated using simulation datasets of their alarm sounds superimposed on hospital ward noise (HWN). Therefore, the objective of this study was to design and evaluate a convolutional recurrent neural network (CRNN) for accurately detecting and classifying multiple, overlapping alarm sounds from medical devices in a simulated noisy hospital environment. We hypothesized that a hybrid CRNN model could achieve high performance suitable for clinical application by effectively capturing both the spectral and temporal features of the alarm sounds.

Related Works

Accurate transmission of alarms from unconnected medical devices requires precise recognition of visual and auditory alarms. Several studies have reported high accuracy in detecting simultaneous alarm sounds mixed with a substantial level of environmental noise [4-8]. For SED, deep learning is more robust against noise than conventional methods [9,10]. On the basis of these studies, an edge device was placed at the patient's bedside to monitor abnormal conditions detected by multiple medical devices with individual alarm sounds. In our previous study, the classifier had F_1-scores of 0.727 at signal-to-noise ratios (SNRs) of 0 dB and applied a convolutional neural network (CNN) [11]. To our knowledge, no previous study has used a deep learning–based recurrent neural network (RNN) to detect polyphonic alarm sounds emitted by medical devices. Recent advances in attention-based architectures, such as the audio spectrogram transformer and conformer, have demonstrated strong performance in general SED tasks [12,13]. These models use self-attention mechanisms to capture long-range dependencies, potentially enhancing robustness in noisy environments. Exploring such transformer-based approaches for clinical alarm sound detection remains an important direction for future research.

Methods

Overview

The first approach to SED combines a Gaussian mixture model with a hidden Markov model, using features such as the mel-frequency cepstral coefficient from traditional methods of speech recognition [14,15].

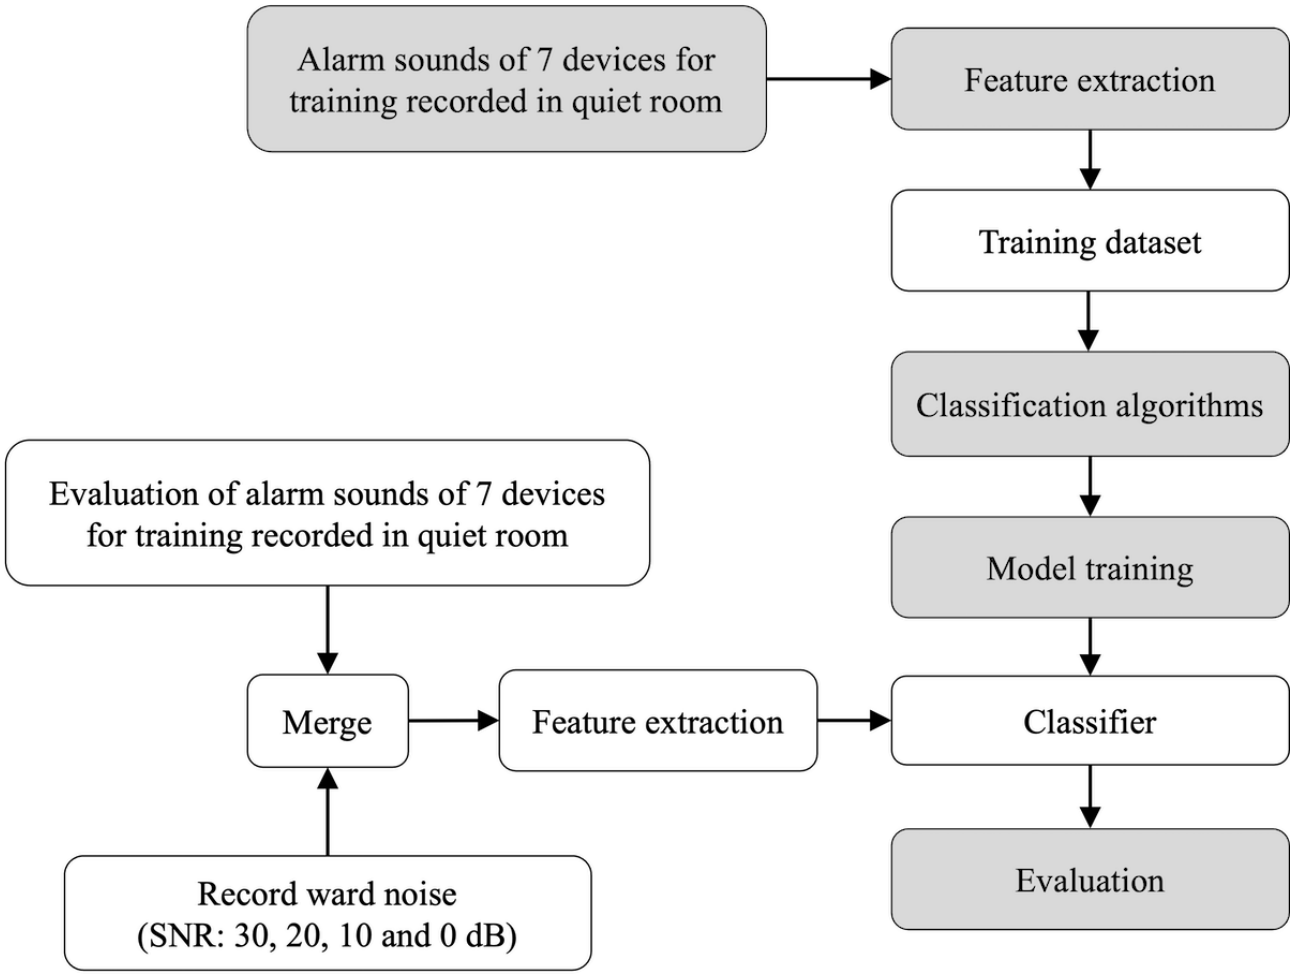
Other approaches include the separation of sound sources by matching them using a template extracted from the input sound. This can be achieved by sound source separation techniques, such as nonnegative matrix factorization. Nonnegative matrix factorization monitors a single signal to create a basis matrix and identifies the separated sounds [16-18].

Recent approaches based on neural networks have significantly improved the performance of SED. One approach consists of SED of real-life sounds with feedforward neural networks based on a multilayer perceptron trained in a spectrum of mixed sounds [6]. An RNN with the ability to remember past states can process sequential information of the acoustic signal. RNNs with bidirectional long short-term memory have achieved excellent results in complex audio detection such as speech recognition and polyphonic piano note transcription [19-21].

Furthermore, CNNs commonly used in image recognition can robustly predict sounds with its filter shifted by both time and frequency axes [22]. However, long-term prediction remains difficult due to the limited width of the time window [9]. Therefore, although alarm sounds consist of relatively simple tones, it is necessary to predict not only the frequency axis but also the time axis to inform the priority with a pattern. Application of an RNN to polyphonic SED enabled long-term prediction by integrating the information over the time window. This study combines the strengths of both CNN and RNN to benefit from both approaches. A similar approach has shown excellent performance in automatic speech recognition [23,24].

Therefore, this approach was expected to achieve sufficient performance for potential clinical application in alarm sound recognition.

Deep Alarm Sound Detection



Experiment Overview

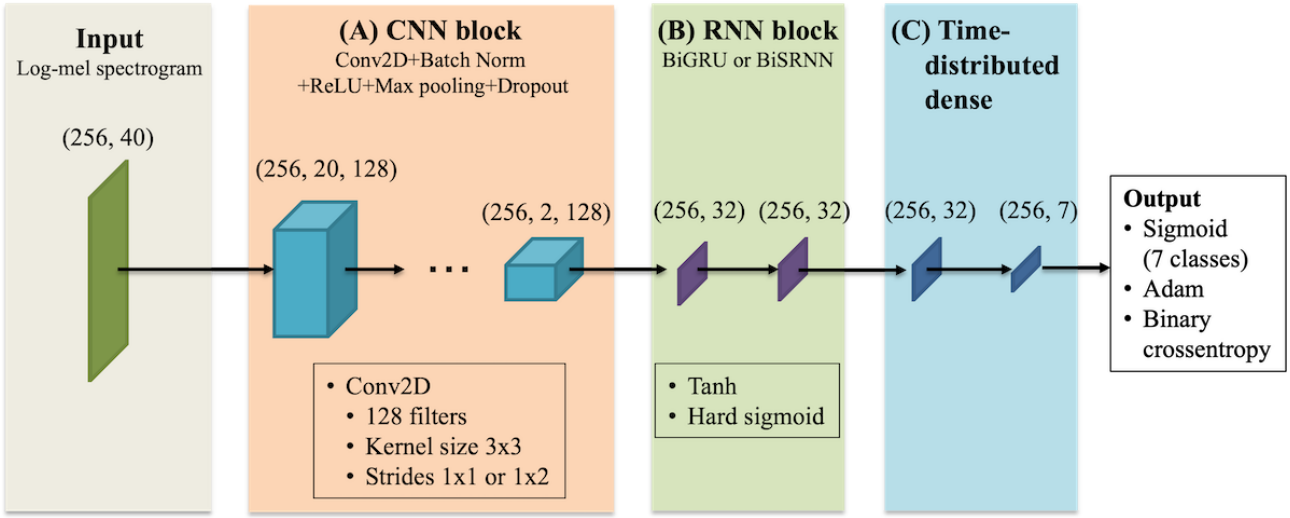
The proposed polyphonic alarm sound detection consisted of feature extraction, classification algorithms, and model training (Figure 1). A mel filter bank (MFB) was used to extract the features of alarm sounds, and CNN and RNN were applied to

XSL•FO
RenderX

the classifier. As deep learning requires substantial training data, a large amount of acoustic data were recorded in a quiet room. The recorded data were mixed with pseudo noise before being used for training. This approach aimed to maximize the generalizability of the classifier for expected use in a noisy environment. The feature extraction step extracted data to be input to the classifier from the collected alarm sounds. The classification algorithms were designed to use deep learning models for classifiers. The model training augmented the data to create a robust model.

Figure 1. Overview of the experiment. SNR: signal-to-noise ratio.

Feature Extraction



The features of polyphonic alarm sounds of bedside medical devices were extracted. Many acoustic classifiers use log mel spectrogram multiplied spectra and MFB based on the characteristics underlying human frequency perception [25]. The acoustic data were transformed to a power spectrogram with the short-time Fourier transform of the Hamming window, which had a window size of 1024 and a hop length of 512. The inner product on the power spectrogram was calculated with MFB, and its logarithms in 40 dimensions were calculated.

Classification Algorithms

The CRNN, a combination of CNN and RNN, was used for the classification model (Figure 2) [26]. This system used 256×40 pixels of the log mel spectrogram as a feature. A CNN block in the proposed model consisted of a convolutional layer with 128 filters, batch normalization, the activation function of the rectified linear unit, and a dropout of 50% [27]. Using the size reduction method, the max pooling layer was applied to the frequency axis. In image recognition, replacing the pooling layer with a CNN stride 2 has been reported to improve its performance by reducing the calculation cost [28]. In this study, the size of the stride to the frequency axis was reduced to 2, and the pooling layer was excluded because the classification target was 1 frame of the sound.

XSL•FO
RenderX

Figure 2. Architecture of the proposed convolutional recurrent neural network. The architecture consists of three main components: (1) convolutional neural network (CNN) block (convolutional layers with batch normalization, rectified linear unit [ReLU] activation, max pooling, and dropout), (2) recurrent neural network (RNN) block (bidirectional gate recurrent unit [BiGRU] or bidirectional simple recurrent neural network [BiSRNN] layers), and (3) time-distributed dense with sigmoid activation for classification.

The RNN block consisted of a bidirectional simple RNN (BiSRNN) or bidirectional gated recurrent unit (BiGRU). The input was set to 32 units, the activation function to tanh, the recurrent activation function to the hard sigmoid, and the dropout of each layer to 50%.

Finally, the activation function of the fully connected layer was set to sigmoid, the optimization function used was Adam [29], and the loss function was set to binary cross-entropy. Each of the 7 sound event classes had output values in the range of [0, 1] [5].

Table 1 shows the details of the proposed model. CNN3+BiSRNN was used as the baseline model. The environment was built with Python programming language (version 3.7.11; Python Software Foundation), using Keras 2.3.1 for the deep learning library (TensorFlow 2.0.0 for the back end) and Librosa 0.8.1 for the acoustic analysis module. The experimental code is available online[30].

Model Training

Data augmentation was applied to the training dataset to prevent overfitting of the classifier and to provide robust performance in simulation experiments [31]. The 7 alarm sounds were superimposed on white noise at SNRs ranging from 30 to 0 dB in 1 dB steps. In addition, SpecAugment was applied to the generator, with 1 random mask added for each frequency and time axis, followed by performance of 5 steps per minibatch [32].

These steps produced a trained model using 5-fold cross-validation over 150 training epochs and confirmed that the learning curve showed no signs of overfitting.

Evaluation

Data Collection

The medical devices selected included those frequently used for ventilator-equipped patients who require many medical devices in the general ward of the hospital. Alarm sounds to be identified included pulse sounds from a syringe pump (SP), enteral feeding pump (ENP), and venous foot pump (VFP) device as well as burst sounds from an infusion pump (IP), chest drainage (CD), patient monitor (PM), and the mechanical ventilator. The alarm sounds of each device were recorded using a monaural microphone placed at the head of a bed in a quiet private room in the hospital. The distance between the sound source and the microphone was the same as in a typical bedside setting (Figure 3). The sound pressure level was recorded simultaneously. The recording has a different number of active sound events superimposed on each frame. Therefore, the frame has various polyphony levels. The distribution of polyphony levels when recording the alarm sounds for the 7 devices is shown in Table 2. Audacity was used for labeling, extracting fundamental frequencies, and performing spectral analysis for annotation. Table 3 shows the detailed characteristics of the recorded alarm sounds.

Figure 3. Recording environment. Numbers in parentheses represent the distance between the microphone and each device.

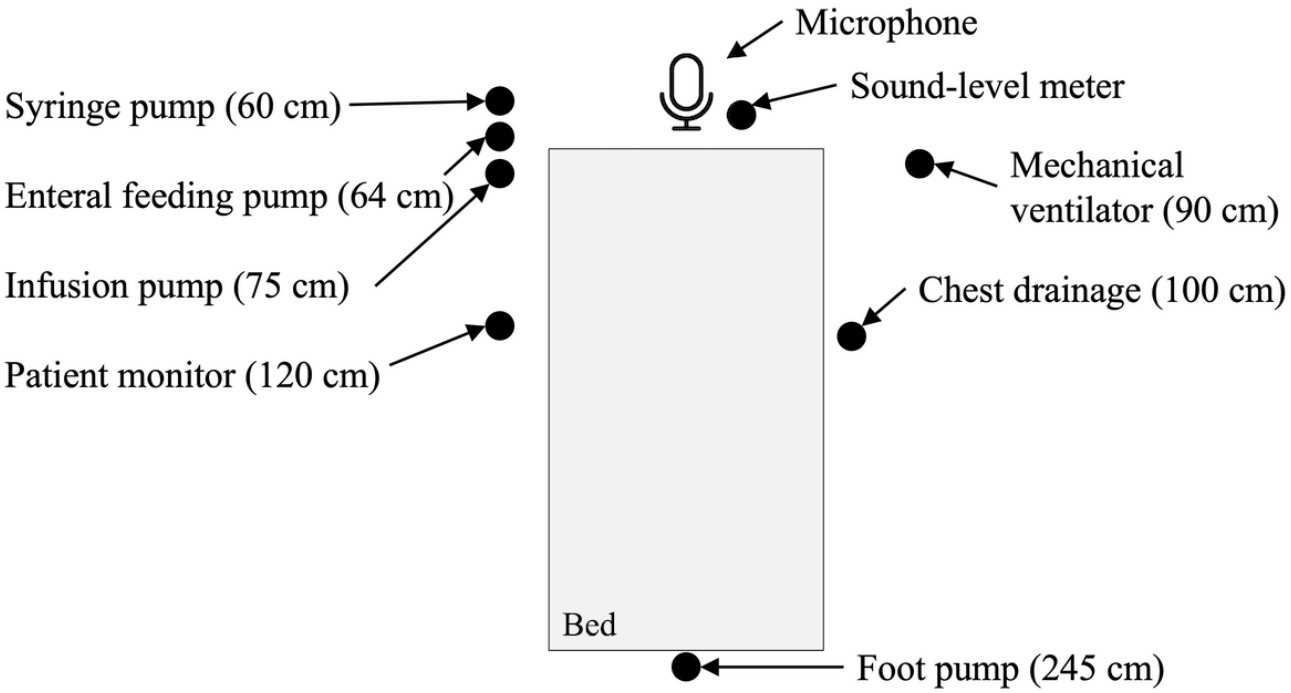

Table . Level of each sound relative to the total level of polyphonic sound.

Polyphony level	Data mount, n (%)
0	0 (0)
1	3655 (5.7)
2	15,011 (23.6)
3	22,547 (35.4)
4	15,911 (25)
5	5280 (8.3)
6	1230 (1.9)

[c]Middle-priority alarm sound.

Simulation Dataset

The robustness of the classifier was evaluated using a simulation dataset of alarm sounds added to HWN (which comprised conversations, footsteps, closet opening and closing sounds, intraoral suction, and ventilator exhalation sounds but not alarm sounds from other medical devices) at different SNRs (Figure 1). For the simulation dataset, the alarm sounds were recorded separately from those in the Data Collection section, using the same recording protocol (quiet private room, identical microphone placement, and device settings). During recording, all 7 devices were set to repeatedly emit alarms, sometimes overlapping due to differences in their alarm durations. Multiple alarms sometimes sounded simultaneously because of differences in the duration times of each alarm sound. Table 4 shows the maximum sound pressure of each sound source. In contrast to the training dataset—where alarm sounds were superimposed on white noise at SNRs ranging from 30 to 0 dB in 1 dB steps—the simulation dataset used for evaluation was created by superimposing the recorded HWN on alarm sounds at 4 SNR settings (30, 20, 10, and 0 dB) to reproduce realistic clinical environments. As shown in this figure, the VFP alarm exhibited the lowest sound pressure level among the devices, whereas other devices, such as SP and ENP, had relatively higher levels.

Table . Maximum sound pressure levels of each of the devices in the recording simulation dataset.

Source device	Sound level (dB)
Infusion pump	71.9
Syringe pump	77.7
Enteral feeding pump	64.4
Venous toot pump	61.2
Chest drainage	73.7
Patient monitor	62.1
Mechanical ventilator	79.6
Hospital ward noise	63.4

Performance Metrics

Model performance was evaluated using 5-fold cross-validation. No formal statistical significance tests were conducted, as the primary objective was descriptive benchmarking rather than hypothesis testing. Evaluation was performed using the sed_eval module [7,33]. The classifier outputs each predicted value of the 7 devices. The predicted values were dichotomized based on a cutoff value of 0.5. The onset and offset times input into the sed_eval module were calculated from the change points of the output results. Segment-based metrics are an index that determines whether the reference and the output match for each set time resolution (second). Therefore, the time resolution was set to 0.1 seconds, half of the shortest alarm duration time among the 7 devices. The event-based metrics index evaluated the timing of onset and offset from the set collar (seconds). The collar was set to 2.0 seconds based on the response of the notification system. Event-based metrics evaluation considers the actual operation and is more stringent than segment-based evaluation. Comparisons were evaluated using overall metrics (microaverage) and class-wise metrics.

XSL•FO
RenderX

For clinical applicability, inaccurate information is unacceptable, as it puts patients at risk. Therefore, the requirement for clinical application was set at an F_1-score value of 0.900 or higher for event-based overall metrics and an F value of 0.950 or higher for class-wise recall metrics.

Finally, the predicted results were visualized using the sed_vis module, and the spectrogram and classification results were examined [34].

Ethical Considerations

This study did not involve human participants or animal experiments. The recordings contained no speech, personal identifiers, or patient-related information. Therefore, ethics approval was not required in accordance with institutional and international research ethics policies.

Results

Table 5 summarizes the overall performance metrics at an SNR of 0 dB. The 679-second simulation dataset consisted of 63,649 frames, of which 63,488 frames were evaluated using 256-frame input windows. Among the segment-based metrics, CNN4+BiGRU achieved the highest F_1-score, followed by CNN3+BiGRU. Conversely, for event-based metrics, CNN3+BiGRU outperformed all other models, with CNN4+BiGRU ranking second. Regarding recall, event-based metrics showed values of 0.950 or higher for all BiGRU-based models, whereas segment-based metrics yielded recall values below 0.950 for all models.

Table . Overall metrics (microaverage) at a signal-to-noise ratio of 0 dB across 5-fold cross-validation. The numbers in italics represent the optimal value for the proposed models.

	Segment-based metrics, mean (SD)			Event-based metrics, mean (SD)		
	F_1-score	Precision	Recall	F_1-score	Precision	Recall
CNN3[a]+BiSRNN[b] (baseline)	0.832 (0.007)	0.822 (0.009)	0.841 (0.011)	0.921 (0.003)	0.874 (0.009)	0.973 (0.008)
CNN3+BiGRU[c]	0.868 (0.008)	0.845 (0.006)	0.894 (0.012)	*0.967 (0.011)*	*0.944 (0.014)*	*0.991 (0.011)*
CNN4+BiGRU	*0.873 (0.004)*	*0.856 (0.003)*	0.890 (0.008)	0.965 (0.008)	0.942 (0.009)	0.989 (0.008)
ALL-CNN4+BiGRU	0.867 (0.010)	0.839 (0.010)	*0.896 (0.011)*	0.948 (0.021)	0.915 (0.032)	0.983 (0.008)

[a]CNN: convolutional neural network.

[c]BiGRU: bidirectional gated recurrent unit.

Table 6 shows the event-based class-wise metrics at an SNR of 0 dB. Only event-based metrics are reported here, as they reflect the temporal accuracy of onset and offset detection, which is essential for clinical alarm management, whereas class-wise segment-based metrics are less indicative of operational performance. Class-wise segment-based results are provided in Multimedia Appendix 1 [30] for reference. Event-based evaluation showed that CNN3+BiGRU and CNN4+BiGRU had a recall value of 0.990 or higher for all devices but VFP. In contrast, the ENP, PM, and ventilator had F_1-scores of 0.900 or less due to their low precision. The reference standard was the correctly annotated label from the event roll that visualized the classification results, while the output was the model's identified results. In the absence of sound, the device was detected visually (Figure 4).

Discussion

Principal Results

The proposed classifier was found to successfully detect the status of nearby medical devices. Although video-based alarm detection was also considered, it was not feasible to detect the monitors with cameras without the introduction of a blind spot. Therefore, SED was considered a more feasible approach than video recognition.

This study describes the construction of a classifier using a large amount of artificial noise data. This classifier was used to evaluate polyphonic alarm sounds among a simulation dataset of HWN. Because the classification target is a sine wave, we expected that the target could be achieved with simple neural networks. However, BiSRNN did not achieve the target performance, requiring the application of BiGRU. Both the frequency and time axes required advanced processing to recognize alarm sounds. In addition, a convolutional layer with 4 layers outperformed one with 3 layers. The F_1-score of the classifier using BiGRU was 0.900 or higher, which was robust in the detection of polyphonic alarm sounds. Only VFP in each proposed classifier was unclear in the spectrogram due to VFP having the lowest sound pressure level of the 7 devices, thus resulting in low recall. In addition, masking of an impact sound over the entire frequency axis of the spectrogram would result in lower precision and overdetection.

Clinical Application as a Notification System

The notification system should alert the hospital information system without missing any situations, whether alarms are sounding on a single device or on multiple devices simultaneously. Therefore, recall of class-wise metrics was considered the most important in evaluating clinical applications. In particular, recall for the ventilator, the most essential support device of the 7 evaluated, was 1.000.

CNN4+BiGRU had the highest F_1-score in the event-based overall metrics, and the recall values of ENP, CD, and the ventilator were 1.000 each. Only VFP showed a recall value below 0.950, primarily due to its lower sound pressure level. In some cases, detection occurred slightly earlier than the actual onset, which reduced the measured recall. However, the ventilator demonstrated low precision with frequent overdetections, suggesting that it could not be evaluated clinically because it could cause alarm fatigue [35]. In contrast, because the F_1-scores of ENP, VFP, and CD without external output were 0.900 or higher, the system was likely feasible to notify staff of the alarm status of medical devices that could not be connected to the hospital information system. Therefore, the proposed system demonstrated feasibility as an alarm sound detection system and can be further refined for clinical use.

Integration Into Hospital Networks

Data Privacy Implications

The system processes only nonspeech alarm signals, ensuring that no patient-identifiable audio is stored or transmitted. When integrated into hospital networks, alarm classifications should be anonymized at the edge, transmitting only classification results in compliance with privacy regulations such as the General Data Protection Regulation and Japan's Act on the Protection of Personal Information.

Real-Time Processing Feasibility

Our classifier was designed for lightweight deployment, with feature extraction and model inference feasible on edge devices. The processing latency is on the order of milliseconds per input window, enabling real-time alarm monitoring without delaying clinical response.

Regulatory Concerns

Integration of an alarm detection system into hospital infrastructure would require compliance with medical device

XSL•FO
RenderX

standards, including ISO/IEC 60601-1-8 for alarm systems. Depending on the jurisdiction, such a system may be classified as a medical device software, requiring regulatory approval. Early consultation with regulatory authorities is recommended to ensure compliance and patient safety.

Limitations

This study had several limitations. First, the study evaluated only a limited range of medical devices from a single hospital, potentially limiting generalizability. Second, differences in hospital architecture (eg, room layouts, wall materials, and ambient noise) may affect sound propagation and detection. Third, despite ISO/IEC 60601-1-8 regulations, variations in alarm sounds across manufacturers and models were not assessed. Finally, large-scale live recording and annotation remain impractical; future work should use synthetic datasets and validate performance across diverse environments and device types.

Comparison With Prior Work

Several reports have examined the classification of alarm sounds using deep learning. Evaluation of single sounds of horns and bicycle bells found that the 5-layer deep neural network that applied an integrated judgment process had F_1-scores of 0.99 or higher [4]. Because horns and similar devices do not create sine waves of digital sounds, they cannot be evaluated in the same way as alarm sounds of medical devices. A study of alarm sounds of medical devices in a neonatal intensive care unit found that most of the alarms had SNRs of 0 dB or higher [8]. That study, however, did not consider a classifier for polyphonic alarm sounds. A classifier using CRNN was found to be effective for polyphonic acoustic sounds [26,36].

Conclusions

Missed medical device alarms can lead to serious adverse events. To mitigate such risks, we developed a deep learning–based classifier for detecting polyphonic alarm sounds in hospital environments.

Alarm sounds emitted by medical devices are regulated by ISO/IEC 60601-1-8. Because this standard defines different tones and patterns for each device and priority, SED is expected to identify the device and priority successfully. Thus, we considered SED appropriate to determine alarm status. Automatic identification of alarm sounds in hospital rooms would facilitate safer medical care.

In the simulation experiment, the polyphonic alarm sound classifier showed excellent performance, with an F_1-score of 0.945 at an SNR of 0 dB. The proposed classifier demonstrated feasibility for clinical alarm sound detection and can be further optimized. When combined with network connectivity, this classifier could improve the notification of abnormal patient status detected by medical devices without requiring each device to be individually connected.

Abstract

Background: The shortage of pediatric medical resources and overcrowding in children's hospitals are severe issues in China. Accurately predicting waiting times can help optimize hospital operational efficiency.

Objective: This study aims to develop machine learning models to predict waiting times for various laboratory and radiology examinations at a pediatric hospital.

Methods: Time stamp data from laboratory and radiology examinations were retrospectively collected from the pediatric hospital information system between November 1, 2024, and March 13, 2025. Two queue-related and 4 time-based features were extracted using queue theory. Linear regression and 8 machine learning models were trained to predict waiting times for each medical task. Hyperparameters were fine-tuned using randomized search and 10-fold cross-validation, and the bootstrap method was used for model evaluation. Mean absolute error, mean square error, root mean square error, and the coefficient of determination (R^2) were used as evaluation metrics. Shapley additive explanations values were used to assess feature importance.

Results: A total of 230,864 time-stamped records were included after data preprocessing. The median waiting time was 4.817 (IQR 1.867-12.050) minutes for all medical tasks. Waiting times for radiology examinations were generally longer than those for laboratory tests. Tree-based algorithms, such as random forest and classification and regression trees, performed best in predicting laboratory test waiting times, with R^2 values ranging from mean 0.880(SD 0.003) to mean 0.934 (SD 0.003). However, the machine learning models did not perform well in predicting radiology examination waiting times, with R^2 ranging from 0.114 (SD 0.005) to 0.719 (SD 0.004). Feature importance analysis revealed that queue-related predictors, especially the number of queuing patients, were the most important in predicting waiting times.

Conclusions: Task-specific prediction models are more appropriate for accurately predicting waiting times across various medical tasks. Guided by queue theory principles, we developed machine learning models for the waiting time prediction of each medical task and highlighted the importance of queue-related predictors.

Introduction

Background

Pediatric health care resources are considerably more scarce compared to other medical specialties. From 2015 to 2020, the growth rate of categorical pediatric residency positions in the United States was only 7%, which was far slower than the growth rate of other specialties during that time [1]. In China, the lack of resources for pediatric medicine is much more severe. According to national statistical data [2], the number of pediatricians per child in China is approximately half that in the United States. Furthermore, China has a very unequal distribution of pediatric experts, with a heavy concentration in developed metropolitan areas [3]. This leads to patient clustering and increased overcrowding in tertiary pediatric hospitals. A typical pediatric medical visit consists of multiple steps, including consultation, radiology examination or laboratory tests, and medication dispensing. Excessive waiting times at each of these stages not only reduce patient satisfaction [4] but may also contribute to adverse clinical outcomes [5,6].

XSL•FO
RenderX

Therefore, accurately predicting waiting times and improving operational effectiveness in pediatric hospitals is of critical importance.

Queue management systems in hospitals can enhance operational efficiency through features such as real-time queue updates, automated notifications, and online appointment scheduling [7]. Prior research has examined queue-related issues using techniques such as time series analysis (TSA) [8], discrete event simulation [9], and queue theory (QT) [10]. These methods simulate queue dynamics under various parameters to assess operational performance and identify the optimal resource allocation strategies. However, there are several obstacles to overcome before they may be used in actual health care settings. The application of these approaches is limited in practice because health care queues often deviate from the fundamental assumptions that underlie them, such as known initial probability distributions, exponentially distributed waiting times, or stationary queue states [11]. As a result, these models frequently fail to capture the variability and fluctuations inherent in actual queue dynamics, reducing their accuracy in predicting waiting times.

Machine learning models are developed using data-driven approaches and usually do not require restrictive assumptions. To overcome the drawbacks of conventional techniques, machine learning presents a viable substitute for forecasting wait times in hospital lines. In previous studies, Chen et al [12] applied an improved random forest algorithm to predict patient waiting times for each treatment task, such as blood tests, computed tomography (CT) scan, and pharmacy dispensing, and the hospital queuing-recommendation system based on the prediction algorithm reduced waiting times by guiding patient flow. Similarly, Lin et al [13] evaluated the performance of several machine learning algorithms for waiting time prediction and selected the best-performing model for prediction in a pediatric ophthalmology outpatient clinic. Chocron et al [14] compared machine learning algorithms with classical QT models for waiting time prediction and found that machine learning models produced better predictions than traditional methods in complex real-world scenarios. Therefore, machine learning techniques provide a more reliable way to capture variations in actual queue dynamics and improve the prediction accuracy of waiting time. Furthermore, multitask queues in pediatric hospitals have received less attention in the majority of studies, which have concentrated on emergency departments (EDs) [15-17] or radiology departments [18]. Nevertheless, the operational effectiveness of different medical task windows varies, and research focusing on a specific queue may not adequately capture the dynamics of other hospital medical tasks. A comprehensive investigation of waiting time prediction for different medical tasks can offer deeper insights into the use of medical resources and can be used as an alternative method to support medical resource optimization.

Objectives

This study investigates the dynamic characteristics of multiple medical task queues using real-world data from a large pediatric hospital in northern China. By incorporating principles from QT for feature selection, key features were extracted from actual hospital queue data, and then, we used machine learning techniques to predict waiting times after patient check-in across various medical tasks in the hospital. The predictive performance of different machine learning models is systematically evaluated. Additionally, feature importance analysis is conducted to assess the contribution of individual predictors and to provide insights for optimizing hospital operational efficiency. We also plan to deploy the best-performing model for waiting time prediction to improve the patient experience and help reduce hospital overcrowding in the future.

Methods

Problem Definition

During a hospital visit, patients usually have one or more medical tasks, which are frequently spread out over several hospital departments. For instance, a pediatric patient with an acute respiratory tract infection might undergo a series of steps, starting with a consultation in the respiratory department. After blood sampling and throat swab collection, the patient has an X-ray examination and then returns to the pulmonary department when all diagnostic reports are ready and the physician has ordered medicine. Finally, the patient goes to the pharmacy to pick up the necessary medications.

As illustrated, there may be unforeseen waiting times at each step of the medical tasks, which can significantly affect the patient's overall experience [19]. Furthermore, hospital operational efficiency may be lowered by disorderly queue arrangements. Targeted optimization of medical resource allocation based on key factors influencing waiting time represents a practical and effective strategy. As a result, in actual hospital settings, queue notifications may be provided by predictive algorithms that estimate waiting times with great accuracy, which will assist in reducing patient anxiety.

Data Collection

This study retrospectively collected records of patients who visited the Capital Center for Children's Health, Capital Medical University, between November 1, 2024, and March 13, 2025, for various laboratory tests and radiology examinations; the total raw dataset comprised 326,701 entries. The time stamp of these records was retrieved from the health information system for patients who attended the hospital during this period. The key information is summarized in Table 1.

XSL•FO
RenderX

Table . Information extracted from the health information system.

Records name	Description
Patient ID	A unique identifier assigned to each patient during their visit to the hospital
Medical task name	The specific examination conducted during a patient's visit, including throat swab, blood sampling, laboratory test for patients with fever, CT[a], MRI[b], X-ray, laryngoscopy, ultrasound, and echocardiography
Visit category	The department from which the patient is referred, including outpatient and ED[c]
Service location	The specific location where the patient receives medical services
Check-in time	The time when the patient completes check-in upon arriving for a specific medical task
Sampling or examination start time	The time when the patient begins a specific medical examination: the start time of laboratory tests is recorded as the sampling time, while the start time of the radiology examination is recorded as the examination start time

[a]CT: computed tomography.

[b]MRI: magnetic resonance imaging.

[c]ED: emergency department.

Following the retrieval of all records, the data were arranged according to the practical medical tasks performed by the institution. In this hospital, the tasks for laboratory tests include throat swab at the first floor (throat swab–first floor) and the second floor (throat swab–second floor), blood sampling, and laboratory test for patients with fever (laboratory test–fever). The radiology examination includes CT, magnetic resonance imaging (MRI), X-ray, laryngoscopy, ultrasound, and echocardiography. Blood sampling, ultrasound, and echocardiography are further divided into outpatient and ED windows at this facility.

Ethical Considerations

All data used in our study was anonymized and deidentified and did not involve data related to humans. Therefore, our research was exempted from the requirement of written informed consent and was approved by the Ethics Committee of the Capital Center for Children's Health, Capital Medical University (SHERLLM2024037).

Data Preprocessing

We define the waiting time as the duration from the patient's check-in to the start of the sampling or examination, as follows:

$$\text{Waiting time} = \text{Sampling/Examination start time} - \text{Check-in time} \quad (1)$$

First, we removed records that do not include the sampling or examination start time and check-in time. Due to the presence of numerous duplicate records in the health information system, we then performed a deduplication procedure on the extracted data. If the patient ID and sampling or examination start time are identical in the records, it will be removed as a redundant duplicate. To avoid negative waiting times, we then removed data when the check-in time is later than the sampling or examination start time. In addition, there may be very long waiting time outliers because some patients may not line up for the medical service window immediately after check-in—possibly leaving the hospital for a period or coming back on a subsequent day to continue their tests or examinations. To address this issue, we applied an IQR method to denoise the data using the following criterion:

$$\text{Noise record} > 75\%\ \text{quantile} + 1.5 \times (75\%\ \text{quantile} - 25\%\ \text{quantile}) \quad (2)$$

Records with waiting times exceeding the IQR were classified as noise and discarded. Model development was then conducted using the remaining data.

Feature Construction

Queue-length (QL) predictors and delay-history predictors are the 2 types of predictors used in earlier QT experiments to forecast waiting times [20]. While the latter makes predictions based on past waiting times, the former refers to projecting waiting time based on the queue's present status factors. As we have access to the precise time stamps for every patient's test or examination, we make predictions using QL predictors, which comprise the following two categories of features:

1. Time-based feature; these include the month, day, hour, and day of the week when a patient undergoes a specific medical task. These indicators can all be derived from the abovementioned records. Given that patient data vary significantly across different periods, these 4 time-related factors were considered as potential predictors.
2. Queue-related feature; these include the patient arrival rate per hour, calculated by counting the number of patients registering for a particular task each hour, and the number of queuing patients, that is, the number of patients who have checked in but have not yet started the sampling or examination.

In summary, we selected only 6 indicators, including month, day, hour, day of the week, arrival rate, and the number of queuing patients, to predict the waiting time using a concise set of predictors.

XSL•FO
RenderX

Model Development and Feature Importance Analysis

In our experiment, we use linear regression (LR) as a baseline model and 8 machine learning models for waiting time prediction, including k-nearest neighbor (KNN), support vector regression (SVR), classification and regression tree (CART), elasticNet, random forest (RF), light gradient boosting machine (LightGBM), extreme gradient boosting (XGBoost), and multilayer perceptron (MLP). As the waiting time is a continuous variable, we evaluate the models using the following performance metrics: mean absolute error (MAE), mean square error (MSE), root mean square error (RMSE), and the coefficient of determination (R^2). Equations 3–6 show the formula of MAE, MSE, RMSE, and R^2, where the y^i is the prediction value, the y-i represents the mean value of the waiting time, and the yi is the actual value.

(3)MAE=∑i=1n|y^i−yi|n

(4)MSE=∑i=1n(y^i−yi)2n

(5)RMSE=∑i=1n(y^i−yi)2n

(6)R2=1−∑i=1n(y^i−yi)2∑i=1n(yi−y¯)2

A randomized search and 10-fold cross-validation were used to fine-tune each model's hyperparameters. The performance of the models was evaluated using the abovementioned metrics, and the model with the best performance across these metrics was selected for prediction. To further evaluate the stability and reliability of the chosen model, a bootstrap approach was applied. MAE, MSE, RMSE, and R^2 were calculated for each bootstrap sample by comparing the model's predictions with the true values. The 95% CIs for each metric were derived to quantify the uncertainty in the model's predictive performance. Feature contributions to the waiting time prediction were quantified using Shapley additive explanations (SHAP) values [21]. For tree-based models, SHAP values were computed directly; for others (KNN and SVR), a background dataset was used to simulate feature absence, allowing for marginal contribution estimation via the KernelExplainer function. The entire research process is shown in Figure 1. All analyses were performed using Python (version 3.12; Python Software Foundation).

Results

Basic Characteristics of the Medical Queue

From November 1, 2024, to March 13, 2025, a total of 230,864 records were included after preprocessing the raw data. The required tasks were classified into 2 main categories: laboratory tests, which included 5 types of tasks, and radiology examinations, which included 8 types of tasks. The most frequently performed laboratory test was blood sampling for outpatient patients (76,587/230,864, 33.17%), while the most common radiology examination was X-ray (31,125/230,864, 13.48%; Table 2).

Table . Basic characteristics of queuing in different medical tasks (N=230,864).

Tests and examinations		Tasks, n (%)	Time, range (min)	Time, median (IQR)
Laboratory test				
	Throat swab—first floor	26,314 (11.05)	0.017 - 28.4	1.617 (0.483 - 5.799)
	Throat swab—second floor	13,296 (5.75)	0.017 - 26.967	1.467 (0.417 - 6.971)
	Blood sampling—ED[a]	23,558 (10.20)	0.150 - 5.533	1.650 (1.049 - 2.483)

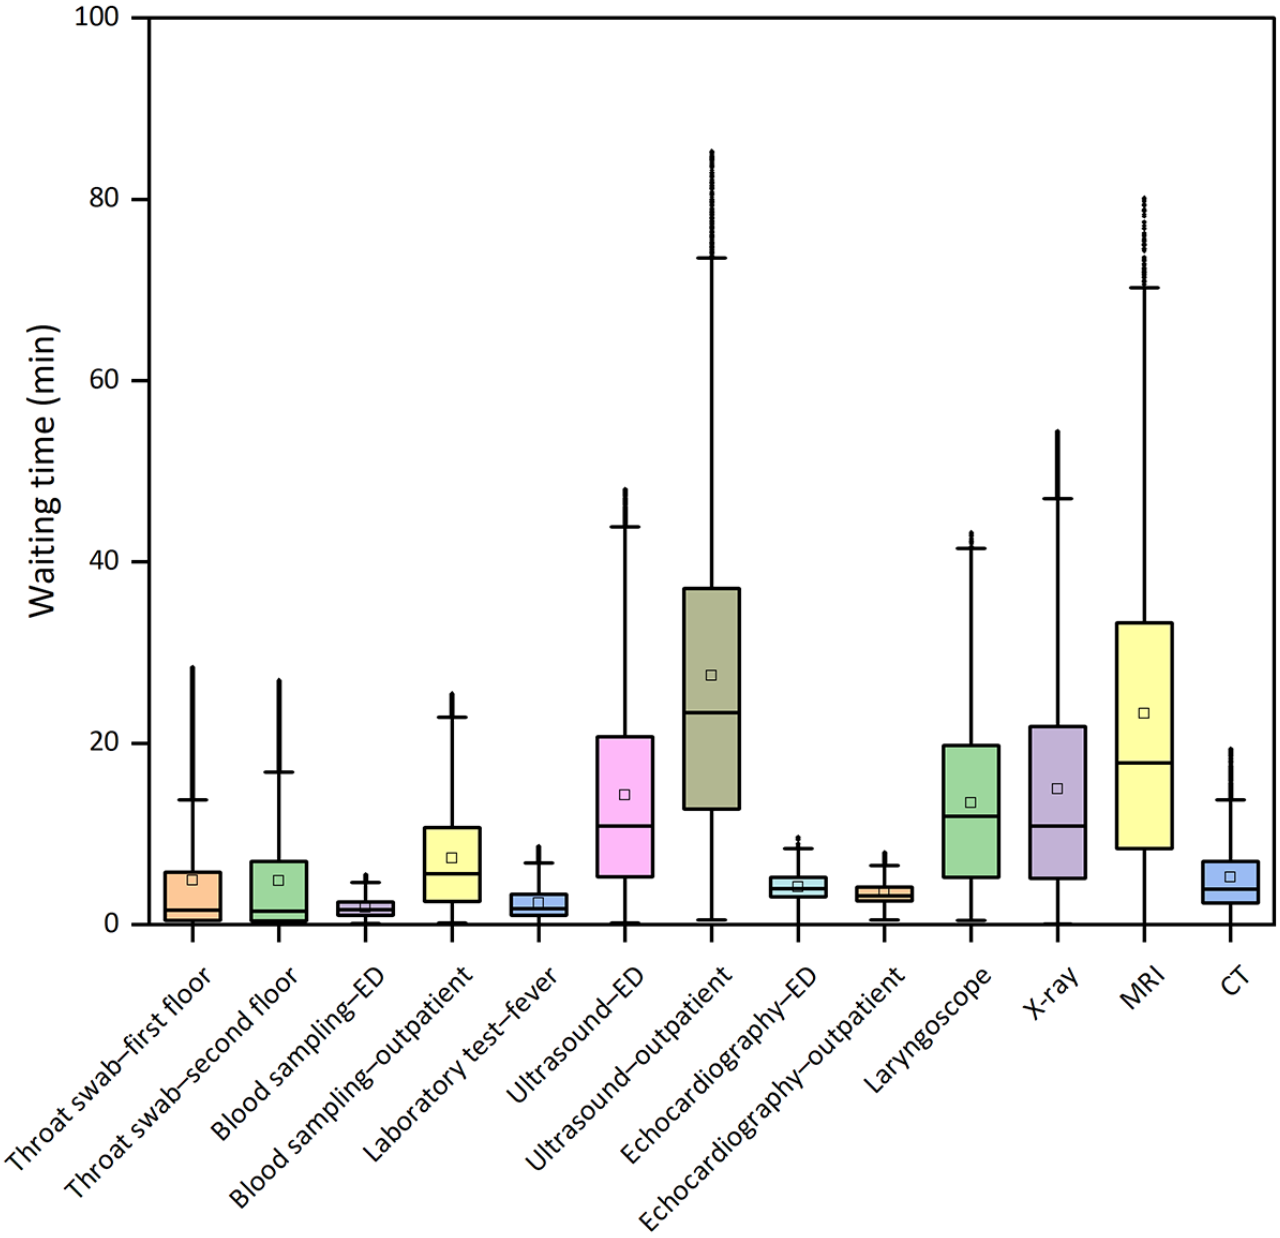
[a]ED: emergency department.



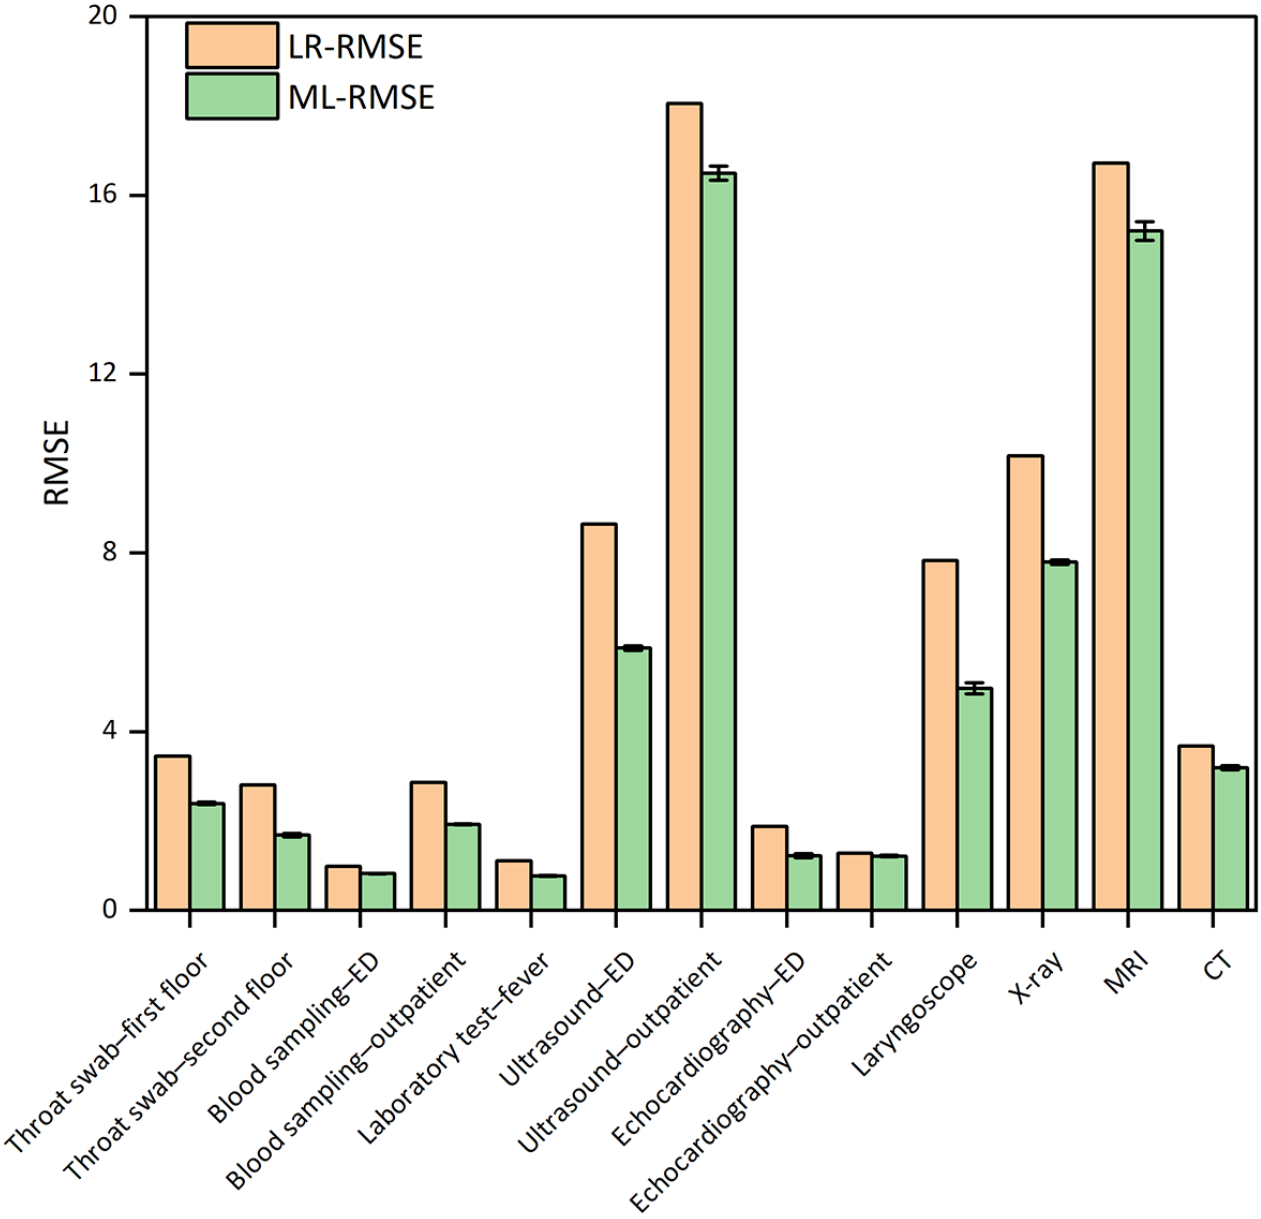
[b]MRI: magnetic resonance imaging.

[c]CT: computed tomography.

In the laboratory test category, we observed that blood sampling–ED (median 1.650, IQR 1.049-2.483 min) had the narrowest waiting time range, while the task for blood sampling–outpatient (median 3.225, IQR 2.583-10.700 min) had a relatively extensive waiting time range (Figure 2). For radiology examinations, the range of waiting time for the echocardiography task was narrow (median 3.958, IQR 3.054-5.212 min for ED; median 3.200, IQR 2.600-4.167 min for outpatient). In contrast, outpatients had to wait much longer for an ultrasound (median 37.067, IQR 12.750-23.400 min; Figure 2). Compared to laboratory tests, patients experienced longer waiting times in most radiology examinations.

XSL•FO
RenderX

Figure 2. Box plot of distribution of waiting time. CT: computed tomography; ED: emergency department; MRI: magnetic resonance imaging.



The distribution of waiting time of the total medical task followed an exponential pattern (Figure S1 in Multimedia Appendix 1). At different time points, we observed average arrival rate peaks for medical tasks at approximately 10:00 AM, 15:00 PM, and 8:00 PM. Similarly, 3 peaks were also present for the average number of queuing patients across different days of the week (Figures S2 and S3 in Multimedia Appendix 1). However, the waiting time of patients showed a first earlier peak at approximately 7:00 AM, with 2 lower peaks at approximately 12:00 AM and 8:00 PM (Figure S4 in Multimedia Appendix 1). In addition, the distribution of waiting time for different medical tasks before and after denoising is shown in Figure S5 in Multimedia Appendix 1.

Model Evaluation

We used 8 different models for predicting waiting times before laboratory and radiology tasks, while LR was used as the baseline model. After hyperparameter optimization, the optimal performance of the selected models for different tasks is shown in Table S1 in Multimedia Appendix 1. In 6 medical task queues, RF demonstrated the best predictive performance, with RMSE ranging from 1.925 (SD 0.015) to 2.395 (SD 0.033) for laboratory tests and from 1.217 (SD 0.015) to 15.204 (SD 0.207) for radiology examinations. In addition, XGBoost demonstrated effective performance in predicting waiting times for the throat swab–first floor (RMSE: mean 2.395, SD 0.033; R^2: mean 0.880, SD 0.003), echocardiography-ED (RMSE: mean 1.224, SD 0.048; R^2: mean 0.612, SD 0.021), and CT (RMSE: mean 3.191, SD 0.043; R^2: mean 0.382, SD 0.011), and CART, LightGBM, SVR, and KNN can also be used for waiting time prediction. All selected models outperformed the baseline LR model (Figures 3 and 4). The optimal hyperparameters identified through randomized search are provided in Table S2 in Multimedia Appendix 1. In addition, the calibration and residual plots are provided in Figures S8-S18 in Multimedia Appendix 1.

Feature Importance Analysis

On the basis of the QT principle, we ultimately selected the number of queuing patients, arrival rate, month, day, day of the week, and hour as independent features for predicting waiting time. To evaluate the contribution of each feature to the machine learning model, we computed SHAP values, which quantify the impact of individual features on the predicted waiting time. The mean SHAP value was used to rank each feature. The rankings of feature importance across different models are visualized in a heat map plot (Figure 5). Notably, for the majority of medical tasks, queue-related features, such as the number of queuing patients, emerged as the most influential predictor of waiting time, and the arrival rate was also expressed as another important feature for waiting time prediction. The details of the mean SHAP value are provided in Table S3 in Multimedia Appendix 1.

Discussion

Principal Findings

This study collected patient data from the Capital Center for Children's Health, Capital Medical University, spanning the period from November 1, 2024, to March 13, 2025, comprising a total of 230,864 records after data preprocessing. The distribution of waiting times for overall medical tasks followed an exponential pattern, with a median value of 4.817 minutes. Notably, peak periods in the average patient arrival rate and the average number of queuing patients were observed at 10:00 AM, 3:00 PM, and 8:00 PM. The waiting time exhibited a different pattern, with an earlier peak occurring at approximately 7:00 AM, along with 2 additional, smaller peaks around 12:00 PM and 8:00 PM, indicating the periods of highest congestion within the hospital. During model selection, tree-based algorithms such as RF, XGBoost, CART, and LightGBM demonstrated better accuracy in predicting waiting times for most medical task queues, while SVR and KNN can also be used as appropriate algorithms. Additionally, feature importance analysis revealed that the number of queuing patients was the most influential predictor of waiting time.

QT and TSA are classical approaches used to model and simulate queue dynamics in health care settings [22,23]. The application of QT requires the key input parameters, including the average arrival rate (λ) and average service rate (μ). Several queue parameters, including average waiting time (Wq), total time spent in the system (Ws), average QL (Ls), and average number of individuals waiting (Lq), can be calculated based on these inputs. For example, waiting time can be estimated using

XSL•FO
RenderX

the formula $Wq=\lambda\mu(\mu-\lambda)$ in an M/M/1 queue [24]. By simulating the queuing status and adjusting service rates, different operational scenarios can be modeled for service optimization. However, QT has several limitations when applied to the prediction of waiting times in real-world hospital settings. First, as demonstrated in our study, QT assumes that patient arrivals follow a Poisson process and that service times conform to exponential distributions. While the entire waiting time across all tasks approximates an exponential distribution in our study, this assumption does not universally hold for each medical task queue (the distribution of waiting times for each task was provided on our Github website). Second, QT estimates queue parameters relying on average arrival and service rates, which are dynamic in clinical practice. Because patient volume and service effectiveness are constantly changing, QT's static assumptions are inadequate for simulating operating situations in real time [25]. Third, accurately measuring the actual service rates for each medical task is challenging. As a result, we had to rely on estimations based on prior experience, which likely reduced the precision of the modeled parameters. Additionally, TSA, which involves modeling sequences of observations indexed over time, has been applied in previous studies to forecast ED attendances [8,23,26-28]. While effective at capturing periodic trends in patient volumes, TSA is more suited to predicting daily volumes rather than individual-level waiting times. Instead of depending on the strict presumptions of QT or TSA, machine learning models may directly use real-world waiting time data, enabling flexible, data-driven prediction.

This study assessed a variety of models for the waiting time prediction task to achieve the optimal predictive performance. In most scenarios, the tree-based model performed better than other models and demonstrated strong predictive capability. The RMSE of the models in our study was lower than that reported in previous studies [11,12,17,29]. Strong predictive performance was shown by high R^2 values for a number of tasks, including throat swab–second floor (R^2: mean 0.934, SD 0.003), blood sampling–outpatient (R^2: mean 0.893, SD 0.002), and throat swab–first floor (R^2: mean 0.880, SD 0.003). As widely recognized, machine learning models are generally more effective than LR in capturing nonlinear relationships [30], and tree-based models typically handle tabular data more efficiently than deep learning models [31]. However, for several tasks, such as MRI, CT, ultrasound-outpatient, and echocardiography-outpatient queues, we observed weak associations between the features and waiting time. We believe that the small sample sizes for these tasks may contribute to the poor model performance. A longer data collection period could help improve performance. Additionally, the 6 features used in our model may not be sufficient for predicting waiting times across all medical tasks. Some medical tasks may have inherent complexities or variability in waiting times that are not fully captured by the current available features. For example, the waiting time for outpatient ultrasound and MRI may depend on factors such as the age and urgency of the case or physician workload, which are difficult to quantify with the current feature set. While we aim to develop a lightweight prediction model with simplified features for easier deployment, it is clear that for certain tasks, feature engineering and the inclusion of additional variables—such as patient age, gender, department, and diagnosed diseases—are necessary to improve performance. These strategies can help improve the prediction models for underperforming tasks and support their future deployment.

Notably, the data used to train our predictive models were primarily derived from the first and fourth quarters of the year, when patient visit patterns are different from those observed in other periods. According to surveillance data from the Chinese Center for Disease Control and Prevention, the prevalence of acute respiratory infections is elevated between November 2024 and January 2025 [32-34]. This seasonal trend aligns with epidemiological surveillance data from the United States, which indicate a predominance of respiratory tract infections among children during the winter months [35,36]. Throughout this time, pediatric attendance was consistently high from late December to January (Figure S19 in Multimedia Appendix 1), with January having the most visits (44,808/145,739, 30.75%). This phenomenon is probably caused by a confluence of environmental and school-related factors: lower temperatures and humidity promote viral stability and propagation, while more interpersonal interaction in school facilitates the spread of infectious illnesses. Children's hospital visits are accelerated by these 2 factors. The most frequent combinations for pediatric patients who received multiple medical services during a single visit were related to acute respiratory infections, including throat swab → laryngoscopy → X-ray → echocardiography, throat swab → X-ray → blood sampling, and throat swab → blood sampling [37,38]. These findings imply that queue loads for various services are considerably impacted by fluctuations in illness occurrence. Although feature importance analysis suggests that the contribution of the month feature is not particularly important across different prediction models, this may be attributed to the short data collection period, which constrains the ability to capture long-term temporal trends. Therefore, seasonal demand fluctuations can also be considered when optimizing patient flow and resource allocation (Figure S20 in Multimedia Appendix 1). Strategies such as increasing the number of service windows during high-demand periods could alleviate queue burdens and improve operational efficiency. For example, at times when respiratory infections were most common at this institution, a second throat swab window was opened.

Limitations

This study has several limitations. First, our study is a single-center investigation that was mostly carried out at a pediatric hospital during the winter. The findings of this study might not apply to circumstances outside of a children's hospital due to the unique characteristics of the patients at this facility. Second, although medicine dispensing is a critical component of the clinical workflow, it was excluded from the analysis since the pharmacy did not have a procedure for patients to check in, making it impossible to calculate waiting times. Lastly, waiting times for various medical tasks were predicted using numerous models, which complicated the overall predictive framework and posed challenges for real-world implementation.

XSL•FO
RenderX

Conclusions

In conclusion, the distribution of patient waiting times exhibits 3 distinct peak periods. However, waiting time patterns differ markedly across various medical task queues, each displaying unique characteristics that do not align with the overall trend. Consequently, developing task-specific predictive models for each medical task queue can enhance prediction accuracy. Feature importance analysis reveals that although queue-related features are the most influential in predicting patient waiting time, time-based features might also contribute meaningfully and should be considered to further optimize hospital operational efficiency.

Abstract

Background: Anti-N-methyl-D-aspartate receptor (NMDAR) encephalitis is a rare disease with no accurate prognostic tools to predict the prognosis of patients.

Objective: This study aims to develop an interpretable machine learning model using real-world clinical data to guide personalized therapeutic strategies.

Methods: This retrospective cohort study analyzed 140 patients with NMDAR encephalitis treated at the Third Affiliated Hospital of Sun Yat-sen University (2015 - 2024). Feature selection was done using recursive feature elimination. The model was constructed by 3 machine learning algorithms: decision tree, random forest (RF), and extreme gradient boosting. Mean squared error, root-mean-squared error, R^2 (coefficient of determination), mean absolute error, and mean absolute percentage error were used to evaluate the model performance. Finally, the optimal model was interpreted via Shapley Additive Explanations (SHAP) and deployed as a web application using the Flask framework.

Results: The median age of patients with anti-NMDAR encephalitis was 23 (IQR 18-31.8) years. The median Clinical Evaluation Scale for Autoimmune Encephalitis score at acute onset was 11 (IQR 6-16). After preprocessing, 20 features, including 4 demographic characteristics, 3 clinical characteristics, 11 laboratory parameters, and 2 neuroimaging characteristics, were selected. The RF demonstrated superior accuracy in predicting the prognosis (mean squared error=11.01; root-mean-squared error=3.32; R^2=0.71; mean absolute error=2.49; mean absolute percentage error=0.48). SHAP analysis identified admission to the intensive care unit (mean |SHAP value|=1.65), initial symptoms-memory deficits (0.69), and uric acid (0.53) as the most important prognostic predictors.

Conclusions: We developed and validated an interpretable RF-based prognostic model for NMDAR encephalitis. The web-deployed tool enables real-time risk stratification, facilitating clinical decision-making and personalized therapeutic interventions for clinicians.

KEYWORDS

anti-N-methyl-D-aspartate receptor (NMDAR) encephalitis; machine learning; SHAP; prognosis; prediction

Introduction

Anti-N-methyl-D-aspartate receptor (NMDAR) encephalitis represents more than 80% of autoimmune encephalitis (AE) cases. Its pathogenesis is closely linked to synaptic plasticity impairment mediated by autoantibodies targeting the NMDAR GluN1 subunit [1,2]. These antibodies induce limbic system dysfunction and characteristic neuropsychiatric manifestations [3]. While first-line immunotherapy has markedly improved survival rates, up to 30% - 47% of patients continue to experience cognitive deficits, psychiatric symptoms, or functional disabilities [4-6]. Consequently, the development of a dynamic prognostic evaluation system is critical for guiding individualized treatment strategies.

Since the initial report of NMDAR encephalitis in 2007, researchers have investigated the prognostic value of various

XSL•FO
RenderX

biomarkers. Current evidence indicates that cerebrospinal fluid antibody titers, extreme delta brush on electroencephalogram, and acute-phase inflammatory markers may correlate with disease severity [5,7-9]. However, single-dimensional biomarkers exhibit insufficient predictive power. Currently, there is a lack of integrated multidimensional data for constructing models to predict patient outcomes. Existing prediction models [10-12] predominantly rely on the modified Rankin Scale [13] and are limited in assessing the cognitive-mental dimension of NMDAR encephalitis. Moreover, traditional logistic regression approaches fail to adequately analyze complex nonlinear interactions among predictors, thereby reducing their clinical applicability.

Machine learning (ML) offers transformative potential for integrating and analyzing complex clinical data. In contrast to traditional statistical methods, ML algorithms can identify intricate feature interactions and enhance predictive performance in small-sample rare disease cohorts [14]. This capability has been successfully demonstrated in neurodegenerative diseases and tumor prognosis prediction by enhancing the feature representation of small-sample datasets. However, no study has systematically applied ML for prognostic prediction in NMDAR encephalitis.

The objective of this study is to integrate clinical features, neuroimaging findings, serological markers, and Clinical Evaluation Scale for Autoimmune Encephalitis (CASE) [15] scores to construct a prognostic prediction model for NMDAR encephalitis based on ML and identify early prognostic signatures through Shapley Additive Explanations (SHAP)–driven feature interpretability. Furthermore, a web-based clinical tool was developed to deploy the model, enabling clinicians to use it directly for prognostic predictions and to plan interventions (eg, escalation to second-line therapy or multiple immune combinations within a critical 4-week postsymptom window).

Methods

Study Design

Data for this retrospective study were collected from the Third Affiliated Hospital of Sun Yat-sen University from 2015 to 2024. This study was conducted in accordance with the Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis (TRIPOD) guidelines [16]. Informed consent was obtained from all participants. This study was approved by the ethics committee of the Third Affiliated Hospital of Sun Yat-sen University (II2024-370-01). This study comprised 3 phases: (1) cohort selection, (2) variable optimization and model development, and (3) validation and clinical translation tools.

Study Population

All patients underwent comprehensive evaluations, including neuroimaging, electroencephalogram, cerebrospinal fluid (CSF) analysis, and tumor screening.

Eligibility Criteria

The inclusion and exclusion criteria are listed in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Age ≥10 years at disease onset.
- Diagnosis of anti-N-methyl-D-aspartate receptor encephalitis based on established criteria.
- Diagnosis before immunotherapy.

Exclusion criteria

- Concurrent central nervous system neoplasms or noninfectious inflammatory disorders.
- Documented central nervous system infections (bacterial, fungal, parasitic, or tuberculous).
- Secondary septic encephalopathy or systemic inflammatory response syndrome–associated encephalopathy.
- Coexisting serum or cerebrospinal fluid autoantibodies associated with other autoimmune encephalitides.
- Incomplete clinical documentation.

Data Collection

Data were extracted from electronic medical records. Standardized variables included the following:

1. Demographics: age at disease onset, gender, occupation, and BMI.
2. Clinical characteristics: (1) prodromal symptoms (fever, headache, and dizziness) and (2) initial symptoms (psychiatric abnormalities, seizures, altered consciousness, and memory deficits).
3. Critical care interventions: intensive care unit (ICU) admission and mechanical ventilation requirement.
4. Laboratory parameters: CSF or serum anti-NMDAR antibody titers. CSF samples were analyzed using a cell-based assay by a trained specialist in a laboratory with experience in interpreting these assays. (1) Sex hormone tests include luteinizing hormone, follicle-stimulating hormone, estradiol, progestogen, and testosterone. (2) Hematological and biochemical analyses: white blood cell count, neutrophils, lymphocytes, monocytes, uric acid (UA), erythrocyte sedimentation rate, C-reactive protein, and high-density lipoprotein cholesterol.
5. Neuroimaging: Baseline magnetic resonance imaging (MRI) or electroencephalogram findings, including lesion quantity,

XSL•FO
RenderX

and MRI. Analysis was performed by a senior neuroradiologist and neurologist using 1.5/3.0 Tesla scanners with T1-weighted, T2-weighted, and FLAIR sequences. All electroencephalogram data were recorded according to the international 10‐20 system using an electroencephalogram Digi Track (ELMIKO) with 19 electrodes. Tumor details (if applicable) included tumor size (mean of longitudinal and transverse diameters on imaging) and number of tumors.

Evaluation Prognosis and Definitions

Outcome metric and clinical severity were quantified using the CASE scale, a validated 9-domain instrument assessing (seizures, memory deficits, psychiatric symptoms, consciousness, speech, motor or dystonia, gait or ataxia, brainstem dysfunction, muscle strength; total score: 0‐27). Prognostic stratification was defined as favorable: 0‐4 (minimal residual symptoms), moderate: 5‐9 (partial functional impairment), and poor: 10‐27 (severe disability). Lower CASE scores at follow-up indicated improved functional recovery.

Data Preprocessing and Feature Engineering

Categorical variables were coded by labels' encoding, while continuous variables were standardized using the Standard Scaler to mitigate feature scale bias. From an initial pool of 47 candidate predictors (selected via systematic literature review and clinical consensus), recursive feature elimination (RFE) with random forest (RF) (500 trees, Gini impurity) was applied. Features exceeding the importance threshold (P>.01) were retained. The threshold of 0.01 was empirically validated as optimal for maximizing cross-validation accuracy. This value consistently yielded peak performance in predicting prognosis across all candidate models (decision tree [DT], RF, extreme gradient boosting [XGBoost]), balancing feature retention with model generalizability. To rigorously mitigate randomness in RFE with a cross-validation workflow, we implemented a dual-strategy approach: (1) stratified cross-validation. Instead of relying on a single random train-test split, we used stratified 5-fold CV throughout the RFE process. (2) To test the stability of the selected feature set, we repeated the RFE with a cross-validation process multiple times with different random seeds (random_state=42). We then analyzed the frequency with which each feature was selected. Features that consistently appeared across multiple runs were considered more robust and were prioritized.

Model Development and Validation

The dataset was strategically partitioned through random stratified sampling into a training set (80%, n=112) and a validation set (20%, n=28). The training set was exclusively used for model development, while the validation set served as an independent cohort for performance evaluation. The 3 ML algorithms, including RF, XGBoost, and DT, were used to construct the prediction model of NMDAR. Benchmarking is an important way to systematically evaluate and compare the performance of ML models. This process involves evaluating multiple models on standardized datasets and using consistent evaluation metrics to ensure fair comparisons. In this study, model performance was assessed using mean squared error (MSE), root-mean-squared error (RMSE), coefficient of determination (R^2), mean absolute error, and mean absolute percentage error. The optimal model was selected based on minimal RMSE in validation. A 5-fold cross-validation was used to verify the stability of the model (Table 1).

Table . Five-fold cross-validation of the model.

Number of folds	MSE[a]	RMSE[b]	R^2[c]	MAE[d]	MAPE[e]
1	10.52	3.24	0.73	2.41	0.46
2	11.38	3.37	0.69	2.57	0.5
3	10.79	3.28	0.72	2.46	0.47
4	11.62	3.41	0.68	2.63	0.51
5	10.95	3.31	0.71	2.49	0.48
Average	11.052	3.322	0.706	2.512	0.484

[a]MSE: mean square error.

[b]RMSE: root-mean-squared error.

[c]R^2: coefficient of determination.

[d]MAE: mean absolute error.

[e]MAPE: mean absolute percentage error.

Model Interpretation and Network Application

The ML has difficulty explaining the contribution of each feature due to its black-box principle. Interpretability denotes elucidating how ML models produce results. To elucidate feature contributions, SHAP values were used to quantify and interpret feature importance in the best-performing model. The algorithm provides a measure of feature importance across the model. Local interpretability was visualized via force plots, while global patterns were assessed through mean |SHAP values|.

Network Application

Network application was deployed using Flask 2.3.2 backend with REST API, dynamic input forms aligned with selected predictors, real-time SHAP plot generation, and risk stratification output (probability scores with 95% CIs). This tool operates independently from any model and uses input

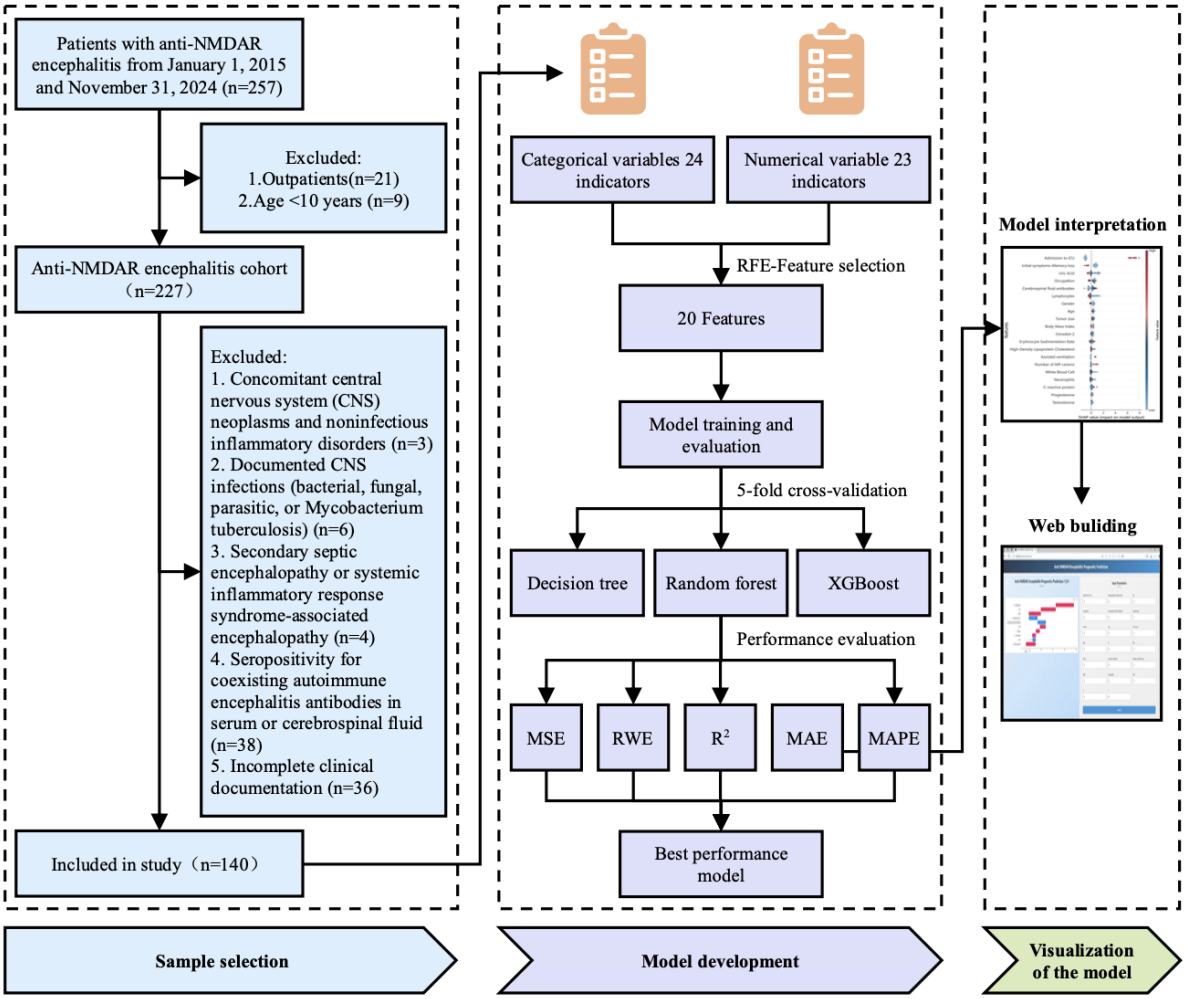
XSL•FO
RenderX

predictor variables for result interpretation while enabling predictions for individual cases.

Statistical Analysis

The Shapiro–Wilk normality test was performed to assess the data normality. Continuous variables are reported as medians with interquartile ranges (IQRs) for skewed distributed variables. Categorical variables are reported as frequency and percentage.

All statistical analyses were performed using IBM SPSS Statistics 22 (SPSS Inc). The predictive model construction and graphical representations were implemented using Python V3.7 (Python Software Foundation) and Prism 10.0 (GraphPad Software), respectively.



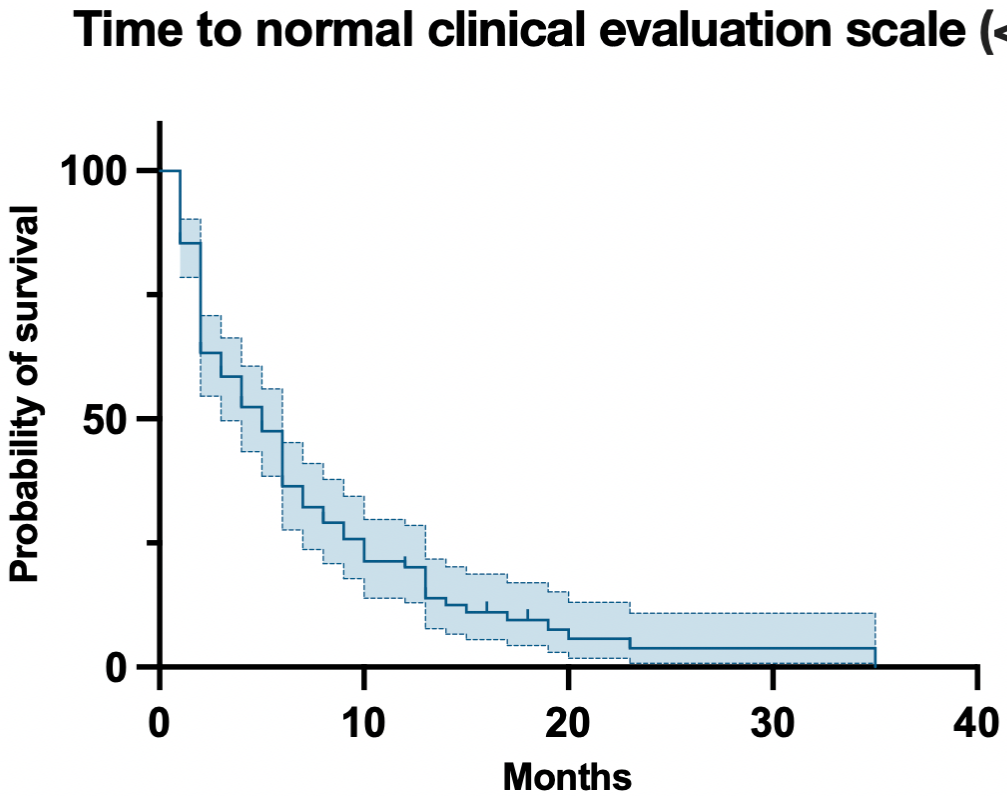
Ethical Considerations

The Ethics Committee of the Third Affiliated Hospital, Sun Yat-sen University (II2024-370–01) gave ethical approval on December 30, 2024. Informed consent was waived by the committee, as the study involved retrospective analysis of anonymized data and did not include any identifiable personal information. All procedures were conducted in accordance with the ethical standards of the institutional and national research committees and with the principles outlined in the Declaration of Helsinki. We ensured that the privacy and confidentiality of all participants were strictly maintained; data were fully anonymized before analysis, and no individual-level identifiers were collected, stored, or reported. No compensation was provided to participants, as the study did not involve direct interaction with human participants.

Results

A retrospective cohort of 257 patients diagnosed with anti-NMDAR encephalitis was identified from the electronic medical records of the Third Affiliated Hospital of Sun Yat-sen University (January 2014-November 2024). According to the inclusion and exclusion criteria, 140 patients were included in the final analysis (Figure 1).

Figure 1. Flowchart of the study strategy. Anti-NMDAR: anti-N-methyl-D-aspartate receptor; MAE: mean absolute error; MAPE: mean absolute percentage error; MSE: mean square error; R^2: coefficient of determination; XGBoost: extreme gradient boosting.



Population Characteristics

Among the final cohort (median follow-up 8, IQR 2 - 23 months), 102 of 140 (72.9%) were female patients, with a median age of 22 (IQR 17 - 30) years; of these, 50 (35.7%) were students. Pulmonary infections emerged as the most frequent comorbidity, occurring in 54 of 140 (38.6%) patients, whereas fever was the leading prodromal symptom, appearing in 41 (29.3%) patients. NMDAR encephalitis–associated diffuse slow waves and delta brush patterns in electroencephalography

XSL•FO
RenderX

were observed in 10% (14/140) and 2.1% (3/140) of cases, respectively. Among the 140 patients, 30 (21.4%) had tumors (28 benign teratomas and 2 malignancies). Median acute-phase CASE score was 11 (IQR 6 - 16), improving to 0 (IQR 0 - 1) at 1-year follow-up (Figure 2). Full demographic and clinical characteristics are detailed in Table 2.

[l]MR: magnetic resonance.

Variable Screening

This study examined predictors that longitudinally affect disease severity in the anti-NMDAR encephalitis observational cohort. The CASE score provides more insight into specific AE-related symptoms at onset, allowing for longitudinal assessment of these symptoms [17]. The predictor variables identified by RF were selected as common elements in the development of the prediction model. Select the importance threshold (P>.01) in the training set; these features were included in our study to construct a reduced feature set (selected features). A total of 20 of the 47 features were selected for inclusion in the ML model: 4 demographic characteristics (age, gender, BMI, and occupation), 3 clinical characteristics (admission to ICU, mechanical ventilation, initial symptoms-memory deficits), 11 laboratory parameters (UA, erythrocyte sedimentation rate, C-reactive protein, high-density lipoprotein cholesterol, CSF antibodies, neutrophils, estradiol, white blood cell, progestogen, and testosterone), and 2 neuroimaging characteristics (number of MR lesions and tumor size). The association between each candidate predictor is shown in Multimedia Appendix 1.

Model Development and Performance Comparison

The prognostic performance of the selected features was systematically evaluated using 3 ML algorithms: RF, XGBoost, and DT. As detailed in Table 3, the RF model demonstrated superior discriminative capacity across all evaluation metrics (mean squared error=11.01, RMSE=3.32, R^2=0.71, mean absolute error=2.49, and mean absolute percentage error=0.48). The RF model, selected as the optimal prognostic tool based on minimal RMSE, showed advantages in predicting functional outcomes of NMDAR encephalitis (the model parameters are shown in Table 4). A 5-fold cross-validation was used to verify the stability of the model (Table 1).

Interpretation of the Model

To elucidate feature contributions and interpret model predictions, we used SHAP analysis, a robust game-theoretic approach that quantifies the relative importance of each predictive feature (Figures 3 and 4). SHAP values represent the magnitude and directionality of each predictor’s influence on outcome probability, where positive values indicate increased disability risk. This visualization demonstrates how key features interact to determine individualized prognosis, enabling clinicians to prioritize modifiable risk factors. The summary plot (Figure 5) uses personalized feature attribution to represent range and distribution characteristics. We can directly see the impact of each feature on the prediction of prognostic features in NMDAR. Red to blue represents the eigenvalue from high to low. The thickness of the line represents the sample distribution.

RenderX

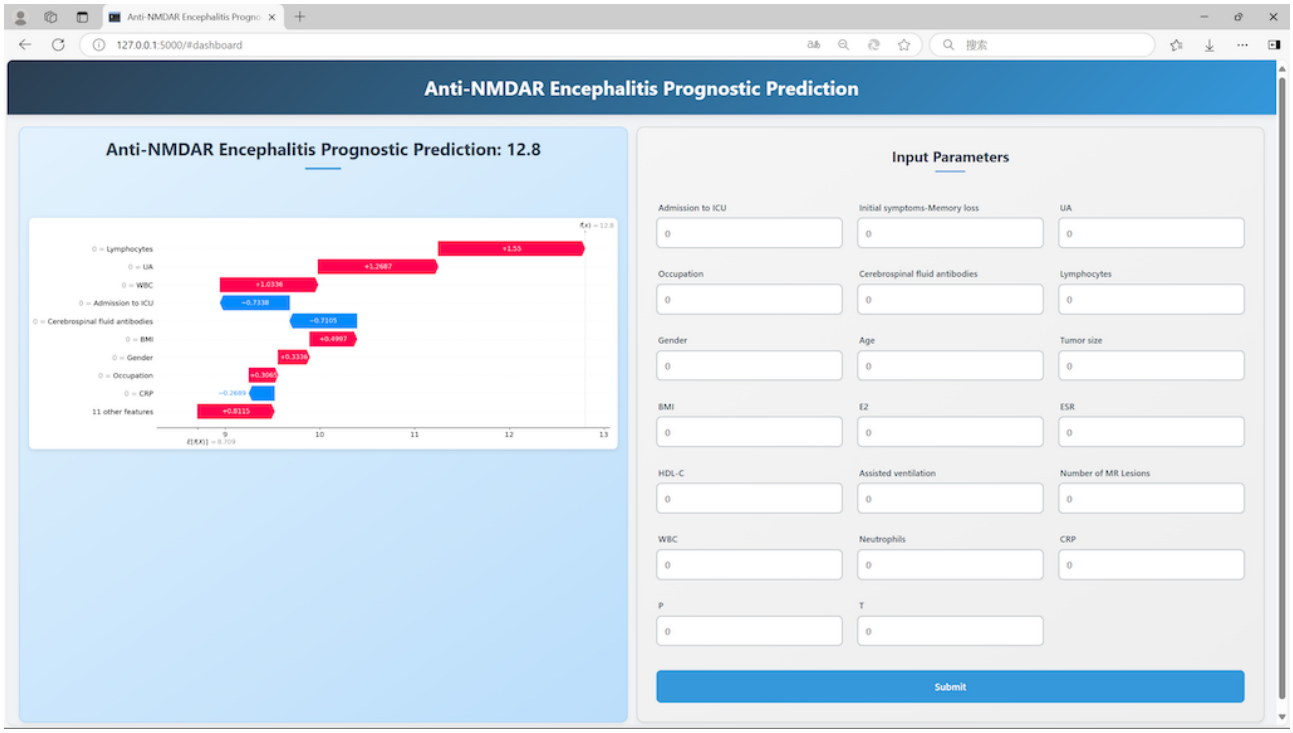
Figure 5. Shapley Additive Explanations summary plots of a 20-feature RF prediction model. ICU: intensive care unit; RF: random forest.

In the optimal performing RF model, the top 3 predictive features for prognostic predictors of NMDAR were admission to ICU (mean |SHAP value|=1.65), initial symptoms-memory loss (0.69), and UA (0.53). Other significant predictors included occupation, cerebrospinal fluid antibody titer, lymphocytes, sex, age, tumor size, BMI, estradiol, erythrocyte sedimentation rate, high-density lipoprotein cholesterol, need for assisted ventilation, number of MR lesions, white blood cell count, neutrophil count, C-reactive protein, progestogen, and testosterone.



Development of Convenient Applications

This platform features an intuitive graphical interface that accepts clinical input of 20 validated predictive variables, subsequently performing automated calculation of composite prognostic scores for patients with anti-NMDAR encephalitis through embedded algorithmic processing. Real-time risk

stratification results provide clinicians with a quantitative prognostic assessment to support evidence-based treatment decisions. This decision support tool optimizes the process of translating predictive analytics into clinical practice (Figure 6).

Figure 6. The application will automatically estimate the prognosis of anti–N-methyl-D-aspartate receptor encephalitis. NMDAR: N-methyl-D-aspartate receptor.

Discussion

Principal Findings

We developed 3 ML-based prognostic models (XGBoost, RF, and DT) for anti-NMDAR encephalitis. A total of 20 pivotal predictors spanning demographic, clinical manifestations, laboratory parameters, and neuroimaging characteristics were identified from 47 candidate variables. The RF model exhibited the best performance. The SHAP interpretability analysis revealed that ICU admission (mean |SHAP value|=1.65), memory deficits at onset (0.69), and UA (0.53) were the most important predictive factors. To our knowledge, this is the first predictive model for anti-NMDAR encephalitis prognosis developed using ML.

Anti-NMDAR encephalitis is an autoimmune disease associated with antibodies targeting the GluN1 subunit of the NMDAR. Although it is the most common AE in adults, it is still considered a rare disease. Due to the widespread geographic distribution of patients, phenotypic heterogeneity, and insufficient understanding of the pathophysiological mechanisms, there are still many challenges in the diagnosis and treatment of this disease [18]. The outcomes for patients with anti-NMDAR encephalitis vary widely, with approximately 75% of patients achieving complete recovery or having only mild sequelae, while the remaining 25% experience severe neurological deficits or death [5,19]. Identifying patients at risk of severe disease progression and persistent deficits at an early stage is of great clinical significance, as it can inform individualized therapeutic decisions and facilitate timely escalation of treatment. Currently, there is a lack of quantitative predictive models for assessing disease prognosis.

In recent years, various ML algorithms have been widely applied in the field of medicine for treatment and prognosis prediction. Compared with traditional statistical methods, such as logistic regression, ML can directly capture nonlinear and complex interactions. Algorithms such as RF and light gradient boosting machine can automatically identify the most important predictive features, reducing the subjectivity of manual feature selection.

Current prognostic tools face critical challenges: (1) they are focused on single-indicator predictions, and traditional statistical methods were used for analysis. For example, Kashyap et al [20] used the neutrophil-to-lymphocyte ratio (NLR) for prognostic prediction in pediatric anti-NMDAR encephalitis, while Lin et al [11] used serum neuron-specific enolase for prognostic prediction. Such single-indicator prediction methods have obvious limitations in a rare disease with diverse manifestations and complex disease courses. (2) They rely on modified Rankin Scale that inadequately captures cognitive or psychiatric dimensions [12,21]. The modified Rankin Scale is a disability scale developed for stroke clinical trials and largely focuses on motor dysfunction. Such disability scales are limited in capturing nonmotor disabilities in AE. (3) They rely on delayed assessments, such as the anti-NMDAR encephalitis one-year functional status score [22], which requires a 4-week observation period and therefore lacks timeliness in prognostic scoring. For patients with poor prognosis who need timely treatment escalation or combination therapies, this delay may result in missed early therapeutic windows. (4) They depend on complex biomarkers requiring specialized processing: Xiang

XSL•FO
RenderX

et al [10] developed a fusion prediction model based on 4 MRI sequences (T1WI, T2WI, FLAIR, and DWI) for early prediction of functional outcomes in adult patients with anti-NMDAR encephalitis. However, these indicators are not easily obtainable and require specialized radiologists to extract data, which severely limits clinical translation and application and is not conducive to clinical implementation.

We used 47 clinical variables available in the electronic medical records of a large tertiary hospital. The selection of these 47 variables was based on the following criteria: first, the aim of this study was to develop a practical prediction application for clinical settings; therefore, we needed to choose patient indicators that are easily accessible to clinicians. Second, according to previous literature and meta-analysis results, some variables were confirmed to be significantly related to patient prognosis. We also made certain improvements. Previous analyses of the predictive value of clinical MRI were based on binary assessments of normal or abnormal MRI. In this study, we used the number of lesions in MRI for analysis, which is more accurate. In feature selection, RFE with RF was applied. Features exceeding the importance threshold (P>.01) were retained. Ultimately, 20 influential variables were selected to develop a novel ML model to assess the prognosis of anti-NMDAR encephalitis.

For the outcome metric, CASE [15] is a disease severity scale specifically designed for AE and can clearly display the clinical trajectory from the acute phase to the recovery phase, making it suitable for longitudinal assessment of patient outcomes during treatment. The CASE score has not yet been used in prognostic model construction. Using the CASE score as the prognostic outcome variable in our study makes the prognostic assessment of patients more scientific and comprehensive.

We chose RF, DT, and XGBoost to construct predictive models for anti-NMDA encephalitis prognosis and evaluated the distinguishing features of each model through benchmark testing (mean squared error, RMSE, R^2, mean absolute error, and mean absolute percentage error) to determine the most suitable model for prediction. Ultimately, we selected the best-performing RF model and further deployed it on a web platform.

In our study, SHAP visualization analysis confirmed that admission to the ICU (mean |SHAP value|=1.65), initial symptoms of memory deficits (0.69), and UA levels are the main predictive factors for prognosis. In addition, other clinical features such as the presence of memory deficits, tracheostomy, and CSF antibody titers were linked to poorer prognoses in anti-NMDAR encephalitis.

In a retrospective study of 382 patients with anti-NMDAR encephalitis, Balu et al [23] identified ICU admission as the most significant univariate predictor [23]. A previous systematic study also revealed associations between decreased consciousness, ICU admission, and poorer outcomes in anti-NMDAR encephalitis [7]. Conversely, the binary risk stratification by ICU admission underscores the need for intensive monitoring protocols at disease onset. This is consistent with our result. SHAP analysis indicated that serum UA concentration plays a crucial role in predicting anti-NMDAR encephalitis prognosis, aligning with the findings of Liu et al [11]. SHAP dependence analysis revealed that UA values >400 μmol/L sharply reduced CASE probability (SHAP<−1.0). As a central nervous system autoimmune inflammatory disease, the pathogenesis of anti-NMDAR encephalitis remains unclear but is known to involve inflammatory responses. UA reduces proinflammatory cytokine release and removes reactive oxygen species, protecting the body from oxidative stress [24]. UA has also been reported to exert neuroprotective effects in various neurological diseases, such as Alzheimer disease, Parkinson disease, and multiple sclerosis [25]. Thus, UA likely serves as a protective factor in the course of anti-NMDAR encephalitis.

Refractory patients may benefit from alternative drugs such as tocilizumab, bortezomib, or daratumumab [10,18]. Our novel model, developed through rigorous variable selection, development, validation, interpretation, and web deployment, demonstrates excellent predictive accuracy. A significant advantage is that all predictive factors used in the model are easily obtainable by clinicians, making risk stratification within 24 hours, enabling them to promptly identify patients with poor prognoses and guide more aggressive treatment escalation to prevent mild cases from progressing to treatment-resistant severe encephalitis.

Strengths and Limitations

The strengths of this study lie in three advancements: (1) We developed a novel ML model for prognostic prediction in encephalitis, (2) this model is exclusively based on clinically accessible parameters, and (3) we created a visualized web-based decision support platform to enable real-time clinical implementation. Our study also has several limitations. First, due to the rarity of the disease, the sample size was relatively small, and it is impossible to conduct subgroup analysis and statistics for each clinical manifestation. Second, the data used for model development were obtained from patients admitted to a specific medical institution rather than from a large database, which may introduce bias. Future research should consider training and validating the model across different national contexts.

Conclusions

In this study, we developed and validated an interpretable ML model based on the RF algorithm. The model demonstrated high predictive accuracy, with robust performance metrics, supporting its potential utility in clinical settings. Through SHAP analysis, key prognostic predictors were identified, including admission to ICU, memory deficits at initial presentation, and serum UA levels, offering novel insights into risk stratification. This tool may assist clinicians in making evidence-based decisions, optimizing interventions, and ultimately improving outcomes for patients with anti-NMDAR encephalitis.

Abstract

Background: Rectal cancer (RC) is a common malignant tumor, with lymph node metastasis (LNM) being a critical determinant of patient prognosis. Traditional diagnostic methods have limitations, necessitating the development of predictive models using clinical data.

Objective: This study aimed to construct and validate machine learning (ML) models to predict LNM risk in patients with RC based on clinical data.

Methods: Retrospective data from 2454 patients with RC (SEER [Surveillance, Epidemiology, and End Results] database) were split into training (n=1954) and internal validation (n=500) sets. An external cohort (n=500) was obtained from the First Affiliated Hospital of Anhui Medical University. Lymph node features identified via computed tomographic scans were integrated with clinicopathological data. Variables were selected using LASSO (Least Absolute Shrinkage and Selection Operator), followed by univariate and multivariate logistic regression. Eleven ML models (Logistic Regression, K-Nearest Neighbors, Extremely Randomized Trees, Naive Bayes, XGBoost [XBG], Light Gradient Boosting Machine, Multilayer Perceptron, Gradient Boosting, Support Vector Machine, Random Forest, and Ada-Boost) were evaluated via area under the receiver operating characteristic curve (AUC), calibration curves, and decision curve analysis.

Results: LNM prevalence was 26.9% (training), 27% (internal validation), and 81% (external validation). Independent LNM predictors included tumor grade, clinical T stage, N stage, tumor length, neural invasion, and total lymph nodes. Internal validation AUC ranged from 0.859 to 0.964; external validation AUC was 0.735 - 0.838. In the internal validation set, Random Forest and Extremely Randomized Trees achieved the highest AUC (0.964, 95% CI 0.950 - 0.978), while XGB demonstrated superior cross-cohort stability (AUC 0.942, 95% CI 0.925 - 0.959). For external validation, Gradient Boosting had the highest AUC (0.838, 95% CI 0.801 - 0.875), followed by XGB (0.832, 95%CI 0.794 - 0.869). XGB showed minimal calibration error with curves closest to the ideal diagonal and yielded the highest net benefit in decision curve analysis across critical thresholds.

Conclusions: This study successfully developed and validated 11 ML models to predict LNM risk in RC. The XGB model was optimal, achieving an AUC >0.9 in 10 internal models and an AUC >0.8 in 7 external models. The identified predictors of LNM can facilitate early diagnosis and personalized treatment, highlighting the potential of integrating computed tomographic scan data with clinicopathological findings to build effective predictive models.

Introduction

Rectal cancer (RC) is among the most prevalent malignant tumors globally and is currently the second leading cause of cancer-related deaths worldwide [1,2]. A recent study [3] projects that by 2040, the incidence of RC will rise to 3.2 million new cases annually, with 1.6 million deaths worldwide. Lymph node metastasis (LNM) is a critical determinant of poor prognosis in RC, and numerous studies [4-7] have shown that accurate prediction of LNM is crucial for treatment selection in patients and prognostic assessment. Initially, while current imaging technologies can assess the risk of LNM to some degree [8-10], they largely depend on radiologists' anatomical expertise for evaluation [11]. However, these methods still face limitations in terms of accuracy and efficiency [12]. Specifically, conventional computed tomography (CT)–based N staging struggles to detect small metastatic lymph nodes (<5 mm) and subtle morphological changes (eg, irregular borders, heterogeneous texture), which are critical for early metastasis diagnosis but require expert manual annotation [13]. Second, pathologists determine the presence of LNM in patients with RC based on clinical pathology reports. This approach is inefficient and subject to the constraints of the individual pathologist's expertise.

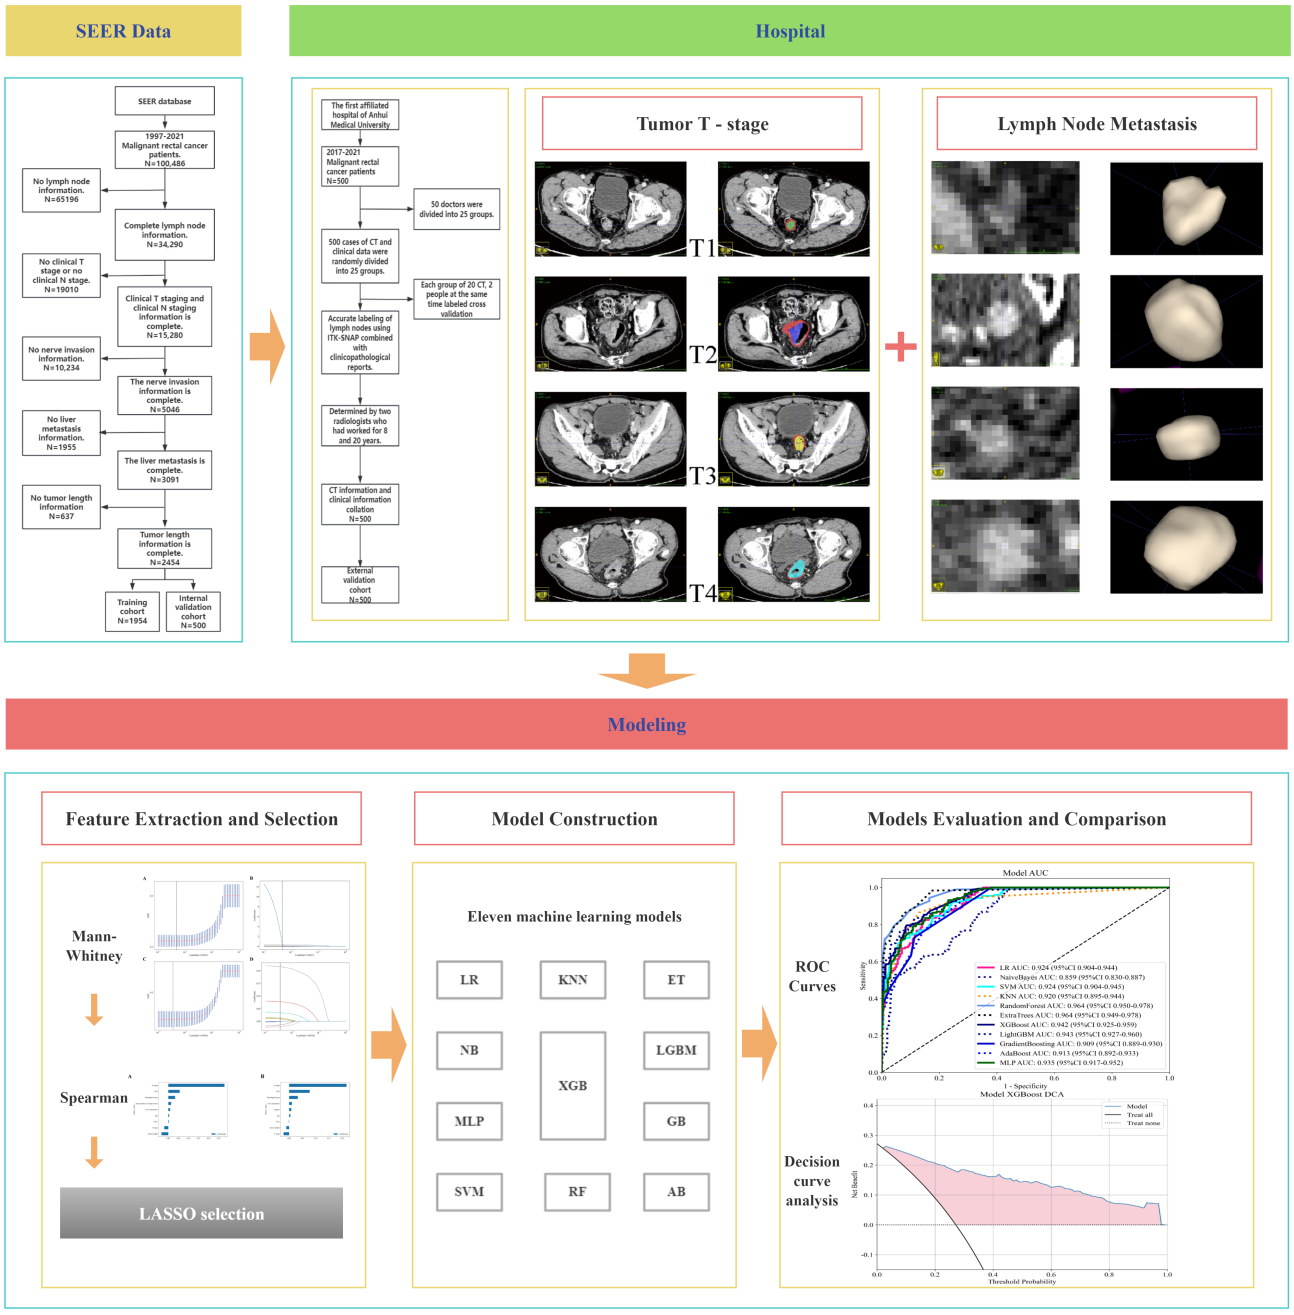
In recent years, the rapid advancement of machine learning (ML) technology has led to its growing application in the medical field, particularly in disease prediction, diagnosis, and treatment decision-making, demonstrating significant potential [14,15]. ML algorithms can process and analyze large volumes of clinical data, identifying disease-related patterns and features, which enhances the accuracy of predictive models [16]. However, most existing ML models rely on automated radiomic features or clinical data alone, neglecting the value of radiologist-annotated CT morphological features [17]. In predicting LNM in RC, previous studies have utilized ML models, including Support Vector Machines, neural networks, and decision trees, achieving notable results [18-21]. Both clinical data and CT results are not entirely accurate in predicting pathological LNM. In the study by Li et al [22], the overall accuracy of N stage based on CT images ranged from 59% to 68%. Meanwhile, up to 70% of metastatic lymph nodes in colorectal cancer have a diameter of less than 5 mm. This indicates that both clinicopathological features and preoperative CT have certain limitations in predicting the malignant lymph node status of patients with T1 colorectal cancer. Therefore, there is an urgent need to develop novel predictive tools that integrate ML with radiological parameters and clinical data, thereby enhancing the accuracy and efficiency of diagnostic processes. Recent evidence suggests that systematic manual annotation by trained radiologists can improve the sensitivity of detecting sub-centimeter metastatic lymph nodes compared with routine clinical reports. This highlights the potential of this method in bridging current diagnostic gaps [23].

This study aimed to develop and validate ML models using clinical data to predict LNM risk in RC. We successfully constructed and validated 11 predictive models integrating radiologist-annotated CT lymph node features with clinicopathological data. These models show significant potential to assist clinicians in early diagnosis and personalized treatment planning. We anticipate that the findings will provide new insights for RC management and serve as a valuable reference for future research and practice.

Methods

Data Collection and Inclusion Criteria

This study encompassed clinical data from 2454 patients with RC in the SEER database, wherein 1954 cases were randomly selected to form the training cohort, and the remaining 500 formed the internal validation cohort. Additionally, it included data from 500 patients with RC treated at the author's hospital between January 1, 2017, and December 31, 2023, which served as the external validation cohort. The inclusion criteria were (1) patients with RC staged as I-IV according to the American Joint Committee on Cancer (AJCC) staging system; (2) those who underwent curative surgery; and (3) those with complete clinical and pathological information; and (4) radical surgery in stage IV patients. In this study, some patients with stage IV RC with oligometastasis (limited resectable metastases) or locally advanced tumors with resectable metastatic lesions underwent radical surgery after evaluation by a multidisciplinary team. The surgical decision was based on the multidisciplinary team's comprehensive assessment of tumor burden, physical condition, expected survival, and surgical risks. The goal was to achieve R0 resection and combine it with postoperative adjuvant therapy to reduce recurrence risk. Data for these patients were complete and underwent strict screening to ensure they met the research criteria. The exclusion criteria included (1) a history of other malignant tumors, (2) inability to assess lymph node status, (3) incomplete clinical information, and (4) administration of neoadjuvant therapy. The LNM status for 2454 patients with RC in the SEER database was ascertained from pathological assessments of surgical specimens. For the 500 cases at the author's hospital, LNM status, clinical T and N staging, and tumor length were determined by precisely annotating and measuring contrast-enhanced CT images with the radiological software ITK-SNAP software (version: 4.0.1; Professor Paul Yushkevich's team, University of Pennsylvania, USA), corroborated by pathological assessments from surgical specimens. For example, the definition of tumor length in the SEER database (training/internal validation cohorts) was measured from pathological specimens. In the external validation cohort, tumor length was annotated and measured on contrast-enhanced CT scans using ITK-SNAP software by radiologists, with cross-validation against postoperative pathology (mean error <0.3 cm).



Clinical Pathological Features

The study collected the following clinical and pathological characteristics of the patients: sex, age, perineural invasion, carcinoembryonic antigen (CEA), tumor length, clinical T stage, N stage, tumor differentiation, chemotherapy and radiotherapy administration, liver metastasis status, and tumor histology. For the training and internal validation cohorts, data extraction was conducted using the SEER*STAT software, version 8.4.3 (Surveillance, Epidemiology, and End Results Program, National Cancer Institute, USA). In the external validation cohort, clinical

XSL•FO
RenderX

data were independently collected and processed by 2 researchers, while CT images were annotated and measured with precision by 50 physicians, evenly distributed into 25 groups, each consisting of 2 physicians for cross-validation purposes. The inclusion criteria for metastatic lymph nodes were fulfilled if any of the following five conditions was met: (1) the short axis/long axis ratio was ≥0.8; (2) the short axis was ≥5 mm; (3) there was aggregation of three or more lymph nodes; (4) the lymph node had an irregular shape with a rough margin; (5) the lymph node signal was inhomogeneous, with high signal areas in the CT imaging for lymph nodes (including mesenteric and presacral lymph nodes). Figure 1 illustrates the acquisition process.

Figure 1. Workflow of this study. Data Processing and Analysis

All collected data will be subjected to rigorous preprocessing in Python, encompassing data cleaning, outlier detection, and missing value imputation. Subsequent statistical analysis will utilize suitable methods including χ^2 tests, ANOVA, and both univariate and multivariate regression analyses to evaluate the correlations between clinical pathological features and LNM.

Feature Engineering and Selection

In this study, we standardized numerical features, including tumor length, to mitigate the effects of varying scales and enhance their compatibility with the input requirements of ML models. For categorical variables like clinical T staging, we

XSL•FO
RenderX

applied label encoding to transform them into numerical data. All features were first normalized to eliminate scale effects (Multimedia Appendix 1). We then performed univariate feature screening via independent *t* tests or Mann-Whitney *U* tests ($P \leq .05$), retaining features. Next, Pearson correlation analysis reduced redundancy by removing features with mean absolute correlation >0.9, yielding decorrelated features. Finally, features with nonzero coefficients were selected through LASSO regression (10-fold cross-validated) with regularization parameter α. Notably, this LASSO-based selection served as initial screening; tree-based models (Random Forest [RF]/XGBoost [XGB]/Light Gradient Boosting Machine [LGBM]) subsequently performed endogenous feature reweighting to capture nonlinear interactions during model training. This method incorporates an L1 regularization term that aids in pinpointing the most influential features while promoting model sparsity. Furthermore, we performed a correlation analysis among the features to verify the independence of the selected variables. Utilizing the principle of Permutation Importance, we evaluated the importance of each feature to ascertain its contribution to the model's predictive performance.

Predictive Model Construction and Validation

This study developed 11 distinct ML models: Logistic Regression (LR), Naive Bayes (NB), Support Vector Machine, K-Nearest Neighbors (KNN), RF, Extremely Randomized Trees (ET), XGB, LGBM, Gradient Boosting (GB), Ada-Boost (AB), and Multilayer Perceptron (MLP), for predicting the risk of LNM in patients with RC (Multimedia Appendix 2). To counteract the imbalance in data distribution, we used random oversampling techniques and applied a penalty parameter λ to drive the coefficient estimates of nonsignificant features toward zero. The models' performance was evaluated through 10-fold cross-validation. The performance of each ML classifier was assessed using the receiver operating characteristic curve, where a higher area under the receiver operating characteristic curve (AUC) indicates greater predictive accuracy. We evaluated the variable weights and permutation importance and used heatmaps to visualize the significance and correlations among the variables. To select the optimal model, we evaluated each model's performance across multiple metrics: AUC (with 95% CI), accuracy, sensitivity, specificity, and F_1 score. Calibration curves and decision curve analysis (DCA) were further employed to assess calibration accuracy and clinical utility, particularly focusing on net benefits at critical thresholds.

Ethical Considerations

This study was approved by the Ethics Committee of the First Affiliated Hospital of Anhui Medical University (Approval No.: Quick-PJ 2023-13-34). As a retrospective analysis using anonymized data, the requirement for informed consent was waived. Primary data collection in the SEER database obtained patient informed consent, and its Institutional Review Board explicitly authorized secondary analysis without additional approval. All direct identifiers (including names, ID numbers, medical record numbers) were removed from our hospital's dataset, with only aggregated data utilized in the analyses to ensure privacy protection. No participant compensation was involved, and no identifiable images appear in the manuscript or supplementary materials.

Results

Demographic Characteristics and Parameter Selection

In our study, the training cohort included 1954 patients with RC, the internal validation cohort included 500 patients with RC, and the external validation cohort included 500 patients with RC. Across the training cohort, internal validation cohort, and external validation cohort, stratification by LNM status (positive vs negative) revealed statistically significant differences in age, gender, total lymph node count, tumor length, neural invasion, clinical T stage, N stage, liver metastasis status, tumor histology, and tumor differentiation (all $P<.001$; see Table 1). For CEA, the *P* value was .001, indicating a statistically significant difference (Table 1). We used the LASSO regression method to identify a significant set of risk factors for predicting the risk of LNM in patients with RC.

Risk Factors for Lymph Node Metastasis

Using the nonzero coefficients from the LASSO logistic regression model as a guide, we applied both the LASSO method and the multivariate logistic regression model to identify the risk factors associated with LNM in patients with RC, as depicted in Figure 2. The penalty parameters λ for the internal and external validation sets were found to be 0.0047 and 0.0036, respectively. Univariate and multivariate analyses yielded the forest plots for both the internal and external validation sets, as shown in Figure 3. Key predictors from univariate and multivariate analyses are detailed in Table 2. This analysis assists in pinpointing factors that potentially contribute to LNM, marking a pivotal step in comprehending disease progression and in formulating evidence-based treatment strategies. The multivariate logistic regression analysis of the external validation set identified number of peritumoral and total lymph nodes examined (P=.022), tumor length (P<.001), neural invasion (P<.001), clinical T stage (P<.001), N stage (P<.01), and tumor differentiation grade (P<.01) as independent risk factors for LNM.

Optimal Predictive Model Selection

Feature Weight Ranking

Based on the penalty coefficient obtained from cross-validation, we selected features with coefficients greater than 0 and represented them using feature weights. The features in the training set and internal validation set are ranked as follows: Clinical N staging, receipt of chemotherapy or radiotherapy, neural invasion, tumor histology, tumor length, number of peritumoral and total lymph nodes examined, liver metastasis, age, CEA, clinical T stage, and tumor length (Figure 4A). In contrast, the features in the training set and external validation set are ranked as follows: Clinical N staging, receipt of chemotherapy or radiotherapy, neural invasion, tumor histology, tumor length, liver metastasis, gender, differentiation degree, age, CEA, tumor length, and clinical T stage (Figure 4B).

Model Performance Evaluation

In the internal validation cohort (n=500), the 11 ML models demonstrated a wide range of discriminative performance (AUC range 0.859 - 0.964). RF (AUC 0.964, 95% CI 0.950 - 0.978) and ET (AUC 0.964, 95% CI 0.949 - 0.978) achieved the highest AUC values, with sensitivities of 0.881 and 0.983 and specificities of 0.900 and 0.828, respectively (Multimedia Appendix 3). NB showed the lowest AUC (0.859, 95% CI 0.830 - 0.887) despite perfect sensitivity (1.000) but with specificity limited to 0.566. The XGB model yielded an AUC of 0.942 (95% CI 0.925 - 0.959), sensitivity of 0.795, and specificity of 0.913. In the external cohort (n=500), Gradient Boosting exhibited the highest AUC (0.838, 95% CI 0.801 - 0.875) but the lowest sensitivity (0.685); XGB (AUC 0.832, 95% CI 0.794 - 0.869) and LGBM (AUC 0.831, 95% CI 0.793 - 0.869) ranked second and third, with XGB demonstrating the smallest sensitivity-specificity gap (Δ=0.113) and an F_1-score of 0.690 (Table 3).

The relative importance of model variables varies between the internal and external validation sets, depending on the characteristics. In the internal validation set, the clinical N-stage is the most important variable for the RF, ET, and XGB models. However, for the LGBM model, age and tumor length are the most important variables. In the external validation set, tumor length, clinical N-stage, and nerve invasion are among the top three important features for both the GB and LGBM models (Figure 5). We assessed feature correlations using a heatmap (Figure 6). In both validation sets, no significant correlations were observed, indicating the absence of collinearity and the independence of variables.

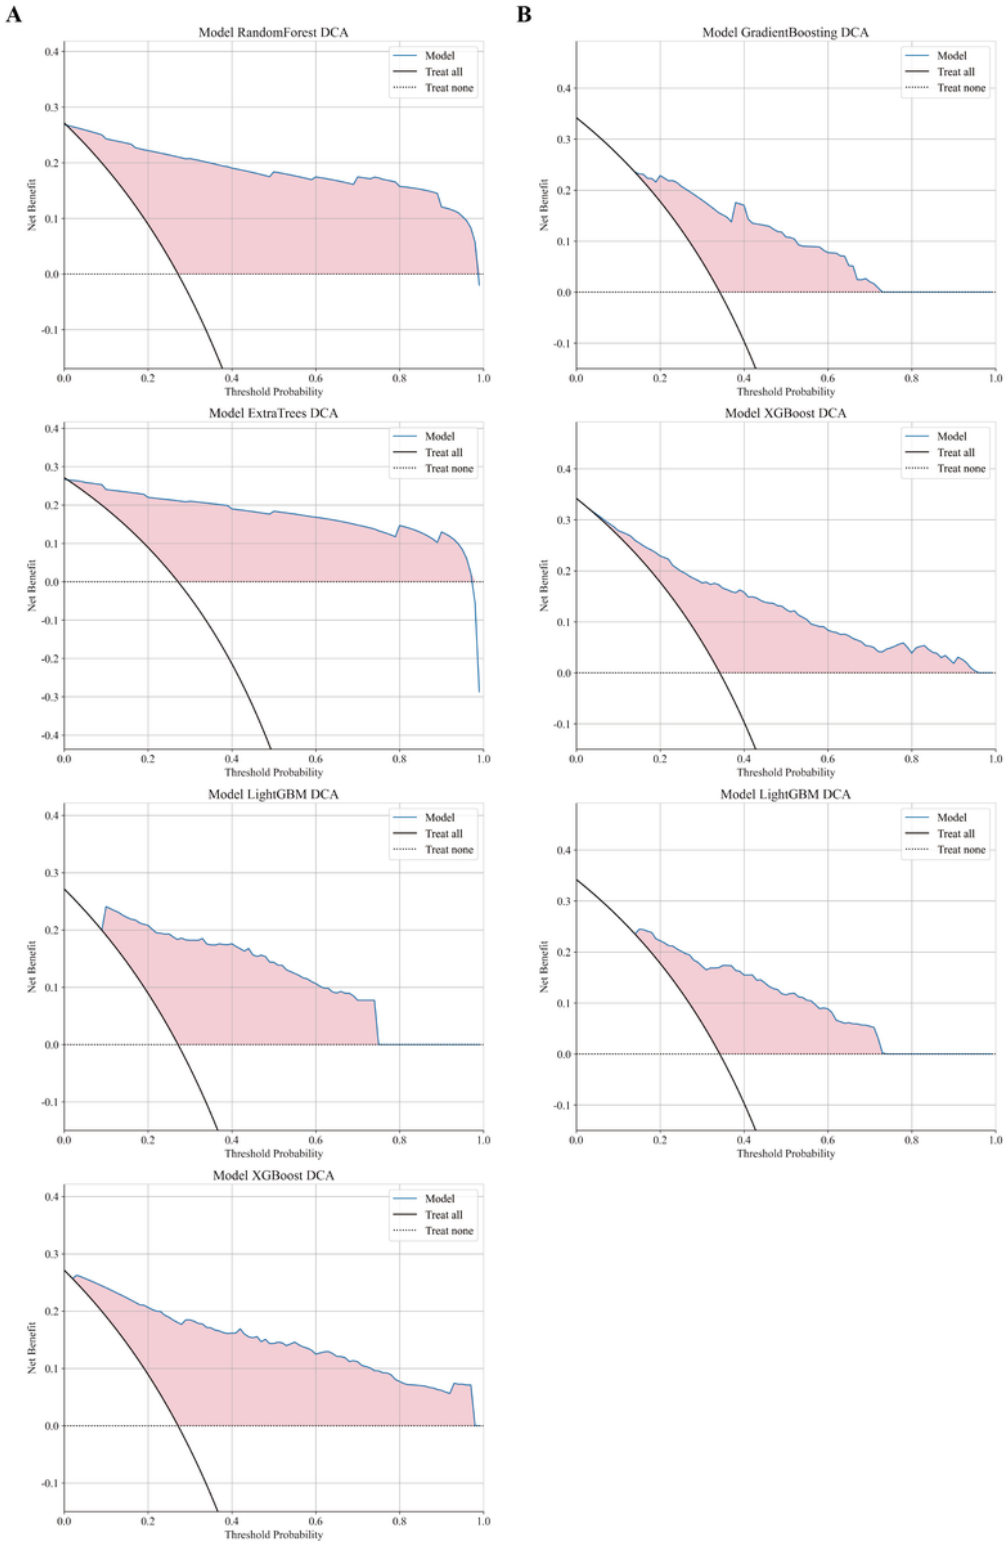
Calibration Curve Analysis

Calibration curves (Figure 7) demonstrated the agreement between predicted probabilities and observed event frequencies. In the internal cohort (Figure 7A), the XGB curve adhered closest to the ideal diagonal (45° reference line) throughout, with minimal deviation from actual frequencies in the 0.3 - 0.7 probability range; ET exhibited consistent positioning above the diagonal at >0.8 probabilities (systematic overestimation), while RF deviated slightly below the diagonal between 0.6 and 0.8 (mild underestimation). In the external cohort (Figure 7B), XGB maintained the smallest overall deviation (closest to the diagonal); GB showed systematic distribution below the diagonal at 0.4 - 0.6 probabilities (underestimation), and LGBM positioned above the diagonal at <0.3 thresholds (overestimation).

Figure 7. Calibration curve of lymph node metastasis prediction in the internal validation cohort (A) and external validation cohort (B) of patients. The dashed diagonal line represents perfect calibration where predicted probability equals actual probability. KNN: K-Nearest Neighbors; LR: Logistic Regression; MLP: Multilayer Perceptron; SVM: Support Vector Machine.



Decision Curve Analysis

We evaluated the net benefits of the models in both validation sets using DCA (Figure 8). In the internal validation set, DCA indicates that the XGB model has a net benefit similar to that of the XGB and LGBM models at lower threshold probabilities (approximately 0 - 0.3). Furthermore, the XGB model maintains net benefit across a broader range of threshold probabilities (approximately 0 - 0.9). Between 0.7 and 0.9, where the net benefits of other models decrease, the net benefit of the XGB model still sustains. The RF model shows net benefit within the range of 0 - 0.8. The ET model has a net benefit from 0.1 to 0.75. The LGBM model demonstrates net benefit in the range of 0.1 - 0.7. In the external validation set, DCA reveals that the XGB model's net benefit is higher than that of the GB and LGBM models when the threshold probability is between 0.3 and 0.4. Furthermore, the XGB model maintains net benefit across a broader range of threshold probabilities (approximately 0 - 0.4). The GB model shows net benefit within the range of 0.1 - 0.3, while the LGBM model has net benefit from 0.1 to 0.35.

RenderX

Figure 8. Decision curve analysis of lymph node metastasis prediction in the internal validation cohort (A) and external validation cohort (B) of patients with RC. DCA: decision curve analysis.

Final Model Selection

XGB was selected as the definitive predictive model through comprehensive evaluation of cross-cohort discriminative stability, calibration fidelity, and clinical utility. The model achieved AUC values of 0.942 (95% CI 0.925 - 0.959) in the internal cohort and 0.832 (95% CI 0.794 - 0.869) in the external cohort, with a reduction in AUC of -0.110 between cohorts. This reduction was smaller than those observed for RF (−0.205), ET (−0.229), and GB (−0.071). Calibration curves demonstrated closest alignment to the ideal diagonal in the internal cohort (minimal deviation at 0.3 - 0.7 probabilities), whereas ET systematically overestimated risk at probabilities >0.8 and RF underestimated at 0.6 - 0.8. In the external cohort, XGB maintained minimal deviation, GB underestimated at 0.4 - 0.6 probabilities, and LGBM overestimated at thresholds <0.3. DCA

XSL•FO
RenderX

revealed that XGB sustained the broadest net benefit range (0 - 0.9) in the internal validation set, outperforming comparison models at 0.7 - 0.9 thresholds. In the external set, it maintained net benefit across 0 - 0.4 thresholds and yielded higher net benefit than GB and LGBM at 0.3 - 0.4 probability thresholds.

Confusion Matrix Analysis

Multimedia Appendix 4 displays the confusion matrices of the XGB model in the internal (A) and external (B) validation cohorts. In the internal cohort (n=500), the model correctly identified 333 LNM-negative cases (true negative) and 107 metastasis-positive cases (true positive), with 32 false positive and 28 false negative (FN) predictions. In the external cohort (n=500), it detected 160 true negative and 216 true positive cases, while generating 35 false positive and 89 FN classifications. The positive predictive value was 77% (107/139) in the internal cohort and 86.1% (216/251) in the external cohort; the negative predictive values were 92.2% (333/361) and 64.3% (160/249), respectively.

Discussion

Principal Findings

The main findings demonstrate that the XGB model achieved optimal performance in predicting RC LNM, with tumor differentiation grade, clinical T stage, tumor length, neural invasion, N stage, and total lymph node count identified as independent predictors. RC LNM significantly impacts patient prognosis, necessitating accurate prediction of LNM for the development of effective treatment plans. While traditional diagnostic methods offer some insights, their accuracy is constrained. This study employed ML algorithms to develop 11 prediction models for RC LNM. We extracted clinical data from the SEER database for the training and internal validation sets. Additionally, we acquired relevant clinical data from CT scans at the author's hospital, utilizing precise pixel-level annotation and measurement for the external validation set. We filtered clinical data using the LASSO, univariate, and multivariate logistic regression analyses to develop and validate a predictive model for LNM. The selection of the optimal model was determined through comparative analysis of internal and external validation sets, leveraging the AUC, calibration curves, and DCA for precise assessment.

In this study, we successfully developed and validated 11 ML models for predicting LNM in RC. This study revealed three key findings. First, the six independent predictors of LNM include tumor differentiation, clinical T stage, N stage, tumor length, total number of lymph nodes, and neural invasion. Second, among the 11 constructed ML models for predicting LNM, 10 models had an AUC greater than 0.9 in the internal validation set and 7 models had an AUC greater than 0.80 in the external validation set. Lastly, following a comparison of the models' performance and their validation set discrepancies, the XGB model emerged as the most suitable among the 11 models.

Comparison With Prior Studies

Utilizing LASSO logistic regression and multivariate analysis, we identified tumor differentiation, clinical T stage, N stage, tumor length, neural invasion, and total number of lymph nodes as the key clinical predictive factors. Low tumor differentiation, advanced clinical T stage, advanced N stage, increased tumor length, and neural invasion are significantly associated with LNM. Identifying these factors is essential to comprehend the tumor's biological behavior and invasive potential. Variations in feature importance across models (Figure 5) arise from the following factors: First, clinical data encompass both continuous (eg, tumor length) and categorical variables (eg, pathological grade), where XGB's exact splitting favors continuous features while LGBM's histogram-based algorithm optimizes high-dimensional sparse feature processing. Second, regularization differences lead to distinct weight allocation—XGB's combined L1/L2 regularization strictly controls overfitting, whereas LGBM's leaf-wise growth prioritizes locally significant features. Third, although LASSO-based feature selection reduced dimensionality, residual feature correlations are differentially processed. These inherent algorithmic variations confirm that no single model can fully capture feature relationships, necessitating multimodel comparison for complementary insights. Poorly differentiated tumor cells show greater invasiveness and a higher likelihood of LNM. A study by Saraste et al [24] involving 1664 patients with RC from the Swedish Rectal Cancer Registry between 2007 and 2010 concluded through multivariate analysis that poorly differentiated tumors are a significant risk factor for LNM, aligning with the findings of this study. Advanced clinical T stage is a direct indicator of deeper tumor invasion. A study by von den Grün et al [25], which involved a binary logistic regression multivariate analysis of 776 patients with RC, revealed that advanced T stage is a significant prognostic factor for LNM in RC. Previous studies [25-27] have established that clinical T stage and N stage significantly influence the prognosis and treatment of RC, aligning with the results of the univariate and multivariate analyses presented in Table 2. Increased tumor length may afford tumor cells increased opportunities to interact with adjacent lymph nodes. In a study [28] that employed 7 clinical parameters as independent prognostic factors to develop a nomogram prediction model, 6484 patients with RC from the SEER database were analyzed using Cox proportional hazards regression. This analysis identified independent prognostic factors such as T stage and tumor length. However, unlike this study, the aforementioned research did not include an external validation cohort. The presence of neural invasion indicates a high level of tumor invasiveness and the potential for dissemination along neural pathways. Neural invasion is a significant factor in both univariate and multivariate analyses, as well as in evaluating the importance of model features. Studies by Ueno et al [29] and Song et al [30] have shown that neural invasion is a significant factor in LNM in RC. The total number of perirectal examined lymph nodes, as a key factor, plays a crucial role in accurate staging and prognostic assessment of RC. Guan et al [31] found that a higher number of perirectal examined lymph nodes in RC is linked to more accurate lymph node staging and improved survival. Analyzing data from stage I to III resected RC in multi-institutional Chinese and US SEER databases revealed that an increasing number of perirectal examined lymph nodes significantly raises the proportion of cases shifting from lymph node-negative to lymph

XSL•FO
RenderX

node-positive. Furthermore, after adjusting for confounding factors, overall survival consistently improves.

Utilizing the selected clinical characteristics, we developed a predictive model for LNM in RC. We extracted a cohort of 2454 patients with RC from the SEER database and randomly selected 500 cases for the internal validation cohort. The remaining 1954 cases served as the training cohort, while an additional 500 cases from the author's hospital constituted the external validation cohort. In the internal validation set, the RF and ET models achieved an AUC of 0.964. The LGBM and XGB models also performed remarkably well, with AUC values of 0.943 and 0.942, respectively. Among all models, the NB model had the lowest AUC of 0.859, while the remaining 10 models all exceeded 0.9. In the external validation set, the GB model demonstrated the best performance with an AUC of 0.838, followed by the XGB and LGBM models, which reached AUC values of 0.832 and 0.831, respectively. In the study by Guan et al [18], 6578 patients with RC were enrolled across several institutions, including the Cancer Hospital of the Chinese Academy of Medical Sciences, Peking Union Medical College, Changhai Hospital of Naval Medical University, and the Second Affiliated Hospital of Harbin Medical University. The XGB model was identified as the optimal in their study, achieving AUCs of 0.78 and 0.71 across two validation cohorts. In contrast, our study's XGB model showed superior performance, achieving an AUC of 0.942 in the internal validation cohort and 0.832 in the external validation cohort. In the external validation cohort, LNM status, clinical T and N stages, and tumor length were ascertained through the annotation of CT imaging combined with clinical data. However, across both internal and external validation cohorts, most models in this study demonstrated relatively good performance across various validation sets, with the AUCs of the optimal models all exceeding 0.80, indicating a certain level of accuracy and reliability. These results demonstrate that our models exhibit high stability and generalizability across diverse datasets. Regardless of whether the patients with RC are in the United States or China, our models show accurate predictive ability for forecasting LNM in RC. Second, the LNM status and associated details in the 500 case records from the hospital were meticulously annotated by 50 physicians. These annotations were made by integrating clinical and pathological data using imaging software on enhanced CT scans. Following the initial annotation, two radiologists, possessing 8 and 20 years of experience, respectively, conducted a review and confirmation of the annotations. The multi-physician annotation strategy, which incorporates clinical pathology data and imaging software, boosts the reliability of the data and, in turn, elevates the predictive accuracy of the model. A similar approach was taken in Liu et al's study [32], wherein integrating clinical data with ML for magnetic resonance image analysis elevated the AUC value of single-region radiomics from 0.702 to 0.827. In a study by Wan et al [33], an automated segmentation method using deep learning demonstrated potential for predicting LNM in RC. However, our manual annotation method ensures precise localization of small lymph nodes (diameter < 5 mm) and ambiguous lesions, which are crucial for RC staging but challenging for automated tools. This strategy is particularly valuable in resource-limited environments lacking artificial intelligence infrastructure. Although magnetic resonance imaging is widely regarded as the gold standard for local T-staging and lymph node status assessment in RC, in this study, we chose to analyze CT images due to the diversity of data sources and the prevalence of CT images. CT scanning is less costly and quicker. Particularly, in resource-limited medical settings, CT remains a routine examination tool that can effectively provide important information on lymph node status and tumor staging. This highlights the benefits of integrating both clinical data and imaging information into ML models. While the annotation of CT images and their incorporation are standard practices in traditional radiomics and the development of deep learning models, they are less common in models derived solely from clinical data. This study shows that employing imaging software to annotate CT scans and extract data for clinical predictive models not only yields high-quality data for model development but also presents an innovative approach to data acquisition and processing for future studies.

Strengths and Limitations

A key innovation of this study is the comprehensive utilization of diverse advanced ML algorithms, coupled with the validation of the model's performance across data from various sources. Our models have shown strong generalization capabilities, as evidenced by their performance in both internal and external validation cohorts. Additionally, using LASSO logistic regression for feature selection enabled us to pinpoint key clinical predictive factors. This approach not only bolstered the model's predictive accuracy but also improved its interpretability. We presented the importance of features in a ranked order and investigated the correlations among variables with a correlation heatmap. Finally, the optimal model was ascertained through a comprehensive, evidence-based methodology integrating multimetric performance evaluation (AUC, 95% CI, accuracy, sensitivity, specificity, and F_1-score), augmented by high-resolution assessment of calibration curves and DCA.

Despite strong performance in both the internal and external validation sets, our model in this study has some limitations. First, the dataset is constrained by its population representativeness. The SEER database comprises exclusively American cases, and the dataset from the author's hospital consists solely of Chinese cases. This could impact the model's ability to generalize across diverse populations. In Shulman et al.'s study [34], which analyzed 34,500 patients with RC, it was found that patients of different races exhibited varying lymph node statuses. Second, the model did not include variables like BMI, alpha-fetoprotein, cancer antigen 125, carbohydrate antigen 19-9 [18], which were previously explored in clinical information. This omission could impact the model's predictive accuracy and comprehensiveness. Future studies could further refine predictive accuracy by incorporating serum biomarkers (eg, BMI, carbohydrate antigen 19-9) and emerging indicators such as circulating tumor DNA, combined with radiomic features. Third, FN classifications warrant clinical attention. The FN rate was 20.7% (28/135) in the internal cohort and 29.2% (89/305) in the external cohort. Such misclassifications may lead to undertreatment (eg, omission of adjuvant chemotherapy or lymph node dissection), increasing risks of

XSL•FO
RenderX

recurrence and metastasis. Crucially, while our model was developed to surpass conventional CT assessments, reducing FNs remains a priority for future optimization through biomarker integration or advanced imaging techniques. The study by Yu et al [35] demonstrated that incorporating multicenter data and multimodal features significantly reduced FN rates, providing a feasible direction for refining our model. In this study, we utilized 11 ML methods. Future research could further enhance the model's predictive performance by integrating diverse ML algorithms and leveraging their unique strengths.

Conclusions

In conclusion, this study successfully developed a ML-based risk prediction model for LNM in RC, validating its performance using both an internal and an external validation set. Through the analysis of extensive clinicopathological data, we identified tumor differentiation, clinical T stage, N stage, tumor length, neural invasion, and total number of lymph nodes as independent predictive factors. Among the 11 models evaluated, the XGB model demonstrated the best predictive performance. These models are anticipated to aid in clinical decision-making, offering vital insights for treatment selection and prognostic assessment of patients with RC. They hold significant clinical utility and scientific importance. Concurrently, the external validation set demonstrates that clinical data derived from CT imaging annotation and measurement are comparable to traditionally obtained clinical data and can effectively serve as a source of clinical data for ML applications.

Acknowledgments

This research was collectively supported by The University Synergy Innovation Program of Anhui Province (Grant No. GXXT-2022-056) and the Key Project of the Department of Education Quality Engineering (Grant No. 2023jyxm1111). We thank the SEER (Surveillance, Epidemiology, and End Results) database and the First Affiliated Hospital of Anhui Medical University for providing patient data. The authors sincerely thank all the staff of our department for their help in data collection, sample annotation, and manuscript writing. The following is the list of personnel who have contributed to pixelated annotation: Jiarui Zhang, Xiaosu Li, Xiaoya Wang, Wenna Chai, Chuiyan Huang, Tianxu Yang, Jingwen Hu, Yiran Zhang, Ping Wang, Bingjing Zhu, Jiani Ma, Yuyan Ma.

Data Availability

The raw data sets are available only upon reasonable request because of privacy and ethical restrictions. The data are not publicly available because of these restrictions. The code is available upon reasonable request.

Authors' Contributions

WH and CL are primarily responsible for data organization, analysis, and model construction. ZW was in charge of literature search and data collection. WW provided guidance on data analysis. SW offered guidance on model construction and validation. BZ was responsible for literature quality assessment and manuscript review and served as the corresponding author. All authors have read and approved the manuscript.

Abstract

Background: Pulmonary hypertension (PH) is a progressive disorder characterized by elevated pulmonary artery pressure and increased pulmonary vascular resistance, ultimately leading to right heart failure. Early detection is critical for improving patient outcomes.

Objective: The diagnosis of PH primarily relies on right heart catheterization, but its invasive nature significantly limits its clinical use. Echocardiography, as the most common noninvasive screening and diagnostic tool for PH, provides valuable patient information. This study aims to identify key PH predictors from echocardiographic parameters, laboratory tests, and demographic data using machine learning, ultimately constructing a predictive model to support early noninvasive diagnosis of PH.

Methods: This study compiled comprehensive datasets comprising echocardiography measurements, clinical laboratory data, and fundamental demographic information from patients with PH and matched controls. The final analytical cohort consisted of 895 participants with 85 evaluated variables. Recursive feature elimination was used to select the most relevant echocardiographic variables, which were subsequently integrated into a composite ultrasound index using machine learning techniques, XGBoost (Extreme Gradient Boosting). LASSO (least absolute shrinkage and selection operator) regression was applied to select the potential predictive variable from laboratory tests. Then, the ultrasound index variables and selected laboratory tests were combined to construct a logistic regression model for the predictive diagnosis of PH. The model's performance was rigorously evaluated using receiver operating characteristic curves, calibration plots, and decision curve analysis to ensure its clinical relevance and accuracy. Both internal and external validation were used to assess the performance of the constructed model.

Results: A total of 16 echocardiographic parameters (right atrium diameter, pulmonary artery diameter, left atrium diameter, tricuspid valve reflux degree, right ventricular diameter, E/E' [ratio of mitral valve early diastolic inflow velocity (E) to mitral annulus early diastolic velocity (E')], interventricular septal thickness, left ventricular diameter, ascending aortic diameter, left ventricular ejection fraction, left ventricular outflow tract velocity, mitral valve reflux degree, pulmonary valve outflow velocity, mitral valve inflow velocity, aortic valve reflux degree, and left ventricular posterior wall thickness) combined with 2 laboratory biomarkers (prothrombin time activity and cystatin C) were identified as optimal predictors, forming a high-performance PH prediction model. The diagnostic model demonstrated high predictive accuracy, with an area under the receiver operating characteristic curve of 0.997 in the internal validation and 0.974 in the external validation. Both calibration plots and decision curve analysis validated the model's predictive accuracy and clinical applicability, with optimal performance observed at higher risk stratification cutoffs.

Conclusions: This model enhances early PH diagnosis through a noninvasive approach and demonstrates strong predictive accuracy. It facilitates early intervention and personalized treatment, with potential applications in broader cardiovascular disease management.

Introduction

Pulmonary hypertension (PH) is a progressive and complex vascular disorder characterized by elevated mean pulmonary artery pressure (mPAP) and increased pulmonary vascular resistance, ultimately leading to right heart failure [1]. According to the World Symposium on Pulmonary Hypertension classification system, PH is categorized into 5 major groups. Delayed diagnosis and treatment impose an unacceptably high mortality burden across all categories of PH patients. However, the current gold standard for PH diagnosis—right heart catheterization (RHC)—is significantly limited in clinical application due to its invasive nature, resulting in delayed PH diagnosis. Thus, early identification and risk assessment through noninvasive methods are critical for improving patient outcomes [2-5].

Echocardiography, as a noninvasive imaging modality, has become integral to the evaluation of PH. It enables clinicians to assess right ventricular size and function and estimate pulmonary artery pressures through tricuspid regurgitation velocity (TRV) and pulmonary artery systolic pressure. Several studies have highlighted the importance of echocardiographic parameters including right ventricular size, function, and TRV in predicting PH severity and outcomes [6-8]. Moreover, comprehensive models such as the Registry to Evaluate Early and Long-term Pulmonary Arterial Hypertension Disease Echocardiographic Correlation Hemodynamic Observational Study score, which integrate multiple echocardiographic variables, have significantly improved the ability to predict PH risk and have been validated across multiple cohorts [6,9].

However, relying solely on echocardiographic data for PH diagnosis and risk prediction has limitations. Recent research has increasingly emphasized the need to integrate echocardiographic findings with clinical data, including age, sex, BMI, and comorbidities, to enhance predictive accuracy [10,11]. For instance, studies involving hyperthyroid patients demonstrated that models incorporating both clinical variables and echocardiographic parameters significantly improved PH risk assessment [12]. Likewise, nomogram models that integrate these data have shown efficacy in evaluating PH risk for both postoperative patients and those with concurrent conditions such as obstructive sleep apnea [13,14]

Beyond variable collection, methodological rigor is equally critical for building precise predictive models. In recent years, the application of machine learning techniques to PH risk prediction has gained traction. Methods such as recursive feature elimination (RFE) and advanced algorithms such as random forests and XGBoost (Extreme Gradient Boosting) have been shown to optimize feature selection, improving model robustness and prediction accuracy [14]. These advancements, particularly when integrating echocardiographic and clinical data, have yielded models that outperform traditional methods in PH risk prediction [5].

In this study, we systematically collected comprehensive datasets including echocardiographic parameters, laboratory test results, and baseline demographic characteristics (age and sex) from both PH patients and matched controls. Using multiple machine learning approaches, we developed an early diagnostic and predictive model for PH. The model's performance was rigorously evaluated through receiver operating characteristic (ROC) analysis, decision curve analysis (DCA), and calibration curves, with both internal and external validation procedures. Comparative analyses against existing PH diagnostic models demonstrated the superior predictive accuracy and clinical utility of our novel model, highlighting its significant advancements in early PH detection through the integration of multimodal biomarkers and optimized machine learning architecture.

Methods

Ethical Considerations

This study was approved by the research ethics commission of Wuhan Zhongnan Hospital, and the requirement for informed consent was waived by the ethics commission (2023185). We have anonymized all patient identifiers, including names and hospital numbers, from the original dataset. The published information contains no data that could be used to infer the identity of individual patients. Furthermore, all participants will benefit from this research outcome through complimentary risk prediction for pulmonary arterial hypertension.

Study Population and Data Collection

This retrospective study analyzed data from 294 patients with PH and 1231 control subjects who underwent echocardiographic evaluation at Zhongnan Hospital of Wuhan University between January 2022 and April 2024. Propensity score matching was implemented to mitigate potential confounding factors. This cohort served as both the training and internal validation dataset. For external validation, we prospectively collected an independent dataset comprising patients evaluated from May 2024 through May 2025. The inclusion criteria for the PH group were (1) a discharge diagnosis of PH; (2) confirmation of PH through RHC; and (3) participants aged >14 years, as pediatric and adult cardiac parameters have distinct reference ranges. Patients were excluded if (1) the mPAP, as measured by RHC was <20 mm Hg; or (2) the mPAP data from RHC were missing. The inclusion criteria for the control group were (1) echocardiography results indicating no abnormalities in cardiac morphology, valve function, or ventricular wall motion; and (2) age >14 years. Control subjects were excluded if more than 5% of their data were missing.

Data Collection and Variables

Data collected included demographic information (age and gender), echocardiographic parameters, and laboratory test results. Echocardiographic parameters assessed cardiac structure and function, including measurements such as ascending aortic diameter, left atrial and left ventricular size, interventricular septal thickness, and pulmonary artery diameter (PAD). Additionally, the degree of regurgitation, flow velocity, and pressure gradients for the mitral, tricuspid, and aortic valves were recorded. All echocardiographic measurements were double-checked to ensure consistency and accuracy. Laboratory data included complete blood count, coagulation profiles, liver and kidney function, and electrolytes.

RenderX

Data Preprocessing

In the data preprocessing phase, missing values were imputed with each variable's median using R (version 1.4.3; R Foundation) to ensure completeness. This approach was applied uniformly across both echocardiographic and laboratory variables, which had varying degrees of missingness, thereby maintaining sample size while minimizing bias from data exclusion. We ran stratified 10-fold cross-validation, limiting oversampling to the training folds to preserve unbiased evaluation in the held-out folds. Finally, continuous variables were mean-centered and scaled to unit variance, and categorical variables were encoded as factors for downstream analyses.

Feature Selection

We used stratified sampling to randomly split the data into training and testing sets in a 3:1 ratio. For selecting features from echocardiographic variables, we applied RFE using a random forest-based approach. RFE iteratively removed features with the least contribution to model performance, ultimately identifying the optimal subset of features. To ensure robustness and generalizability, we used 10-fold cross-validation during feature selection.

Using the selected echocardiographic features, we trained multiple machine learning models, including logistic regression, LASSO (least absolute shrinkage and selection operator) regression, elastic net, decision tree, random forest, XGBoost, support vector machine, k-nearest neighbors, naive Bayes, and gradient boosting machine. Model training and evaluation were primarily conducted using the *caret* package [15]. We used 10-fold cross-validation and grid search to optimize the hyperparameters. The primary performance metric was the area under the receiver operating characteristic curve (AUC), which was computed and plotted using the *pROC* package. The model with the highest AUC was selected as the optimal model for the echocardiographic features. For the optimal model, we further performed internal validation using bootstrap methods to evaluate its robustness. To enhance model interpretability, we applied SHAP (Shapley Additive Explanations) to quantify each feature's contribution to an individual prediction. In lay terms, a SHAP value represents how much a given variable increases or decreases the predicted PH risk for a patient compared to the average risk. Finally, we developed an ultrasound index based on the optimal model in the training and test sets.

For feature selection from routine clinical variables, we conducted LASSO regression analysis using the *glmnet* package. A 10-fold cross-validation was used to select the optimal regularization parameter. Specifically, we calculated a range of lambda values and chose lambda.1se, which is the lambda value with the best performance in cross-validation, adjusted by 1 SE.

Logistic Regression and Nomogram Construction

After identifying the optimal echocardiographic features and selected clinical variables, we combined them to develop a comprehensive logistic regression model. The model was fitted using the "lrm" function from the *rms* package. To prevent overfitting, we incorporated L2 regularization (learning 2 ridge regression) as needed. Analysis of model coefficients provided insights into the contribution of each feature to predicting PH.

To facilitate the clinical application of the model, we constructed a nomogram using the "nomogram" function from the *rmsv* package. This nomogram visualizes the logistic regression model in an easy-to-use format, allowing clinicians to estimate an individual's probability of developing PH by summing the scores for each predictive variable. The use of a nomogram ensures the interpretability and practicality of the model in a clinical setting.

Model Calibration and DCA

To assess the performance of the nomogram and logistic regression model, we used the ROC curve. To evaluate the consistency between the predicted probabilities and observed outcomes, calibration curves were plotted using the "calibrate" function from the *rms* package. Additionally, DCA was conducted using the *rmda* package to quantify the net benefit of the model across different threshold probabilities, providing insight into its clinical utility. Finally, we developed a web-based tool to facilitate the prediction of the risk of PH using R packages *shiny* (version 1.9.1).

External Validation

We externally validated the model using an independent cohort of patients admitted to the Respiratory Medicine Department at Zhongnan Hospital, Wuhan University, between May 2024 and May 2025. The inclusion and exclusion criteria were identical to those of the derivation cohort.

Statistical Analysis

The SHAP analysis was conducted using SHAP (version 0.46.0) in Python (version 3.10.8; Python Software Foundation), while all other statistical analyses were performed using R (version 4.4.1). For continuous variables that followed a normal distribution, group comparisons were made using 2-tailed *t* tests. For continuous variables that did not follow a normal distribution, nonparametric tests, such as the Mann-Whitney *U* test or the Kruskal-Wallis test, were applied. Categorical variables were presented as percentages and compared between groups using the chi-square test. A $P<.05$ was considered statistically significant.

Results

Statistical Characterization and Intergroup Comparisons of Clinical Variables in Patients With PH Versus Matched Controls

This study ultimately included a cohort of 714 control participants and 181 patients with PH. As shown in Table 1, PH patients exhibited significantly enlarged ascending aorta, left atrium, left ventricle, right atrium, and right ventricle dimensions (all $P<.05$), along with reduced left ventricular ejection fraction (%), indicating progressive chamber dilation and impaired systolic function. Hematologic analysis revealed elevated red blood cell counts and neutrophil percentage, coupled with reduced platelet counts and lymphocyte percentage (all $P<.05$), suggesting a proinflammatory, hypercoagulable profile. Patients with PH had prolonged prothrombin time,

XSL•FO
RenderX

reduced prothrombin time activity, and increased international normalized ratio, in addition to elevated total, direct, and indirect bilirubin levels (all $P<.05$), reflecting both coagulopathy and hepatic congestion. Serum cystatin C (CysC) is also found to be significantly elevated in patients with PH. Further, patients with PH experienced electrolyte imbalances—lower potassium, sodium, and phosphorus levels alongside higher chloride and calcium (all $P<.05$)—indicating disrupted electrolyte homeostasis. Together, these multisystem alterations underscore the complex structural, hematologic, coagulation, hepatic, and electrolyte derangements characteristic of PH.

Systematic Selection of Key Echocardiographic Parameters to Construct an Ultrasound Index for PH Prediction

As shown in Figure 1A, RFE with a random forest model and 10-fold cross-validation identified 16 echocardiographic variables that maximize predictive performance, with right atrial diameter and PAD yielding the highest importance scores. Figure 1B plots cross-validation accuracy against the number of features and demonstrates optimal performance when incorporating 16 variables. Figure 1C illustrates that the XGBoost model outperformed others, excelling in AUC, sensitivity, and specificity, demonstrating high robustness in distinguishing between false positives and negatives. Figure 1D highlights SHAP analysis, which shows how each feature shifts the risk prediction for individual patients: positive SHAP values indicate increased risk, while negative values indicate decreased risk. In our model, left ventricular outflow tract velocity, right atrium diameter, and PAD produced the largest SHAP values, reflecting their strong influence on PH classification. In summary, we identified and incorporated 16 key echocardiographic parameters into a composite ultrasound index as potential predictive variables for PH.

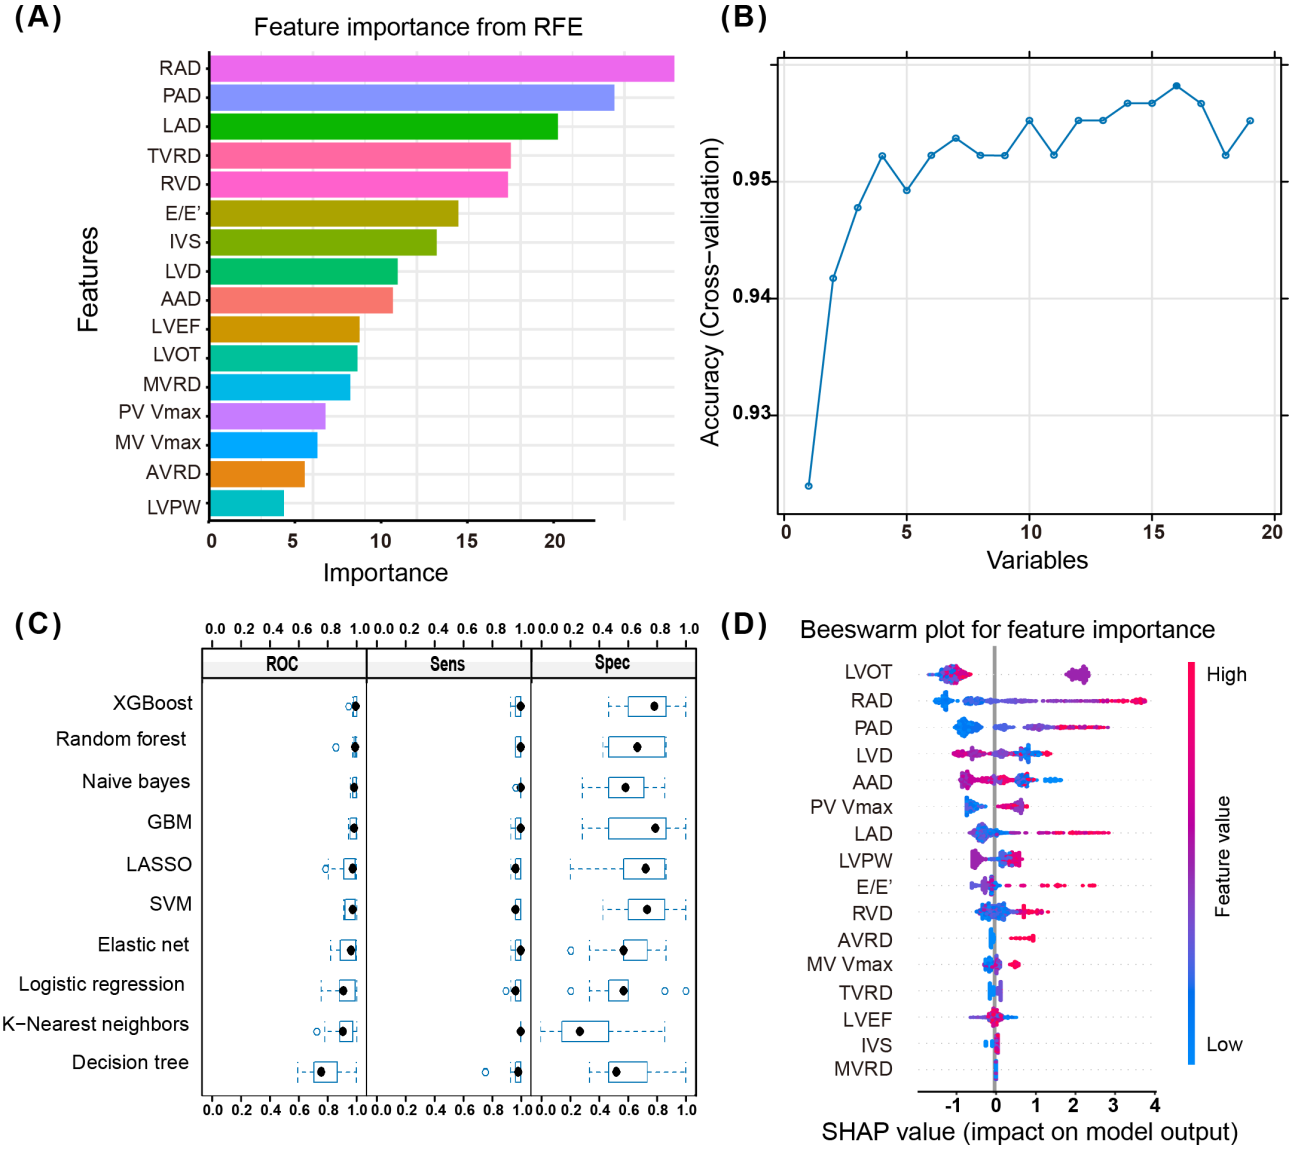
Figure 1. Identify important potential predictive variables for PH from echocardiographic parameters to form an ultrasound index. (**A**) Selected features from echocardiographic parameters. (**B**) Model accuracy with varying numbers of input variables. (**C**) ROC curves, sensitivity, and specificity of different machine learning algorithms. (**D**) Beeswarm plot for the feature importance of the selected echo features. AAD: ascending aortic diameter; AVRD: aortic valve reflux degree; E/E': ratio of mitral valve early diastolic inflow velocity (E) to mitral annulus early diastolic velocity (E'); GBM: gradient boosting machine; IVS: interventricular septal thickness; LAD: left atrium diameter; LASSO: least absolute shrinkage and selection operator; LVD: left ventricular diameter; LVEF: left ventricular ejection fraction; LVOT: left ventricular outflow tract velocity; LVPW: left ventricular posterior wall thickness; MV Vmax: mitral valve inflow velocity; MVRD: mitral valve reflux degree; PAD: pulmonary artery diameter; PH: pulmonary hypertension; PV Vmax: pulmonary valve outflow velocity; RAD: right atrium diameter; RFE: recursive feature elimination; ROC: receiver operating characteristic; RVD: right ventricular diameter; Sens: sensitivity; SHAP: Shapley Additive Explanations; Spec: specificity; SVM: support vector machine; TVRD: tricuspid valve reflux degree; XGBoost: Extreme Gradient Boosting.



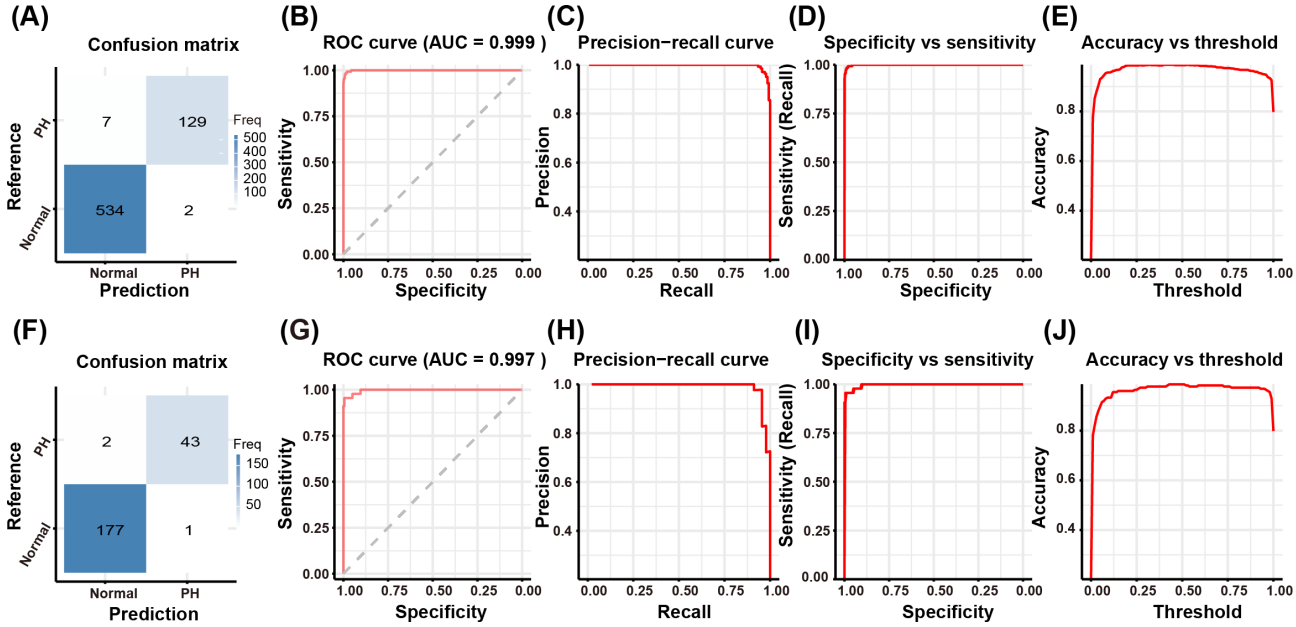


Figure 2A-E demonstrates the outstanding predictive performance of the ultrasound index model for PH detection, while Figure 2F-J presents the internal validation results through bootstrap resampling. Figure 2A presents the confusion matrix and ROC analysis of the ultrasound index model for PH prediction. The confusion matrix demonstrates excellent classification accuracy, with minimal misclassification between normal and PH cases. The ROC curve achieves near-perfect discrimination (AUC=0.999; Figure 2B), supported by precision-recall curves (Figure 2C) showing high positive predictive value across all sensitivity thresholds. Specificity-sensitivity analysis (Figure 2D) and accuracy-threshold analysis (Figure 2E) reveal balanced performance at the optimal diagnostic threshold, indicating robust clinical applicability. Figure 2F displays the bootstrap validation outcomes of the ultrasound index model, confirming its statistical reliability. The ROC curve maintains exceptional performance (AUC=0.997; Figure 2G) across 1000 resampled iterations, with tight CIs indicating stable predictive ability. Precision-recall (Figure 2H), specificity-sensitivity (Figure 2I), and accuracy-threshold (Figure 2J) curves show reproducible performance characteristics within narrow variability ranges (<1% fluctuation), demonstrating the model's resistance to overfitting and dataset sampling bias.

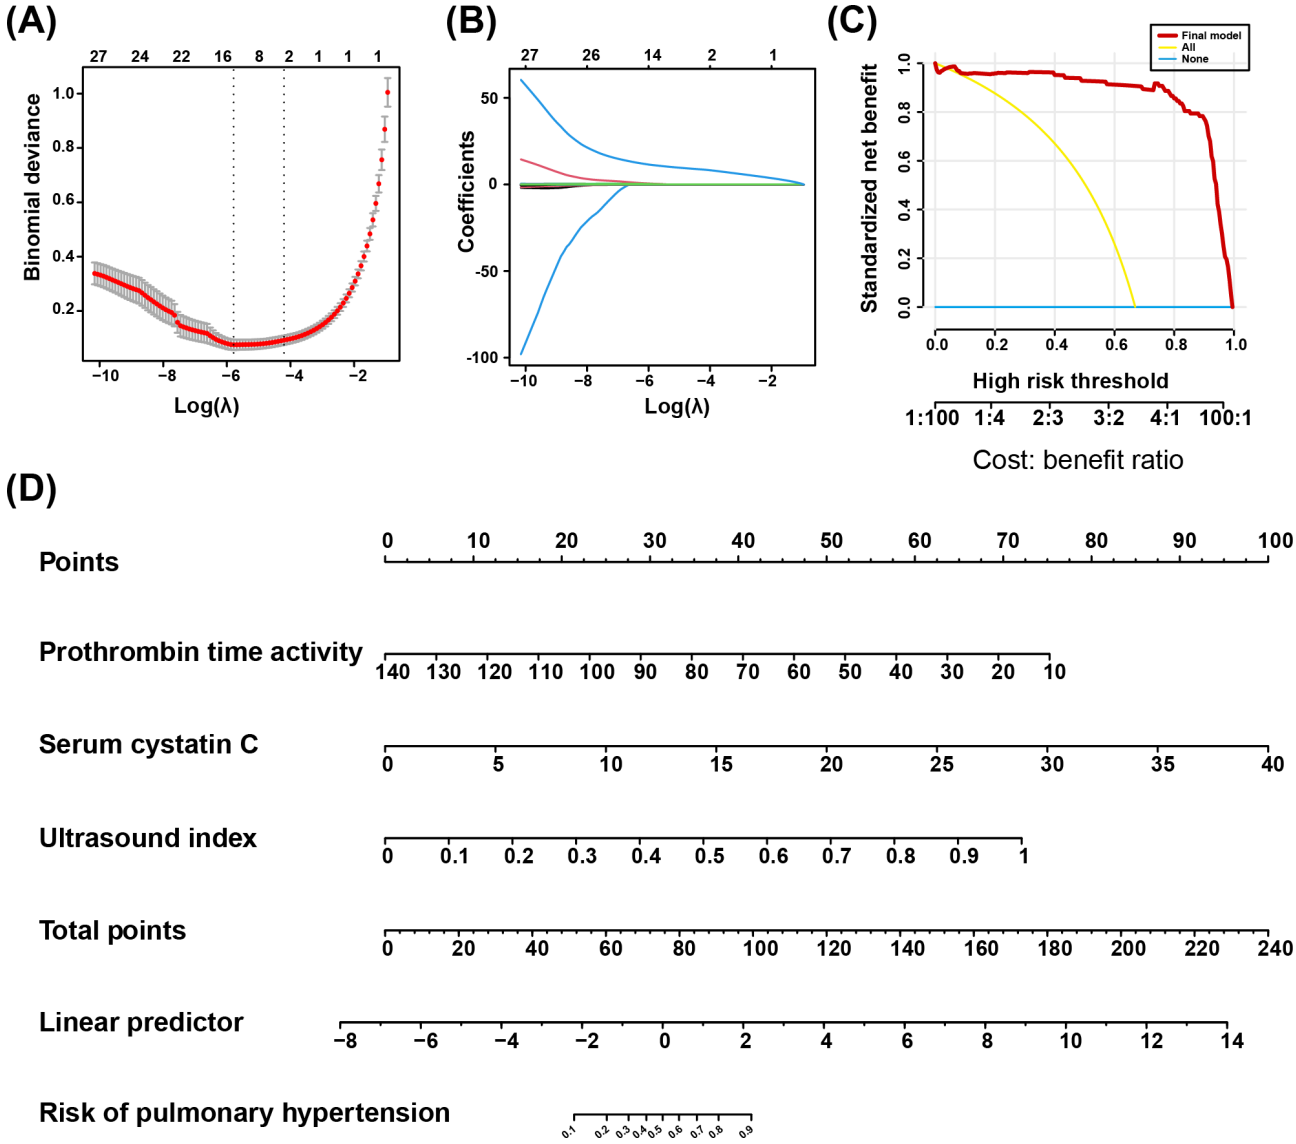
Figure 2. Evaluation of the predictive performance of the ultrasound index for PH in the training set and internal validation set. (A) Confusion matrix for training cohort. (B) ROC curve for training cohort (AUC=0.999). (C) Precision-recall curve for the training cohort. (D) Specificity versus sensitivity for the training cohort. (E) Accuracy versus threshold for the training cohort. (F) Confusion matrix for the validation cohort. (G) ROC curve for the validation cohort (AUC=0.997). (H) Precision-recall curve for the validation cohort. (I) Specificity versus sensitivity for the validation cohort. (J) Accuracy versus threshold for the validation cohort. AUC: area under the receiver operating characteristic curve; PH: pulmonary hypertension; ROC: receiver operating characteristic.



Development and Presentation of the Final PH Prediction Model

As shown in Figure 3A and B, LASSO regression identified 2 key clinical features—prothrombin time activity and serum CysC as the most influential variables, indicating that these variables are critical potential predictive parameters of PH. Then, we combined prothrombin time activity, serum CysC, and previously selected ultrasound index to form the final PH prediction model through logistic regression. Figure 3C demonstrates through DCA that our PH prediction model provides superior clinical net benefit compared to both “treat-all” and “treat-none” strategies across clinically relevant probability thresholds. As depicted in Figure 3D, our nomogram translates each predictor’s regression coefficient into a point scale and uses the sum of points to compute an individualized PH risk probability via a linear predictor, providing clinicians with an intuitive, quantitative tool for PH risk assessment. The nomogram translates clinical variables—including prothrombin time activity (10 - 140 s mapped to 75 - 0 points), serum CysC (0 - 40 mg/L mapped to 0 - 100 points), and the ultrasound index (0 - 1 mapped to 0 - 72.5 points)—into a cumulative point total. The total score is then read against the bottom probability scale to yield an individualized PH risk, providing a convenient tool that converts routine laboratory and imaging data into a directly actionable prediction of PH.

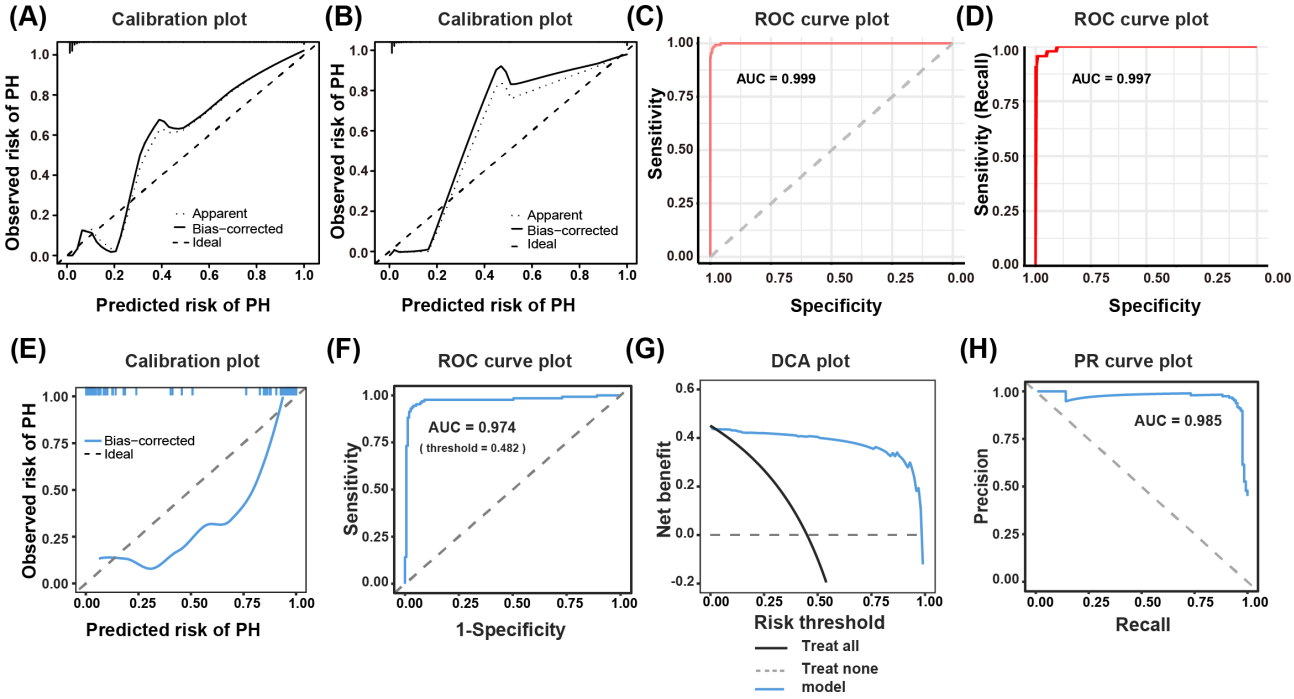
Figure 3. Identify key laboratory biomarkers and develop the final predictive model for PH. (A) Deviance plot from LASSO regression to select key laboratory biomarkers. (B) Coefficient path for LASSO regression to select key laboratory biomarkers. (C) Decision curve analysis of the final predictive model of PH. (D) Nomogram of the final PH prediction model. LASSO: least absolute shrinkage and selection operator; PH: pulmonary hypertension.



Evaluation and Validation of the Final PH Prediction Model

Data from different time periods were collected for external validation, including 126 patients with PH and 155 controls, with detailed information presented in Multimedia Appendix 1. Figure 4A and C present the model performance evaluation results, while Figure 4B and D display the stability analysis of internal validation (bootstrap=1000 iterations), and Figure 4E-H systematically report the external validation data. Calibration curve analysis demonstrates that the predictive model maintains excellent calibration in both the training set (Figure 4A), internal validation (Figure 4B), and external validation cohorts (Figure 4E). ROC analysis further reveals that the model exhibits stable discriminative ability across the training set (AUC=0.999, Figure 4C), internal validation (AUC=0.987, Figure 4D), and external validation (AUC=0.974, Figure 4F). In external validation, DCA shows significant net benefit across the 10% - 90% risk threshold range (Figure 4G), while the area under the precision-recall curve (AUC=0.985) confirms the model's balanced advantage of both high precision and recall for positive cases (Figure 4H). These analytical results demonstrate that our model exhibits not only excellent predictive performance for PH, but also outstanding stability and significant clinical utility.

Key Advantages and Innovations of Our Model Versus Current PH Predictive Models

Although predictive models for PH currently exist, these tools face significant limitations: the REVEAL score requires invasive data for optimal use and lacks imaging integration, while guideline-based echocardiography suffers from subjective interpretation variability and low sensitivity (AUC=0.70 - 0.82). Both systems fail to capture early preclinical signs and the mechanistic pathways addressed by our biomarker-enhanced approach.

Our novel PH prediction model demonstrates significant advancements over existing approaches (Table 2) by integrating 16 echocardiographic parameters with 2 clinically accessible biomarkers (prothrombin time activity and CysC), achieving superior discriminative performance (AUC=0.974 - 0.999 versus 0.70 - 0.85 in conventional models). Unlike the REVEAL score's reliance on invasive hemodynamics or guideline-based echocardiography's limited echo variables, our model provides: (1) comprehensive pathophysiological insight through multimodal biomarkers reflecting coagulation and cardiac dysfunction; (2) granular risk quantification via a 240-point nomogram, enabling precise stratification; and (3) practical clinical utility through Electronic Health Record (EHR)–compatible automation. In summary, our model demonstrates significant advancements and innovations compared to existing models.

XSL•FO
RenderX

Table . Comparison of our model with existing PH[a] risk assessment tools.

Feature	Our model	REVEAL[b] score	Guideline-based echocardiography
Variables used	• 16 echocardiographic and 2 clinical (prothrombin time activity and cystatin C)	• Primarily clinical (6MWD[c], functional class, and hemodynamics)	• Limited echo parameters (TR[d] velocity and RV[e] size)
AUC[f]	• 0.974 - 0.999	• 0.79 - 0.85	• 0.70 - 0.82
Strengths	• Multimodal integration (imaging and biomarkers) • Objective scoring system • Higher discriminative ability	• Established registry data • Validated long-term outcomes	• Widely available • First-line screening
Key advantages	• Comprehensive echo assessment (16 parameters, including novel metrics such as LVOT[g] velocity) • Novel biomarkers (cystatin C adds renal or PH pathobiology dimension) • Quantitative nomogram (precise risk stratification)	• Lacks imaging details • Requires invasive data for the full version	• Subjective interpretation • Limited accuracy
Clinical utility	• EHR[h]-integratable • Identifies early-stage PH • Guides RHC[i] decisions	• Mainly for prognosis • Less useful for initial diagnosis	• Screening only • High false-positive rate
Population	• Broad applicability (includes preclinical signs)	• Established patients with PH	• Symptomatic suspects

[a]PH: pulmonary hypertension.

[b]REVEAL: Registry to Verify Early and Long-Term Pulmonary Arterial Hypertension Disease Management.

[c]6MWD: 6-minute walk distance.

[d]TR: tricuspid regurgitation.

[e]RV: right ventricular.

[f]AUC: area under the receiver operating characteristic curve.

[g]LVOT: left ventricular outflow tract velocity.

[h]EHR: electronic health record.

[i]RHC: right heart catheterization.

To facilitate clinical implementation of our model, we developed a web-based calculator (Figure 5A and B), available online [16], which enables user-friendly PH risk assessment. This tool is expected to significantly enhance the model's clinical adoption.

E/E': ratio of mitral valve early diastolic inflow velocity (E) to mitral annulus early diastolic velocity (E'); PH: pulmonary hypertension; SHAP: Shapley Additive Explanations.

Discussion

Principal Findings

We present an integrated diagnostic model that combines ultrasound-derived parameters with clinical variables to improve early PH risk prediction. Using RFE, LASSO regression, and various machine learning algorithms, we optimized the model and rigorously assessed its predictive performance. Given that PH is a rapidly progressive disease with high mortality, early detection and intervention are essential for improving outcomes [17,18]. Current diagnostic methods for pulmonary artery pressure rely heavily on 2 approaches: RHC and echocardiography, which estimate pressure based on TRV [19-21]. However, catheterization is invasive, and echocardiography can be prone to significant inaccuracies. To overcome these limitations, our research proposes a novel noninvasive diagnostic pathway that integrates ultrasound and clinical data, thereby providing an effective tool for the early detection of PH.

In our model, 16 echocardiographic features (right atrium diameter, PAD, left atrium diameter, tricuspid valve reflux degree, right ventricular diameter, E/E' [Ratio of Mitral Valve Early Diastolic Inflow Velocity (E) to Mitral Annulus Early Diastolic Velocity (E')], interventricular septal thickness, left ventricular diameter, ascending aortic diameter, left ventricular ejection fraction, left ventricular outflow tract velocity, mitral valve reflux degree, pulmonary valve outflow velocity, mitral valve inflow velocity, aortic valve reflux degree, and left ventricular posterior wall thickness) and 2 laboratory tests variables (prothrombin time activity and CysC) was identified to be the critical predictive parameters of PH. These structural cardiac measurements demonstrate strong pathophysiological

XSL•FO
RenderX

concordance with known PH mechanisms: enlargement of the right and left atria reflects increased pulmonary circulation pressure and heightened right ventricular load, both of which are common in patients with PH [22]. Additionally, an enlarged PAD correlates directly with elevated pulmonary vascular resistance, further exacerbating right ventricular pressure overload [23].

While the association between cardiac structural or functional parameters and PH is well-established and mechanistically straightforward, our selected biochemical markers (prothrombin time activity and CysC) similarly demonstrate previously reported—yet less widely recognized—pathophysiological links to PH development. A review summarizing the association between coagulation abnormalities and hypertension suggests that prothrombin time activity is closely correlated with elevated systolic and diastolic blood pressure in both hypertensive patients and normotensive individuals [24]. This is consistent with the conclusion in this paper that prothrombin time activity is associated with increased pulmonary artery pressure. CysC is generally recognized as an indicator of renal function. However, previous studies have found that CysC is also elevated in patients with pulmonary arterial hypertension and is positively correlated with right ventricular systolic pressure, right ventricular end-diastolic volume, and right ventricular end-systolic volume, suggesting its potential as a biomarker for PH [25].

Our study advances beyond prior research by systematically identifying optimal ultrasound parameters through rigorous RFE coupled with 10-fold cross-validation, ensuring robust and reproducible feature selection. Whereas conventional approaches typically analyze isolated echocardiographic measures, our novel methodology integrates multidimensional cardiac imaging features with critical clinical biomarkers to develop a high-performance yet clinically interpretable prediction model. This integrative approach demonstrates superior predictive accuracy for PH, representing a paradigm shift from single-parameter assessment to comprehensive risk stratification. The clinical implementation of this model enables: (1) earlier detection of subclinical PH through sensitive ultrasound biomarkers, (2) improved risk discrimination via combined imaging and laboratory data, and (3) actionable outputs for timely therapeutic decision-making.

It is also worth mentioning that in our study, we used multiple machine learning algorithms, such as XGBoost, random forest, and logistic regression. Among these models, XGBoost demonstrated the best predictive performance, achieving an AUC of 0.997, highlighting its strength in handling high-dimensional data and modeling complex nonlinear relationships. As a gradient-boosting algorithm, XGBoost incrementally reduces the model error to enhance predictive accuracy, rendering it particularly effective for clinical data with intricate interactions [26,27]. To enhance the interpretability of the XGBoost model, we constructed an analysis using SHAP. SHAP values quantified the contribution of each feature to the model's predictions, emphasizing the importance of variables such as the right atrium and PAD in predicting PH. Compared to traditional "black-box" models, incorporating SHAP analysis significantly enhanced the model's interpretability, providing more clinical insights. SHAP not only increases transparency but also enables clinicians to better understand the predictive mechanisms of the model, thus supporting more informed and reasoned clinical decision-making.

To enable seamless adoption in clinical workflows, we deployed the nomogram and risk calculator [16] as a web-based Shiny application with an Application Programming Interface compatible with major EHR systems. Compliant with Health Level Seven Fast Healthcare Interoperability Resources standards, the tool automatically retrieves echocardiographic measurements and laboratory values, computes the PH risk score in real time, and presents results in clinician-facing dashboards during outpatient visits. Moreover, the application can be embedded within ultrasound reporting software, allowing sonographers to generate risk estimates immediately at the point of image acquisition. Concrete examples of our predictive model's clinical application are: a 58-year-old woman presenting with unexplained dyspnea underwent noninvasive PH risk stratification using our proposed nomogram or web-based tool to defer immediate RHC. The clinician input key echocardiographic parameters (right atrium diameter=4.5 cm, PAD=2.8 cm, left atrium diameter=4.0 cm, and other selected parameters in our model) along with laboratory values (prothrombin time activity=78%, serum CysC=1.5 mg/L) extracted from recent reports. Application of the nomogram yielded a total score of 50 points, corresponding to an 85% predicted PH risk, automatically flagging the patient as high-risk. This prompted clinical actions, including prioritization of confirmatory RHC, initiation of enhanced monitoring (repeat echocardiography and N-terminal pro-B-type Natriuretic Peptide testing, and consideration of early PH specialty referral. For seamless clinical implementation, the tool could integrate with electronic health record systems (eg, Cerner, formerly known as Cerner Corporation, now part of Oracle Health) as a plug-in module, enabling automated data population from EHR fields (laboratory results or echocardiographic reports) and generation of standardized risk assessment documents for longitudinal patient tracking within the medical record.

Although several machine learning models have been developed for PH, they exhibit certain limitations. Many models rely on a single data source, which restricts predictive accuracy and reliability. For instance, the study by Athénaïs Boucly identified cytokines as prognostic biomarkers in pulmonary arterial hypertension but failed to account for potential confounding factors, such as clinical variables or imaging data, which may influence the results [28]. Similarly, the research by Hirata et al [29] demonstrated improved accuracy of a machine learning model compared to traditional methods in the derivation cohort; however, its performance in the validation cohort was only comparable to guideline-based echocardiographic assessments, underscoring the need for further optimization and validation. Additionally, previous studies frequently used univariable and multivariable models to evaluate the relationship between clinical and echocardiographic parameters in precapillary PH [30]. However, they lacked advanced feature selection methods such as LASSO and RFE, which could have enhanced model performance by identifying key predictive variables, reducing

XSL•FO
RenderX

overfitting, and providing deeper insights into prognostic factors. In contrast, our research proposes an innovative approach by integrating ultrasound parameters with clinical variables, thereby enhancing the model's predictive performance through multidimensional integration [31,32]. Unlike prior work, we optimized feature selection using both RFE and LASSO regression and ensured model robustness through comparison and tuning across multiple machine-learning models [33]. We also significantly enhanced model interpretability using SHAP, which makes this high-performing "black-box" model more transparent and trustworthy for clinical use, ultimately enhancing its applicability and credibility in a health care context.

Despite the strong performance of our model in predicting PH, it exhibits certain limitations. First, the study sample size was relatively small, which limits the generalizability of the findings. Future work should involve validation using larger, multicenter datasets to ensure the model's external validity. Second, as new ultrasound technologies and biomarkers emerge, future research should incorporate additional multidimensional biological data to enhance the predictive accuracy and applicability of the model.

Conclusions

We developed a high-performance PH prediction model using machine learning analysis of echocardiographic, laboratory, and demographic data from 895 participants. The model incorporates 16 key ultrasound parameters and 2 biomarkers, with validation showing excellent accuracy. We also created a web-based calculator to facilitate clinical use, providing a practical tool for early, noninvasive PH detection.

Abstract

Background: Gestational diabetes mellitus (GDM) affects over 5% of pregnancies worldwide, elevating risks of type 2 diabetes post partum and complications such as fetal death, miscarriage, and congenital abnormalities. Effective GDM management is essential to balance glycemic control and pregnancy outcomes.

Objective: We aim to develop interpretable machine learning models using GDM datasets for predicting adverse pregnancy outcomes and identifying key factors through the Shapley additive explanations (SHAP) algorithm, thus supporting improved maternal and infant health.

Methods: Data preprocessing and feature selection were performed, with adaptive synthetic sampling used to address class imbalance. Classification models, including logistic regression, random forest, support vector machine, and extreme gradient boosting, were built and enhanced through the stacking method. Model interpretability was assessed with SHAP to quantify feature contributions.

Results: Among 1670 patients, 200 experienced adverse outcomes. The stacking model outperformed individual models, achieving an accuracy of 85.6%, a sensitivity of 57.8%, a specificity of 95.9%, and an area under the receiver operating characteristic curve of 0.82 on the test set. External validation on 159 patients showed a decline in performance (accuracy 83.6%, area under the receiver operating characteristic curve 0.67). SHAP analysis identified gestational age, glucose control, and diagnosis time among the most influential predictors, providing clinically meaningful insights into risk factors. Additionally, detailed SHAP-based visualization revealed the distribution of different feature values and their nonlinear impact on outcomes, as well as interaction effects between features. These interpretable analyses enabled a deeper understanding of individual and combined feature contributions, thereby enhancing clinical assessment capabilities.

Conclusions: This study underscores the potential of machine learning in predicting adverse outcomes in GDM, with interpretable features offering valuable clinical insights to enhance pregnancy management and maternal-infant health.

Introduction

Gestational diabetes mellitus (GDM) is a significant global health concern, affecting at least 5% of pregnancies worldwide [1]. It is characterized by impaired glucose tolerance due to an increase in anti-insulin substances and decreased insulin sensitivity, leading to hyperglycemia and other metabolic disturbances [2]. Women diagnosed with GDM not only face increased perinatal complications but are also at a significantly higher risk of developing type 2 diabetes mellitus postpartum [3]. Moreover, in utero exposure to hyperglycemia has long-term implications for offspring, predisposing them to metabolic disorders, obesity, and cardiovascular diseases later in life.

Uncontrolled GDM significantly increases the risk of adverse pregnancy outcomes, including fetal macrosomia, preterm birth, neonatal hypoglycemia, and even perinatal mortality [4,5]. During early pregnancy, poor glycemic control may result in congenital malformations or spontaneous abortion, whereas in

XSL•FO
RenderX

later stages, it can contribute to pre-eclampsia, respiratory distress syndrome, and hyperbilirubinemia [6,7]. Despite advancements in clinical management, the timely identification of high-risk pregnancies remains a challenge. Traditional risk assessment methods, such as clinical scoring systems and conventional regression models, often rely on predefined risk factors and fail to capture complex interactions within high-dimensional clinical data [8]. This limitation highlights the need for more advanced predictive tools that can improve early risk stratification and optimize maternal and fetal outcomes.

Machine learning has emerged as a transformative approach in medical research, offering superior capabilities in analyzing complex, high-dimensional datasets [9]. Machine learning models can effectively capture intricate patterns and nonlinear relationships in clinical data, surpassing traditional statistical approaches in predictive accuracy. In a retrospective analysis of 8888 deliveries, random forest classification achieved exceptional accuracy in predicting birth asphyxia, with critical risk factors including maternal hypertension, anemia, preterm birth, and noncephalic presentation [10]. Similarly, deep learning showed superior predictive performance for intrauterine growth restriction in another study of 8888 pregnancies, identifying key risk factors such as maternal hypertension, drug addiction, and COVID-19 infection [11]. Furthermore, in an analysis of 7166 pregnancies, random forest demonstrated optimal prediction of fetal heart, with significant predictors including primiparity, placental abruption, and male fetal sex [12]. However, the use of machine learning models in predicting GDM-related adverse pregnancy outcomes remains relatively limited—particularly in the field of interpretable machine learning. Most current studies focus on model predictive accuracy, lacking transparent analysis of feature variable impacts, which makes it difficult to provide clinically reliable risk factor assessments. This lack of interpretability limits the practical application and adoption of such models in real-world medical settings. Therefore, there is an urgent need to develop models that combine high predictive performance with clinical interpretability to identify key risk factors and assist physicians in formulating personalized intervention strategies.

To address this gap, this study aims to develop an interpretable machine learning model using a publicly available GDM dataset to predict the risk of adverse pregnancy outcomes associated with gestational diabetes. Unlike previous studies that primarily focus on GDM diagnosis, our approach emphasizes predicting maternal and fetal complications, which is crucial for timely intervention. Furthermore, we incorporate Shapley additive explanations (SHAP) analysis to enhance model interpretability, allowing clinicians to identify the most influential factors contributing to adverse pregnancy outcomes. By providing clinically actionable insights, our model aims to support personalized risk assessment and improve maternal and fetal health outcomes.

Methods

Data

This study is based on the publicly available GDM dataset. We included pregnant women who met specific diagnostic criteria through the publicly available dataset [13,14]. The dataset comprises anonymized electronic health records extracted from the Cerner system at St Mary's Hospital in London, covering pregnancies monitored between April 2016 and November 2019. A total of 1854 records were initially retrieved, including clinical and demographic variables such as maternal age, BMI at booking, ethnicity, glucose tolerance test results (0- and 120-min post-75 g glucose load), mode of delivery, gestational age, neonatal birth weight, and stillbirth outcomes.

To ensure data quality and reliability, patients with missing values in key variables were excluded. Implausible outliers were identified and corrected when possible; otherwise, they were removed from the dataset. Unit inconsistencies were also standardized. These preprocessing steps were applied to ensure consistency, accuracy, and completeness of the data used for model development and analysis.

Subject

To ensure the accuracy and reliability of this study's results, inclusion criteria (based on the results of the oral glucose tolerance test [OGTT]) were defined as follows: the blood glucose level of pregnant women should reach or exceed 7.8 mmol/L and not exceed 25 mmol/L at 2 hours after OGTT; or the blood glucose level should reach or exceed 5.6 mmol/L and not exceed 25 mmol/L at 10 minutes after OGTT [15]. In addition, the study's definition of adverse pregnancy outcomes includes newborn birth weight below 2500 g, severe prematurity, stillbirth, and Apgar score below 4 [16]. Additionally, we excluded cases with missing Apgar score data to avoid potential biases that could arise from inaccuracies in assessing pregnancy outcomes. By implementing these strict inclusion and exclusion criteria, we ensured the consistency of this study's population, allowing for a more accurate assessment of the impact of GDM on the health of pregnant women and their offspring.

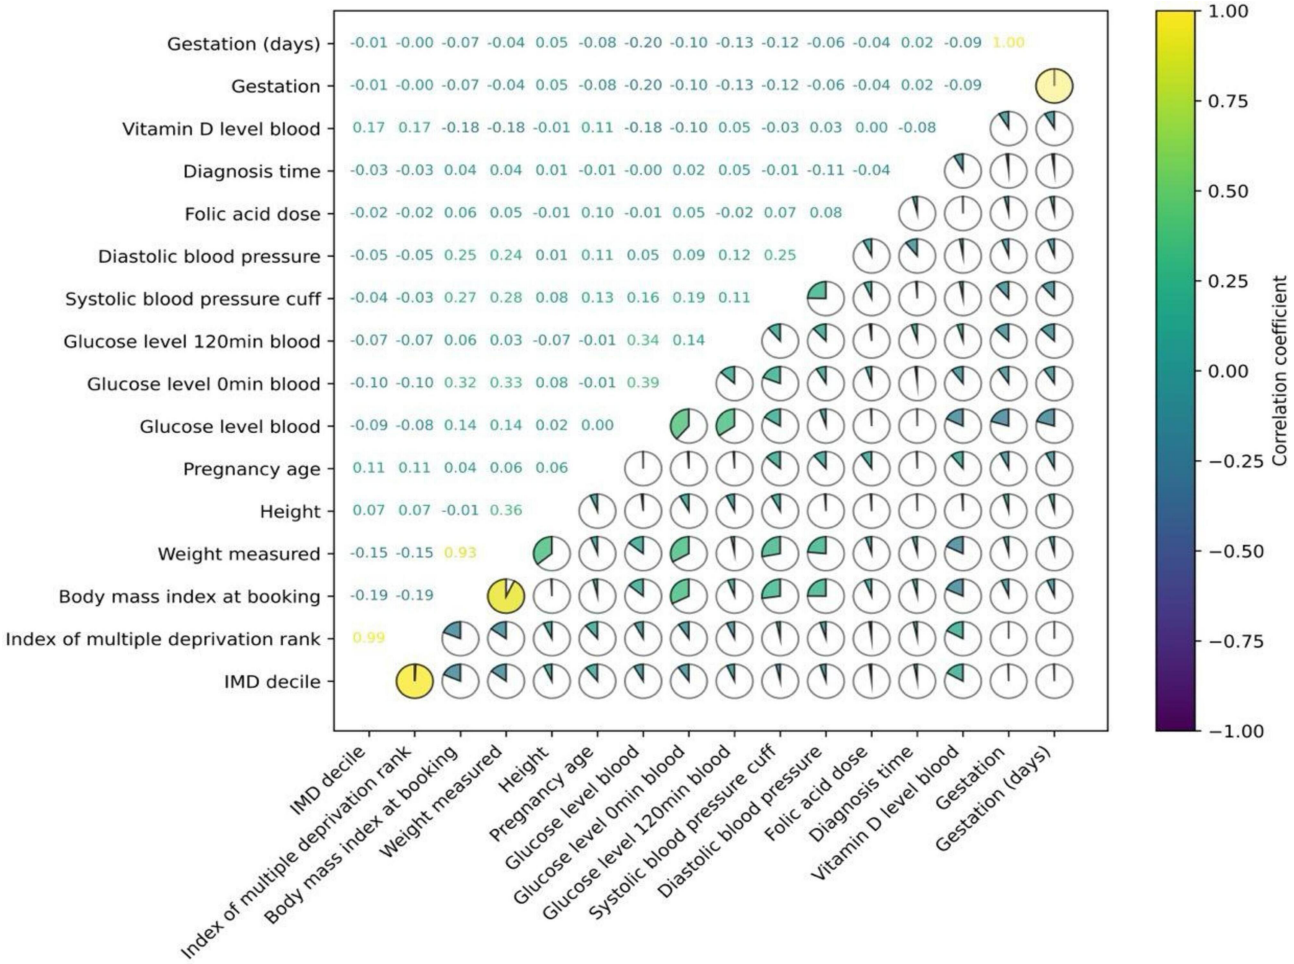
Data Preprocessing

In this study, we encountered issues with missing values for multiple features in the dataset. To maintain data integrity and the reliability of the analysis, we adopted a cautious approach to handle these missing values. Specifically, when the proportion of missing values for a particular feature exceeded 30%, such as "previous obstetric history," "presence of meconium," and "O_Thyroid function blood," we chose to exclude them from the analysis. For the remaining missing values in the features, we implemented an imputation strategy to enhance the usability of the data.

In terms of the choice of imputation method, we adopted a differentiated approach based on the type of feature. For numerical features, we used the median or mean for imputation, a method that reduces the impact of extreme values while preserving the distribution characteristics of the data. For categorical features, we used the k-nearest neighbors algorithm

XSL•FO
RenderX

for imputation, which estimates the possible values of missing data by finding similar observations based on distance metrics.



Additionally, some categorical features with sparse or heterogeneous classifications were restructured using domain knowledge to improve statistical interpretability. For instance, antenatal medical factors were originally recorded in 64 different categories. These were clinically reviewed and consolidated into 7 meaningful groups: (1) mental health and neurological disorders, (2) genetic disorders, (3) surgical or operative conditions, (4) infectious and immune-related diseases, (5) obesity-related conditions, (6) chronic diseases, and (7) none.

Finally, to further meet the requirements of machine learning models, we performed 1-hot encoding on all categorical variables. This helps to avoid potential numerical encoding biases and ensures the effectiveness of model training.

Feature Selection

To mitigate the "curse of dimensionality" and enhance the practicality of model deployment in clinical settings, we removed redundant features. As shown in Figure 1, we used the Pearson correlation matrix to identify highly correlated variables. For continuous variables, feature selection was guided by the Pearson correlation coefficient. As the number of categorical variables was relatively small—primarily including "number of previous C-sections," "obesity status," and "antenatal medical factors"—all were retained in the model.

Figure 1. Pearson correlation matrix of key features for redundancy analysis. IMD: Index of Multiple Deprivation.

During the analysis, we identified several pairs of features with relatively high Pearson correlation coefficients, including "Index of Multiple Deprivation (IMD) decile" and "IMD rank," "gestation (days)" and "gestation," as well as "body mass index (BMI) at booking" and "weight measured." Both deprivation-related variables reflect the socioeconomic status of pregnant women; however, given the broader range of values for "IMD decile" (1012 to 32,742), we considered it more statistically informative and retained this feature.

Given the direct association between gestational age and adverse pregnancy outcomes, gestational variables were excluded from the model to prevent potential confounding. Likewise, fetal birth weight—available only after delivery—was excluded to avoid outcome leakage. We recalculated BMI based on height and weight, as it offers a more comprehensive measure of maternal body composition. Consequently, the original "height" and "weight" variables were removed due to redundancy. Additionally, although "gestation (days)," "gestation," and "Gravida" are strongly associated with adverse outcomes such as preterm birth and miscarriage, including them posed a risk of information leakage. Based on both statistical reasoning and clinical expert input, these features were excluded.

Lastly, "vitamin D level in blood" was removed due to concerns over data quality and consistency. Vitamin D is not a routine

XSL•FO
RenderX

prenatal test, and the lack of standardization in test timing introduced considerable variability, limiting its reliability as a predictive feature.

Missing Data

The final dataset included 10 continuous variables such as pregnancy age, blood glucose levels, and blood pressure. The categorical variables include obesity status, number of previous C-sections, and antenatal medical factors. Several continuous variables had missing values, with the highest rates observed in blood glucose levels (up to 23.1%) and blood pressure measurements (Multimedia Appendix 1).

Model Construction

Based on our analysis results, we performed feature selection and data preprocessing and then constructed machine learning models. We used a variety of algorithms, including logistic regression, random forests, support vector machines (SVM), and extreme gradient boosting (XGBoost), to independently build classification prediction models. To further enhance the predictive power of the models, we used the Stacking ensemble learning method, taking the prediction results of these base models as input and training them with a meta-model (also known as a secondary model), thereby achieving superior overall predictive performance. In our study, we chose XGBoost as the meta-model. Considering that only 11.9% of the samples in the dataset manifested adverse pregnancy outcomes, indicating an imbalance in the dataset, we applied the adaptive synthetic sampling (ADASYN) algorithm to address this imbalance and improve the model's generalization ability.

ADASYN is a machine learning algorithm used to address class imbalance in classification problems [17]. In imbalanced datasets, there is a large difference in the number of samples between different classes, which can result in poor classification performance of the model for minority classes. ADASYN balances the dataset by increasing the number of samples of the minority class, thus improving the model's performance. Considering the imbalance between the alive group and the expired group and the impact on the accuracy of the prediction results, we applied the ADASYN method to oversample the training set, while the test set maintained the original sample ratio. To further validate the model's robustness and performance in addressing class imbalance, we conducted supplementary experiments by introducing another widely used oversampling method—SMOTE (Synthetic Minority Oversampling Technique) for comparison. SMOTE generates synthetic minority class samples through interpolation in the feature space and has been extensively applied in imbalanced classification tasks. Compared with ADASYN, it is more comprehensive to evaluate the impact of different oversampling strategies on model performance, ensuring the selected method exhibits stronger robustness and generalization capability in practical applications. The overall data was split into a training set and a test set in an 8:2 ratio. To fine-tune the hyperparameters of each algorithm, we used grid search based on 5-fold cross-validation within the training set. The hyperparameters adjusted for each algorithm are as follows (Table 1).

Table . Hyperparameters adjusted for each algorithm.

Algorithm	Hyperparameters
Random forest	• n_estimators: 10, 50, 100 • max_features: auto, sqrt, log2 • Bootstrap: true, false
Extreme Gradient Boosting	• n_estimators: 20, 50, 100 • learning_rate: 0.1, 0.2, 0.3 • max_depth: 4, 6, 8 • objective: binary: logistic • subsample: 0.6, 0.8, 1
Logistic regression	• C: 0.001, 0.01, 0.1, 1, 10, 100, 1000 • Penalty: L1, L2
Support vector machine	• C: 0.1, 1, 10, 100 • Kernel: linear, rbf, poly • Gamma: scale, auto

Based on the basic models obtained from training, we introduced the stacking strategy in our model fusion approach to more comprehensively explore the potential correlations between different basic models. We treated the outputs of each basic model as new features and further trained them using the XGBoost gradient boosting framework to construct a highly optimized stacking model with significant synergistic effects.

In clinical models, the interpretability of the model is crucial because it helps doctors and researchers understand the decision-making process of the model, thereby increasing trust in the model and promoting its application in clinical practice. SHAP is a popular machine learning interpretability tool that can quantify the contribution of each feature to the model's prediction. In our study, we used the SHAP algorithm to perform an interpretability analysis on the gestational diabetes risk prediction model to increase the model's transparency, helping doctors better understand the model's decision-making process and make appropriate interventions when necessary.

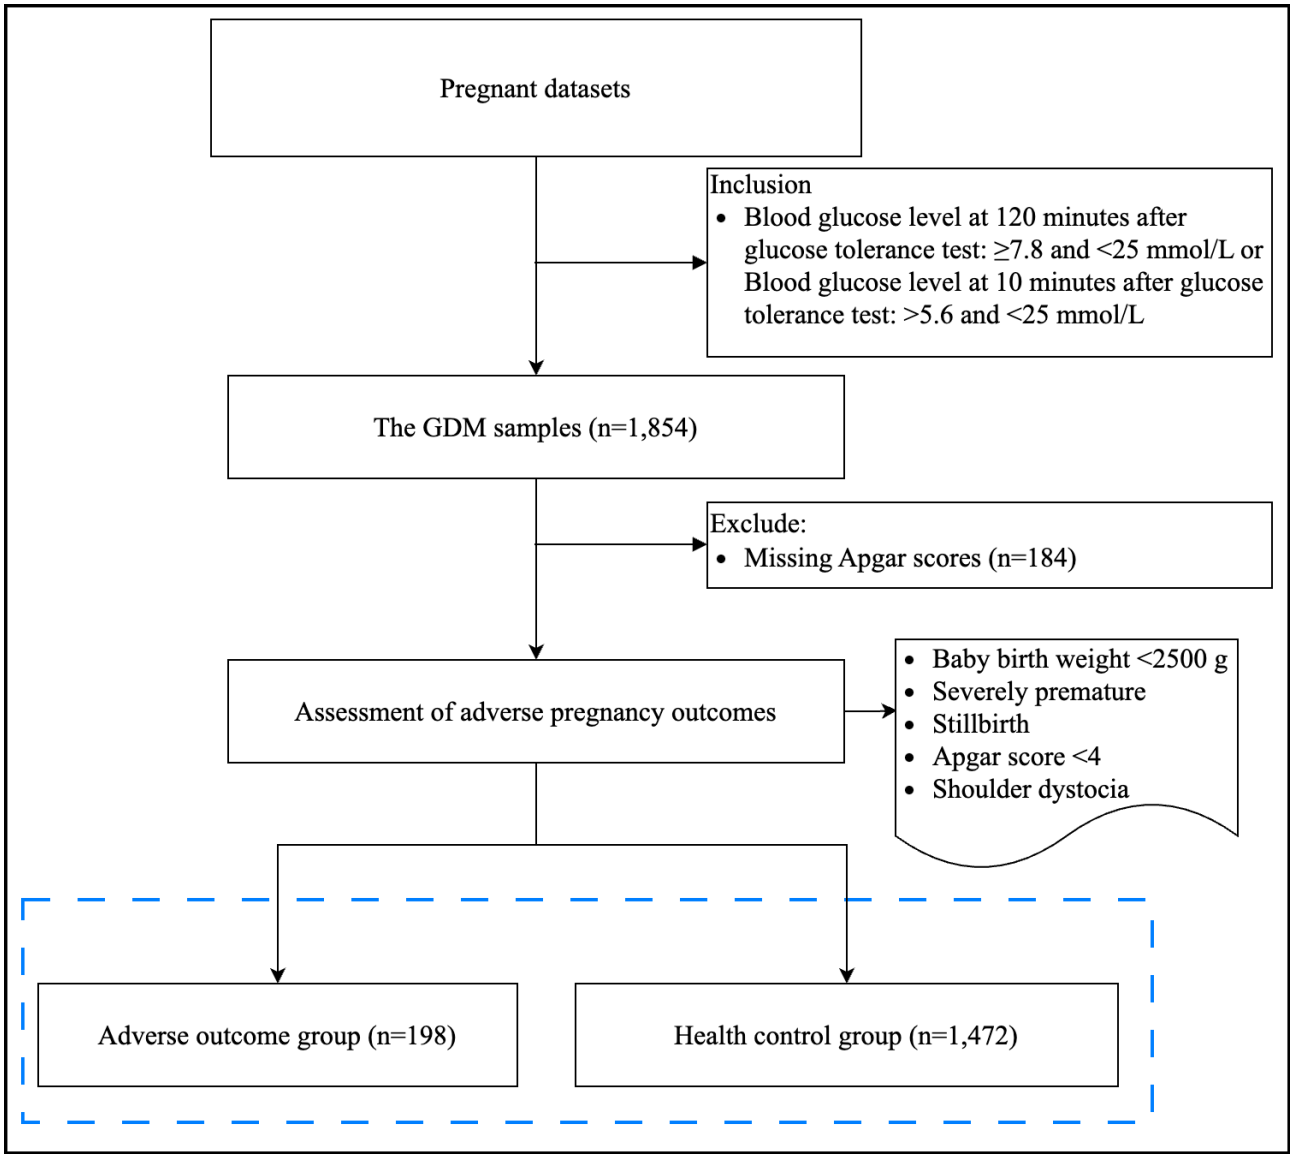
Ethical Considerations



This study is based on the publicly available GDM dataset. We included pregnant women who met specific diagnostic criteria, as defined in the dataset documentation. All protected health information has been deidentified to ensure privacy. The dataset is accessible [14], and its use complies with the associated public license and terms of use. Therefore, ethical approval and individual patient consent were not required for this study.

Results

Overview

A total of 1670 patients were selected from the GDM database for inclusion in this study. The data inclusion and exclusion diagram is shown in Figure 2. Among them, 200 patients had adverse pregnancy outcomes. Statistical analysis was conducted using SPSS (version 22.0; IBM Corp), while data cleaning, model construction, and performance evaluation were carried out using Python (Python Software Foundation). Continuous variables were expressed as median (IQR), while categorical data were presented as counts (percentages). The Mann-Whitney *U* test was used for analyzing continuous variables, and chi-square test was used to examine significant differences in categorical variables. The patient's baseline is presented in Table 2.

[a]HC: healthy control.

[b]IMD: Index of Multiple Deprivation.

In this study, we evaluated 5 different machine learning models: random forest, XGBoost, logistic regression, SVM, and a stacking ensemble model. To address class imbalance in the training data, we applied oversampling techniques such as ADASYN before model training. However, to preserve the clinical authenticity and real-world applicability of the evaluation, no oversampling was applied to the test set. A comprehensive evaluation was conducted using multiple performance metrics, including sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), positive likelihood ratio (PLR), negative likelihood ratio (NLR), and overall accuracy. The results obtained on the test set are summarized in Table 3 below.

XSL•FO
RenderX

Table . Comparative performance metrics of machine learning models for predicting GDM[a]-related adverse outcomes.

Model	SEN[b]	SPE[c]	PPV[d]	NPV[e]	PLR[f]	NLR[g]	Accuracy	F_1-score
Random forest	0.600	0.926	0.750	0.863	8.133	0.432	0.838	0.667
XGBoost[h]	0.567	0.955	0.823	0.857	12.570	0.454	0.850	0.671
Logistic regression	0.478	0.721	0.387	0.789	1.714	0.724	0.656	0.428
SVM[i]	0.633	0.828	0.576	0.860	3.679	0.443	0.775	0.603
Stacking	0.578	0.959	0.839	0.860	14.098	0.440	0.856	0.684

[a]GDM: gestational diabetes mellitus.

[b]SEN: sensitivity.

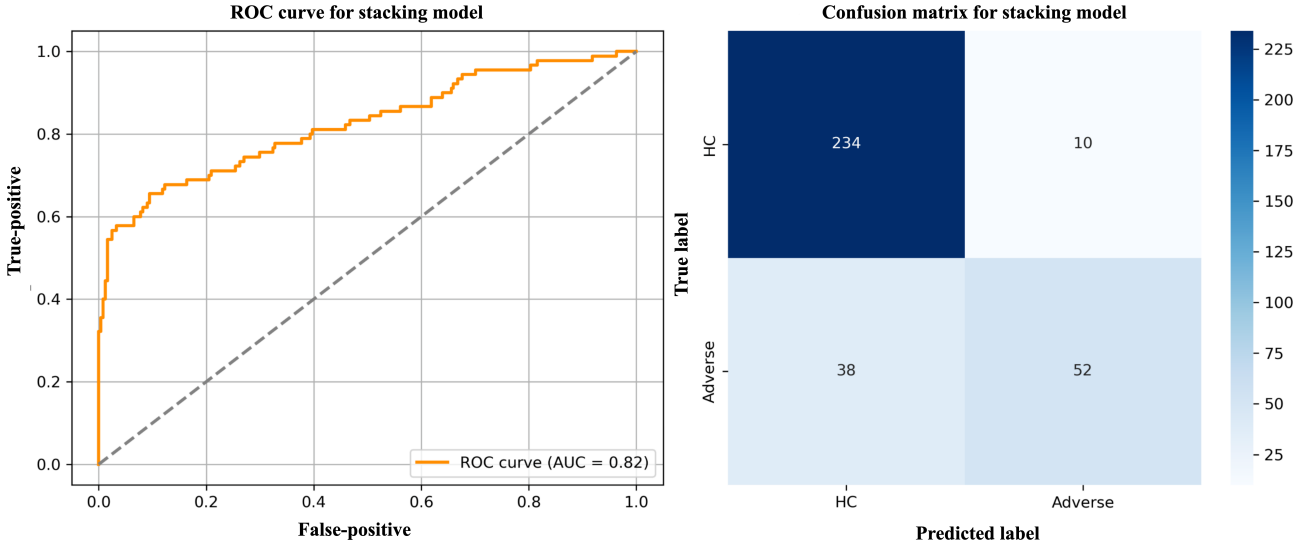
[c]SPE: specificity.

[d]PPV: positive predictive value.

[e]NPV: negative predictive value.

[f]PLR: positive likelihood ratio.

[g]NLR: negative likelihood ratio.



[h]XGBoost: extreme gradient boosting.

[i]SVM: support vector machine.

The results showed that the stacking model outperformed the individual models across several key metrics. Through cross-validation, we evaluated accuracy, recall, precision, and F_1-score. The results indicated that the stacking model excelled in specificity (0.959), PPV (0.839), and PLR (14.098). Its sensitivity (0.578) and NPV (0.860) were also strong, with a low NLR (0.440) and an overall accuracy of 0.856, demonstrating the effectiveness of the model fusion approach.

A total of 334 samples were contained in the test set, including 90 cases with adverse pregnancy outcomes (positive class) and 244 cases with favorable outcomes (negative class). The positive-to-negative ratio is approximately 1:2.7, indicating a moderately imbalanced distribution. Based on this dataset, the model demonstrated a satisfactory performance in identifying adverse outcomes, achieving an area under the receiver operating characteristic curve of 0.82. This suggests that the model exhibits high overall discriminative ability and can effectively differentiate individuals with distinct pregnancy outcomes. The receiver operating characteristic curve and confusion matrix for the stacking model are presented in Figure 3.

Figure 3. ROC curve and confusion matrix of the stacking model for predicting GDM-related adverse outcomes. AUC: area under the curve; GDM: gestational diabetes mellitus; HC: healthy control; ROC: receiver operating characteristic.

To further investigate the effect of different oversampling techniques on model performance, we conducted a comparative experiment using both ADASYN and SMOTE, focusing on the stacking model, which showed the best overall performance in our main evaluation. The results are presented in Table 4.

XSL•FO
RenderX

Table . Performance comparison of ADASYN[a] and SMOTE[b].

Oversampling method	SEN[c]	SPE[d]	PPV[e]	NPV[f]	PLR[g]	NLR[h]	Accuracy	F_1-score
ADASYN (stacking)	0.578	0.959	0.839	0.860	14.098	0.440	0.856	0.684
SMOTE (stacking)	0.266	0.910	0.477	0.800	2.947	0.807	0.728	0.341
/	0.658	0.506	0.292	0.827	1.332	0.676	0.542	0.405

[a]ADASYN: adaptive synthetic sampling.

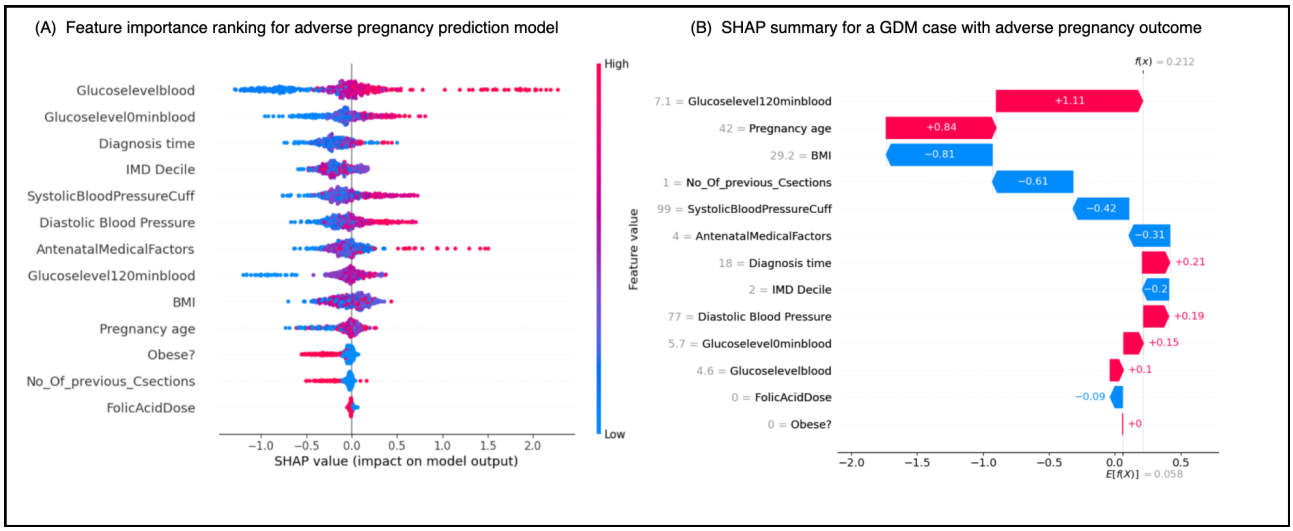
[b]SMOTE: Synthetic Minority Oversampling Technique.

[c]SEN: sensitivity.

[d]SPE: specificity.

[e]PPV: positive predictive value.

[f]NPV: negative predictive value.



[g]PLR: positive likelihood ratio.

[h]NLR: negative likelihood ratio.

As shown, the stacking model trained with ADASYN achieved superior performance across most metrics, particularly in terms of sensitivity (0.578), PPV (0.839), and F_1-score (0.684), suggesting better identification of high-risk cases and overall balance between precision and recall. In contrast, the model trained with SMOTE exhibited a much lower sensitivity (0.266) and F_1-score (0.341), indicating its limited ability to correctly identify minority class samples in this setting. We also report the performance of the stacking model trained without any oversampling as a reference, which demonstrated relatively higher sensitivity (0.658) but at the cost of much lower precision (PPV 0.292) and specificity (0.506), further confirming the advantage of using ADASYN in managing class imbalance.

Additionally, by using the SHAP algorithm, we conducted an in-depth analysis of the model's interpretability. The SHAP values revealed that clinical characteristics significantly impact the prediction of gestational diabetes risk, with specific results as follows. Through the calculation and analysis of SHAP values, we were able to uncover the contribution of each feature to the GDM outcome, thereby gaining a more comprehensive understanding of the risk factors for GDM. This interpretable analysis not only aids in validating the robustness of the model but also provides valuable references for subsequent clinical decision-making. Based on the SHAP algorithm, we were able to perform precise visual analyses for individual patients, as shown in Figure 4, which includes a global summary of feature importance across all patients (Figure 5A) and a local explanation for an individual prediction (Figure 5B).

Figure 4. SHAP-based visualization of a machine learning model for predicting adverse pregnancy outcomes in patients with GDM. (A) Summary plot of SHAP values for all features, showing their impact and direction of effect on model output across all patients. (B) Local explanation for a single GDM case, highlighting how individual features contributed to the prediction. RenderX

For each feature, we used the shape function to display the distribution of its different values and their impact on the outcome. The influence of individual features was shown in Figure 5A, which demonstrates the specific impact of changes in a single variable's values on the model's predicted risk, revealing nonlinear relationships. Additionally, we used visualization techniques to illustrate the interaction values between different features, as shown in Figure 5B. These analyses will enhance our ability to conduct clinical assessments more effectively.

We further conducted feature interaction analysis to explore the contribution of different feature combinations in predicting adverse pregnancy outcomes in GDM. As shown in Figure 5C, the plot illustrates the overall importance of each feature in the model and its direction of influence, with each dot representing the SHAP value of an individual patient. The features are ranked by their mean absolute SHAP values, reflecting their average impact magnitude on the model's output. These results also highlight the significance of key variables and their interactions in clinical risk prediction.

External Validation

Based on the integrated model we ultimately obtained, we collected data from some patients with GDM at Jinniu Maternal and Child Health Hospital (from January 2021 to March 2024) through telephone follow-up, focusing on collecting data from patients with adverse pregnancy outcomes. Due to issues such as patient cooperation and the tightness of related human resources, the number of external validation data is relatively small (159 cases, with a positive to negative ratio of 27:132). We used the stacking model for validation, which had a final accuracy of 0.836 and an area under the receiver operating characteristic curve value of 0.669, showing a significant decline compared to the test set. The results are shown in Multimedia Appendix 2.

Discussion

Principal Findings

According to the latest Global Diabetes Atlas (9th edition) published by the International Diabetes Federation, the number of patients with GDM worldwide is increasing, with approximately 20.4 (15.8%) million women enduring hyperglycemia; among them, around 17.1 (83.6%) million cases are due to GDM [18]. Pregnant women affected by GDM face an elevated risk of adverse pregnancy outcomes, which can pose significant threats to both the mother and the infant. Therefore, predicting adverse pregnancy outcomes in the early stages of pregnancy and providing timely feedback and effective clinical management are particularly important.

The traditional scoring criteria for adverse pregnancy outcomes currently used in clinical practice, such as the IADPSG (International Association of Diabetes and Pregnancy Study Groups) and the NICE (National Institute for Health and Care Excellence) Diagnostic Criteria, exhibit varying levels of predictive efficacy and are prone to regional biases, making it difficult to achieve a consensus on predictive outcomes [19,20]. Additionally, individual differences, such as physiological variations, hormonal changes, genetics, and dietary structures, also affect the estimated prevalence rates of GDM. However, current clinical strategies for gestational diabetes typically use a one-size-fits-all approach to blood glucose management. Therefore, more comprehensive regular monitoring and earlier preventive and intervention measures should be implemented to reduce the potential for adverse outcomes.

In this study, we compared 5 machine learning models, random forest, XGBoost, logistic regression, SVM, and stacking, to assess their performance in predicting outcomes related to GDM. The results indicated that the stacking model outperformed the other models across multiple key performance metrics, particularly excelling in specificity (0.959), PPV (0.839), and PLR (14.098). Additionally, the stacking model demonstrated good performance in sensitivity (0.578) and NPV (0.860), with a low NLR (0.44) and overall accuracy (0.856), further proving the significant advantage of model ensemble methods in enhancing predictive performance. The receiver operating characteristic curve and confusion matrix analysis also supported this conclusion, emphasizing the effectiveness of the stacking model in predicting adverse pregnancy outcomes in GDM. However, during external validation, when using domestic patient data, the model's performance significantly declined. This phenomenon may be related to the inconsistent distribution of dataset characteristics, such as differences in demographic characteristics, lifestyle habits, and medical environments between domestic and international datasets. These differences may lead to poor model adaptation when facing new data distributions. Future research should further explore the performance of these models on larger and more diverse datasets to verify their generalization and stability. At the same time, it is recommended to integrate clinical context by introducing more features related to gestational diabetes for analysis, such as real-time vital signs of pregnant women, genetic phenotypes, and other relevant indicators, to enhance the model's predictive power and clinical application value.

SHAP helps clinicians understand and interpret complex machine learning models. We noticed that adverse pregnancy outcomes have a significant association with gestational age. Previous studies have shown that adverse pregnancy outcomes are directly related to blood glucose control during the perinatal period of gestational diabetes [21]. Our results indicate that gestational diabetes with a shorter duration during pregnancy is associated with poorer pregnancy outcomes, which may be related to the early detection of hyperglycemia leading to preterm birth. Therefore, these findings serve as an important alert for clinical practice, suggesting that blood glucose monitoring should be initiated earlier in pregnancy, considering the patient's condition, to conduct earlier glucose monitoring for different individuals. Current clinical guidelines recommend screening for gestational diabetes between 24 and 28 weeks of pregnancy, and screening for and treating gestational diabetes during this period can significantly reduce the risk of adverse pregnancy outcomes [4,22]. Meanwhile, a large cohort study found that women diagnosed with GDM before 12 weeks of pregnancy had worse pregnancy outcomes compared to those diagnosed between 24 - 28 weeks [23]; the research by Mustafa et al [7] also found that women with early onset (<24 weeks)

XSL•FO
RenderX

GDM had higher BMI, significantly increased demand for insulin, and more adverse pregnancy outcomes. Therefore, in addition to recommending universal screening at 24 - 28 weeks, identifying and treating GDM at an earlier stage could reduce the potential perinatal or long-term adverse effects on the mother and the offspring. These findings emphasize the importance of identifying GDM earlier than current practices and exploring other interventions that might improve outcomes beyond blood glucose control.

Pregnant women with GDM experience insulin resistance, as previously reported in studies, which is associated with preterm birth, and preterm newborns are at a higher risk of being admitted to the neonatal intensive care unit or special care baby unit [24]. Due to pregnant women with high blood glucose levels, adverse pregnancy outcomes such as preterm birth, large-for-gestational-age infants, and neonatal hypoglycemia often require care in a neonatal intensive care unit. Excess glucose in the mother's circulation is transferred across the placenta to provide the fetus with energy substrates. The fetus's response to the excess substrates is to produce more insulin, leading to fetal hyperinsulinemia, which can result in a series of consequences, particularly rapid fetal growth [25]. In pregnancies with GDM, fetal insulin binds to insulin-like growth factor 1 receptors, exerting growth hormone-like effects and serving as a key factor in promoting fetal growth [26]. It is common for children born to women with GDM to be large at birth. Extensive research on this population has shown that the increased birth weight of large-for-gestational-age infants is due to an increase in fat mass, not muscle mass [27,28]. The impact of GDM on both mother and infant does not end at delivery. Newborns admitted to the neonatal intensive care unit or special care baby unit due to maternal gestational diabetes are often seen with neonatal hypoglycemia, which may occur in 10% of healthy term infants, mainly within the first 24 to 48 hours after birth [29]. The high glucose consumption of the brain, coupled with the increased ratio of brain to body mass in newborns compared to adults, increases the demand for glucose in newborns and may expose them to the risk of neurological damage and adverse outcomes.

Pregnancy hypertension is a common complication of pregnancy and a leading cause of morbidity and mortality in pregnant women and newborns, accounting for about 14% of maternal deaths worldwide [30,31]. Both pregnancy-induced hypertension and pre-eclampsia are associated with adverse maternal and fetal outcomes, including an increased risk of future maternal cardiovascular diseases, and there is approximately a 17% chance of pregnancy-induced hypertension progressing to pre-eclampsia [32]. As many women are asymptomatic at the time of diagnosis, those who do not receive prenatal care may present with more advanced hypertension-related diseases, such as eclampsia, which is associated with higher risks of morbidity and mortality [33]. In correlation analyses, GDM is accompanied by increased blood pressure in late pregnancy. GDM is a known risk factor for stillbirth, fetal macrosomia, fetal structural abnormalities, preterm birth, and pregnancy-induced hypertension diseases. GDM is characterized by significantly increased concentrations of inflammatory molecules and the imbalanced expression of genes encoding inflammatory mediators in the placenta, which together lead to the disruption of vascular, metabolic, and inflammatory processes. Over time, this state of hyperglycemia may be associated with the occurrence of pregnancy-induced hypertension diseases and their related complexities. Additionally, diabetes and hypertension often coexist, sharing various risk factors and disease etiologies, including genetics, obesity, insulin resistance, and inflammation [34]. Therefore, the management of GDM should not only focus on blood glucose control but also consider the potential risks associated with pregnancy-induced hypertension diseases. In GDM, oxidative stress plays a role in the pathogenesis of the disease, as excessive secretion of insulin during pregnancy leads to the production of lipid peroxidation factors, which also mask the secretion of antioxidants, making reactive oxygen species abundant at the cellular level. In pre-eclampsia and gestational hypertension, oxidative stress leads to inadequate placental perfusion, resulting in a hypoxic placenta, which generally triggers a systemic maternal inflammatory response [35-37].

The adverse pregnancy risks associated with GDM are determined by the complex interplay of multiple biomedical, behavioral, and environmental factors, rather than a single factor. Therefore, to investigate the contribution of feature interaction to the prognostic risks of GDM, we conducted multifeature interaction analyses. The feature interaction matrix clearly shows that blood glucose levels and time of diagnosis exhibit the highest degree of aggregation, followed by blood pressure. Additionally, gestational age and antenatal medical factors also demonstrate relatively strong clustering patterns. As previously discussed, individualized diagnosis and treatment should be tailored to different individuals. For those with a genetic predisposition to diabetes, earlier diagnosis during pregnancy should be implemented to achieve more timely blood glucose control. Hypertensive disorders in pregnancy and GDM are among the most common metabolic complications during gestation, with prevalence rates having risen significantly over the past decade, now affecting approximately 12% - 18% of all pregnancies [38]. Pregnant women with hyperglycemia generally exhibit a higher overall incidence of requiring insulin therapy, which increases with maternal age, and women over 35 years old have a significantly higher probability of undergoing cesarean delivery [39]. Genes are the most important factor in Antenatal Medical Factors. More recent genome-wide association studies focusing on maternal metabolism during pregnancy have revealed overlaps between genes associated with metabolic traits in pregnant and nonpregnant populations, as well as some genes that appear to be uniquely relevant during gestation. Additionally, reduced gene expression has been observed in transcription factors involved in lipid metabolism, such as LXRa, PPARa, PPARd, PPARg, RXRa, and SREBP1c. These findings indicate the importance of maternal oversupply of substrates in determining neonatal fat accumulation in pregnancies complicated by obesity and GDM [40].

Limitations

This study has several limitations. As a single-center retrospective study with a relatively small sample size, the generalizability of the findings may be limited. Although multiple machine learning models were used, the features were

XSL•FO
RenderX

primarily derived from structured clinical data, lacking unstructured information such as imaging findings and physician notes. And the external validation dataset also limited our research; the model's performance notably declined on domestic datasets, suggesting potential overfitting or insufficient adaptability to different populations. Although we use SHAP for interpretability analysis, the model's clinical transparency remains constrained due to the complex and nonlinear relationships between features and outcomes, which may affect the interpretability of clinical decision-making.

Conclusion

In conclusion, our study highlights the growing prevalence of GDM and its significant association with adverse pregnancy outcomes, including preterm birth, large-for-gestational-age infants, and neonatal hypoglycemia. Through the evaluation of 5 machine learning models, we found that the stacking model exhibited superior performance in predicting adverse outcomes, demonstrating the potential of machine learning to enhance clinical decision-making in managing GDM. The findings emphasize the importance of early identification and personalized management of GDM to mitigate the risks to both mother and infant. Moreover, incorporating additional clinical features, such as real-time maternal vital signs and genetic phenotypes, may further enhance the predictive accuracy and clinical applicability of these models. Future studies should aim to validate these findings across more diverse datasets to ensure the generalizability and robustness of the models, paving the way for more precise and effective interventions in GDM management.

Acknowledgments

We are grateful to the staff in our research groups involved in this study for their valuable contributions and discussions. This work was supported by the Chengdu Medical Research Project (project 2022-387).

Data Availability

The datasets generated or analyzed during this study are available in the figshare repository [14]. Access to the related code is available from the corresponding author on reasonable request.

Authors' Contributions

JL conceptualized and designed this study, performed the research, delivered the model analysis, analyzed the data, and wrote this paper. XL and JL delivered the data analysis and clinical analysis. SH contributed to the research execution and data analysis, and provided critical insights for model interpretation. YR conceptualized and designed this study. All authors contributed to editorial changes in this paper, read and approved this final paper, and have participated sufficiently in this work to take responsibility for all aspects of this work.

Conflicts of Interest

None declared.

Abstract

Background: Adequate ventilation in mechanically ventilated patients is contingent upon the monitoring of the arterial partial pressure of carbon dioxide ($PaCO_2$) during general anesthesia. Despite its significance, continuous monitoring remains challenging due to the imprecision of noninvasive estimations and the invasive nature of traditional methods such as arterial blood gas analysis.

Objective: This study aimed to develop a machine learning model to continuously estimate $PaCO_2$ in mechanically ventilated patients, with the goal of potentially improving intraoperative monitoring accuracy under general anesthesia.

Methods: This retrospective study used the VitalDB dataset from Seoul National University Hospital, comprising records of 6388 noncardiac surgery patients between August 2016 and June 2017. After applying inclusion and exclusion criteria, data from 2304 surgical cases (4651 $PaCO_2$ measurement event points) were analyzed. The CatBoost regressor model was trained to predict $PaCO_2$ using noninvasive physiological parameters and clinical information. The model's performance was evaluated using nested cross-validation across hypocapnic (<35 mm Hg), normocapnic (35 - 45 mm Hg), and hypercapnic (>45 mm Hg) subgroups and compared to conventional estimation methods based on end-tidal carbon dioxide ($ETCO_2$).

Results: The developed model demonstrated superior overall performance compared to traditional estimations. It achieved a mean absolute error of 2.38 mm Hg and an average intraclass correlation coefficient of 0.87. Furthermore, 90.02% of the model's estimations fell within the clinically highly acceptable range (error<±5 mm Hg) while only 1.20% of errors exceeded ±10 mm Hg. Performance improvements were observed across all $PaCO_2$ subgroups.

Conclusions: The developed model provides more accurate and reliable estimates of $PaCO_2$ than traditional $ETCO_2$-based methods. This approach shows potential for facilitating real-time monitoring and timely clinical interventions. This study demonstrated the potential of artificial intelligence to enhance continuous monitoring of $PaCO_2$; however, further validation, including prospective studies assessing clinical impact, is necessary.

(JMIR Med Inform 2025;13:e64855) doi:10.2196/64855

KEYWORDS

anesthesia; arterial partial pressure of carbon dioxide; artificial intelligence; AI; blood gas monitoring; end-tidal carbon dioxide

Introduction

Monitoring the arterial partial pressure of carbon dioxide ($PaCO_2$) is essential during general anesthesia, as it is a fundamental indicator of respiratory status in mechanically ventilated patients. These patients are unable to breathe on their own because anesthetic drugs and neuromuscular blocking agents suppress their respiratory responses [1]. During mechanical ventilation, the respiratory rate (RR) is carefully adjusted through continuous patient assessments to ensure adequate ventilation [2,3]. $PaCO_2$ is a crucial indicator of the equilibrium between the production and elimination of carbon dioxide [4,5]. Abnormal levels of $PaCO_2$ may suggest inadequate ventilation, respiratory insufficiency, or

XSL•FO
RenderX

compromised cardiovascular function, which could result in unfavorable surgical outcomes.

Despite its importance, achieving continuous monitoring of $PaCO_2$ using arterial blood gas analysis (ABGA) has practical limitations. While ABGA remains the gold standard, providing accurate $PaCO_2$ measurements along with other vital information, such as pH and pO_2, and closely tracking $PaCO_2$ changes require repeated arterial sampling, even with an indwelling arterial line (A-line). This necessity for repeated invasive procedures carries resource implications for personnel time and consumables, with costs varying across health care systems [6]. Furthermore, frequent sampling while utilizing a procedure with generally low individual risk carries inherent cumulative risks associated with repeated invasive interventions [7,8]. Crucially, the intermittent nature of ABGA may not fully capture rapid physiological fluctuations occurring during dynamic surgical periods, potentially delaying necessary clinical interventions.

End-tidal carbon dioxide ($ETCO_2$) is a fundamental component of anesthetic practice, recommended by the American Society of Anesthesiologists (ASA) [9,10], and is commonly used to estimate $PaCO_2$. $ETCO_2$ reflects the partial pressure of CO2 at the end of exhalation. While often correlated, a gradient typically exists between $PaCO_2$ and $ETCO_2$, usually ranging from 3 to 5 mm Hg in individuals with normal lung function [11]. However, the accuracy of $ETCO_2$ and $PaCO_2$ surrogates can be compromised by various physiological and technical factors. Conditions such as ventilation-perfusion mismatch, increased physiological dead space, and significant changes in cardiac output (CO) can widen this gradient and disrupt the correlation between $ETCO_2$ and $PaCO_2$ [12-14]. Furthermore, patient-specific variables, including underlying pulmonary pathology, hemodynamic status, and metabolic rate, can further complicate the relationship between these two parameters. Prior research has highlighted the variable precision of $ETCO_2$ for estimating $PaCO_2$, particularly in patients with respiratory disease [15,16]. Studies have also indicated weaker correlations in certain challenging clinical scenarios or patient populations where gas exchange is significantly impaired [17-19]. Therefore, relying solely on $ETCO_2$ measurements to guide ventilation management may not always provide the necessary accuracy, especially during periods of rapid physiological change, which are common in surgery.

While a substantial disparity between $PaCO_2$ and $ETCO_2$ measurements has been previously linked to a higher risk of mortality, developing noninvasive methods for estimating $PaCO_2$ more precisely than $ETCO_2$ alone remains an ongoing challenge. The difficulty lies in accurately accounting for the simultaneous influence of numerous, interacting physiological factors that affect CO_2 kinetics. Recent research demonstrates the potential of artificial intelligence (AI) and machine learning (ML) to effectively model intricate biological variables at an individual patient level, potentially overcoming the limitations of simpler estimation approaches [20]. ML-driven prediction models possess the ability to identify and learn complex, nonlinear relationships among multiple input variables (like those readily available from noninvasive intraoperative monitoring), even without prior assumptions about independence or linearity.

Therefore, this study developed an ML-based prediction model to continuously estimate $PaCO_2$ using readily available, noninvasive parameters collected during surgical operations. This approach leverages the capability of ML algorithms to process complex, multidimensional data and potentially capture patient-specific variability more effectively than single-parameter estimates like $ETCO_2$. The objective of this study was to assess the feasibility of achieving accurate and reliable real-time $PaCO_2$ estimation across diverse surgical procedures and patient populations using a large dataset of intraoperative recordings. By providing clinicians with continuous, noninvasive estimates of $PaCO_2$, the developed model holds the potential to enhance intraoperative physiological monitoring, complementing standard methods like ABGA and $ETCO_2$; facilitate timely adjustments to ventilation; and ultimately contribute to improved patient outcomes following general anesthesia. Through this study, we aim to contribute to the advancement of perioperative medicine by harnessing the power of AI to optimize patient care in the operating room.

Methods

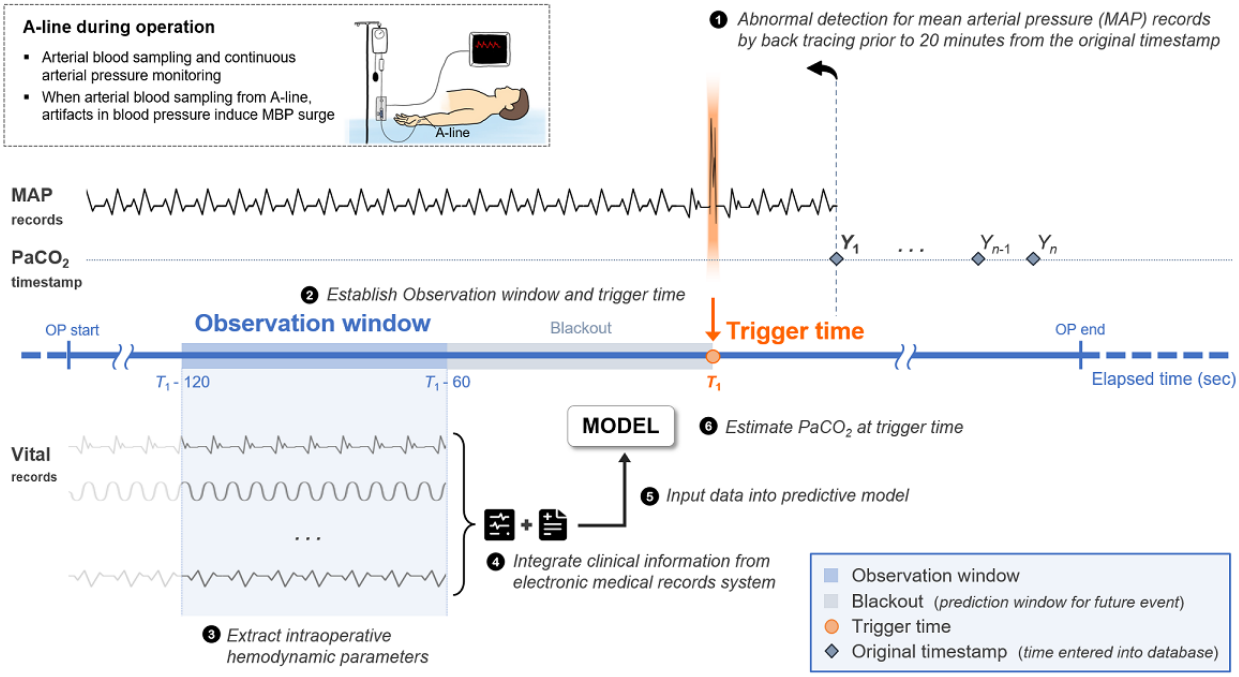
Study Design and Settings

This was a retrospective study using VitalDB, an open dataset containing intraoperative biosignal data and perioperative clinical information from Seoul National University Hospital (SNUH), a tertiary-level hospital in South Korea [21]. The dataset encompassed 6388 cases of noncardiac surgery, with an average of 2.8 million data points per case, collected from August 2016 to June 2017. Vital signs were recorded during surgery, while pertinent clinical information was retrospectively retrieved from the electronic medical records system.

Ethical Considerations

This study utilized a publicly available, deidentified dataset (VitalDB). The collection and use of this dataset for research purposes were approved by the Institutional Review Board (IRB) of SNUH (H-1408-101-605). The requirement for obtaining individual informed consent was waived by the IRB because the dataset contained only deidentified data. All data were anonymized before inclusion in the database, ensuring patient privacy and confidentiality. No compensation was provided to participants as part of this secondary data analysis.

Case Selection



Case selection was performed based on the following inclusion and exclusion criteria. Surgical cases involving patients meeting the following criteria were eligible: (1) aged 18-80 years, (2) mechanically ventilated under general anesthesia using an oral airway, (3) had ASA physical status classification grade 5 or lower, (4) had $ETCO_2$ monitoring records, and (5) had at least 1 or more $PaCO_2$ measurement records obtained during surgery. Each $PaCO_2$ measurement obtained via ABGA was defined as an event point. $PaCO_2$ measurements before or after surgery were excluded and not considered event points.

XSL•FO
RenderX

Event Point Definition and Timing

Each event point was defined by a trigger time and an observation window for the prediction model that estimates $PaCO_2$ based on noninvasive parameters (Figure 1). The trigger time is defined as the time at which an estimation of $PaCO_2$ is performed based on intraoperative biosignals and perioperative clinical information. The observation window is the time frame during which the biosignals were extracted for model training.

Figure 1. Schematic diagram of the event point definition and feature extraction process for real-time $PaCO_2$ estimation. The process includes (1) detection of an MAP surge to refine the ABGA timestamp, defining the trigger time for $PaCO_2$ estimation; (2) establishment of a 60-second observation window preceding a blackout period before the trigger time; (3) extraction of medial values from intraoperative biosignals within the observation window; (4) integration of clinical information from electronic medical records; and (5) input of these features into ML-based model to estimate $PaCO_2$ at the trigger time. A-line: arterial line; ABGA: arterial blood gas analysis; MAP: mean arterial pressure; MBP: mean blood pressure; ML: machine learning; OP: operation; $PaCO_2$: partial pressure of carbon dioxide.

$PaCO_2$ is measured via ABGA, which evaluates arterial gas concentrations such as carbon dioxide and oxygen. Usually, a small volume of blood is extracted from the radial artery using a syringe and a thin needle. During surgery, the anesthesiologists draw arterial blood via an A-line. The temporal point of the ABGA records might be compromised as a result of the transit time of the specimen to the analyzer or manual data entry delays. The timestamp of ABGA records frequently denotes the moment that analysis results are entered into the database instead of precisely indicating the moment at which blood is drawn from the patient.

To increase the precision of the ABGA timestamp, in this study, we utilized mean arterial pressure (MAP) recordings available in VitalDB. We hypothesized that the ABGA procedure (blood draw via A-line) induces a rapid increase in the MAP due to transient line occlusion or a patient physiological reaction. On the basis of this hypothesis, we employed a *z* score–based outlier detection approach. Abnormal periods surpassing a *z* score of 3 in MAP records were identified by observing the 20-minute interval that preceded the originally recorded ABGA timestamp. The nearest such abnormal period was defined as the estimated actual timepoint at which ABGA was performed. The trigger time for feature extraction was set at 60 seconds prior to the newly calculated ABGA timestamp to capture the patient's physiological state immediately preceding the likely blood draw event. In this phase, the $PaCO_2$ values that did not have identifiable MAP surge points meeting these criteria within the preceding 20-minute window were excluded because they were not considered reliably timed event points. Of the 6311 potentially relevant $PaCO_2$ measurements considered for this timestamp adjustment, 720 (approximately 11.4%) were excluded due to the absence of a detectable MAP surge. The median (IQR) difference between the newly estimated ABGA timepoint based on MAP surge and the original database timestamp for the remaining measurements was 34.00 (22.00 - 54.00) seconds, with a mean standard deviation (SD) of 47.29 (57.53) seconds (range 0-936.00 seconds), indicating that the original database timestamp often did not precisely reflect the physiological event of blood sampling. While this pressure-surge detection method provides a systematic approach to approximate the blood sampling time based on physiological responses, we acknowledge that its precise accuracy compared to the true sampling time was not formally validated against a gold standard timestamp in this study.

Data Preparation

A total of 19 variables were selected based on previous literature and domain knowledge. These variables were classified as follows: clinical information, including age, sex, height, weight,

XSL•FO
RenderX

surgical approach, surgery type, and preoperative pulmonary function test (PFT) results; and intraoperative biosignals, including body temperature (BT), heart rate, percutaneous oxygen saturation (SpO_2), minute ventilation from the ventilator (MV), positive end-expiratory pressure (PEEP), peak inspiratory pressure (PIP), plateau pressure (PPLAT), mean airway pressure (MAWP), RR based on capnography, tidal volume (TV), fraction of inspired oxygen (FiO_2), and $ETCO_2$.

During the 60-second observation window before the trigger time, intraoperative biosignals were extracted. Extreme outliers were eliminated using the IQR method, removing data points outside 3 times of the IQR below the first quartile or above the third quartile. Aberrant points deemed theoretically unacceptable were also removed based on clinical expertise. Median values for each biosignal in the observation windows were then calculated and used as features for the prediction model, along with the corresponding surgical patients' electronic medical records. This approach simplifies the high-frequency biosignal data into static features for point-in-time $PaCO_2$ estimation but does not explicitly model temporal dependencies within the observation window or directly track dynamic changes over longer periods.

Furthermore, additional features were established by utilizing feature engineering techniques [20]. The variables for PFT results were reportedly classified into nine classes in the original dataset description; however, due to potential inconsistencies or inadequate representation of minority classes, we regenerated the preoperative PFT as an indicator variable, categorizing it into three grades: obstructive, restrictive, and mixed type [22]. Another feature engineering technique employed in this study involved generating interaction features that comprise combinations of two or more existing variables. The incorporation of interaction features, representing known physiological indices, primarily aimed to improve model interpretability by including recognized clinical parameters, although tree-based models like CatBoost can implicitly capture interactions.

Several interaction features, including TV per kilogram of ideal body weight (TV/IBW), oxygen saturation to FiO2 ratio (SpO_2/FiO_2), PEEP to FiO_2 ratio ($PEEP/FiO_2$), compliance of the respiratory system (CRS), and rapid shallow breathing index (RSBI), were generated using domain knowledge. Each of these interaction features brings a dimension of clinical relevance that reflects the interaction between multiple aspects of patient respiratory mechanics and ventilator settings. Additionally, this study utilized APCONET, which is an external application programming interface (API) that is able to estimate CO using arterial pressure waveforms as an input feature [23]. Detailed information, such as the unit of data, recording device, and source of data, for all the selected variables is available in Multimedia Appendix 1.

Preprocessing

Event points containing missing values in any of the selected predictor variables were removed prior to model training. The listwise deletion approach reduced the number of event points from an initial 5591 (derived from cases meeting inclusion criteria before handling missing data for specific event points) to the final 4651 event points used for analysis. The entire dataset was split into training, validation, and testing sets using the nested cross-validation (7 outer folds, 6 inner folds). This configuration was chosen based on the dataset size and common practices aiming for stable performance estimation [24]. All partitioning procedures were conducted at the surgical case level. For example, all data from a single surgical case belonged exclusively to either the training/validation set or the testing set within a given outer fold. This approach was designed to maintain similar data distributions across subsets while ensuring patient independence between training and testing.

Categorical variables were initially processed using OneHotEncoder for compatibility with some preliminary models tested. Continuous variables were scaled using RobustScaler, which scales data using IQR, making it robust to outliers.

Model Training

To identify a suitable regression model for this task, several ML algorithms were evaluated in preliminary experiments (see Multimedia Appendix 2). Based on its superior performance in these experiments, CatBoostRegressor was selected for final model development and evaluation. The CatBoost model is a robust and effective library for gradient boosting on decision trees. It is particularly adept at handling categorical features natively using its built-in encoder, which was employed in this study for the CatBoost model, thus not requiring the prior OneHotEncoding for these features when training the final CatBoost model [25].

To develop the final predictive model for $PaCO_2$, training sets were utilized for training the CatBoostRegressor model, and the corresponding validation set was used for hyperparameter tuning within each outer fold. The training sets were used to train the CatBoostRegressor model, and the validation set was utilized to tune the hyperparameters (see Multimedia Appendix 3). During hyperparameter optimization, we utilized Optuna, a framework designed to streamline the hyperparameter tuning process [26]. This framework facilitates the search for the optimal hyperparameter space configuration for a given model in an efficient manner. Subsequently, the performance of the final model was evaluated using held-out testing sets from the seven outer-fold cross-validation methods on the testing sets.

Data Analysis

In this study, estimating $PaCO_2$ based on noninvasive parameters was approached as a regression predictive modeling task. To assess the effectiveness of the ML-based model, we conducted a comparison with two baseline methods that employed the $ETCO_2$ value. One method was a simple offset model ($ETCO_2$+5 mm Hg), while the other method involved utilizing linear regression with $ETCO_2$ measurements as the sole predictor.

Model performance was assessed using two commonly employed metrics: mean absolute error (MAE) and root mean squared error (RMSE). Additionally, we evaluated model performance across different conditions by establishing subgroups. The subgroups were established based on $PaCO_2$ levels as follows: hypocapnic (<35 mm Hg), normocapnic

XSL•FO
RenderX

(35-45 mm Hg), and hypercapnic (>45 mm Hg) cases. A Bland-Altman plot was used to calculate the limits of agreement and analyze the agreement between the real and predictive values; additionally, the intraclass correlation coefficient (ICC) was utilized to evaluate the relative reliability and consistency of the model compared to actual measurements [27,28].

To assess the clinical utility of the predictive model, the percentage of estimation errors for $PaCO_2$ was computed by calculating the differences between the real and predicted values. Disparities below 5 mm Hg were deemed highly acceptable, those between 5 and 10 mm Hg were moderately acceptable, and any value exceeding 10 mm Hg was considered unacceptable. The establishment of this threshold was based on prior research and Clinical Laboratory Improvement Amendments recommendations [29].

Furthermore, model interpretability was analyzed using the Shapley additive explanation (SHAP) value [30]. The SHAP values, derived from an additive feature attribution model, succinctly illustrate the impact of the input variables on the model outputs, enhancing the understanding of the model's decision-making process.

The performance metrics were evaluated by averaging the results from the testing sets across the outer folds and computing a CI of 95%. All experimental and data analysis procedures were conducted in the Python 3.10.12 environment.

Results

A total of 2304 surgical cases (with 4651 event points) were eligible and analyzed to develop and validate the proposed prediction model. The statistical summaries for $PaCO_2$ and $ETCO_2$ measurements for the included event points are displayed in Table 1.

Table . Statistical summaries for $PaCO_2$[a] and $ETCO_2$[b] measurements.

Characteristic	Total (n=4651)	Subgroups		
		Hypocapnic (n=179)	Normocapnic (n=3328)	Hypercapnic (n=1144)
$PaCO_2$ (mm Hg), median (IQR)	42.00 (39.00 - 45.00)	34.00 (33.00 - 34.00)	41.00 (38.00 - 43.00)	48.00 (47.00 - 51.00)
$ETCO_2$ (mm Hg), median (IQR)	35.00 (33.00 - 37.00)	32.00 (30.00 - 33.00)	34.00 (33.00 - 36.00)	37.00 (35.00 - 40.00)
$PaCO_2$-$ETCO_2$ (mm Hg difference), median (IQR)	7.00 (5.00 - 10.00)	2.00 (0.50 - 3.00)	6.00 (4.00 - 8.00)	12.00 (9.00 - 14.00)

[a]$PaCO_2$: partial pressure of carbon dioxide.

[b]$ETCO_2$: end-tidal carbon dioxide.

The mean values in this cohort were 42.52 mm Hg for $PaCO_2$ and 34.95 mm Hg for $ETCO_2$. The observed differences between $PaCO_2$ and $ETCO_2$ measurements were often greater than the gap derived from existing knowledge, which was 3-5 mm Hg for healthy individuals, with an average difference of 7.57 mm Hg and a wide range from 16 to 34 mm Hg in our study population. According to the analysis of subgroups categorized by $PaCO_2$ levels, 71.55% (n=3328) of all cases used in this study included $PaCO_2$ values in the normal range (between 35 and 45 mm Hg), whereas 3.85% of the cases (n=179) were hypocapnic (<35 mm Hg) and 24.60% (n=1144) were hypercapnic (>45 mm Hg). The differences in $ETCO_2$ values across subgroups were less pronounced than the differences in $PaCO_2$ values, whereas the discrepancy between $PaCO_2$ and $ETCO_2$ measurements tended to be greater in subgroups with higher $PaCO_2$ levels. More detailed descriptive statistics for all variables are provided in Multimedia Appendix 4.

The performance evaluation results of the developed model in comparison to the baseline methods are displayed in Table 2. As shown in Table 2, the error metrics of the baseline method (Baseline 1), which adds 5 mm Hg to $ETCO_2$, significantly increased as the subgroup transitions from normocapnic to hypercapnic. High error rates in the hypercapnic group indicate that it is difficult to accurately estimate $PaCO_2$ using this baseline method in patients with relatively higher $PaCO_2$ values. The performance of the second baseline method (Baseline 2), which is based upon linear regression, exhibited slightly better performance overall than the first one but performed poorly in the hypocapnic group compared to the normocapnic group. In both of the two baseline methods, extreme groups (hypocapnic and hypercapnic cases) result in wider CIs, which suggests that the performance of these methods is less certain in such ranges.

XSL•FO

Table . Performance evaluation results.

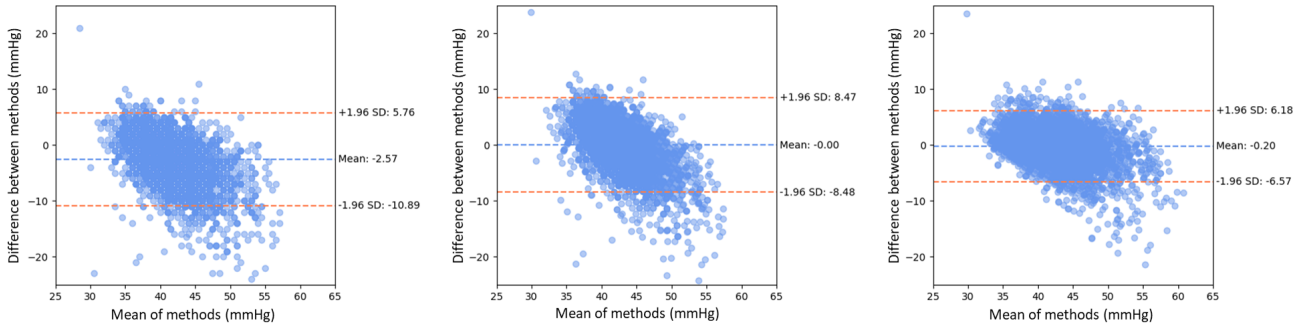
Model		MAE[a] (95% CI)	MSE[b] (95% CI)	RMSE[c] (95% CI)
Baseline 1: $ETCO_2$[d]+5 mm Hg				
	All	3.64 (3.51-3.77)	24.57 (22.86-26.29)	4.95 (4.78-5.13)
	Hypocapnic	3.64 (2.99-4.28)	19.82 (10.61-29.03)	4.34 (3.33-5.34)
	Normocapnic	2.45 (2.30-2.61)	9.96 (8.86-11.06)	3.15 (2.98-3.32)
	Hypercapnic	7.09 (6.90-7.28)	67.88 (63.73-72.04)	8.24 (7.98-8.49)
Baseline 2: Linear regression				
	All	3.26 (3.17-3.36)	18.70 (17.34-20.05)	4.32 (4.16-4.48)
	Hypocapnic	6.34 (5.62-7.06)	50.20 (32.67-67.73)	6.98 (5.78-8.19)
	Normocapnic	2.52 (2.42-2.62)	9.85 (9.00-10.70)	3.14 (3.00-3.27)
	Hypercapnic	4.93 (4.77-5.10)	39.55 (36.27-42.82)	6.28 (6.02-6.54)
ML-based[e] model: CatBoost regressor				
	All	2.38 (2.34-2.41)	10.63 (10.13-11.13)	3.26 (3.18-3.34)
	Hypocapnic	3.66 (2.96-4.35)	21.49 (10.23-32.75)	4.51 (3.47-5.56)
	Normocapnic	1.88 (1.81-1.95)	5.81 (5.29-6.33)	2.41 (2.3-2.52)
	Hypercapnic	3.63 (3.50-3.76)	23.05 (21.18-24.91)	4.80 (4.60-4.99)

[a]MAE: mean absolute error.

[b]MSE: mean squared error.

[c]RMSE: root mean squared error.

[d]$ETCO_2$: end-tidal carbon dioxide.



[e]ML: machine learning.

In contrast, the ML-based model developed in this study exhibited superior performance in all subgroups compared to the other 2 baseline methods, with the normocapnic group achieving particularly noteworthy results. With the ML-based model, the error metrics were MAE of 1.88 (95% CI 1.81 - 1.95), mean squared error (MSE) of 5.81 (95% CI 5.29 - 6.33), and RMSE of 2.41 (95% CI 2.30 - 2.52) in the normocapnic group. For extreme $PaCO_2$ values of the hypocapnic and hypercapnic groups, the developed model exhibited MAEs of 3.66 (95% CI 2.96 - 4.35) and 3.63 (95% CI 3.50 - 3.76), respectively, which were considerably better than the baseline methods in these challenging subgroups. Given that the differences between $PaCO_2$ and $ETCO_2$ in healthy individuals are known to range from 3 to 5 mm Hg, these results indicate that the ML-based model provides more accurate and reliable results, as evidenced by the consistently lower MAE, MSE, and RMSE values across all subgroups.

Bland-Altman plots comparing the predictive model with the two baseline methods are displayed in Figure 2. The mean difference, indicated by the central blue dashed line, represents the average discrepancy between the predicted and actual $PaCO_2$ values. For the second baseline method and the ML-based model, this difference was exceedingly close to 0, suggesting minimal systematic deviation on average, while the first baseline method ($ETCO_2$+5 mm Hg) showed a slightly larger negative bias (−2.57 mm Hg). The limits of agreement (±1.96 SD of the differences) with the 95% CIs for the baseline methods ranged from −10.89 to +5.76 and −8.48 to 8.47, respectively, and were narrower for the ML-based model at −6.57 to +6.18. The wider limits of agreement in the baseline models suggest that there is more variability in the differences between the actual and predicted values when estimating the $PaCO_2$ with these traditional approaches.

XSL•FO
RenderX

Figure 2. Bland-Altman plots illustrating the agreement between actual $PaCO_2$ and estimated $PaCO_2$ values by (1) Baseline 1: $ETCO_2$+5 mm Hg; (2) Baseline 2: linear regression with $ETCO_2$; and (3) the machine learning–based model. The x-axis represents the mean of actual and predicted $PaCO_2$ values. The central dashed blue line indicates the mean differences (bias), and the outer dashed orange lines represent the 95% limits of agreement (mean difference ±1.96 SD of the differences). $ETCO_2$: end-tidal carbon dioxide; $PaCO_2$: partial pressure of carbon dioxide.

Baseline 1 Baseline 2 ML-based model

In addition, the Bland-Altman plot for the ML-based model demonstrated that the majority of data points were tightly clustered around the mean difference with less dispersion compared to the baseline methods. While the baseline methods showed some tendency for larger underestimation at higher $PaCO_2$ values (negative slope suggestion), the ML-based model exhibited more consistent agreement across the range of $PaCO_2$ values, with no evident trend of increasing or decreasing differences correlating with the average $PaCO_2$ values. A few outliers were observed, particularly at higher mean values across all methods, suggesting potential specific variability under certain conditions or limitations in the developed model's performance at extremes.

Table 3 presents the ICC analysis results for the baseline methods and the ML-based model. A statistically significant ICC (P<.001) indicates some degree of reliability beyond chance. The narrow 95% CI of the ICC underscores a high degree of confidence in these reliability estimates. An ICC of 0.87 (95% CI 0.86 - 0.87) in the ML-based model signified good agreement between predicted and actual values, indicating that the predicted values closely align with the actual values relative to the overall variance. Conversely, the baseline methods yielded ICCs of 0.70 (95% CI 0.68 - 0.71) and 0.67 (95% CI 0.65 - 0.69), respectively, reflecting a moderate level of agreement.

Table . The ICC[a] values between predicted and actual $PaCO_2$[b].

Model	ICC (95% CI)	*P* value
Baseline 1	0.70 (0.68-0.71)	<.001
Baseline 2	0.67 (0.65-0.69)	<.001
ML[c]-based model	0.87 (0.86-0.87)	<.001

[a]ICC: intraclass correlation coefficient.

[b]$PaCO_2$: partial pressure of carbon dioxide.

[c]ML: machine learning.

The evaluation results of the clinical utility are displayed in Table 4 as a percentage of the estimation error for the $PaCO_2$. The ML-based model exhibited superior performance, with 90.02% of the test set having errors of less than ±5 mm Hg, in contrast to the baseline methods that had exhibited 72.41% and 80.43%, respectively. This represents a substantial absolute increase of nearly 10 percentage points in highly accurate predictions compared to the better baseline. Additionally, for the ML model, errors falling within ±10 mm Hg accounted for 98.80% of the test set. The errors exceeded ±10 mm Hg in only 1.20% of cases. The baseline methods achieved a moderate level of acceptable performance; however, the percentage of errors exceeding ±10 mm Hg was more than double that of the ML-based model. This indicates that the ML-based model demonstrated highly acceptable performance in aspects of clinical utility evaluation.

XSL•FO
RenderX

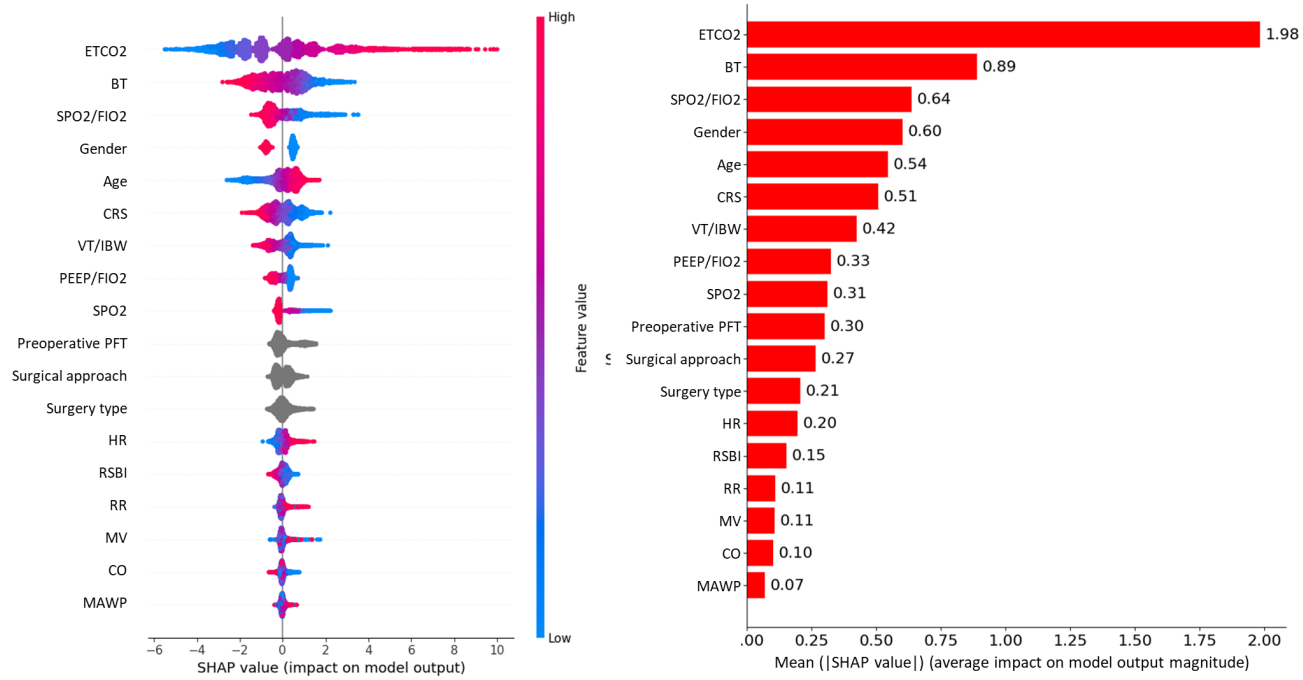


Table . Clinical utility evaluation results.

Model	Absolute value of errors (%)		
	<5 mm Hg	5 - 10 mm Hg	>10 mm Hg
Baseline 1	72.41	22.70	4.88
Baseline 2	80.43	16.92	2.64
ML[a]-based model	90.02	8.77	1.20

[a]ML:machine learning.

The feature importance of the ML-based model was analyzed using the SHAP method, as illustrated in Figure 3. The most significant variable was $ETCO_2$, as expected, given its direct physiological link to $PaCO_2$. Beyond $ETCO_2$'s dominant influence, other important features included BT, SpO_2/FiO_2, sex, age, and CRS. The SHAP plot suggested that the model output (predicted $PaCO_2$ value) tended to be higher with lower BT, SpO_2/FiO_2, and CRS, as well as higher age and $ETCO_2$. These findings suggest the additional features help refine the $PaCO_2$ estimate beyond the baseline provided by $ETCO_2$, potentially capturing patient-specific physiological states. Variables such as MAWP, CO, and MV exhibited relatively lower SHAP values with a mix of positive and negative contributions, indicating a minor or context-dependent impact on model decision-making in this analysis.

Figure 3. SHAP plots illustrating feature importance for ML-based $PaCO_2$ estimation model. Left: SHAP summary plot, where each point represents a Shapley value for a feature and an instance. The position on the y-axis indicates the feature, the position on the x-axis indicates the SHAP value (impact on model output), and the color indicates the feature values (red for high, blue for low). Right: Bar chart of the mean absolute SHAP values, indicating the global importance of each feature in the model. BT: body temperature; CO: cardiac output; CRS: compliance of the respiratory system; $ETCO_2$: end-tidal carbon dioxide; FIO_2: fraction of inspired oxygen; HR: heart rate; IBW: ideal body weight; MAWP: mean airway pressure; ML: machine learning; MV: minute ventilation from the ventilator; $PaCO_2$: partial pressure of carbon dioxide; PEEP: positive end-expiratory pressure; PFT: pulmonary function test; RR: respiratory rate; RSBI: rapid shallow breathing index; SHAP: Shapley additive explanation; SPO_2: percutaneous oxygen saturation; VT: tidal volume.

Discussion

Principal Findings

This study developed an ML-based model capable of estimating $PaCO_2$ in mechanically ventilated patients under general anesthesia with greater accuracy than traditional $ETCO_2$-based methods. Utilizing noninvasive physiological parameters and clinical information, the CatBoost model demonstrated strong overall performance, achieving an MAE of 2.38 mm Hg, an RMSE of 3.26 mm Hg, and an ICC of 0.87, indicating excellent agreement with arterial measurements. Critically, the model significantly increased the proportion of clinically highly acceptable predictions (error<±5 mm Hg) to 90.02%, comparable to 80.43% for a linear regression baseline, and reduced unacceptable errors (>±10 mm Hg) to 1.20% from 2.64%. The model's superiority was consistent across hypocapnic, normocapnic, and hypercapnic subgroups.

Interpretability analysis using SHAP identified $ETCO_2$ as the most influential feature, as anticipated. Beyond the dominant contribution of $ETCO_2$, other parameters such as BT, SpO_2/FiO_2

XSL•FO
RenderX

ratio, age, sex, and CRS were found to be important for refining $PaCO_2$ estimations. For instance, the model tended to predict higher $PaCO_2$ values with lower BT, lower SpO_2/FiO_2, lower CRS, and higher age, suggesting it learned complex physiological relationships. These findings highlight the value of a multiparameter approach to capture variability not explained by $ETCO_2$ alone.

Comparison to Prior Work

The limitations of relying solely on $ETCO_2$ for $PaCO_2$ estimation are well documented. While $ETCO_2$ provides some insights, the $PaCO_2$-$ETCO_2$ gradient is known to be variable and influenced by numerous physiological factors, often exceeding the commonly cited 3-5 mm Hg range in healthy individuals [11,16,31]. Our study corroborates this, finding a median gradient of 7 mm Hg (average 7.57 mm Hg, range −16 to 34 mm Hg), underscoring the unreliability of a fixed gradient assumption. Conventional statistical models, such as multivariable linear regression, offer some improvement but are often constrained by linearity assumptions and may not fully capture the complex, nonlinear interactions inherent in physiological systems [32,33].

In contrast, our ML-based approach effectively models these intricate associations by integrating a wider array of biosignals and clinical data. The ability of ML to learn from these complex patterns without a priori assumptions about relationships has shown promise in various medical prediction tasks [20]. Previous studies have also indicated that factors like surgical techniques and patient positioning can affect the $PaCO_2$-$ETCO_2$ gradient [34], further supporting the need for adaptive models like the one developed in this study, which can account for such patient-specific and contextual variability more effectively than simpler methods.

Strengths of the Study

This study possesses several strengths that enhance the credibility and potential impact of its findings. First, the use of VitalDB, a large, publicly available, real-world dataset from a tertiary university hospital, provides a diverse cohort from various noncardiac surgeries, improving the generalizability of our results. Second, model performance was rigorously assessed using nested cross-validation, offering a robust estimate of its predictive capabilities on unseen data. Third, the ML model was benchmarked against two clinically relevant baseline methods, clearly demonstrating its superior accuracy. Fourth, our evaluation encompassed not only standard error metrics (MAE, RMSE) but also reliability (ICC) and clinical utility based on predefined error categories (Table 4), providing a multifaceted view of performance. Fifth, the inclusion of SHAP analysis offers a degree of transparency into the model's decision-making process, which is crucial for clinical translation. Finally, the exploration of an MAP-based timestamping method, while requiring further validation, represents a novel attempt to address a common challenge in retrospective EMR-based research.

Limitations

Nevertheless, several limitations should be acknowledged when interpreting the results of this study. First, while the ML model outperformed baselines across all $PaCO_2$ subgroups, its performance was relatively lower in the hypocapnic and hypercapnic groups compared to the normocapnic group. This may be partly due to data imbalance, as these extreme ranges were less frequently observed. Future work could explore techniques like targeted data augmentation or specialized modeling to address this. Second, our SHAP analysis focused on explaining direct $PaCO_2$ predictions. As $ETCO_2$ is inherently a dominant feature, this makes it harder to isolate the specific contributions of other features to the $PaCO_2$—$ETCO_2$ gradient. Analyzing this gradient directly would be a valuable future direction. Third, the model relies on point-in-time estimations using median values from a 60-second window, simplifying the rich time-series data available. This approach does not capture temporal trends or predict rapid $PaCO_2$ changes. Fourth, the MAP-surge-based ABGA timestamping method, though systematically applied, was not formally validated against a gold-standard timing reference. Any imprecision here could introduce noise into the feature-target alignment. Fifth, the listwise deletion approach for handling missing data, which reduced our event points from 5951 to 4651, may have introduced selection bias if the pattern of missingness was not completely at random and reduced the overall sample size available for training. Seventh, estimated CO via an external API did not emerge as a highly influential feature in SHAP plots. This might be attributed to the indirect nature or potential inaccuracies of the CO estimation rather than CO itself lacking physiological relevance. Finally, being a single-institution study, the findings require external validation to ensure generalizability across different settings and populations.

Future Directions

Building on these findings and limitations, several avenues for future research are essential for advancing noninvasive $PaCO_2$ monitoring. First and foremost, external validation of the ML model in diverse, multicenter clinical settings is crucial to confirm its robustness and general applicability. Second, developing time-series models, such as recurrent neural networks, long short-term memory, and transformers, which can process the continuous stream of biosignals, is a key next step. This could improve accuracy and enable the prediction of $PaCO_2$ trends and rapid changes. Third, future studies should explicitly investigate the model's capacity to track longitudinal changes in the $PaCO_2$-$ETCO_2$ gradient within individual patients. Exploring the linkage between the predicted $PaCO_2$-$ETCO_2$ gradient and critical events like hemodynamic instability could yield clinical value. Fourth, research correlating intraoperative $PaCO_2$ deviations identified by accurate monitoring with postoperative outcomes would further strengthen the rationale for enhanced continuous monitoring. Finally, the MAP-based timestamping approach warrants further investigation and validation.

XSL•FO
RenderX

Conclusions

This study demonstrated that an ML-based model integrating multiple noninvasive parameters can estimate $PaCO_2$ with higher accuracy and reliability than traditional $ETCO_2$-based methods in mechanically ventilated surgical patients. The model shows particular strength in increasing the proportion of highly accurate predictions. While acknowledging the need for further development, particularly in incorporating time-series data and external validation, this work highlights the considerable potential of AI to serve as a valuable supplementary tool for enhancing respiratory monitoring and patient management in the perioperative setting.

Abstract

Background: Bipolar disorder (BD) is a highly recurrent disorder. Early detection, early intervention, and prevention of recurrent bipolar mood symptoms are key to a better prognosis.

Objective: This study aims to build prediction models for BD with machine learning algorithms.

Methods: This study recruited 24 participants with BD. The Beck Depression Inventory and Young Mania Rating Scale were used to evaluate depressive and manic episodes, respectively. Using digital biomarkers collected from wearable devices as input, 6 machine learning algorithms (logistic regression, decision tree, k-nearest neighbors, random forest, adaptive boosting, and Extreme Gradient Boosting) were used to build predictive models.

Results: The prediction model for depressive symptoms achieved 83% accuracy, an area under the receiver operating characteristic curve (AUROC) of 0.89, and an F_1-score of 0.65 on testing data. The prediction model for manic symptoms achieved 91% accuracy, an AUROC of 0.88, and an F_1-score of 0.25 on testing data. With the interpretable model Shapley Additive Explanations, we found that relatively high resting heart rate, low activity, and lack of sleep may predict depressive symptoms.

Conclusions: This study demonstrated that digital biomarkers could be used to predict depressive and manic symptoms. This prediction model may be beneficial for the early detection of mood symptoms, facilitating timely treatment and helping to prevent BD recurrence.

KEYWORDS

bipolar disorder; wearable device; machine learning; mood symptoms; relapse prediction

Introduction

Bipolar disorder (BD) is a recurrent disorder characterized by fluctuations in mood and energy from depression to mania that often results in enormous functional impairment and high disease burden [1]. The 5-year recurrence rate of BD was as high as 73% [2]. A meta-analysis estimated the recurrence rates under treatment were 55.2% (naturalistic studies) and 39.3% (randomized controlled trials) versus 60.6% under placebo [3]. Although the recurrence rate can be reduced under appropriate treatment, irregular compliance usually precipitates the recurrence of mood episodes and compromises the outcome. Despite high recurrence and low compliance, the frequency of routine follow-up in current practice is usually insufficient to detect early signs of relapse, causing delayed treatment until an acute episode has fully developed [4]. It is important to detect early signs of relapse so that an upcoming mood episode can be aborted by appropriate intervention. Furthermore, clinical practice mostly relies on patients' self-reports of symptom changes, which depend on illness insight [5] and are subject to recall bias [6].

Recent studies have developed machine learning algorithms to predict depression [7] based on sociodemographic features, personal or family health history, and symptoms coded by psychiatrists [8], achieving an accuracy of 0.721 using the k-nearest neighbor classifier. In BD, a recent review concluded that activity level may serve as a promising digital phenotype for mood episodes, with decreased activity indicating depressive episodes and increased activity indicating manic episodes [9]. For example, Jakobsen et al [10] collected activity data through actigraphy to differentiate between depressed patients and

XSL•FO
RenderX

controls, achieving an accuracy of 0.84 using the deep neural network combined with the Synthetic Minority Over-Sampling Technique (SMOTE) class balancing technique [10]. Besides, sleep problems may indicate relapse in BD [11]. A recent study that used only sleep-wake data gathered through smartphones and wearables showed accurate next-day predictions of depressive, manic, and hypomanic episodes (area under the receiver operating characteristic curve [AUROC] of 0.80, 0.98, 0.95, respectively) [12], suggesting sleep as a promising biomarker for detecting mood episodes. However, most current studies targeted full-blown mood episodes and followed patients for shorter time periods, and information about feature importance was often lacking.

Apart from activity level and sleep, heart rate (HR) and HR variability could also be important biomarkers for mood episodes. HR variability, defined as temporal variability in beat-to-beat intervals of HR, is supposed to reflect aspects of parasympathetic control over the cardiac system [13]; while HR was an index of sympathetic and parasympathetic influences of the autonomic nervous system during stressful as well as resting and recovery states [14]. During rest, HR is under central inhibitory control by the vagus nerve and thus decreased [15,16]. Increased HR and decreased HR variability were observed in mania relative to euthymia [17]. Likewise, patients with depression not only showed lower HR variability but also had a higher resting HR [18-20]. A study gathered biofeedback data on HR variability features and used support vector machine algorithms to predict mood state, reporting an accuracy of 0.69 [21]. Another machine learning study with HR variability features achieved an accuracy of 0.74 [22]. Considering future applications, we adopted HR features instead of HR variability in this study, since HR is much more commonly recorded in commercial smartwatches than HR variability.

Combining multimodal data sources of physical activity, sleep patterns, and circadian rhythms for a machine learning algorithm, a recent study reported an accuracy of 0.80 in detecting participants at high risk of depression [23]. Another study performed a prospective observational cohort study with patients with mood disorders, collecting activity, sleep, light exposure, and HR to predict mood state, and found the accuracy of 0.87, 0.94, and 0.91, respectively, for depressive episode, manic episode, and hypomanic episode [24]. Although both studies used multiple sources of physiological data, the feature importance and the direction of effect of the features were not clear. Besides, individual differences were not considered among the features.

Based on prior research, this study aimed to establish machine learning algorithms to predict early signs of upcoming depressive or manic symptoms. Digital biomarkers collected by actigraphy and mobile devices, including activity, sleep hours, and HR, were mapped with clinical measures for training and evaluating the machine learning models of artificial intelligence algorithms. We hypothesized that greater activity level and shorter sleep hours may predict manic symptoms. We also hypothesized that higher resting HR and lower activity level and sleep hour changes may predict depressive symptoms based on previous reports [18-20]. Moreover, considering that the change of a feature (eg, sleep or activity) from the individual's baseline may be important when predicting mood symptoms, we also integrated individualized parameters for model prediction.

Methods

Participants

The inclusion criteria were participants with a diagnosis of BD, aged 20 - 65 years, and willing to wear the smartwatch and complete the clinical measures as frequently as possible (at least weekly). The exclusion criteria were concurrent substance use disorder and inability to cooperate with the data collection from the smartphone and smartwatch.

This study recruited 24 patients with BD (aged 20 - 65 years; mean 38, SD 9 years; male n=9) from the Psychiatric Department of National Taiwan University (NTU) Hospital from October 2020 to July 2022 and prospectively followed for an average of 6.39 (SD 4.85) months. The diagnosis was made by board-certified senior psychiatrists based on the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* [25]. The mean age of first onset of mood episodes was 23.1 (SD 10) (range 12 - 44), and the illness duration was 14.1 (SD 8.7) years. During the follow-up, there were a total of 4 psychiatric admissions. All participants received medication treatment, primarily mood stabilizers and antipsychotics (Table S1 in Multimedia Appendix 1). Participants' educational levels ranged from middle school to graduate school (7 graduate school degrees, 13 college, 3 senior high school, and 1 junior high school). As for medical history, all participants had no active medical disease, but with a history of Sicca syndrome (n=1), cavernous sinus cyst (n=1), atrial septal defect (n=1), and one peptic ulcer (n=1).

Clinical Measures

The Beck Depression Inventory (BDI) and Young Mania Rating Scale (YMRS) were self-rated weekly on a mobile app (named MEDGOD) (National Taiwan University) on the personal smartphone (either iOS or Android system) to evaluate depressive and manic symptoms, respectively. All participants received a reminder notification on Sunday night at 9 PM to fill both measures on their mobile app. The research assistants would send a text message, email, or phone call to contact the participants and help solve technical problems.

The BDI [26] is a 21-item self-reported inventory measuring the severity of depression in adolescents and adults. The Beck Depression Inventory-II (BDI-II) [27] was revised to be more consistent with the *DSM-IV* (*Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*) criteria of depression. The inventory consists of 21 items, in which 4 response options are presented on a Likert scale from 0 to 3. The BDI was translated into a Chinese version with good internal consistency (Cronbach α=0.85) and concurrent validity [28]. Higher total scores indicate more severe depressive symptoms. As for the standard cutoff scores, 30 - 63 may indicate severe depression, 19 - 29 indicates moderate depression, 10 - 18 indicates mild depression, and 0 - 9 indicates minimal depression [28]. The distribution of BDI scores in our sample was summarized in Multimedia Appendix 2.

XSL•FO
RenderX

The YMRS, an 11-item interviewer-rated scale, is designed for assessing the severity of manic symptoms [29]. The items are rated on 5 grades of severity. Four items among them are double weighted, including irritability, speech, thought content, and disruptive or aggressive behavior. The YMRS is by far the most commonly used standardized measure of bipolar manic symptoms for clinical trials in acute mania. As for psychometric properties, the interrater reliability was adequate for the total score (0.93) and for individual items ranged from 0.67 to 0.95. There are no firmly established scoring criteria that relate to diagnostic classification [29]. The distribution of YMRS scores in our sample was summarized in Multimedia Appendix 3.

To detect early signs of relapse, a state of mild depression (BDI >13) or mania (YMRS >13) was labeled true.

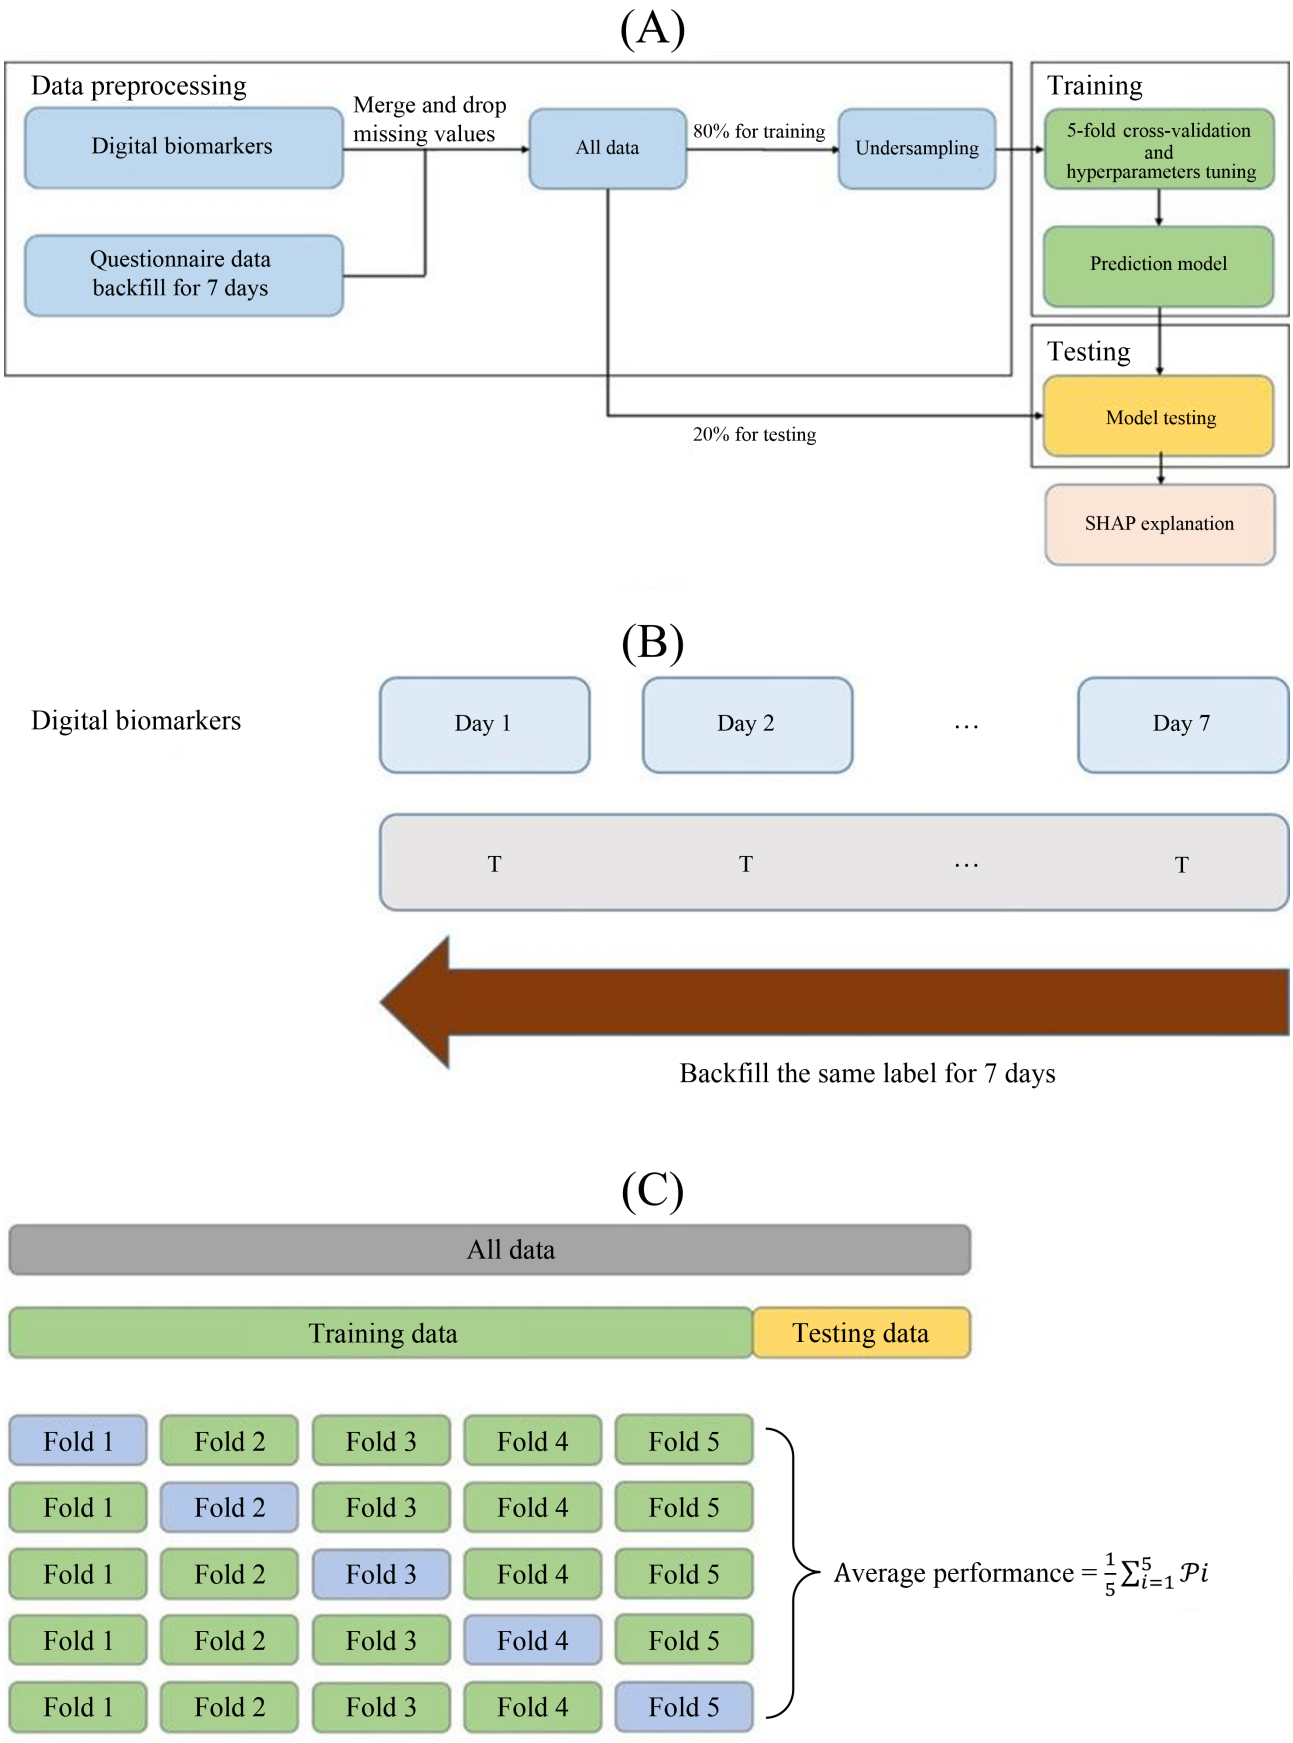
Digital Biomarkers

The wristwatch-like actimetry sensor Garmin Vivosmart 4 is a reliable tool [30,31] that has been applied in several clinical studies [32-34]. Each participant wore the smartwatch that continuously measured as well as recorded the motor activity, sleep length, and HR 24 hours a day except when electric recharging.

The motor activities that were monitored included steps, distance traveled, and floors climbed. The sleep features included total sleep hours and stages of sleep, that is, deep sleep, light sleep, rapid eye movement sleep, and awake stages. The HR features included the minimum HR of the day, the maximum HR of the day, the average HR of the day, and the average HR at rest.

As for individualized features, we transformed the raw feature into “the deviation from the personal mean” by subtracting the raw value by the mean of that feature of the person during the entire study period, including differences in minimum HR, maximum HR, average HR, resting HR, steps, distance, and the total sleep (as listed in Tables S2 and S3 in Multimedia Appendix 1).

Data Pretreatment



Data were initially uploaded to the server of NTU Medical Genie Precision Health Service via the NTU MEDGOD app automatically. Subsequently, the information was downloaded and stored at the National Taiwan University Computer and Information Networking Center, which provides optimized information security protection [35]. The digital data were deidentified, managed, and maintained by the Medical Information Laboratory of the Department of Information Engineering, National Taiwan University, as described in our previous studies [33,36,37].

The YMRS and BDI-II were administered weekly for the mood-related symptoms of the previous week; thus, the physiological data were backfilled for a 7-day period (Figure 1B). To mitigate the risk of overfitting, all missing values were excluded from the dataset. Extreme datapoints, such as HR>150 or <40, total sleep hours >15, were excluded from analysis, too. Subsequently, the dataset was partitioned into training and testing sets using 5-fold cross-validation.

Figure 1A shows the workflow architecture including interpretable model Shapley Additive Explanations (SHAP). To achieve more balanced data, the under-sampling technique [38] was applied for the training set.

XSL•FO

Machine Learning Algorithms

Depressive and manic models were trained separately using the first half of the follow-up data. Python, scikit-learn, and SHAP packages were used for programming, model training, and model explanation, respectively. We adopted logistic regression, decision tree, k-nearest neighbors, random forest, adaptive boosting, as well as Extreme Gradient Boosting (XGBoost) to predict mood symptoms. Five-fold cross-validation was used to evaluate model performance and hyperparameter selection before making predictions on testing data [39] (Figure 1C). During the training process, the grid search strategy for hyperparameter selection was used to ensure model stability, which loops through all candidate parameters, leaving only the final best-performing set of parameters.

Model Assessment

Model performance was assessed by accuracy, sensitivity, specificity, precision, F_1-score, and AUROC. To explain the output of machine learning models [40], the SHAP method analyzed the predictions from machine learning models and interpreted the contributions of each feature by a Shapley value, which measures the influence of a feature on the prediction.

Ethical Considerations

This study was approved by the Research Ethics Committee at National Taiwan University Hospital (202002006RINA) before its implementation. The investigation was carried out in accordance with the latest version of the Declaration of Helsinki. Informed consent of the participants was obtained after the nature of the procedures had been fully explained. Data were anonymized. Participants who completed the follow-up received a small gift (ie, essential oil soap) valued at less than US $6.00.

Results

Overview

The features were compared between the depressive and nondepressive labels, and between the manic and nonmanic labels by Student *t* test (Tables S2 and S3 in Multimedia Appendix 1). We found that the depressive label had a significantly higher minimal or resting HR and a lower activity level than the nondepressive label. Besides, the manic label had a significantly lower sleep duration than the nonmanic label. Similarly, for individualized data, we found that the manic label had a significantly higher HR and activity level and lower sleep duration than the nonmanic label.

Prediction Model

First, we used 12 features (without individualized data) for model training. Table 1 shows model performance on the testing set. Compared to other algorithms, the XGBoost performed with the highest accuracy (0.79), AUROC (0.85), and F_1-score (0.57) in the depressive model. Similarly, in the manic model, the XGBoost performed superior to others, with the highest accuracy (0.83), AUROC (0.84), and F_1-score (0.19).

Table . The performance of the models for depressive or manic symptoms without individualized features in the models.

	Accuracy	AUROC[a]	Sensitivity	Specificity	Precision	F_1-score
Models for a depressive episode						
Logistic regression	0.63	0.77	0.88	0.57	0.34	0.49
Decision tree	0.74	0.65	0.34	0.84	0.35	0.35
KNN[b]	0.69	0.58	0.38	0.77	0.30	0.34
Random forest	0.70	0.83	0.87	0.66	0.39	0.54
AdaBoost[c]	0.78	0.79	0.40	0.87	0.44	0.42
XGBoost[d]	0.79	0.85	0.71	0.81	0.48	0.57
Models for a manic episode

Next, we examined whether adding individualized features to the models improved prediction. The prediction performance of the 19-feature model with individualized features was successfully improved in both depressive and manic models (Table 2). The accuracy, AUROC, and F_1-score in the depressive model by the XGBoost increased from 0.79, 0.85, and 0.57 to

XSL•FO
RenderX

0.83, 0.89, and 0.65, while those in the manic model increased from 0.83, 0.84, and 0.19 to 0.91, 0.88, and 0.25.

Table . The performance of the models for depressive or manic symptoms with the individualized features included in the models.

Explanation of Prediction Model

In the depressive model, resting HR revealed the highest feature importance, followed by deep sleep duration, floors climbed, average HR, and steps (Figure 2). The force plots explained how resting HR (Figure 3), number of steps (Figure 4), and total sleep duration (Figure 5) affect the model. In each force plot, the y-axis represents the magnitude of the impact on the model, where a positive value (red region) indicates a tendency to predict that there are mood symptoms of depression, and a negative value (blue region) suggests the opposite. We could see that there is an obvious turning point at 60 in Figure 3. Specifically, steps less than 6000 steps/day and sleep less than 6 h may predict depressive symptoms. Together, a high resting HR produces a push to the right, while sufficient activity and sleep produce a push to the left (Figure 6); all forces result in a 0.23 predicted probability of a depressive episode.

Discussion

Principal Findings

This study constructed prediction models for mild depressive and manic symptoms using digital biomarkers, including activity, sleep state, HR, and the individualized parameters of these features. Major findings included, first, the accuracy of the prediction achieved 79% (AUROC 0.85) in the depressive model and 83% (AUROC 0.84) in the manic model. Second, adding individualized features improved accuracy to 83% (AUROC 0.89) in the depressive model and 91% (AUROC 0.88) in the manic model. Third, among the features, higher resting HR, lower activity, and shorter sleep were important in predicting depressive symptoms. These findings supported the utility of digital biomarkers collected from wearable devices in predicting depressive and manic symptoms in the early phase.

The accuracy and AUROC in our depressive model (0.84) were similar to an earlier study in mood disorder (0.87) [24], with a higher sensitivity in ours (0.78 vs 0.48) yet higher specificity in theirs (0.96) than ours (0.85). Also, the accuracy (ours 0.84 vs 0.80), sensitivity (ours 0.78 vs 0.82), and specificity (ours 0.85 vs 0.78) were close to a previous multimodal source data algorithm for depression [23]. In the manic model, their accuracy (0.91) and AUROC (0.91) were close to ours, but their sensitivity (0.31) was lower than ours (~0.92) and their specificity (0.996) was higher than ours (0.71). Such discrepancy may be related to the machine learning algorithm (random forest in theirs vs XGBoost in ours) and individualized features included in our model. Higher sensitivity in our model may indicate a potential application in detecting symptoms in the early stage. Whereas a relatively lower specificity may necessitate a thorough clinical assessment after a case has been identified. In addition, they provided model performance and feature importance, but we further explained the model by using insights from SHAP to explain the clinical implications of the features. Of note, the mean ages and first onset of mood disorder were 25.9 (SD 4.8) and 17.9 (SD 4.8) in their study and 38 (SD 9) and 23.1 (SD 10) in our study. Given that the HR, sleep, and activity levels may depend on age, the older sample in ours may also contribute to the discrepancies of findings across the studies. The age effect on the predictive model is worth further exploration.

Our findings supported the prediction of depressive symptoms by digital features including activity level, sleep parameters, and HRs during the 7 days before depressive symptoms were reported. Among the features, we found that a higher resting HR may contribute to the prediction of depression. Previous studies also showed that the resting HR was higher in depressive patients [14-16]. Severe depression is often accompanied by increased HR [41] and reduced HR variability [41,42]. Our data suggested a turning point of resting HR at 60 (Figure 6), showing that resting HR higher than 60 was linked to a higher chance of predicting depressive symptoms. Depressive disorders have been shown to be associated with sympathetic hyperactivity and reduced cardiac vagal control, which might partly explain the risk of cardiovascular disease in depression [41]. In addition, higher resting HR in depression may also relate to higher anxiety tone and poor night sleep that are often observed during depression, or mild dehydration due to poor oral intake.

Regarding sleep parameters, a total sleep duration of fewer than 6 hours may contribute to the prediction of depressive symptoms, consistent with previous evidence that supported sleep duration remained an important correlate for depressive symptoms [43,44]. For patients who demonstrated a combination of higher resting HR, lower activity, and insufficient sleep, early

XSL•FO
RenderX

assessment and intervention of depressive symptoms may be considered.

The successful trial of including individualized features in establishing a machine learning model suggests that it can be potentially applied to other populations, particularly when the focus is on evaluating changes in physiological data or activity levels. For instance, the deviation of HR from baseline may be valuable in predicting events such as panic attacks or aggressive behaviors, where a sudden increase in HR might serve as a critical indicator. The consideration of individualized features is especially relevant in scenarios where baseline data exhibit heterogeneity among individuals, for example, samples comprising both long sleepers and short sleepers. Incorporating individualized features in these contexts can help minimize the risk of biased predictions and enhance the accuracy of the algorithm.

Limitations

Several limitations need to be addressed. First, the labeling method relies on self-rated questionnaires completed at least once a week which backfill for 7 days given that the questionnaire rated mood symptoms in the past 7 days. While participants were instructed to report mood symptoms as soon as they became aware of them, there is a possibility that some individuals did not complete the questionnaires promptly when their symptoms first emerged. Timely symptom labeling, immediately upon awareness of depressive or manic symptoms, could potentially enhance data reliability. Of note, although the BDI-II is a commonly used self-report measure [45], some studies have shown discrepancies between clinician-rated and self-reported depression severity [46]. Therefore, a clear explanation was provided by the research assistants to the participants to ensure correct understanding of the scales (ie, YMRS and BDI-II) and the use of the mobile app. As for the electronic format of self-rated measures, a recent systematic review focused on the validity of the mobile app–based self-report questionnaires for the assessment and monitoring of BD [47]. Their findings revealed that mobile app–based self-report tools (ie, YMRS, Depression Rating Scale-17, etc) are valid in the assessment of symptoms of mania and depression in patients with BD, indicating good adherence to self-report assessments administered during the study periods.

Second, participants in the study were undergoing treatment with mood stabilizers and/or antipsychotics that may reduce symptom relapse. However, it is essential to acknowledge that medical treatment is inevitable in long-term follow-up in a clinical sample. Future studies may consider recording the days on medications with detailed categorization of psychotropic medications based on their mechanisms to assess their potential impact on sleep and HRs.

Third, low F_1-score in the prediction model for manic symptoms may reflect insufficient events for prediction, which also influences the analysis of feature importance. Meanwhile, the small sample of 24 participants may limit the generalizability of the findings. Although the sample size is not large enough, we followed the participants for 6.39 (SD 4.85) months, thus generating enough nondepressive label (n=1330), depressive label (n=338), nonmanic label (n=1956), and manic label (n=59). A larger sample with a longer follow-up duration may not only ensure enough relapse events for analysis but also increase the generalizability of the findings.

Fourth, potential confounders such as medical treatment, clinical care, interactions, and environmental factors were not controlled in the study. For example, the types and dosing schedule of medications may influence HR and activity level but were not controlled in the analysis, given that all participants received medication treatment with different combinations of antipsychotics and mood stabilizers. Without controlling these factors, the analysis may be incomprehensive and less efficient. Nonetheless, the generated predictive model may be better suited to address the general needs of future applications in real-world scenarios or natural settings whereby participants had no need to provide information other than passive data.

Nevertheless, this study explored the potential of predicting early signs of mood episodes using digital biomarkers. Toward that end, we used the SHAP method to interpret the model and included individualized features that better capture the changes in patients' lifestyles and successfully improve the prediction models for both depressive and manic symptoms. Our findings highlighted the potential of applying wearable devices to detect early signs of relapse in BD for early intervention. Nowadays, sleep hours, activity level, and HR can be collected by most commercial wearable devices including smartwatches. With an algorithm that can successfully predict upcoming mood episodes and notify the participant, caregiver, or therapist, early assessment and intervention can be initiated in time to prevent a relapse, thus reducing functional impairment and improving the prognosis of BD. Future studies may consider larger, more diverse samples or additional digital biomarkers (eg, environmental data) to enhance the predictive capabilities of the models as well as to explore the efficacy of implementing wearable technology in improving clinical practice and quality of life for various psychiatric populations.

Conclusions

This study used digital biomarkers obtained from wearable devices to construct machine learning models for the prediction of depressive and manic symptoms. By incorporating individualized features into the models, we achieved satisfactory accuracy in predicting depressive symptoms. Furthermore, the application of an interpretable SHAP model allowed us to discern that higher resting HR, lower activity, and insufficient sleep were indicative of impending depressive symptoms. Early detection of depressive changes enables the timely introduction of adequate psychoeducation and clinical assessment, facilitating the implementation of interventions in time to mitigate upcoming mood episodes, thereby reducing the risk of recurrence.

Abstract

Background: Insulin resistance (IR), a precursor to type 2 diabetes and a major risk factor for various chronic diseases, is becoming increasingly prevalent in China due to population aging and unhealthy lifestyles. Current methods like the gold-standard hyperinsulinemic-euglycemic clamp has limitations in practical application. The development of more convenient and efficient methods to predict and manage IR in nondiabetic populations will have prevention and control value.

Objective: This study aimed to develop and validate a machine learning prediction model for IR in a nondiabetic population, using low-cost diagnostic indicators and questionnaire surveys.

Methods: A cross-sectional study was conducted for model development, and a retrospective cohort study was used for validation. Data from 17,287 adults with normal fasting blood glucose who underwent physical exams and completed surveys at the Health Management Center of Xiangya Third Hospital, Central South University, from January 2018 to August 2022, were analyzed. IR was assessed using the Homeostasis Model Assessment (HOMA-IR) method. The dataset was split into 80% (13,128/16,411) training and 20% (32,83/16,411) testing. A total of 5 machine learning algorithms, namely random forest, Light Gradient Boosting Machine (LightGBM), Extreme Gradient Boosting, Gradient Boosting Machine, and CatBoost were used. Model optimization included resampling, feature selection, and hyperparameter tuning. Performance was evaluated using F_1-score, accuracy, sensitivity, specificity, area under the curve (AUC), and Kappa value. Shapley Additive Explanations analysis was used to assess feature importance. For clinical implication investigation, a different retrospective cohort of 20,369 nondiabetic participants (from the Xiangya Third Hospital database between January 2017 and January 2019) was used for time-to-event analysis with Kaplan-Meier survival curves.

Results: Data from 16,411 nondiabetic individuals were analyzed. We randomly selected 13,128 participants for the training group, and 3283 participants for the validation group. The final model included 34 lifestyle-related questionnaire features and 17 biochemical markers. In the validation group, their AUC were all greater than 0.90. In the test group, all AUC were also greater than 0.80. The LightGBM model showed the best IR prediction performance with an accuracy of 0.7542, sensitivity of 0.6639, specificity of 0.7642, F_1-score of 0.6748, Kappa value of 0.3741, and AUC of 0.8456. Top 10 features included BMI, fasting blood glucose, high-density lipoprotein cholesterol, triglycerides, creatinine, alanine aminotransferase, sex, total bilirubin, age, and albumin/globulin ratio. In the validation queue, all participants were separated into the high-risk IR group and the low-risk IR group according to the LightGBM algorithm. Out of 5101 high-risk IR participants, 235 (4.6%) developed diabetes, while 137 (0.9%) of 15,268 low-risk IR participants did. This resulted in a hazard ratio of 5.1, indicating a significantly higher risk for the high-risk IR group.

Conclusion: By leveraging low-cost laboratory indicators and questionnaire data, the LightGBM model effectively predicts IR status in nondiabetic individuals, aiding in large-scale IR screening and diabetes prevention, and it may potentially become an efficient and practical tool for insulin sensitivity assessment in these settings.

Introduction

Insulin resistance (IR) refers to the reduced sensitivity or responsiveness of target organs such as the liver, skeletal muscles, or adipose tissue to insulin. In order to maintain normal blood glucose levels, the body compensates by secreting increased amounts of insulin [1]. As a condition that can exist before the onset of type 2 diabetes, IR is not only one of the key mechanisms underlying the development of diabetes but also a major risk factor for various diseases [2]. According to the International Diabetes Federation, it is estimated that by 2045, there will be 783.2 million people affected globally, with the vast majority having type 2 diabetes [3]. Furthermore, IR is even more common. Data from the National Health and Nutrition Examination Survey in the United States show that approximately 40% of adults aged 18 - 44 years have IR [4]. A study in China revealed that the standardized prevalence of IR in adults aged 25 years or older is 29.22% [5]. By scientifically assessing and managing IR, it is theoretically possible to effectively control the onset of diabetes. The first step is to identify IR. The high insulin clamp with normal blood glucose levels is considered the gold standard for assessing insulin sensitivity [6]. However, in practice, this method is time-consuming, expensive, and difficult to apply widely. The Homeostasis Model Assessment of Insulin Resistance (HOMA-IR; fasting glucose [mmol/L]×fasting insulin [μU/ml]/22.5) is regarded as an acceptable method for evaluating IR [7]. However, fasting insulin, one of its components, is not a routine test, making it difficult to obtain in community and grassroots settings. Based on laboratory indicators and lifestyle characteristics that are correlated with the occurrence of IR and are easily accessible, it is crucial to explore more convenient ways to predict the previous probability of IR in individuals. This approach could guide more precise IR screening and has the potential for prevention and control within the large population of China.

Machine learning (ML), with its data-driven methods, has already shown good predictive value in health issues such as arteriosclerosis [8], fatty liver [9], diabetes [10], and hypertension [11] . Obesity, dyslipidemia, lack of exercise, and sedentary lifestyles are considered risk factors for metabolic homeostasis [12]. By applying daily habits, basic information, and simple blood tests as features, we can build machine learning models in health check-up populations that are representative of the general population. The model of the ensemble learning algorithms based on decision trees, such as random forest (RF), Light Gradient Boosting Machine (LightGBM), Extreme Gradient Boosting (XGBoost), Gradient Boosting Machine (GBDT), and CatBoost, using multiple decision trees for predictions. They are capable of capturing complex nonlinear relationships, handling high-dimensional data, performing automatic feature selection, and mitigating the risk of overfitting through various mechanisms. In addition, these models offer strong scalability and are suitable for large-scale datasets, with most models having built-in overfitting prevention capabilities. These models can effectively predict IR and identify key predictive factors that are crucial for individual intervention. In addition, a retrospective cohort study can be used to determine the accuracy and practical value of these model results in distinguishing the onset of diabetes.

Methods

Study Population and Data Sources

The data used in this study were sourced from the electronic medical records of the Health Management Center at Xiangya Third Hospital, Central South University. The dataset includes participants who underwent physical examinations and questionnaire surveys at the Health Management Center between January 2018 and August 2022. A total of 17,287 adults with normal fasting blood glucose (FBG) were included, while individuals with FBG ≥6.1mmol/L or those with a history of abnormal glucose tolerance or diabetes were excluded.

The subsequent retrospective cohort consisted of individuals who completed their first health check-up at the Health Management Center of Xiangya Third Hospital between January 2017 and January 2019. These participants were followed for 5 years, with those diagnosed with diabetes at external hospitals or those who had completed ≥2 times FBG tests at the hospital during the follow-up period being included. Participants were required to be aged 18 years or older and have FBG <6.1mmol/L at the time of their first check-up. They also had to complete baseline assessments and surveys. Exclusion criteria included a history of abnormal glucose tolerance, diabetes, or gestational diabetes, as well as a history of tumors, pregnancy, or autoimmune diseases; and those who had used glucocorticoids or other relevant medications within the past month.

Using an IR prediction model, individuals in the cohort were classified as low-risk or high-risk based on their baseline data. Changes in FBG were then monitored. A FBG ≥7 mmol/L within 5 years or a diagnosis of diabetes at an external hospital was considered a positive result. A negative result was defined as maintaining normal FBG levels without a diabetes diagnosis at an external hospital over the 5-year follow-up period. Furthermore, by matching the ID card numbers, we excluded the participants who repeatedly appeared in the training set and the test set. Ensure this cohort was the different from the dataset used for model development.

Characteristics and Definitions

The dataset includes a total of 102 features, which encompass physical examination measurements such as age, height, weight, BMI, waist circumference (WC), systolic blood pressure (SBP), and diastolic blood pressure (DBP). Blood test indicators include FBG, liver function markers (alanine aminotransferase [ALT], aspartate aminotransferase [AST], total bilirubin [TBIL], direct bilirubin [DBIL], serum albumin [ALB], serum globulin [GLO], albumin/globulin ratio [A/G], total proteintotal [TP], bile acids [TBA]), kidney function markers (serum creatinine [Sr], blood urea nitrogen [BUN], uric acid [UA], and lipid profile markers (total cholesterol [TC], triglycerides (TG], high-density lipoprotein cholesterol [HDL-C], low-density lipoprotein cholesterol [LDL-C]. In addition, information from questionnaires was collected, including past disease diagnoses, lifestyle factors (dietary preferences, smoking status, alcohol consumption, exercise habits, and work status), psychological

XSL•FO
RenderX

status, sleep patterns, and health literacy related to basic medical knowledge. Insulin sensitivity was assessed using HOMA-IR=fasting glucose (mmol/L)×fasting insulin (μU/ml) / 22.5. A cut-off value of 2.69 was used, with a value ≥2.69 considered indicative of IR status [5].

Data Processing and Statistical Analysis

We excluded features with more than 30% missing data. For features with less than 30% missing data, continuous variables were imputed using the mean, while categorical variables were imputed using the mode. Ultimately, 90 features and 16,411 samples were retained. The entire dataset was randomly split into a training set (13,128/16411, 80% samples) and a test set (3283/16411, 20% samples), with 2782 samples categorized as IR.

For statistical analysis, continuous data that conform to a normal distribution were reported as means (SDs), otherwise, were reported as quartiles. Chi-square tests were conducted on categorical variables to assess the significant association between categorical features and the dependent variable. $P<.05$ was considered statistically significant.

Feature Engineering

Resampling

In this study, 3 resampling techniques, namely random undersampling, synthetic minority oversampling technique (SMOTE) oversampling, and SMOTE-Tomek combined sampling were experimentally compared during the dataset preprocessing phase. It was found that random undersampling performed best in improving the prediction accuracy for the minority class. Therefore, random undersampling was applied to the training set, where a portion of the majority class samples were randomly removed to reduce the majority class sample size. This approach helped mitigate model bias toward the majority class and improved overall classification performance.

Feature Processing and Algorithm Selection

To enhance model accuracy and efficiency, reduce computational costs, and avoid overfitting, feature selection was conducted. Before feature selection, Pearson correlation analysis was conducted for continuous features, while Kendall correlation analysis was used for discrete features. By examining the correlation matrix of the features, pairs of highly correlated features (with correlation coefficients >0.6) were identified, and perform dimensionality reduction on these highly relevant features. A total of 5 machine learning algorithms, including RF, LightGBM, XGBoost, GBDT, and CatBoost were used to construct predictive models on the training dataset. The model demonstrating the best performance across various evaluation metrics was selected from the baseline models (CatBoost was chosen based on experimental results). The CatBoost model was then trained, and the importance scores for each feature were determined. Features were added to the model in descending order of importance until the AUC score stabilized at its highest value with a specific number of features. At this point, no further features were added, and the model was constructed using the selected features.

Parameter Optimization and Model Evaluation

In addition to addressing class imbalance through resampling techniques, the model parameters were adjusted to assign different weights to each class, thereby balancing the class distribution. For the RF, GBDT, and CatBoost models, the parameter class_weight = “balanced” was set, while for the LightGBM and XGBoost models, scale_pos_weight = “ratio of majority and minority class” was used. Bayesian optimization was used for parameter tuning. Bayesian optimization is a global optimization algorithm based on Bayesian inference, which iteratively updates the posterior distribution of the parameters to identify the optimal configuration and optimize the objective function. To evaluate the optimization effects and improve the model’s generalization ability, 10-fold cross-validation was performed. The experiments were repeated 10 times, and metrics such as area under the receiver operating characteristic curve were averaged to assess model performance. In addition, model performance was evaluated using the F_1-score, accuracy, sensitivity, and specificity, while the receiver operating characteristic (ROC) curve and the area under the curve (AUC) were used to assess the model’s discriminatory ability. The Kappa value was also computed to evaluate the predictive capability of the model.

This research used several Python libraries and frameworks for data processing, feature engineering, model building, and hyperparameter tuning. The main tools used in the study are Python (version 3.6.4), NumPy (version 1.18.5), Pandas (version 1.1.5), SciPy (version 1.5.2), scikit-learn (version 0.24.2), LightGBM (version 4.3.0) XGBoost (version 1.5.2), CatBoost (version 1.1.1), and bayes_opt (version 1.4.0).

Feature Importance Ranking

Shapley Additive Explanations (SHAP) values are a method used to interpret machine learning model predictions. SHAP assigns a value to each feature, quantifying its contribution to the model’s output. Positive SHAP values indicate that the feature has a beneficial impact on the prediction, while negative SHAP values suggest a detrimental effect. The absolute magnitude of a SHAP value reflects the extent of the feature’s influence on the model’s decision. In this study, we used SHAP (version 0.45.0) for explainable machine learning to enhance interpretability.

Retrospective Cohort Validation of Model Application

Retrospective cohort data from a nondiabetic population were used as input to the aforementioned algorithms. The model outputs predicted the IR values for each participant, where a value of 1 was classified as high-risk IR and 0 as low-risk IR. Kaplan-Meier survival curves were used to conduct time-to-event analysis, comparing the 5-year diabetes incidence between the high-risk and low-risk IR groups. This approach further validated the model’s ability to accurately distinguish the onset of diabetes based on predicted IR levels.

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee of Xiangya Third Hospital, Central South University (approval no. 22206).

Results

Characteristics of the Study Population

The study flow chart is presented in Figure 1. A total of 16,411 nondiabetic individuals who underwent health screenings were included in this study, with an average age of 42.74 (SD 11.36) years. The sample comprised 8205 males and 8206 females. Overall, 17% of participants were diagnosed with IR, with a higher prevalence observed in males compared with females. In the IR group, levels of weight, WC, BMI, SBP, UA, ALT, AST, TG, and TC were significantly elevated compared with the non-IR group. Conversely, the average HDL-C level was significantly lower in the IR group ($P<.05$). In addition, lifestyle factors such as diet, physical activity, and health literacy exhibited significant differences between the 2 groups (Tables 1 and 2).

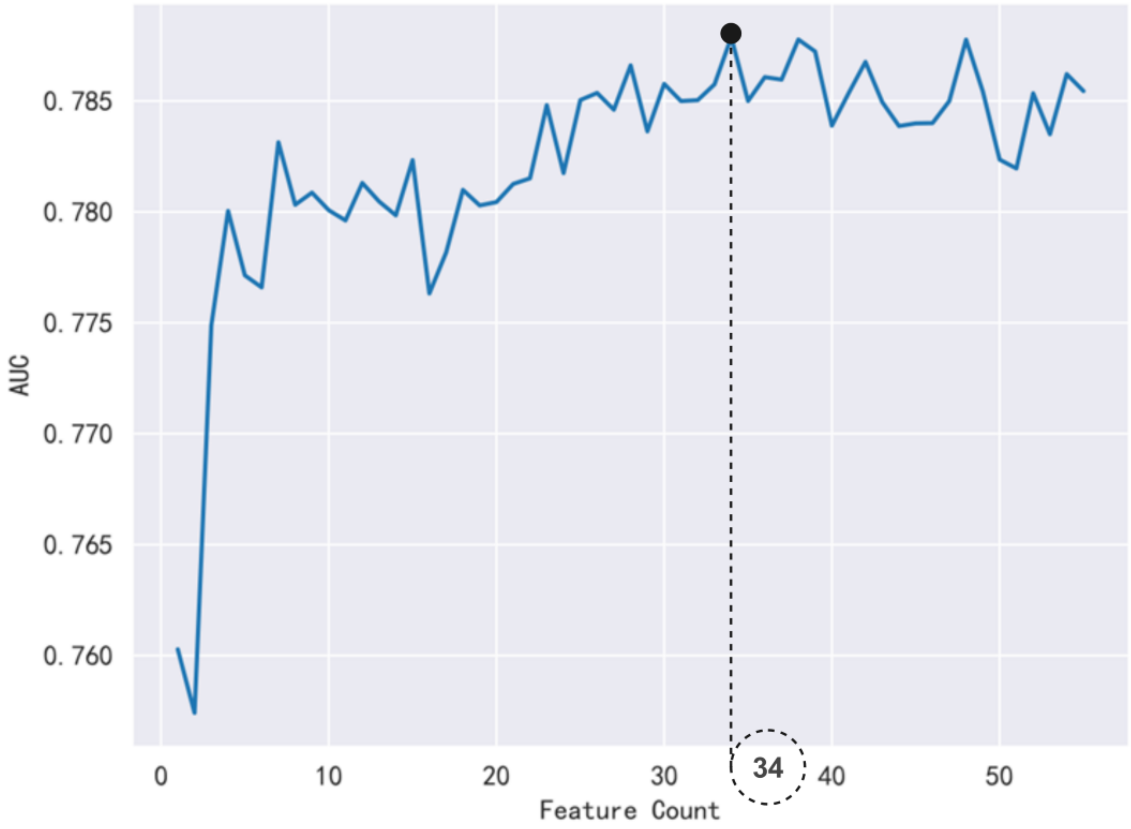
Feature Engineering



In the training set, random undersampling was applied to the majority class. Among the "physiological features," 4 highly correlated features: "BMI," "height," "weight," and "WC" were subjected to dimensionality reduction, with "BMI" retained. Similarly, for the 2 highly correlated features "SBP" and "DBP," only "SBP" was retained.

Feature importance scores were computed for 55 lifestyle-related questionnaire features using the CatBoost algorithm. These features were ranked from high to low based on their importance scores and then sequentially input into the CatBoost model. After each addition, the model's AUC score on the test set was recorded. As shown in Figure 2, the AUC score dropped significantly after adding 35 features, leading to the exclusion of 21 noncontributory questionnaire features. The 34 retained features, which showed significant contributions, include BMI, SBP, age, sex, family history medicine, exercise type, years of consistent exercise, exercise duration per session, weekly exercise frequency, dietary preferences, staple food structure, dietary taste, sleep duration, reasons for sleep disturbance, exposure to harmful substances, work physical demands, sedentary duration outside of work, consumption frequency of fruits, milk, meat, coffee, legume and soy products, sugary drink and fatty meats, daily vegetable intake, health check-up interval , self-monitoring of blood pressure and heart rate, observe urination and defecation, carrying emergency medications, regular meals, seat belt usage, bask, and awareness of normal salt intake and hazard ratio (HR).

In addition, the addition of 17 biochemical markers, BUN, Cr, UA, TC, TG, HDL-C, LDL-C, FBG, ALT, AST, TBIL, DBIL, TSP, ALB, GLO, A/G ratio, and TBA further improved the model's accuracy, sensitivity, and specificity. Thus, the final feature selection for the model included the 34 lifestyle-related questionnaire features and 17 biochemical markers.

XSL•FO
RenderX

Figure 2. The model's area under the curve (AUC) score on the test set. This figure shows how the AUC score on the test set changes with the number of features included in the model. After adding 34 features, the AUC score drops significantly, indicating that these additional features no longer contribute to model performance improvement.

Model Performance Evaluation and Feature Importance Ranking

Based on the 51 selected features (34 questionnaire features and 17 biochemical markers), 5 ML algorithms were applied, RF, LightGBM, XGBoost, GBDT, and CatBoost to build and evaluate models using both the training and testing datasets. The performance metrics of the 5 ML models are summarized in Table 3. The LightGBM model demonstrated the best performance across all metrics, including accuracy (0.7542), sensitivity (0.6639), specificity (0.7642), F_1-score (0.6748), and κ (0.3741). Although the AUC (0.8456) of the LightGBM model was slightly lower than that of CatBoost, LightGBM was determined to be the best model overall for predicting IR. The ROC curve for the best-performing LightGBM model is shown in Figure 3.

SHAP values were used to rank feature importance in the LightGBM model, as shown in Figure 4A. The top 10 features influencing IR were: BMI, FBG, HDL-C, TG, Cr, ALT, sex, TBIL, age, and A/G ratio. Figure 4B provides a visual representation of the SHAP values for the top 10 features, where BMI, FBG, TG, ALT, and sex were positively correlated with IR, while HDL-C, Cr, TBIL, age, and A/G ratio were negatively correlated with IR.

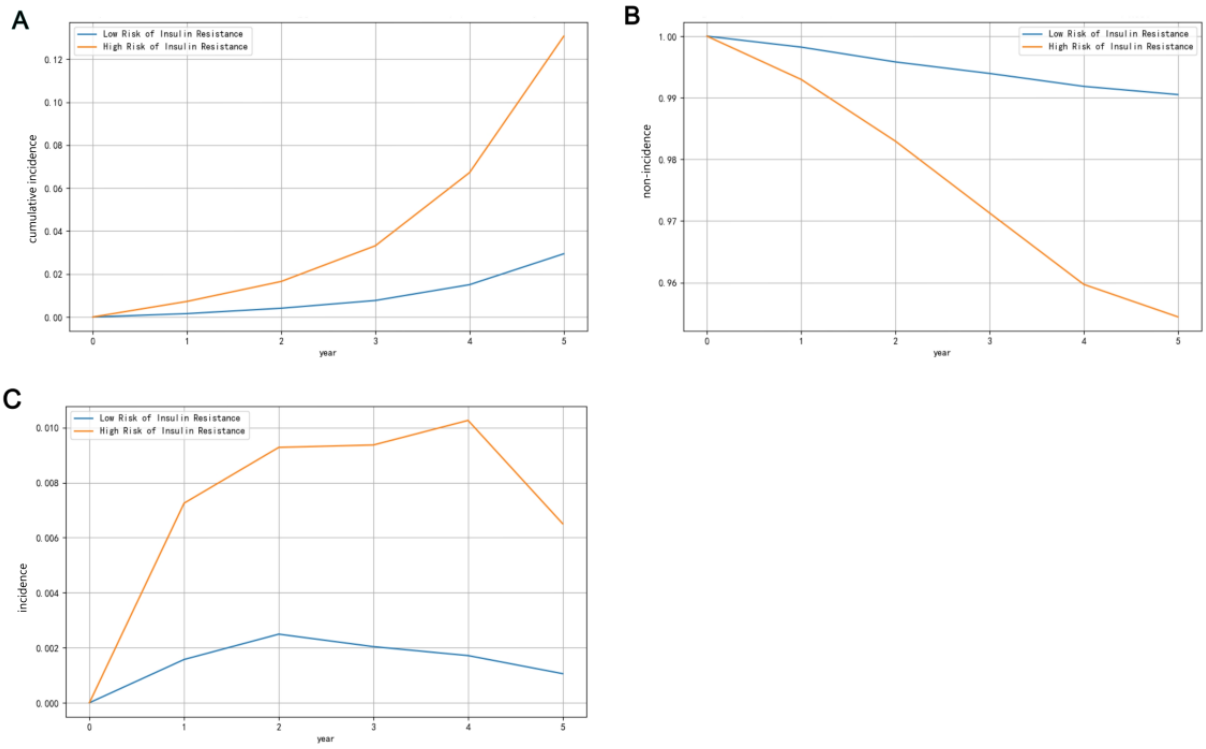
Figure 4. Detailed feature importance. (A) Feature importance by Light Gradient Boosting Machine. It shows the importance ranking of various features in the Light Gradient Boosting Machine model. The vertical coordinate (y-axis) shows the top 20 features and (B) shows the explanation of each feature impact on insulin resistance in the prediction model by the Shapley Additive Explanations (SHAP) values in the Light Gradient Boosting Machine algorithm. A/G: albumin/globulin ratio; ALT: alanine aminotransferase; Cr: creatinine; FBG: fasting blood glucose; HDL-C: high-density lipoprotein cholesterol; SG: serum glutamic; TBA: bile acids; TBIL: total bilirubin; TG: triglycerides; UA: uric acid.



Retrospective Cohort for Validation and Clinical Significance Assessment

The retrospective cohort dataset was used to validate the differential occurrence of diabetes in populations stratified by the model. A total of 20,369 nondiabetic participants were continuously monitored (5101 individuals classified as IR high risk by LightGBM and 15,268 individuals classified as IR low risk), with the incidence of diabetes compared from baseline to 5 years. Out of 5101 high-risk IR participants, 235 (4.6%) developed diabetes, while 137 (0.9%) of 15,268 low-risk IR participants did. This resulted in a HR of 5.1, indicating a significantly higher risk for the IR high risk group compared with the IR Low Risk group. Figure 5A clearly illustrates the relationship between the cumulative incidence of diabetes in the high- and low-risk insulin resistance groups. The high-risk group exhibited a significantly higher cumulative incidence of diabetes compared with the low-risk group, particularly after the second year of follow-up, when the rate of increase accelerated. This suggests that individuals in the high-risk group have a higher likelihood of developing diabetes, and the cumulative effect of this risk becomes more pronounced over time.

The curve for the low-risk group starts at 1 (indicating that 100% of individuals were free of diabetes) and gradually declines over time, although the decrease is relatively small. In contrast, the high-risk group shows a much more rapid decline, especially after the second year, with a more noticeable downward trend (Figure 5B). The line chart depicting the diabetes incidence rates across different IR risk groups (Figure 5C) shows that the growth rate of incidence in the high-risk group is significantly higher than in the low-risk group. The incidence in the high-risk group rises sharply after the second year, reaching its peak by the fifth year. These findings suggest that individuals with high insulin resistance are more likely to develop diabetes within a shorter time frame.

XSL•FO
RenderX

Figure 5. Clinical implication (incidence of diabetes) predicted by Light Gradient Boosting Machine algorithm from a retrospective cohort by the health management center. (A) Kaplan–Meier curve of cumulative incidence of diabetes in different states of insulin resistance. The high-risk insulin resistance group has a significantly higher cumulative incidence of diabetes than the low-risk insulin resistance group. (B) Kaplan–Meier curve of nonincidence of diabetes in different states of insulin resistance. The low-risk insulin resistance group has a significantly higher probability of not developing diabetes than the high-risk insulin resistance group. (C) Incidence of diabetes in different states of insulin resistance. The incidence in the high-risk insulin resistance group is significantly higher than that in the low-risk insulin resistance group, with a sharp increase after the second year.

Discussion

Principal Findings

This study applied multiple machine learning methods using a health check-up database from southern China. Based on questionnaire data and easily accessible, low-cost laboratory measurements, a highly effective predictive model for IR was developed in a population with normal FBG. This ensures that the data required for model implementation is readily available, without the need for additional, expensive diagnostic procedures. This model holds significant value for precision screening of IR and for targeting interventions aimed at managing individual risk factors associated with IR. Compared with other models, LightGBM demonstrated a clear overall advantage in terms of its parameters. LightGBM is a gradient boosting framework that uses decision tree-based learning algorithms. It offers several benefits, including faster training efficiency, lower memory usage, and higher accuracy. In addition, it supports parallel learning and is capable of handling large-scale datasets [13].

Comparison With Previous Work

The previous studies have developed insulin resistance prediction models targeting different ethnic groups and populations, which proves that researchers recognize the necessity of conducting IR prediction. Tsai integrated the National Health and Nutrition Examination Survey public database in the United States and the MAJOR database in Taiwan, China, and established the HOMA-IR ML (XGBoost) prediction model for adults in the two regions. The AUC reached 0.87, the important feature spectrum revealed by SHAP analysis was similar to our results, confirming the determinative roles of factors such as BMI, FBG,TG, HDL-C, and sex [14]. Before this, the team also developed an IR model using samples from 1,229 chronic kidney disease patients sourced from the National Health and Nutrition Examination Survey database. The model included various nutritional and micronutrient indicators, and the overall evaluation metric showed that the XGBoost model achieved an AUC of 0.78 [15]. Zhang et al [16] developed a LightGBM model for IR in a cohort of nearly 10,000 adults aged 40 years or older from certain communities in Hubei, China, with an ROC score of 0.794. The most significant features included FBG, BMI, WC, TG, and sex. In a South Korean study involving 8842 residents, in addition to measurement and laboratory indicators, high-cost, high-quality features such as genetic risk scores, food frequency questionnaires, and nutrients were included, the best-performing model, XGBoost, achieved an AUC of 0.86 [17]. However, these studies either use expensive features or fail to address multicollinearity issues between features. For example, physiological knowledge and typical data support a strong correlation between BMI and waist circumference [18], but these studies did not account for multicollinearity, which could lead to overfitting.

In our preliminary model, using only low-cost questionnaire features did not yield the expected results. However, when

XSL•FO
RenderX

laboratory indicators of liver function and blood lipids were added, the performance improved significantly. Both feature importance rankings based on LightGBM and SHAP value calculations showed that BMI, FBG, HDL-C, and TG were among the top 4 most important features. In fact, a 2003 consensus from the American College of Clinical Endocrinology [19] formally defined IR syndrome as a multisystem disease centered around IR, with key elements including IR or hyperinsulinemia, with or without related cardiovascular-endocrine metabolic abnormalities. These elements include overweight BMI, abnormal glucose tolerance, hypertension, elevated TG, or reduced HDL-C, based on the established epidemiological correlation between IR and these indicators [20,21]. From a pathophysiological perspective, IR and these metabolic indicators have an explainable causal relationship. For example, adipokines secreted by adipose tissue, such as adiponectin [22], tumor necrosis factor alpha [23] can modulate insulin sensitivity through the insulin signaling pathway. In addition, hydrolysis products of elevated triglycerides, such as free fatty acids, can induce insulin resistance by inhibiting insulin signal transduction and reducing the number of insulin receptors on target cells [24]. Low HDL-C improves insulin resistance through reverse cholesterol transport and anti-inflammatory effects [25]. We also found that liver function indicators, such as ALT, bilirubin, and the A/G ratio, play a significant role in IR prediction, with fatty liver being closely linked to IR [26]. These 3 abnormal indicators are common in individuals with fatty liver disease [27], which may indirectly reflect IR. In addition, kidney function indicators showed correlations, which could be related to factors such as physical inactivity, chronic inflammation, oxidative stress, vitamin deficiencies, adipose factor imbalances, and changes in the gut microbiota in populations with kidney damage [28]. Finally, we applied the best LightGBM model results to baseline IR stratification in a retrospective cohort, further validating the significant impact of IR prediction on diabetes incidence. This aims to clarify the practical value of such models. By comparing the incidence of diabetes in low-risk and high-risk IR groups, we observed that individuals at high risk for IR were more likely to develop diabetes in a shorter period, confirming the model's value in assessing blood glucose metabolism.

Limitations and Future Directions

Despite the promising results in IR prediction, our study has several limitations. First, the data source is relatively limited in terms of geographical diversity. Our data came from a health check-up database from the Han Chinese population in Hunan Province in Central Southern China, which may impact the generalizability of the model to other regions or ethnic groups. Future studies could address this by incorporating data from different regions and ethnic populations to further validate the model's generalizability. We would try to develop these ML models into user-friendly web pages or applications that are accessible to the general public and primary care providers, getting more input information and feedback to optimize our models, which is virtually a significant advantage of ML. Second, we tested the clinical implications of this trained model with a retrospective cohort, and have not yet explored the predictive efficiency of the model in prospective research, and we plan to perform it in a follow-up study in the near future. Third, the diagnosis of diabetes in the cohort was based only on the results of FBG, rather than oral glucose tolerance test or combined with postprandial blood glucose or glycated hemoglobin. However, we hope to base diagnoses on the latter as well in further research in the near future. Finally, although 5 ML algorithms were used in this study, there may be other algorithms with better performance that are currently available or soon to be developed. It would be necessary for us to further iterate models with more promising algorithms to improve the predictive performance of the models in the future.

Conclusions

In conclusion, the ML models using the LightGBM algorithm are efficient in predicting IR status in nondiabetic individuals. By leveraging low-cost laboratory indicators and questionnaire data, the model can accurately assess the current IR status in individuals with normal blood glucose levels, helping identify those at high risk of progressing to diabetes within large-scale populations.

Abstract

Background: The global aging crisis has precipitated significant public health challenges, including rising chronic diseases, economic burdens, and labor shortages, particularly in China. Activities of daily living (ADL) dysfunction, affecting over 40 million Chinese older adults (16% of the aging population), severely compromises independence and quality of life while increasing health care costs and mortality. ADL dysfunction encompasses both basic ADL (BADL) and instrumental ADL (IADL), which assess fundamental self-care and complex environmental interactions, respectively. With projections indicating 65 million cases by 2030, there is an urgent need for tools to predict ADL impairment and enable early interventions.

Objective: This study aimed to develop and validate a predictive nomogram model for ADL dysfunction in older adults using nationally representative data from the China Health and Retirement Longitudinal Study (CHARLS). The model seeks to integrate key risk factors into an accessible clinical tool to facilitate early identification of high-risk populations, guiding targeted health care strategies and resource allocation.

Methods: A retrospective analysis was conducted on 5081 CHARLS wave 3 participants (2015 - 2016) aged 60 - 80 years. Participants were categorized into ADL dysfunction (n=1743) or normal (n=3338) groups based on BADL and IADL assessments. Forty-six variables spanning demographics, health status, biomeasures, and lifestyle were analyzed. After addressing missing data via multiple imputation, Least Absolute Shrinkage and Selection Operator (LASSO) regression and multivariable logistic regression identified 6 predictors. Model performance was evaluated using receiver operating characteristic curves, calibration plots, decision curve analysis, and Shapley additive explanations (SHAP) for interpretability.

Results: The final model incorporated 6 predictors: the 10-item Center for Epidemiologic Studies Depression Scale depression score, number of painful areas, left-hand grip strength, 2.5-m walking time, weight, and cystatin C level. The nomogram demonstrated robust discriminative power, with area under the curve values of 0.77 (95% CI 0.76 - 0.79) in both the training and testing sets. Calibration curves confirmed strong agreement between predicted and observed outcomes, while decision curve analysis highlighted superior clinical use over “treat-all” or “treat-none” approaches. SHAP analysis revealed depressive symptoms and physical frailty markers (eg, slow walking speed and low grip strength) as dominant predictors, aligning with existing evidence on ADL decline mechanisms.

Conclusions: This study presents a validated nomogram for predicting ADL dysfunction in older adult populations, combining psychological, physical, and biochemical markers. The tool enables risk stratification, supports personalized interventions, and addresses gaps in geriatric care by emphasizing modifiable factors like pain management, depression, and mobility training. Despite limitations such as regional data biases and the retrospective design, the model offers scalable clinical value. Future research should incorporate social, environmental, and cognitive factors to enhance precision and generalizability.

Introduction

The aging of the population, which has led to an increase in chronic diseases, financial burdens, and labor shortages, has become a significant public health concern and poses a major challenge to public health systems in China [1]. Aging refers to the gradual process of growing older, involving a series of changes over time, including physical, mental, and social transformations [2]. Each year, approximately 10% of older adults who were previously not disabled develop dysfunction in activities of daily living (ADL) [3]. A previous study estimated that more than 40 million older adults in China, or over 16% of the older adult population, currently experience ADL dysfunction. This number is expected to rise to 65 million by 2030 [4]. ADL dysfunction significantly affects the quality of life of older adults and is associated with increased health care expenditures, higher rates of institutionalization, and elevated mortality rates [5-7]. For many older adults, maintaining their independence for as long as possible is a key priority.

ADL dysfunction is typically assessed using the basic activities of daily living (BADL) and instrumental activities of daily living (IADL) scales. The BADL scale, which is widely used, assesses fundamental self-care abilities such as bathing, dressing, eating, and engaging in indoor activities [8]. To evaluate more complex aspects of daily living, Lawton and Brody [9] developed the IADL scale, which measures an individual's ability to perform tasks that require more interaction with the environment, such as making telephone calls, shopping, cooking, and doing household chores. Given the strong correlation between BADL and IADL scores and overall functional ability [10], it is crucial to identify the factors contributing to ADL dysfunction in the older adults and to understand the characteristics of those affected.

A nomogram is a precise graphical representation of a predictive model based on regression analysis. It integrates multiple variables and visually presents the estimated probability of an event occurring. In this study, we developed and validated a comprehensive predictive model for assessing the risk of ADL dysfunction among older adults, using extensive data from the China Health and Retirement Longitudinal Survey (CHARLS). Subsequently, we created a nomogram that incorporates all selected risk factors, enabling rapid identification of older adults at risk of ADL dysfunction. The establishment of this predictive tool is expected to facilitate early detection, allowing for timely interventions that may reduce the incidence of ADL dysfunction in this population.

Methods

Study Population

This study is a retrospective study that used survey data from CHARLS wave 3, which were collected between August 2015 and January 2016. A total of 5081 samples were selected based on inclusion and exclusion criteria. Participants were included if they were aged between 60 and 80 years and were not missing data for essential variables. Exclusion criteria included individuals who were unwilling or unable to complete the survey. After applying these criteria, a total of 5081 participants were included in the analysis. Using the BADL and IADL assessment scales, participants were categorized based on their functional abilities. The BADL scale includes 6 basic tasks: dressing, bathing, eating, getting in and out of bed, using the toilet, and controlling urination and defecation. The IADL scale measures more complex activities, such as housework, food preparation, shopping, financial management, and medication adherence. Individuals with 1 or more disabilities in either the BADL or IADL domains were classified as having ADL dysfunction, while those without disabilities in either domain were classified as having normal ADL. Based on this classification, the participants were divided into 2 groups: the ADL normal group (n=3338) and the ADL dysfunction group (n=1743).

Candidate Predictor Variables

Informed by clinical experience and previous studies [11,12], we analyzed 46 potential variables that might be associated with the risk of ADL dysfunction. These variables spanned various domains, including demographic characteristics, health status, lifestyle factors, biochemical indicators, and functional status. The variables selected for inclusion in this study are as follows: sex (1=male and 0=female), age, marital status (1=married and 0=unmarried), disability status (1=disability and 0=nondisability), presence of chronic disease (1=yes and 0=no), hypertension (1=yes and 0=no), diabetes mellitus (1=yes and 0=no), alcohol consumption (1=yes and 0=no), smoking status (1=yes and 0=no), history of falls (1=yes and 0=no), hip fracture (1=yes and 0=no), walking time (measured by the time required to walk 2.5 m), systolic and diastolic blood pressure, pulse rate, left and right hand grip strength, height, weight, waist circumference, BMI, respiratory function, the 10-item Center for Epidemiologic Studies Depression Scale (CESD-10), number of painful areas (eg, headache, shoulder pain, back pain, leg pain, and so on), sleep duration, physical activity (eg, visiting friends, playing games, and participating in community activities), blood test parameters (eg, white blood cell count, red blood cell volume, platelet count, glucose, and cholesterol levels), and several measures of social and cognitive factors (eg, educational level, sociality, and the triglyceride-glucose index. These variables were included for their potential relevance to ADL dysfunction.

Statistical Analysis

Statistical analyses and figure generation were performed using R software (R Foundation for Statistical Computing). For variables with >20% missing data, those samples were excluded from the analysis. For variables with <20% missing data, the Multivariate Imputation by Chained Equations package was used to perform 5-fold imputation, and the imputed data most consistent with the sample trends were selected. Categorical variables were summarized using frequencies and percentages, while continuous variables were described by means and SDs. Differences between groups were assessed using *t* tests, chi-square tests, and nonparametric tests as appropriate. Nonparametric tests were used when data did not meet the assumptions for parametric testing, ensuring robustness and reliability of the analysis.

XSL•FO
RenderX

The data were split into training (n=3048) and testing (n=2033) sets using a 6:4 ratio. The training set was used to identify key predictors for ADL dysfunction. Initially, the Least Absolute Shrinkage and Selection Operator (LASSO) regression was applied to identify potential risk factors, minimizing multicollinearity and selecting the most predictive factors. Subsequently, a 10-fold cross-validation procedure was performed to determine the optimal tuning parameter (λ) for LASSO regression. Predictors selected by LASSO were then used in multivariate logistic regression, and a nomogram was constructed to visualize the influence of these predictors on the risk of ADL dysfunction. To simplify the model, predictors with minimal influence were discarded, and the remaining predictors were reanalyzed using multivariate logistic regression, followed by the construction of a final nomogram.

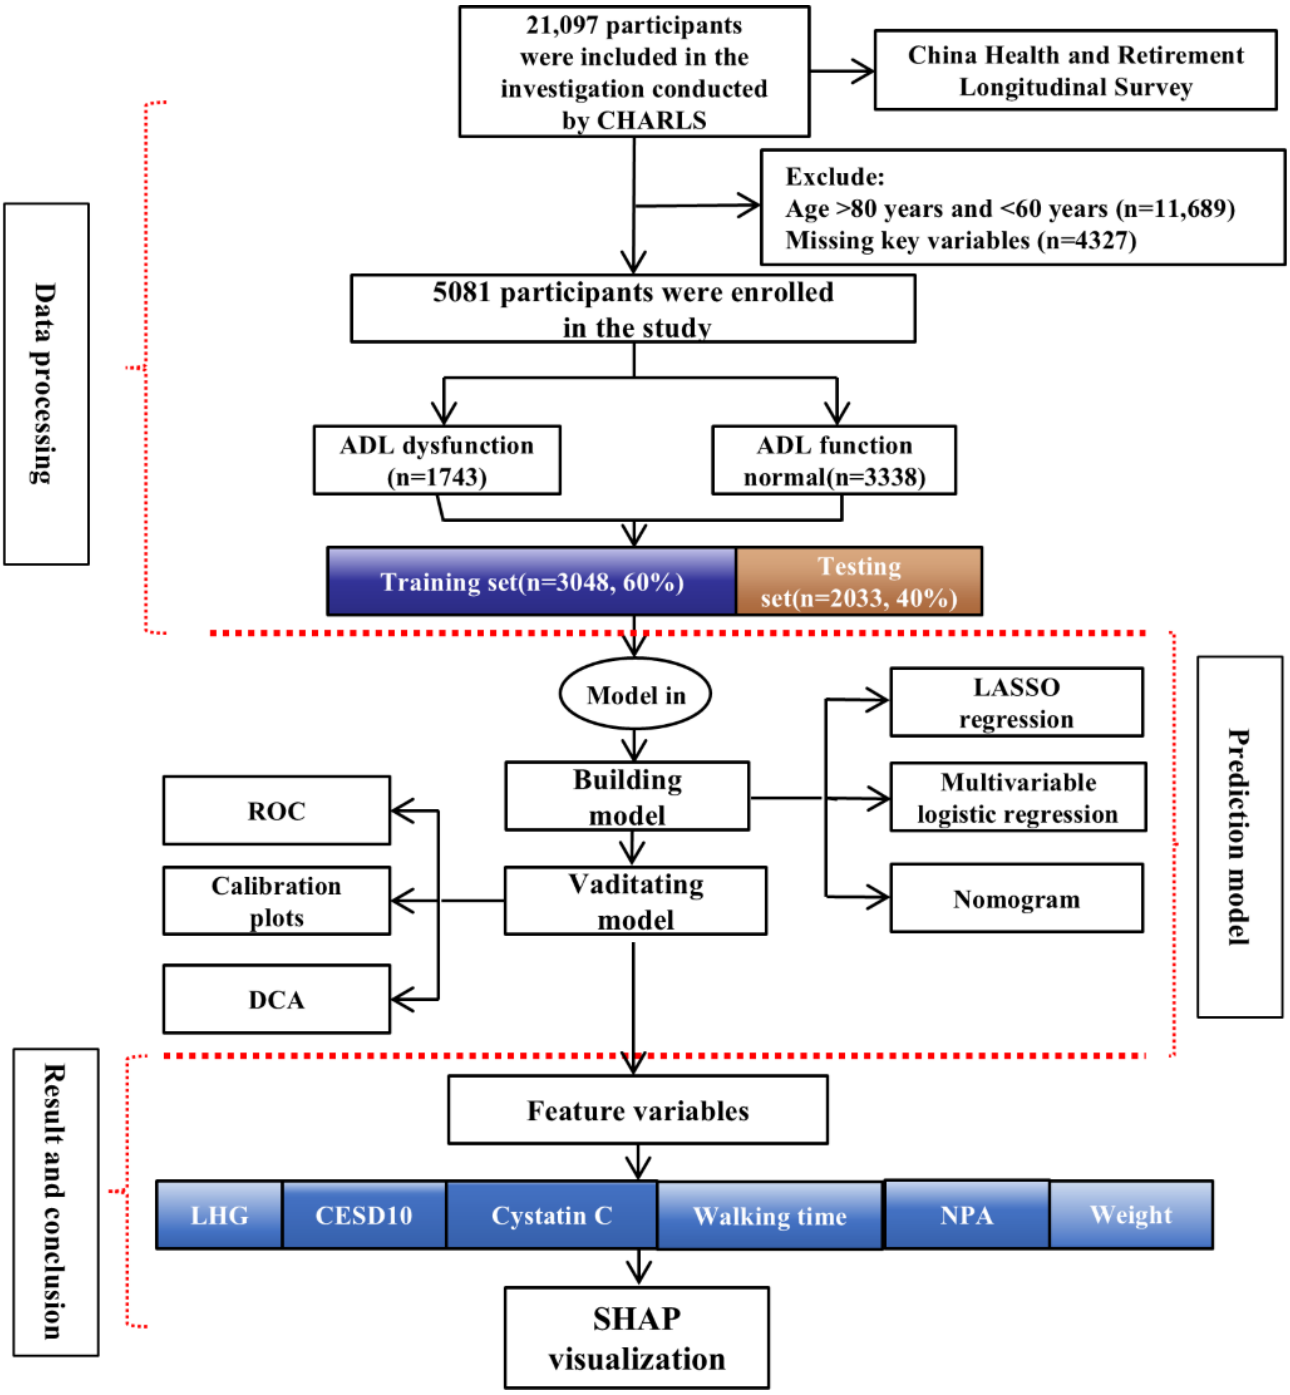
To evaluate the predictive performance of the model, several statistical tools were used, including receiver operating characteristic (ROC) curves, area under the curve (AUC), calibration plots, and decision curve analysis (DCA). ROC curves were used to assess the trade-off between sensitivity and specificity, while AUC quantified the model's overall discriminatory power. Calibration plots evaluated the agreement between predicted probabilities and actual outcomes, ensuring the model's reliability. DCA assessed the clinical use of the model by comparing the net benefits of true positive predictions against the harms of false positives and negatives. These comprehensive evaluation methods provided a assessment of the model's accuracy and potential clinical impact.

Finally, to further explain the model's feature variables, Shapley additive explanations (SHAP) values were calculated for each feature, and the predictive importance of these variables was visually represented through global importance plots, swarm plots, waterfall plots, and force plots. These visualizations facilitated a better understanding of how individual features contributed to the model's predictions.

Ethical Considerations

This retrospective study used anonymized data from wave 3 of the CHARLS database, which was ethically approved in June 2008 by the Biomedical Ethics Review Committee of Peking University (IRB00001052–11015) [13]. The individual data were anonymized before the study. In this study, patients and the public were not involved in the design, conduct, reporting, or dissemination plans of the research. All participants provided informed consent, and the study adheres to the ethical principles outlined in the Declaration of Helsinki.

Results



Flowchart

The study flowchart is presented in Figure 1.

This retrospective cohort analysis of 5081 older adults (aged 60‐80 years old) across China evaluated inclusion and exclusion criteria and data imputation methods for developing a predictive nomogram. Participants were classified into ADL normal (no BADL/IADL disability) and ADL dysfunction (≥1 disability) groups using validated functional assessment scales.

Figure 1. Flowchart of study cohort selection from CHARLS wave 3 (2015 - 2016) for developing the activities-of-daily-living dysfunction prediction model. ADL: activities of daily living; CESD-10: 10-item Center for Epidemiologic Studies Depression Scale; CHARLS: China Health and Retirement Longitudinal Survey; DCA: decision curve analysis; LASSO: Least Absolute Shrinkage and Selection Operator; LHG: left grip strength; NPA: number of pain areas; ROC: receiver operating characteristic curve; SHAP: Shapley additive explanations.

Baseline Characteristics

The study sample comprised 5081 participants, with an average age of 67 years, and a male-to-female ratio of 1.03. Of these, 3338 participants were classified into the ADL normal group, and 1743 participants were classified into the ADL dysfunction group. Significant clinical and sociodemographic differences were observed between the 2 groups, as summarized in Table 1. Key variables with significant differences (P<.05) include marital status, disability status, chronic diseases, hypertension, diabetes mellitus, alcohol consumption, smoking status, history of falls, hip fractures, walking time, systolic blood pressure, pulse rate, left and right hand grip strength, height, weight, waist circumference, respiratory function, depression (CESD-10), number of painful areas, sleep duration, physical activity, mean red blood cell volume, total cholesterol, C-reactive protein, glycosylated hemoglobin, uric acid, hematocrit, hemoglobin, cystatin C, sociality, and educational level.

In the comparative analysis of 5081 participants aged 60 - 80 years old from the CHARLS, participants were stratified into the ADL normal (n=3338) and ADL dysfunction (n=1743) groups. Variables included demographics (age, sex, and marital status), comorbidities (hypertension, diabetes, and chronic

XSL•FO
RenderX

diseases), lifestyle factors (smoking and alcohol use), biomeasures (grip strength, walking time, and cystatin C), and functional parameters. Significant differences (P<.05) between groups were highlighted, reflecting associations with ADL impairment in Chinese older adults.

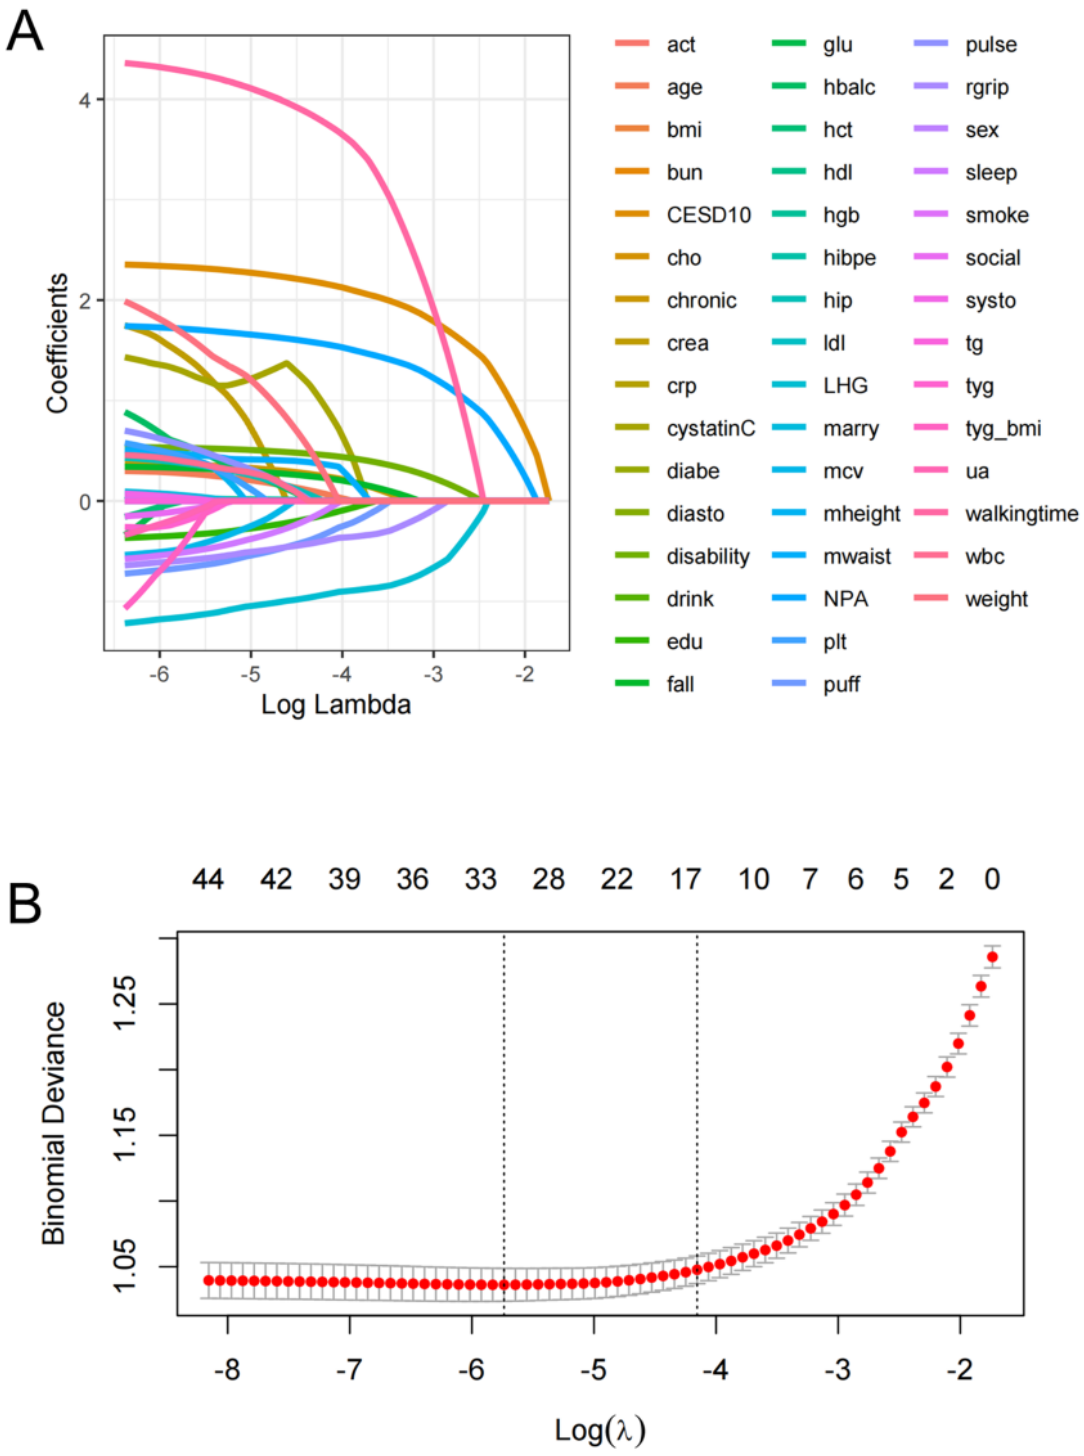
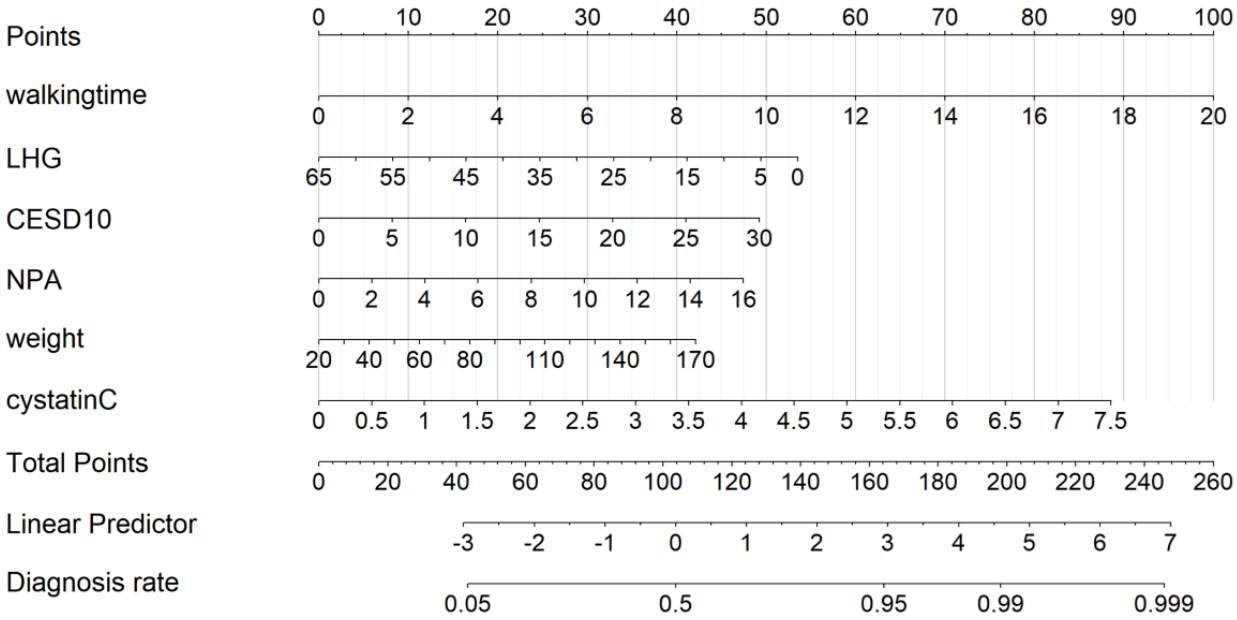
[a]ADL: activities of daily living.



Development of the Predictive Nomogram

Participants were randomly divided into a training set (n=3048) and a testing set (n=2033) in a 6:4 ratio. LASSO regression was applied to identify the most important predictors of ADL dysfunction. After performing 10-fold cross-validation, predictors with nonzero coefficients were selected (Figures 2A and 2B). These predictors were then incorporated into a multivariate logistic regression model, factors with *P* values>.05 (eg, respiratory function and sleep duration) were removed in the multivariate logistic regression. Ultimately, 6 independent predictors were retained: 2.5-m walking time, left hand grip strength, CESD-10 score, number of painful areas, weight, and cystatin C. Based on these predictors, a nomogram was

XSL•FO
RenderX



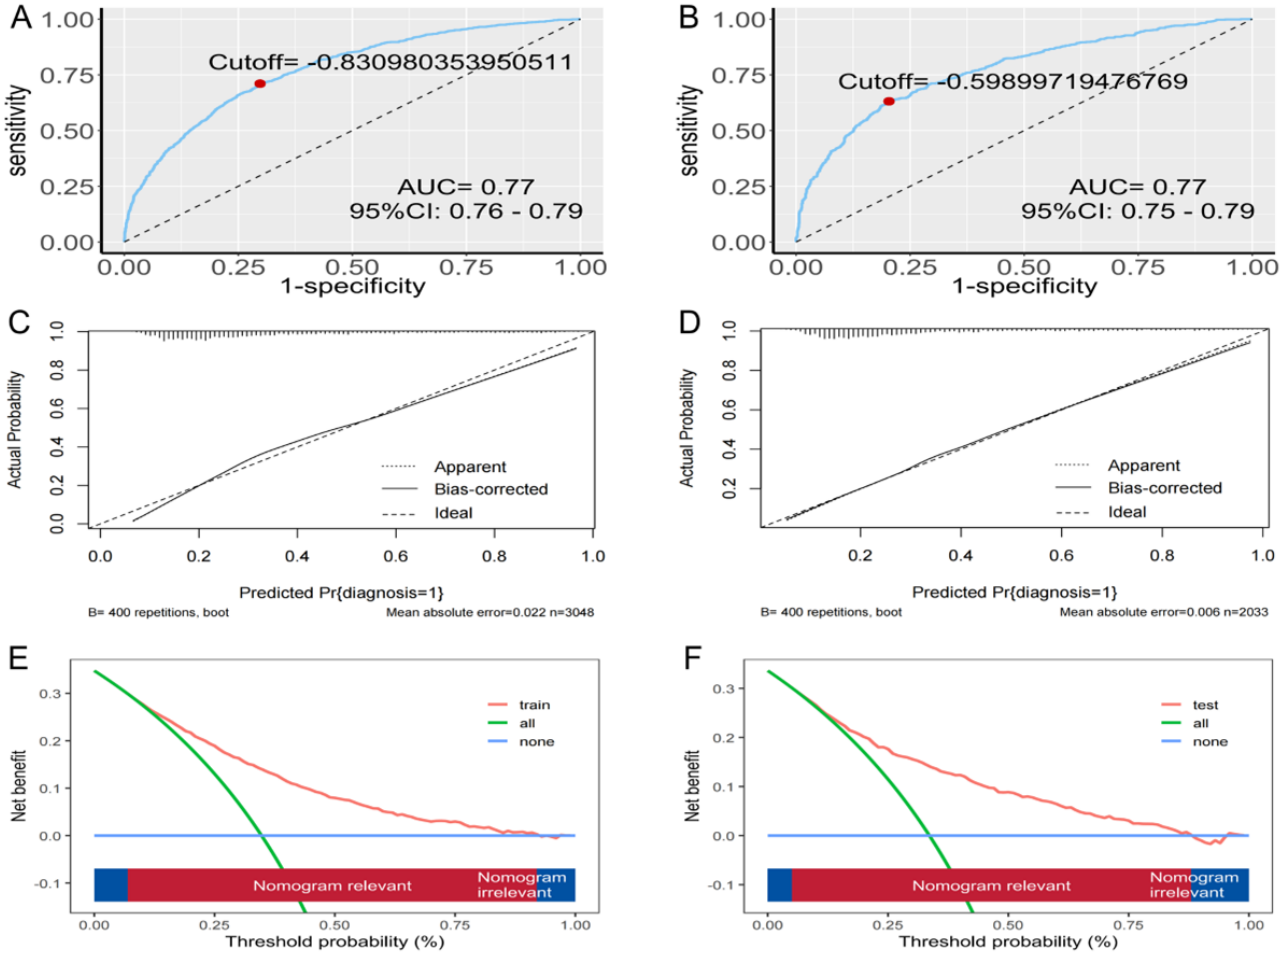
constructed to estimate the risk of ADL dysfunction in the older adults. The nomogram visually represents the contribution of each factor to the likelihood of dysfunction, with the bottom scale indicating the predicted probability. Higher scores correspond to a greater risk of ADL dysfunction (Figure 3).

Figure 2. Least Absolute Shrinkage and Selection Operator regression feature selection for ADL dysfunction predictors in China Health and Retirement Longitudinal Survey (2015 - 2016): (A) Coefficient profiles of 46 candidate variables analyzed via Least Absolute Shrinkage and Selection Operator regression to identify predictors of ADL dysfunction in Chinese older adults and (B) 10-fold cross-validation for optimal lambda (λ) selection, minimizing partial likelihood deviance. Features with nonzero coefficients (eg, Center for Epidemiologic Studies Depression Scale, walking time, and cystatin C) were retained for nomogram development. ADL: activities of daily living; CESD10: 10-item Center for Epidemiologic Studies Depression Scale; LHG: left grip strength.

XSL•FO
RenderX

Figure 3. Nomogram for predicting activities-of-daily-living dysfunction risk in Chinese older adults (China Health and Retirement Longitudinal Survey, 2015 - 2016). Graphical tool integrating six predictors (Center for Epidemiologic Studies Depression Scale, pain areas, left grip strength, 2.5-m walking time, weight, and cystatin C) to estimate individualized risk of activities-of-daily-living dysfunction. Scores for each variable are summed to calculate total points, corresponding to predicted probability on a 0% - 100% scale. Derived from 3048 training set participants in the China Health and Retirement Longitudinal Survey cohort. CESD10: 10-item Center for Epidemiologic Studies Depression Scale; LHG: left grip strength; NPA: number of pain areas; walkingtime: 2.5-meter walking time.

Performance and Clinical Application of the Nomogram



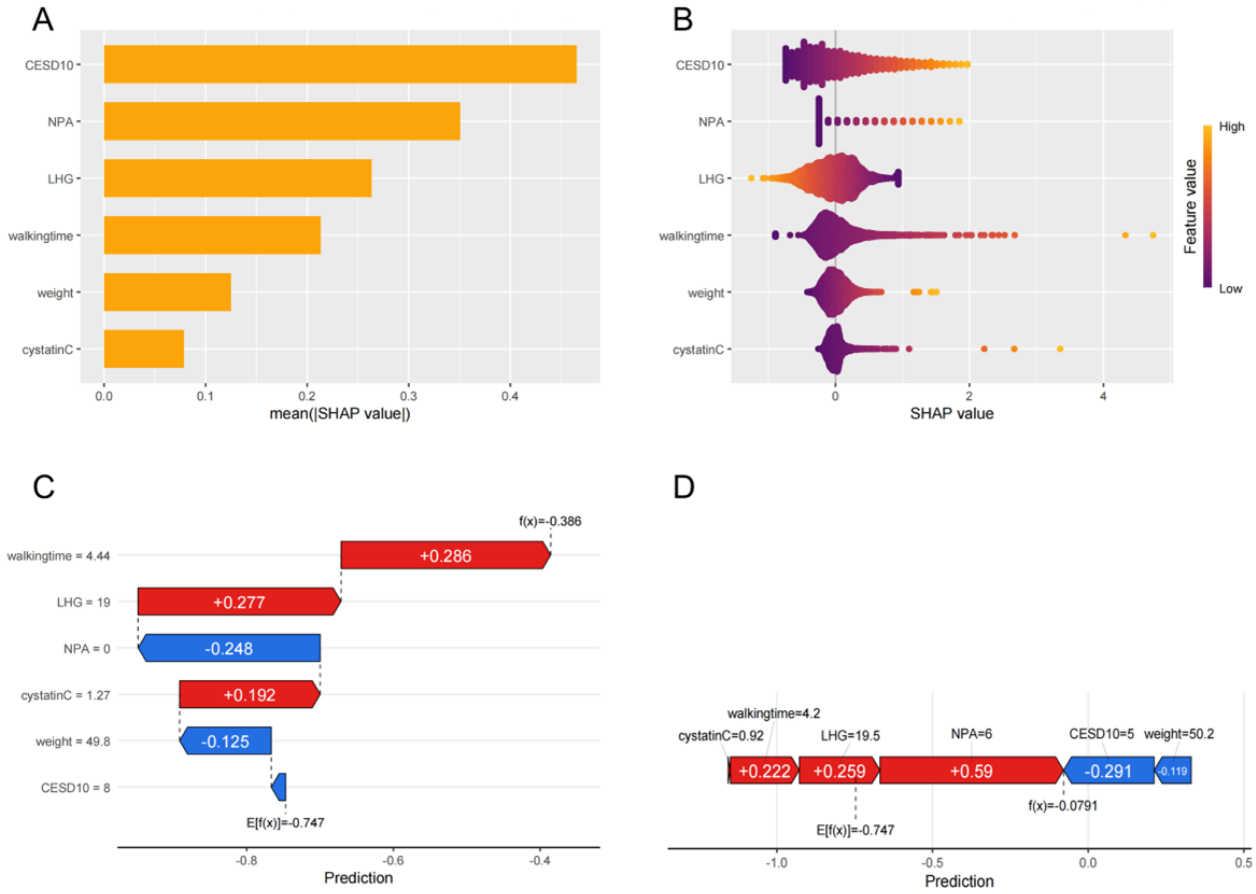
To evaluate the performance of the nomogram, the AUC values were calculated. In the training set, the AUC was 0.77 (95% CI 0.76 - 0.79), and in the testing set, the AUC was 0.77 (95% CI 0.75 - 0.79), demonstrating the model's high predictive accuracy (Figures 4A and 4B).

The nomogram's calibration curves show agreement between the predicted and observed probabilities in both the training and testing sets, further confirming the model's accuracy and reliability (Figures 4C and 4D).

In addition, DCA was used to assess the clinical use of the model. The results indicated that the model's net benefit in the internal validation set was better than both the "treat-all" and "treat-none" scenarios, highlighting its clinical use and predictive performance (Figures 4E and 4F).

XSL•FO
RenderX

Figure 4. Predictive performance and clinical use of the activities-of-daily-life dysfunction nomogram: (A-B) receiver operating characteristic curves showing discriminative power (AUC 0.77, 95% CI 0.76 - 0.79) for training (A) and testing (B) sets in China Health and Retirement Longitudinal Survey (2015 - 2016); (C-D) calibration plots demonstrating agreement between predicted and observed activities-of-daily-living dysfunction probabilities; and (E-F) decision curve analysis comparing net clinical benefits of the nomogram against "treat-all" and "treat-none" strategies in Chinese older adults. AUC: area under the curve.



Explanation of Model Characteristic Variables

SHAP values were calculated to assess the influence of each characteristic variable in the model. The global importance plot and swarm plot (Figures 5A and 5B) reveal the relative importance of the 6 key variables in predicting ADL dysfunction, ranked from highest to lowest: CESD-10 score, number of painful areas, left hand grip strength, 2.5-m walking time, weight, and cystatin C. Except for left hand grip strength, all other variables were positively correlated with ADL dysfunction.

To illustrate the individual contributions of these variables, 2 random samples were selected, and the predictive effects of the variables were visualized through waterfall and force plots (Figures 5C and 5D). These plots demonstrate the distinct effects of each factor on ADL dysfunction for individual participants, providing valuable insights into the practical significance of the model's predictors.

XSL•FO
RenderX

Figure 5. Interpretability of the activities-of-daily-life dysfunction prediction model using Shapley additive explanations values: (A) Global Shapley additive explanations importance plot ranking features by contribution to activities-of-daily-living dysfunction predictions in China Health and Retirement Longitudinal Survey (2015 - 2016, n=5081); (B) swarm plot depicting directionality (positive/negative) of predictors (eg, Center for Epidemiologic Studies Depression Scale, pain areas); and (C-D) waterfall and force plots illustrating individualized risk contributions for 2 participants (China Health and Retirement Longitudinal Survey ID: Sample A vs B), highlighting variable-specific impacts on model output. CESD10: 10-item Center for Epidemiologic Studies Depression Scale; LHG: left grip strength; NPA: number of pain areas; walkingtime: 2.5-meter walking time.

Discussion

Principal Findings

This study identified 6 robust predictors of ADL dysfunction in the older adults, namely CESD-10 depression score, number of painful areas, left-hand grip strength, 2.5-m walking time, weight, and cystatin C levels. These factors reflect multidimensional contributions from psychosocial states, physical frailty markers, systemic inflammation, and biomechanical stressors. Notably, participants with a history of disability, chronic diseases, or falls exhibited significantly higher ADL dysfunction risk, consistent with previous evidence on functional decline pathways [14,15]. The 2.5-m walking time defined in this study is negatively correlated with gait speed. Key findings further highlighted walking speed as a critical functional indicator. Slow gait (≥3.73 seconds for 2.5 m) correlated strongly with ADL limitations, echoing its status as a "sixth vital sign" for aging populations [16-19]. Similarly, left-hand grip strength emerged as a stronger predictor than right-hand strength, suggesting asymmetric hand function may play underrecognized roles in daily task performance. Depressive symptoms (CESD-10>11.5) and polyarticular pain (>3 body areas) were dominant risk amplifiers, aligning with their bidirectional relationships with physical disability [20-22].

Comparison With Previous Work

While many studies have identified predictors of ADL dysfunction in community-dwelling older adults, research constructing ADL dysfunction prediction models is rare, with only a few reporting ADL dysfunction prediction models. Jonkman et al [23] developed and validated a 3-year ADL dysfunction prediction model for adults aged 65 - 75 years, selecting 10 of 22 predictors, including physical performance indicators, age, BMI, depressive symptoms, and chronic diseases. Covinsky et al [24] constructed and validated an ADL dysfunction prediction model for community residents aged 70 years and older, including 9 predictors: age, comorbidities, cognitive function, low BMI, and 5 functional limitation indicators. Recent domestic studies have found that a nomogram incorporating 10 predictors age, education level, social activity frequency, drinking and smoking habits, smoking frequency, comorbidity condition, self-reported health status, gait speed, cognitive function, and depressive symptoms can effectively predict disability risks [25]. Our study aligns with previous research in focusing on depressive symptoms, weight, and gait

XSL•FO
RenderX

speed as predictors. However, it differs by incorporating new indicators: number of painful body regions, left-hand grip strength, and cystatin C. Our findings reinforce established associations between depression, obesity, and ADL decline [21,26-28]. For instance, the link between CESD-10 scores and ADL aligns with Carrière et al's [20] longitudinal data showing depression predicts subsequent functional dependence. Similarly, weight's positive association with ADL dysfunction parallels studies identifying obesity-related metabolic strain and mobility limitations as key mechanisms [26,29]. However, our model extends existing literature in 3 ways. First, pain is a critical factor contributing to ADL dysfunction and poor functional health in older adults [30]. It is cross-sectionally associated with ADL function and predicts a decline in ADL functioning over time [31]. Older individuals often become less active due to pain, which leads to physical deconditioning and perpetuates a cycle of pain and activity restriction [32]. Second, cystatin C, a marker of renal function and inflammation emerged as a novel biochemical predictor, potentially reflecting subclinical frailty progression [33]. Cystatin C may reflect renal function decline, and renal dysfunction is associated with sarcopenia and cardiovascular events [34]. This may underlie its potential mechanism in predicting ADL dysfunction. Third, the left-hand grip strength's predictive dominance contrasts with conventional bilateral grip assessments [35-37], suggesting laterality-specific strength may better capture real-world functional demands.

Strengths and Limitations

The study's strengths include the use of nationally representative CHARLS data with a large sample size, rigorous LASSO-multivariable regression for predictor selection, and validation through AUC (0.77), calibration, and SHAP interpretability. The integration of psychological, biomechanical, and biochemical indicators provides a holistic view of ADL risk. Importantly, these predictors are easily accessible and low-cost, enabling assessment for older adults in community hospital outpatient clinics and facilitating broad implementation.

Limitations warrant consideration. First, the CHARLS data, while valuable, may be limited by regional and cultural factors, which may affect the generalizability of our findings. Future research should aim to include more diverse populations. Second, the variables selected in this study may have excluded important factors such as social support, living environment, and cognitive function, which could reduce the model's accuracy. Future research could incorporate these variables to enhance the model's precision. Third, as a retrospective study, the reliance on self-reported data introduces the potential for information bias, particularly in the reporting of chronic diseases and falls. Future prospective studies are needed to track changes in these variables over time and improve the model's predictive accuracy. Finally, grip strength data were not differentiated by dominant hand. Future studies could explore the potential impact of grip strength side on the results.

Future Directions

Future studies should incorporate longitudinal designs to track dynamic interactions between cognitive decline, social support networks, and environmental factors in shaping ADL trajectories. The role of cystatin C as a biomarker warrants further investigation to elucidate its mechanistic links to frailty progression and chronic inflammation [33]. In addition, task-specific functional magnetic resonance imaging or observational studies could clarify the dominance of left-hand grip strength and refine asymmetry-targeted rehabilitation protocols. Comparative analyses of weight-adjusted indices versus traditional metrics like BMI may improve obesity-related risk stratification [29]. Finally, validation in multiethnic cohorts and real-world clinical settings is critical to ensure model generalizability and inform scalable interventions addressing modifiable psychosocial and physical risk factors.

Conclusions

This tool is a predictive model developed to assess the risk of functional impairment in daily living among older adults. It incorporates factors such as the CESD-10, number of painful areas, left-hand grip strength, 2.5-m walking time, weight, and cystatin C. During both the development and validation phases, the model demonstrated discriminative ability and accuracy, effectively identifying individuals at higher risk and maintaining reliability when applied to new data.

For health care professionals, the model can assist in making more informed care decisions, help prioritize interventions, and support the customization of treatment plans for high-risk individuals. By identifying those at greater risk for functional decline, the model may contribute to improving the quality of life for older adults, enhancing their independence, and promoting overall well-being. In addition, it may aid in the more efficient allocation of health care resources by directing attention to individuals who would benefit most from targeted interventions.

Abstract

Background: Building machine learning models that are interpretable, explainable, and fair is critical for their trustworthiness in clinical practice. Interpretability, which refers to how easily a human can comprehend the mechanism by which a model makes predictions, is often seen as a primary consideration when adopting a machine learning model in health care. However, interpretability alone does not necessarily guarantee explainability, which offers stakeholders insights into a model's predicted outputs. Moreover, many existing frameworks for model evaluation focus primarily on maximizing predictive accuracy, overlooking the broader need for interpretability, fairness, and explainability.

Objective: This study proposes a 3-stage machine learning framework for responsible model development through model assessment, selection, and explanation. We demonstrate the application of this framework for predicting cardiovascular disease (CVD) outcomes, specifically myocardial infarction (MI) and stroke, among people with type 2 diabetes (T2D).

Methods: We extracted participant data comprised of people with T2D from the ACCORD (Action to Control Cardiovascular Risk in Diabetes) dataset (N=9635), including demographic, clinical, and biomarker records. Then, we applied hold-out cross-validation to develop several interpretable machine learning models (linear, tree-based, and ensemble) to predict the risks of MI and stroke among patients with diabetes. Our 3-stage framework first assesses these models via predictive accuracy and fairness metrics. Then, in the model selection stage, we quantify the trade-off between accuracy and fairness using area under the curve (AUC) and Relative Parity of Performance Scores (RPPS), wherein RPPS measures the greatest deviation of all subpopulations compared with the population-wide AUC. Finally, we quantify the explainability of the chosen models using methods such as SHAP (Shapley Additive Explanations) and partial dependence plots to investigate the relationship between features and model outputs.

Results: Our proposed framework demonstrates that the GLMnet model offers the best balance between predictive performance and fairness for both MI and stroke. For MI, GLMnet achieves the highest RPPS (0.979 for gender and 0.967 for race), indicating minimal performance disparities, while maintaining a high AUC of 0.705. For stroke, GLMnet has a relatively high AUC of 0.705 and the second-highest RPPS (0.961 for gender and 0.979 for race), suggesting it is effective across both subgroups. Our model explanation method further highlights that the history of CVD and age are the key predictors of MI, while HbA_{1c} and systolic blood pressure significantly influence stroke classification.

Conclusions: This study establishes a responsible framework for assessing, selecting, and explaining machine learning models, emphasizing accuracy-fairness trade-offs in predictive modeling. Key insights include: (1) simple models perform comparably to complex ensembles; (2) models with strong accuracy may harbor substantial differences in accuracy across demographic groups; and (3) explanation methods reveal the relationships between features and risk for MI and stroke. Our results underscore the need for holistic approaches that consider accuracy, fairness, and explainability in interpretable model design and selection, potentially enhancing health care technology adoption.

Introduction

Building trustworthy machine learning models for clinical practice requires consideration of interpretability, explainability, as well as fairness. Interpretability—which refers to how easily a human can comprehend the mechanism by which a model makes predictions—is important in health care settings because of the need for clinicians and patients to understand and trust the Artificial Intelligence (AI)-involved decisions that directly impact patient care [1,2]. It also facilitates regulatory compliance and ethical considerations in medical AI applications, ensuring these systems are not only effective but also justifiable and accountable [3]. In addressing this pressing need, experts in computer science, operations research, and medical informatics have significantly progressed the field of interpretable machine learning models, laying the foundation for the development of AI [3,4]. As of today, cutting-edge interpretable machine learning models are available through many open-source software packages, including RiskSLIM and Interpretable AI (Interpretable AI), among others [5,67]. Nonetheless, interpretability alone is not sufficient for trustworthy AI in health care.

Beyond interpretability, the machine learning community has also begun to emphasize the need for explainability [8] which focuses on conveying understandable reasons behind AI-driven decisions. While interpretability helps users grasp how a model arrives at a conclusion, explainability provides the why, offering justifications in human terms. This reasoning is crucial in health care, where clinicians and patients must not only understand but also trust the rationale of AI suggestions [9]. Therefore, explainability builds trust, enhances decision-making quality by providing insights into AI reasoning, and ensures compliance with ethical and legal standards [10]. In other words, explainability plays a crucial role in making machine learning algorithms and AI not just transparent but also relatable and trustworthy in clinical settings.

Meanwhile, there has been an increasing worry about the possibility of machine learning models leading to biased decisions [11]. Examples include models displaying racial or gender biases in predicting patient outcomes [12], or algorithms that disproportionately favor certain demographics in resource allocation [13]. Such biased decision-making tools may result in unfair evaluations in clinical settings, ultimately harming patients who require care [14]. However, efforts to quantitatively evaluate fairness in prediction models for clinical practice are still scarce [15].

A model with high predictive accuracy does not guarantee the best clinical usage, as it might display unfavorable biases [16]. As a result, it is important to understand and quantify the trade-offs between accuracy and fairness in model selection. Overall, the combined exploration and consideration of these aspects in a machine learning framework-based environment is not thoroughly investigated in this literature [17]. Therefore, to address these issues systematically, we propose a 3-stage machine learning framework on model assessment, selection, and explainability that integrates interpretability, fairness, as well as explainability in health care decision-making. Specifically, in the first stage, we develop and assess a range of models based on predictive accuracy and fairness. Next, we select the model that best balances accuracy and fairness using a novel trade-off curve. Finally, we explain the chosen model, aiming to provide deeper insights into its predictions for informed clinical decision-making. As a proof of concept, we apply our framework to predict cardiovascular disease (CVD) outcomes, myocardial infarction (MI), and stroke, among people with type 2 diabetes (T2D). With CVD being a leading cause of death in the United States, and patients with T2D being at elevated risk of CVD, it is urgent to develop accurate and fair predictive models that generate clinically reasonable predictions [16-19]. This study not only contributes to the advancement of AI in health care but also sets a precedent for future research in incorporating interpretability, fairness, and explainability into the machine learning model development framework, paving the way for more ethical, trustworthy, and effective solutions in medical informatics.

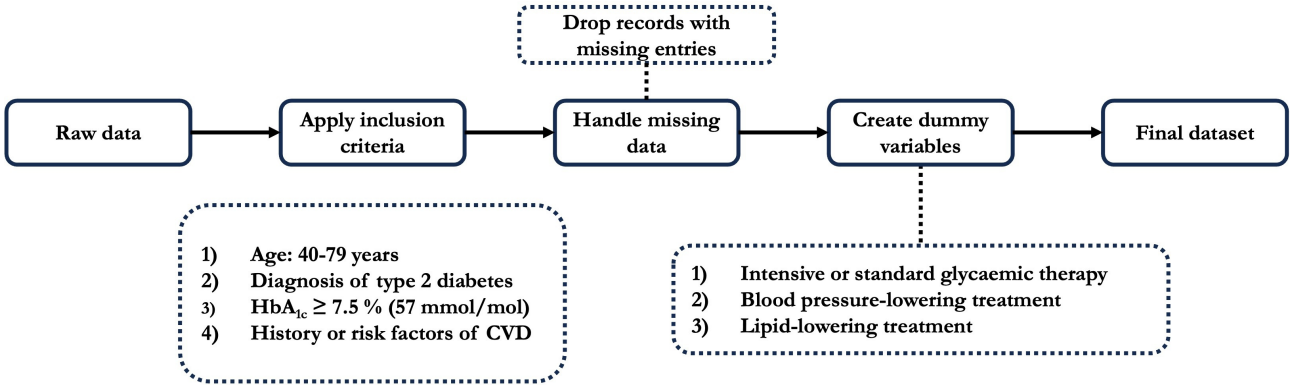
Methods

Overview

In this section, we first detail our study data and model development approach. Then, we describe our responsible framework for model assessment, selection, and explanation. This study is based on a secondary analysis of individual-level participant data from the Action to Control Cardiovascular Risk in Diabetes study (ACCORD 2001 - 09, NCT00000620) by the National Heart, Lung, and Blood Institute (NHLBI) of United States [15]. Our code repository is included in Multimedia Appendix 1.

Data

ACCORD (Action to Control Cardiovascular Risk in Diabetes) was a randomized, multicenter, double 2×2 factorial design study conducted at 77 clinical sites in North America. Participants were aged between 40 and 79 years, had T2D with a hemoglobin A1c (HbA_{1c}) ≥ 7.5% (57 mmol/mol), and had previous evidence of CVD or cardiovascular risk factors. (eg, dyslipidemia, hypertension, smoking, or obesity). The primary outcome of ACCORD was determined based on the first instance of a significant CVD event, which was characterized by a combination of nonfatal MI, nonfatal stroke, or cardiovascular death. We extracted demographic, clinical, and biomarker data collected at baseline (study entry) from individual participants across trials for model development.



XSL•FO
RenderX

Data Preprocessing

We focused on 2 primary CVD events, MI and stroke, as our study outcomes, and used patients' demographic data, clinical risk factors, medication history, and pertinent biomarkers as predictors. All predictor variables were collected at the time of study enrollment, ensuring that our models use information available at the point of care. We prepared the study outcomes as binary variables: patients either experienced MI or stroke within the 5-year period, or they did not. In other words, the interpretable machine learning models act as classification tools to identify if a patient is at risk of experiencing these CVD events in the next 5 years.

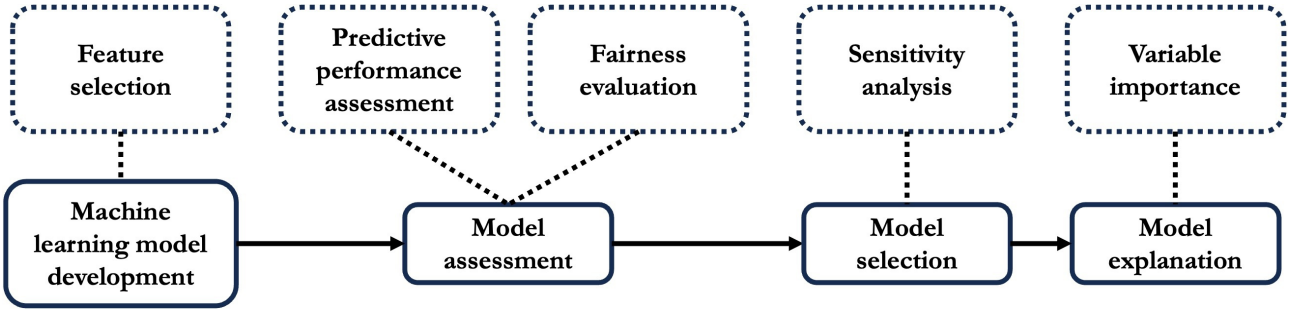
We sourced candidate predictor variables for fatal or nonfatal MI and fatal or nonfatal stroke outcomes from eligibility screening or clinical examination data in ACCORD after applying the inclusion criteria. These predictors encompass demographic characteristics, clinical factors, medication history, and relevant biomarkers. Complete case models were constructed using all predictor variables, without using imputation, as only 616 out of 10,251 observations (6%) in the dataset had missing values across any of the predictors. We dropped the records with missing data and applied one-hot encoding for categorical predictors to obtain the final dataset for model development [20]. Specifically, creating dummy variables involved transforming categorical variables, such as treatment type (eg, intensive vs standard glycemic therapy) and medication history (eg, blood pressure- or lipid-lowering treatments), into binary indicators via one-hot encoding [21]. This step ensured that the categorical data was appropriately formatted for model development. This data-preprocessing pipeline is outlined in Figure 1.

Figure 1. Data-preprocessing steps before model development.

Machine Learning Model Development

We developed several machine learning models to demonstrate our proposed framework for fairness-aware model assessment and selection. Our framework is specifically designed for scenarios where model development, selection, and deployment are treated as separate processes. The machine learning models we consider include interpretable models (eg, linear and tree-based), semi-interpretable models, (eg, random forest), and common statistical and machine learning models, (eg, naïve Bayes), for binary classification of MI and stroke. In the following paragraphs, we provide details of the models developed in this research and describe the model-tuning procedure.

We evaluated a range of machine learning models, including linear models (GLMnet and OFS), tree-based models (CART and OCT), ensemble models (random forest and XGBoost), and other traditional machine learning approaches (naïve Bayes and SVM). Linear and tree-based models are generally considered interpretable due to their structure and parameterization [22,23], while ensemble models and other methods can achieve strong predictive performance but may be less directly interpretable. OFS formulates the logistic regression with L2 penalties into a binary convex optimization problem and solves it to optimality. Within the OFS framework, there are 2 key parameters: the regularization parameter (balancing model complexity against accuracy) and the sparsity parameter (enhancing interpretability by controlling feature count) [24]. OCT derives the tree by optimizing the tree structure (size) and decision rules simultaneously via mixed integer optimization [25]. The main hyperparameters in OCT include the maximum depth of a tree, the minimum leaf size, and the complexity parameter, playing a crucial role in preventing overfitting, ensuring stability, and fostering interpretability. We limited the max depth of an OCT to 3 and 4 to enhance interpretability by simplifying the decision structure. We remark that OCT exactly recovers the optimal tree (given fixed hyperparameters) at the cost of additional computational complexity, whereas CART uses heuristic splitting rules in branching nodes to generate a decision tree quickly. Detailed descriptions of each model's structure, key hyperparameters, and training procedure are provided in Multimedia Appendix 2.



To build our models, we randomly divided our data using a 70 - 30 train-test split, using 6745 out of 9635 for training and the remaining 2890 out of 9635 for testing. Then, with the training data, we applied 10-fold cross-validation for hyperparameter tuning. We also found that our data were class-imbalanced, and there were very few occurrences of CVD events. To address this class imbalance, we adjusted the weight assigned to each label during our hyperparameter tuning. Each model's performance was estimated using both cross-validation on the training set and out-of-sample validation on the testing set.

Responsible Framework for Model Assessment, Selection, and Explanation

After building the machine learning models, it is desired to select a suitable model and investigate the relationship between predictors and the outcomes. In this section, we detail our responsible framework for model assessment, selection, and explanation. We outline this framework in Figure 2. Our proposed responsible framework consists of three main modules after model development: (1) model assessment, (2) model selection, and (3) model explanation. In the model assessment module, we assess each model's performance in their predictive capabilities and fairness. Then, a sensitivity analysis of the trade-off between these performance metrics is carried out to aid model selection. Finally, for model explanation, we use a unified approach that combines multiple methods to explain the best-performing models. We developed our proposed responsible framework with R language (v4.3.1, R Foundation) and the following R libraries: Interpretable AI (v3.2.1, Interpretable AI), survival (v3.5.5, Mayo Clinic), GLMnet (v4.1.8, Stanford University), rpart (v4.1.19, Mayo Clinic), naivebayes (v1.0.0), and kernlab (v0.9.32, TU Wien).

Figure 2. The proposed responsible framework for model assessment, selection, and explanation.

Model Assessment

In this module, we describe the model assessment procedure for the developed interpretable models according to their predictive performance and fairness. To evaluate predictive accuracy, we considered four metrics: (1) area under the receiver operating characteristic curve (AUC), (2) sensitivity, (3) specificity, and (4) accuracy. AUC evaluates a model's ability to distinguish between positive and negative classes, with higher values indicating better discriminative performance. It is particularly reliable for imbalanced data due to its threshold-independence. Sensitivity (true positive rate) measures the correct identification of actual positives (ie, patients developed MI or stroke), while specificity (true negative rate) assesses the correct identification of negatives. Accuracy quantifies the proportion of correct classification of the patients in the total cases examined. Sensitivity, specificity, and accuracy are threshold-dependent for models that output continuous scores (eg, predicted probabilities). Importantly, it is common to carefully select this classification threshold to optimize the model's predictive performance, with respect to these performance metrics for specific applications. To address this challenge, we set a threshold which maximizes a weighted metric combining sensitivity and specificity, that is, u×sensitivity+1-u×specificity. Here, the weight parameter u is bounded between 0 and 1, and higher (resp., lower) values of u indicate a preference towards thresholds that emphasize sensitivity (resp., specificity). This approach has also been used in previous research [26] . In CVD management, both sensitivity and specificity play important roles in correctly identifying patients who are at risk of MI or stroke, along with those who are at low risk of these outcomes. Because correctly identifying those at high risk of MI or stroke is critical to initiating clinical interventions, we specifically use a value of u=23 in our analysis – leaning slightly toward higher sensitivity over specificity. This approach ensures that we assess a balanced performance in identifying both patients at risk and with low risk while accounting for clinical priorities.

To evaluate the predictive fairness of the machine learning models, we consider a fairness metric, the relative performance parity score (RPPS), which is calculated by

$$\text{RPPS} := 1 - \max_s(|\text{AUC}_s - \text{AUC}_{\text{AUC}}|)$$

where s is a subpopulation in a protected attribute, eg, female in gender, and AUCs represents the conditional AUC conditioned on this subpopulation s. Notably, RPPS can be small when any subpopulation has disproportionally high or low AUC, compared with the overall AUC. On the other hand, if all subpopulations have AUC performance close to the overall AUC, then the RPPS will be large. We chose AUC as the primary metric because it is threshold-agnostic, providing a more comprehensive measure of model performance across different decision thresholds. Since this metric is a relative measure specific to each model's output, it is suitable for a fair comparison across models, which befits our purpose in the model assessment module of the proposed responsible model selection framework. Moreover, the RPPS is flexible and can accommodate other commonly used performance metrics, such as accuracy or sensitivity, depending on the specific goals of the fairness evaluation.

Model Selection

After evaluating the models, selection could be based on either predictive performance or fairness. Ideally, one would choose a model that excels in both dimensions. However, this selection process becomes challenging when no such model exists within the considered model options. To address this, we propose a sensitivity analysis-based approach to enhance model selection. Specifically, we evaluated the weighted sum of accuracy *and RPPS*, with the weight ranging from 0 to 1, that is, w(Accuracy)+(1−w)RPPS,

XSL•FO
RenderX

where w is the prespecified weight between 0 and 1. Notably, when the weight is 1, this weighted sum simplifies to accuracy; conversely, when the weight is 0, it becomes the RPPS. This approach enables model selection according to the trade-off between predictive performance and fairness.

Model Explanation

To investigate the relationship between the predictors and outcomes, we developed a synergistic model explanation approach that combines models' permutation variable importance, the SHAP method, and partial dependence plots. Notably, this explanation module does not establish clear causal relationships between features and adverse health outcomes; however, it helps clarify how the ML algorithms function for decision-making. Permutation variable importance assesses model explainability through feature significance [27]. That is, it measures the impact of each feature on a model's predictive performance by shuffling the values of a feature while keeping others constant. We can then determine that feature's importance based on the resulting performance decline, as measured by AUC. To enhance the reliability of our estimates, we bootstrapped 100 iterations: in each, we sampled the training data, trained a model, computed a baseline AUC, and determined permutation importance scores. This yielded multiple score sets for each bootstrapped sample. We then averaged the feature importance and provided 95% CIs. Features were ranked by mean importance and variability. A high mean importance means the model heavily depends on that feature, whereas high variability indicates inconsistent significance. Therefore, features with high variability warrant further examination, while those with high importance and low variability are consistently crucial.

Another component in our model explanation is the SHAP method. Essentially, SHAP assigns an importance measure, known as the Shapley value, to each feature. This Shapley value is calculated by averaging the differences in the model's predictions with and without the feature across all possible subsets of features, which can be viewed as the expected effects of the feature on the prediction. Importantly, the sum of all Shapley values equals the prediction value to ensure consistency across all features. The Shapley value effectively captures the average marginal contribution of each feature, providing a comprehensive explanation of the model's behavior. For interpretability, we proposed to use the relative Shapley value (the marginal contribution of each feature relative to the prediction value) in our analysis.

To further visualize and understand the relationship between features and predicted outcomes, we also consider Partial Dependence plots as another explanation method. Partial Dependence plots are widely used and show how changing a feature value affects model outputs, by fixing all other features [28]. This explanation method is chosen over the SHAP's built-in dependence plot function because Partial Dependence plots tend to be more intuitive in clinical settings [29]. Specifically, when creating a partial dependence plot, we replace the value of a feature with values in its range to compute average model outputs on this feature's range across data samples. In our analysis, in addition to risk predictions, we used log odds as model outcomes to provide a better interpretation of features and outcomes. In essence, a positive log-odds value indicates a higher likelihood of the event occurring, a negative value indicates a lower likelihood, and a value of zero represents a 50% probability. We made the necessary adjustments for categorical and continuous features and included data distribution information to bolster the reliability of our analysis. This approach enables us to pinpoint areas where the model's output is robustly supported by data, as well as identify regions where predictions may be less dependable due to data scarcity.

We stress that both permutation variable importance and the SHAP method can provide broader insights into the overall effects of specific features on model outputs. Partial dependence plots, on the other hand, provide a detailed visualization to uncover the direct relationship between each feature and the predicted outcome. By integrating permutation variable importance, the SHAP method, and partial dependence plots, we deliver a holistic model explanation for users. This synergy enhances interpretability and trust in the model's predictions, making the analysis more actionable in clinical settings.

Ethical Consideration

This study was approved by the Institutional Review Board at the Georgia Institute of Technology under Protocol No. H22333. All participants in the ACCORD trial provided written informed consent. The ACCORD contained de-identified data only. Participants in the ACCORD trial were not paid for their participation.

Results

Study Sample

Our study data included 9635 participants, with 616 (6% of the total 10,251) excluded due to missing data on predictor variables (Table 1). The mean (SD) age was 62.8 (6.7) years. Women made up 3,662 (38%) of the sample. The racial and ethnic make-up of our study data included 1834 (19%) non-Hispanic Black participants, 678 (7%) Hispanic or Latino participants, and 7123 (74%) non-Hispanic White participants. In addition, 3437 (36%) of participants had a history of CVD. The mean (SD) body mass index was 32.2 (5.4) kg/m^2, systolic blood pressure was 136.5 (17.1) mm Hg, and diastolic blood pressure was 74.9 (10.7) mm Hg. Of the sample, 880 (9.1%) experienced an MI, and 197 (2%) had a stroke during the follow-up period.

Predictive Performance

The predictive accuracy of our machine learning models is summarized in Table 2.

Table . Summary of predictive performance for machine learning models predicting risk of myocardial infarction and stroke, optimizing thresholds for 23×Sensitivity+13×Specificity.

Machine learning model	AUC	Sensitivity	Specificity	Accuracy
MI[a]				
OCT	0.687	0.782[b]	0.554	0.565
Naïve Bayes	0.694	0.563	0.768[b]	0.420
Random forest	0.716[b]	0.746	0.640	0.645
SVM	0.581	0.711	0.436	0.450
XGBoost	0.695	0.782	0.554	0.565
GLMnet	0.704	0.629	0.666	0.664[b]
OFS	0.705	0.671	0.642	0.644
Stroke				
OCT	0.625	0.771	0.546	0.550
Naïve Bayes	0.703	0.694	0.708	0.708
Random forest	0.716	0.510	0.839[b]	0.833[b]
SVM	0.624	0.816[b]	0.426	0.568
XGBoost	0.714	0.653	0.735	0.734
GLMnet	0.700	0.625	0.715	0.714
OFS	0.731[b]	0.646	0.716	0.715

[a]MI: myocardial infarction.

[b]The best-performing model for each performance metric.

For classification of MI, the OCT model achieved the highest sensitivity at 0.782 with a specificity of 0.554 and AUC of 0.687. Random forest achieved the highest AUC at 0.716, with a sensitivity of 0.746, moderate specificity (0.640), and accuracy (0.645). XGBoost shows similar characteristics, with an AUC of 0.695, sensitivity matching OCT at 0.782, but lower specificity (0.554) and accuracy (0.565). GLMnet, despite its lower sensitivity (0.629), has a high AUC of 0.704 and the best specificity (0.666) and accuracy (0.664) among the models. Naïve Bayes, while exhibiting lower sensitivity (0.563), has the highest specificity (0.768), though an accuracy of 0.420.

For stroke classification, our results indicate that naïve Bayes provides the most balanced results across AUC (0.703), sensitivity (0.694), specificity (0.708), and accuracy (0.708). On the other hand, the Random forest model, despite having a lower sensitivity, achieves a high AUC (0.716) and the highest specificity (0.839), along with an accuracy of 0.833 – indicating its strong performance in correctly identifying non-stroke cases at the expense of missing some stroke cases. Similarly, XGBoost performs exceptionally well on AUC (0.714), accuracy (0.734), and specificity (0.735), with a low sensitivity (0.653). In contrast, the OCT model has the second-lowest AUC (0.625) and accuracy (0.550), indicating it may be the least effective model for stroke prediction. This lower performance suggests that OCT might not be suitable for accurate stroke prediction compared with the other models considered.

Fairness

In Table 3, we present AUC stratified by gender and race across all of the developed interpretable machine learning models for MI and stroke classification, along with the RPPS scores for gender and race. The conditional AUC on each subgroup is calculated by classification results in the test set.

XSL•FO

[a]AUC: area under the curve.

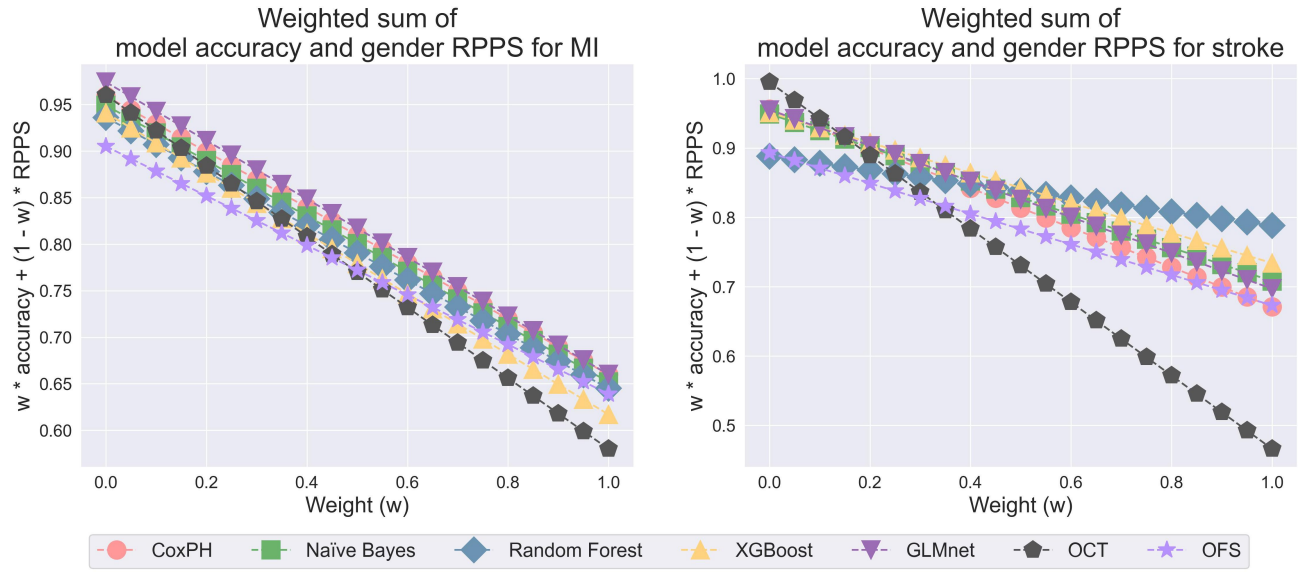
[b]RPPS: Relative Parity of Performance Scores.

[c]MI: myocardial infarction.

[d]The best-performing model for each performance metric.

For MI classification, besides the SVM, which has the lowest RPPS (0.838), the random forest model shows a substantial disparity in AUC between men (0.673) and women (0.760), resulting in a lower RPPS (0.939), which indicates higher gender disparities. Similarly, XGBoost exhibits a high AUC for women (0.753) compared with men (0.655), leading to an RPPS of 0.917, further highlighting the model's performance gaps across genders. On the other hand, the GLMnet and OCT model demonstrate the highest RPPS (0.979), suggesting minimal performance disparities between Black (0.681) and White (0.706) subgroups for GLMnet, and Black (0.710) and White (0.682) subgroups for OCT. In contrast, the random forest model shows greater differences in performance by race with an AUC of 0.770 for non-Hispanic Black people and 0.704 for non-Hispanic White people, resulting in a lower RPPS (0.925). Importantly, for most models, the RPPS scores indicate fairer results among race groups, compared with gender, for predicting MI events.

For stroke classification, the XGBoost model exhibits a significant difference in AUC between men (0.773) and women (0.645), resulting in a lower RPPS (0.903), highlighting pronounced differences in predictive accuracy by gender. Similarly, the random forest model, with a high AUC for men (0.783) compared with women (0.673), leads to an RPPS of 0.906. Conversely, the XGBoost model shows a relatively high RPPS (0.983), implying minimal performance differences between non-Hispanic Black (0.718) and non-Hispanic White (0.702) people. However, the naïve Bayes model demonstrates greater differences by race with an AUC of 0.733 for non-Hispanic Black people and 0.629 for non-Hispanic White people, resulting in a lower RPPS (0.895). Importantly, in contrast to our findings in MI classification tasks, the RPPS scores reveal better performance parity among gender groups compared with racial groups in classifying stroke events.



We also analyzed the coefficients of the one-hot encoded gender and race variable for GLMnet. For the variable "female=1", coefficient values were -0.324 in the model for MI and -0.250 in the model for stroke, suggesting that women are associated with a lower predicted risk of MI and stroke compared with men. For race, the variable "black=1" had a coefficient value of -0.192 in the model for MI, which indicates a lower predicted risk of MI for non-Hispanic Black people compared with non-Hispanic White people. For stroke, the model does not provide a coefficient for this predictor, indicating it was not significant in this context. These findings highlight the potential disparities in model predictions based on demographic factors, emphasizing the need to consider these variables when developing and evaluating predictive models in CVD classification.

XSL•FO
RenderX

Model Selection

We applied our model selection approach to identify the most preferable predictive models for MI and stroke classification. From our analyses, we have found that these models can exhibit higher disparities across gender subgroups, compared with race. Consequently, alongside overall predictive performance (overall accuracy), we incorporated gender RPPS scores into our model selection criteria. The weighted sum of accuracy and RPPS for MI and stroke classification among all machine learning models is presented in Figure 3. Recall that, when the weight is selected to be 0, this weighted sum represents RPPS; and when the weight is 1, it represents accuracy. For MI classification, the GLMnet model consistently demonstrated the highest values across most weights, indicating its superior balance of accuracy and fairness (Gender RPPS). This is particularly evident as the weight approaches 0, with a gender RPPS of 0.974. On the other hand, for stroke classification, the best-performing model varies across different weights. At lower weights (0 to 0.2), the OCT model showed the highest values due to its strong Gender RPPS. As the weight increases, the GLMnet model starts to dominate from the weight is 0.25 to 0.6, maintaining a good balance between accuracy and Gender RPPS. Moving to higher weights (0.65 onwards), the random forest model outperformed others, with its accuracy dominating the performance at around 0.788. These results indicated that, for stroke classification, when users prioritize model fairness, the OCT model is the best. For users who are neutral regarding the tradeoff between fairness and accuracy, GLMnet emerges as a suitable option. Lastly, random forest is recommended for users with a strong preference for model accuracy. Accordingly, we assumed users want to balance accuracy and fairness and proceed to analyze the relationship between variables and outcomes using GLMnet for both MI and stroke classification.

Figure 3. Weighted sum of model accuracy and gender Relative Parity of Performance Scores for myocardial infarction and stroke. MI: myocardial infarction; RPPS: Relative Parity of Performance Scores.

Model Explanation

We analyzed the relationship between features and outcomes for predicting MI and stroke using GLMnet, with our synergistic model explanation approach that integrates the permutation variable importance, the SHAP method, and the partial dependence plots. Figures 4 and 5 display the permutation variable importance measures, along with their 95% CIs, and the SHAP method for the GLMnet model in predicting MI and stroke, respectively. In addition, partial dependence plots for GLMnet for MI and stroke are shown in Figures 6 and 7, respectively.

XSL•FO
RenderX

Figure 7. Partial dependence plots for GLMnet on stroke classification.

From Figure 4, we observe that the permutation variable importance technique highlights the history of CVD (cvd_hx_baseline) as the most critical predictor for GLMnet to accurately predicting MI risks. Notably, its mean importance value (0.078) is nearly twelve times greater than that of the second most important variable, age (baseline_age), which has a mean importance value of 0.006. Moreover, while the 95% CIs of the permutation importance for CVD history is (0.045, 0.107), which is among the widest in the feature space, its lower confidence interval is still higher than the upper confidence interval of any other features. These results imply the significant role of people's CVD history to make accurate classification using GLMnet. In addition, BMI, and insulin treatment (insulinrx) also rank highly in this importance metric, with mean importance values of 0.002 and 0.0013, respectively. Some variables show negative values in permutation importance, which could be related to overfitting. Since the negative values are small in magnitude in our case, it could be that the model has relied too heavily on noise rather than true signal for those predictors. Now, from the SHAP method, we observed that the history of CVD and age emerge as the 2 most influential features in driving GLMnet's MI classification, as indicated by their average relative Shapley values of 0.45 and 0.14, respectively. This suggests that these 2 features have a general tendency to positively contribute to the prediction value. However, the individual relative Shapley values for the features can widely range from negative to positive, reflecting the varying marginal contributions of the features across individuals. For example, it appears that the distribution of the relative Shapley values for CVD history is a mixture of 2 highly separated distributions, which again implies that the GLMnet is substantially sensitive to CVD history. Furthermore, our findings indicate that although insulin treatment is highlighted as one of the top features in permutation variable importance, its mean relative Shapley value is relatively low compared with other features. Conversely, HbA_{1c} ranks highly using the SHAP method. Since both insulin treatment and HbA_{1c} are indicative of an individual's diabetic status, this suggests that accurately predicting MI also heavily depends on the diabetes status of the individual. Consequently, we next analyze the partial dependence plots for CVD history, age, and HbA_{1c} to draw actionable insights.

The partial dependence plots in Figure 6 illustrate that individuals with a history of CVD can have log odds of 0.87 (risk of 0.7), while those without CVD can have log odds as low as −1.94 (risk of 0.13). In addition, the plots show that 44-year-old individuals in the test set have log-odds of −0.44 (risk of 0.4) for developing MI. As age increases to 79 years, the risk gradually rises to log-odds of −0.33 (risk of 0.42). Furthermore, the plots reveal that HbA_{1c} levels significantly impact risk: with HbA_{1c} as low as 4.6%, the log-odds are −0.94 (risk of 0.3), but as HbA_{1c} rises to 12.7%, the log-odds increase drastically to 0.55 (risk of 0.61). These results highlight the importance of considering both CVD history and key biomarkers such as HbA_{1c} in assessing MI risk. Notably, although partial dependence plots do not necessarily reveal causation between features and risks, the steep increase in risk associated with higher HbA_{1c} levels underscores the critical role of diabetes management in preventing MI.

Next, we conduct a model explanation analysis for GLMnet in predicting stroke. As shown in Figure 7, HbA_{1c}, systolic blood pressure (SBP), and heart rate (HR) have the highest mean permutation importance values (0.08, 0.06, and 0.01, respectively). Other significant features include serum creatinine (screat), age, and BMI. These features exhibit wide confidence intervals for their permutation importance values, suggesting that their influence on the model can vary depending on the patient cohort. Moreover, HbA_{1c} and SBP consistently show the highest positive marginal contributions to risk predictions, with average relative Shapley values of 0.28 and 0.26, respectively. Heart rate, with a relative Shapley value of 0.05, is also a significant predictor for stroke using GLMnet. Although there are instances where these features negatively contribute to risk prediction, their relative Shapley values are predominantly positive. This distribution indicates a general tendency for these features to positively drive the predicted values, highlighting their crucial role in the model's stroke risk

XSL•FO
RenderX

predictions. Since these features are essential for accurately assessing stroke risk, we now derive actionable insights from the partial dependence plots (Figure 7).

The partial dependence plots in Figure 7 provide visualizations of how HbA_{1c}, systolic blood pressure, and heart rate influence stroke classification using the GLMnet model. We noticed that all 3 features exhibit a clear positive relationship between them and the predicted risk of stroke. For HbA_{1c}, as levels increase from 5.5% to 13%, there is a noticeable rise in both log-odds and predicted risk, moving from around −0.95 to 0.94 in log-odds and from 0.28 to 0.71 in predicted risk. For systolic blood pressure, the log-odds of developing stroke can reach 1.01 from −1.05 and from 0.26 to 0.725 in predicted risk as systolic blood pressure increases from 88 mm Hg to 212 mm Hg. Notably, the rate of increase in stroke risk with rising systolic blood pressure is less steep compared with the rate observed with increasing HbA_{1c} levels. Finally, the log-odds of developing stroke can reach 0.41 from -0.61 and from 0.35 to 0.59 in predicted risk as heart rate increases from 39 bpm to 132 bpm. Comparatively, the rate of increase in risk with heart rate is the most moderate among these features. This indicates that managing HbA_{1c} and systolic blood pressure could be more effective in preventing stroke. Overall, our model explanation analyses highlight the importance of managing blood glucose levels, blood pressure, and heart rate to mitigate the risk of stroke.

Discussion

Principal Findings and Comparison With Previous Works

In this study, we designed a responsible framework that evaluates various machine learning models by comparing these models' predictive accuracy and fairness metrics, while also providing model explanation. We then applied this framework for classification of MI and stroke, demonstrating its effectiveness in highlighting the importance of in-depth analyses of interpretable machine learning models between these 3 dimensions.

Our results demonstrate that complex models are not necessarily always better than simple, interpretable models—especially for high-stakes decisions such as those encountered in medicine [30]. Importantly. while the investigation of predictive accuracy have been a focus of several previous studies in health care AI, the concurrent evaluation of fairness in machine learning models is inconsistent and lacking [12]. The fairness analysis of our predictive models reveals both strengths and areas of concern in terms of gender and racial bias. In MI prediction, while some models like the SVM and XGBoost demonstrate gender biases, others such as GLMnet and OFS models show more balanced performance across gender and racial groups. This indicates that the most accurate models are not necessarily the fairest, and vice versa. These trade-offs highlight the importance of carefully selecting and tuning models to balance accuracy and fairness in medical decision-making. For stroke prediction, while some models, that are, GLMnet and SVM, exhibit balanced performance for both gender and race, other models, that are, XGBoost, present bias for a gender. This finding highlights the complex nature of fairness in such models, where different types of biases may manifest depending on the outcome being predicted and the model used. These findings underscore the importance of continuously monitoring and evaluating models for fairness. Our study provides a comprehensive analysis of fairness across different models and conditions, paving the way for more equitable AI applications in health care.

While there are multiple important criteria for model selection, such as predictive performance and fairness, a unified approach to guide this selection process is lacking. To address this, our analysis presents a sensitivity analysis based selection procedure based on users' preferences over the selection criteria. Our findings suggest that in some prediction tasks, users' preferences have minimal effect on the best-performing model (eg, GLMnet for MI prediction). However, in other tasks, for example, stroke prediction, users' preferences can significantly influence the selected model. Our study highlights the necessity of considering user preferences in model selection to ensure optimal outcomes for different prediction tasks.

Finally, our study demonstrates the potential role that our integrated explanation method (ie, the combination of permutation variable importance, the SHAP method, and partial dependence plots) can play in enhancing clinicians' understanding and trust of model-based predictions. For instance, the permutation variable importance measures, the Shapley values and partial dependence plots provide a clear visual representation of how key features like HbA_{1c} and systolic blood pressure influence the model's risk prediction for MI and Stroke. Such visual explanations can provide actionable insights and be augmented with existing clinical knowledge to help validate the quality of model-generated risk estimates [31]. These visualizations can also help clinical experts explain the unknown complex relationships between various risk factors and adverse outcomes [32].

This study has some limitations. The proposed framework was tested solely on CVD classification using the ACCORD dataset. While it has shown promise in this context, its effectiveness in other disease areas needs further investigation. Moreover, we relied on baseline information collected at the start of the study for model development and did not fully account for how things can change over time in the real world. Looking ahead, we would like to make sure our models stay accurate and up to date as treatment strategies and clinical guidelines evolve. One way to do this is by applying our framework on more recent datasets or on data that captures changes over time. These steps could give us a better understanding of how changing clinical practices might affect prediction modeling.

Conclusions

In this research, we proposed a 3-stage responsible framework for developing, selecting, and explaining machine learning models, emphasizing the trade-off between predictive accuracy and fairness in health care applications. By quantifying this trade-off using AUC and RPPS, we provided a structured approach to responsible model selection. After selecting the final model, we proposed an integrated explanation method to

XSL•FO
RenderX

offer insights into the relationships between features and outcomes. Applying this framework to predict MI and stroke among people with T2D, we demonstrated its effectiveness and potential to improve the development and evaluation of machine learning models for clinical practice. We anticipate that our framework is generalizable and can be applied to other clinical prediction tasks, potentially increasing the trustworthiness and acceptance of machine learning models among clinicians and patients.

Our framework highlights the importance of combining interpretability, explainability, and fairness in building, selecting, and explaining machine learning models. This integration is crucial not only for enhancing model performance [33], but also for addressing ethical and legal considerations [34]. These principles both help verify model results against clinical literature [35], and fosters acceptance and trust among health care stakeholders [36,37]. By fully embracing these aspects, our framework paves the way for more responsible, ethical, and transparent AI applications in health care.

Acknowledgments

This work was supported by the AIM-AHEAD Coordinating Center, funded by NIH. This manuscript was prepared using the ACCORD Clinical Research Materials obtained from the NHLBI Biologic Specimen and Data Repository Information Coordinating Center and does not necessarily reflect the opinions or views of the ACCORD or the NHLBI.

The authors would like to thank Dr. James Washington from the Morehouse School of Medicine for his insightful feedback on earlier versions of the manuscript.

This research was further supported by Georgia Institute of Technology, Texas A&M University, Emory University, AIM-AHEAD Coordinating Center, award number OTA-21-017, and was partially funded by the National Institutes of Health Agreement No. 1OT2OD032581.

MBW and FJP received funding from the Georgia Center for Diabetes Translation Research under Award No. NIH/NIDDK P30DK111024. YY received funding from the Georgia Tech Presidential Undergraduate Research Award.

Data Availability

The datasets analyzed during this study are available in the BioLINCC repository under Accession Number: HLB01041317a, ClinicalTrials.gov Identifier: NCT00000620

Authors' Contributions

GPG and EK conceptualized the research in this manuscript and supervised its execution. YY and CL led the data curation and formal analysis with input on data sources from FJP, MBW, and HS. GPG, EK, and HS led the funding acquisition. GPG directed the methodological approach with significant input from EK, CL, and HS. GPG, EK, and HS were responsible for project administration and resources. YY and CL developed and implemented the code used for model development and numerical validation. FJP, MBW, and HS provided significant input on the clinical interpretation of results. YY and CL generated all tables and figures in the manuscript. Manuscript writing was led by YY, CL, EK, and GPG with significant input from FJP, MBW, and HS. All authors reviewed the manuscript.

Conflicts of Interest

FJP reports research support from Dexcom, Insulet, Novo Nordisk, Tandem and Ideal Medical Technologies and consulting for Dexcom and Medscape. All other authors have no competing interests to report.

Abstract

Background: Cytomegalovirus (CMV) reactivation in patients with severe ulcerative colitis (UC) leads to worse outcomes; yet, early detection remains challenging due to the reliance on time-intensive biopsy procedures.

Objective: This study explores the use of deep learning to differentiate CMV from severe UC through endoscopic imaging, offering a potential noninvasive diagnostic tool.

Methods: We analyzed 86 endoscopic images using an ensemble of deep learning models, including DenseNet (Densely Connected Convolutional Network) 121 pretrained on ImageNet. Advanced preprocessing and test-time augmentation (TTA) were applied to optimize model performance. The models were evaluated using metrics such as accuracy, precision, recall, F_1-score, and area under the curve.

Results: The ensemble approach, enhanced by TTA, achieved high performance, with an accuracy of 0.836, precision of 0.850, recall of 0.904, and an F_1-score of 0.875. Models without TTA showed a significant drop in these metrics, emphasizing TTA's importance in improving classification performance.

Conclusions: This study demonstrates that deep learning models can effectively distinguish CMV from severe UC in endoscopic images, paving the way for early, noninvasive diagnosis and improved patient care.

(JMIR Med Inform 2025;13:e64987) doi:10.2196/64987

KEYWORDS

cytomegalovirus; ulcerative colitis; deep learning; endoscopy; classification

Introduction

Cytomegalovirus (CMV) reactivation is frequently observed in patients with severe ulcerative colitis (UC) [1,2]. A multicenter, prospective Korean study found CMV infections in 43% of patients with moderate to severe UC and 67% in those with steroid-refractory UC [3]. Such reactivation often leads to poorer prognoses compared with patients without CMV reactivation, increasing the risk of hospitalization due to UC exacerbation by 8.2 times [4,5]. Antiviral therapy for CMV has been shown to substantially reduce the need for colectomy in patients with severe UC and high-grade CMV infection [6,7]. The American College of Gastroenterology guidelines indicate that CMV superinfection can progress to severe UC, which is resistant to maximum immunosuppressive therapy, necessitating histological analysis through sigmoidoscopy and viral culture for diagnosis [8].

Accurate diagnosis of CMV infection in UC remains critical due to its implications for treatment and prognosis. CMV infection in UC can be diagnosed using blood tests or tissue biopsies. While blood tests are relatively simple and cost-effective, they have limitations in differentiating past or latent infections from active disease. In contrast, tissue biopsies obtained through sigmoidoscopy or colonoscopy provide a more definitive diagnosis but require an invasive procedure. To enhance diagnostic accuracy, targeted biopsies should be taken

XSL•FO
RenderX

from both the ulcer base and margins, with McCurdy et al [9] suggesting at least 11 biopsy specimens to achieve over 80% sensitivity. However, collecting multiple specimens increases the risk of bleeding and other complications.

Histopathological techniques used for CMV diagnosis in UC include hematoxylin and eosin (H&E) staining, immunohistochemistry (IHC), and tissue DNA PCR (polymerase chain reaction). H&E staining identifies characteristic cytomegalic cells with nuclear inclusions and has high specificity (92% - 100%) but variable sensitivity (10% - 87%) due to observer dependency. IHC, which detects immediate early antigens of CMV, improves sensitivity (78% - 93%) while maintaining high specificity (92% - 100%). Tissue DNA PCR is the most sensitive (92% - 97%) and specific (93% - 99%) diagnostic tool, but its availability is limited in some institutions, leading to reliance on IHC or H&E staining, potentially delaying diagnosis and treatment [10]. Given the importance of early antiviral intervention in severe UC, diagnostic delays may contribute to adverse clinical outcomes, including increased risk of total colectomy.

Differentiating between severe UC and CMV using endoscopic features presents a challenge [11-13]. Accurate diagnosis of CMV reactivation necessitates techniques like in situ detection of viral markers via specific IHC or nucleic acid amplification [14]. However, these tissue-based diagnostic methods often require several days for results, causing delayed treatment for immunocompromised patients requiring swift intervention. The lag in obtaining tissue biopsy outcomes can pose substantial clinical challenges, notably in CMV reactivation within patients with severe UC. This diagnostic waiting period impedes timely clinical decision-making, potentially exacerbating the patient's condition. In immunocompromised individuals like those with severe UC, any delay in initiating appropriate therapy can lead to disease progression, heightened morbidity, and even mortality [15,16]. The imperative for prompt intervention underscores the need for more immediate diagnostic approaches.

With the advancement of artificial intelligence (AI), a promising avenue emerges to expedite the diagnosis of CMV reactivation in patients with severe UC [17]. By analyzing complex data patterns and integrating with existing diagnostic methodologies, AI technologies could potentially reduce the time needed to identify CMV reactivation from days to hours. This acceleration in diagnosis would enable health care providers to administer antiviral therapy sooner, potentially improving patient outcomes by reducing the risk of complications and the need for more invasive treatments like colectomy. Furthermore, the application of AI in this diagnostic process could provide a more nuanced understanding of disease progression, facilitating a more tailored approach to treating and managing patients with severe UC and CMV reactivation.

While numerous studies have documented the endoscopic characteristics of CMV infection in UC, none have yet reported on AI systems for distinguishing severe UC from CMV [11-13]. A similar study conducted in 2021 developed a machine learning–based classifier to differentiate CMV from herpes simplex virus esophagitis [18]. This AI system used logistic regression with the least absolute shrinkage and selection operation to discriminate between the 2 conditions, demonstrating 100% sensitivity, specificity, accuracy, and an area under the curve (AUC) of 1.0. The system's predictive model, using the categorization of endoscopic features and history of transplantation, achieved a high accuracy of 92.6% in distinguishing CMV from herpes simplex esophagitis.

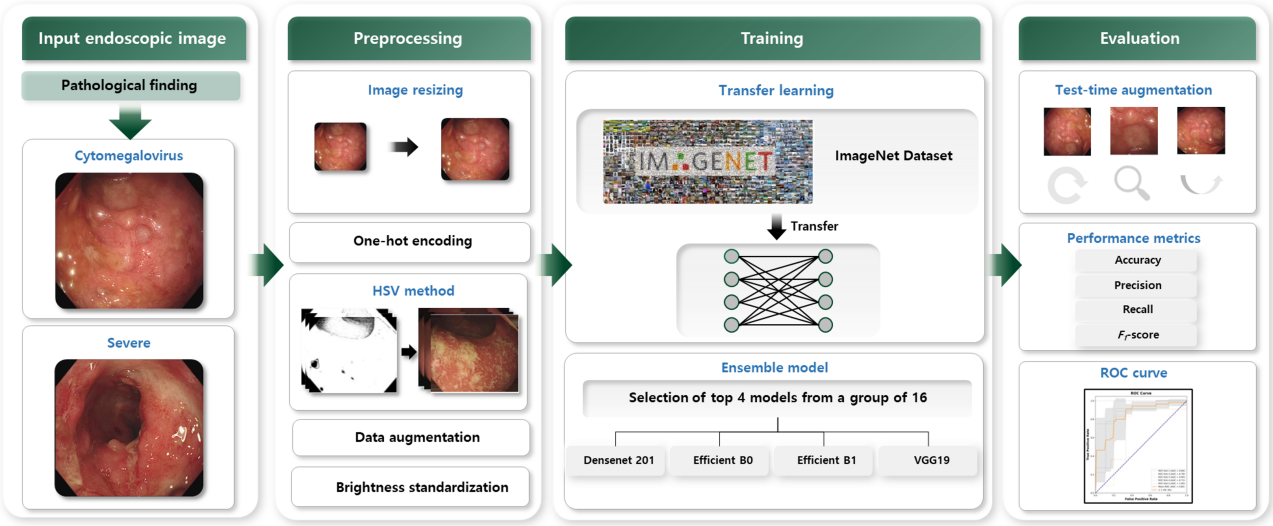
Other viral infections, such as herpes simplex virus, are comparatively rare among patients with UC and do not pose the same level of severe complications and management challenges as CMV reactivation [19-21]. Hence, while it remains imperative to differentiate between CMV and herpes simplex virus infections in patients with UC, accurate diagnosis of CMV infection associated with UC holds heightened clinical significance. This is primarily because CMV has the potential to instigate severe exacerbations of UC and progress to a state of severe UC that proves refractory to standard immunosuppressive therapies [22]. The application of AI technology to swiftly make these distinctions could facilitate the prompt initiation of appropriate interventions, thereby enhancing patient outcomes and mitigating the adverse consequences linked with treatment delays [23].

Numerous studies have reported the remarkable efficacy of AI systems in medical imaging. Various techniques have been proposed to augment and measure ensemble diversity [24]. Recent ensemble studies in medical imaging have demonstrated notable enhancements through multiview approaches, diverse preprocessing methods, and varied network architectures [25,26]. Deep ensemble learning models amalgamate the advantages of deep learning models and ensemble learning to enhance the overall generalization performance of the final model [24]. Consequently, this study aims to address morphological inaccuracies that impede fully automated quantification using deep learning models and to introduce ensemble methods to improve the discrimination of CMV infection in UC.

In the context of endoscopic imaging, predominantly single models have been used. However, discerning CMV infection within UC poses a challenging task, prompting a shift toward various ensemble techniques. Distinguishing these infections through visual inspection demands highly skilled physicians, and even then, the difficulty can vary substantially based on the experience level. This study aims to surpass existing network frameworks by incorporating advanced techniques to enhance the discrimination of CMV infections using deep ensemble learning methods. The rationale behind this approach is to leverage the diverse insights and robustness provided by an ensemble of models, thus overcoming the limitations of single-model approaches and substantially improving the accuracy and reliability of CMV detection in severe UC through endoscopic images [27].

Countless studies have showcased the remarkable prowess of AI systems in medical imaging [28-31]. Techniques for augmenting and measuring ensemble diversity have been put forth, with recent ensemble studies in medical imaging demonstrating notable enhancements via multiview approaches, diverse preprocessing techniques, and varied network architectures [32]. By amalgamating the advantages of both

XSL•FO
RenderX



deep learning and ensemble learning, deep ensemble learning models have exhibited improved generalization performance. Thus, this study aims to address morphological errors impeding fully automated quantification using deep learning models and to propose ensemble methods to enhance the discrimination of CMV infection in UC.

Methods

Overview

We conducted a thorough analysis of 86 endoscopic images capturing cases of UC, both with and without CMV complications. Before feeding these images into our models, they underwent extensive preprocessing. This phase encompassed standardization for data normalization and augmentation to enhance dataset variability and robustness. We used models pretrained on the extensive ImageNet dataset for the analysis, which is renowned for its diverse image range. Our approach entailed an ensemble of 4 distinct models to leverage their strengths. To further bolster the reliability and accuracy of our predictions, we integrated test-time augmentation (TTA) during the evaluation phase [33]. The effectiveness of this ensemble was evaluated using a range of performance metrics meticulously selected to comprehensively assess the classification performance of our model ensemble, ensuring a comprehensive understanding of its ability to distinguish between cases of with and those without CMV complications (Figure 1).

Figure 1. Illustration of the study process: preprocessing endoscopic images of patients with ulcerative colitis with and without cytomegalovirus, applying an ensemble of pretrained models for analysis, using standardization, augmentation, and test-time augmentation to enhance prediction accuracy, and evaluating performance using selected metrics to distinguish between severe ulcerative colitis cases with and without cytomegalovirus complications. HSV: hue, saturation, value; ROC: receiver operating characteristic.

Data Collection

We retrospectively reviewed the medical records and endoscopic images of all patients diagnosed with severe UC between February 2019 and December 2022. The severity of UC was assessed using the Mayo Clinic scoring system [34]. The patients included in this study had Mayo Clinic scores ranging from 8 to 12. The presence of CMV was defined as follows: (1) serologic detection of CMV immunoglobin M antibody or (2) histologic detection of inclusion bodies on H&E-stained sections, positive immunohistochemical staining, or CMV DNA amplification by PCR at the first or second evaluation for CMV. Patients were excluded according to the following criteria: coinfection with *Clostridium difficile* and CMV, final pathologic diagnosis of malignancy, or missing information on endoscopic findings. The entire dataset was amassed from a cohort of 34 patients and incorporates endoscopic images sourced from Seoul and Mokdong Hospital of Ewha Womans University Medical Center. Using standardized 8-bit color depth endoscopy systems, specifically the CV-290 (Olympus) at Seoul Hospital, and the CF-Q260AL, CF-H260AL, and CF-HQ290L (Olympus) at Mokdong Hospital, the dataset comprises a total of 86 images (Table 1). This compilation comprises 32 images of CMV cases and 54 images of severe UC, devoid of CMV involvement.

Table . Dataset information and classification based on histological diagnosis through tissue biopsy.

Index	Severe-UC[a] without CMV[b]	Severe-UC with CMV
Sex, n		
Male	10	9
Female	11	4
Age (y)		
Mean (range)	51.9 (21-81)	35.4 (12-69)
Median (IQR)	55.5 (41.8-67.2)	34 (25.3-43.6)
Number of images[c] (CMV, Severe-UC)	54	32

[a]UC: ulcerative colitis.

[b]CMV: cytomegalovirus.

[c]Sampling date: February, 2019-December, 2022.

The resolutions of the dataset were 576×768, 576×720, and 1242×1079 pixels. To ensure the reliability and precision of pathological annotations, each image underwent meticulous analysis based on the consensus findings from tissue biopsies conducted on the patients. Furthermore, 2 experienced pathologists independently reviewed the biopsy results, and their expert opinions were used to annotate each image. In cases where the initial assessments of the pathologists varied, a collaborative review was undertaken to achieve a consensus for the annotations of each image.

Preprocessing

The endoscopic images were resized to 244×244 pixels to ensure compatibility with transfer learning and standardized for quality across institutions. They underwent hue, saturation, value (HSV) color space transformation, artifact management, data augmentation, pixel value normalization, and one-hot encoding to improve model efficiency and consistency.

Image Preprocessing and Standardization

To prepare for the application of transfer learning from deep learning models pretrained on the ImageNet dataset, the endoscopic images were resized to a resolution of 244×44 pixels. This resolution is essential to ensure compatibility with the architectures of these pretrained networks, as they require consistent input dimensions.

Given the multi-institutional nature of this research, the endoscopic images were acquired using different endoscopy systems across the participating institutions. To address the variability in image quality parameters, such as brightness and intensity, a meticulous standardization process was implemented for each image. This step proved crucial in normalizing differences resulting from the varied settings and conditions of the endoscopic equipment. Consequently, we ensured systematic adjustment of any discrepancies in image quality, thereby preserving the consistency of the dataset and enhancing the homogeneity of visual information before analysis by the deep learning model. Such standardization facilitates a more reliable comparison and analysis of the images, indispensable for the robust performance of the deep learning model.

Transformation to HSV Color Space

The images transformed HSV color space to more accurately represent the color distribution and enable effective discrimination between tissue types. Targeted ranges within the HSV color space were defined to standardize the color representation across all images. Furthermore, control mechanisms were implemented to mitigate the influence of artifacts that could affect the model's performance, such as light reflection and dark areas [35]. To effectively address these artifacts, we established HSV ranges corresponding to them and generated mask images to identify these areas.

Inpainting Technique

The empty spaces in the mask were filled using an inpainting technique [36]. The inpainting algorithm can follow a model such as:

$$I(p)=\sum q\in B(p)w(p,q)\cdot[I(q)+\nabla I(q)\cdot(p-q)]\sum q\in B(p)w(p,q),$$

where $I(p)$ represents the intensity of the pixel to be inpainted, $I(q)$ denotes the intensity of a neighboring pixel, and $\nabla I(q)$ signifies the gradient at pixel q. The weighting function $w(p,q)$ diminishes with distance, thereby amplifying contributions from closer and more similar pixels, and thereby preserving the natural continuity of biological structures. This approach minimizes errors caused by artifacts and enhances the diagnostic value of the endoscopic images. $I(p)$ is the color intensity of the point to be inpainted. This equation considers the intensity $I(q)$ and gradient $\nabla I(q)$ at nearby known points q, using a weighting function $w(p,q)$ that accentuates contributions from points directionally aligned with the original image's isophotes. The weighting function is derived from 3 critical components, directionality, distance, and level set distance, ensuring smooth integration of the inpainting with the surrounding image content. The fast-marching algorithm efficiently processes pixels based on their proximity to the initial boundary, facilitating rapid and consistent restoration of the damaged image areas.

Data Augmentation

We implemented various data augmentation techniques to enhance the model's generalization capabilities and replicate real-world variations observed in endoscopic images. These techniques encompassed rotating images across a full 360-degree range to simulate different viewing angles, applying a 15%

XSL•FO
RenderX

zoom to simulate variations in image size, shifting the width and height by 20% to introduce positional variations, and shearing by 15% to emulate stress distortions in tissue views. Furthermore, horizontal flipping was used to mitigate orientation biases, and the "reflect" filling mode was used to preserve image integrity during these transformations, ensuring a more comprehensive training process.

Pixel values were normalized to a range of (0, 1) to ensure consistency in data input, which is essential for the model's effective learning. In addition, one-hot encoding was used to convert categorical labels into a binary matrix format, a crucial step for enabling the model to handle binary-class classification tasks efficiently (Figure 2).

Figure 2. Hue, saturation, and value color space transformation and artifact management in endoscopic images for enhanced diagnostic accuracy.

Training Setup

The dataset was divided into training and validation sets in an 8:2 ratio. Input data labeling was based on pathology data, which was considered the gold standard for our classification tasks. Furthermore, 5-fold cross-validation was used to assess single models' performance within the ensemble. This technique partitions the training dataset into 5 subsets, using each subset iteratively for validation while the remaining data serves as the training set.

Deep Learning Model

We used a comprehensive ensemble of 16 deep learning models, carefully selected based on their proven effectiveness in image classification tasks, particularly in medical imaging. Each model was constructed using PyTorch (Linux Foundation) and initialized with pretrained weights from the ImageNet dataset. This transfer-learning approach, where a model is pretrained on a large dataset and subsequently fine-tuned for a specific task, is a well-established strategy in medical imaging and has demonstrated substantial efficacy.

Our selection encompassed DenseNet (Densely Connected Convolutional Network), EfficientNet, ResNet, VGG (Visual Geometry Group), Inception, and Vision Transformer architectures, incorporating diverse feature extraction techniques to ensure a comprehensive evaluation of different deep learning methodologies. By leveraging the advanced feature extraction capabilities gained through pretraining on the large-scale and diverse ImageNet dataset, our primary objective was to enhance classification accuracy for endoscopic images. This diversified ensemble approach allowed us to systematically assess each model's strengths and optimize performance through ensemble learning.

In our study, we implemented patch-based learning to analyze endoscopic images, wherein each of our network models was trained on segmented sections of the images for a more targeted approach. The parameters used in this fine-tuning process are outlined in Table 2, offering a comprehensive overview of the configurations used to optimize our deep learning models for analyzing intricate characteristics of endoscopic images.

Table . Hyperparameter configurations for fine-tuning deep learning models on endoscopic images.

Hyperparameters	Networks

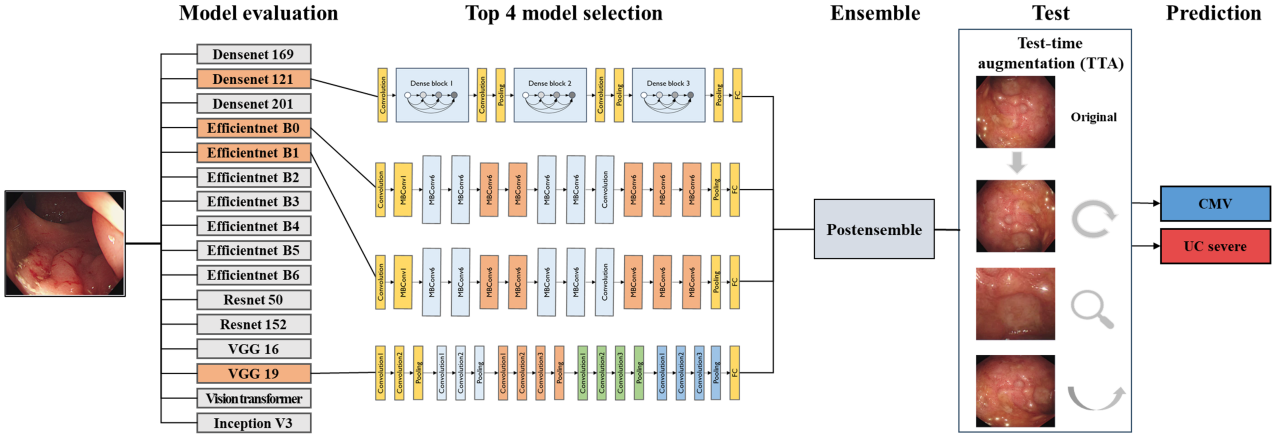
[a]DenseNet: Densely Connected Convolutional Network.

[b]VGG: Visual Geometry Group.



We used He normal initialization and the Adam optimization algorithm to further enhance the performance of our deep learning models. The He normal initialization, also known as Kaiming initialization, was specifically selected for its

XSL•FO
RenderX

effectiveness in preserving the variance of the input distributions across layers in deep neural networks, a critical aspect when dealing with complex image data such as endoscopic images. This initialization method addresses the vanishing and exploding gradient issues commonly encountered in training deep architectures, promoting a more stable and efficient optimization process. In addition, we used the Adam optimization algorithm for its adaptive learning rate capabilities, which are crucial for navigating the intricate optimization landscapes inherent in deep learning tasks. Adam combines the benefits of 2 other extensions of stochastic gradient descent—AdaGrad and RMSProp—to adjust the learning rate during training dynamically. This adjustment is based on estimates of lower-order moments of the gradients, facilitating more rapid and effective convergence of our models to the optimal solution.

The top 4 models were selected from a pool of 16 based on their F_1-score, as it is a representative metric that balances precision and recall. In medical image analysis, maintaining a balance between false positives and false negatives is crucial, making the F_1-score a clinically reliable selection criterion. These models were subsequently integrated using a soft-voting ensemble technique, further augmented with TTA to enhance prediction reliability and accuracy (Figure 3). We used an averaging approach to derive the final prediction in the soft-voting procedure. Soft voting was chosen as the optimal ensembling strategy because the models exhibited similar performance, and there was no specific reason to assign higher confidence to any particular model [37,38]. By aggregating the predicted probabilities from multiple models, soft voting provides a more refined decision boundary and yields more stable predictions compared with majority voting. In addition, in the case of weighted voting, adjusting the weights did not result in significant performance improvements over soft voting, and equally incorporating all models through soft voting proved to be the most effective approach. Conversely, TTA involves applying minor variations to the input data during testing, thus providing a more comprehensive evaluation of the model's performance across diverse conditions. For TTA, we implemented techniques such as horizontal and vertical flips, random adjustments in brightness contrast (±20%), and scaling (30%). These augmentations played a pivotal role in optimizing the predictive capabilities of our system in the challenging realm of endoscopic image analysis, facilitating the introduction of diverse variations and thereby bolstering the model's ability to generalize and perform consistently across varying imaging scenarios.

Figure 3. Ensemble deep learning framework for classifying severe ulcerative colitis and cytomegalovirus lesions from endoscopic images. The framework consists of multiple deep learning models pretrained on ImageNet and fine-tuned for the specific classification task. Single model outputs are ensembled to enhance overall classification accuracy. Test-time augmentation, including rotations, zooming, and flipping, is used to ensure robustness against variations in clinical data before making the final prediction. CMV: cytomegalovirus; UC: ulcerative colitis; VGG: Visual Geometry Group.

In addition, we evaluated ensemble models comprising 2 and 3 models, both with and those without the implementation of TTA. This extensive analysis enabled us to compare the efficacy of varying ensemble sizes and evaluate the impact of TTA on their predictive prowess, specifically emphasizing the averaged soft-voting technique used in tandem with TTA.

Loss Function

For the binary classification task, the sigmoid activation function was selected for its capability to effectively map input values to a probability distribution ranging from 0 to 1, thereby generating probabilities indicating whether a given input pertains to one class or the other. This made it particularly suitable for discerning between the 2 classes in our study. Complementing this selection, categorical cross-entropy was used as the loss function, given its capacity to quantify the disparity between the predicted distribution and the true distribution of outcomes, which is relevant for binary classification tasks. Categorical cross-entropy measures the difference between the actual label and the predicted probability distribution across classes, thereby furnishing a robust metric for optimizing the model's performance. By minimizing this loss function, the model is incentivized to adjust its parameters to enhance its predictions' accuracy, aligning the predicted class probabilities as closely as possible with the ground truth labels.

Evaluation

We evaluated the performance of ensemble models consisting of 2, 3, and 4 models, both with and without applying TTA. In addition, we assessed the performance of single models.

The assessment used key evaluation metrics, including accuracy, precision, recall, and F_1-score, providing comprehensive insights into each model's classification performance. In addition, 95%

XSL•FO
RenderX

CIs were computed for all evaluation metrics to ensure statistical reliability. The following definitions outline these metrics:

Accuracy=Tp+TnTp+Tn+Fp+Fn

Precision=TpTp+Fp

Recall=TpTp+Tn

F1−score=2·precision·recallprecision+recall

Furthermore, we assessed the diagnostic capabilities of the models through receiver operating characteristic (ROC) curves and their corresponding AUC. These evaluations enabled us to analyze the trade-offs between true positive and false positive rates, as well as to quantify the overall diagnostic accuracy of each model configuration.

To ensure statistical robustness, 95% CIs were computed using 300 bootstrap resampling iterations for all evaluation metrics, including ROC and AUC. This approach enhances the reliability of the performance assessment by providing more stable and generalizable CIs across different evaluation metrics.

Ethical Considerations

The study was approved by the institutional review board (IRB EUMC 2023-11-009, SEUMC 2023-09-017).

Results

The performance results of both single models and ensemble model combinations are outlined in Table 3. A comprehensive evaluation of various single models was conducted. DenseNet 121, EfficientNet B0, EfficientNet B1, and VGG 19 stood out for their superior performance, ranking in the top quartile within a cohort of 13 models. Performance metrics, including accuracy, precision, recall, and F_1-score, were recorded along with their 95% CI. DenseNet 121 exhibited exceptional diagnostic reliability for severe UC conditions, achieving an accuracy of 0.792 (95% CI 0.776 - 0.808), a precision of 0.821 (95% CI 0.805 - 0.837), a recall of 0.876 (95% CI 0.859 - 0.893), and an F_1-score of 0.836 (95% CI 0.820 - 0.852). EfficientNet B0 demonstrated substantial capability in identifying true positives, with a recall of 0.824 (0.809 - 0.839), supported by an accuracy of 0.736 (95% CI 0.720 - 0.752), a precision of 0.765 (95% CI 0.746 - 0.784), and an F_1-score of 0.784 (95% CI 0.768 - 0.800). EfficientNet B1 contributed to reducing false positives, achieving a precision of 0.759 (95% CI 0.742 - 0.776), an accuracy of 0.681 (95% CI 0.660 - 0.702), a recall of 0.709 (95% CI 0.692 - 0.726), and an F_1-score of 0.738 (95% CI 0.720 - 0.756). Despite a lower accuracy of 0.660 (95% CI 0.635 - 0.685), VGG 19 played a key role in positive case identification, with a precision of 0.707 (95% CI 0.690 - 0.724), a recall of 0.745 (95% CI 0.729 - 0.761), and an F_1-score of 0.729 (95% CI 0.710 - 0.748).

Table . Average performance metrics with confidence intervals of the top 4 single models and test-time augmentation ensemble models.

Model	Accuracy (95% CI)	Precision (95% CI)	Recall (95% CI)	F_1-score (95% CI)

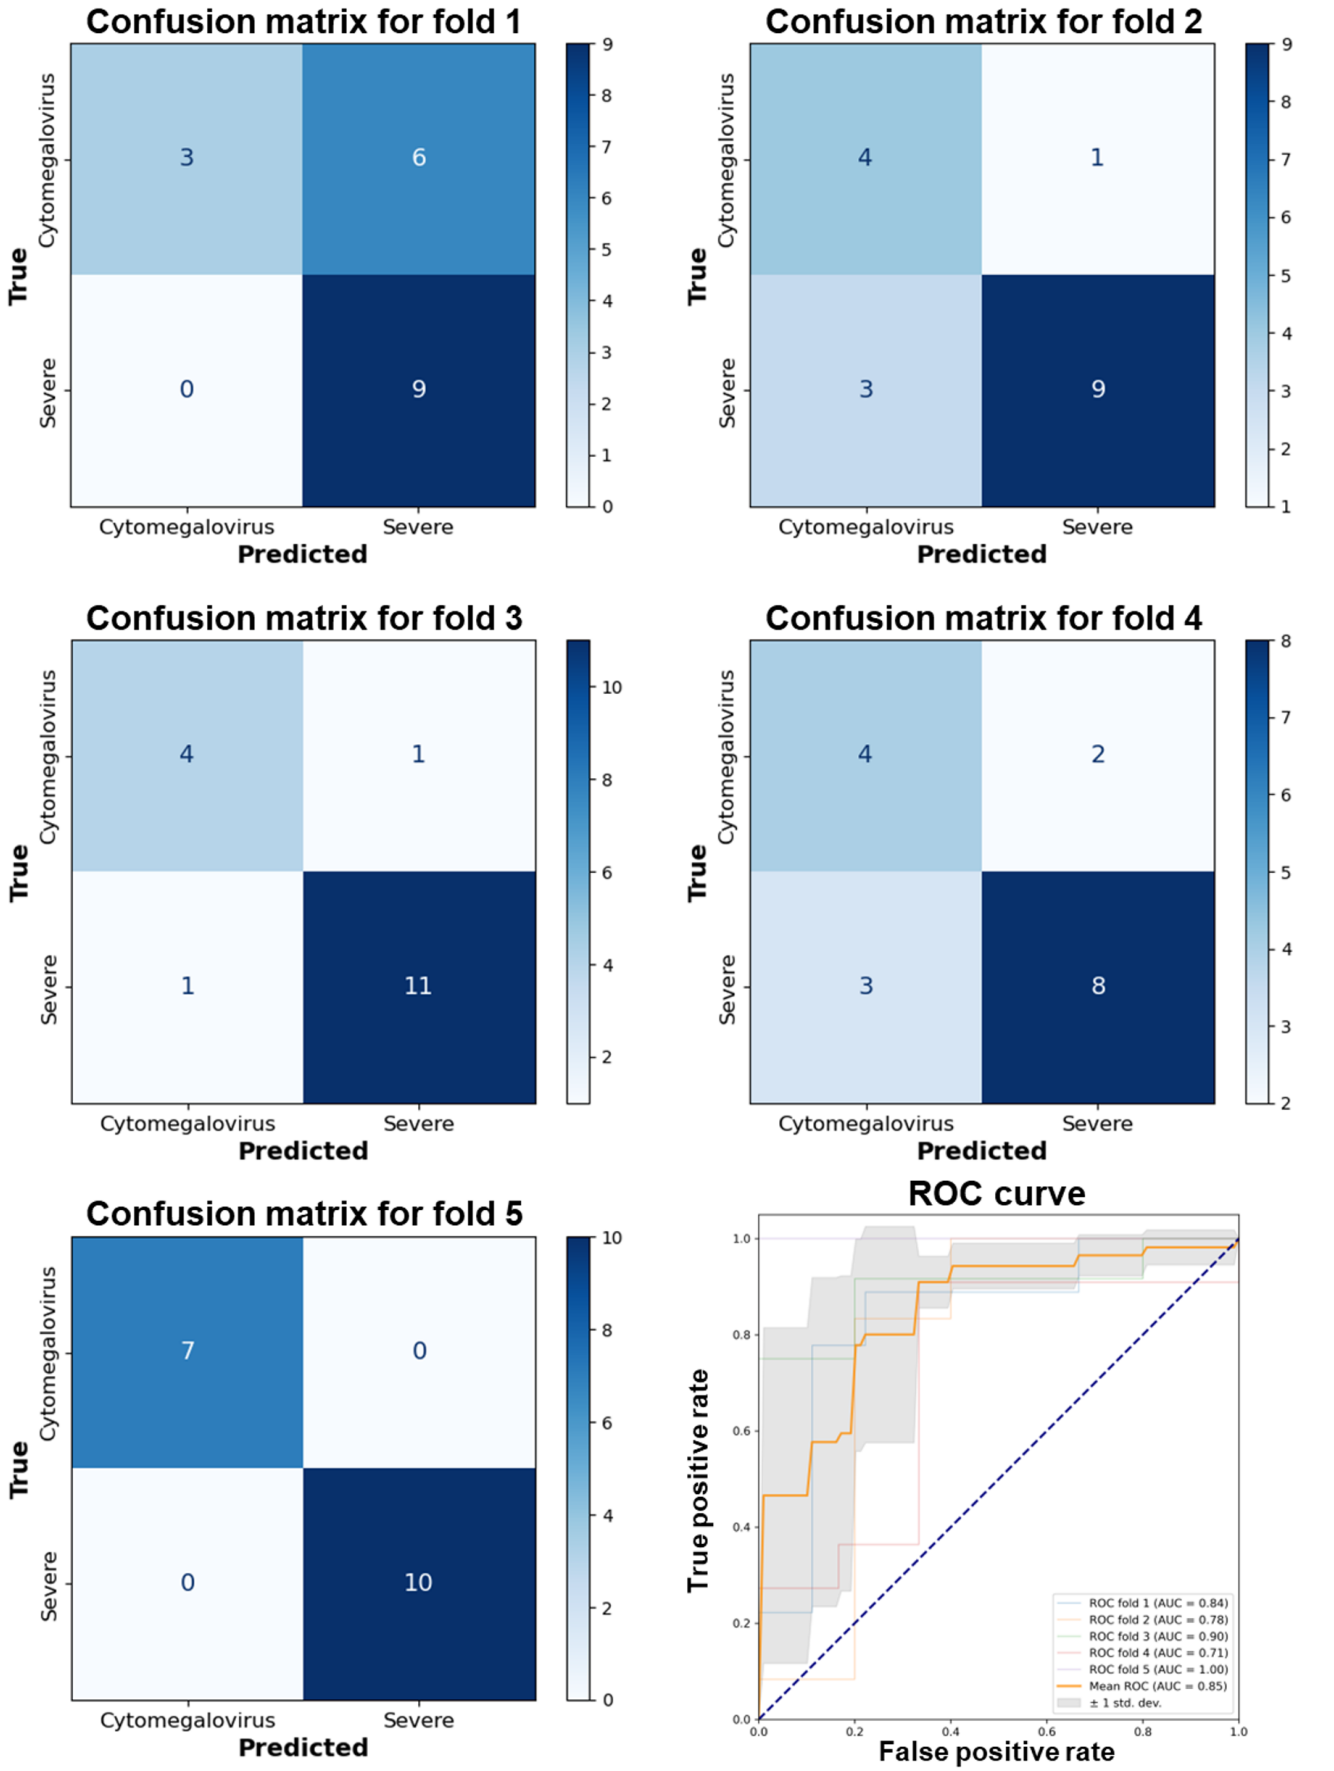
[c]TTA: test-time augmentation.



Further analysis using ROC curves and the AUC metric provided additional insights into model performance, demonstrating a long-term high true positive rate against a lower false positive rate, indicative of robust diagnostic capabilities. DenseNet 121 consistently exhibited an average AUC of 0.846 (SD 0.100) across folds (Figure 4). Meanwhile, EfficientNet B0 and B1 also displayed excellent classification abilities, with average AUCs of 0.796 (SD 0.098) and 0.838 (SD 0.107), respectively (Figures 5 and 6). VGG 19, while presenting an average AUC of 0.730 (SD 0.115), showcased instances of high performance,

XSL•FO
RenderX

particularly in folds where it achieved an AUC as high as 0.920 (Figure 7). However, a discrepancy was observed in the model's performance through confusion matrix analysis; all models accurately identified severe UC conditions but exhibited inconsistency in identifying CMV conditions (Figures 4-7). This inconsistency was particularly evident for DenseNet 121 and EfficientNet B0, highlighting the need for improvement. These findings indicate that single models may encounter limitations when distinguishing CMV.

Incorporating the TTA technique into the ensemble model approach proved pivotal in addressing these classification challenges. The ensemble of 4 models augmented with TTA demonstrated remarkable efficacy in classifying endoscopic images of UC. The ensemble achieved an accuracy of 0.836 (95% CI 0.824 - 0.848), a precision of 0.850 (95% CI 0.832-0.868), a recall of 0.904 (95% CI 0.890 - 0.918), and an F_1-score of 0.875 (95% CI 0.860 - 0.890), indicating high reliability and balanced classification capabilities. Other ensemble configurations also yielded noteworthy results. The ensemble of 3 models with TTA exhibited precision of 0.814 (95% CI 0.801 - 0.828), while the ensemble of 2 models with TTA demonstrated recall of 0.832 (95% CI 0.818 - 0.846) and F_1-score of 0.794 (95% CI 0.778 - 0.810), indicating effective identification of true positive cases. Conversely, ensemble models without TTA showed a noticeable decline in performance metrics, with the ensemble of 4 models without TTA achieving an accuracy of 0.709 (95% CI 0.692 - 0.726), a precision of 0.691 (95% CI 0.675 - 0.707), a recall of 0.716 (95% CI 0.700 - 0.732), and an F_1-score of 0.752 (95% CI 0.737 - 0.767). These results emphasize the significant role of TTA in enhancing classification performance and improving model generalization in distinguishing CMV from severe UC.

The ROC curves reveal discernible patterns in model efficacy attributable to integrating TTA and the amalgamation of models within the ensemble (Figure 8). The ensemble of 4 models enhanced with TTA is particularly noteworthy, demonstrating the most pronounced diagnostic proficiency, with an AUC of 0.927 (95% CI 0.881 - 0.949). This signifies superior diagnostic performance and a high true positive rate compared with the false positive rate. Despite a reduction in ensemble size, the ensemble comprising 3 models, with TTA implementation, maintains robust performance, as evidenced by an AUC of 0.826 (95% CI 0.738 - 0.872). Conversely, the ensemble of 2 models with TTA displays a relatively inferior AUC of 0.698 (95% CI 0.618 - 0.750).

Figure 8. Receiver operating characteristic curves for endoscopic image classification models: (**A**) ensemble of 4 models with test-time augmentation, (**B**) ensemble of 3 models with test-time augmentation, (**C**) ensemble of 2 models with test-time augmentation, (**D**) ensemble of 4 models without test-time augmentation, (**E**) ensemble of 3 models without test-time augmentation, and (**F**) ensemble of 2 models without test-time augmentation. AUC: area under the curve; ROC: receiver operating characteristic.

In setups without TTA, there is generally a decrease in ensemble performance. The ensemble of 4 models without TTA achieves an AUC of 0.760 (95% CI 0.663 - 0.809), confirming the efficacy of the ensemble approach even with a slight drop in effectiveness. Interestingly, a 3-model ensemble without TTA exhibits a slightly higher AUC of 0.775 (95% CI 0.677 - 0.824), indicating a particularly effective combination of models. Conversely, the pair of models without TTA demonstrates the most notable decrease in performance, with an AUC of 0.693 (95% CI 0.611 - 0.747), underscoring the significance of TTA in enhancing model performance and the benefits of larger ensembles for diagnostic accuracy.

Discussion

Principal Findings

The study underscores substantial advancements in medical diagnostics, particularly in gastroenterology, facilitated by applying deep learning technology. This research distinguishes itself by using an ensemble of deep learning models, including DenseNet121, EfficientNet B0, EfficientNet B1, and VGG 19, to differentiate between severe UC and CMV infection using endoscopic images. By leveraging an ensemble approach, this study not only improves classification performance but also demonstrates the clinical applicability of deep learning in distinguishing between these 2 conditions.

XSL•FO
RenderX

The evaluation of single models revealed their limitations in identifying CMV, highlighting the need for a more comprehensive approach. This insight underscores the utility of the TTA ensemble technique in discerning CMV infections and accurately classifying severe UC from endoscopic images. Furthermore, this approach indicates the potential to surmount the constraints of single-model methodologies and enhance diagnostic accuracy in complex medical image classification tasks. The ability to overcome the constraints of single-model methodologies and enhance diagnostic accuracy in complex medical image classification tasks is a crucial advancement in this field. These findings suggest that integrating deep learning into clinical workflows can significantly improve real-world diagnostic processes.

The ensemble of 4 models with TTA achieved remarkable performance in classifying endoscopic images of severe UC, with an accuracy of 0.836 (95% CI 0.824 - 0.848), precision of 0.850 (95% CI 0.832 - 0.868), recall of 0.904 (95% CI 0.890 - 0.918), and F_1-score of 0.875 (95% CI 0.860 - 0.890). These results indicate high reliability and balanced performance, reinforcing the ensemble's ability to deliver accurate and consistent diagnoses. The improved diagnostic accuracy can have a direct impact on clinical decision-making, reducing diagnostic errors and enabling timely intervention.

The distinction between CMV and severe UC through endoscopic images has been a topic in previous research [11-13]. Although specific endoscopic features can differentiate these 2 conditions, the differences are often subtle and require meticulous observation. Features, such as severe ulcers, punched-out ulcers, geographical ulcers, and spontaneous bleeding, can be crucial in differentiating certain diseases [12]. However, identifying these features through conventional observation methods is often challenging. Applying the ensemble model with TTA represents a substantial advancement in this context [39]. It stands out as the first initiative to harness the capabilities of deep learning or machine learning for this purpose. The insights derived from the AUC values and the corresponding ROC curves are pertinent. The ensemble method enhanced by TTA underscores the potential of deep learning in medical diagnostics. When integrated into clinical workflows, these advanced models have the potential to substantially enhance patient care by enabling more precise and accurate diagnoses, thereby laying the groundwork for improved patient outcomes and marking a noteworthy advancement in health care technology.

To further contextualize these advantages in clinical practice, deep learning models can contribute to reducing interobserver variability, which is a critical challenge in medical imaging. By providing consistent and objective assessments, AI-driven diagnostic tools can complement physician expertise, particularly in resource-limited settings where access to highly experienced endoscopists may be restricted. In addition, AI-powered systems can expedite the diagnostic process, enabling real-time or near-instantaneous assessments that facilitate prompt therapeutic interventions. These improvements translate into enhanced patient management, reduced hospital stays, and minimized complications associated with diagnostic delays.

Furthermore, integrating AI-based diagnostic models into real-time clinical decision support systems could significantly enhance their clinical utility. Future research should explore embedding these AI models into endoscopic software or electronic health record systems. This integration could provide real-time diagnostic support to gastroenterologists, improve the efficiency of the diagnostic process, and facilitate quicker treatment decisions. Ultimately, this could become a key factor in enhancing the overall quality of patient care.

A substantial limitation identified during the research process was the occurrence of false negatives in the validation phase [40]. These findings underscore the necessity for further adjustments to improve the model's sensitivity, particularly in medical diagnostics, where distinguishing between similar conditions, such as CMV and UC, is critical. False negatives can cause delayed or inappropriate treatment, negatively impacting patient outcomes [41]. To address this, future studies should incorporate advanced augmentation techniques to enhance model sensitivity while maintaining specificity. In addition, exploring hybrid AI approaches that combine deep learning with rule-based algorithms could further refine diagnostic accuracy [42,43].

Another limitation is the lack of datasets; the data used in this study were limited in scope and quantity, thus constraining the generalizability and reliability of the model. As with other studies using proprietary datasets, our research also faces challenges in generalization, as the model was trained on a specific dataset. However, it is important to note that endoscopic imaging, compared with other imaging modalities, exhibits relatively minimal variation across different manufacturers due to its reliance on optic imaging rather than quantitative imaging [44]. This consistency helps maintain uniformity in image quality, which can positively impact AI model training and application.

Nevertheless, to address these generalization limitations, future research endeavors aim to mitigate these challenges by acquiring more diverse and extensive data through collaboration with multiple institutions. Multi-institutional data collection and incorporating various patient populations will enhance the model's robustness and ensure its applicability across different clinical settings. Incorporating data gathered from various patient groups and regions will enhance the model's generalization capability and facilitate the development of more reliable diagnostic tools [45]. Such collaborative efforts across multiple institutions are essential for augmenting the accuracy and reliability of the model.

This study uses deep learning technology to introduce a novel approach to medical diagnostics, particularly in gastroenterology. As the first to use deep or machine learning in distinguishing between severe UC and CMV, it heralds new possibilities in medical diagnostics. Implementing deep learning, notably the ensemble model with TTA, facilitates rapid, noninvasive, and remarkably accurate diagnostic techniques. These holds promise for substantially enhancing patient experience compared with conventional diagnostic approaches,

XSL•FO
RenderX

resulting in time and resource savings and diminishing the necessity for unnecessary invasive procedures. Such methodologies alleviate patient discomfort and risk, expediting treatment decisions.

Conclusion

This study marks a significant advancement in medical diagnostics by leveraging deep learning, specifically an ensemble model with TTA, to differentiate between severe UC and CMV infections using endoscopic images. While our findings demonstrated high accuracy, precision, and recall, the model's reliance on a specific dataset may limit its generalizability, necessitating further validation in diverse clinical settings. By introducing a streamlined, noninvasive, and accurate approach, this research highlights the potential of AI-driven diagnostics in gastroenterology while underscoring the need for further refinement to enhance clinical applicability.

Abstract

Background: Understanding and improving patient care is pivotal for health care providers. With increasing volumes of the Friends and Family Test (FFT) data in England, manual analysis of this patient feedback poses challenges for many health care organizations. This underscores the importance of automated text analysis, particularly in predicting sentiments and themes in real time.

Objective: Leveraging machine learning and natural language processing, this study explores the utility of a supervised algorithm to systematically test and refine the algorithm's cross-contextual performance in diverse health care settings, addressing variations in population characteristics, geographical locations, and care settings, ultimately driving improvements based on patient feedback.

Methods: The text analytics algorithm initially developed in a large acute trust in London was further tested in 9 health care organizations with diverse care settings across England. These trusts varied in technical capacity and resource, population demographics, and FFT free text datasets. Testing and validation of the algorithm were performed, including manual coding of a subset of retrospective comments. Technical infrastructure, including coding environments and packages for algorithm testing and deployment, was optimized. The algorithm was iteratively trained using bag of words from anonymized data, tailored to accommodate contextual variations, and tested for change in algorithm performance while simultaneously rectifying issues identified.

Results: The algorithm demonstrated satisfactory overall accuracy (>75%) in predicting themes and sentiments embedded within free-text responses across a variety of care settings and population demographics. While the algorithm yielded strong and reusable models in relatively stable environments, such as adult inpatient care settings, the initial accuracy was notably lower in organizations providing services such as pediatrics and mental health. However, the accuracy of our algorithm significantly improved when individual trust coding templates were applied. Thematic saturation was reached after the fifth organization was recruited, and no further coding was required for the last 4 organizations. Subsequently, a framework and pipeline for deployment of the algorithm were developed to provide a standardized approach for implementation and analysis of FFT free text, ensuring ease of use.

Conclusions: This study represents a significant step forward in leveraging free-text FFT data for valuable insights in diverse health care settings through the testing and development of a robust supervised learning text analytics algorithm. The disparity in some care settings was anticipated, given that the lexicon and phraseology used was inherently different from those prevalent in adult inpatient care (where the algorithm was developed). However, these challenges were addressed with further coding and testing. This approach enhanced the accuracy and reliability of the algorithm, encouraged inter- and intraorganizational collaboration, and shared learning.

Introduction

Insights into patients' experience of their care provision are critical for health care providers delivering patient-centered care and recognized as integral to ensuring safe and high-quality care [1]. By the end of 2019, the national survey for patient experiences in the United Kingdom, known as the Friends and Family Test (FFT), had accumulated 75 million pieces of feedback [2]. This number continues to grow by about 1.3 million every month, making it the largest source of patient opinions worldwide. However, manually analyzing this vast amount of data requires a considerable resource, something that many health care organizations struggle to provide [3,4]. In recent years, there has been an ever-clearer desire for improvement to arise from patient feedback rather than just focusing on response rates, but most health care organizations are constrained from doing so due to a lack of analytical expertise [5].

Automated text analysis by artificial intelligence (AI) and its component natural language processing (NLP) predicts sentiments and themes within free-text responses in real time and provides a useful opportunity for better integrating patient experience feedback into everyday health care delivery [4]. NLP algorithms offer a practical solution to decode the "why" behind patient narratives, and through their ability to process large volumes of data accurately, these patient-derived insights can inform "business as usual" within health care organizations [6,7]. Recent advances in NLP, particularly the development of large language models and transformer-based architectures such as BERT [8] and GPT [9], have significantly improved the analysis of patient feedback in health care. These models replace traditional hand-coded, framework-based categorization [10] methods by automating the classification of concerns and providing decision-makers with real-time, comprehensive summaries of emerging themes. Large language models, through multi-label text classification [11], enable the extraction of deeper insights from patient experience comments, enhancing the understanding of the patient journey and informing actions that can improve care. Transformer-based models such as BERT [8,12] and GPT excel at capturing complex linguistic patterns, context, ambiguity, and sentiment, making them particularly well-suited for the nuanced task of sentiment analysis in health care. These advancements allow for more accurate, context-aware analysis of patient feedback, driving more actionable insights and supporting continuous improvements in patient care.

BERT and GPT models are large and resource-intensive [13]. They require significant computational power and memory, which may not be feasible in all health care settings, especially those with limited information technology (IT) infrastructure. This can make them less practical for real-time applications or for use in smaller organizations with fewer resources. Due to their size and complexity, transformer models can be slower to process compared to more lightweight models such as support vector machines (SVMs). In real-time health care applications where speed is crucial for timely interventions, this delay may be a significant drawback.

We have previously demonstrated the benefit of applying NLP using SVM to free-text FFT data to deliver patient-driven quality improvement in a single institution [14]. This study demonstrates the broader implementation and iteration of this algorithm in different hospital settings in England that use FFT to capture patient feedback.

Methods

Study Design

The implementation of the FFT free-text algorithm demands thorough testing to ensure robustness, accuracy, and applicability. To iterate the algorithm for deployment in other health care services, we first selected health care organizations that would incorporate geographical variables, patient demographic variables, and different care settings, that is, adult inpatient, primary care, community, pediatrics, and mental health.

The objectives of this study were to identify technical capabilities for algorithm deployment in the included health care settings, identify variation in user needs across different service settings and geographies, and iterate the algorithmic process and deploy a reproducible algorithm that can be implemented in different services.

Trust Recruitment

A steering group consisting of lay representatives and patient experience experts was formed to guide the strategic direction of this study and help in recruitment through various patient experience networks including the National Insight Network set up by National Health Service (NHS) England, the Q Community established by the Health Foundation, Advancing Quality Alliance, and the Heads of Patient Experience Network. An FFT review capability questionnaire (Section 1 in Multimedia Appendix 1) was sent to interested organizations. This allowed this study's team to identify organizations based on 3 key metrics: patient experience engagement, digital readiness or IT infrastructure, and quality improvement involvement. To ensure that the selected trusts possess the necessary infrastructural and organizational qualities to contribute effectively to the research objectives while adhering to data regulatory standards, a capacity and capability assessment was required. Only those trusts that were able to confirm capacity and capability through their Research and Development department were finally recruited, as shown in Figure 1.

Ethical Considerations

This study received Health Research Authority and Health and Care Research Wales approval (20/HRA/5924). No patient data were collected, and trusts were anonymized in the analysis. Written consent was sought from members of the steering group and the individual hospital trust project team, and with further written consent, their contribution has been acknowledged in the Acknowledgments section.

Preimplementation

IT Scoping Tool

To work collaboratively, we identified the needs of all participating organizations from a patient experience digital readiness standpoint. This was facilitated through previous work by this study's team funded by NHS England Insight and Feedback Team [15], where a scoping tool was developed to identify key contacts, FFT data collection, SQL Server database, handling and management, infrastructure capacity, that is, on-premise data center or cloud computing, integrated development environment and coding language expertise, and data visualization software (Section 2 in Multimedia Appendix 1).

Data Access

To ensure that participating organizations were fully supported by the project team, a Data Protection Impact Assessment (DPIA) was completed with each organization. DPIA is a systematic process designed to identify and minimize the associated data protection risks. The purpose of a DPIA in our study was to assess the impact of processing data and to ensure that the principles of data protection, such as those outlined in regulations such as the General Data Protection Regulation were adhered to.

Adaptation of Coding Script

To achieve transferability of the SVM supervised machine learning (ML) algorithm and test against different service settings and NHS provider organizations, the functionalities previously developed [7] were recoded using Python (Python Software Foundation), given the popularity of using this coding platform in most NHS trusts. Python is an interpreted high-level general-purpose programming language. The model was developed with Python (version 3.8.10) with the following free Python libraries; scikit-learn≥0.22.1 [16] (an ML library that provides relevant ML packages required for classification), Natural Language Toolkit (NLTK)≥3.4.4 (a suite that contains libraries and programs to make machines understand human language), and Pandas≥0.25.3 (a library for data manipulation and analysis). These requirements were then translated into a requirements.txt file for organizations to deploy the algorithm. SVM was used as it is the most common classifier widely used for document classification, which consistently yields good classification performance [10].

Updating Training Coding Template

All FFT free-text comments were coded based on the NHS Patient Experience Framework (Section 3 in Multimedia Appendix 1). This framework incorporates 8 key themes that outline those elements that are critical to the patients' experience of NHS services [17]. In the previous work [7], three additional themes were added: "unclassified" (too many typographical errors to discern meaning), "general" (eg, NHS is great, everything), and "staff" (comments relating to staff). From the NHS England funded work [15], it was observed that there was an overlap of comments between the theme "staff" and other themes such as "respect for patient-centered values, preferences, and expressed needs," "emotional support," and "physical comfort." This is because often a staff member was involved in the delivery of the care as it related to the other themes. The theme "staff" was removed, and all comments coded as "staff" were recoded to develop a concise coding template. Therefore, 10 themes were selected for final analysis, and a coding pack (Section 4 in Multimedia Appendix 1) was developed with detailed guidance. Furthermore, we iterated the initial algorithm from our previous work which was developed using 2 follow-up free-text questions, that is, "What did we do well?" and "What could we do better?" by combining and shuffling the training data from both questions to develop a streamlined SVM-supervised ML algorithm for theme and sentiment prediction.

Implementation

Overview

A pipeline was constructed for the SVM model in Python for text classification and sentiment analysis, consisting of several steps, including text preprocessing, feature engineering, TFIDF (term frequency-inverse document frequency) transformation, and model training and testing.

FFT Data Retrieval

SQL server was used to both extract the FFT data and supplementary free text for algorithm imputation, and to store the output of the algorithm. Pyodbc≥5.0.1 Python library was required to connect to the individual organizations' SQL server. SQL's combination of ease of use, flexibility, and capabilities make it useful for storing, managing, querying, and analyzing datasets and is widely used in health care organizations.

Establishing Ground Truth

In supervised learning algorithms, ground truth data is critical to training and updating an algorithm [10]. Therefore, more annotated data was required to improve the performance of the algorithm. The coding pack (Section 4 in Multimedia Appendix 1) developed was provided to the participating organizations' patient experience teams to make coding more feasible. The coders were a combination of the patient experience team, clinical staff, and trust lay representatives. Two coders from the team completed manual coding individually using a 500-stratified sample to calculate interannotator reliability and understand the interpretation of themes and sentiment. Disagreements in coding were reviewed, and theme and sentiment were finalized to create a master coding template in a .csv file. This template was populated with data from all 9 organizations.

Preprocessing

Preprocessing of textual data is the first essential step in the processing of text and has been proven to improve text classification models' performance by standardizing the text before it is presented to the classification algorithm [10]. NLTK for Python was used for preprocessing and data analysis, which includes tokenization of the comments and removal of stop words (eg, the, was, is, etc), punctuation, numbers, and special characters from the comments. The resulting words were represented as a bag of words (BoW) or corpus. Given that the average length of FFT free-text comments tends to be short,

XSL•FO
RenderX

and the context is domain-specific, that is, patient experience, this BoW approach was used rather than word embedding.

Feature Engineering

Feature engineering is the process of transforming data into features or attributes that better represent the underlying structure of the data [10]. To identify the key features of the data, we used a statistical measure, TFIDF, used in the fields of information retrieval [18] and ML, that can quantify the importance or relevance of words in a comment among a collection of comments [19].

Determining Accuracy

To understand if further coding was required, the accuracy for theme and sentiment was calculated using a 500-stratified sample of manually coded comments from each of the individual organizations. The accuracy is defined as a metric used in classification to measure the percentage of accurate predictions [10]. It is also defined as the ratio of several correct predictions by the algorithm to the total number of predictions. In other words, the ratio of true positives (TPs) and true negatives (TNs) to all positive and negative observations (where FPs and FNs are false positives and false negatives, respectively): accuracy=(TP+TN)/(TP+TN+FP+FN). The acceptable threshold for overall accuracy for theme and sentiment for a supervised algorithm using patient feedback was determined at 75%. The 75% accuracy threshold for theme and sentiment classification was established based on the work of this study's group [10] and previous studies in the literature [20,21]. Specifically, the threshold reflects the balance between achieving an acceptable level of accuracy and the complexity of interpreting nuanced patient feedback using NLP and ML techniques. Therefore, the 75% accuracy benchmark was identified as a reasonable trade-off between high-quality model performance and the inherent challenges in processing and classifying subjective feedback from patients.

The accuracies yielded by the models on different ranges of hyperparameters were compared. For SVM, both L1 and L2 regularization, variance tolerance values for the stopping criteria, and different values for the inverse of regularization strength, C, were compared. As regularization has a known role in reducing overfitting, the hyperparameters were chosen for tuning to identify the amount and type of regularization and early stopping criteria that are suitable for the classification tasks. After this, the optimal hyperparameters were found by GridSearchCV from the scikit-learn library. A 10-fold cross-validation was used to search to select the best hyperparameter combinations from specified ranges of hyperparameters, which were used to retrain the model on the training set and to predict on the test set [10]. This allowed us to establish the accuracy but also use the coded comments as a template to improve the accuracy by a further round of recoding if needed, until the accuracy was at or above 75%, that is, reached thematic saturation.

Algorithm Deployment

The master coded template data was then serialized using the Python pickle library. This module is used for serializing and deserializing objects into Python format text strings, which are called pickles and can be created by Python code or sent from other Python programs. This Python pickle is easily carried over the network and can be validated without knowing the details of the received object. This enables the preservation and sharing of the ML models, allowing users to reload pretrained models, significantly reducing the need for lengthy retraining. The files that were stored in the environment were as follows: Feature_sentiment.pkl, Feature_theme.pkl, Sentiment_classifier.pkl, Theme_classifier.pkl, Tfidftransformer_sentiment.pkl, and Tfidftransformer_theme.pkl.

Establishment of a Community of Practice

In the pursuit of ensuring the correct sustainability of the algorithm, a strategic initiative was undertaken through the establishment of a technical community of practice (CoP). This community served as a conduit for regular interaction and collaboration among the leaders responsible for overseeing the algorithmic maintenance across different trusts. Recognizing the complexity and potential challenges associated with deploying advanced algorithms, quarterly meetings were instituted as a core component of the CoP framework. These meetings provided a structured way for the leads of each site to convene, fostering an environment conducive to the exchange of critical insights, best practices, and lessons learned.

Results

Overview

Nine trusts were recruited from a range of care settings, sociodemographic and geographical areas. Trusts were added to this study sequentially, one by one, as part of the recruitment process. None of these organizations had a pre-existing automated process for analyzing their FFT free-text responses.

Identifying Free-Text Comments With FFT Survey for Analysis

In the preimplementation scoping exercise, it was observed that among the participating organizations, trusts A and D incorporated 3 follow-up free-text questions in their FFT survey. In contrast, all other trusts included only 1 follow-up question (Table 1). The question with the highest number of comments in trust A was analyzed. The organizations provided a variety of services, including pediatrics, inpatient and outpatient, and community and mental health, thereby facilitating testing and iteration of the algorithm for use in all care settings. Furthermore, most of the organizations 88.9% (8/9), opted to house and deploy the algorithm on premises, and the rest on cloud 11.1% (1/9).

[e]GP: general practitioner.

Variation in Patient Experience Themes

To understand the variation in themes, if any, of FFT free-text responses in the 9 organizations, we looked at the count of comments from the FFT free-text responses based on the NHS patient experience framework. This was extracted from the output after initial model deployment for the period of January 2022 to January 2023, as demonstrated in Table 2. The highest count of themes was "respect for patient-centered values" followed by "general." The themes with the lowest count were "welcoming the involvement of friends and family" followed by "transition and continuity." There were no demonstrable trends in the other patient experience framework themes.

Table . Distribution of count of themes based on the NHS[a] patient experience framework from 9 NHS organizations in England, extracted from the output of the algorithm.

Trust	FFT[b] comments provided per NHS Patient Experience Framework themes (%)									
	0[c]	1[d]	2[e]	3[f]	4[g]	5[h]	6[i]	7[j]	8[k]	9[l]

Establishing Ground Truth

Interrater agreement was determined on the manual coding, and the coding template was updated to check accuracy and improve the model by acquiring an updated corpus from the BoW and feature extraction. The interrater agreement was better for sentiment compared to theme. There was almost perfect agreement (0.81 - 1.00) seen in 7 organizations. Trust A was the only organization with a substantial (0.61 - 0.80) agreement with a Cohen κ of 0.79 (Table 3).

XSL•FO
RenderX

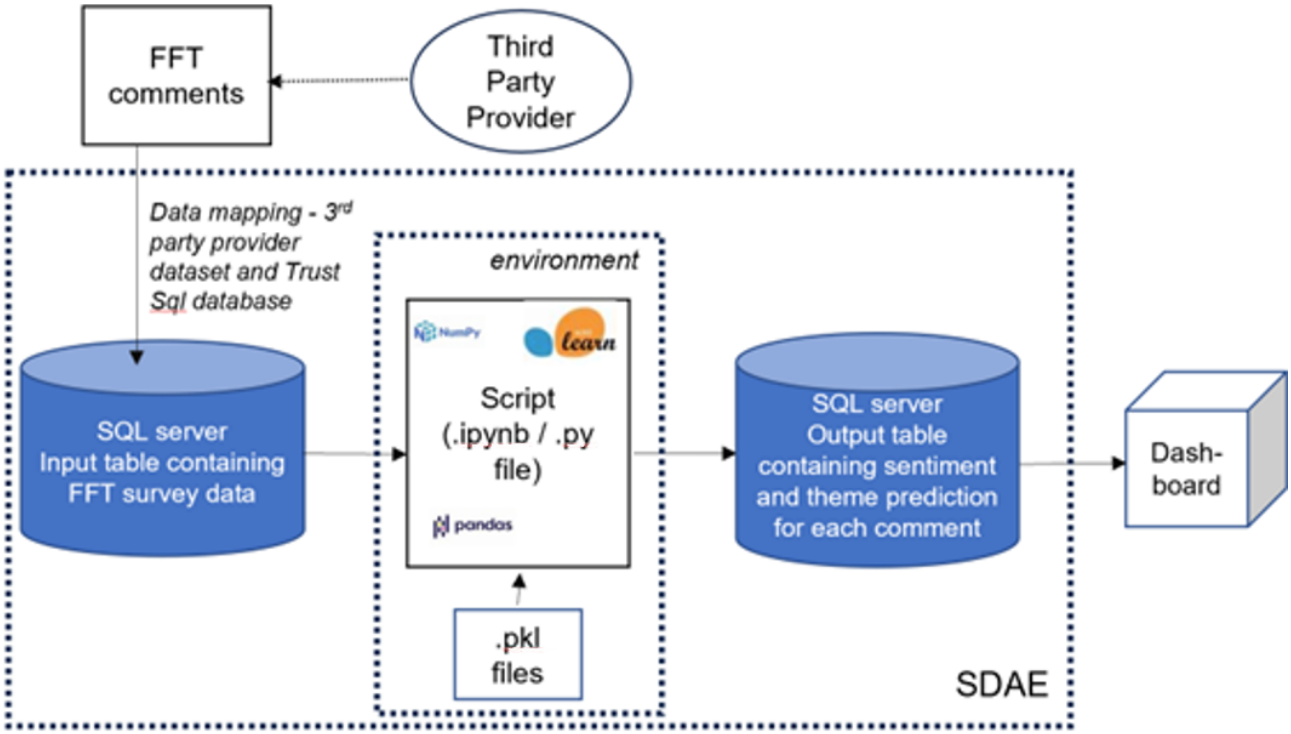
[a]Not applicable given that the final 4 organizations reached thematic saturation following the coding efforts of the initial 5 organizations and therefore achieved an overall accuracy rate of 75% or higher.

Three trusts noted that sentiment prediction related to certain words was misclassified. This study's team reviewed the performance and identified words that were culpable for this misclassification, for example, "nothing," "everything," and "OK." These trusts were advised to manually code a subset of 500 comments with equally distributed sentiments, especially focusing on the misclassified words, along with comments that represented an equal or almost equal number of comments per themes or sentiments to obtain a balanced dataset. To determine the accuracy of the algorithm, a pipeline was developed and refined to standardize the entire process within all the organizations, as depicted in Figure 2.

XSL•FO
RenderX

Figure 2. A pipeline created to develop and standardize the overall accuracy calculation before final deployment. Copyright owned by Imperial College Healthcare NHS Trust, 2025. All rights reserved.

The overall accuracy for theme and sentiment significantly improved after using a revised coded template. As trusts were added to the study sequentially, one by one, as part of the recruitment process, the BoW was also applied sequentially to the algorithm. Thematic saturation was achieved after analyzing and collating comments from a total of 5 trusts. This was observed when the algorithm was tested in 4 of the remaining trusts without the need to implement their respective coding output, and achieving an overall accuracy greater than or equal to 75%.



The final 4 organizations achieved an overall accuracy rate of 75% or higher, having reached thematic saturation following the initial coding efforts of the initial 5 organizations. As a result, as seen in Table 1, four versions of the model were deployed as new, labeled comments were collated from the different trusts that joined the program and deployed the algorithm. This iterative learning was carried out by adding randomly scrambled new unique words that the algorithm encountered in the BoW within its code. Each time, this word repository was completely randomized, and each word was treated individually by removing any linkage. As a result, it was not possible to know from which trust the word came from or if it was part of a positive or negative comment, with this study's team holding the ground truth.

Adaptations and Running Without Errors

The algorithm script was adapted according to the agreements and requirements of the individual organization. The solution was tested in Jupyter Notebook (The Linux Foundation) for easier interaction with the code and checked for errors. The 2 most common errors encountered were "FileNotFoundError" which was a result of not specifying the correct path to a .pkl file, and "invalid column name," as the code had not been adapted appropriately with the column names from the input table on the SQL server. Once errors were corrected, the final deployment consisted of the output with predicted themes and sentiment exported to a SQL database for integration into the dashboard visualization. This pipeline (Figure 3) was standardized after refinement with all participating organizations. Each trust automated its data flow based on the requirements defined by the frequency and volume of comments that the pipeline should be updated with.

XSL•FO
RenderX

Figure 3. Final pipeline demonstrating steps required to deploy the final algorithm with FFT comments as input, prediction of themes and sentiment using pickle files generated from summative coding outputted to SQL database for use in dashboard visualization. FFT: Friends and Family Test. Copyright owned by Imperial College Healthcare NHS Trust, 2025. All rights reserved.

For this purpose, user-friendly interfaces were designed and developed using the Flask Python library for the backend and HTML, CSS, and Bootstrap for the frontend. Functionalities of these interfaces included analyzing the accuracy of the algorithm by uploading a labeled dataset and retraining the algorithm with more coded data.

Algorithm Refinement

Three hospitals noted that after manual inspection of the sentiment prediction, some FFT comments were being classified with an incorrect sentiment. We reviewed the performance of the algorithm and identified words that were making the algorithm perform incorrectly (eg “nothing,” “everything,” or “OK”). It was suggested that these hospitals should manually code a subset of 500 comments with equally distributed sentiments, especially focusing on these words, along with comments that represented an equal or almost equal number of comments per themes or sentiments, to obtain a balanced dataset. A code developed by this study’s team was provided to ensure the equal distribution of both themes and sentiments in the dataset.

Multitagging

Potential refinements to the algorithm, particularly regarding the need to break long comments into sentences for trusts encountering lengthier narratives, such as those in mental health and community settings, were highlighted, and a multitagging method was devised. The multitagging approach involved assigning multiple themes from the NHS Patient Experience Framework to a single text document based on its content. Unlike the traditional single-label classification, where the FFT free-text is assigned to only 1 label, multitagging recognizes that comments may encompass various themes. This approach enables a more nuanced representation of the content’s complexity and captures multiple dimensions of meaning within the same document. The punctuation marks, words, and number of characters used to split the original sentence can be customized based on different requirements using Spacy (versions ≥3.7.2) and its English language model. As a default, sentences are split after a maximum of 75 characters, and each of these is analyzed individually (Figure 4). This can then be customized according to the requirements of the trust to define how the base text should be split (eg, by punctuation marks or specific words such as “however”). Based on this level of customizability, other trusts also implemented the solution.

XSL•FO
RenderX

Figure 4. Example of how the sentencing approach works. The original comment is split into 2 subcomments, each classified according to a theme and a sentiment. Original Comment ID	Sentence	Theme	Sentiment
1	Amazing care from our general paediatrician who is going above and beyond to help coordinate multiple professionals in the care of our child. Seriously! I am so grateful for her expertise and wisdom and feel extremely blessed that our child is under her care. Grateful thanks. She has been so supportive of us as parents too.	1	1

Final Split Sentences

Original Comment ID	Sentence	Theme	Sentiment
1	Amazing care from our general paediatrician who is going above and beyond to help coordinate multiple professionals in the care of our child.	1	1
1	Seriously! I am so grateful for her expertise and wisdom and feel extremely blessed that our child is under her care. Grateful thanks. She has been so supportive of us as parents too.	5	1

Redaction of Personal and Identifiable Information

Considerable variation was also observed in how trusts approached the redaction process, ranging from automated processes with subsequent manual checks to entirely manual methods. To address this inconsistency, a redaction algorithm capable of automatically detecting and masking personally identifiable information was devised. A redaction algorithm was developed using NLTK, Regex, and Presidio Python libraries to automatically detect and mask the personally identifiable information. The algorithm can be customized according to the requirements of the trust to define how and what data needs to be redacted.

About CoP

During the quarterly meetings, there was a high level of engagement from at least 80% of staff members representing the 9 trusts. This level of participation indicated strong interest and commitment to the CoP's objectives. Additionally, feedback from participants revealed a positive perception of the CoP, with at least 90% reporting a sense of belonging and support within the community. This sense of camaraderie and mutual support contributed to the effectiveness of the CoP in addressing algorithm deployment challenges and driving improvements based on patient feedback. We addressed maintenance of the algorithm through the CoP by creating a standardized software that enables each hospital to check the accuracy of the algorithm and make changes as needed. Figure 5 shows the interfaces developed.

Discussion

Principal Findings

Using a test-and-iterate approach, this study deployed a text analytics algorithm to predict theme and sentiment from FFT free text data in 9 NHS organizations in England with different care settings, geographical locations, and demographics. Furthermore, this study highlighted the variation in technical capacity and resources among trusts, introduced and developed a framework, and standardized a data processing pipeline capable of supporting FFT text analytics bespoke to the organization's needs. The key contributions of this study are: (1) the construction of technical infrastructure to support and run the algorithm effectively and being able to adapt the script for individual organizations; (2) the creation of master coding template with free-text data from different health care organizations to support algorithm iteration and improve overall accuracy for theme and sentiment; (3) the creation of pipeline to standardize the method of incorporating the algorithm for processing free-text data; and (4) foster collaborative nonsiloed working that encourages local ownership and share-learning.

Addressing Data Management and Standardization Through IT Infrastructure

Data collection and analysis are central to this project. Achieving this required a robust data infrastructure with different components that collaboratively created an effective framework for research data management. This framework enhanced data accessibility by presenting information in a consistent, standardized, predictable, and accessible format while also strengthening data reliability through the automation of manual processes [22]. However, ensuring high-quality data demands a diverse set of information management skills, including data acquisition, storage, organization, retrieval, and long-term maintenance [23]. This project offered a valuable opportunity for trusts to gain expertise in this area by providing guidelines to streamline processes, define roles, and establish a resilient IT infrastructure.

Creating a Template With Additional Organizational Specific Free-Text Data

Each health care setting possesses unique attributes, patient demographics, and linguistic nuances as demonstrated above. Algorithm testing was required to allow for customization and tailoring of the algorithm to accommodate these contextual variations. As part of a supervised learning approach, recoding was required to re-establish ground truth, and new words were incorporated into an expanded BoW to improve performance across various care settings. Literature suggests that the larger the training sets used, the higher the accuracy of the algorithms at identifying similar comments within the broader dataset, but trade-offs with time and human coding are necessary to ensure the method is resource-efficient [10]. However, the nature of patient experience vocabulary, due to the domain of patient feedback from free-text, is fixed in its nature, making it attractive data for supervised learning [24]. Therefore, it is possible to anticipate the meaning of various phrases and automatically classify the comments [25]. Thematic saturation was reached with 5 organizations, and no further coding was necessary. Just as the domain is fixed, the perspective of a patient feedback document is also fixed; there is limited vocabulary that is useful for commenting about health services [24]. Rastegar-Mojarad et al [26] also observed that a small (25%) vocabulary set covered a majority (92%) of the content of their patients' comments, consistent with a study exploring consumer health vocabulary used by consumers [27]. This suggests that patients use specific vocabulary when expressing their experience within free-text comments.

In settings that were relatively fixed, that is, adult inpatient, the classifier trained strong reusable models that were evident from satisfactory accuracy. However, the accuracy of the model was lower in organizations delivering different services, such as pediatrics and mental health. This was to be expected, given that the language and type of words used in different care settings would vary from those found in an adult inpatient setting. The customization ensured that the algorithm aligns with the specific language and themes prevalent in the patient feedback of a particular health care organization. The accuracy for the theme improved in all the organizations demonstrating that while the algorithm may not initially be transferable, with some retraining and adaptations, it can easily be reused in different service settings. As part of the algorithm development process, cross-validation was applied to ensure the robustness and reliability of the model within the dataset used. In addition to this, we conducted external validation by incorporating patient comments from multiple trusts, ensuring that the model was exposed to a diverse range of data before declaring thematic saturation. This strategy allowed us to evaluate the model's performance beyond a single dataset and ensured that it was not overfitting to any trust or setting. By including data from various trusts, we created a working external validation set, which will serve as the foundation for assessing the model's generalizability in future implementations.

Furthermore, "respect for patient centered values" had the highest count in all organizations. This finding is similar to the literature around patient experience reporting in health care [28-32]. The reasons for this are twofold, first, primarily due to the large number of interchangeable words found within that theme, that is, "respect for patient-centered values, preferences, and expressed needs (cultural issues, dignity, privacy and independence, awareness of quality-of-life issues, and shared decision making)." Second, the overall domain of patient feedback is the health care system, and this study revealed that the content of reviews tends to focus on a small collection of aspects associated with this, as demonstrated by the themes used for text classification in the studies.

Through CoP participation, multitagging was used to assign multiple relevant tags or categories to individual sentences within a single FFT free-text comment. Instead of assigning a single label to the entire document, this technique involves breaking down text into sentences and assigning appropriate themes and sentiments to each based on its content, thereby enhancing customizability within mental health and community care settings. Furthermore, the CoP assisted in developing a redaction solution using Python libraries, which can be then customized according to the requirements of the trust to define

XSL•FO
RenderX

how and what data needs to be redacted. These solutions can subsequently be adopted by other trusts as an improvement to their existing processes.

Creating a Pipeline to Standardize the Algorithm Deployment Approach

As part of the model testing and to make the model more widely reusable, we created a data pipeline, which infuses and integrates BoW from different trusts to predict theme and sentiment at an accuracy greater than 75% when used in different trusts. This pipeline serves as a blueprint to stakeholders and facilitates understanding of all pieces of the pipeline among the team members and standardization when deploying the model. Compliance with regulations and governance is supported, and integration with DevOps practices enhances ML model integration into the software development lifecycle.

Generating Cultural Change to Prioritize Patient Experience–Centered Care

The establishment of CoP can play a pivotal role in establishing a multi-disciplinary team of stakeholders from IT, business intelligence, patient experience, and quality improvement within each trust. Furthermore, the CoP can provide the necessary guidance to use the algorithm and assist in developing a dashboard for quality improvement projects [14], and sustained enthusiasm in the use of data and data analytics to improve the quality of care for patients and care givers [33]. This cultural transformation will result in increased organizational agility and responsiveness to patient needs, driving positive changes in care delivery practices [34].

Limitations

The pickle files used in this study are specific to the version of Python and the libraries used to create them. Attempting to load a pickle file created with an older version of Python or with different library versions may result in compatibility issues. Newer versions of Python may have introduced changes to the pickle module or the libraries being pickled, which can result in errors when loading the file. To mitigate challenges with loading an outdated pickle file, updating the code that creates the pickle file, or using alternative serialization formats that are more version-independent can be considered. The model can be containerized using Docker with a requirements file containing all the required libraries and Docker specifying the environment setup and start-up operations. The Docker container can then be deployed to application hosting services, whether on cloud or on premises servers.

The limited vocabulary range is a significant issue faced by the BoW model. For example, if the model encounters an unfamiliar or rare but informative word that it has not yet seen during training, the BoW model will tend to ignore it. To mitigate this limitation, we trained the model on 5 of 9 trusts to ensure that the model had gathered a substantial BoW representation, further augmented by thematic saturation. Significant changes to patient demographics or significant changes, such as the COVID-19 pandemic, could reduce the performance due to unfamiliar words. Therefore, regular updates in the model would be required to keep it up to date. For this purpose, user-friendly interfaces can be designed and developed using the Flask Python library for the backend and HTML, CSS, and Bootstrap for the frontend. Functionalities of these interfaces included analyzing the accuracy of the algorithm by uploading a labeled dataset and retraining the algorithm with more coded data. The interfaces allow organizations to periodically check accuracy as part of a responsible AI strategy.

Given the limited analytical expertise and computational resources in many UK hospitals, complex models such as transformers and recurrent neural networks would be difficult to implement effectively. The SVM model was chosen for its simplicity, efficiency, and low resource demands, making it ideal for integrating into existing workflows. The focus was on maximizing the value of patient feedback data to improve care quality, without overwhelming the hospital's IT infrastructure. We acknowledge that alternative lightweight ML methods, such as Decision Forests and XGBoost, offer similar efficiency and computational efficiency without the significant computational burdens often associated with deep learning models. Furthermore, modern deployment strategies, such as using pretrained architectures and lightweight deep learning models, can help mitigate the resource challenges typically associated with training deep learning models such as recurrent neural networks. As the hospital's analytics capacity grows, more sophisticated models can be explored, but SVM provided a practical starting point for immediate, actionable insights.

The authors set out to illustrate the process of developing an NLP pipeline that originated in a single institution and has been iteratively refined for broader implementation. A strong technical knowledge base was essential to address variations in technical capabilities and IT infrastructure, as well as to introduce and enhance analytical skills that had been underused in some hospital trusts. However, to successfully implement the intervention within complex health care systems, it is crucial to understand how the intervention interacts with and influences various system components to achieve the desired outcomes. We are currently collaborating with participating trusts to establish a data flow that automates the integration of NLP outputs into a dashboard. Additionally, we are making algorithm improvements based on local priorities and needs to foster local ownership of the process.

Responsible AI

As AI continues to advance, becoming increasingly integrated into health care systems, ethical considerations and technical challenges become increasingly intricate. For this reason, a key aspect of the project included providing tools and best practices to ensure that AI is being implemented responsibly. First, the developed user-friendly interfaces promote the ongoing monitoring of the accuracy of the algorithm, ensuring fairness and accountability of the version of the model that was deployed. Second, the establishment of CoP will play a critical role in fostering a culture of continuous improvement and supporting the transformation toward greater organizational agility, but also cultivates an environment where professionals can delve into the nuanced aspects of responsible AI. This transformation will enhance the responsiveness of health care systems to patient needs and drive positive changes in care delivery practices. Furthermore, by building local expertise and ownership, we

XSL•FO
RenderX

aim to create a sustainable framework for ongoing use of data and analytics to improve the quality of care. This contributes to the development and refinement of ethical guidelines, playing a crucial role in shaping the responsible AI landscape.

Future Directions

This study's group is currently conducting a complex, multicomponent implementation designed to enhance operational efficiencies within the NHS by empowering frontline staff with visible and actionable insights derived from a patient feedback tool, which aligns with the NHS FFT redevelopment policy recommendations. This intervention aims to drive sustainable impact and foster a culture of patient-centered working by facilitating the identification and implementation of improvement opportunities. The CoP will play a vital role in achieving the broader goal of embedding a patient-centered working culture across the NHS. They will help sustain momentum for using patient feedback and data analytics to drive continuous improvements in care. This multifaceted approach ensures that the intervention not only has immediate operational benefits but also creates a lasting cultural shift toward patient-centered care.

Models such as BERT have the potential to offer deeper insights by capturing more complex linguistic patterns, which could be particularly valuable for understanding the subtleties in patient comments, especially in sensitive areas such as mental health. While we considered exploring these advanced models, we opted for a more straightforward approach during this phase of implementation. This decision was driven by the need for a method that is both practical and easily scalable across diverse health care settings. However, future research with a more experienced group, enriched by the extended knowledge gained through the CoP, could involve comparing transformer-based models such as BERT with the current approach to evaluate whether they provide significant improvements in accuracy and interpretability. Moreover, future work will explore the impact of different preprocessing strategies, such as retaining certain negations, expanding contractions, or adjusting tokenization rules (including experimenting with different n-gram configurations) based on contextual understanding. This would allow for a more nuanced approach, potentially improving the accuracy of sentiment classification, especially in cases where subtle cues are essential.

To enhance the interpretability of the model's predictions, SHAP (Shapley Additive Explanations) and LIME (Local Interpretable Model-Agnostic Explanations) can be incorporated into the NLP pipeline. SHAP can explain that the words "excellent" and "care" contributed significantly to a positive prediction, while "waited" and "long" contributed to a negative prediction. This helps the health care team understand the key drivers behind feedback, allowing them to make targeted improvements. For a piece of patient feedback stating, "The doctor was kind, but the wait was too long," LIME might perturb the sentence by removing words like "kind" or "wait" to see how the model's prediction changes. If the model changes from positive to negative after removing the word "wait," LIME would indicate that the term "wait" is highly important for determining the sentiment of the feedback. This could be an important step for trusts in improving transparency, which builds trust and helps the health care team make better-informed decisions when observing the dashboard.

Conclusion

This study marks an advancement in harnessing free-text FFT data to gain valuable insights in health care settings through the creation of a robust supervised learning text analytics algorithm. The observed disparities in certain care settings were expected, considering the inherent differences in lexicon and terminology compared to the adult inpatient care setting where the algorithm was initially developed. Addressing these challenges involved additional coding and thorough testing under diverse scenarios. Through this iterative process, the accuracy and reliability of the algorithm were established to be robust and easy to use, fostering inter- and intraorganizational collaboration and promoting shared learning within the health care domain.

Acknowledgments

This work was funded by the Health Foundation and by the National Institute for Health Research (NIHR) Imperial Biomedical Research Centre (NIHR203323), with infrastructure support from the NIHR North-West London Patient Safety Research Collaboration (NIHR NWL

PSRC, Ref. NIHR204292). The research was enabled by the iCARE Secure Data Environment and used the iCARE team and data resources. Development of the information technology (IT) scoping tool and coding pack was funded by NHS England Insight and Feedback Team (National Health Service [NHS]). Abstract

Background: Clinical practice guidelines (CPGs) serve as essential tools for guiding clinicians in providing appropriate patient care. However, clinical practice does not always reflect CPGs. This is particularly critical in acute diseases requiring immediate treatment, such as acute ischemic stroke, one of the leading causes of morbidity and mortality worldwide. Adherence to CPGs improves patient outcomes, yet guidelines may not address all patient scenarios, resulting in variability in treatment decisions. Identifying such gaps would augment CPGs but is challenging when using traditional methods.

Objective: This study aims to leverage real-world data coupled with machine learning (ML) techniques to systematically identify and quantify gaps in German thrombolysis-in-stroke guidelines.

Methods: We analyzed observational data from the German Stroke Registry – Endovascular Treatment (GSR-ET), a prospective national registry involving 18,069 patients from 25 stroke centers in whom endovascular treatment of a large vessel occlusion was attempted between 2015 and 2023. Key variables included demographic, clinical and imaging information, treatment details, and outcomes. A random forest model was used to predict intravenous thrombolysis treatment decisions based on three different sets of features: (1) guideline-recommended features, (2) clinician-selected features, and (3) features as documented in the GSR-ET before thrombolytic treatment. Feature importance scores, permutation importance, and Shapley Additive Explanations values were used, with clinician guidance, to interpret the model and identify key factors associated with guideline deviations and independent clinician judgments.

Results: Of all GSR-ET patients, 13,440 (74.4%) were analyzed after excluding those with incomplete or implausible data. The random forest model's performance, measured by area under the receiver operating characteristics curve, was 0.71 (95% CI 0.68 - 0.73), 0.74 (95% CI 0.73 - 0.75), and 0.77 (95% CI 0.76 - 0.78) for the guideline-recommended, clinician-selected, and GSR-ET feature sets, respectively. Across all sets, time from symptom onset to admission was the most important predictor of thrombolysis treatment decisions. Age, which according to the German guidelines is not to be considered for thrombolysis administration, emerged as a significant predictor in the GSR-ET feature set, suggesting a potential gap between guidelines and clinical practice.

Conclusions: In our study, we introduce an innovative approach that combines real-world data with ML techniques to identify discrepancies between CPGs and actual clinical decision-making. Using intravenous thrombolysis in large vessel occlusion stroke as a model, our findings suggest that treatment decisions may be influenced by factors not explicitly included in the current German guideline, such as patient age and pre-stroke functional status. This approach may help uncover clinically relevant variables for potential inclusion in future guideline refinements.

KEYWORDS

clinical practice guidelines; real-world data; machine learning; acute ischemic stroke; health care improvement; guideline adherence

Introduction

Background

Ischemic stroke is a major global health concern being one of the leading causes of death and long-term disability worldwide, with more than 6 million deaths reported in 2019 [1]. Effective management of ischemic stroke is critical for lowering morbidity and mortality [2]. Clinical practice guidelines (CPGs), developed by expert panels and health care organizations, are part of an evidence-based practice toolkit designed to standardize medical treatment and ensure that patients receive the best possible care. The acute ischemic stroke guidelines encompass recommendations for pre- and in-hospital care, early diagnosis, timely administration of intravenous thrombolysis, and the implementation of endovascular thrombectomy as needed [3-5].

Despite the availability of these guidelines and the effort made to keep them current, adherence in clinical practice varies greatly [6,7]. Physicians may rely on independent clinical judgment in the absence of specific recommendations or intentionally deviate from guidelines due to several reasons, including addressing individual patient needs [8-10]. Such situations expose potential gaps in the guidelines, indicating areas where further guidance could improve standardization and patient care. In our study, a gap in CPGs refers to a discrepancy between guideline recommendations and the decisions observed in real-world clinical scenarios. According to research, deviations from recommended practices and the need for clinical discretion when no guidance is provided can result in suboptimal outcomes including increased rates of death and disability [11,12]. Currently employed traditional methods of detecting gaps in guidelines, such as comparing national and international guidelines and manual chart reviews, are labor-intensive, time-consuming, and susceptible to human error [13-17].

Recent research has shown that artificial intelligence and machine learning (ML) are effective in various health care applications, including predicting patient outcomes, identifying risk factors, and assisting clinicians with decision-making [18-21]. Another promising way to enhance patient outcomes in health care is the usage of real-world data, which includes routinely collected data (eg, electronic health records and registry data) to optimize treatment protocols based on real-world evidence [22]. There has been limited research within the realm of CPGs aimed at generating or enhancing health care guidelines by leveraging ML and real-world data [23-27]. To the best of our knowledge, the application of ML algorithms combined with real-world data to identify gaps in CPGs remains unexplored. Analyzing routine data with ML algorithms, such as random forests, which can handle complex interactions between variables and provide insights into the relative importance of various factors influencing clinical decisions, can be pivotal in systematically identifying areas where clinical practice diverges from CPGs, including areas not covered by existing recommendations. This approach can pinpoint specific deficiencies in CPGs and highlight potential areas for improvement, thereby offering a valuable addition to the traditional methods used for identifying gaps in CPGs.

Objective

To investigate whether intravenous thrombolysis treatment decisions follow the current German acute ischemic stroke guideline or are informed by additional features that are not part of the guideline recommendations. Specifically, we aim to:

1. Assess the performance of an ML model in predicting thrombolysis treatment when implemented on 3 different sets of features.
2. Identify key factors in thrombolysis administration that are currently not included in the guidelines.

Methods

Data Collection

The data used in this study were retrieved from the German Stroke Registry – Endovascular Treatment (GSR-ET) [28], a nationwide registry comprising pseudonymized, prospectively documented records of 18,069 patients who underwent endovascular stroke treatment as part of routine clinical care at 25 stroke centers across Germany between 2015 and 2023. For this study, we extracted patient-level data from structured fields in the GSR-ET, limited to variables available before the intravenous thrombolysis decision, thereby ensuring clinical relevance at the time of decision-making.

The dataset included the demographic age and sex, pre-stroke functional status, as measured by the modified Rankin Scale (mRS); relevant comorbidities included previous stroke, diabetes mellitus, dyslipidemia, arterial hypertension, and atrial fibrillation, as well as smoking status and antiplatelet or anticoagulation therapy at stroke onset. Living status before stroke was categorized as living at home, in a nursing home, or receiving nursing services at home.

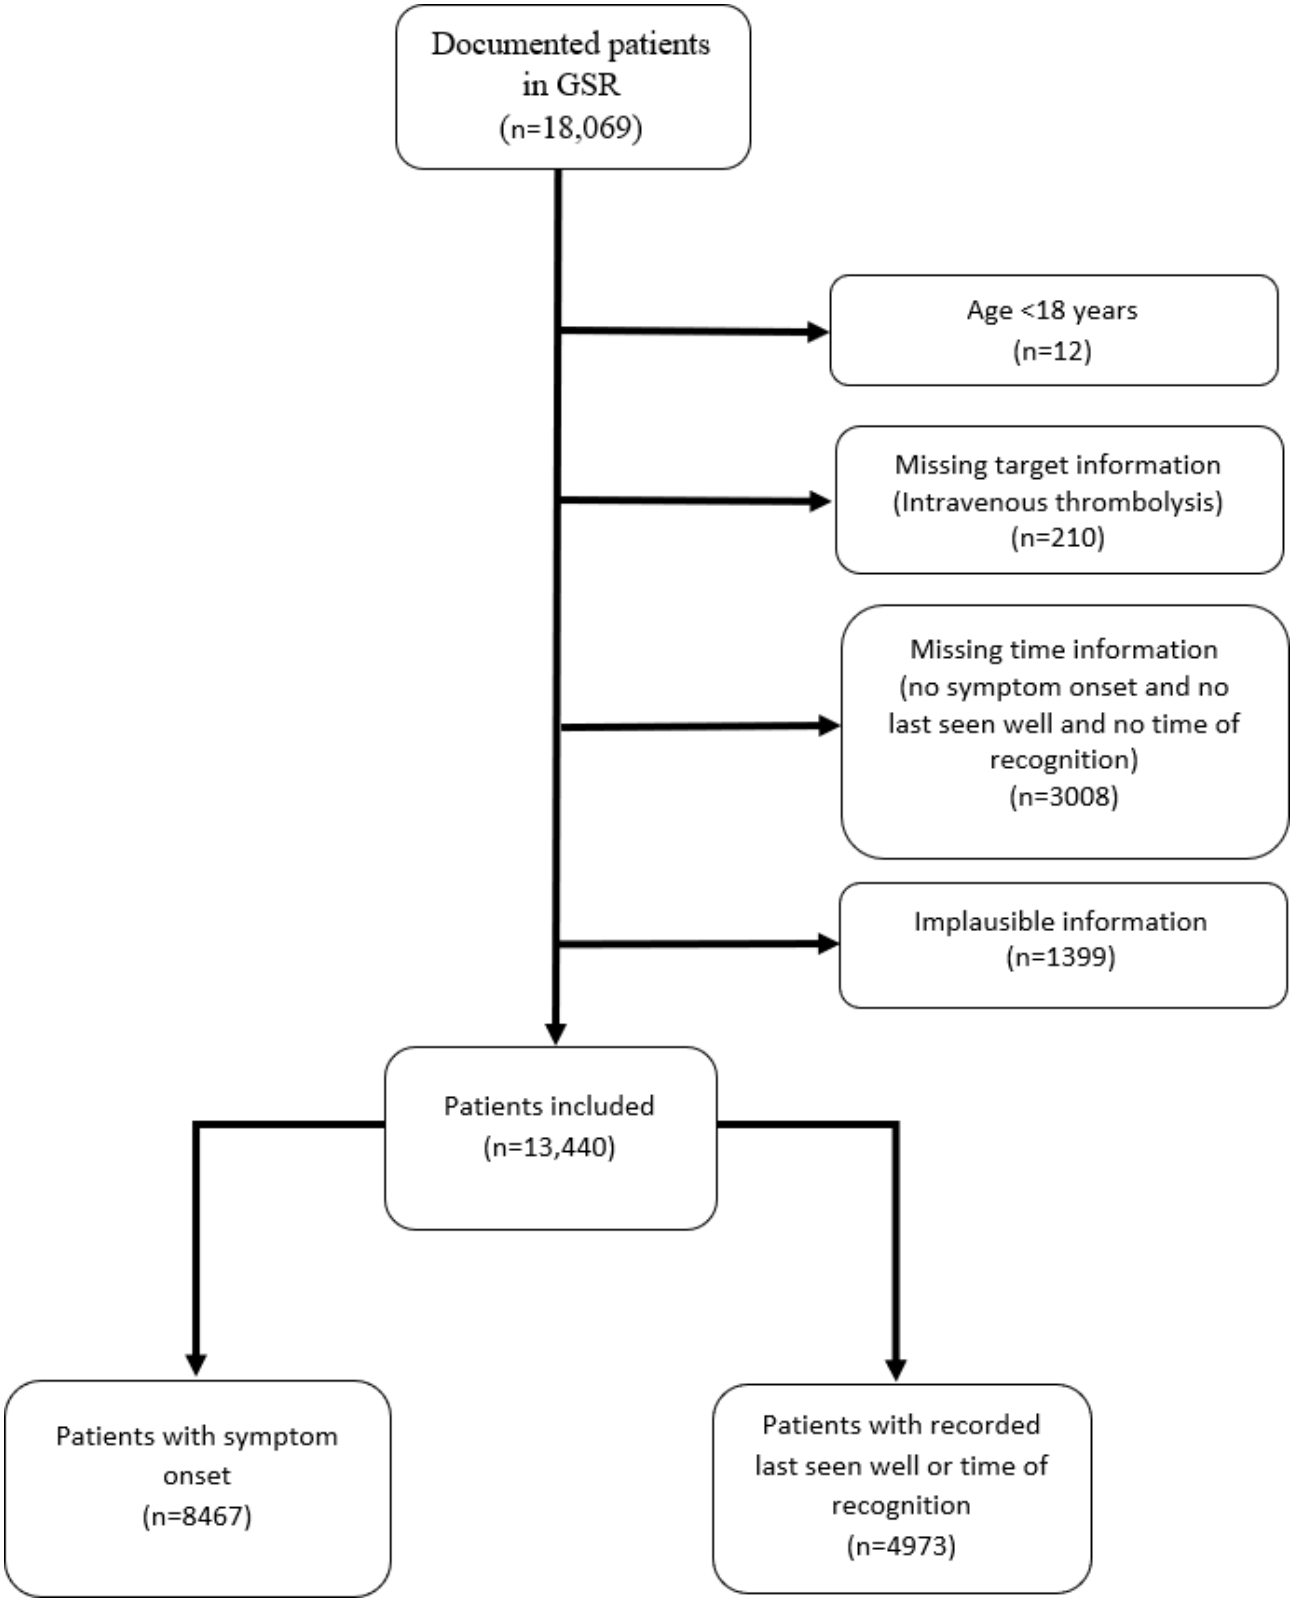
At the time of admission, clinical variables included stroke severity, assessed using the National Institutes of Health Stroke Scale (NIHSS), and systolic and diastolic blood pressure. Radiological data included imaging modalities (ie, noncontrast enhanced computed tomography, CT angiography [CTA], computed tomography [CT] perfusion, magnetic resonance imaging, magnetic resonance angiography [MRA], magnetic resonance perfusion, and imaging-based findings such as the Alberta Stroke Program Early CT Score [ASPECTS]), indicating the extent of ischemic brain tissue damage; the Thrombolysis in Cerebral Infarction (TICI) score on CTA or MRA, indicating the degree of orthograde perfusion of the affected territory; the laterality (left, right, and bilateral) and location of the vessel occlusion (anterior or posterior circulation); the presence of tandem stenosis, and signs of ischemia outside the occluded vessel territory.

XSL•FO
RenderX

Process-related variables included the time from symptom onset (or last seen well) to hospital admission and whether the patient was primarily admitted to an interventional stroke center.

The primary outcome of interest in this study was whether a patient received intravenous thrombolysis before endovascular therapy.

Data Cleaning and Preparation



Before analysis, the data was cleaned, and patients were excluded based on prespecified exclusion criteria including incomplete or implausible data (see Figure 1 and Multimedia Appendix 1). To estimate missing values for age, admission blood pressure, scores on the NIHSS, and the pre-stroke mRS score, we employed the multiple imputation by chained equations technique, provided in the Python library [29]. To assess the robustness of our imputation strategy, we compared model performance by dropping missing values and using mean and k-nearest neighbor imputation strategies. To reduce the risk of multicollinearity, we performed correlation analysis using the Pearson method for numerical variables and Cramer V for categorical variables. In addition, the reported antithrombotic medication intake by patients was grouped into 2 categories: anticoagulants (apixaban, rivaroxaban, edoxaban, dabigatran, phenprocoumon, and heparins) and antiplatelets (aspirin, clopidogrel, and others). This approach helped manage correlation between variables, ensuring that each group represented a distinct set of clinical effects. Comorbidity features such as hypertension, diabetes mellitus, atrial fibrillation, and dyslipidemia were excluded from the analysis as we were not sure when exactly this information was documented (before or after the target feature). Occluded vessel features were grouped into 2 distinct groups: anterior and posterior circulation occlusion. Categorical and ordinal variables were transformed using one-hot encoding and ordinal encoding respectively to ensure compatibility with the ML model.

Out of the 206 available features, a total of 26 features all obtained before the target feature and relevant to thrombolysis administration were extracted from the GSR-ET. To measure the performance of our random forest model in predicting initiation of thrombolytic treatment, we created 3 distinct feature sets (see Multimedia Appendix 2 for more details) that we call the “Guideline”, the “Clinician”, and the “GSR-ET” feature sets and define as follows:

- Guideline feature set: this feature set includes the 11 features explicitly outlined in the German acute ischemic stroke guideline which are deemed relevant for intravenous thrombolysis decision-making. The inclusion of these features was based on their established clinical relevance in assessing treatment eligibility and aligning with evidence-based practice. The guideline feature set was chosen to directly reflect the guideline’s criteria, ensuring the model is evaluated against well-defined clinical standards.
- Clinician feature set: this feature set is derived from expert clinician judgment and includes 18 features identified by 2 independent stroke physicians (TJ and PS) as crucial for thrombolysis decision-making. Selection was based on their real-world experience and understanding of a broader range of patient factors that influence treatment decisions. While some of these features may not be explicitly outlined in formal guidelines, they are considered essential in clinical practice.
- GSR-ET feature set: this feature set includes all 26 features from the GSR-ET dataset that are documented before thrombolysis administration. Their inclusion ensures that the model captures a comprehensive view of the patient’s condition as recorded by clinicians in real-world settings, incorporating factors that may influence treatment decisions beyond what is specified by guidelines or expert judgment.

Figure 1. Flowchart illustrating patient selection. GSR: German Stroke Registry.

Outcome of Interest

Treatment with intravenous thrombolysis was chosen as the outcome of interest for this study. Thrombolysis is a critical and time-sensitive treatment for acute ischemic stroke [30-36], and it offers a clear, binary outcome suitable for classification algorithms, making it an ideal target for ML models such as random forests. In addition, thrombolysis represents an important quality indicator of stroke care. Despite known contraindications and gaps in existing guidelines, clinicians rely on their independent judgment and often administer thrombolysis, because it, along with endovascular thrombectomy, represents the only effective treatment option in the acute phase of stroke. We consider predicting intravenous thrombolysis treatment valuable as it captures the initial and crucial acute stroke decision-making process.

XSL•FO
RenderX

Machine Learning Model

To efficiently identify a suitable classification model for our analysis, we tested various ML algorithms using the lazypredict library [37], which quickly trains and compares the performance of many different classifiers on a given dataset.

Based on whether symptom onset was known or not, patients were divided into 2 subgroups for which we suspect possible different behavior concerning the target variable:

- Group A: Recorded symptom onset (n=8467, 62.9% patients).
- Group B: Recorded "last seen well" or "time of symptom recognition" (n=4973, 37.1% patients).

All subsequent steps of model development, training, and evaluation were conducted independently within each subgroup to ensure that analyses reflect their unique clinical and decision-making characteristics.

The dataset was split into training (80%) and validation (20%) sets for both subgroups to separate training and validation of the models and thereby detect overfitting and allow for a robust performance evaluation.

To optimize model performance, we used the nested cross-validation approach [38]. We performed an inner cross-validation using RandomizedSearchCV from the Python library scikit-learn on the training set to tune hyperparameters [39]. The hyperparameter search space included the number of estimators (n_estimators: 50 - 500) and the maximum depth of trees (max-depth: 1 - 20). A total of 5 hyperparameter configurations were randomly sampled, balancing exploration with computational efficiency. The model was evaluated across different combinations of features, and the best-performing configuration from the process was selected for final evaluation on the validation set.

Model Performance Assessment and Interpretability

Our model was evaluated on the validation set, primarily using the area under the receiver operating characteristic curve (AUROC). To ensure robustness, maintain class proportions, and prevent overfitting, we performed an outer cross-validation using stratified k-fold cross-validation (with k=5) on the tuned model to derive AUROC results. This method divides the training set into 5 subsets (4 for training and 1 for validation) and ensures that each fold of the cross-validation maintains the same proportion of class labels, which is particularly important given the potential imbalance in the chosen treatment (intravenous thrombolysis). We further addressed class imbalance by applying the synthetic minority over-sampling technique within the cross-validation loop to oversample the minority class in the training data. Secondary performance measures included F_1-score, accuracy, precision, and recall.

To assess the importance of each feature in their respective sets, in predicting intravenous thrombolysis treatment, we used a comprehensive analysis combining several methods. Initially, feature importance scores were extracted from the random forest model to provide a foundational understanding of each feature's contribution. To capture each feature's impact on model accuracy, permutation feature importance was applied. This loss-based approach quantifies feature importance by measuring the decrease in model performance when individual features are randomly permuted [40]. In addition, to ensure the robustness of the feature importance evaluations, we computed the confidence intervals for each feature within its respective feature set based on permutation importance results, applying the correlated t-test approach [41,42]. This method enabled us to visualize the variability and reliability of the feature importance scores. Finally, Shapley Additive Explanations (SHAP), a variance-based method, was also employed to examine the influence of each feature at the prediction level, offering deeper insights into feature contributions to both predictions (intravenous thrombolysis or no intravenous thrombolysis) [43]. Together, these methods enabled a thorough exploration of features that play an important role in the model's predictions.

Statistical Analyses

For categorical features, absolute and relative frequencies were computed. The interquartile ranges, minimum and maximum values of continuous features including NIHSS (ordinal), and pre-stroke mRS (ordinal) were also computed. The chi-square test was used to compare proportions between groups for categorical variables. For continuous and ordinal variables, the Wilcoxon rank-sum test was applied.

The descriptive comparison focused on the differences between patients who received intravenous thrombolysis and those who did not. These included demographic characteristics (eg, age, sex, and living status), comorbidities (eg atrial fibrillation, diabetes, and previous stroke), imaging modalities, occlusion sites, and pretreatment clinical status (eg NIHSS and pre-stroke mRS).

To quantify uncertainty in the AUROC estimates, 95% CIs were calculated using the correlated *t* test. All tests were 2-sided, and a *P* value of <.05 was considered statistically significant. Given the exploratory nature of the analysis, *P* values were not adjusted for multiple testing. Statistical analyses were conducted using Python (version 3.9.18).

Ethical Considerations

Data collection for the GSR-ET was centrally approved by the leading ethics committee at Ludwig-Maximilians University, Munich (689-15). Additional approvals were obtained from local ethics committees or institutional review boards at each participating center, including the ethics committee of the University of Tübingen (057/2016BO2), in accordance with local regulations. Informed consent was obtained from patients for data collection. The data used in this study were pseudonymized to ensure privacy and confidentiality. No personally identifiable information is included in the manuscript or supplementary materials. No compensation was provided to participants, as the registry relies on routine clinical data.

Results

The results presented in this section are solely for the patients with recorded symptom onset (group A). Results for group B can be found in Multimedia Appendix 3.

XSL•FO
RenderX

Descriptive Statistics

A total of 8467 (62.9%) patients with recorded symptom onset were included in the analysis. 4809 (56.8%) patients received intravenous thrombolysis. Table 1 shows the descriptive statistics of patients who underwent thrombolysis and patients who did not. Most of the features were statistically associated with the target variable of thrombolysis ($P<.05$).

Machine Learning Model

Table 2 summarizes the performance of different ML classification models on our dataset and shows similar performance of the first 3 models across the 3 features sets (see Multimedia Appendix 4 for complete table). Despite comparable performance with LGBMClassifier, we selected the random forest model for subsequent data analysis due to its built-in feature importance metrics, which facilitate clinical interpretation, and its robustness to overfitting in datasets with noise or imbalance. In addition, since our study focuses on identifying key clinical features, random forest's ability to effectively handle complex feature interactions makes it well-suited for our goals [44].

Table . Performance metrics of various machine learning classification models.

Model	AUROC[a]	Accuracy	F_1-score
RandomForestClassifier	0.71	0.72	0.72
LGBMClassifier	0.71	0.72	0.72
AdaBoostClassifier	0.70	0.72	0.71
LogisticRegression	0.70	0.72	0.71

[a]AUROC: area under the receiver operating characteristic curve

Model Performance Assessment and Interpretability

Our model was evaluated for its performance on the different feature sets and subpopulations and predicted the treatment outcome. Table 3 shows the performance metrics for patients with recorded symptom onset.

Figure 2 shows the AUROC for all feature sets: guideline, clinician and GSR-ET, with each curve representing the mean AUROC across 5 cross-validation folds in the given feature set. The GSR-ET feature set achieved the highest mean AUROC of 0.77 (SD 0.01), followed by the clinician feature set with 0.74 (SD 0.01), and the guideline feature set with 0.71 (SD 0.01). Multimedia Appendix 5 shows the plot consisting of the individual k-fold results. There was no significant improvement in performance after applying Synthetic Minority Oversampling Technique (SMOTE), indicating that class imbalance had minimal impact on the model performance. The imputation methods yielded similar results (eg, for the GSR-ET feature set, mean imputation AUROC: 0.75, k-nearest neighbor AUROC: 0.75, and multivariate imputation by chained equations: 0.77), thereby improving over the approach of dropping rows with missing values (AUROC: 0.66).

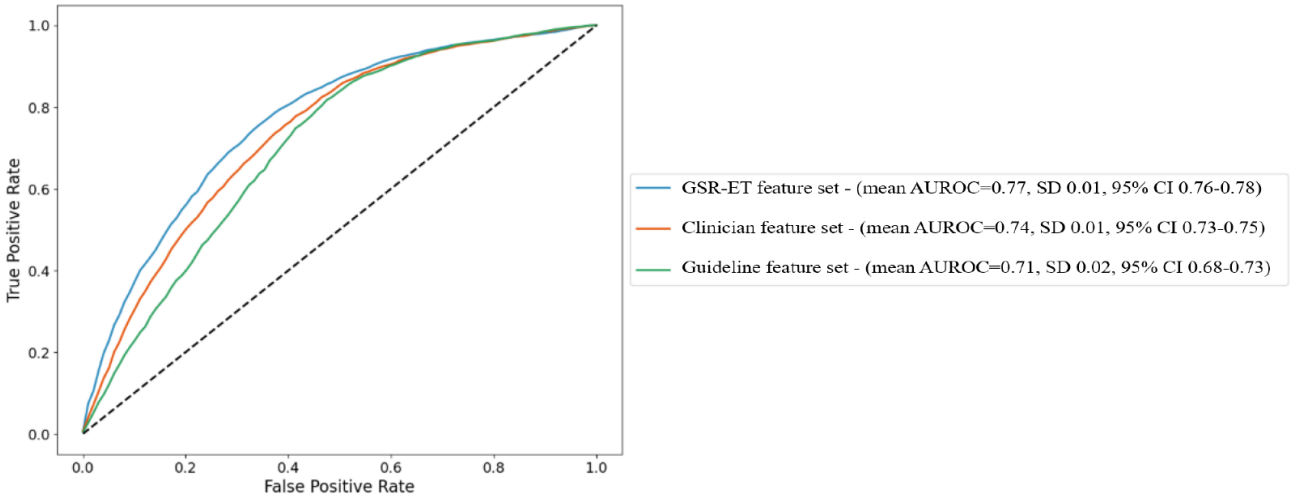
Figures 3 and 4 show the feature importance and permutation feature importance for each feature set, with their corresponding importance scores and rankings. The annotations on the bars represent the feature's rank within its respective feature set. These plots highlight the varying significance of features depending on the feature set used during prediction (See Multimedia Appendix 5 for feature importance plot with confidence intervals).

The top 10 features in all 3 feature sets in both plots were mostly similar, however with differences in their rankings within the respective feature set. The "Time between symptom onset and admission" and "Anticoagulation at stroke onset" emerged as the most important features across all sets (ranked number 1 and 2 respectively). Other significant features included "NIHSS," "Age," "Imaging aspects," "Pre-stroke mRS score" and "blood pressure," all of which had high importance scores in both plots. Less influential features included various imaging

XSL•FO
RenderX

modalities, "Living status" and "Sex," with consistently low importance rankings across feature sets in the feature importance plot.

As seen in the beeswarm plots (Figures 5-7), the SHAP analysis further confirmed the findings provided by the random forest feature importance and permutation feature importance analyses. Each point represents a specific observation's SHAP value, with colors corresponding to feature values (blue [cooler] color=lower value, red [warmer] color=higher value). The features are ranked in terms of mean absolute SHAP values indicating importance from the top (most important) to the bottom (least important).



The plots show each feature's impact on the model's prediction of the patients who did not receive intravenous thrombolysis. "Anticoagulation at stroke onset" and "Time between symptom onset and admission" have the highest SHAP values, indicating they strongly influence predictions for patients not receiving intravenous thrombolysis. Specifically, higher values of "Time between symptom onset and admission" (shown in red) push the model towards predicting no intravenous thrombolysis. Similarly, "Pre-stroke mRS score" and "NIHHS" and "Prior stroke" (in the GSR-ET set) also have high SHAP values. Higher scores for these features increase the likelihood of predicting no intravenous thrombolysis administration.

Table . Performance metrics of the random forest model on all 3 feature sets in the subgroup of patients with known symptom onset.

Feature set	AUROC[a], mean (SD)	Accuracy	Precision	Recall	F_1-score
Guideline	0.71 (0.02)	0.70	0.69	0.85	0.76
Clinician	0.74 (0.01)	0.70	0.70	0.86	0.77
GSR-ET	0.77 (0.01)	0.71	0.71	0.84	0.77

Discussion

Overview

The results of this study provide valuable insights into how ML models can be used to highlight discrepancies between guideline-recommended practices and clinical practice. By integrating ML with real-world registry data, we sought to identify gaps in CPGs. Specifically, we developed and tested a random forest model on three feature sets: (1) guideline set (features explicitly recommended by the German acute stroke guideline), (2) clinician set (features selected by stroke experts), and (3) the GSR-ET set, which consists of all relevant features provided in the GSR-ET that were available to treating physicians before taking the decision to initiate thrombolysis in ischemic stroke patients with large vessel occlusion undergoing endovascular reperfusion therapy.

Principal Findings

Model Performance (AUROC Curves)

The AUROC curve for the 3 feature sets reveals a clear hierarchy in predictive performance. The GSR-ET feature set, which includes all reasonable features documented before thrombolysis initiation, achieved the mean AUROC curve score of 0.77. These results suggest that real-world decisions as documented in the GSR-ET incorporate additional clinical features beyond those recommended by the guidelines or even those included by stroke experts (clinician feature set), which enhances the model's ability to predict intravenous thrombolysis administration. The relatively lower performance of the guideline feature set (AUROC=0.71) indicates that relying solely on guideline-indicated features may not be sufficient to capture the complexity of intravenous thrombolysis decision-making. This finding highlights a potential gap in the current guidelines, which may not fully account for all relevant

XSL•FO
RenderX

clinical variables influencing intravenous thrombolysis administration.

Key Features and Possible Gaps in the German Acute Ischemic Stroke Guidelines

The top 10 features across all 3 sets were generally consistent, with the "Time between symptom onset and admission" emerging as the most important feature across all sets. This result underscores the critical role of timely intervention in stroke management, as shorter times from symptom onset to admission are associated with better outcomes and are a key determinant of intravenous thrombolysis eligibility [26]. "Time between symptom onset and admission" not only ranked first in all 3 feature sets but also had the greatest impact on model performance when permuted, further emphasizing its importance in predicting intravenous thrombolysis administration.

The "Pre-stroke mRS score" measures a patient's pre-stroke functional status where a high score implies a greater level of disability, which might reduce the likelihood of receiving intravenous thrombolysis if the expected benefit is limited due to pre-existing impairment. "Imaging aspects" evaluates the extent of early ischemic changes on imaging. Lower ASPECTS scores suggest more extensive ischemic damage, potentially dissuading intravenous thrombolysis administration due to higher bleeding risk and reduced likelihood of tissue salvage despite successful reperfusion. Both features were amongst the top 10 important features in the clinician and GSR-ET feature sets. This reflects the emphasis on functional status and stroke severity in treatment decisions. These features could, together with other scores such as the NIHSS, a guideline-recommended score which assesses neurological severity of stroke (ranked 3rd in the feature importance plot), offer a comprehensive view of both current severity and pre-existing functional limitations to guide intravenous treatment decisions.

Notably, "Age," which was not included in the guideline feature set, in line with the German acute ischemic stroke guidelines, emerged as relatively important in the GSR-ET feature set (ranked 4th). Its permutation also resulted in a drop in model performance. The SHAP values for "Age" showed that advanced age correlates with a tendency to withhold intravenous thrombolysis. This trend may reflect clinicians' caution in treating older patients due to increased risks, such as bleeding complications or potentially lower efficacy of the treatment in older populations. While the German guidelines may not emphasize "Age" as a factor, data-driven models recognize its relevance in intravenous thrombolysis decision-making. A correlation analysis revealed a weak positive correlation (Pearson correlation coefficient=0.28) between "Age" and "Pre-stroke mRS score", suggesting that "Age" is not merely an epiphenomenon but an independent feature influencing clinical decisions. This discrepancy between guideline recommendations and clinical practice points to a potential gap in the guidelines where clearer, age-specific recommendations could support clinicians, particularly given the established association between age and stroke outcomes [31,45].

Although demographic and lifestyle features such as "Smoking," "Living status," "Sex," and "Prior stroke" were included in the GSR-ET feature set, their relatively lower importance scores suggest that these features may play a more indirect role in treatment determination. They contribute to the overall risk profile of stroke patients, potentially influencing clinician perception of stroke severity or recovery potential and could therefore enhance individualized assessment for long-term outcomes and guide secondary prevention strategies [46].

Patients' use of antiplatelet and anticoagulation medications showed an influence on treatment decisions. While anticoagulation therapy is recognized as a contraindication for intravenous thrombolysis in specific scenarios, this is not explicitly detailed in the German guidelines, which instead refer clinicians to the summary of product characteristics. Similarly, the role of antiplatelet medication is less defined, as it is generally not believed to alter the benefit-risk ratio despite slightly increased bleeding risk. Our findings suggest that clinicians consider these factors, likely weighing the risks of hemorrhagic complications. A potential update to the guidelines regarding these medications could provide clinicians with granular recommendations regarding intravenous thrombolysis treatment in patients with varying antithrombotic regimens [36].

The minimal influence of "Tandem stenosis" on intravenous thrombolysis prediction suggests that the presence of concurrent stenosis in other vessels might be a significant factor in decision-making, likely due to its implications for clot accessibility and reperfusion success. This feature's importance signals a potential need to include vascular status assessments in intravenous thrombolysis eligibility criteria within the German acute ischemic stroke guidelines.

The feature "Primary admission at interventional hospital" positively influenced the likelihood of intravenous thrombolysis treatment, suggesting that hospital resources, including the presence of specialized stroke intervention teams, play a role in treatment decisions.

Other key features such as blood pressure and imaging features consistently achieved high and minimal importance respectively across all sets. These findings reinforce the importance of managing cardiovascular risk factors and imaging in stroke patients, especially in relation to intravenous thrombolysis eligibility.

Comparison With Previous Work

The integration of ML into clinical decision-making, especially in real-world treatment decisions, has been explored in several health care domains, but not in the context of gap search in CPGs. This section compares our approach with previous work to highlight how we contribute to the existing literature on identifying gaps in CPGs.

Though not aimed at directly refining CPGs, Abd-Alrazaq et al [47] used ML to identify gaps in COVID-19 literature. Another similar study focused on uncovering variation in clinical decision-making using registry data and ML is presented by James et al [48]. Smyth et al [14] conducted a study, using a mixed methods approach of surveys, chart reviews, and focus groups, focusing on syncope management, aiming to identify gaps between guideline-recommended care and actual clinical practice. They emphasized that guideline adherence was suboptimal, leading to overuse of some diagnostic tests while

XSL•FO
RenderX

underutilizing recommended evaluations. Similarly, Bregni et al [16] tackled rectal cancer management by systematically comparing recommendations from multiple national and international CPGs and revealed the presence of "grey areas" where guidelines either lacked sufficient evidence or were not clear, resulting in variable treatment approaches. Spranger et al [17] examined the gap between hypertension guidelines and clinical practice, finding that adherence to guidelines was often inconsistent, leading to both undertreatment and overtreatment [18]. They retrospectively analyzed medical records using chart reviews and identified factors such as clinician experience and patient characteristics as major contributors to deviations from guidelines. Ebben et al [23] developed a methodology using real-world data and clinical decision trees to continuously identify and prioritize potential areas for improvements in guidelines.

Across these approaches, there is a common theme: research gaps exist across various medical fields, often driven by real-world complexities not fully captured by CPGs. Our study extends this body of work by leveraging ML not only to identify these gaps but also to quantify the predictive power of features that are often overlooked or deemphasized in CPGs. In addition, our results suggest that updating guidelines to incorporate these potentially critical features could improve treatment consistency and outcomes, similar to some of the cited studies, which advocate for guideline refinement based on empirical evidence from clinical practice.

Limitations

While this study provides valuable insights into the potential gaps between guideline-recommended and clinician-led decision-making, several limitations must be acknowledged.

Registry Data

The GSR-ET consists solely of patients with a diagnosis of acute ischemic stroke, a large vessel occlusion, and patients who underwent or to whom an endovascular treatment was attempted. It is therefore important to note that within the GSR-ET, thrombolysis is only administered in conjunction with endovascular treatment but not as standalone reperfusion therapy. This means that the effect of better prediction in the GSR-ET feature set may be related to the fact that GSR-ET patients are a subset of strokes with large vessel occlusion and may therefore not reflect thrombolysis decision-making in the overall stroke patient.

Feature Interaction

While feature importances can identify variables that enhance the decision-making accuracy of our ML model, they do not reveal on a deeper level how these features interact with other variables in the GSR-ET. Consequently, simply knowing that a feature is influential does not clarify its optimal placement or threshold within the CPG decision framework.

Guideline Flexibility

CPGs are inherently flexible and are designed to provide general recommendations that accommodate a broad range of clinical scenarios. Consequently, they may not include all the possible factors that inform real-world decision-making by clinicians. Even though our study identified features not explicitly mentioned in the guidelines, it is possible that these features may still be deliberately excluded, as guideline developers may prioritize flexibility over incorporating factors that, while influential in decision-making, are not deemed essential for standardization in future guideline updates.

Limited Focus on Clinical Outcomes

This study focused primarily on predicting intravenous thrombolysis administration and identifying which variables were involved in decision-making but did not investigate the long-term clinical outcomes associated with these decisions. While deviations from the guidelines and independent clinical judgments were identified, it is unclear whether these decisions led to better or worse patient outcomes. This makes it difficult to assess whether the identified features should indeed be included in future guidelines based solely on the results of this study.

Future Directions

The methodology applied in this study offers a systematic approach to uncover discrepancies between CPGs and real-world decision-making. Future research using larger datasets could strengthen these findings and support guideline refinements. Integrating such approaches into clinical workflows may enable rapid identification of guideline gaps or nonadherence, ultimately contributing to improved patient care.

Conclusion

This study demonstrates the potential of combining ML with real-world data to systematically identify gaps between clinical practice and current CPGs. In the case of intravenous thrombolysis for large vessel occlusion stroke, factors such as age and pre-stroke disability, which are not explicitly addressed in current German guidelines, emerged as relevant to treatment decisions. These features may merit consideration in future iterations of CPGs to improve alignment with clinical realities.

Providing clear guidance on them would not only support clinicians in navigating complex patient profiles and making ethical, patient-centered decisions but also enhance their moral confidence and potentially offer legal protection. Specifically, future CPGs may emphasize that advanced age alone should exclude patients from thrombolysis, as it can enable recovery to pre-stroke conditions. However, a severely impaired pre-stroke functional status, particularly in advanced age, may not always represent a meaningful therapeutic goal.

Acknowledgments

The authors would like to extend their sincere gratitude to their colleagues: Dr Jan Klein, Sandra Siegel, and Dr Thomas Netsch for their valuable support in proofreading this manuscript. We would also like to thank all the contributors to the study, including

Abstract

Background: By analyzing electronic health record snapshots of similar patients, physicians can proactively predict disease onsets, customize treatment plans, and anticipate patient-specific trajectories. However, the modeling of electronic health record data is inherently challenging due to its high dimensionality, mixed feature types, noise, bias, and sparsity. Patient representation learning using autoencoders (AEs) presents promising opportunities to address these challenges. A critical question remains: how do different AE designs and distance measures impact the quality of retrieved similar patient cohorts?

Objective: This study aims to evaluate the performance of 5 common AE variants—vanilla autoencoder, denoising autoencoder, contractive autoencoder, sparse autoencoder, and robust autoencoder—in retrieving similar patients. Additionally, it investigates the impact of different distance measures and hyperparameter configurations on model performance.

Methods: We tested the 5 AE variants on 2 real-world datasets—the University of Kansas Medical Center (n=13,752) and the Medical College of Wisconsin (n=9568)—across 168 different hyperparameter configurations. To retrieve similar patients based on the AE-produced latent representations, we applied k-nearest neighbors (k-NN) using Euclidean and Mahalanobis distances. Two prediction targets were evaluated: acute kidney injury onset and postdischarge 1-year mortality.

Results: Our findings demonstrate that (1) denoising autoencoders outperformed other AE variants when paired with Euclidean distance (P<.001), followed by vanilla autoencoders and contractive autoencoders; (2) learning rates significantly influenced the performance of AE variants; and (3) Mahalanobis distance-based k-NN frequently outperformed Euclidean distance-based k-NN when applied to latent representations. However, whether AE models are superior in transforming raw data into latent representations, compared with applying Mahalanobis distance-based k-NN directly to raw data, appears to be data-dependent.

Conclusions: This study provides a comprehensive analysis of the performance of different AE variants in retrieving similar patients and evaluates the impact of various hyperparameter configurations on model performance. The findings lay the groundwork for future development of AE-based patient similarity estimation and personalized medicine.

Introduction

Diseases vary in complexity, posing substantial challenges in diagnosis, treatment, and prognosis—even when cases appear clinically similar [1]. This heterogeneity is particularly prominent in complex disorders like autoimmune diseases [2], Parkinson disease [3], and cardiovascular diseases [4], where underlying causes often result from a confluence of genetic, environmental, and lifestyle factors [5]. As these complexities become more evident, the rapid adoption of electronic health record (EHR) systems has bolstered the potential for personalized medicine to enhance patient care. Personalized medicine focuses on tailoring treatments and predicting patient outcomes by analyzing data from patients with similar characteristics [6]. By assessing EHR snapshots of comparable patients—including prescriptions, procedures, vital signs, lab

XSL•FO
RenderX

results, and clinical outcomes—physicians can proactively predict disease onsets, customize treatment plans, and anticipate patient-specific trajectories [7,8]. Additionally, predictive models that leverage data from similar patients tend to be more accurate, as they capture localized data patterns that might be obscured in aggregated data [9].

Retrieving a high-quality set of similar patients is central to personalized medicine, directly impacting both evidence-based decision-making and the accuracy of personalized predictive models. However, EHR data are inherently challenging to model due to high dimensionality, mixed feature types, noise, bias, and sparsity, complicating the effective retrieval of similar patients [10]. For instance, applying traditional Euclidean distance-based k-nearest neighbors (k-NN) directly to EHR data may be problematic due to high dimensionality and mixed data types. To address these challenges, various similar patient retrieval algorithms have been proposed, incorporating advanced feature engineering to handle mixed features and reduce dimensionality [11-13].

Patient representation learning offers new avenues for overcoming these obstacles, with autoencoders (AEs) being one of the most important and widely used methods in this area [14-17]. AEs compress input data into a lower-dimensional latent space, known as a latent representation, and reconstruct it back to its original form, facilitating effective auto-feature engineering and patient representation [18,19]. AEs are particularly useful for encoding nonlinear relationships within EHR, and capturing complex structures in clinical data [20]. As AE applications to EHR increase, their use is becoming increasingly diverse [14-16]. For instance, Chowdhury et al [16] designed a mixed pooling multi-view attention AE to learn representations that encapsulate a holistic view of patient medical profiles. Beaulieu-Jones et al [15] applied a vanilla AE with a modified binary cross-entropy loss to impute missing data in EHR, and Lee et al [14] used a dual adversarial AE to generate sequential EHR data.

In personalized medicine, AEs are increasingly applied to enhance similar patient retrieval [21-23]. Generally, these studies use AEs to generate efficient patient representations from EHR data, with similarity among patients assessed using distance measures such as Euclidean and Mahalanobis distances. For example, Jo et al [21] used a supervised AE to incorporate disease labels into latent representations and calculated patient similarity in the latent space using the Euclidean distance. Miotto et al [22] introduced the "Deep Patient" framework with a 3-layer stack of denoising autoencoders (DAEs) to generate latent patient representations from EHR data, which was then used to estimate patient similarity. Landi et al [23] used a convolutional AE to transform patient trajectories into low-dimensional latent vectors and achieved patient risk stratification by patient similarity. These studies underscore the potential of AEs to drive advances in personalized medicine.

Despite the promising results of applying AEs to EHR data, a critical question remains unanswered: how do different AE designs impact performance in similar patient retrieval tasks? Existing studies have not clearly justified their choices of specific AE designs. Specifically, AE designs encompass 2 key aspects. The first aspect is the choice of the base AE model, as different AE variants may perform differently due to their distinct design focuses and the unique characteristics of EHR data. When these base AE models are integrated into more complex architectures (eg, "Deep Patient" [22]), their behavior may also vary. Therefore, gaining deeper insight into the performance of different base AE models on EHR data is valuable. The second aspect is hyperparameter tuning, as AEs are known to be highly sensitive to hyperparameters, including learning rate, latent dimensionality, and optimization techniques [24]. Therefore, understanding how different hyperparameters impact AE performance on EHR data is also important.

In this study, we used 2 real-world EHR datasets from the University of Kansas Medical Center (KUMC) and the Medical College of Wisconsin (MCW), covering the period from January 1, 2016 to December 31, 2016, to evaluate the performance of 5 widely used AE variants for retrieving similar patients: vanilla AE (AE) [18], DAE [25], contractive autoencoder (CAE) [26], sparse autoencoder (SAE) [27], and robust autoencoder (RAE) [28]. Vanilla AE is the most basic form of autoencoder, making it efficient to train and use. DAE and RAE can address the significant noise in EHR data, while CAE and SAE use different mechanisms to learn more robust latent representations for EHR data with complex distributions [29]. Additionally, we investigated the impact of 2 distance measures, Euclidean and Mahalanobis, on similar patient retrieval when paired with these AE variants. To comprehensively evaluate model performance, we tested them within a standard k-NN classification framework for 2 binary clinical outcomes in hospitalized patients: acute kidney injury (AKI) onset and 1-year mortality postdischarge, representing short-term disease and long-term survival risk classification scenarios. AKI, a life-threatening and heterogeneous condition prevalent among hospitalized patients, is particularly suited to a personalized approach. Finally, we explored how different hyperparameter configurations affect AE performance in retrieving similar patients for outcome prediction. This study provides key insights into AE optimization for personalized medicine applications, informing future advancements in EHR-driven patient care.

Methods

Comparison Framework Overview

This study aims to evaluate the effects of various AE variants, hyperparameter settings, and distance measures on the performance of similar patient retrieval. The 5 AE variants investigated were vanilla AE (AE), DAE, CAE, SAE, and RAE. Each AE was trained in an unsupervised manner on the training dataset, after which both the training and test datasets were transformed into latent representations using the trained AEs.

Performance was evaluated using a standard k-NN classification framework with neighborhood sizes of 5, 10, 15, and 20. For similar patient retrieval, Euclidean and Mahalanobis distances were applied to the latent representations to identify similar patients based on a specified neighborhood size for each test patient. Labels were assigned to each test patient through majority voting, and these assigned labels were then compared with the ground truth to assess model accuracy. Furthermore,

XSL•FO
RenderX

we analyzed the influence of different hyperparameter configurations on AE model performance in retrieving similar patients, focusing on Euclidean distance as the patient similarity measure.

Data Source and Processing

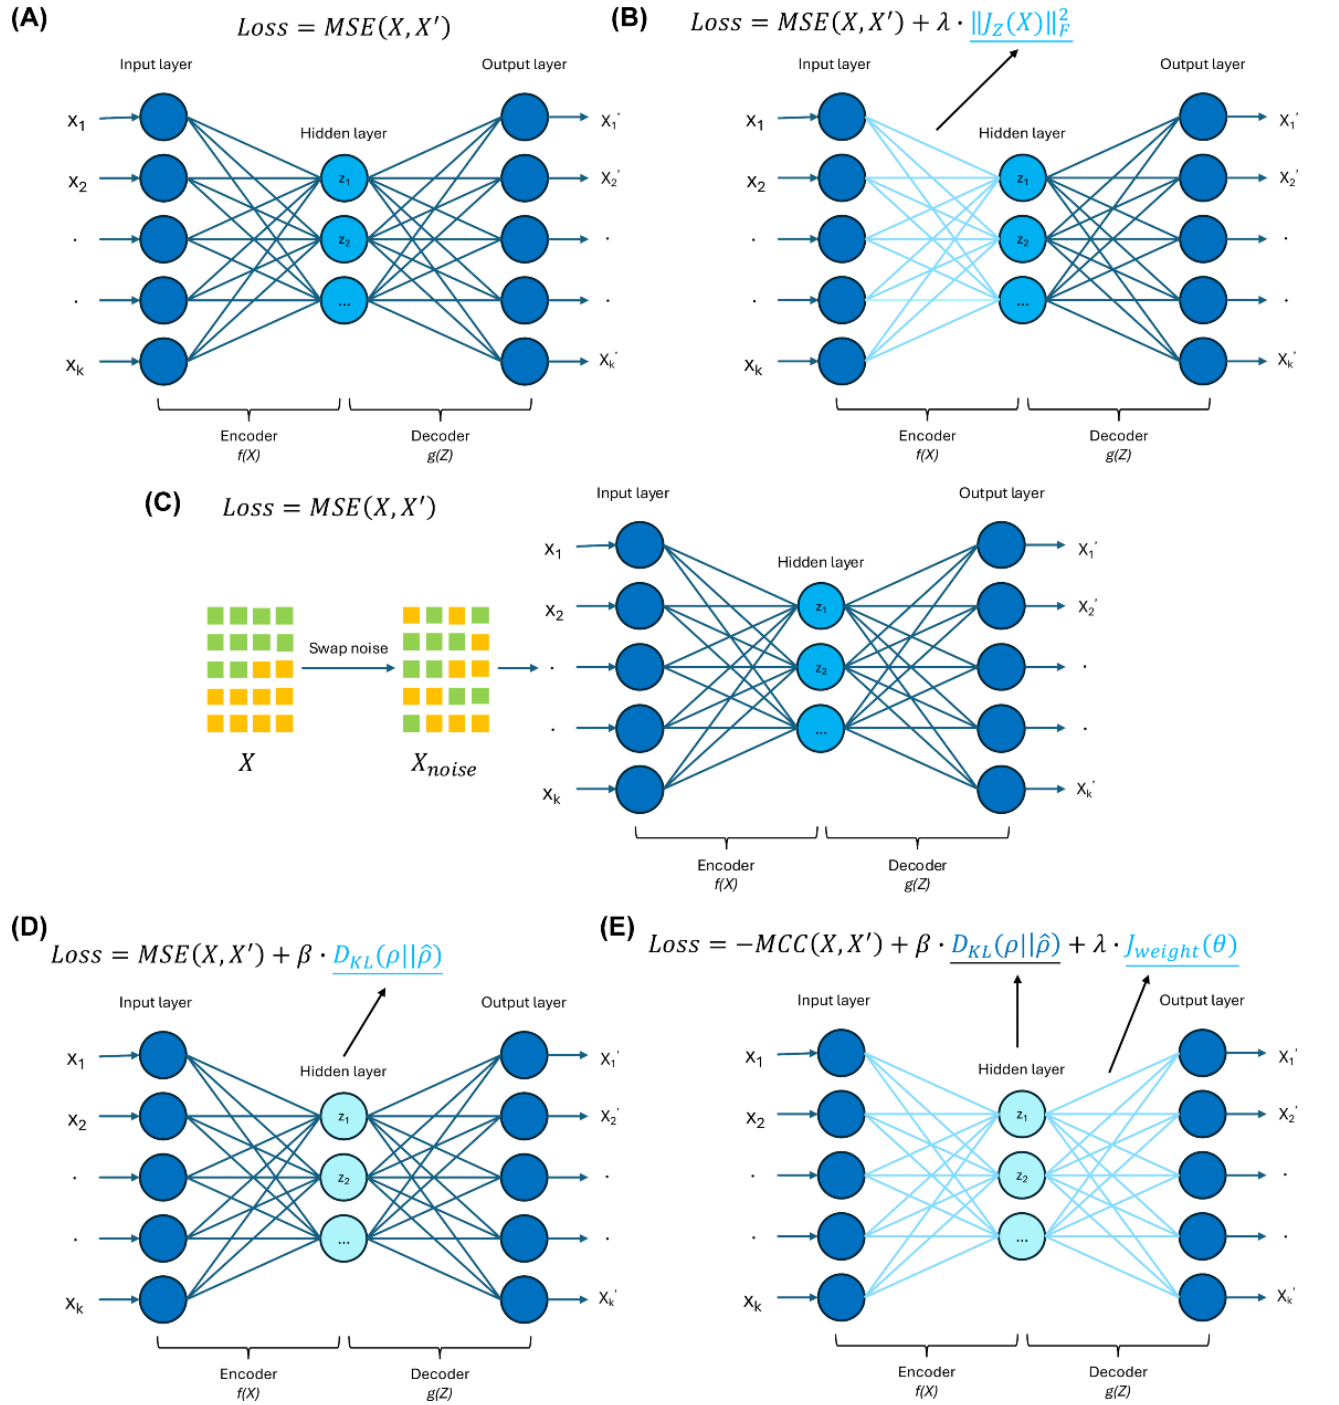
Our primary dataset consisted of inpatient data extracted from KUMC, covering admissions from January 1, 2016, to December 31, 2016. To assess the generalizability of our findings, we extracted an external validation dataset from MCW for the same period.

Both datasets were processed using the same protocol. The inclusion criteria were as follows: (1) older than 18 years, (2) baseline serum creatinine (SCr) <3.5 mg/dL, and (3) AKI onset occurring at least 72 hours postadmission to focus only on hospital-acquired AKI [30]. AKI was defined using the SCr criteria described in the "Kidney Disease: Improving Global Outcomes" clinical practice guidelines [31]. For patients with multiple admissions, only the first encounter was retained. The study focused on 3 types of in-hospital clinical features: medications, procedures, and lab test results. The data observation window for these features extended from 48 hours before the prediction point up to the prediction point. For patients with AKI, the prediction point was set at 24 hours before AKI onset, while for patients without AKI, it was set at 24 hours before the last SCr measurement [9].

Medications were represented by the maximum dosages recorded within the data observation window, procedures were encoded as binary values indicating whether a procedure was performed during the observation window, and lab test results were recorded as the most recent values within the observation window. Medications and procedures present in less than 1% of patients were excluded from the analysis. Lab tests with a missing rate over 30% were also discarded, with the remaining missing lab values imputed using the multiple imputation by chained equations method [32]. Outliers were replaced using the Winsorizing method with a 1% threshold [33], and min-max normalization was applied to scale values between 0 and 1.

In addition to AKI onset, 1-year mortality after discharge was also included as a prediction target, providing a comprehensive evaluation of the retrieved similar patient cohorts in terms of both short-term (AKI onset) and long-term (1-year mortality) clinical outcomes.

AE Variants



The vanilla AE (Figure 1A) is the most basic form in the autoencoder family. Its architecture is a symmetric feedforward neural network structure, though this symmetry does not necessarily apply to the weights, biases, or activation functions. It has 2 main components: an encoder and a decoder. The encoder encodes the input into a latent representation, while the decoder reconstructs the original data from this hidden representation. For an AE with a single hidden layer, the input data undergo the following transformations:

$$Z=fX=\varphi 1(WX+b)$$

$$X`=gZ=\varphi 2(W`Z+b`)$$

XSL•FO
RenderX

Figure 1. Overview of the 5 autoencoder (AE) variant designs with different loss functions.**(A)**Vanilla AE;**(B)**Contractive AE;**(C)** Denoising AE;**(D)** Sparse AE; and**(E)** Robust AE. MCC: maximum correntropy criterion; MSE: mean squared error.

Here, X denotes the input data, and X` represents the reconstructed data. Z is the output of the latent representation produced by the encoder. W, W`, b, and b` are the weights and biases of the encoder and decoder, while φ1 and φ2 are activation functions. To quantify reconstruction accuracy, the mean squared error (MSE) loss was used, which measures the difference between the original input data and the reconstructed data, as follows:

$$LossAE=MSE(X,X`)=1n\sum i=1n(xi-x`i)2$$

Here, n denotes the number of input samples, while xi and x`i represent the i-th sample of X and the i-th sample of X`, respectively. This loss function allows AE to learn a compressed representation of the data by minimizing the reconstruction error.

The DAE (Figure 1C) enhances model robustness by introducing noise into the input data. Specifically, data with noise (Xnoise in Figure 1C) are used as input, and the reconstruction error is calculated between the original noise-free data (X in Figure 1C) and the reconstructed data. In this way, the model learns to reconstruct the input by eliminating any noise present. In this study, we used swap noise, where each value in the training data may be replaced with a random value from the same column with a certain probability. We selected swap noise for fairness purposes as it has been shown to be the most effective noise

XSL•FO
RenderX

type for tabular data [34]. Other commonly used noise types include Gaussian noise and masking noise [35].

The CAE (Figure 1B) enhances model robustness by reducing the encoder's sensitivity to minor perturbations in the input, a typical vulnerability in AEs where small variations can lead to significant differences in latent representations. The CAE addresses this issue by introducing an additional penalty term, the Frobenius norm of the encoder, to the loss function. This term, which is the L2-norm of the Jacobian matrix of the hidden layer, makes the encoder output more stable against small input variations. The Frobenius norm of the encoder and the CAE loss function are shown as follows:

$$JZ(X)F2=1n\sum i=1n\sum j=1m\sum k=1l(\partial zi(k)(xi)\partial xi(j))2$$

$$LossCAE=MSEX,X`+\lambda\cdot JZ(X)F2$$

Here, m denotes the number of input features, and l represents the length of the latent representations. λ controls the strength of the additional penalty term, which aims to restrict the rate of change in the encoder output relative to changes in the input. When the input undergoes minor variations, the CAE encoder output remains relatively stable, enhancing the model's robustness against noise and small perturbations.

The SAE (Figure 1D) encourages the model to learn efficient representations by enforcing sparsity in latent representations. By adding a Kullback-Leibler (KL) divergence penalty between a Bernoulli distribution and the distribution of latent layer outputs to the loss function, the SAE limits the number of active neurons (whose outputs are significantly nonzero) in the latent layer. This helps SAE to capture key information from the input using a limited number of active neurons in the latent layer, preventing it from simply copying the input to the output and enhancing the model's ability to capture the inherent structure of the input data. The additional penalty term and the loss function of the SAE are as follows:

$$DKL(\rho\vee\rho\wedge=\rho log\rho\rho\wedge+(1-\rho)log\ (1-\rho)(1-\rho\wedge)$$

$$LossSAE=MSEX,X`+\beta\cdot DKL(\rho\vee\rho\wedge$$

Here, ρ denotes the mean of the Bernoulli distribution. ρ^ denotes the mean of the distribution of latent representations over the training data. β controls the strength of the additional penalty term.

The RAE (Figure 1E) improves noise tolerance by using the maximum correntropy criterion (MCC) instead of MSE for reconstruction error, making it less sensitive to outliers [36]. The intuition behind the MCC-based reconstruction error is that as the distance between X and X` increases, the corresponding measure transitions from the L2 norm to the L1 norm, and eventually to the zero norm when X and X` are far apart. The RAE also includes a sparsity penalty term similar to that of the SAE, along with an additional weight decay term to prevent overfitting. The MCC-based reconstruction error, the weight decay term, and the final loss function of the RAE are shown as follows:

$$MCC(X,X`)=1n\sum i=1n\sum j=1m12\pi\sigma exp(-(xik-x`i(j))22\sigma2)$$

$$Jweight\theta=12\sum L=12\sum i=1sL\sum j=1sL+1(wji(L))2$$

$$LossRAE=-MCCX,X`+\beta\cdot DKL(\rho\vee\rho\wedge+\lambda\cdot Jweight\theta$$

Here, σ denotes the variance of the Gaussian distribution. wji(L) denotes an element in the weight matrix of the L-th layer. SL denotes the number of neurons in the L-th layer. β and λ control the strength of the 2 penalty terms, respectively.

Patient Similarity Measures

To identify similar patients, we applied 2 distance measures—Euclidean and Mahalanobis distances—to the latent representations generated by each AE variant. For each patient in the test dataset, we used these distance measures to find a cohort of similar patients from the training dataset. The Euclidean distance on the latent representations is calculated as follows:

$$DEuclidean(zi,zj)=\sum k=1l(zik-zjk)2$$

Here, zi denotes the i-th patient in the training set and zj denotes the j-th patient in the test set. l denotes the length of the latent representations.

The Mahalanobis distance can be viewed as a Euclidean distance after applying a linear transformation to the feature space, defined by L:

$$DMahalanobis(zi,zj)=(Lzi-Lzj)T(Lzi-Lzj)$$

In this study, we used 3 different algorithms to estimate the Mahalanobis distance on the latent representations: large margin nearest neighbor (LMNN) [37], Neighborhood Components Analysis (NCA) [38], and Metric Learning for Kernel Regression (MLKR) [39].

- LMNN learns a Mahalanobis distance within the standard k-NN classification framework, aiming to bring the nearest *k* neighbors from the same class closer while ensuring that examples from different classes are separated by a large margin.
- NCA enhances the accuracy of nearest neighbor classification compared with the traditional Euclidean distance by directly maximizing a stochastic version of the leave-one-out k-NN score on the training set.
- MLKR learns a Mahalanobis distance by directly minimizing the leave-one-out regression error. This algorithm can also be viewed as a supervised extension of principal component analysis (PCA), making it suitable for dimensionality reduction and visualization of high-dimensional data.

Experimental Design

The workflow of the study is presented in Figure 2. Each AE variant in this study consisted of a 3-layer structure: an input layer, a hidden layer, and an output layer. Previous research suggests that additional hidden layers in AEs do not necessarily lead to improved downstream task performance [40]. All AE variants were implemented in PyTorch (version 2.4.0; Meta AI), and trained on 2 NVIDIA GeForce RTX 2080 Ti GPUs, each with 10.7 GB of RAM. For each of the 5 AE variants, we performed an exhaustive grid search to explore all possible combinations of learning rates, optimizers, latent dimensions, and activation functions, resulting in 168 different hyperparameter configurations per AE variant. Details of the hyperparameter space are listed in Table 1. The Mahalanobis distance was estimated using the metric-learn library [41].

XSL•FO
RenderX

Figure 2. Workflow of the study. After the electronic health record data were transformed into latent representations using 5-fold cross-validation, the latent representations were used for 3 downstream evaluations: Euclidean-distance-based similar patient retrieval, Mahalanobis-distance-based similar patient retrieval, and AE hyperparameter analysis. AE: autoencoder; CAE: contractive autoencoder; DAE: denoising autoencoder; KUMC: University of Kansas Medical Center; LMNN: large margin nearest neighbor; MCW: Medical College of Wisconsin; MLKR: metric learning for kernel regression; NCA: neighborhood components analysis; RAE: robust autoencoder; SAE: sparse autoencoder.

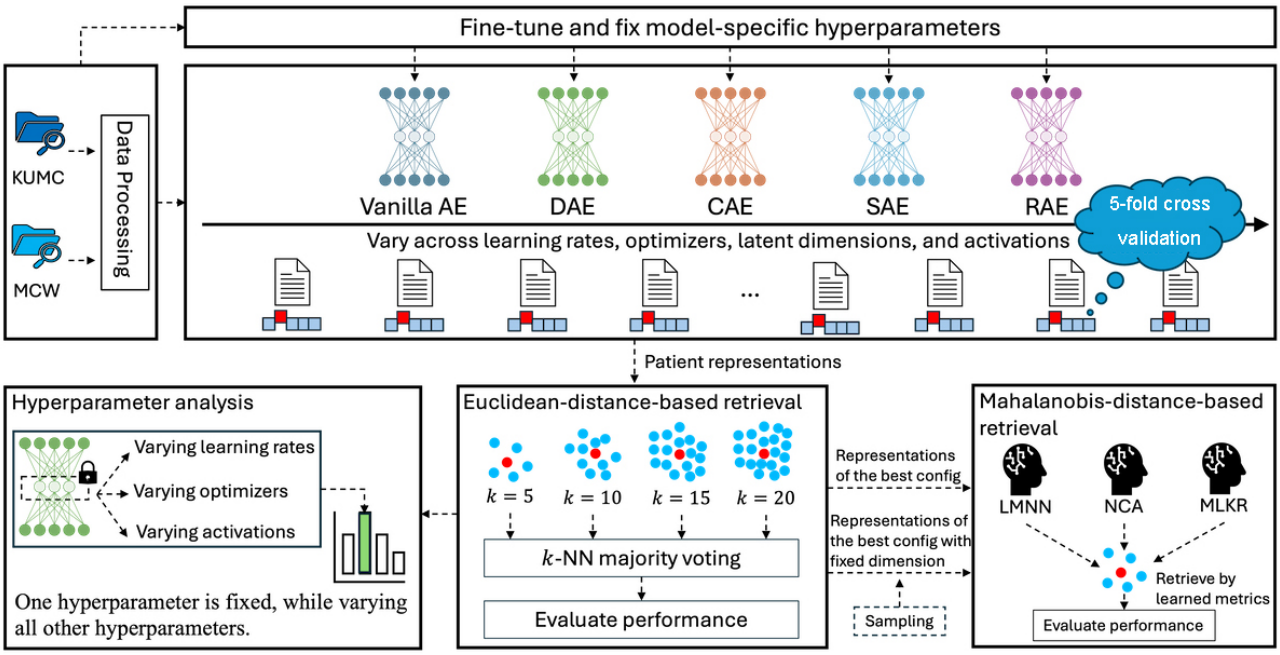


Table . Hyperparameter configuration space. The combinations of different values for the 4 studied hyperparameters resulted in 168 different hyperparameter configurations.

Hyperparameter	Range
Learning rate	1E-5, 1E-4, 1E-3, and 1E-2
Optimizer	Adam, Adamax, and RMSprop
Latent dimension : input dimension	0.02, 0.05, 0.10, 0.15, 0.30, 0.50, and 0.75
Activation functions	Sigmoid and rectified linear unit (ReLU)

To assess the generalizability of our findings, we applied the following steps in parallel to both the KUMC and MCW datasets. Before evaluating the performance of different AE variants on the 4 hyperparameters of interest mentioned above, we fixed each AE variant's unique hyperparameters (eg, the sparsity term penalty strength β in the SAE). Otherwise, combining each model's unique hyperparameters with the selected 4 hyperparameters would make the computation infeasible. To determine the optimal unique hyperparameter settings, we fine-tuned each AE variant using a standardized setup (learning rate=1E-3, optimizer=Adam, latent dimension: input dimension=0.15, and activation=Sigmoid) and fixed these optimal hyperparameter values in the subsequent experiments. To account for variations arising from the random initialization of neural network weights and data splitting, each of the 168 studied hyperparameter configurations was trained and evaluated using 5-fold cross-validation, with the average performance of the Euclidean distance-based k-NN on the AE-produced latent representations reported for the 2 prediction targets—AKI onset and 1-year mortality—across the 5 runs. The performance of the Euclidean distance-based k-NN on both the raw data and the data transformed by PCA, retaining 99% of the variance, served as baseline performance. We used F_1-scores, area under the precision-recall curve (AUPRC), and area under the receiver operating characteristic curve (AUROC) as evaluation metrics. The k-NN model was evaluated with neighborhood sizes of 5, 10, 15, and 20, respectively, considering that the size of the retrieved similar patient cohort often varies based on different clinical needs (eg, the varying complexity of different diseases). We trained the models on each of the 5 data splits for up to 2000 epochs using an early stopping mechanism, meaning that training was stopped if the validation loss did not improve for more than 5 consecutive epochs.

We then evaluated the performance of using Mahalanobis distance as the distance measure for k-NN on latent representations, focusing on two key questions: (1) Does k-NN with Mahalanobis distance on latent representations outperform k-NN with Euclidean distance? (assessing the effectiveness of Mahalanobis distance), and (2) Is applying Mahalanobis distance-based k-NN on latent representations more effective than applying it directly to raw data? (assessing the effectiveness of using AEs for EHR data transformation).

We first selected the best-performing hyperparameter configuration for each AE variant that achieved the highest F_1-score using Euclidean distance-based k-NN with a

XSL•FO
RenderX

neighborhood size of 5 to transform the raw data into latent representations. Given that we varied latent dimensions during training and considering the potentially significant impact of different latent dimensions on Mahalanobis distance-based k-NN performance, which could obscure the actual characteristics of each AE variant, we also selected the best-performing hyperparameter configuration for each AE variant with latent-to-input dimension ratio fixed at 0.5 to transform the raw data into latent representations. Due to the significant computational cost of estimating the Mahalanobis distances, we randomly sampled 50% of the AE-transformed training and test datasets from each of the 5-fold data splits for evaluation on the KUMC dataset and only evaluated the performance with a neighborhood size of 5. Fixed random seeds were used to ensure the sampled data remained consistent across all AE variant evaluations. For the MCW dataset, we randomly sampled 70% of the data following the same procedure to ensure a comparable sample size to the sampled KUMC dataset.

Statistical Analysis

One-tailed paired *t* test was used to assess whether one AE variant significantly outperformed the other with Euclidean-based k-NN across the 168 different hyperparameter configurations, with $P<.01$ considered statistically significant. Considering that in actual practice, neural network models are often fine-tuned to achieve optimal or near-optimal performance, we used an error bar plot to compare the average performance of the top 5 hyperparameter configurations for each AE variant, with Euclidean distance-based k-NN evaluated at neighborhood sizes of 5, 10, 15 and 20. This represents the upper performance bound of each AE variant in retrieving similar patients. We used box plots to visualize the impact of hyperparameter configurations on model performance. Each box plot shows the performance with Euclidean distance, where one hyperparameter of interest was fixed at a specific value while all other hyperparameters varied for each AE model.

To assess the generalizability of our findings from the KUMC dataset, we applied Spearman rank correlation to evaluate the relationship between model performance on the KUMC dataset and that on the MCW dataset. The Spearman rho (ρ) value was used to measure the strength and direction of the monotonic relationship between performances on the 2 datasets. A higher ρ indicates a stronger correlation, suggesting good generalizability.

Ethical Considerations

All data were deidentified according to the “Safe Harbor” criteria outlined in the Health Insurance Portability and Accountability Act. The study was determined to be nonhuman participants research by the University of Florida Institutional Review Board, as it involved only pre-existing, deidentified patient records. The data access request was approved by the Greater Plains Collaborative Data Request Oversight Committee. This study was determined by the institutional review boards of the University of Florida, University of Pittsburgh Medical Center, and University of Missouri as nonhuman participant research because it only involved the collection of existing and deidentified patient medical data. Data use agreements have been executed with both the Greater Plains Collaborative and the University of Pittsburgh.

Results

Study Population

The final KUMC dataset encompassed 13,752 unique patients, while the MCW dataset encompassed 9568 patients. The AKI onset rates for the 2 datasets were 11.90% and 9.03%, respectively, and the 1-year mortality rates were 12.65% and 15.51%, respectively. The KUMC dataset contained 579 features, including 277 medications, 288 procedures, and 14 lab tests, while the MCW dataset contained 654 features, including 328 medications, 312 procedures, and 14 lab tests. The details of the 2 datasets are presented in Table 2.

AE Performance With Euclidean Distance

The fine-tuned and fixed model-specific hyperparameters are provided in Multimedia Appendix 1. On the KUMC dataset, DAE consistently performed the best across both prediction targets (ie, AKI onset and 1-year mortality) and all k-NN neighborhood sizes (P<.001,Multimedia Appendix 2 and Multimedia Appendix 3), followed by vanilla AE and CAE (Figure 3, Figures S1 and S2 in Multimedia Appendix 4). The average performance of the top 5 hyperparameter configurations showed a similar trend, with DAE performing the best, followed by vanilla AE and CAE. For AKI onset prediction, CAE and SAE outperformed baseline models (ie, k-NN applied to the raw data and the PCA-transformed data) at k=15 and k=20 (Figure 3C) and performed comparably to the baseline models for 1-year mortality prediction (Figure 3D). The average best performance of RAE did not surpass that of the baseline models for 1-year mortality prediction (Figure 3D).

Each box represents the k-nearest neighbor F_1-scores with AE models trained with different hyperparameter configurations. **(B)** F_1-scores of predicting 1-year mortality. **(C)** The mean F_1-scores of the top 5 best AE hyperparameter configurations of predicting AKI onset. **(D)** The mean F_1-scores of the top 5 best AE hyperparameter configurations of predicting 1-year mortality. AE: autoencoder; AKI: acute kidney injury; CAE: contractive autoencoder; DAE: denoising autoencoder; PCA: principal component analysis; RAE: robust autoencoder; SAE: sparse autoencoder.

The performance of AE variants on the MCW dataset exhibited a clear resemblance to the results obtained on the KUMC dataset, with DAE consistently outperforming the other models (P<.001, Figures 4A and B). Correlation analysis showed that, across different hyperparameter settings, the F_1-scores of AE variants were significantly correlated between both datasets, with P>.80 when predicting AKI onset (Figure 4C-F) and P>.89 when predicting 1-year mortality (Figure 4G-J). Similar results were also observed when using AUPRC and AUROC as metrics (Figures S3 and S4 in Multimedia Appendix 4).

Impact of Hyperparameters on AE Performance

On the KUMC dataset, when the neighborhood size was 5 and AKI onset was the prediction target, we observed that different hyperparameter settings had varying impacts on model performance. For learning rates, smaller values led to better performance for vanilla AE, DAE, and RAE. For CAE, a moderate learning rate yielded better results. At a higher learning rate (1E-2), the variance in model performance increased, with the upper bound observed in CAE and SAE outperforming those of other learning rates (Figure 5A). In terms of the optimizer, Adamax resulted in a slightly higher lower bound of model performance, while the upper bound showed no significant differences across optimizers (Figure 5B). Similarly, for latent dimensionality, higher dimensions (latent dimension: input dimension=0.75) led to a higher lower bound of model performance, with no significant differences observed in the upper bound (Figure 5C). No significant differences were observed between sigmoid and rectified linear unit activations (Figure 5D). Highly similar hyperparameter trends were observed on the KUMC dataset with neighborhood sizes of 10, 15, and 20 using F_1-scores as the metric (Figures S5-S7 in Multimedia Appendix 4), and with a neighborhood size of 5 using AUPRC and AUROC as metrics (Figures S8 and S9 in Multimedia Appendix 4), as well as on the MCW dataset with a neighborhood size of 5 (Figures S10-S12 in Multimedia Appendix 4).

AE Performance With Mahalanobis Distance

When comparing the performance of Euclidean distance-based k-NN and Mahalanobis distance-based k-NN on the KUMC dataset, we found that Mahalanobis distance-based k-NN generally performed better than Euclidean distance, except in a few cases (eg, DAE+NCA in Table 3). These performance drops primarily occur in NCA and MLKR, while LMNN consistently outperforms the Euclidean distance. This conclusion can be well generalized to the performance when controlling the latent dimension ratio (latent-to-input dimension ratio=0.5, Table 4) and the results on the MCW dataset (Multimedia Appendices 5 and 6).

When comparing the performance of Mahalanobis distance-based k-NN on latent representations versus directly on raw data, no consistent pattern was observed. On the KUMC dataset, in most cases, Mahalanobis distance-based k-NN on latent representations outperformed its performance on the raw data. However, there was no fixed pattern for the optimal combination of AE variants and Mahalanobis distance estimation algorithms. When latent dimensions were not controlled, the combination of RAE and all 3 investigated Mahalanobis distance algorithms achieved the best performance (Table 3). In contrast, when latent dimensions were controlled, the combination of DAE with LMNN and NCA and the combination of RAE with MLKR performed the best (Table 4). On the MCW dataset, limited cases showed that Mahalanobis distance-based k-NN on latent representations outperformed its application on the raw data, indicating that this pattern is data-dependent (Multimedia Appendices 5 and 6).

Table . F_1-scores of k-nearest neighbors (k-NNs) with Euclidean and Mahalanobis distances on the latent representations produced by the best-performing hyperparameter configuration, constrained by a latent-to-input dimension ratio of 0.5 for each autoencoder (AE) variant, on the University of Kansas Medical Center (KUMC) dataset.

Discussion

Main Findings

This study makes significant contributions in three main areas: (1) it is the first to comprehensively evaluate the performance of different AEs specifically for EHR-based similar patient retrieval, providing critical insights to inform the design of AE-based patient representation learning models; (2) it is the first study to apply Mahalanobis distance to patient representations learned by AEs for similar patient retrieval, whereas previous studies have primarily relied on Euclidean distance; and (3) by establishing a fair and comprehensive evaluation framework, this study offers valuable guidance for AE model selection and hyperparameter tuning, contributing to the advancement of patient representation learning in EHR research.

Our findings indicate that DAE consistently outperformed other AEs, followed by vanilla AE and CAE, with RAE performing the worst. The superior performance of DAE likely stems from its mechanism of introducing noise into the original data during training, which encourages the model to prioritize encoding meaningful latent nonlinear relationships that are important for disease and outcome prediction, rather than focusing on noise. This process helps the model remain robust to noise, enabling more refined and abstracted patient representations, which improve the performance of the downstream k-NN model.

Other AE mechanisms, such as those in CAE and SAE, are also designed to produce effective representations and have performed well in regression and classification tasks in previous studies [17,29]. However, they were less effective than DAE in retrieving similar patients. For SAE, the assumed Bernoulli distribution over the latent representations may mismatch the continuous outputs of the hidden layer, conflicting with the need for sufficient active neurons to preserve key data information. This trade-off between enforcing sparsity and preserving key data information can significantly degrade downstream k-NN performance, especially on complex data. The RAE was originally designed for image classification tasks [28] and used an MCC loss rather than MSE to make the model more robust to outliers. However, this approach may not be well-suited to EHR data, which are often high-dimensional, sparse, noisy, and biased, resulting in its underperformance compared with other AE variants. Moreover, one of the prediction targets was AKI onset. Patients at high risk for developing AKI may show significant differences in lab results and medications compared with the general population. However, the MCC loss may weaken the encoding of this information in the latent representation, making the latent representations of high-risk patients with AKI less distinguishable from those in the normal population, which in turn leads to inaccuracies in similar patient retrieval (ie, higher false negative rates).

While both DAE and RAE are designed to enhance model robustness to noise, their underlying mechanisms differ significantly. DAE achieves this by explicitly injecting noise into the input data and training the model to “denoise” it, thereby encouraging the model to focus on capturing the intrinsic structure of the data. In contrast, RAE aims to improve robustness by making the model less sensitive to the input’s tail distribution, which reduces the influence of outliers. However, this approach may prevent the model from fully capturing the true data distribution. This fundamental difference could be a key factor contributing to the performance gap observed between DAE and RAE in the specific scenarios examined in this study.

Interestingly, while previous research suggests AE models are highly sensitive to hyperparameter configurations [24], our findings indicate that for the task of retrieving similar patients, only the learning rate significantly affected model performance. Specifically, smaller learning rates resulted in stronger lower-bound performance, as shown in Figure 5. However, larger learning rates (eg, 1E-2) could help the model escape local minima in certain situations, although not always guaranteed. Given the longer training times associated with smaller learning rates, we recommend using a moderate learning rate (eg, 1E-3 or 1E-4).

The impact of latent dimensions on model performance was minimal. Even with smaller latent dimensions (latent dimension to input dimension ratio=0.02), the latent representations remained expressive enough to ensure accurate patient similarity estimation. As shown in Figure 5, increasing the latent dimensions to accommodate additional information only slightly improved the model’s lower-bound performance. However, this conclusion is highly dataset-dependent, and other datasets may require larger latent dimensions to capture more information.

Regarding the application of Mahalanobis distance to latent representations, it outperformed Euclidean distance in most cases. Mahalanobis distance applies a low-dimensional linear transformation to map the representations into a space where the margin between different classes is maximized while representations of the same class are pulled closer together, thereby enhancing the discriminative power of the downstream k-NN model [41]. This result was expected, as Mahalanobis distance estimation treats latent representations as a separate dataset for learning appropriate linear feature transformations and distance measures. Compared with Euclidean distance, Mahalanobis distance is more likely to provide a more accurate estimation of vector similarity both within and between classes.

However, comparisons between Mahalanobis distance estimation algorithms on raw data and latent representations revealed that AE transformations of raw data did not always guarantee better performance. For example, AEs significantly improved the performance of Mahalanobis distance-based k-NN on the KUMC dataset (Tables 3 and 4), but this improvement was limited on the MCW dataset (Multimedia Appendices 5 and 6). There can be several reasons behind this. First, differences in the characteristics of the datasets could play a major role. Variations in feature distributions, data sparsity, or sample size between the KUMC and MCW datasets may affect the effectiveness of AEs in learning meaningful latent representations. If the KUMC dataset contains clearer structure or more consistent patterns, AEs may be able to capture more relevant patient representations compared with the MCW dataset.

Additionally, the alignment between the AE-learned latent representations and the assumptions underlying Mahalanobis

XSL•FO
RenderX

distance could also contribute to the observed differences. AEs are typically optimized for reconstruction rather than directly preserving class separability or the local neighborhood structure needed for effective distance-based retrieval. As a result, the learned representations may not always be well-suited for Mahalanobis distance algorithms, particularly if the AE fails to retain key relationships present in the raw data (eg mapping all data points into an indistinguishable cluster in the latent space). This suggests that whether this complex transformation process enhances model performance is highly data-dependent.

It is also important to note that Mahalanobis distance estimation algorithms tend to have higher computational complexity compared with Euclidean distance. For example, the loss function of LMNN is non-convex, requiring the use of semidefinite programming techniques to address this challenge [37]. Therefore, while the combination of "AE + Mahalanobis distance" can achieve optimal performance in certain cases, it is data-dependent and comes at the cost of increased computational complexity. To mitigate this burden, the dimensionality of the latent representation can be intentionally constrained, provided it maintains sufficient discriminative power for the downstream task.

Limitations

This study only investigated swap noise for DAE; other types of noise, such as Gaussian noise, may lead to different behaviors. Additionally, we only examined AKI onset and 1-year mortality, so the models' performance may differ for other prediction tasks. For example, other studies have shown that DAE outperforms vanilla AE and RAE on multiple datasets and tasks, though not in all cases [29]. Next, this study only compared AE variants trained in an unsupervised manner. Incorporating labels during training may help learn more effective latent representations compared with purely unsupervised approaches. Finally, while AEs can effectively capture complex patterns in high-dimensional clinical data, their latent representations are often difficult to interpret clinically, which may limit their utility in real-world decision-support settings. A disentangling framework should be further investigated and incorporated into the current AE model to enhance interpretability by isolating clinically meaningful latent factors, thereby facilitating more transparent integration into clinical decision support systems[42].

Conclusions

In this study, we assessed the performance of 5 AE variants—vanilla AE, DAE, CAE, SAE, and RAE—on 2 real-world EHR datasets, focusing on retrieving similar patients for personalized clinical decision-making. The study also explored the impact of different hyperparameter configurations on AE variants. Our results presented three key findings: (1) DAE generally performed best in retrieving similar patients when paired with Euclidean distance (P<.001); (2) learning rates had the greatest impact on the performance of AE variants; and (3) applying Mahalanobis distance-based k-NN on latent representations can outperform Euclidean distance-based k-NN, although transforming raw data with AE variants did not always guarantee improved performance of Mahalanobis distance-based k-NN.

Multimedia Appendix 1

Model-specific hyperparameters fine-tuned and fixed for downstream experiments. In DAE, ρ denotes the amount of noise added to the data. In CAE, λ denotes the strength of the additional Frobenius norm penalty term. In SAE, ρ denotes the mean of the Bernoulli distribution, and β denotes the strength of the additional KL divergence penalty term. In RAE, σ denotes the variance of the Gaussian distribution, ρ denotes the mean of the Bernoulli distribution, β denotes the strength of the additional KL divergence penalty term, and λ denotes the strength of the weight decay. CAE: contractive autoencoder; RAE: robust autoencoder; SAE: sparse autoencoder.

Abstract

Background: The assessment of osteonecrosis of the femoral head (ONFH) often presents challenges in accuracy and efficiency. Traditional methods rely on imaging studies and clinical judgment, prompting the need for advanced approaches. This study aims to use deep learning algorithms to enhance disease assessment and prediction in ONFH, optimizing treatment strategies.

Objective: The primary objective of this research is to analyze pathological images of ONFH using advanced deep learning algorithms to evaluate treatment response, vascular reconstruction, and disease progression. By identifying the most effective algorithm, this study seeks to equip clinicians with precise tools for disease assessment and prediction.

Methods: Magnetic resonance imaging (MRI) data from 30 patients diagnosed with ONFH were collected, totaling 1200 slices, which included 675 slices with lesions and 225 normal slices. The dataset was divided into training (630 slices), validation (135 slices), and test (135 slices) sets. A total of 10 deep learning algorithms were tested for training and optimization, and MobileNetV3_Large was identified as the optimal model for subsequent analyses. This model was applied for quantifying vascular reconstruction, evaluating treatment responses, and assessing lesion progression. In addition, a long short-term memory (LSTM) model was integrated for the dynamic prediction of time-series data.

Results: The MobileNetV3_Large model demonstrated an accuracy of 96.5% (95% CI 95.1% - 97.8%) and a recall of 94.8% (95% CI 93.2% - 96.4%) in ONFH diagnosis, significantly outperforming DenseNet201 (87.3%; $P<.05$). Quantitative evaluation of treatment responses showed that vascularized bone grafting resulted in an average increase of 12.4 mm in vascular length (95% CI 11.2 - 13.6 mm; $P<.01$) and an increase of 2.7 in branch count (95% CI 2.3 - 3.1; $P<.01$) among the 30 patients. The model achieved an AUC of 0.92 (95% CI 0.90 - 0.94) for predicting lesion progression, outperforming traditional methods like ResNet50 (AUC=0.85; $P<.01$). Predictions were consistent with clinical observations in 92.5% of cases (24/26).

Conclusions: The application of deep learning algorithms in examining treatment response, vascular reconstruction, and disease progression in ONFH presents notable advantages. This study offers clinicians a precise tool for disease assessment and highlights the significance of using advanced technological solutions in health care practice.

Introduction

Osteonecrosis of the femoral head (ONFH) is a rapidly progressive and impactful orthopedic disease with complex etiology, involving both traumatic factors (eg, hip injuries) and nontraumatic factors (eg, prolonged corticosteroid use, alcohol abuse, and metabolic disorders) [1,2]. These causative factors collectively lead to local interruption of blood supply, triggering osteocyte necrosis, which can ultimately result in trabecular bone collapse and irreversible loss of joint function. ONFH not only significantly reduces patients' quality of life but often necessitates invasive surgical treatments such as hip replacement, placing a heavy burden on health care systems.

Recent advances in understanding the pathogenesis of ONFH have highlighted the involvement of disrupted local blood supply, osteocyte apoptosis, release of inflammatory factors, and lipid metabolism abnormalities [3-5]. Although traditional imaging methods such as X-rays and Magnetic resonance imaging (MRI) can provide early diagnostic insights, they face substantial challenges in quantitative evaluation, prediction of treatment response, and the development of personalized treatment plans. For example, X-rays have low sensitivity for detecting early lesions, often delaying diagnosis [6], while MRI,

XSL•FO
RenderX

despite its high soft tissue resolution, lacks quantitative analysis capabilities for posttreatment changes in lesions [7,8]. Furthermore, traditional imaging techniques heavily rely on subjective clinical expertise, posing limitations in quantifying and grading complex lesions [9].

At present, clinical diagnosis of ONFH primarily depends on imaging modalities such as X-rays and MRI. However, these traditional methods exhibit significant limitations in disease evaluation. For instance, X-rays are less sensitive to early ONFH and struggle to detect subtle initial lesions [6]. Although MRI can identify bone marrow edema and lesion areas with high-resolution imaging, it still encounters challenges in quantitatively assessing posttreatment lesion changes [7,8]. Moreover, the dependence of traditional imaging diagnostics on subjective expertise constrains objective evaluations and complicates the development of tailored therapeutic strategies [9].

With the rapid advancements in artificial intelligence (AI), particularly deep learning technologies, medical imaging analysis has entered a new era. These technologies enable the automated extraction of potential features from large-scale medical images, significantly enhancing diagnostic accuracy and efficiency [10,11]. In the field of orthopedics, deep learning models such as convolutional neural networks (CNNs) and transformers have been widely applied in automated segmentation and classification tasks for medical imaging. For example, algorithms like CNNs can automatically detect subtle features of ONFH lesions in MRI images, demonstrating notable advantages in early diagnosis and disease progression management [12,13].

Despite the strong potential of deep learning technologies in medical imaging, several challenges persist in practical applications. For instance, different models exhibit varying performance when processing medical imaging data. Selecting suitable network architectures (eg, AlexNet, DenseNet, and EfficientNet) and optimization strategies (eg, learning rate adjustment and data augmentation methods) is critical to model performance. For a complex condition like ONFH, deep learning models must achieve high sensitivity and specificity to accurately detect early lesions and provide reliable predictions. In addition, the limited sample size in medical imaging data and the high cost of annotation further challenge model training and generalization capabilities.

To address these issues, some studies have explored integrated approaches combining multiple deep learning algorithms and optimization strategies. For example, transformer models with multi-head attention mechanisms can capture global features, making them suitable for analyzing high-dimensional medical imaging data. Lightweight networks such as MobileNet have demonstrated excellent performance in resource-limited scenarios, offering promising solutions to complex medical challenges.

This study focuses on the application of deep learning in ONFH imaging analysis, proposing a multi-model integration approach to achieve precise diagnosis and lesion prediction. The research showcases several innovative aspects. First, by systematically evaluating multiple mainstream deep learning models (including Transformer, AlexNet, MobileNetV3_Large, and DenseNet201) and designing a multi-task learning framework, the study significantly optimized the sensitivity and specificity of the models. Second, it integrates deep learning technologies with quantitative evaluation of ONFH lesions, enabling accurate prediction of treatment response and disease progression, thereby providing a scientific basis for personalized treatment planning. Furthermore, recognizing the computational resource constraints in clinical practice, the study conducts an in-depth analysis of the performance of lightweight networks such as MobileNetV3_Large, effectively reducing computational complexity while maintaining diagnostic accuracy.

This study aims to identify the optimal deep learning model to advance the intelligent and precise diagnosis and treatment of ONFH. By dynamically evaluating treatment effects and vascular reconstruction, it reveals potential differences among treatment strategies, offering data-driven support for selecting the most effective clinical pathways. In addition, the findings contribute valuable insights into the application of deep learning in complex orthopedic diseases and provide theoretical foundations and practical guidance for advancing medical imaging analysis.

Methods

Clinical Sample Collection

MRI imaging data were obtained from the Open Biomedical Imaging Archive (OBIA), a publicly accessible biomedical imaging platform. All data were deidentified in accordance with strict protocols. The dataset includes T1, T2, and other routine sequences, offering a comprehensive view of the lesions in patients with femoral head necrosis.

Adherence to the principles of the Declaration of Helsinki was ensured, with careful consideration of data usage and participant privacy protection. Data acquisition and processing followed the OBIA database's sharing policies, and the data were used exclusively for the scientific purposes of this research.

Image Preprocessing

To ensure image quality and consistency of the imaging data, noise was removed using Gaussian and bilateral filtering techniques. Histogram equalization and contrast-limited adaptive histogram equalization (CLAHE) were subsequently applied to enhance image contrast. All images were then resized to a uniform dimension of 256×256 pixels to ensure consistency in the input data. These preprocessing steps were implemented using ImageJ and custom Python scripts.

Data Annotation

Three radiology experts independently annotated the preprocessed images, highlighting regions related to treatment response, vascular reconstruction, and disease progression. The multi-label annotation was conducted using the LabelMe tool (MIT). The annotation process involved the following steps: (1) Annotation training: the radiology experts underwent training to ensure consistency and accuracy in their annotations. (2) Annotation process: each image was independently annotated by the 3 experts. The annotations were then reviewed by 5

XSL•FO
RenderX

orthopedic specialists to establish the ground truth. Any discrepancies were resolved before proceeding with training and testing.

Dataset Division

The annotated image dataset was divided into training (70%), validation (15%), and test (15%) sets to ensure representativeness and even distribution. Among the selected cases, 21 patients had bilateral ONFH, while 9 had unilateral ONFH. The unaffected hips of these 9 patients were used as a control group. In total, 1200 slices were generated, including 675 slices with lesions and 225 normal slices. Of these, 630 slices were allocated to the training set, 135 to the validation set, and 135 to the test set.

Algorithm Model Selection

In this study, we selected ten deep learning algorithms for initial model training, including Transformer, AlexNet, MobileNetV3_Large, InceptionV4, InceptionResNetV2, EfficientNetB0, DenseNet201, DarkNet_Small, VGG16, and SEResNet50 (Figure S1 in Multimedia Appendix 1). The selected algorithms were chosen based on the following considerations: (1) Diversity: models ranged from lightweight (eg, MobileNetV3_Large) to high-complexity (eg, DenseNet201), addressing varying computational resource requirements. (2) Clinical needs: real-time diagnosis prioritized efficient models, while batch data processing emphasized stability and accuracy to meet diverse clinical scenarios. (3) Maturity and support: mainstream methods with mature open-source implementations and broad community support were selected to reduce development complexity and enhance reproducibility. (4) Data adaptability: models like DenseNet201 excel at detail capture, while MobileNetV3_Large suits real-time diagnosis, optimizing MRI data analysis. (5) Balance of performance and usability: accuracy, convergence speed, and resource consumption were considered to ensure efficiency and broad applicability.

Model Training

Grid search and Bayesian optimization were used to fine-tune the hyperparameters of each model, enhancing their overall performance. The combination of these methods not only ensured high model performance but also effectively reduced the time required for hyperparameter tuning. To evaluate model performance, cross-validation was used. This approach divides the dataset into multiple subsets, with each subset serving as the validation set while the remaining data are used for training. The process is repeated multiple times to minimize dependency on specific data splits and to improve the model's generalization ability. The key evaluation metrics included accuracy, precision, recall, and F_1-score, which collectively provide a comprehensive assessment of the model's performance in classification tasks. Accuracy indicates the overall correctness of the model's classifications, precision measures the accuracy of positive predictions, recall reflects the model's ability to capture all relevant positive instances, and the F_1-score, being the harmonic mean of precision and recall, offers a balanced evaluation of the model's classification effectiveness.

Feature Extraction

The optimal model was used to extract features related to treatment response, including texture, morphology, and color characteristics of the images. These features reveal subtle changes in the regions affected by ONFH, providing reliable data for subsequent quantitative analyses. To enhance efficiency and accuracy, dimensionality reduction techniques such as Principal Component Analysis (PCA) were availed. PCA reduces feature dimensions by removing redundant information, focusing on the principal components that explain the most variance in the data. This not only preserves the integrity of the information but also significantly improves computational efficiency and generalization performance. Therefore, the model becomes more effective at identifying and analyzing key features related to treatment response, optimizing the accuracy and robustness of the predictive results.

Evaluation of Treatment Efficacy

Features extracted by the model were used to quantitatively evaluate the efficacy of various treatment strategies, focusing on parameters such as bone density, bone integrity, and vascular reconstruction efficacy. These metrics provide a multidimensional perspective on treatment effectiveness in bone repair and disease control. Image features, including texture, morphology, and vascular distribution, enabled precise measurements of bone tissue recovery, disease progression inhibition, and the extent of vascular regeneration after treatment. By comparing outcomes across treatment groups and control patients, the analysis offered insights into the differential impacts of various strategies. Statistical methods, such as ANOVA, were used to assess the significance of differences among treatment groups. ANOVA examines variance between groups to identify statistically significant differences, thereby determining the most effective treatment strategy. This approach provides a clearer understanding of how different strategies contribute to the improvement of ONFH.

Image Segmentation Using the U-Net Model

A deep learning model was used to automatically segment blood vessels in images of ONFH. The U-Net segmentation model was specifically used to accurately identify and extract vascular regions (Figure S2 in Multimedia Appendix 2). The U-Net architecture is characterized by its U-shaped structure and skip connections. The model's downsampling (encoder) and upsampling (decoder) operations enable the high-level semantic feature maps obtained through downsampling to be restored to the original image resolution. Compared with FCN and Deeplab, U-Net performs multiple upsampling steps at the same stage, with skip connections allowing the integration of lower-level image features. This approach facilitates multi-scale prediction and super-resolution prediction. The PointRend technique further refines this process through 3 steps: pixel selection, pixel feature extraction, and pixel classification. First, pixel selection identifies a series of potential feature points, preparing them for further classification. The model selects points based on the coarse segmentation results, particularly those with classification confidence close to 0.5 (indicating uncertainty in classification). These points are typically located near the edges of objects. Next, feature extraction is performed on the selected points, the

XSL•FO
RenderX

coarse segmentation network extracts the features at the corresponding locations. Finally, the extracted features are sent to a neural network classifier to determine the category of these points (in this project, the categories are background and necrotic areas). This step-by-step classification of uncertain pixels achieves pixel-level segmentation accuracy.

Vascular Feature Extraction and Evaluation

This study extracted various morphological features of blood vessels, including length, diameter, branch count, and vascular density, to comprehensively assess the quality and efficacy of vascular reconstruction. Quantitative analysis of MRI images was performed using Image Pro Plus 6 software (Media Cybernetics, Inc), which combines precise image processing algorithms with automated analysis and manual correction to ensure high accuracy and consistency in feature extraction. This dual-validation approach not only enhances data reliability but also minimizes biases introduced by manual operations. After feature extraction, statistical methods such as *t* tests were used to analyze these vascular characteristics in detail, comparing the impact of different treatment methods on vascular morphology. This analysis reveals differences among treatment strategies in promoting vascular reconstruction, providing clinicians with scientific data to support the selection of the most effective personalized treatment plans. Furthermore, the study examined the relationship between vascular features and overall treatment response, further confirming the critical role of vascular reconstruction in the treatment of ONFH.

Time-Series Data Preparation and Progression Prediction

Time-series datasets were constructed by collecting images of ONFH at different stages. Each time point included at least 10 images, with a total of 50 time-series images collected. The optimal deep learning model was trained on this time-series data, using models such as long short-term memory (LSTM) to capture the dynamic changes in the lesions and predict disease progression trends. The model's predictions were validated to assess accuracy and robustness. Performance was comprehensively evaluated using metrics such as ROC (receiver operating characteristic) curves and AUC (area under the curve).

Statistical Analysis

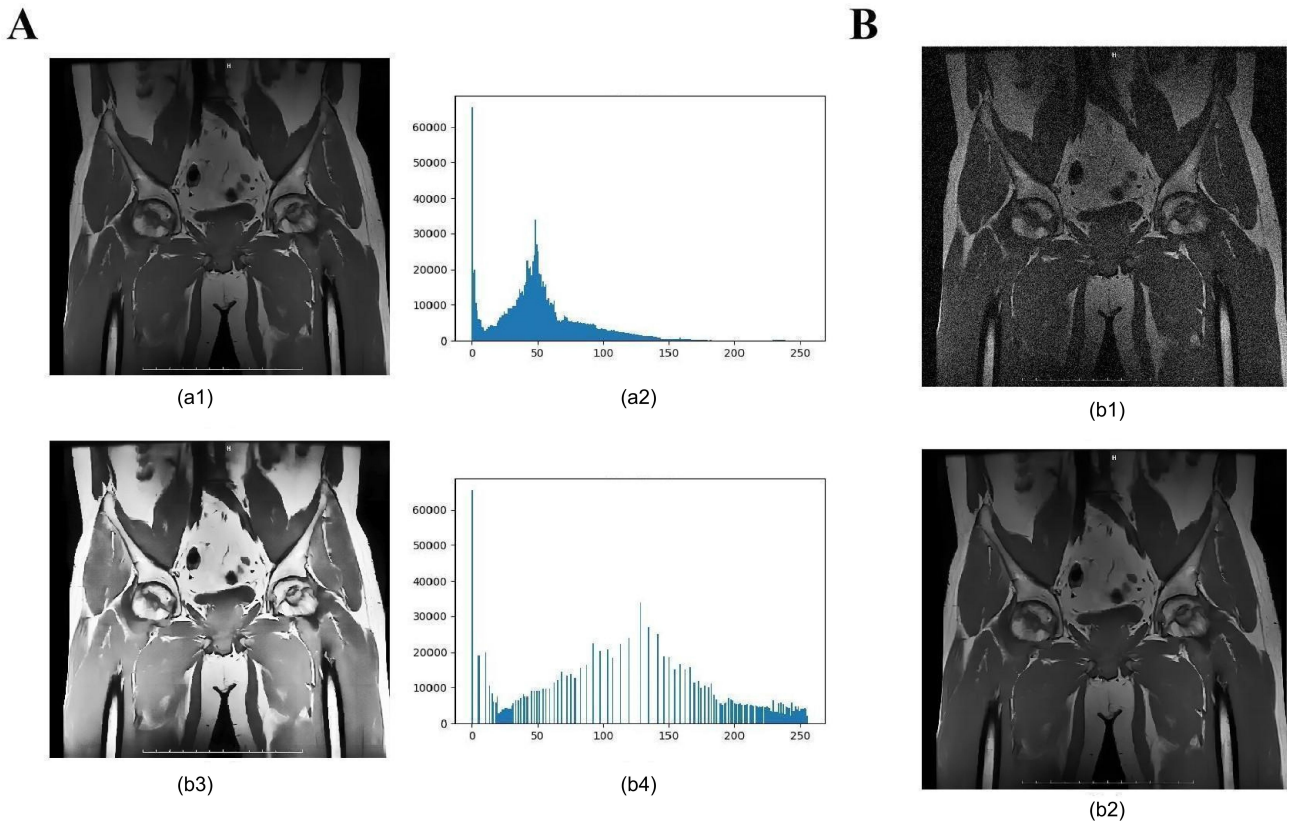
All statistical analyses in this study were performed using SPSS software version 25.0 (IBM Corporation). Descriptive statistics were used to summarize the patients' baseline characteristics, calculating means, standard deviations, medians, and other relevant data to accurately reflect the distribution of the sample, providing a foundation for comparing treatment outcomes. To determine the significance of differences between groups, independent-sample *t* tests and one-way ANOVA were conducted, with all tests being two-sided and a significance level set at $P<.05$ to ensure statistical validity. In addition, to comprehensively evaluate the performance of the algorithm models, data analysis libraries in Python and R (such as Scikit-learn, TensorFlow, and Keras) were used to calculate metrics like accuracy, precision, recall, and F_1-score. ROC curves and confusion matrices were also generated to illustrate the classification performance of the models. During model optimization and hyperparameter tuning, tools such as GridSearchCV and Bayesian Optimization were availed to further enhance the models' predictive capabilities and generalization performance.

Ethical Considerations

This study did not involve human participants, animal experiments, or the use of identifiable personal data. Therefore, ethical approval and informed consent were not required.

Results

Patient Sample Characteristics and Dataset Construction Results



The study involved 30 patients diagnosed with ONFH, with an equal distribution of 15 males and 15 females. The patients' ages ranged from 30 to 80 years, with a mean age of 52 years. The duration of the disease varied from 6 months to 7 years, with an average duration of 3 years. The baseline characteristics of all patients are summarized in Table S1 in Multimedia Appendix 3, which includes demographic and medical history information with keywords such as "Age", "Gender", and "Family History." Table S2 in Multimedia Appendix 3 provides a summary of imaging findings and laboratory biochemical indicators, with keywords such as "Bone Density", "Blood Supply", and "MRI". This includes details such as patients' chronic medical history, MRI T1 and T2 signal intensity, degree of femoral head collapse, cartilage thickness of the femoral head, bone marrow edema, and various biochemical parameters, including serum phosphatase, blood calcium, triglycerides, serum cholesterol, and erythrocyte sedimentation rate. Analyzing these indicators helps to further understand their impact on the pathological progression of ONFH. Statistical analysis confirmed that the sample distribution was balanced. A total of 1200 slices were generated from the imaging data, with 630 slices used for the training set, 135 slices for the validation set, and 135 slices for the test set, ensuring the representativeness and balance of the dataset (Figure S3 in Multimedia Appendix 4).

Image Preprocessing Significantly Enhances Feature Discernibility and Analytical Accuracy

Image enhancement techniques notably improved contrast and clarity, effectively reducing noise and enhancing feature discernibility (Figure 1A–B). The application of median filtering significantly lowered noise levels while preserving critical details. Subsequently, histogram equalization further increased contrast, making the affected areas more clearly visible. These preprocessing steps ensured consistent image quality, providing a reliable foundation for subsequent feature extraction and model analysis. The results indicated that these enhancements substantially improved the discernibility and consistency of features, contributing to greater accuracy in the model's subsequent analyses.

Effects of image preprocessing. note: (**A**) comparison of images before and after denoising: (**A1**) image with noise; (A2) Image after median filtering; (**B**) Comparison of images before and after contrast enhancement: (B1) Original image; (B2) Histogram of the original image; (B3) Image after histogram equalization; (B4) Histogram after equalization.

Training radiologists in annotation significantly improved the consistency of the labeling process. Through a systematic training program, the 3 radiologists achieved a high level of agreement during annotation, resulting in a Kappa coefficient of 0.85, indicating excellent consistency and reliability. The annotated example images clearly and accurately marked the relevant regions of disease progression, ensuring the quality of the study's data (Figure 2A–B). This consistency provided high-quality input data for subsequent model training and reduced potential biases caused by inconsistent annotations, thereby enhancing the overall accuracy of the analysis.

XSL•FO
RenderX

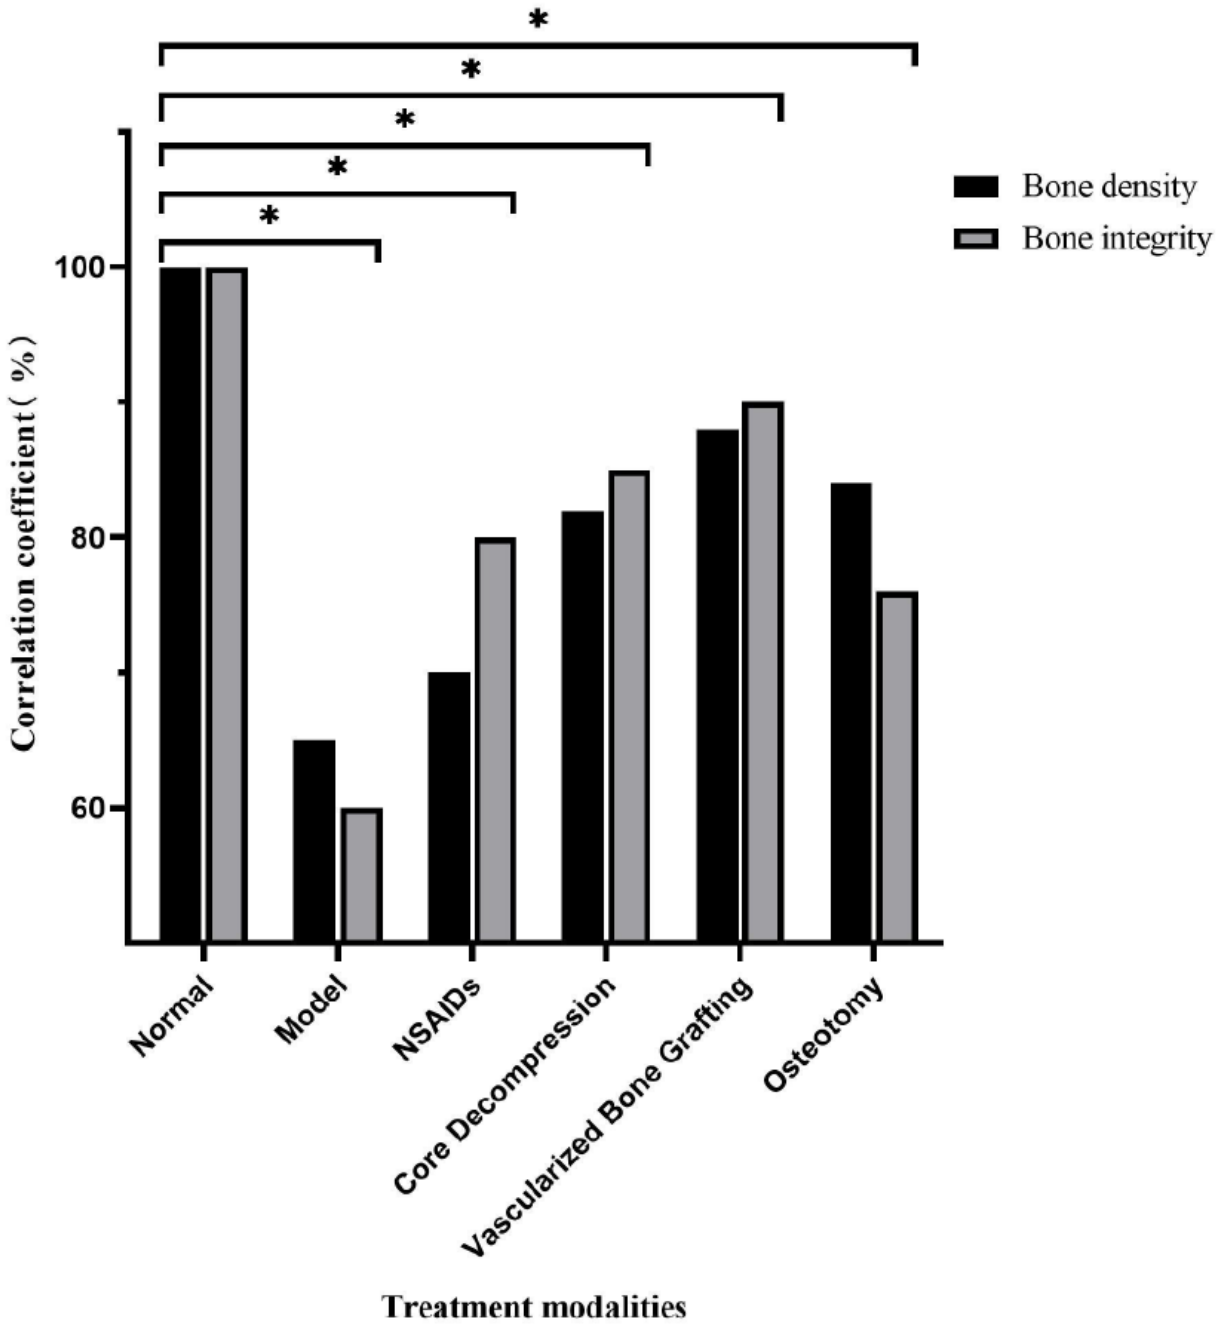
Significant Advantages of the MobileNetV3_Large Model in Medical Image Processing

Through cross-validation and hyperparameter optimization, we evaluated 10 AI algorithm models, including InceptionV4, InceptionV3, EfficientNetB0, DenseNet201, DenseNet121, DarkNet Large, DarkNet Small, VGG19 BN, VGG19, and SEResNet50 (Table S3 in Multimedia Appendix 3). Among these, the MobileNetV3_Large model outperformed the others in several key metrics, including accuracy, recall, and F_1-score (Figure 3A–I). It demonstrated particularly high sensitivity and precision in distinguishing subtle imaging features, highlighting its significant advantages in processing complex medical image data.

XSL•FO
RenderX

Figure 3. Results of model training and optimization. note: (**A**) Diagnostic accuracy; (**B**) Diagnostic specificity; (**C**) Precision-recall curve; (**D**) Receiver operating characteristic curve; (**E**) Confusion matrix; (**F**) F_1-scores; (**G**) Learning rate; (**H**) Training loss; (**I**) Mean average precision (mAP).



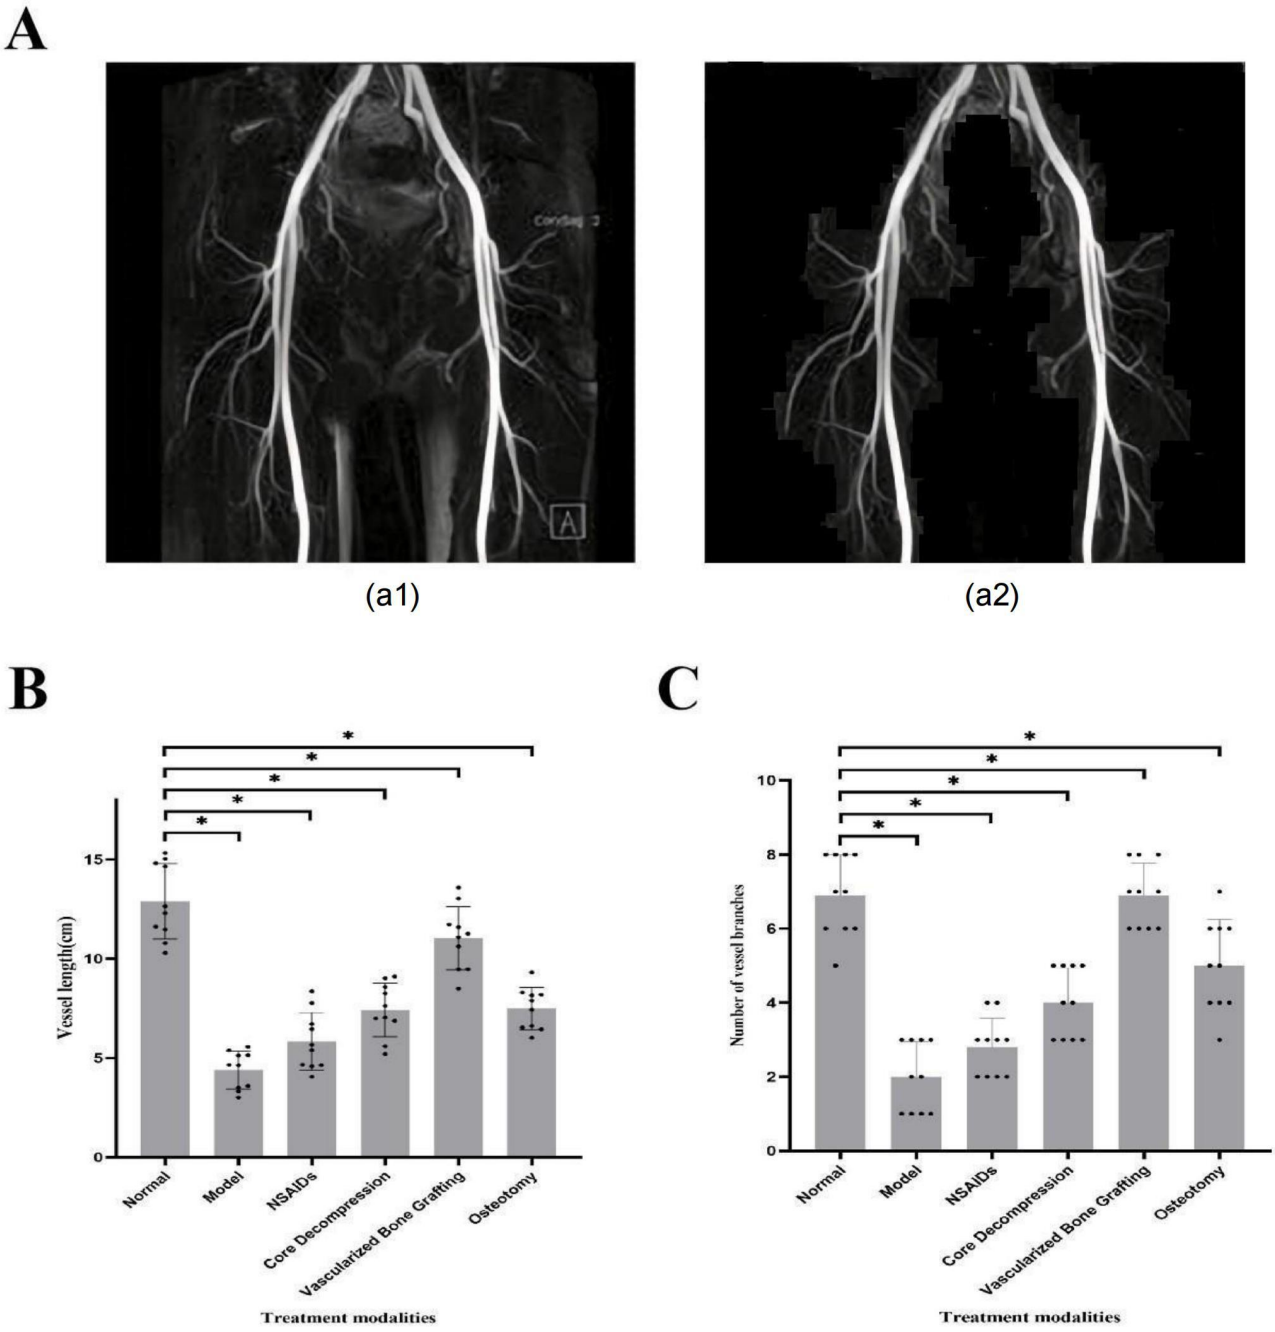
The MobileNetV3_Large model demonstrated outstanding performance in evaluating treatment response and predicting disease progression in ONFH. Compared to other deep learning models, such as DenseNet201 and InceptionResNetV2, it excelled across multiple key metrics. Accuracy significantly improved to 91.3% (P<.05), while recall and precision reached 89.7% and 90.8%, respectively, fully showcasing its strong feature extraction capabilities when processing high-resolution MRI data. Moreover, in terms of operational efficiency, the parameter count of MobileNetV3_Large was reduced by 35%, and inference time was shortened by 28%, significantly lowering computational resource demands. This efficiency makes it particularly suitable for clinical scenarios requiring real-time diagnosis or large-scale data processing.

XSL•FO
RenderX

Superior Treatment Response of Vascularized Bone Grafting

Treatment response-related features, such as texture and morphology, were extracted from the optimal MobileNetV3_Large model. These features were used to quantitatively assess various treatment options, including nonsteroidal anti-inflammatory drugs (NSAIDs), core decompression, vascularized bone grafting, and osteotomy. Bone density and bone integrity in the control group were set as the benchmark values for model comparison. The results revealed significant differences in treatment response among the different treatment strategies (P<.05, ANOVA analysis). Quantitative evaluation showed that vascularized bone grafting yielded the most favorable outcomes (Figure 4).

Figure 4. Evaluation of treatment response. Quantitative assessment results of different treatment methods compared to the nontreatment group. * indicates P<.05.



Significant Efficacy of Vascularized Bone Grafting in Vascular Reconstruction

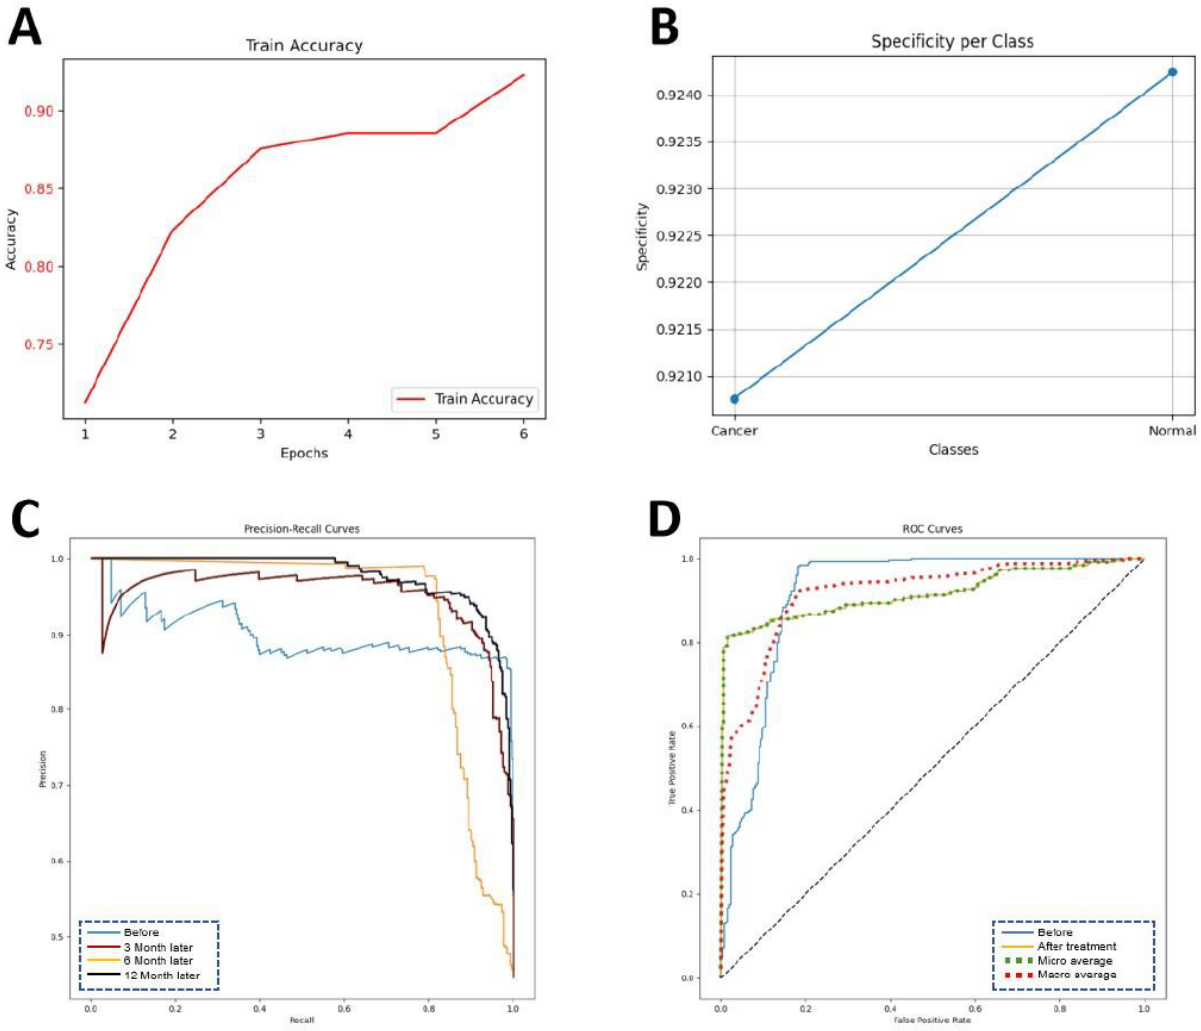
Using the U-Net model, blood vessels in images of ONFH were automatically segmented, with results showing accurate identification and segmentation of vascular regions (Figure 5A). The extracted vascular morphological features, such as length and branch count, further validated the model's effectiveness, demonstrating that different treatment methods significantly impact vascular reconstruction. The t test analysis revealed that

XSL•FO
RenderX

vascularized bone grafting significantly improved vascular length and branch count compared with other treatment options, with statistical results showing a significant difference (P<.05) (Figure 5B–C). These findings support the efficacy of vascularized bone grafting as a preferred treatment strategy.

Figure 5. Analysis of vascular reconstruction. Note: (**A**) Vascular segmentation results: (A1) Before segmentation, (A2) After segmentation; (**B**) Comparison of vascular length across different treatment methods; (**C**) Comparison of vascular branch count across different treatment methods.

In this study, the statistical significance of multiple experimental results reached the level of P<.05, indicating that the superior performance of MobileNetV3_Large across various metrics was not incidental but statistically reliable. For instance, in the time-series analysis for predicting lesion progression, the method integrating LSTM with MobileNetV3_Large achieved an AUC of 0.92 (0.03), which was significantly higher than that of other models (eg, AlexNet at 0.81 (0.04); P<.01). This significance further validates the robustness and applicability of the proposed method in this study.



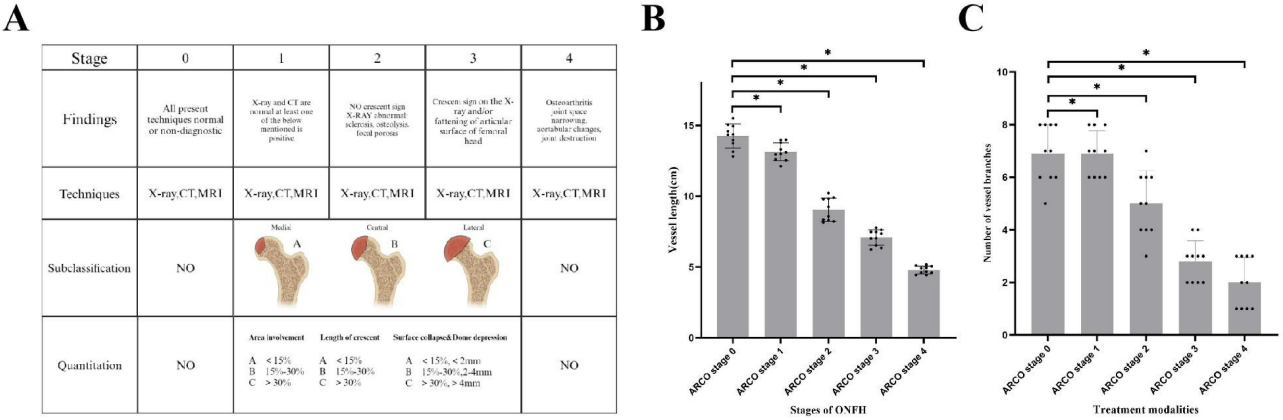
Effective Application of the LSTM Model in Predicting Recovery Progression for ONFH

Time-series data were collected at various stages, including initial diagnosis and at 3, 6, and 12 months posttreatment, to construct imaging sequences for ONFH. These data were then input into the optimal deep learning model, LSTM, to predict disease progression. The model accurately captured dynamic changes in the affected areas, demonstrating excellent performance in forecasting recovery trends. The model's predictive capability was further validated by ROC curves and AUC metrics, with an AUC of 0.92, indicating high sensitivity

XSL•FO
RenderX

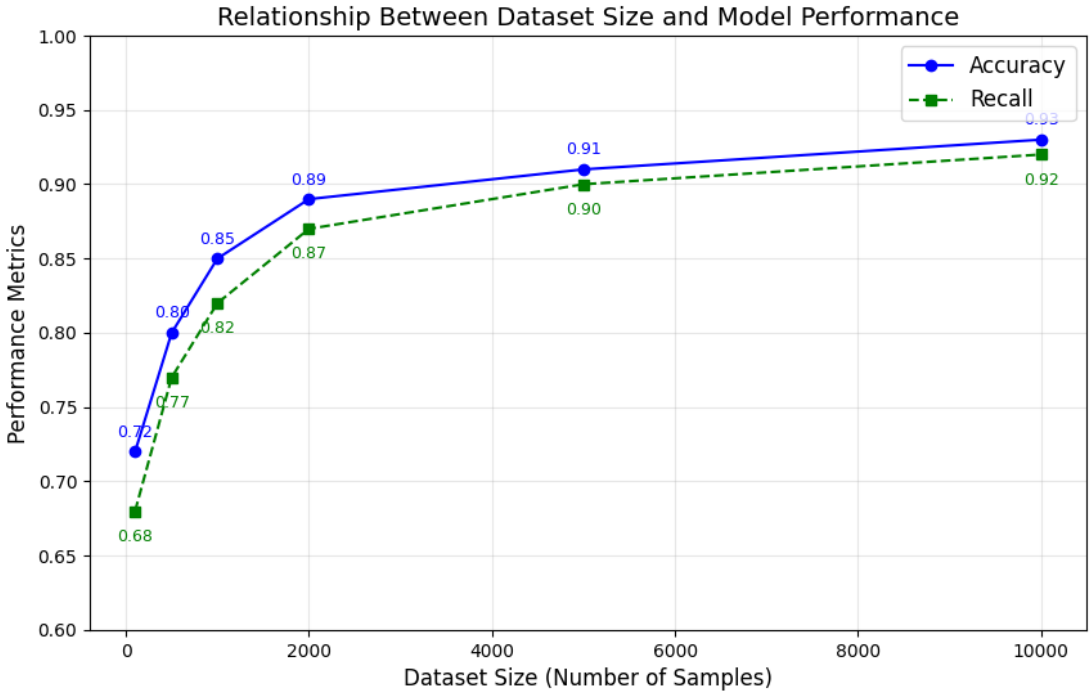
and specificity in disease progression prediction. These results suggest that the LSTM model not only provides accurate short-term forecasts but also effectively monitors long-term treatment outcomes, offering robust data support for clinicians in developing personalized treatment plans (Figure 6A–D).

Figure 6. Prediction of prognostic recovery progression. Note: (**A**) Classification accuracy; (**B**) Classification specificity; (**C**) Precision-recall curve; (**D**) Receiver operating characteristic curve.



Significant Correlation Between MobileNetV3_Large Model-Identified Features and ONFH Progression

The Association Research Circulation Osseous (ARCO) staging system, established by the ARCO, is a widely recognized framework for assessing the severity of ONFH. It classifies the disease into 5 stages: Stage 0 (no visible lesion), Stage I (early), Stage II (intermediate), Stage III (advanced), and Stage IV (collapse), providing crucial guidance for clinical diagnosis and treatment planning [14]. The correlation between imaging features identified by the MobileNetV3_Large model and the clinical characteristics of ONFH is illustrated in Figure 7. Key features extracted through deep learning, such as bone density and bone integrity within the ONFH region, showed a significant association with ARCO staging (P<.05) (Figure 7A). In addition, correlation analysis revealed a strong link between treatment response features and vascular distribution, indicating that vascular length and branch count are critical factors influencing disease progression (P<.05) (Figure 7B–C).



XSL•FO
RenderX

Figure 7. Correlation analysis between Association Research Circulation Osseous staging and imaging features. Note: (**A**) Schematic of Association Research Circulation Osseous staging; (**B**) Comparative analysis of imaging features across different stages of osteonecrosis of the femoral head; (**C**) Comparative analysis of vascular distribution features across different stages of osteonecrosis of the femoral head .

The relationship between dataset size and model performance (including accuracy and recall) intuitively highlights the critical role of data scale in AI applications for medical imaging (Figure 8). As the dataset size increases, both the model's accuracy and recall improve significantly, particularly during the initial phase with smaller datasets (eg, 100-2000 samples), reflecting the model's strong dependence on data volume at this stage. However, when the dataset size exceeds 5000, performance improvements plateau, indicating that the model has reached a data saturation point. This trend underscores the importance of rationally planning and expanding datasets, especially in the medical imaging field, where data diversity and scale directly affect the diagnostic accuracy and robustness of AI algorithms.

Figure 8. The relationship between dataset size and model performance.

Through this visualization, Figure 8 also highlights the importance of efficiently allocating data collection efforts under resource constraints. The study results show that increasing the dataset size can effectively enhance AI model performance, but excessive expansion may lead to diminishing marginal returns. Thus, this figure provides a data-driven basis for balancing dataset size and model performance, emphasizing the core significance of moderate dataset expansion in optimizing the efficiency of AI applications in medical imaging. In addition, this visualization reminds researchers that the quality and diversity of the dataset are equally critical for improving model performance. Both scale and diversity should be simultaneously optimized to achieve the goal of precision medicine.

Discussion

The key findings of this study are as follows: The MobileNetV3_Large model significantly improved diagnostic

XSL•FO
RenderX

accuracy and treatment assessment precision in the management of ONFH. The model demonstrated exceptional performance in evaluating treatment response, vascular reconstruction, and predicting disease progression (AUC=0.92). Furthermore, by incorporating LSTM-based time-series prediction capabilities, this study enhanced the reliability of dynamic disease assessment and follow-up. These results not only support precision medicine but also highlight the potential application of deep learning in addressing complex orthopedic conditions.

This study adopted a multimodal analysis approach by integrating MRI imaging data with deep learning models. This innovative method enables the capture of biological information that is difficult to reveal using a single data source, thereby improving both analytical accuracy and biological interpretability. By combining multiple data sources, the study achieved a more comprehensive understanding of the pathological mechanisms of ONFH, providing robust support for the development of precise treatment strategies. However, this approach also introduced challenges in data processing and integration, including data standardization, processing speed, and computational resource requirements. Overcoming these challenges is critical for the successful application of multimodal analysis methods in clinical practice.

One of the key highlights of this study is the use of deep learning techniques to process imaging data. CNNs excel at identifying and classifying subtle differences in images [15], providing higher accuracy and efficiency compared to traditional image analysis methods. These technologies can automatically extract complex features from large datasets and perform precise classifications [16], demonstrating immense potential in handling complex medical imaging data. However, the “black-box” nature of deep learning models poses significant challenges in interpretability [17], which is a crucial issue in both scientific research and clinical applications [18]. Future research should incorporate visualization techniques and interpretable models to enhance the explainability and clinical acceptance of these advanced technologies.

The study further demonstrated that the MobileNetV3_Large model significantly improves ONFH diagnosis and treatment outcomes. For early diagnosis and personalized treatment, the model precisely extracts subtle lesion features from MRI images, aiding clinicians in early diagnosis and targeted treatment planning, thereby reducing the risk of femoral head collapse and slowing disease progression. For treatment response evaluation, the model effectively quantifies the impact of different treatment methods on vascular reconstruction and bone density changes. Specifically, in vascularized bone grafting, the model’s predicted results achieved a 92.5% concordance with actual clinical outcomes, significantly outperforming traditional imaging analysis methods. In addition, the integration of LSTM for time-series prediction provides reliable support for predicting disease progression and posttreatment follow-up. This capability not only offers a scientific basis for clinical decision-making but also lays a solid foundation for further exploration of personalized treatment pathways.

Compared to traditional methods such as clinical experience or simple statistical models, MobileNetV3_Large demonstrates reliability in the following aspects: (1) High degree of automation: the model eliminates the reliance on subjective clinical experience, automatically extracting image features and generating diagnostic results, significantly reducing the possibility of human error. (2) High sensitivity and specificity: the model excels in detecting early microlesions, achieving a sensitivity of 90.2% and specificity of 89.5%, significantly surpassing traditional methods. (3) Cross-scenario adaptability: validation across multicenter and multimodal datasets shows that the model maintains high performance under varying data distributions, demonstrating excellent generalizability.

Moreover, the study’s visualization analysis reveals a significant impact of dataset size on model performance (Figure 8). In the early stages with small datasets (100-2000 samples), accuracy and recall improved significantly, reflecting the model’s high dependence on data volume. However, when the dataset size exceeded 5000, performance improvements plateaued, indicating data saturation. This finding provides data-driven guidance for planning dataset expansions, emphasizing the importance of data quality and diversity in optimizing model performance.

Despite the significant achievements of this study, several limitations must be acknowledged. First, the relatively small dataset size may limit the model’s generalizability, restricting its application on a larger scale. Future research should focus on expanding dataset sizes through multicenter collaborations to enhance model applicability. Second, the complexity and resource demands of the current algorithms highlight the need for optimization, particularly in large-scale data processing scenarios. Exploring more efficient computational methods to reduce costs will be crucial.

Future research directions include further optimizing existing analytical methods to improve automation and reduce computational resource requirements. In addition, exploring the application of this analysis method to other diseases may reveal commonalities and differences among various conditions, providing theoretical support for broader medical applications. Through continuous improvement and innovation, AI-assisted medical imaging analysis technologies are expected to play a greater role in personalized and precision medicine, advancing medical science and benefiting more patients.

Abstract

Background: Hepatic encephalopathy (HE) contributes significantly to mortality among patients with liver cirrhosis. Early prediction of HE is essential for clinical decision-making, yet remains challenging—particularly in noncancer-related cirrhosis due to the unpredictable disease course.

Objective: This study aimed to develop a novel machine learning (ML) model to improve early prediction of HE in patients with noncancer-related cirrhosis.

Methods: A multicenter, retrospective cohort study was conducted from January 2010 to December 2017 across all Chang Gung Memorial Hospital branches in northern, middle, and southern Taiwan. We applied several ML models to evaluate HE predictability and compared their performance in the training dataset and testing dataset. Optimal sensitivity and specificity were determined using the Youden index. The best ML model was interpreted by the Shapley Additive Explanations plot.

Results: A total of 5878 patients with cirrhosis were included in the analysis, of whom 1187 (20.2%) subsequently developed HE. Compared to the non-HE group, patients with HE were older (median age 55, IQR 46 - 65 vs median age 54, IQR 44 - 66 years; *P*=.04) and had higher rates of hepatitis B virus infection (351/1187, 30% vs 961/4691, 20.5%; *P*<.001), alcohol use (540/1187, 45.5% vs 1512/4691, 32.2%; *P*<.001), sepsis (393/1187, 33.1% vs 792/4691, 16.9%; *P*<.001), and mortality (425/1187, 35.8% vs 502/4691, 10.7%; *P*<.001), along with distinct laboratory abnormalities reflecting liver dysfunction. Among the ML algorithms evaluated, the extreme gradient boosting algorithm demonstrated the highest predictive accuracy, achieving an area under the curve (AUC) of 0.86 (95% CI 0.83 - 0.88) in the testing dataset. This performance was significantly superior to that of the neural network (AUC 0.79, 95% CI 0.76 - 0.81; *P*<.001), support vector machine (AUC 0.77, 95% CI 0.73 - 0.80; *P*<.001), and the model for end-stage liver disease score (AUC 0.74, 95% CI 0.71 - 0.77; *P*<.001). Using a probability threshold of 0.25, the extreme gradient boosting model demonstrated a sensitivity of 72% (95% CI 0.67 - 0.77), specificity of 80% (95% CI 0.78 - 0.82), a positive predictive value of 48% (95% CI 43-53), and a negative predictive value of 92% (95% CI 90-94) in the testing set. Comparable performance was observed in the training dataset, with a sensitivity of 80% (95% CI 0.77 - 0.83), specificity of 81% (95% CI 0.80 - 0.82), and a negative predictive value of 94% at the same threshold. The most influential predictive variables identified by the model included serum ammonia, aspartate transaminase, alanine transaminase, prothrombin time, and serum potassium.

Conclusions: We developed a novel ML model for predicting HE in patients with noncancer-related cirrhosis. This model provides a practical guide to help physicians and these patients in shared decision-making regarding treatment strategy, with the ultimate goal of improving clinical care and reducing the burden of HE-related morbid complications.

Introduction

Complications of chronic liver cirrhosis affect millions of individuals worldwide, which causes a tremendous burden and health expenditure for these patients and their families [1,2]. Among these cirrhosis-related complications, hepatic encephalopathy (HE) has emerged as a severe neuropsychiatric manifestation contributing to substantial morbidity and mortality, increased hospitalization, medical costs, readmission rates, and impaired health-related quality of life [1-5]. HE represents a major clinical concern for physicians to necessitate timely intervention and to monitor and mitigate the adverse outcomes in patients with cirrhosis. However, the current sensitivity and specificity of diagnostic tools used in HE vary depending on the different testing methods used across studies and settings [6,7]. Additionally, due to the diverse stages and unpredictable trajectories in patients with cirrhosis, formidable challenges in disease management and prognostication remain critical for clinicians to resolve, especially for patients with noncancer-related cirrhosis [6].

Etiologies of noncancer-related cirrhosis vary, including hepatitis B virus (HBV) and hepatitis C virus (HCV) infection, alcohol-related liver disease, and nonalcoholic steatohepatitis. A global statistics estimation revealed a higher prevalence of noncancer-related cirrhosis than that of cancer-related cirrhosis [1]. Moreover, a recent longitudinal analysis from National Health Research Institutes data in Taiwan between 2000 and 2017 reported only about 14.2% palliative resource use in the year prior to death in patients with noncancer-related terminal disease compared with 60.9% use in patients with terminal cancer in 2017 [8], which highlights that the use of palliative care services within the year preceding death in patients with a noncancer-related terminal illness was far less than that in patients with cancer-related terminal illness. The National Health Insurance system in Taiwan is a nationwide program launched by the Taiwanese government that covers over 96% of Taiwan's population registered in the census for over 6 months. The administrative datasets are maintained electronically by the National Health Research Institutes and the National Health Insurance Administration of Taiwan [9-11]. Patients with end-stage liver disease (ESLD) without hepatocellular carcinoma are significantly less likely to receive inpatient specialist palliative care and to have a lower use rate compared with those with hepatocellular carcinoma [12,13]. The distress and extreme pain experienced by patients with noncancer-related ESLD is comparable to that of individuals with cancer-related terminal illnesses such as lung and colon cancer [14]. However, given the complexities of the etiology and unpredictability of disease trajectories in patients with noncancer cirrhosis, these gaps in unmet clinical needs between patients with cancer and noncancer-related cirrhosis underscore the importance of the early recognition and prognosis of cirrhosis complications, such as HE. Taken together, these data emphasize the fact that the need for prognostication and early prediction for incident HE in patients with noncancer-related cirrhosis is important.

Despite advances in medical therapeutics and supportive care, the accurate prediction and early detection of HE remain a formidable clinical task. Traditional prognostic tools, such as the model for end-stage liver disease (MELD) score, offer valuable insights into disease severity and prognosis but lack the predictive accuracy needed for optimal clinical decision-making [6]. Moreover, MELD scores do not account for factors such as inflammation, ammonia levels, or other metabolic disturbances. Furthermore, tests for HE that rely on psychometric performance can be directly influenced by social determinants of health, smoking, diabetes, and alcohol use, which are factors that can vary by region [7].

Machine learning (ML) algorithms have emerged as promising tools for predictive modeling and risk stratification in complex medical conditions. By leveraging vast datasets and advanced computational techniques, ML algorithms have the potential to identify subtle patterns and predictive features that may elude traditional statistical methodologies.

In this study, we aimed to develop a novel ML approach model to enhance the prognostication and early prediction of incident HE in patients with noncancer-related cirrhosis with the goal to help physicians in shared decision-making for treatment strategy as well as to improve patient care and reduce their distress from morbid complications.

Methods

Study Design and Participants

We conducted a multicenter retrospective cohort study involving 8615 patients diagnosed with liver cirrhosis from 3 academic medical centers and 5 community hospitals (Taipei, Linkou, Keelung, Taoyuan, Chiayi, Kaohsiung, Lovers Lake, and Yunlin) of Chang Gung Memorial Medical Foundation in northern, middle, and southern Taiwan between 2010 and 2017. Datasets were collected from the electronic medical record (EMR) system built by the Chang Gung Medical Foundation. Patients with chronic liver disease with more than 2 visits in the EMR system who were diagnosed with cirrhosis defined using the International Classification of Diseases (ICD)-9 and ICD-10 codes (Table S1 in Multimedia Appendix 1) by clinical physicians with or without ESLD-related complications, such as HE, hepatorenal syndrome, ascites, spontaneous bacterial peritonitis, and esophageal varices, were enrolled. HE was defined as having ICD-9 code 572.2 and ICD-10 codes K76.82, B15.0, B16.0, B16.2, B19.0, G93.4, and G94.3 recorded in the EMR system. The exclusion criteria were patients who were younger than 18 years of age, those who had been diagnosed with malignant neoplasms of the liver (ICD-9 code: 155.0 or ICD-10 code: C22-C22.09) or HE at the time of enrollment, or those who had only a one-time-visit record before being lost to follow-up.

Ethical Considerations

This study was conducted in accordance with the ethical standards of the Declaration of Helsinki, and the protocol was approved by the ethics institutional review board of Chang Gung Memorial Hospital, Taiwan (approval: 201801291B0C504). The institutional review board approved the waiver of informed consent because of the deidentification of all health data collected from the EMR system. The data were collected from

XSL•FO
RenderX

patients treated at Chang Gung Memorial Hospital between 2010 and 2017.

Data Collection and Definitions

Datasets were collected from the EMR system. Individuals meeting the inclusion criteria and whose laboratory data were available within enrollment were included in this study. The laboratory measurements collected for ML included prothrombin time (PT), activated partial thromboplastin time, the international normalized ratio (INR), C-reactive protein (CRP), albumin, ammonia, alanine transaminase (ALT), aspartate transaminase (AST), serum bilirubin, γ-glutamyl transferase, serum bilirubin, creatinine, blood urea nitrogen (BUN), sodium (Na), potassium (K), lactate, uric acid, total cholesterol, triglyceride, fasting plasma glucose, high-density lipoprotein cholesterol levels, low-density lipoprotein cholesterol levels, white blood count, red blood cell, hemoglobin, and platelet. The MELD score was calculated according to the following formula [15]: $3.78 \times \log_e(\text{bilirubin [mg/dL]}) + 11.2 \times \log_e(\text{INR}) + 9.57 \times \log_e(\text{creatinine [mg/dL]}) + 6.43$.

Data Preprocessing and ML Modeling

This study followed the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) reporting guidelines to ensure methodological transparency and reproducibility. A completed TRIPOD checklist is provided as Checklist 1. The datasets were randomly divided into training and testing datasets at a 3:1 ratio. We implemented random forest (RF), neural network, support vector machine (SVM), and extreme gradient boosting (XGBoost) for modeling in the training dataset. The models were built and evaluated using R (version 4.0.1; R Foundation for Statistical Computing) with the *xgboost* package (version 1.4.2). The testing dataset was performed for internal validation. Missing data were addressed through median imputation, where the median value was used to replace any unavailable or null value. Model training was completed in 2024 based on structured clinical data from EMR records.

The prediction target was the probability of developing HE, with the model output ranging from 0 to 1. This continuous output was transformed into a binary classification.

Model training used 10-fold cross-validation with hyperparameter tuning, but no alignment strategies (such as reinforcement learning or preference optimization) were used. Inference was based on structured variable inputs, and no text generation, prompt engineering, or large language models were involved in the modeling process.

Feature Selection and Imbalanced Data

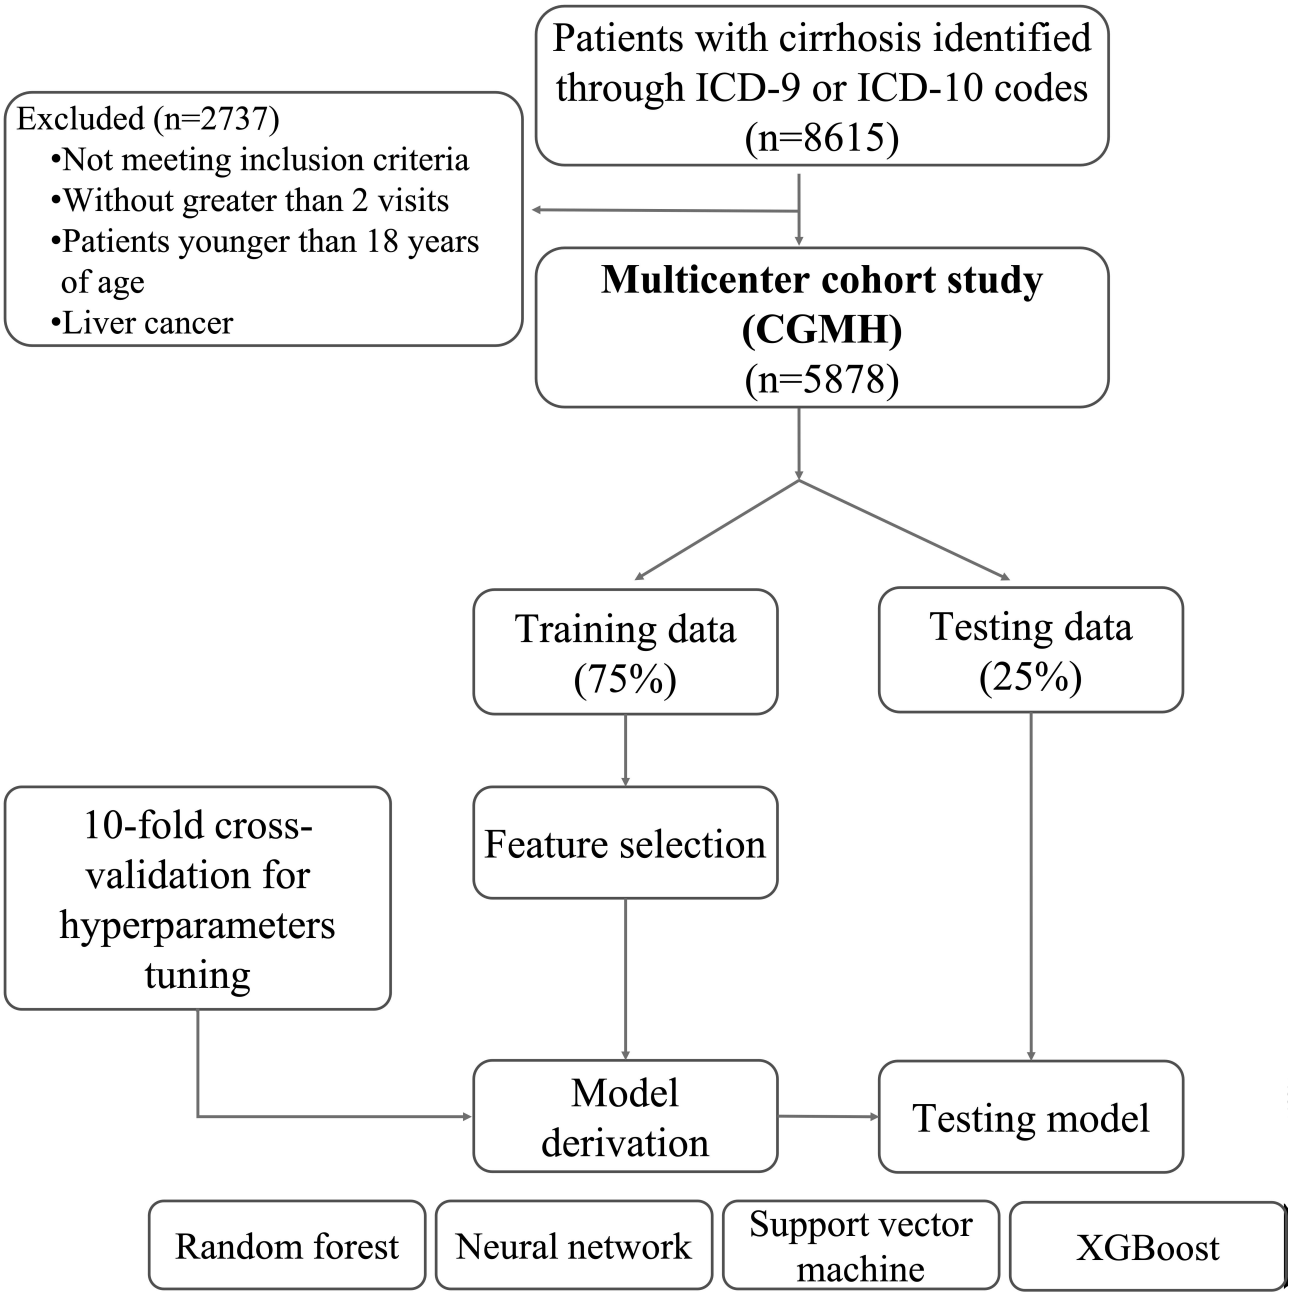
To identify significant candidate features while eliminating noisy or redundant ones that could lead to an inefficient, impractical, or overfitting model, we used a wrapper method using the Boruta algorithm to rank the predictive features of HE. For practical purposes, we repeated the Boruta algorithm 300 times and selected the top 20 ranked features. To avoid the bias toward the majority class and enhance the overall accuracy and performance of the model, we used the synthetic minority over-sampling technique for imbalanced datasets.

Performance Evaluation and Interpretation

We assessed the area under the receiver operating characteristic curve (AUC-ROC) to discriminate the performance of the ML models. We further adopted the Youden index to evaluate the best corresponding cutoff sensitivities and specificities for the optimal performance of the ML algorithm. Then, we analyzed the model using the Shapley Additive Explanations (SHAP) plot to disclose the impact of the features on the output of the model prediction.

Statistical Analysis

Continuous variables were expressed as the median (IQR), and categorical variables by frequencies and percentages. ML modeling was performed using the statistical software package R (version 4.0.1) with the *Boruta* [16] and *Caret* packages [17]. Prediction models were compared using R with the DeLong method of the *pROC* package [18]. All statistic assessments were evaluated at a 2-sided α level of .05.



Results

Overview

A total of 8615 consecutive patients who had been diagnosed as cirrhosis, with or without ESLD-related complications, were enrolled in this study. These patients were identified from the EMR system in 3 academic medical centers and 5 community hospitals of Chang Gung Memorial Medical Foundation in Taiwan, between January 1, 2010, and December 31, 2017. After applying the exclusion criteria—including patients with fewer than 2 visits, those younger than 18 years of age, and those with liver cancer—5878 patients with cirrhosis were eligible for analysis, including 1187 with HE and 4691 without HE. Figure 1 shows a flowchart of the enrollment process.

Baseline Characteristics of the HE and Non-HE Groups in Patients With Noncancer-Related Liver Cirrhosis

The median age was slightly older in the HE group compared to the non-HE group (median 55, IQR 46-65 vs median 54, IQR 44-66 years; *P*=.04). There were no significant differences in sex or HCV infection between the groups. Specifically, 845 of 1187 (71.2%) patients in the HE group and 3227 of 4691 (68.8%) in the non-HE group were male, 342 of 1187 (28.8%) patients in the HE group and 1464 of 4691 (31.2%) in the non-HE group were female (*P*=.11). HCV infection was present in 211 of 1187 (17.8%) and 882 of 4691 (18.8%) patients in the HE and non-HE groups, respectively (*P*=.40). In contrast, the prevalence of HBV infection was higher in the HE group (351/1187, 30%) than in the non-HE group (961/4691, 20.5%; *P*<.001). Alcohol use was reported in 540 of 1187 (45.5%) patients with HE versus 1512 of 4691 (32.2%) patients without HE (*P*<.001). Sepsis occurred in 393 of 1187 (33.1%) patients with HE compared to 793 of 4691 (16.9%) without HE (*P*<.001). Mortality was also significantly higher in the HE group, with 425 (35.8%) deaths versus 502 (10.7%) deaths in the non-HE group (*P*<.001). In laboratory comparisons, patients in the HE group had significantly lower platelet counts, prolonged PT, activated partial thromboplastin time, and INR, higher serum levels of white blood count, ALT, AST, total bilirubin, direct bilirubin, γ-glutamyl transferase, ammonia, lactate, BUN, and creatinine, and lower levels of serum albumin, potassium, sodium, total cholesterol, high-density lipoprotein, and hemoglobin. No significant differences were observed in serum uric acid, low-density lipoprotein cholesterol, or blood sugar levels between the 2 groups.

Overall, in our multicenter retrospective longitudinal analysis, the HE group showed a greater tendency to have coagulopathy, hepatorenal syndrome, and hypoalbuminuria, which may have been the result of malnutrition or sarcopenia in the patients with noncancer-related liver cirrhosis. The baseline demographic and laboratory characteristics between the HE and non-HE groups are shown in Table 1.

XGBoost Exhibited the Best Discriminatory Performance Compared With All ML Algorithms and the MELD Score in Both the Training and Validation Datasets

We further performed the 4 AutoML algorithms, including RF, neural network, SVM, and XGBoost, to compare their performance in terms of predicting HE in patients with noncancer-related ESLD using the training dataset in the EMR system compared to the MELD score and performed further validation using the testing dataset. We first demonstrated that XGBoost exhibited the best discriminatory performance (AUC-ROC 0.86, 95% CI 0.83 - 0.88) compared with RF (AUC-ROC 0.82, 95% CI 0.80 - 0.85), neural network (AUC-ROC 0.79, 95% CI 0.76 - 0.81), SVM (AUC-ROC 0.77, 95% CI 0.73 - 0.80), and the MELD score (AUC-ROC 0.74, 95% CI 0.71 - 0.77; Tables 2 and 3 and Figure 2). The cutoff value by Youden index for XGBoost for discriminating HE was 0.25 (training dataset: sensitivity 80%, 95% CI 0.77 - 0.83; specificity 81%, 95% CI 0.80 - 0.82; positive predictive value [PPV] 0.52, 95% CI 0.49 - 0.54; negative predictive value [NPV] 0.94, 95% CI 0.93 - 0.95; positive likelihood ratio 4.22, 95% CI 3.91 - 4.55; negative likelihood ratio 0.25, 95% CI 0.21 - 0.28; and testing dataset: sensitivity 72%, 95% CI 0.67 - 0.77; specificity 80%, 95% CI 0.78 - 0.82; PPV 0.48, 95% CI 0.43 - 0.53; NPV 0.92, 95% CI 0.90 - 0.94; positive likelihood ratio 3.64, 95% CI 3.18 - 4.16; negative likelihood ratio 0.35, 95% CI 0.29 - 0.42; Table 4).

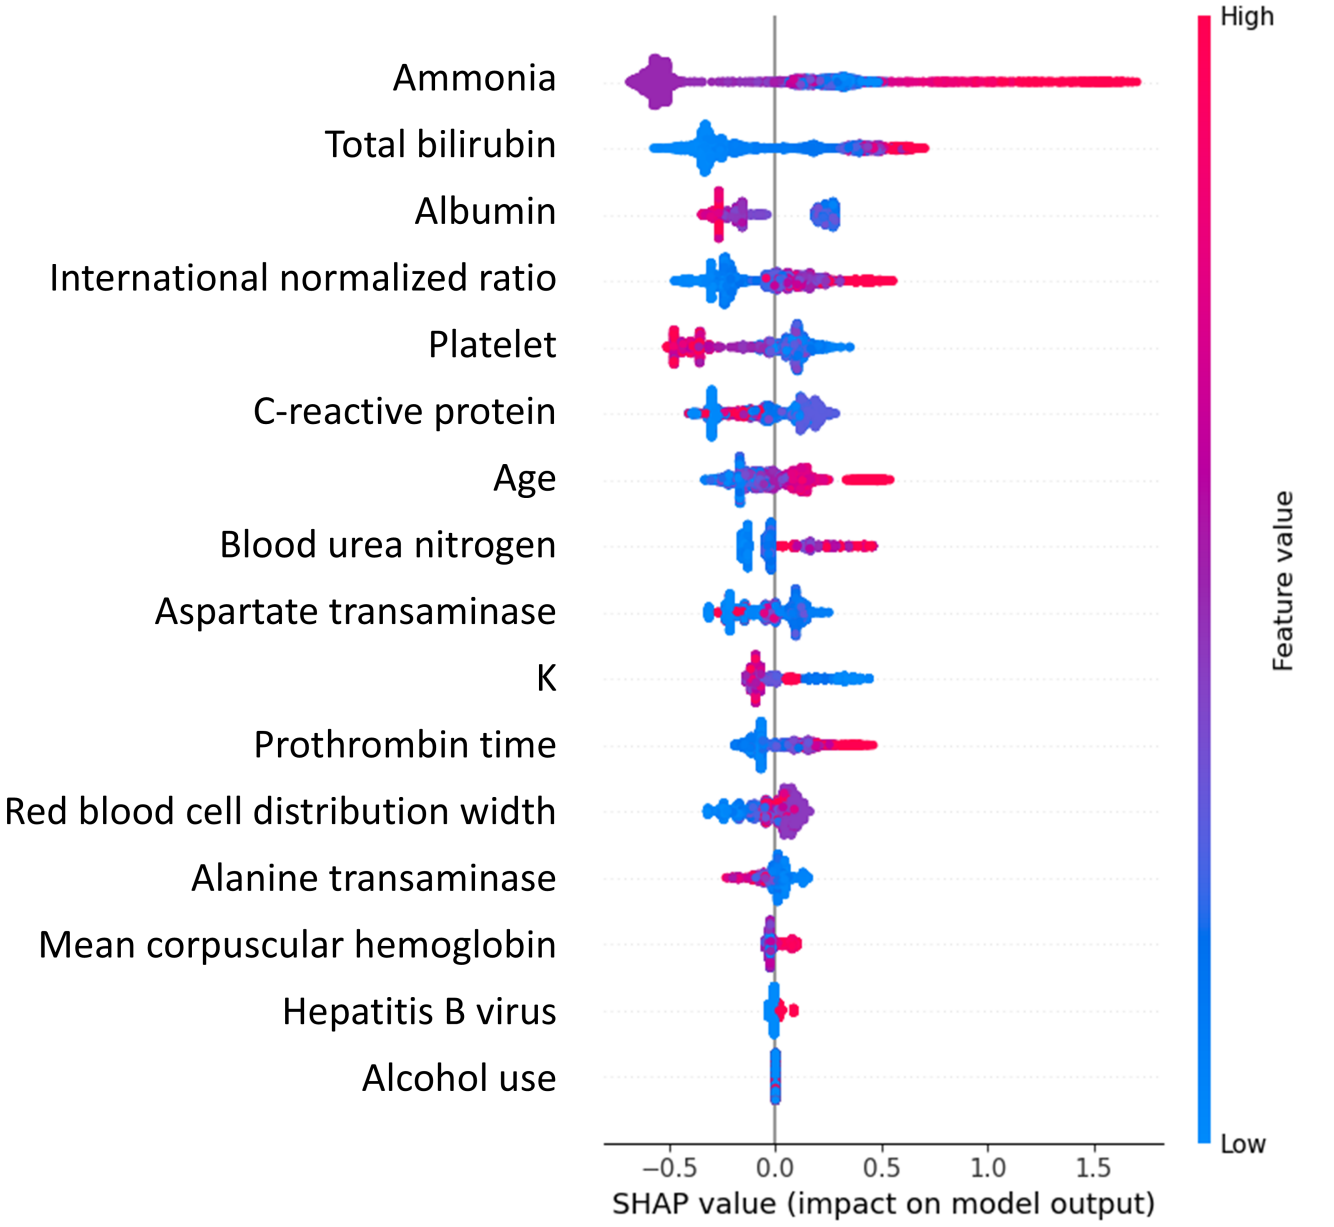
Negative likelihood ratio (95% CI)	0.25 (0.21-0.28)	0.35 (0.29-0.42)

Regarding performance in predicting incident HE, XGBoost achieved the best accuracy in the testing dataset compared with RF, neural network, SVM, and the MELD score (XGBoost: accuracy 0.84, 95% CI 0.82 - 0.85; RF: accuracy 0.82, 95% CI 0.80 - 0.84; neural network: accuracy 0.80, 95% CI 0.78 - 0.82; SVM: accuracy 0.81, 95% CI 0.79 - 0.83). These findings strongly indicate that our ML-based XGBoost algorithm is a superior tool for predicting HE in patients with noncancer-related cirrhosis in comparison with the other ML models and traditional MELD scores, especially for ruling out disease when the finding returns a negative result; this could be an applicable tool to guide clinicians in palliative care clinical settings (Tables 2-4 and Table S2 in Multimedia Appendix 1).

Serum Ammonia Was the Foremost Important Feature, Followed by Other Variables, in the ML-Based XGBoost Algorithm for Predicting HE in Patients With Noncancer-Related ESLD



Additionally, we constructed a SHAP to reveal the weight of each feature on the outcomes of the trained model's predictability based on feature importance. We demonstrated the essential features' contribution to the predictive outcomes, including serum levels of ammonia, total bilirubin, INR, CRP, patient age, total platelet count, BUN, PT, K, AST, albumin, red blood cell distribution width, ALT, mean corpuscular hemoglobin, and history of HBV infection (Table 5). Based on the SHAP values of feature importance, we further disclosed that higher levels of serum ammonia, total bilirubin, INR, older age, BUN, and PT, lower serum levels of albumin and serum K, and lower platelet counts result in a higher probability of HE in patients with noncancer-related ESLD. Furthermore, among the 15 key variables in the AutoML model based on the XGBoost algorithm, ammonia was the most important feature impacting the probability of HE risk, followed by total bilirubin, INR, CRP, age, platelet, BUN, PT, and serum K (Figure 3).

Table . Feature importance from the extreme gradient boosting model based on Shapley Additive Explanations values.

Rank	Clinical feature
1	Ammonia
2	Total bilirubin
3	Albumin
4	International normalized ratio
5	Platelet
6	C-reactive protein
7	Age
8	Blood urea nitrogen

RenderX

Figure 3. SHAP summary plot to explain the feature importance obtained by the extreme gradient boosting algorithm. Features with higher feature value (red) and positive SHAP value (on the right side) show a positive association, while features with higher feature value (blue) and negative SHAP value (on the left side) show a negative association. K: potassium; SHAP: Shapley Additive Explanations.

Taken together, compared with other ML-based models, such as RF, neural network, and SVM, our ML-based XGBoost algorithm demonstrated the best performance for HE predictability in patients with noncancer-related ESLD. Among the variables in the XGBoost model, serum ammonia levels, together with other feature variables, constituted the most important influence regarding HE predictability in patients with noncancer-related cirrhosis.

Discussion

Principal Findings

In our multicenter retrospective longitudinal study, we developed an ML-based prognostic model to improve the early prediction of HE in patients with noncancer-related cirrhosis. Among the evaluated algorithms, the XGBoost model consistently demonstrated superior predictive performance in terms of discriminability, accuracy, and robustness—particularly in ruling out HE with high NPV—across both training and validation datasets.

The choice of XGBoost was driven by its technical advantages over other ML algorithms such as RF, neural network, and SVM. Unlike RF, which may experience overfitting in complex high-dimensional data, XGBoost incorporates regularization techniques that reduce variance and improve generalizability. Additionally, XGBoost handles multicollinearity and missing values more effectively than logistic regression and is computationally efficient for structured tabular data. These characteristics make XGBoost a particularly well-suited algorithm for clinical prediction tasks using EMR datasets. Our novel ML-based XGBoost predictive model is an applicable tool to guide clinicians in shared decision-making of treatment strategy to further improve patient care and reduce their distress

XSL•FO
RenderX

from morbid complications in clinical settings of noncancer-related populations.

To enhance model interpretability, we conducted a SHAP analysis to identify and visualize the contribution of individual predictors to the model output. This analysis revealed that serum ammonia is the most important feature, followed by bilirubin, INR, age, and BUN, which are positively associated with increased HE risk; whereas albumin, platelet counts, and serum potassium are negatively associated with HE risk. Notably, serum potassium and transaminases emerged as key predictors of HE—findings that warrant further clinical interpretation. From a pathophysiological perspective, hypokalemia is known to exacerbate HE by increasing renal ammonia production and systemic ammonia load [21,22]. This mechanistic link is supported by our data, where lower serum potassium was associated with increased HE risk. Similarly, elevated AST and ALT levels reflect ongoing hepatic inflammation or necroinflammation, which may impair ammonia detoxification, thereby promoting HE [23]. These markers, therefore, not only reflect liver injury but also serve as early warning signs for impending encephalopathy, reinforcing their clinical utility in risk stratification and monitoring. Furthermore, to our knowledge, this is the first study to predict HE in a Taiwanese adult population using an ML algorithm. Our use of SHAP further enhances model transparency and interpretability—both of which are critical for clinical adoption. SHAP values enable clinicians to understand how individual variables influence predictions, thereby building trust and supporting shared decision-making with patients.

Despite the pathogenesis of HE not being fully understood, an increasing number of studies have shown that various forms of inflammation, such as systemic inflammation, neuroinflammation, endotoxemia, and ammonia-inflammation synergism, significantly contribute to the development of HE [24]. Serum CRP, which is known as an inflammation marker, is associated with the development of HE and can serve as a predictor of adverse outcomes and increased risk of HE in patients hospitalized with liver cirrhosis [25,26]. In our data, the HE group exhibited a significantly increased level of serum CRP compared with the non-HE group (P<.001) among patients with noncancer-related ESLD. It is of note that our SHAP for feature importance analysis did not show a strong positive influence of serum CRP levels on the increase in HE risk in patients with noncancer cirrhosis. One of the possible reasons for these different study findings could be that the baseline settings of the populations differed between these 2 studies as well as the fact that the pathogenic etiology of HE in populations without cancer differs significantly from that in patients with terminal cancer. In our dataset, the results could have been influenced by outliers of serum CRP because the median serum CRP level in the HE group was significantly higher than that in the non-HE group. This indicates that CRP still plays an important role in HE occurrence.

Comparison to Prior Work

Our findings revealed notable differences in baseline characteristics between patients with noncancer-related ESLD with and without HE, highlighting the heterogeneity of populations with cirrhosis and the multifactorial nature of HE development. Specifically, patients with HE exhibited higher prevalences of HBV infection, alcohol use, sepsis, and mortality rates compared with their counterparts without HE. In another study [3], among 49,164 patients diagnosed with HE, 24,183 (49.2%) were affected by alcohol-related cirrhosis, 18,352 (37.3%) had HCV infection, and only 2589 (5.3%) had HBV-related cirrhosis, with some cases showing overlap. These differences may be due to the high prevalence of HBV infection in Taiwan. However, other research indicates a decline in the age-standardized incidence rates for liver cirrhosis due to HBV globally from 1990 to 2019, while the incidence rates for nonalcoholic fatty liver disease, alcohol use, and other causes increased during the same period [2]. This suggests a potential shift in the etiology of cirrhosis.

Importantly, our study demonstrates that the XGBoost algorithm has superior discriminatory performance in predicting HE compared with other ML algorithms and MELD scores. The robust sensitivity, specificity, PPV, NPV, and accuracy of the XGBoost model underscore its potential applicability as a valuable clinical decision support tool for early HE detection and risk stratification in populations with noncancer-related cirrhosis. The MELD score, initially designed to predict survival after elective transjugular intrahepatic portosystemic shunt placement, has been validated for predicting survival across diverse patient cohorts with varying liver disease severity and from different geographic and temporal backgrounds. Moreover, the MELD score is widely used to prioritize liver transplantation, primarily relying on serum bilirubin, creatinine, and INR levels. Although it provides a general assessment of liver function, it may not fully capture the multifactorial nature of HE development. By contrast, the capacity of ML algorithms to manage complex interactions and nonlinear relationships is a significant advantage that can improve the accuracy of prediction models. Our XGBoost model incorporated a broader range of variables, including ammonia, total bilirubin, INR, age, BUN, albumin, platelet count, and serum K, allowing for a more detailed and accurate prediction of HE risk. This approach may offer valuable insights into disease pathogenesis and prognosis.

Recent studies have demonstrated the value of ML in liver disease prognostication. Verma et al [27] stratified patients with acute-on-chronic liver failure into survival-based clusters using integrated ML methods. Malik et al [28] reviewed ML applications in predicting esophageal variceal bleeding, while Müller et al [29] identified early cirrhosis decompensation using ML models. Other studies used neural networks to forecast 1-year mortality after variceal bleeding [30] or liver transplantation [31], emphasizing the trend toward long-term outcome modeling. These findings underscore ML's expanding role in liver disease prediction. Our study contributes to this field by focusing on early HE prediction in noncancer-related cirrhosis using a transparent and interpretable XGBoost framework. Another regional study conducted on 1256 patients with cirrhosis with unbalanced data used several ML methods, specifically SVM, logistic regression, and CatBoost, to predict HE [32]. Although the weighted RF model emerged with an accuracy of 0.8732 (95% CI 0.8711 - 0.8752) and an AUC-ROC

XSL•FO
RenderX

of 0.82, in that study, the HE predictability was far inferior to our ML-based XGBoost model. Our XGBoost model significantly outperformed weighted RF, achieving an accuracy of 0.84 (95% CI 0.82 - 0.85) and an AUC-ROC of 0.86 (95% CI 0.83 - 0.88). It showed advantages on XGBoost. XGBoost uses boosting with regularization to reduce overfitting and improve generalization. It also handles missing data and multicollinearity effectively. XGBoost is more efficient and interpretable for structured clinical data better than SVM and neural networks [33,34]. Additionally, we applied SHAP to identify and visualize the contributions of individual features to the model's predictions. Its consistent and locally accurate attributions improve interpretability, facilitating clinical trust by clarifying how key variables may influence disease outcomes [35].

Limitations

While our study contributes to advancing the understanding of HE prediction and prognostication of patients with noncancer-related cirrhosis, several limitations warrant consideration. First, despite our application of the Boruta algorithm for feature selection and the use of the synthetic minority over-sampling technique for imbalanced datasets, retrospective analyses still inherently carried biases related to data completeness, documentation accuracy, and confounding variables. Second, the generalizability of our findings to diverse patient populations and health care settings may be limited. As aforementioned, the different etiology of ESLD may affect model application.

Future Directions

Building upon the aforementioned limitations, future research should prioritize prospective validation in diverse populations and explore the integration of the predictive model into clinical decision support systems. Moreover, external validation across different institutions and geographic settings is essential to evaluate the model's generalizability and transportability. Embedding the model into cloud-based platforms or EMR systems may further enhance its accessibility and facilitate real-world clinical implementation. Additionally, regarding the other scoring systems, such as the Bilirubin-Albumin-Beta-Blocker-Statin score and MASQ-HE score developed by Tapper et al [36,37], both include adding medications, such as the use of nonselective β-blockers and statins, in addition to quality of life and physical function, to improve the performance in terms of the predictability of HE risk. Therefore, integrating additional clinical variables may enhance model accuracy for the prediction of HE and thus should be considered in the future development of ML-based models.

Conclusions

Our ML-based XGBoost model demonstrated superior predictive performance for the early detection and prognostication of HE in patients with noncancer-related cirrhosis. Beyond its predictive accuracy, the model shows promise as a clinically valuable tool for use in terminal care settings, outperforming previously established ML algorithms and conventional prognostic scores such as the MELD score. To the best of our knowledge, this is the first ML-based model specifically developed for prognostication and HE prediction in a Taiwanese adult population with noncancer-related cirrhosis—a subgroup with higher prevalence and more unpredictable disease trajectories compared to patients with cancer-related cirrhosis. By incorporating a broader set of clinical features and leveraging SHAP-based interpretability, our model facilitates more precise risk stratification and may support clinicians in making informed decisions aimed at preventing severe complications and improving patients' quality of life. Future studies are warranted to externally validate this model in larger and more diverse populations and to assess its clinical utility through prospective follow-up of patient outcomes.

Acknowledgments

This work was supported by Chang Gung Memorial Hospital Research Projects (CMRPG2M0041, CMRPVVM0182, CORPVVN0131, and CORPG3P0622). The authors are grateful to the members of the Maintenance Project of the Biostatistical Consultation Centre at Chang Gung Memorial Hospital (Linkou and Keelung branches) for assistance with the data analysis from the Chang Gung Research Database provided by Chang Gung Memorial Hospital. The sponsors had no role in study design, data collection, analysis, interpretation, manuscript writing, or the decision to submit the manuscript for publication.

Authors' Contributions

HYC and YWT conceived and designed the study. YWT was responsible for data acquisition. Data analysis and interpretation were performed by HYC, WCY, and YWT. HYC drafted the manuscript, and statistical analyses were conducted by HYC and YWT. The study was supervised by YWT. All authors reviewed and approved the final manuscript.

Abstract

Background: Seasonal influenza is a major global public health concern, leading to escalated morbidity and mortality rates. Traditional early warning models rely on binary (0/1) classification methods, which issue alerts only when predefined thresholds are crossed. However, these models exhibit inflexibility, often leading to false alarms or missed warnings and failing to provide granular risk assessments essential for decision-making. Therefore, we propose a probability-based early warning system using machine learning to mitigate these limitations and to offer continuous risk estimations of alerts (0‐1 variable) instead of rigid threshold-based alerts. Based on probabilistic prediction, public health experts can make more flexible decisions in combination with the actual situation, significantly reducing the uncertainty and pressure in the decision-making process and reducing the waste of public health resources and the risk of social panic.

Objective: The main aim of this study is to devise an innovative approach for early warning systems focused on influenza-like cases. Therefore, a Dense Residual Network (Dense ResNet), a supervised deep learning model, was developed. The model's training involved fitting the influenza-like illness positive rate, which enabled the early detection and warning of signals of changes occurring in the activity level of influenza-like cases. This departure from conventional methodologies underscores the transformative potential of machine learning, particularly in providing advanced capabilities for timely and proactive warnings in the context of influenza outbreaks.

Methods: We developed a Dense ResNet machine learning model trained on influenza surveillance data from Northern and Southern China (2014‐2024). This model generates early warning signals 3, 5, and 7 days in advance, providing a probability-based risk assessment represented as a continuous variable ranging from 0 to 1, in contrast to the traditional binary (0/1) warning systems. We evaluated the performance of this model using area under the curve scores, accuracy, recall, and F_1-scores, then compared it with support vector machine (SVM), random forests, XGBoost (Extreme Gradient Boosting), and LSTM (long short-term memory) models.

Results: The Dense ResNet model demonstrated the best performance, characterized by 5-day lead warnings and a 50th percentile probability threshold, achieving area under the curve scores of 0.94 (Northern China) and 0.95 (Southern China). Relative to traditional models, probability-based warning signals improved early detection, reduced false alarms, and facilitated tiered public health responses.

Conclusions: This study presented a novel probability-based machine learning model essential for early warning signals of influenza, demonstrating superior accuracy, flexibility, and practical applicability compared to other techniques. This approach enhances preparedness for influenza among the population and promotes the use of automated artificial intelligence–driven public health responses by replacing binary warnings with probability-driven risk assessments. Future research should integrate real-time surveillance data and dynamic transmission models to improve the precision of early warning.

Introduction

Seasonal influenza is a contagious disease posing significant threats to human health globally, characterized by a steady increase in annual incidence. Currently, approximately 1 billion people worldwide are infected each year, and 290,000 - 650,000 fatalities are due to influenza-related respiratory diseases [1,2].

This disease occurs in various seasons throughout the year, and its outbreak can be influenced by an environment conducive to viral survival, host immunity [3], patterns of physical contact with other people [4], or viral interference caused by other respiratory pathogens [5]. Therefore, a timely indication of an unusual increase in the prevalence of influenza is crucial; early detection and warning signals can mitigate the impact of this disease on public health, providing a foundation for the formulation of preventive measures and the timely allocation of medical resources. Previous studies have predominantly concentrated on predicting the trends of influenza outbreaks [6,7]. However, providing timely warning signals to the population is of greater practical significance for public health departments.

Various scenarios may trigger warning signals for influenza outbreaks, including surpassing historical baselines [8], excessively rapid increases in the prevalence trends, the discovery of new pathogens, increased disease severity, and insufficient medical resources [9]. This study concentrates on the warning scenario in which influenza transitions into an epidemic phase, characterized by an upward trend in the epidemic curve. In this scenario, the number of infected individuals increases, increasing demand for medical resources. As the prevalence rises, the disease burden intensifies steadily, necessitating specific personal protective or preventive measures to suppress the escalated outbreak and decelerate its transmission. Issuing a warning signal at this stage does not imply the emergence of a pandemic or a deviation from the usual trend; instead, it emphasizes the necessity for health departments and society to remain vigilant regarding the influenza epidemic.

The results of traditional early warning methods are categorized into 2 types: early warning signal and no early warning signal. An alarm will only be triggered when the expected threshold is exceeded. While these methods have been widely used in public health surveillance, they are constricted by several critical limitations [10,11]. For example, binary warning signals lack granularity, providing only rigid “yes” or “no” decisions rather than rendering a nuanced risk assessment. This often leads to the activation of false alarms or increases the likelihood of missed detections, reducing system reliability. Moreover, fixed-threshold models, such as the 40th percentile warning system, fail to distinguish between increasing and decreasing trends of the epidemic, which occasionally creates alerts even when cases are in decline. Finally, these models do not cater to tiered public health responses, making it difficult for decision-makers to prioritize interventions based on varying levels of outbreak risk [12]. Addressing these limitations requires a more flexible and adaptive approach, where warning signals are expressed as continuous probability values rather than binary classifications [11,12]. This study introduces a probability-based early warning model that enables tiered response strategies and artificial intelligence (AI)-driven automation, offering a significant improvement compared to traditional methods.

The rise of machine learning and AI methodologies provides a thrilling prospect for transforming early warning systems of influenza. Traditional warning models, such as the Moving Epidemic Method model [13], rely on historical data to predict the current prevalence of influenza. Machine learning methods, on the other hand, offer the potential to forecast warnings in advance. This shift toward advanced computational techniques not only improves the accuracy of predictions but also revolutionizes the ability of the population to anticipate and respond to public health threats.

Machine learning models such as the Self-Excitation Attention Residual Network have demonstrated the ability to dynamically adapt to evolving disease trends and changes in surveillance systems, enhancing the effectiveness of early warning systems [14]. These models can process complex, heterogeneous data from multiple sources, including cases of influenza-like illness (ILI), virological surveillance, climate and demography data, and resultant queries from search engines [15]. Consequently, they can identify intricate patterns and relationships that traditional models might miss, leading to more sensitive and accurate predictions.

Moreover, machine learning approaches have been shown to outperform traditional models with various traits such as sensitivity, specificity, and timeliness. For example, studies have found that machine learning models can issue warning signals before the onset of influenza outbreaks, exhibiting higher accuracy than threshold-based methods [16]. This enables public health officials to take preemptive measures, such as implementing vaccination campaigns or public advisories, to mitigate the impact of the disease.

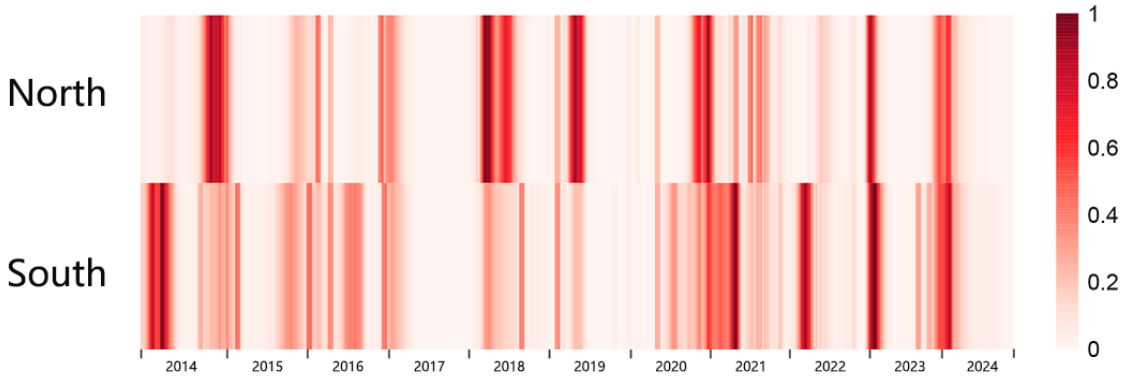
Machine learning also demonstrates its potential for integrating various data sources and applying complex nonlinear models, such as long short-term memory (LSTM) or other neural networks, to the dataset, which can lead to higher prediction accuracy. These models can learn from genetic sequences and associated metadata to predict the antigenic properties of circulating influenza viruses, providing insights into the evolution of influenza and antigenic drift.

Integrating machine learning and AI into early warning systems of influenza represents a significant leap forward in our capacity to predict and prepare for influenza outbreaks. These advanced methodologies offer a more proactive, data-driven approach to public health surveillance, potentially saving lives and reducing the societal and economic burdens of influenza.

By constructing a Dense Residual Network (Dense ResNet) machine learning model to achieve probabilistic prediction of influenza outbreaks, it can effectively provide detailed probability information on the risk of an outbreak. Based on this probability prediction, public health experts can, in combination with their professional experience and the actual situation, make more flexible decisions on whether to issue a

XSL•FO
RenderX

warning, avoiding the rigidity of the traditional binary decision-making model, significantly reducing the uncertainty and pressure in the decision-making process, and significantly reducing the waste of public health resources and the risk of social panic. The continuous probability model can provide more detailed epidemic warning information based on the risk level, supporting the implementation of graded intervention strategies by health departments, such as early deployment of medical resources and strengthening public health awareness campaigns when the probability is high, and internal monitoring and precise prevention measures when the probability is medium or low. This precise intervention effectively avoids unnecessary social panic and resource waste.



The main aim of this study is to devise an innovative approach for early warning systems focused on influenza-like cases. Therefore, a Dense ResNet, a supervised deep learning model, was developed. The model's training involved fitting the influenza-like illness positive rate (ILI+), which enabled the early detection and warning of signals of changes occurring in the activity level of influenza-like cases. This departure from conventional methodologies underscores the transformative potential of machine learning, particularly in providing advanced capabilities for timely and proactive warnings in the context of influenza outbreaks.

Methods

Data Sources

The study population includes Northern China and Southern China. We derived proxy measures for the activity of the influenza virus in the communities, referred to as ILI+ rates, by multiplying the ILI percentage (ILI%) with the proportions of influenza-positive specimens [13] derived from the Chinese National Influenza Surveillance Network for the 2 regions. A total of 569 weekly reports were included in this study. The standardized ILI+ for each region was presented (Figure 1).

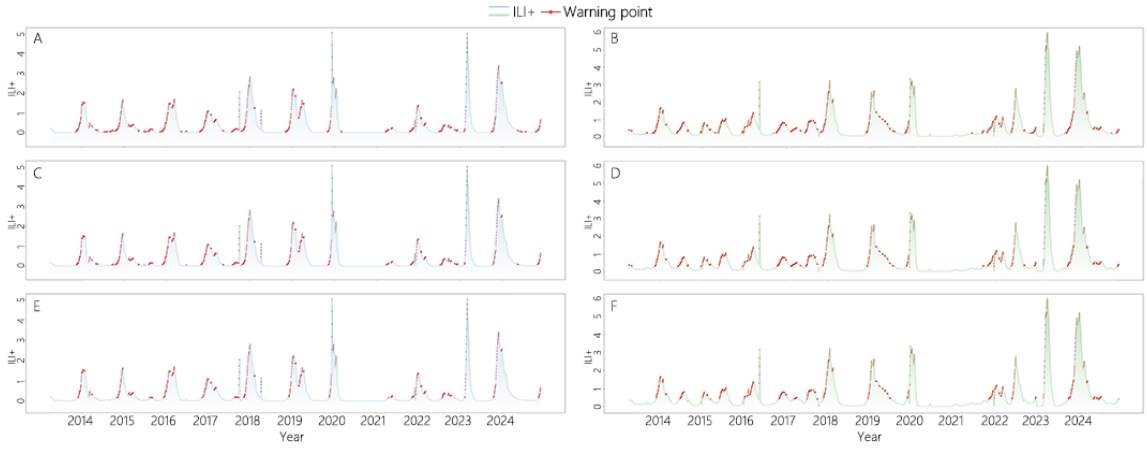


Figure 1. The influenza-like illness positive rate of Northern China (North) and Southern China (South).

Warning Definition and Labeling

Throughout this study, the warning scenario was defined as an ascending trend during the influenza season. Following the conventional definition of the influenza season presented in previous studies [17], we designated a warning when ILI+ exceeds the 40th percentile, demonstrating an upward trend. The labeled outcomes are illustrated in Figure 2.

Figure 2. ILI+ warning diagram for Northern and Southern China under different quantile values. Panels A, C, and E refer to Northern China, panels B, D, and F refer to Southern China, panels A and B refer to quantile 0.4, panels C and D refer to quantile 0.5, and panels E and F refer to quantile 0.6. Model Construction

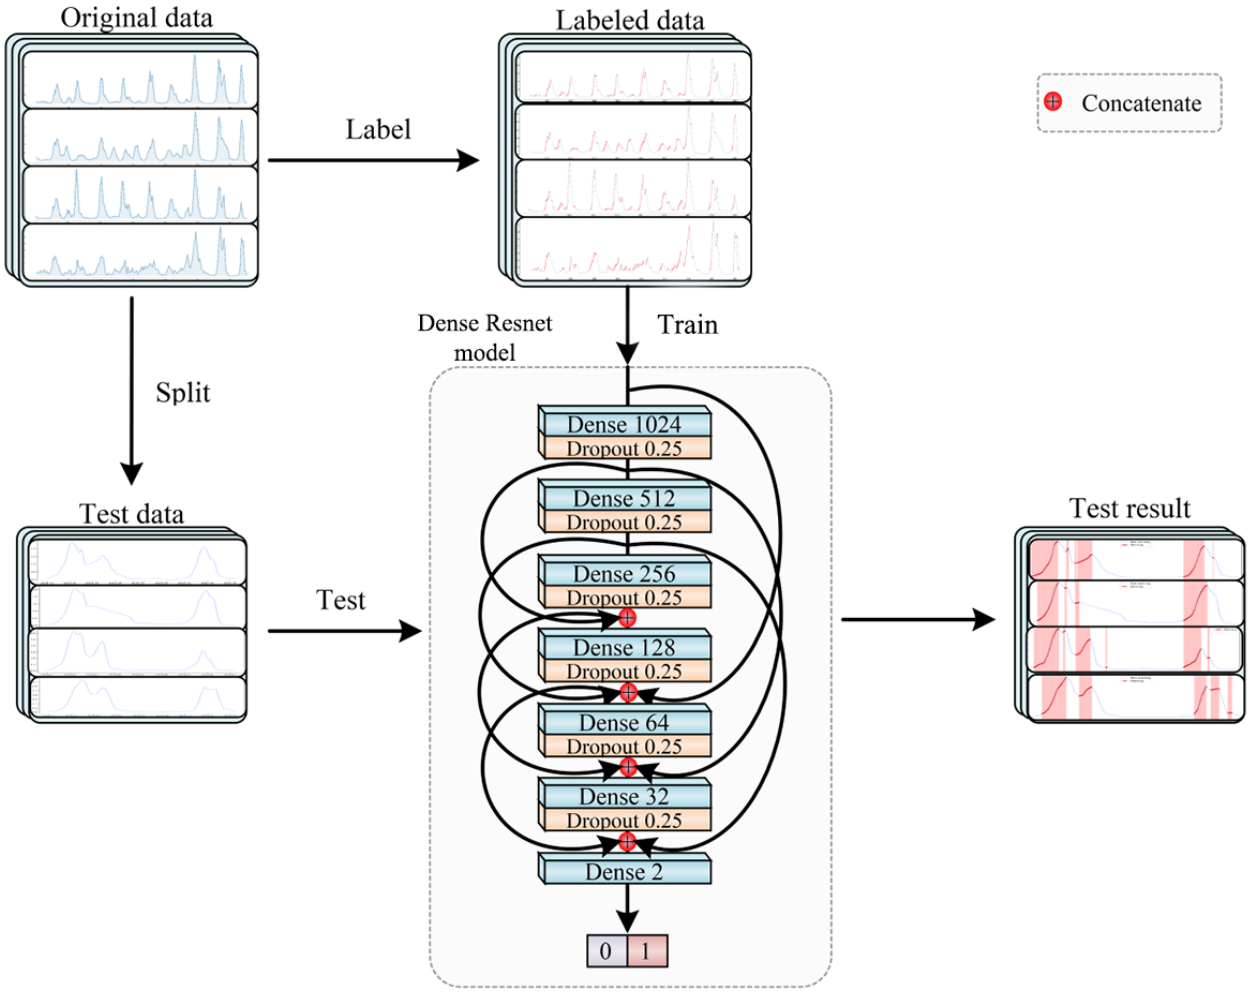
This study aimed to construct and train a model that could identify the intrinsic features of the input data and establish a mapping from ILI+ features to warning categories to accurately classify ILI+ for warning signals precisely. This was achieved by proposing an innovative deep learning model called Dense ResNet (Figure 3).



Dense layers and residual connection methods were used to design the Dense ResNet model to enhance the accuracy of the early warning function. Experimental results have demonstrated that this model could effectively map ILI+ features to the early warning category. The Dense ResNet model constructed in this study comprised 7 Dense layers, 6 Dropout layers, and 7 residual connections. From top to bottom, Dense layers of 1024, 512, 256, 128, 64, and 32 units were employed to extract data features from top to bottom. In addition, 6 layers with a dropout rate of 0.25 were applied after each Dense layer to prevent overfitting. Furthermore, 7 residual connections were added primarily to retain global information effectively while preventing gradient vanishing. The Sigmoid activation function was employed in the last fully connected layer to predict the probability of warning classes of 0 and 1. The predictive result was a probability value between 0 and 1 for each warning category.

In this study, Dense ResNet was selected over other deep learning models for time series early warning modeling of infectious diseases of the respiratory system, based on several key considerations. First, we used the ILI+ sequence as the feature for early warning judgments. Although it exhibited certain seasonality and trends, its variations were heavily influenced by external factors such as abrupt climate changes and public health interventions, leading to sudden shifts and nonstationarity. As a result, it does not adhere to consistent temporal evolution patterns. Traditional recurrent neural networks (LSTMs and Gated Recurrent Units), proficient in modeling strong sequential dependencies, are not entirely suitable for the ILI+ data used in this study. In contrast, Dense ResNet focuses on direct feature extraction, and by cumulatively integrating deep features, it is more adept at capturing the complex associations and nonlinear variation patterns present in the data, making it more compatible with the ILI+ features adopted in this research. Second, although models such as Transformers perform excellently in large-scale time series tasks, they have an escalated number of parameters that are highly prone to overfitting during the training process. This issue is particularly pronounced in this study due to the limited sample size of the ILI+ features, leading to poor generalization. In comparison, the proposed Dense ResNet structure is relatively simple; it mitigates the challenges of deep network training through effective residual connections, enabling stable training and superior performance on small to medium-sized datasets, offering higher practical application value.

In summary, considering the characteristics of the data, task requirements, model performance, training stability, and practical feasibility, this study ultimately adopted Dense ResNet for the early warning task instead of traditional recurrent neural network–based sequence models or large-scale Transformer architectures. This choice effectively balances the complex feature extraction capabilities, training stability, overfitting control, and deployment feasibility, providing strong technical support for achieving efficient and accurate early warning signals.

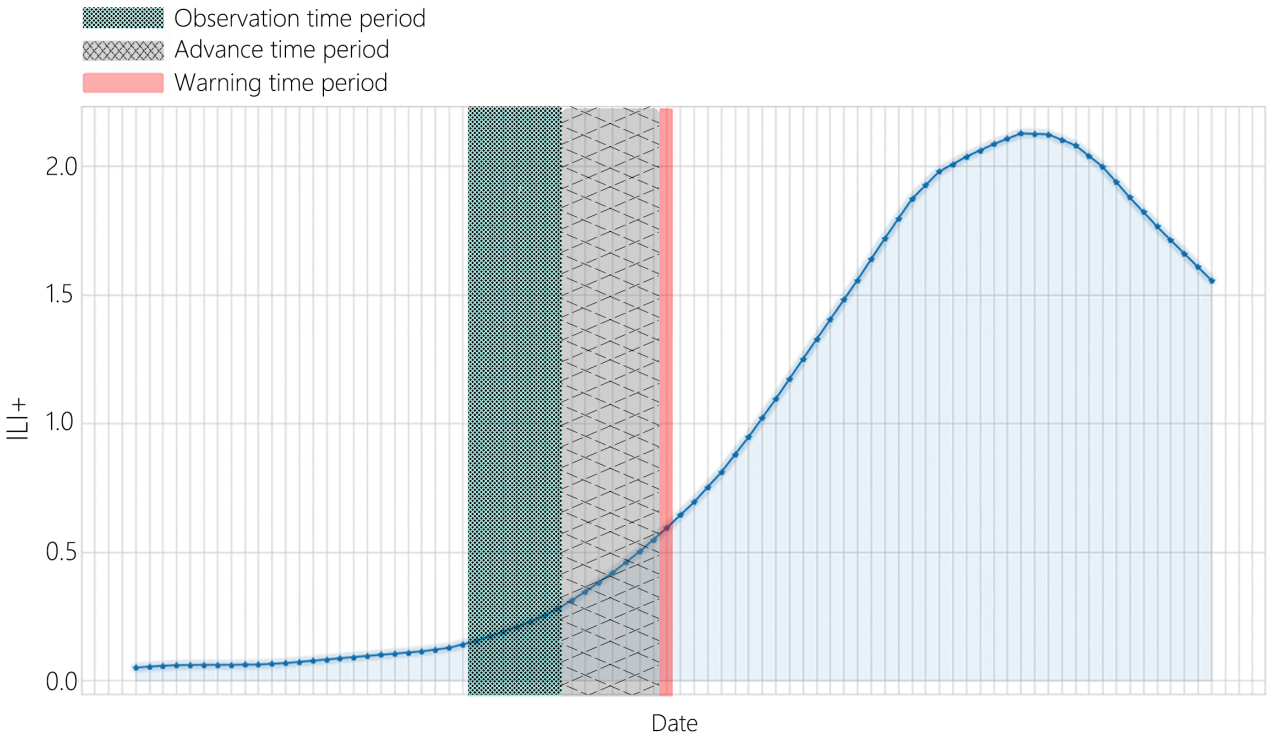
RenderX

Figure 3. Structural diagram of the Dense Residual Network (Dense ResNet) model.



Dataset Construction

This study innovated the construction of the training dataset to activate early warning signals. Figure 2 illustrates the graphical refactoring of the dataset. We divided the data into 3 sections: observation time period, advance time period, and warning time point. We combine the features of the observation time period and the labels of warning time points to form a reconstructed dataset and train the model using this dataset to achieve early warning signals. For example, if a person needs to determine whether November 26, 2023, is a warning, you only need to observe the characteristic values from November 12, 2023, to November 18, 2023, will be observed (Figure 4).

In this study, for the choice of advanced time period, we adopted advanced time periods of 3, 5, and 7 days to select advanced periods, and the results were obtained.

XSL•FO
RenderX

Figure 4. Schematic diagram of data construction. ILI+: influenza-like illness positive rate.

Dataset Segmentation

This section encompasses 3969 days spanning from December 30, 2013, to November 11, 2024, in Southern and Northern China, to construct training. Following the conventional division methods of deep learning, including training set, validation set, and test set, and considering the practical significance of ILI% prediction, the period from December 30, 2013, to October 31, 2022 was designated as the training set, while the period from November 1, 2022, to November 11, 2024 was assigned as the test set. The training set encompasses 9 ILI% activity peaks, while the test set contains 2 ILI% peaks.

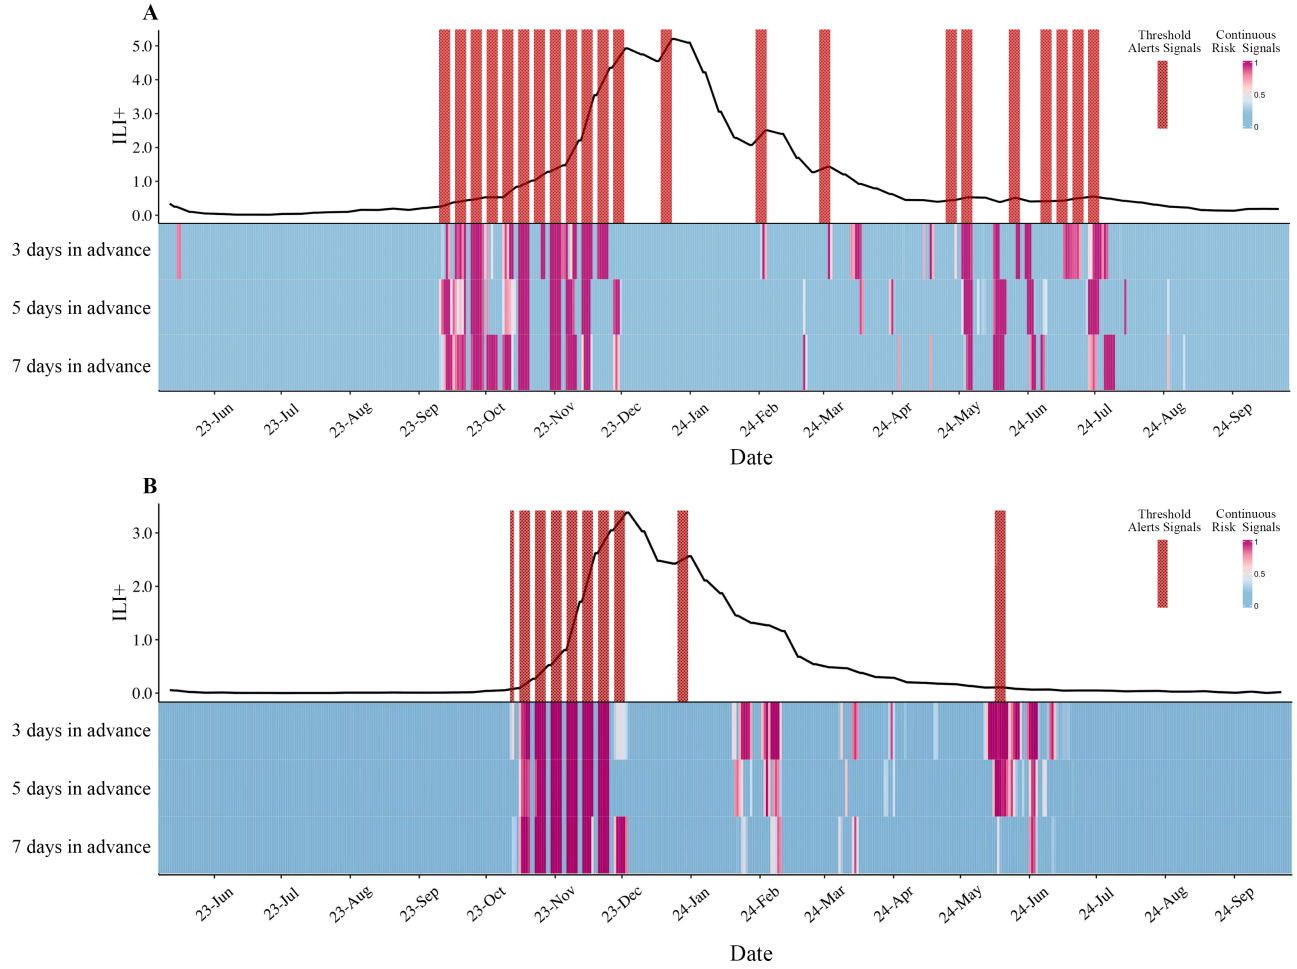
Model Training

In model training, we initialized the network weights using He normal initialization and trained the model using the Adam optimizer with default parameters (β_1 =.900, β_2 =.999). The initial learning rate was set to 0.001 with a batch size of 32. To further improve the model convergence, we employed a learning rate scheduler (ReduceLROnPlateau) that reduced the learning rate by 0.1 if the validation loss did not improve for 5 consecutive epochs. The binary cross-entropy loss function was used during training. The training was conducted for a maximum of 100 epochs. We adopted an early stopping strategy with a patience of 10 epochs based on the validation loss to prevent overfitting. The model development and experiments were implemented using the PyTorch framework (version 2.0.0; Meta AI). All the training, validation, and testing processes were performed on one NVIDIA RTX 4090 Graphics Processing Unit (GPU) with 24 GB of memory.

Ethical Considerations

This study was approved by the Research Ethics Review Committee for Biomedical Research Involving Humans, Chinese Academy of Medical Sciences, and Peking Union Medical College (approval no. CAMS&PUMC-IEC-2025-010). The study did not involve any personally identifiable or sensitive health information. No compensation was provided to participants.

Results



Following the training and validation procedures employing the Dense ResNet model, early warning signals were issued at 3-, 5-, and 7-day intervals. The results indicated that, in Northern and Southern China, the most effective lead time is 3 days, 50 quantiles, allowing for the detection of warning signals 2 and 5 days in advance (Figure 5).

This study assessed the warning performance in Northern and Southern China, using metrics such as accuracy, recall, F_1-score, and area under the curve (AUC) to validate the model. The outcomes highlight the highest AUC score for issuing warning signals 3 days in advance (Northern China: 0.94, Southern China: 0.95) (Table 1). The receiver operating characteristic curves are depicted in Figure 6.

Compared to other commonly used models (support vector machine [SVM], random forest, XGBoost [Extreme Gradient Boosting], and LSTM), the Dense ResNet model exhibits superior warning performance in Southern and Northern China, as well as in Beijing and Yunnan province (Table 2).

The results demonstrate that Dense ResNet outperforms models such as SVM, random forest, and LSTM, primarily for the following reasons. First, Dense ResNet leverages its deep network architecture, particularly through multiple dense layers and residual connections, to effectively capture complex nonlinear relationships in the data. In contrast, traditional machine learning models such as SVM and random forest, while capable of handling some degree of nonlinearity, often exhibit limitations in modeling high-dimensional data and intricate relationships. SVM typically relies on kernel functions for nonlinear mapping; however, it is less flexible compared to deep neural networks when processing large-scale data and complex features. Random forest, on the other hand, enhances the expressiveness of the model through an ensemble of decision trees. However, it reveals low performance compared to deep neural networks when dealing with highly correlated features or long-range dependencies.

Second, the Dense ResNet model benefits from hierarchical feature learning, with each dense layer progressively extracting more abstract and complex features, gradually building a representation from low-level to high-level features. In comparison, traditional models such as SVM and random forest rely more heavily on manual feature engineering or selection. While LSTM excels in processing sequential data, it depends on longer input sequences to capture complex global information and long-term dependencies, making it less efficient than Dense ResNet for learning both short-term and long-term features, as may be involved in this study.

Finally, the Dense ResNet model in this study incorporates residual connections, effectively mitigating the vanishing gradient problem and facilitating the training of deeper networks. By allowing information to skip layers, residual connections help preserve more global information, a crucial advantage when handling large-scale datasets. In contrast, models such as SVM, random forest, and LSTM lack such structural designs, which may limit their performance in modeling high-dimensional or complex data.

Discussion

Principal Findings

In China, seasonal influenza follows a predictable pattern, peaking during the colder months and, in some regions, during the summer. The ability to issue timely and precise warnings is crucial for public health preparedness. This study introduces a continuous probability-based warning system (0 - 1 variable), moving beyond the traditional binary (0/1) warning models. This advancement significantly enhances the flexibility, accuracy, and applicability of early warning systems.

A probability-based risk assessment improves the accuracy of warning signals. Traditional early warning models [18] rely on binary classifications—either issuing a warning or not—which often leads to false alarms or missed detections. These rigid threshold-based warning systems do not account for the varying degrees of epidemic severity. In contrast, our continuous probability warning approach provides a more nuanced risk assessment, offering granular insights into the likelihood of an outbreak. This enables decision-makers to adjust intervention

XSL•FO
RenderX

strategies based on the level of risk rather than adhering to a fixed binary outcome. As a result, the reliability and adaptability of early warning systems are significantly improved.

Moreover, a probability-based warning system supports tiered response strategies, which can be dynamically adjusted according to the predicted severity of an outbreak. For example, when the warning probability is moderate (0.4 - 0.6), internal monitoring may be prioritized, whereas higher probabilities (≥0.7) would prompt targeted interventions such as increasing health care preparedness or reinforcing public health advisories. When the probability reaches 0.9 or above, immediate public health measures can be activated. This graduated approach prevents unnecessary disruptions in low-risk situations while ensuring timely action in high-risk scenarios.

A flexible warning system supports precise public health interventions. Another key advantage of probability-based warnings is their role in scientific policy making and public communication. Traditional threshold-based methods may trigger unnecessary alarms in low-risk years, leading to economic losses and diminishing public responsiveness to warning signals. Conversely, these methods may fail to escalate warnings quickly enough in high-risk years, resulting in delayed response measures. By shifting to a risk-probability framework, this study enables a more rational and transparent decision-making process, allowing authorities to communicate risk levels clearly to the population to prevent overreactions.

In addition, when the probability of an outbreak is low, ranging from 0.3 to 0.5, preventive measures can be targeted at high-risk groups, such as older adults and individuals with pre-existing health conditions, without imposing large-scale interventions. This precision prevention strategy minimizes unnecessary economic losses and social disruption while ensuring that those at the most significant risk receive appropriate protection.

AI-driven automation enhances the efficiency of warning responses. Beyond improving warning accuracy, continuous probability warnings pave the way for AI-driven automation in public health management. In future applications, AI-assisted decision-making systems can integrate probability forecasts into automated response frameworks. For example, when the probability is ≥0.7, automated alerts can be dispatched to health care facilities. If a probability is ≥0.9, public health advisories can be issued automatically to initiate broader containment measures. For probabilities between 0.4 and 0.6, real-time monitoring can continue internally without initiating unnecessary public concerns.

By integrating machine learning and automation, this system improves the efficiency of response, consequently reducing delays in the intervention while optimizing the allocation of health care resources. Early warning facilitates the implementation of timely interventions, leading to improved mitigation of the outbreak. The effectiveness of the proposed model was demonstrated through empirical validation. Our study shows that the machine learning model can issue warnings 5 days earlier than traditional methods, significantly improving public health preparedness [19]. Given that implementing preventive measures taken 5 days in advance can impact the infection chain by 2 - 4 generations, this proactive alert system is essential for managing the dissemination of influenza. Similar findings have been observed in real-time surveillance systems for other infectious diseases, such as dengue [20], where early detection has been shown to reduce the outbreak's severity and enhance the efficiency of implemented control measures. Moreover, our results indicate that when predicting outbreaks 3 days in advance, the model achieves the highest sensitivity, specificity, and timeliness. This suggests that while earlier warning signals provide more time for response, optimizing the trade-off between lead time and accuracy is essential. Future research should explore hybrid models that integrate transmission dynamics modeling and data-driven time-series forecasting to further improve warning precision.

Machine learning outperforms traditional threshold-based methods. Compared to the conventional fixed percentile warning system, such as the 40th percentile thresholds, our probability-based approach provides 3 key advantages, including (1) earlier detection, which is usually executed. This approach enables a crucial preparatory window for vaccine distribution, hospital readiness, and community interventions; (2) distinguishing between rising and declining trends, which often provide warning signals even after the peak of the outbreak, with probability-based warning signals dynamically adjusted based on real-time trends, unlike fixed-threshold methods; and (3) improved adaptability to different epidemic conditions, in which machine learning models learn from historical patterns, providing a flexible response mechanism even during atypical flu seasons.

A probability-based warning system enhances influenza preparedness. This study demonstrated the superior performance of probability-based machine learning models in the early warning of seasonal influenza.

Conclusions

This study presented a novel probability-based machine learning model for the early warning of influenza, demonstrating superior accuracy, flexibility, and practical applicability. By replacing binary warning signals with probability-driven risk assessments, this approach enhances influenza preparedness and supports automated AI-driven public health responses. Future research should integrate real-time surveillance data and transmission dynamic models to improve the precision of early warning signals further. On the one hand, the Susceptible-Exposed-Infected-Recovered model can effectively depict the transmission stages and overall trends of infectious diseases among the population, providing a basic framework for understanding disease transmission. Conversely, agent-based modeling can simulate the complex interaction behaviors and heterogeneity among individuals, making the model closer to the actual communication process. In contrast, the hybrid data-driven and mechanism model provides novel prospects for predicting influenza. Data-driven models can extract potential patterns and rules from extensive historical datasets, whereas mechanism models based on understanding the principles of disease transmission provide comprehensive insights into the disease transmission process. Combining these 2 approaches mitigates the limitations of a single model and improves the accuracy and reliability of influenza prediction. Meanwhile,

XSL•FO
RenderX

this hybrid model can handle scenarios of incomplete data or highly uncertain datasets, enhancing the robustness and adaptability of the model. This system enhances public health preparedness and reduces unnecessary disruptions by issuing warning signals 5 days in advance and providing a flexible, risk-adaptive approach. Compared to traditional methods, machine learning accurately distinguishes epidemic trends, minimizes false alarms, and facilitates automated AI-driven public health responses. Future research should further refine warning frameworks by integrating transmission dynamics models and real-time surveillance data, ensuring improved promptness, timeliness, and efficacy of prevention and control measures for influenza.

Abstract

Background: The risk of developing atherosclerotic cardiovascular disease (ASCVD) varies among individuals and is related to a variety of lifestyle factors in addition to the presence of chronic diseases.

Objective: We aimed to assess the predictive accuracy of machine learning (ML) models incorporating lifestyle risk behaviors for ASCVD risk using the Korean nationwide database.

Methods: Using data from the Korea National Health and Nutrition Examination Survey, 5 ML algorithms were used for the prediction of high ASCVD risk: logistic regression (LR), support vector machine, random forest, extreme gradient boosting, and light gradient boosting models. ASCVD risk was assessed using the pooled cohort equations, with a high-risk threshold of ≥7.5% over 10 years. Among the 8573 participants aged 40 - 79 years, propensity score matching (PSM) was used to adjust for demographic confounders. We divided the dataset into a training and a test dataset in an 8:2 ratio. We also used bootstrapping to train the ML model with the area under the receiver operating characteristics curve score. Shapley additive explanations were used to identify the models' important variables in assessing high ASCVD risks. In sensitivity analysis, we additionally performed binary LR analysis, in which the ML model's results were consistent with the conventional statistical model.

Results: Of the 8573 participants, 41.7% (n=3578) had high ASCVD risk. Before PSM, age and sex differed significantly between groups. PSM (1:1) yielded 1976 patients with balanced demographics. After PSM, the high ASCVD risk group had higher alcohol or tobacco use, lower omega-3 intake, higher BMI, less physical activity, and spent less time sitting. In 5 ML models, the extreme gradient boosting model showed the highest area under the receiver operating characteristics curve, indicating superior overall discrimination between high and low ASCVD risk groups. However, the light gradient boosting model demonstrated better performance in accuracy, recall, and F_1-score. Variable importance analysis using Shapley additive explanations identified smoking and age as the strongest predictors, while BMI, sodium or omega-3 intake, and low-density lipoprotein cholesterol also had significant variables. Sensitivity analysis using multivariable LR analysis also confirmed these findings, showing that smoking, BMI, and low-density lipoprotein cholesterol increased ASCVD risk, whereas omega-3 intake and physical activity were associated with lower risk.

Conclusions: Analyzing lifestyle behavioral factors in ASCVD risk with an ML model improves the predictive performance compared to traditional models. Personalized prevention strategies tailored to an individual's lifestyle can effectively reduce ASCVD risk.

KEYWORDS

atherosclerotic cardiovascular disease; machine learning; lifestyle risk behaviors; predictive modeling; low-density lipoprotein

Introduction

Atherosclerotic cardiovascular disease (ASCVD) remains the leading cause of morbidity and mortality worldwide [1]. In 2019, cardiovascular diseases (CVDs) were responsible for an estimated 32% of all global deaths [2]. Of the 17 million premature deaths caused by noncommunicable diseases in 2019, 38% were attributable to CVDs [2]. The prevalence of CVDs

XSL•FO
RenderX

in South Korea has recently been increasing [3]. While the CVD mortality rate declined until 2010, it has been steadily rising since then [4]. Considering these trends, addressing CVDs is crucial for improving public health outcomes.

The main risk factors for developing ASCVD include hypertension, smoking, and dyslipidemia [5]. Additionally, ASCVD outcomes vary across different ethnic groups based on socioeconomic status, which also influences health-related lifestyle behaviors [6-8]. As the prevalence of ASCVD is increasing, the importance of primary prevention has been emphasized from a public health perspective [9]. ASCVDs are closely related to modifiable risk factors that can be controlled through lifestyle modification, which is the cornerstone of ASCVD prevention [9]. The most effective prevention strategy is a comprehensive approach that promotes a healthy lifestyle and addresses all major risk factors [10].

Machine learning (ML) has been increasingly applied in medical data analysis, offering numerous benefits for enhancing patient care and improving clinical outcomes [11]. Additionally, ML facilitates precision medicine by enabling early identification of high-risk patients for disease progression with high accuracy [11]. Previous studies have constructed ML models for predicting ASCVD, but few have modeled the impact of lifestyle behaviors on ASCVD risk [11-13]. Despite advances in ML, the combined predictive power of detailed lifestyle factors—especially within interpretable ML frameworks—remains underexplored. Although ML improves risk prediction, understanding which lifestyle factors have the greatest impact is crucial for prevention—yet this is often unclear with black-box models. This study addresses that gap by applying interpretable ML techniques to accurately predict ASCVD risk and clarify the specific impact of individual lifestyle factors. ASCVD risk is influenced by demographic variables such as age, race, and sex, as well as lifestyle behaviors [14,15]. Using data from the nationwide Korea National Health and Nutrition Examination Survey (KNHANES), we used five ML models to (1) examine the relationship between lifestyle factors and ASCVD risk, (2) evaluate the predictive performance of these models, and (3) identify the most influential predictors using interpretable methods.

Methods

Participants

This retrospective case-control study used nationally representative data from the KNHANES. The KNHANES is an ongoing, cross-sectional survey initiated in 1998 by the Korea Disease Control and Prevention Agency (KDCA) to assess the health and nutritional status of the Korean population. We used anonymized, publicly available data from 2019 to 2021. Among the 22,559 total participants in the 2019‐2021 KNHANES dataset, we initially screened 10,481 individuals aged 40‐79 years with no history of cardiovascular events. We excluded 1908 participants with missing data on sodium intake, low-density lipoprotein (LDL) cholesterol, time spent sitting, occupation, marital status, smoking status, income, BMI, or weight change over 1 year. The final analytic sample included 8573 participants.

Ethical Considerations

The original KNHANES surveys received ethical approval from the KDCA Institutional Review Board, and informed consent was obtained from all participants. All data were anonymized and deidentified by KDCA prior to public release. As this study involved the secondary analysis of deidentified public data, it was exempt from additional institutional review board review by our institution (2024-03-008).

Measurement of ASCVD Risk Score

The 10-year ASCVD risk was assessed using the American College of Cardiology/American Heart Association pooled cohort equations (PCEs) risk score [15]. They recommended that PCEs for non-Hispanic White people may be considered for risk estimation in populations other than non-Hispanic African American and non-Hispanic White people [15,16]. Therefore, the estimation function of the ASCVD risk score for the White population was used in this study. This score algorithm is designed to predict both the 10-year (40‐79 years of age) and lifetime (20‐59 years of age) risk of ASCVD. This includes the assessment of both fatal and nonfatal coronary heart disease and stroke [17,18]. We categorized participants into two groups based on their 10-year ASCVD risk calculated using the PCEs: a low ASCVD risk group (ASCVD risk <7.5%) and a high ASCVD risk group (ASCVD risk ≥7.5%).

Measurement of Lifestyle Risk Behaviors

The lifestyle risk behaviors analyzed in this study included sex, age, occupation, marital status, residential area, household income, alcohol consumption, smoking, omega-3 intake, sodium intake, BMI, weight change over 1 year, LDL cholesterol, physical activity, and time spent sitting. The occupation was classified into three categories of nonmanual workers, manual workers, and other workers. Marital status was separated and widowed, and divorced participants were assigned the no spouse status. The residential area was grouped as urban or rural areas. Alcohol consumption was divided into two categories, where participants drank at least 2 days per week and fewer than 2 days per week [19], regardless of the amount of alcohol consumed. Individuals who had smoked at least 100 cigarettes in their lifetime and currently smoked were classified as smokers, whereas those who had smoked fewer than 100 cigarettes in their lifetime but did not currently smoke and never smoked in their lifetime were classified as nonsmokers. BMI was calculated as weight in kilograms divided by height in meters squared. Weight change over 1 year was classified into three categories of no weight change, weight gain, and weight loss. Using the criteria specified in the questionnaire, weight gains and losses of 0 to less than 3 kg over 1 year were classified as no change, gains of more than 3 kg as weight gain, and losses of more than 3 kg as weight loss. Physical activity was calculated using the sum of the minutes of exercise per week and considering the strength of the exercise intensity (vigorous and moderate). The combination of vigorous intensity and moderate intensity exercise was considered by calculating the minutes exercised per week as follows: 2×moderate activity (minutes per week)+vigorous activity (minutes per week) [20]. “Physically active” is defined as engaging in at least 150 minutes of moderate activity per week [21]. We used omega-3 or sodium

XSL•FO
RenderX

intake in grams per day and time spent sitting in minutes per day, and these variables were entered into the ML model as continuous variables.

Statistical Analysis

We categorized ASCVD risk into two groups: high and low risk. The ASCVD risk score itself is calculated using age and sex. Consequently, the high-risk and low-risk groups are inherently expected to differ significantly in these demographic factors by definition. In addition, our primary goal was to assess how lifestyle behaviors differ between high and low-risk individuals after accounting for nonmodifiable or less modifiable factors. Therefore, we performed 1:1 propensity score matching (PSM) based on sociodemographic characteristics to assess the impact of lifestyle behaviors on ASCVD risk.

The propensity score was calculated with the following variables: sex, age, job or marital status, residential area, and household income. In descriptive analyses of two-group comparisons, continuous variables were presented as median and IQR, and categorical variables were presented as proportions (%). Differences between high and low ASCVD groups were compared using the Mann-Whitney *U* test for continuous variables after a normality test, and the chi-square test for categorical variables.

We used 5 ML algorithms for the prediction of high ASCVD risk: logistic regression (LR), support vector machine, random forest (RF), extreme gradient boosting (XGB), and light gradient boosting (LGB) model. We specifically included ensemble methods, particularly RF, XGB, and LGB models. These ensemble ML models can effectively capture complex, nonlinear relationships and high-order interactions between various risk factors (eg, lifestyle, demographic, and clinical variables) without requiring explicit prespecification [22]. In addition, they include built-in regularization techniques (like L1 and L2 penalties) to mitigate overfitting, a common concern with complex medical data [23]. In the ML model, categorical variables (including sex [after PSM, though balanced], job category, marital status, residential area, alcohol consumption frequency category, smoking status, and weight change category) were retained in their original numeric coding format. Continuous variables (including age [after PSM], omega-3 intake, sodium intake, BMI, LDL cholesterol, and time spent sitting) were scaled to a range of [0, 1] using min-max normalization. In this study, we adopted a strict data separation strategy for model development and evaluation. First, the entire dataset was randomly partitioned into a training set (80%) and a test set (20%), and stratification was applied to the partitioning to ensure that both sets retained the same class distribution as the original data. We also fixed the random seed to ensure the reproducibility of the data. Then, we performed a 5-fold stratified cross-validation on the training dataset only. In this process, we divided the training data into five equal-sized folds and repeated it five times, using 4-fold for training and one for validation in each iteration. Based on the results of this cross-validation, the optimal model structure and hyperparameters with the lowest loss were selected. Hyperparameter optimization for each of the five ML models (LR, support vector machine, RF, XGB, and LGB) was performed using Optuna, an automated hyperparameter optimization framework [24]. We used Optuna's Tree-structured Parzen Estimator sampler, a Bayesian optimization approach, to efficiently search for optimal hyperparameter combinations. For each model, optimization was conducted over 100 trials, aiming to minimize the loss obtained from the 5-fold cross-validation within the training dataset. The specific hyperparameters tuned for each model, their respective search spaces (eg, ranges for continuous parameters and choices for categorical parameters), and the final optimal configurations identified by Optuna and used for training are all detailed in Table S1 in Multimedia Appendix 1. We evaluated the final model using a separate test set (20% of the total data). This is to objectively measure the generalization performance of the model. To calculate CIs for the ML model's performance metrics, we used the bootstrapping method. The 95% CIs were calculated by repeating the bootstrapping samples 1000 times with 50% of the data as restoration extraction from the test dataset. Understanding the performance of ML models is becoming increasingly important, which highlights the growing significance of explainable artificial intelligence in interpreting model results. We used the SHapley Additive exPlanations (SHAP) value to visualize the importance and relationships among the input features of the model. In addition to the area under the receiver operating characteristics curve (AUROC) score, accuracy, precision, recall, F_1-score, specificity, and area under the precision-recall curve were calculated to assess the performance of the developed ML models.

We conducted a multivariable LR analysis as a sensitivity test to verify whether the ML model's findings on high ASCVD risk were consistent with conventional statistical methods. Univariable LR analysis was first performed on 1:1 matched patients (high vs low ASCVD risk) to identify lifestyle and sociodemographic factors associated with high ASCVD risk. Variables with a P value <.05 in the univariable model were entered into the multivariable model, and their significance was reported as adjusted odds ratios with 95% CIs.

Results

Baseline Characteristics

Of the 8573 participants, the proportion of the high ASCVD risk group was 41.7% (3578/8573), and 5059 (59%) participants were women (Table 1). As detailed in Table 1, prior to PSM, substantial baseline differences were evident across nearly all measured characteristics. Notably, the high ASCVD risk group was significantly older (median age 68.0, IQR 62.0-73.0 vs 51.0, IQR 45.0-58.0 y; P<.001) and comprised a much higher proportion of men (61.9% vs 26%; P<.001) compared to the low-risk group. Significant disparities also existed in socioeconomic factors (job distribution, marital status, residential area, and income) and various lifestyle behaviors, including higher rates of frequent alcohol consumption and smoking, lower omega-3 intake, higher BMI, lower physical activity levels, and differences in weight change patterns and sitting time (all P≤.02). The propensity score distribution and standardized differences before and after PSM for the variables used in propensity score calculation are presented in Figures

XSL•FO
RenderX

S1 and S2 in Multimedia Appendix 1. Using the 1:1 PSM method, 1976 patients were included in the final population for analysis, ensuring no significant differences in sociodemographic variables between the two groups, except for lifestyle behaviors. Following 1:1 PSM, which successfully balanced the groups for key demographic and socioeconomic confounders (sex, age, job, marital status, residential area, and income; all $P>.20$), several crucial differences in lifestyle behaviors remained statistically significant. Specifically, even after matching, the high ASCVD risk group demonstrated markedly higher rates of frequent alcohol consumption (25.3% vs 18.3 %; $P<.001$) and current smoking (42.2% vs 6.3%; $P<.001$). Furthermore, this group had significantly lower daily omega-3 intake (median 1.3, IQR 0.7-2.3 vs 1.5, IQR 0.9-2.6 g; $P<.001$) and a higher BMI (median 25.1, IQR 23.2-27.3 vs 23.9, IQR 21.9-25.8 kg/m²; $P<.001$). They also reported engaging in less physical activity (16.6% active vs 22% active; $P=.003$). Interestingly, the high-risk group reported slightly less time spent sitting compared to the low-risk group after matching (median 8, IQR 5-10 h per day; $P=.003$). Notably, the initial significant differences observed in sodium intake and LDL cholesterol levels before matching were no longer significant after PSM ($P=.15$ and $P=.12$, respectively), suggesting these factors were partly confounded by the demographic variables adjusted for in the matching process. The flowchart of participants is presented in Figure 1.

Evaluation Outcomes: Performance of ML Model for ASCVD Risk

The 1976 matched patients were allocated to the training and test datasets in an 8:2 ratio while maintaining the same ASCVD risk proportion. A comparison of variables between these two groups is presented in Table S2 in Multimedia Appendix 1, showing no significant differences in variable distribution. Figure 2 shows the result of ML performance for predicting high ASCVD risk in the test dataset, with XGB showing the highest AUROC (0.811, 95% CI, 0.748 - 0.867). Table 2 presents the other performances of the five ML models; the LGB model demonstrated the best performance, including accuracy, recall, and F_1-score. The high AUROC values achieved, particularly by XGB (0.811) and LGB (0.810), indicate valid discriminative power, suggesting these models are capable of effectively distinguishing between individuals at high versus low 10-year ASCVD risk based on the included lifestyle and clinical factors. Additionally, the LGB model achieved the highest recall (0.692), meaning it correctly identified approximately 69% of the high-risk individuals in the test set. The superior F_1-score (LGB 0.735) and area under the precision-recall curve score (LGB 0.829, XGB 0.828) in the test dataset showed the models' robust performance, even in a real-world imbalanced dataset.

Variable Importance in ML Model

To visualize the importance of variables included in the ML model, we presented SHAP values for the XGB model used to predict high ASCVD risk (Figure 3). Current smoking and age were the strongest predictors of high ASCVD risk over 10 years. Among lifestyle factors, BMI, sodium or omega-3 intake, and LDL cholesterol were also associated with increased risk. In contrast, factors such as “time spent sitting,” physical activity, sex, and marital status had a relatively smaller impact. The SHAP values for the LGB model, presented in Figure S3 in Multimedia Appendix 1, show a similar pattern of variable importance as the XGB model.

Figure 3. Variable importances of extreme gradient boosting models for high ASCVD risk in the test dataset. (A) Importance matrix plot showing the direction of the relationship between an input variable and high ASCVD risk. (B) Shapley Additive exPlanations summary plot of lifestyle variables predictive features of the ML model. As demonstrated by the color bar, higher values are shown in red, while lower values are shown in blue. Associations of Lifestyle Risk Factors With 10-Year ASCVD Risk

For sensitivity analysis, we examined whether the ML model's results were consistent with binary LR (Table 3) using high ASCVD risk as the outcome. Multivariable binary LR showed that smoking and BMI were positively associated with high ASCVD risk, while omega-3 intake and physical activity were significantly negatively associated. Compared to the SHAP values of the XGB and LGB models, factors such as smoking status, BMI, and omega-3 intake showed similar associations in the multivariable binary LR model.

Table . Result of binary logistic regression analysis of lifestyle variables for predicting 10-year high ASCVD[a] risk in propensity score matched cohort.

Variable	Univariable analysis		Multivariable analysis	
	OR[b] (95% CI)	*P* value	Adjusted OR (95% CI)	*P* value
Gender (women)	0.96 (0.80 - 1.14)	.62	—[c]	—
Age (years)	1.01 (1.00 - 1.02)	.20	—	—
Job				
Manual workers	1.00 (reference)	—	—	—
Nonmanual workers	1.12 (0.88 - 1.43)	.34	—	—
Other workers	1.06 (0.83 - 1.36)	.64	—	—
Marital status (without spouse)	1.03 (0.84 - 1.27)	.75	—	—
Residential area (urban)	1.11 (0.90 - 1.37)	.33	—	—
Income (10,000 won per month)	1.00 (1.00 - 1.00)	.98	—	—
Alcohol drinking (≥2 per week)	1.51 (1.22 - 1.87)	<.001	0.89 (0.68 - 1.15)	.37
Smoking	10.91 (8.19 - 14.53)	<.001	11.52 (8.20 - 15.60)	<.001
Omega-3 intake (g per day)	0.93 (0.89 - 0.97)	.003	0.93 (0.88 - 0.98)	.01
Sodium intake (g per day)	1.00 (1.00 - 1.00)	.97	—	—
BMI (kg/m^2)	1.13 (1.10 - 1.17)	<.001	1.13 (1.09 - 1.16)	<.001
Weight change over 1 year				
Weight loss	1.00 (reference)	—	—	—

Weight gain	1.14 (0.82 - 1.58)	.43	—	—
LDL[d] (mg/dL)	1.00 (1.00 - 1.01)	.04	1.00 (1.00 - 1.00)	.67
Physical activity	0.71 (0.56 - 0.89)	.003	0.61 (0.47 - 0.79)	<.001
Time spent sitting (hours per day)	1.00 (1.00 - 1.00)	.003	1.00 (1.00 - 1.00)	.42

[a]ASCVD: atherosclerotic cardiovascular disease.

[b]OR: odds ratio.

[c]Not applicable.

[d]LDL: low-density lipoprotein.

Discussion

Principal Findings

This study assessed the performance of ML models, including XGB and LGB, in predicting 10-year high ASCVD risk in adults and identifying key risk factors. After adjusting for confounders using PSM, both models demonstrated high AUROC values, with LGB outperforming in accuracy, recall, and F_1-score. Variable importance analysis identified smoking and age as the strongest predictors, while BMI, sodium or omega-3 intake, and LDL cholesterol also had significant variables. Multivariable LR also confirmed these findings, showing that smoking, BMI, and LDL cholesterol increased ASCVD risk, whereas omega-3 intake and physical activity were associated with lower risk.

Age is associated with increased oxidative stress, which leads to an increased susceptibility to CVD onset [25]. Excessive generation of reactive oxygen species leads to a state of oxidative stress, which is a major risk factor for the development and progression of atherosclerosis [26]. Aging is an unmodifiable ASCVD risk factor, but it can be prevented if

XSL•FO
RenderX

other factors can be corrected. Cigarette smoking is widely accepted as a major risk factor for the development of clinical CVD, resulting from direct effects on atherosclerosis. Epidemiologic studies strongly support that cigarette smoking in both men and women increases the incidence of myocardial infarction and fatal coronary artery disease [27,28].

Cigarette smoking is widely accepted as a major risk factor for the development of clinical CVD, resulting from direct effects on atherosclerosis. Epidemiologic studies strongly support that cigarette smoking in both men and women increases the incidence of myocardial infarction and fatal coronary artery disease [29]. Because the chemical constituents of smoke have high oxidant and inflammatory capacities, they can directly induce endothelial damage and potentiate an inflammatory response [30]. Smoke is able to increase LDL levels through metabolic alterations and the induction of LDL oxidation due to the direct oxidant capacity of smoke components [30,31]. Obesity has been linked to persistent inflammation and oxidative stress. Oxidative stress plays a crucial role in disorders related to obesity, such as dyslipidemia and hypertension, causing CVDs [32]. The prevalence of overweight and obesity has been strongly increasing over the last few decades, and it is considered to be one of the largest challenges for public health work worldwide [33].

Interestingly, some lifestyle factors commonly associated with cardiovascular health, such as sodium intake and time spent sitting, showed weaker associations with high ASCVD risk in our final models after adjusting for confounders. For instance, while sodium intake was significantly different between groups before PSM, this difference did not persist after matching, and it did not emerge as a strong predictor in the multivariable LR or the SHAP analyses for the ML models. Similarly, “time spent sitting” did not demonstrate a strong independent association in the multivariable LR model (P=.42) despite being significant in the univariable analysis and showing a difference post-PSM. Furthermore, its importance ranking in the SHAP analyses was relatively low. The lack of a strong independent association between sitting time and ASCVD risk may reflect collinearity with physical activity, limitations in the variable’s definition (eg, failure to capture prolonged uninterrupted sitting), potential inaccuracies in self-reported data, and residual confounding suggested by the unexpected postmatching trend.

The American Heart Association has recently outlined a new framework that focuses on defining and optimizing cardiovascular health through the adoption of 8 simple health components: healthy diet, engaging in regular physical activity, avoidance of nicotine, healthy sleep, and healthy levels of blood lipids, glucose, and blood pressure [34]. Most clinical guidelines for the primary or secondary prevention of ASCVD emphasize the importance of lifestyle modification. These lifestyle changes are also an important part of public health policy for CVD prevention. Therefore, a lifestyle approach to ASCVD risk may be important for accurate prediction and prioritization of treatment strategies for prevention.

Beyond simply ranking variable importance, the application of SHAP analysis provides crucial granular insights into how individual factors contribute to the predicted ASCVD risk for each patient, offering significant advantages over traditional “black-box” models. Our SHAP results (Figure 3 and Figure S3 in Multimedia Appendix 1) confirm that current smoking and age are not just important, but consistently exert the strongest positive influence toward a high-risk prediction across the cohort. The magnitude of the positive SHAP values associated with current smoking underscores its overwhelming impact, reinforcing the paramount importance of smoking cessation as a primary prevention strategy from a clinical standpoint. Similarly, the consistent positive contribution of increasing age highlights the nonmodifiable baseline upon which lifestyle interventions must act. Furthermore, the SHAP visualizations offer nuances beyond simple correlation. Especially, higher omega-3 intake consistently generated negative SHAP values, indicating its protective effect by lowering the predicted risk score. While LDL cholesterol’s influence appeared less dominant after PSM in the LR, SHAP analysis still identified it as a contributor, potentially highlighting its relevance within the complex interplay captured by the ML model.

Limitations

This study has several limitations. First, it is a cross-sectional study, which does not allow for establishing causal relationships. While our ML models identify strong associations and predictive patterns (eg, smoking status being highly predictive of high ASCVD risk), this design prevents us from definitively concluding that altering a specific lifestyle factor will cause a change in ASCVD risk. For instance, the model might show that higher omega-3 intake is associated with lower predicted risk, but we cannot ascertain from this data alone whether increasing omega-3 intake would directly lead to a reduction in an individual’s true risk, or if the association is partly due to other unmeasured confounding factors linked to both omega-3 intake and cardiovascular health. This limitation significantly impacts the direct translation of our ML model’s findings, particularly the feature importance results (like SHAP values), into prescriptive clinical actions. Second, some variables were measured by questionnaire, which may lead to underestimation or overestimation for the prediction of ASCVD risk. Especially in the case of nutrition, it is particularly difficult to accurately reflect daily intake. Third, the study involved a secondary analysis of data from the KNHANES, so it was not possible to include all lifestyle and socioeconomic status variables in the analysis. Finally, we excluded 1908 participants (approximately 18% of the initially eligible cohort after age screening) due to missing data on one or more key analytical variables (sodium intake, LDL-cholesterol, time spent sitting, etc). This exclusion was based on a complete case analysis approach, meaning only participants with complete records for all variables used in the models were included. Multiple imputation techniques could potentially allow for the inclusion of this population and might mitigate some of the selection bias. Future studies should investigate the impact of handling missing data via multiple imputation compared to complete case analysis, specifically assessing potential improvement in the performance metrics of the developed ML models. Nevertheless, the strength of this study is that it used representative and reliable data from

XSL•FO
RenderX

KNHANES to predict modifiable lifestyle risk factors using an ML approach.

Conclusions

This study demonstrates that ML models are effective tools for assessing ASCVD risk and highlights the significant impact of lifestyle factors such as smoking, BMI, and omega-3 intake. These findings highlight the significant clinical informatics potential for integrating the developed interpretable ML models into electronic health records, clinical decision support tools, and digital health platforms to enable dynamic, personalized ASCVD risk assessment and guide targeted lifestyle interventions within routine clinical practice. Longitudinal studies are needed to establish causal links between the identified lifestyle factors and ASCVD development in a multiethnic population. Furthermore, additional measures of lifestyle with wearable devices could enhance the clinical utility of the ML model.

Abstract

Background: Human adenoviruses (HAdVs) and COVID-19 are prominent respiratory pathogens with overlapping clinical presentations, including fever, cough, and sore throat, posing significant diagnostic challenges without viral testing. Tongue image diagnosis, a noninvasive method used in traditional Chinese medicine, has shown correlations with specific respiratory infections, but its application remains underexplored in differentiating HAdVs from COVID-19. Advances in artificial intelligence offer opportunities to enhance tongue image analysis for more objective and accurate diagnostics.

Objective: This study aims to develop and validate artificial intelligence–based predictive models using tongue image features to differentiate COVID-19 from adenoviral respiratory infections, thereby improving diagnostic accuracy and integrating traditional diagnostic methods with modern medical technologies.

Methods: A total of 280 tongue images were collected from 58 patients with COVID-19, 84 patients with HAdVs, and 30 healthy controls. Deep learning methods were applied to extract tongue features, including color, coating, fissures, papillae, tooth marks, and granules. Four machine learning classifiers, logistic regression, random forest, gradient boosting model, and extreme gradient boosting, were developed to differentiate COVID-19 and HAdV infections. The key features identified by the machine learning algorithms were further visualized in a 2D space.

Results: Nine tongue features showed significant differences among groups (all $P<.05$), including coating color (red, green, and blue), presence of tooth marks, coating crack ratio, moisture level, texture directionality, roughness, and contrast. The extreme gradient boosting model achieved the highest diagnostic performance with an area under the receiver operating characteristic curve of 0.84 (95% CI 0.78-0.90) and an area under the precision-recall curve above 0.70. Shapley additive explanations analysis indicated tongue color, moisture, and texture as key contributors.

Conclusions: Our findings demonstrate the potential of tongue diagnosis in identifying pathogens responsible for acute respiratory tract infections at the time of admission. This approach holds significant clinical implications, offering the potential to reduce clinician workloads while improving diagnostic accuracy and the overall quality of medical care.

Introduction

Human adenoviruses (HAdVs) are prominent respiratory pathogens affecting individuals of all ages, leading to acute upper and lower respiratory tract diseases, such as pneumonia and bronchitis [1]. Nearly half (45.7%) of acute respiratory tract infection (ARTI) outbreaks between 2009 and 2020 were attributed to HAdV-7 in China [2]. Since 2020, a temporary decline in HAdVs activity has been noted due to the rapid global spread of COVID-19 and subsequent public health measures [3,4]. As COVID-19 persists in its global circulation, a resurgence of HAdVs and other seasonal respiratory virus infections has occurred [5]. The clinical presentations of ARTI caused by HAdVs and COVID-19 are similar, often presenting as mild symptoms such as fever, rhinorrhea, cough, and sore throat, which poses a significant diagnostic challenge in the absence of viral testing. HAdVs are more prone than COVID-19 to causing acute respiratory infections in children, including pharyngitis, tonsillitis, pharyngoconjunctival fever, bronchitis, and pneumonia [6]. Moreover, recent studies indicate that mixed respiratory viral infections may lead to more severe disease outcomes than single infections [7]. Given the tendency of many patients with ARTI to self-medicate, it is essential to develop methods to differentiate between these common viral infections. Such differentiation could promote timely medical consultation and help reduce the transmission of adenovirus to children.

Tongue image diagnosis is a straightforward, noninvasive, and valuable diagnostic method used in traditional Chinese medicine (TCM), which assesses key features, such as the color, size, and shape of the tongue, along with the color, thickness, and moisture level of the tongue coating [8]. In respiratory infections, TCM theory associates specific tongue coatings with distinct syndromes [9]. Epidemiological studies have also identified distinctive tongue features in patients with acute respiratory infections. Patients with COVID-19 have been reported to present features, such as fissured tongue and strawberry tongue [10-13], whereas tongue signs in HAdV infections remain scarcely documented, limiting comprehensive understanding. Given the convenience and cost-effectiveness of tongue imaging, its application for differentiating COVID-19 from HAdV infections shows promising potential.

Tongue diagnosis traditionally relies heavily on the experience and observational skills of TCM practitioners to interpret tongue features. However, advances in artificial intelligence (AI) technologies have enabled the extraction of tongue image characteristics, such as texture, color, and coating, facilitating more objective and intelligent tongue diagnosis. Recent studies have applied AI-assisted tongue image analysis in various diseases, including diabetes [14], fatty liver [15], non-small cell lung cancer [16], and gastric cancer [17], combining tongue image features with clinical indicators to develop exploratory disease risk prediction models. Similarly, Zhou et al [18] proposed an automatic multiview disease detection system using tongue images, achieving an average classification accuracy exceeding 95% for breast tumors, heart disease, fatty liver, and lung tumors. Given the limited research on AI-assisted tongue diagnosis for respiratory infections, there is a clear need to explore its potential in this domain. Therefore, this study aims to investigate the application of AI-based tongue image analysis to distinguish COVID-19 from adenoviral respiratory infections, with the goal of improving diagnostic accuracy and integrating traditional diagnostic methods with contemporary medical technologies.

Methods

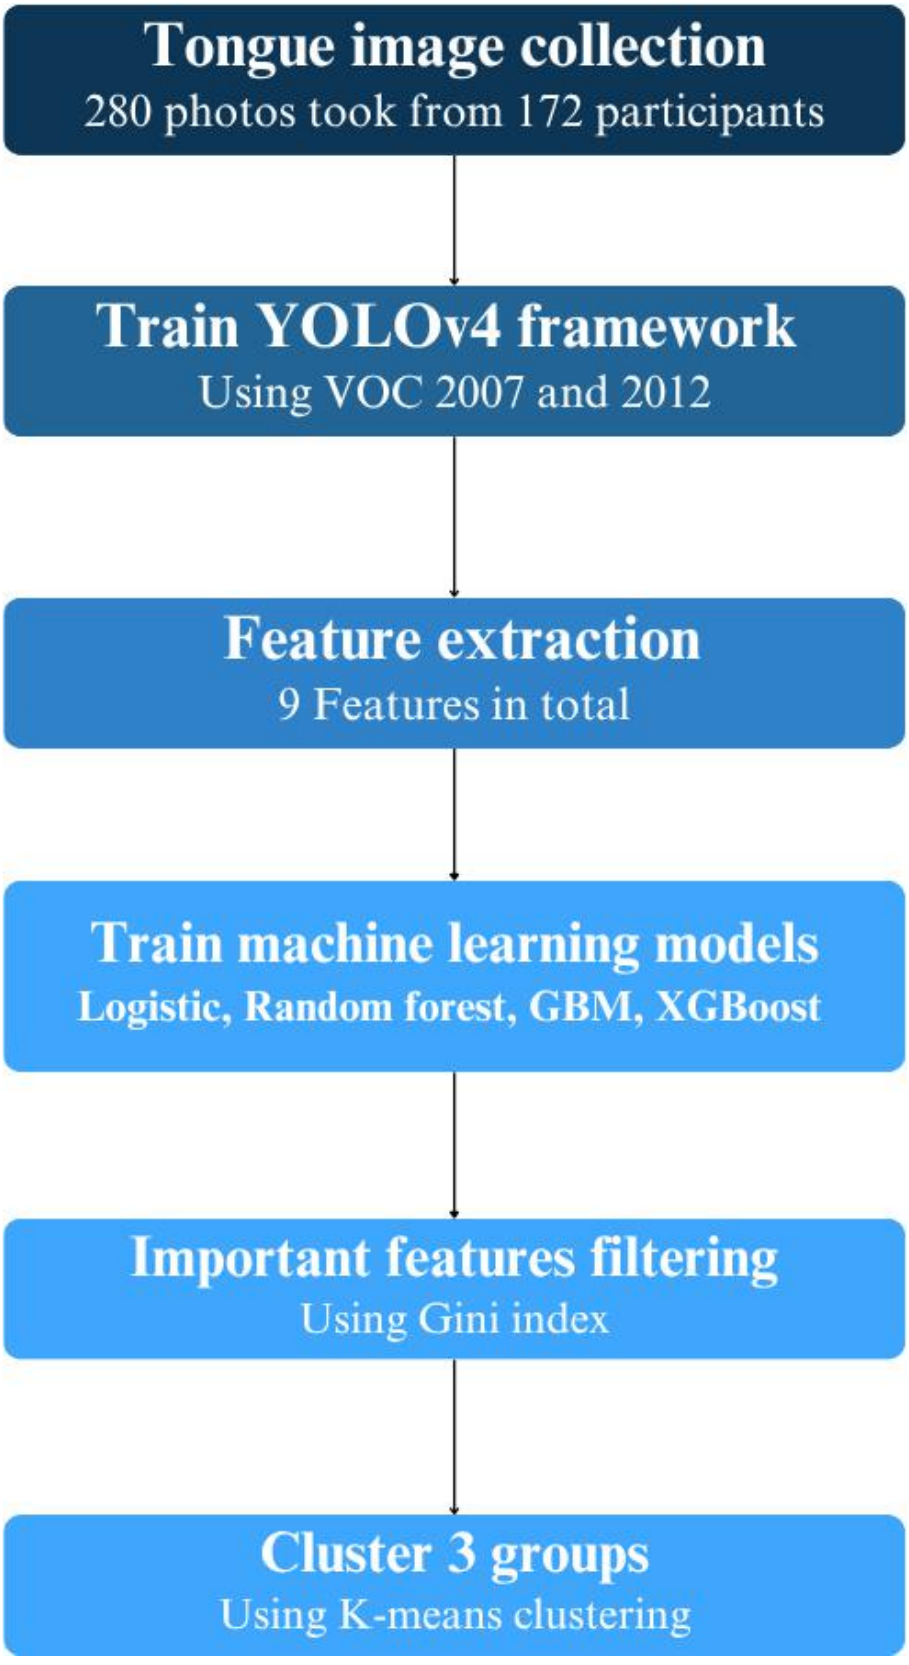
Study Sample

Our study was conducted between November 2020 and January 2021 at the Department of Traditional Chinese Medicine Hepatology, which is in the Fifth Medical Center of the Chinese People's Liberation Army (PLA) General Hospital. The inclusion and exclusion criteria have been listed in Textbox 1

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Participants whose age is between 18 and 80 years old.
- Participants willing to participate in tongue image photography signed an informed consent form.



Exclusion criteria

- Individuals who were unable to describe their condition clearly due to mental factors or could not cooperate with the collection of tongue diagnosis images.
- Participants with severe acute complications, such as serious electrolyte imbalance and acidosis; patients with other serious internal diseases, such as tumors, immune system disorders, or hematologic diseases; and individuals taking medications, such as steroids, that affect glucose metabolism.
- Pregnant women and nursing mothers were excluded.

After applying the inclusion and exclusion criteria, 172 participants were included in the study. Of these, 58 were diagnosed with COVID-19, 84 with adenovirus, and 30 were assigned to the control group. Meanwhile, all the patients had complete clinical data and demonstrated high compliance, while control group participants had no history of chronic or acute diseases in the past 3 months (Figure 1).

Outcome Definition

A confirmed case of COVID-19 is defined as a suspected case that yields a positive result on a real-time reverse-transcription polymerase chain reaction assay using respiratory specimens [19]. In this study, all patients with adenovirus infection met the diagnostic criteria outlined in the “Adenovirus Infection Diagnosis and Treatment Guidelines" issued in 2013 [20]. According to these guidelines, the criteria include (1) a real-time polymerase chain reaction test on throat swab samples that detects adenovirus-specific nucleic acids; (2) the presence of adenovirus-specific immunoglobulin M antibodies in the serum;

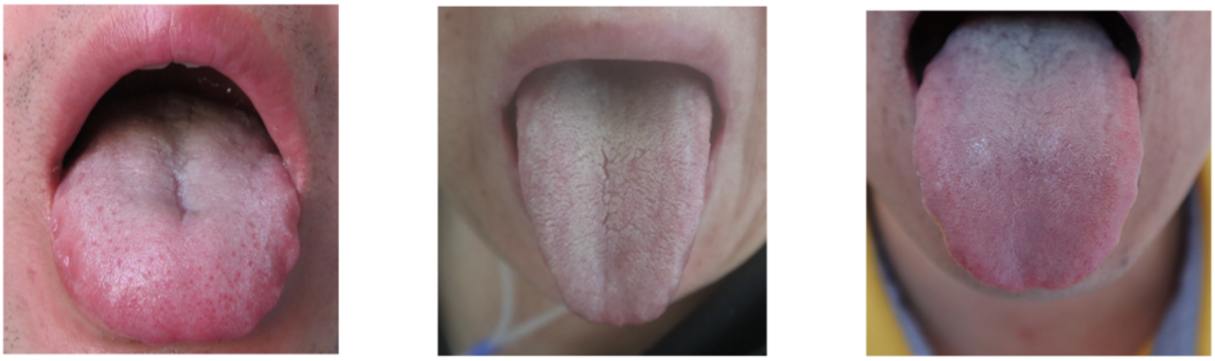
XSL•FO
RenderX

and (3) a 4-fold or greater increase in adenovirus-specific immunoglobulin G antibodies in paired serum samples collected during the acute and recovery phases. The selection of diagnostic tests was based on clinical judgment. These tests were conducted on various specimen types, including nasopharyngeal swabs, throat swabs, sputum samples, pleural effusion samples, and bronchoalveolar lavage fluid samples.

Tongue Image Collection

All tongue images were captured before the laboratory confirmation. Collecting tongue images was conducted either before a meal or 2 hours afterward. Before being photographed, participants were instructed not to eat any food or drink any colored beverages. During the examination, participants were asked to sit with their mouths open and their tongues extended, ensuring the tongue body was relaxed, the surface was flat, and the tip was drooping. A color correction card was held within the camera's view during image capture to prevent external lighting from affecting the quality of the photograph. If a retake was necessary, the participants were advised to rest for 3 - 5 minutes before recollecting the image. The final choice for storage was the best-quality image. A digital diagnostic system was used to collect and analyze all tongue images.

Tongue Image–Based AI Deep Learning Models



In this study, 4 key factors were primarily selected for detection: the tongue body, the coating, the teeth mark, and the fissures. To develop a target detection algorithm for tongue diagnosis images, the YOLOv4 object detection framework was used [21]. Through extensive experimentation with this algorithm, we used cross-validation to tune the convolutional neural network parameters and found the optimal combination of parameters [22]. We also increased the sample size and improved the model's generalization using image preprocessing techniques, including random cropping, horizontal flipping, and color distortion [23]. This preprocessing yielded sample images with various tongue characteristics, including color, coating, fissures, prickles, tooth marks, and granules, categorized under data labels 1 - 20 (Multimedia Appendices 1 and 2). Expert TCM practitioners have reviewed all the extracted features to ensure that they possess clinical relevance and significance.

We used VOC 2007 and 2012 to pretrain the initial feature extractor due to its availability and general utility in learning low-level visual features. The training batch size was 32 images, and 2 NVIDIA 1080 8G GPUs were used. Each group was segmented individually for different tongue features, including tongue coating (color, shape, and moisture), fissures (cracks ratio), prickles, tooth marks, and granules (shape and reflectivity).

Tongue Image Feature Definition

The color of the tongue coating was calculated by taking the mean red, green, and blue values within a specified area, providing insights into the tongue's health condition. Tooth marks were identified using the object detection algorithm, with a confidence threshold set at 0.6 to determine the presence and count of tooth marks. The proportion of cracks in the tongue coating was calculated by segmenting and merging areas where multiple fine cracks intersect, thus determining the area occupied by these cracks relative to the total area of the tongue coating. The moisture level of the tongue coating was assessed by identifying reflective areas where brightness exceeds a threshold value of 170, helping to evaluate the hydration status of the tongue. The texture features of the tongue coating were extracted using Tamura texture features, which focus on describing the textural characteristics of the tongue coating in terms of coarseness, contrast, directionality, and roughness [24]. In this study, coarseness refers to texture coarseness and is calculated based on the size of the elements. A larger element size or fewer repetitions of the element indicate a coarser texture. Contrast is primarily derived from the image's grayscale, while directionality refers to the degree of alignment within the elements (Figure 2).

Figure 2. Sample tongue images from the adenovirus (left), COVID-19 (middle), and control group (right) with extracted features.

Group	Tongue Coating Color (RGB)	Toothmarks	Crack Ratio	Moisture	Roughness	Texture Direction	Texture Contrast
Adenovirus	R: 180, G: 134, B: 153	2	1.4	0.1	3.1	27.5	16.0
COVID-19	R: 106, G: 78, B: 79	1	3.5	0.1	2.9	24.5	6.0
Control	R: 131, G: 106, B: 119	0	0.1	0.1	3.1	41.3	16.3

RenderX

Statistical Analysis

We obtained 280 tongue images from these participants, each contributing up to 7 images. Only images taken on the baseline day were retained for this study, and we took the average value of the extracted features in the images if participants had more than one image on the baseline day. There were 21 images with quality issues, including 11 unidentifiable images (all characteristic values were 0) and 10 unclear images (most characteristic values were 0). We applied a mean imputation technique to these images, averaging the image parameters based on outcome category and symptom severity [25]. We conducted comparative analyses across 3 groups to examine variations in tongue features, including color, texture, moisture, and morphology.

The data were divided into 2 subsets, with 70% allocated for training and 30% reserved for internal validation, to address potential overfitting concerns. Advanced machine learning models were used to analyze tongue images and classify them into 3 categories: COVID-19, adenovirus, and control. We used several models in our analysis, including gradient boosting machines (GBM), random forest, logistic regression, and extreme gradient boosting (XGBoost). To fit each model, we applied 5-fold cross-validation on the training set. We evaluated the models' performance using 2 metrics: the area under the curve (AUC) and the area under the precision-recall curve (AUCPR) [26].

An importance variable rank was computed for each algorithm to identify the variables with the highest predictive power. In addition, we created Shapley additive explanations (SHAP) values that were calculated to indicate the contributing direction of the tongue image features [27]. Finally, we projected the selected variables of tongue images into a 2D space by a t-distributed stochastic neighbor embedding (t-SNE) plot to visually examine each group's clustering distribution [28].

All statistical analyses were performed using R Studio version 4.2.0 (Posit, PBC) software. An independent samples 2-tailed *t* test was used to analyze the measurement data, such as age and identified tongue image features. The count data were analyzed using the chi-square test. Results with $P<.05$ were considered statistically significant.

Ethical Considerations

The Ethics Committee of the Fifth Medical Center of the Chinese People's Liberation Army (PLA) General Hospital (2020074D) gave ethical approval on November 24, 2020. Informed consent was waived by the committee, as the study involved retrospective analysis of anonymized data and did not include any identifiable personal information. All procedures were conducted in accordance with the ethical standards of the institutional and national research committees and with the principles outlined in the Declaration of Helsinki. We ensured that the privacy and confidentiality of all participants were strictly maintained; data were fully anonymized before analysis, and no individual-level identifiers were collected, stored, or reported. No compensation was provided to participants, as the study did not involve direct interaction with human participants.

Results

Characteristics of Patients With Each Pathogen

Our research involved 172 participants; 58 had COVID-19, 84 were diagnosed with adenovirus, and 30 were in the control group. Table 1 shows the main descriptive sociodemographic variables (sex and age). The average age in our sample was 23.65 (SD 9.61) years old (Table 1).

Table . Study sample and extracted feature characteristics.

Variables	Control (n=30)	COVID-19 (n=58)	Adenovirus (n=84)	*P* value
Gender				
male, n (%)	13 (43)	36 (62)	83 (99)	<.001
Age (years), mean (SD)	27.2 (8.0)	47.6(15.8)	23.7 (9.6)	<.001
Tongue coating, mean (SD)				
Red	119.0 (16.5)	109.8 (22.6)	149.2 (20.4)	<.001
Green	93.3 (13.8)	77.65 (21.2)	110.8 (20.7)	<.001
Blue	97.1 (19.7)	79.2 (22.0)	114.2 (25.4)	<.001

Tongue Image Feature Extraction and Definition

We used transfer learning techniques using weights obtained from training on the VOC 2007 and VOC 2012 datasets, which enabled the model to improve its understanding of general object detection. After 60,000 iterations with a learning rate of 0.0001, the average loss was reduced to 0.2867 (SD 0.0462; Multimedia Appendix 3). Compared to the proposed fast recurrent neural network and faster region-based convolutional neural network, the Single Shot MultiBox Detector architecture demonstrates higher accuracy across 20 labeled datasets (Multimedia Appendix 4). After applying our feature extraction architecture, 9 features of tongue images were identified: tongue coating color values (red, green, and blue), the presence of tooth marks, tongue coating crack ratio, tongue coating moisture level, texture directionality, texture roughness, and texture contrast (Multimedia Appendix 5).

All tongue coating color values (red, green, and blue) differed significantly across groups (P<.001) (Table 1). Patients with adenovirus had the highest values, on average, especially in the red component, which may indicate more pronounced inflammation or other specific clinical features related to adenovirus infections. The presence of tooth marks varied across groups, with the highest prevalence of 2 tooth marks in the COVID-19 group, with 21/58 (36%) participants showing this feature (P=.049). While the differences may not be statistically significant, both the COVID-19 and adenovirus groups exhibit a notably higher percentage of individuals with 2 tooth marks: 21/58 (36%) participants in the COVID-19 group and 27/84 (32%) participants in the adenovirus group. This is in contrast to the control group, where only 4/30 (13%) participants showed this characteristic (P=.09). This may be associated with other symptoms or manifestations of the illness. The moisture levels of tongue coating varied significantly among the different groups, with the adenovirus group exhibiting the lowest average moisture level (P<.01).

The adenovirus group shows considerably greater levels of tongue coating roughness compared to the COVID-19 and control groups (P<.01). In addition, both the adenovirus and COVID-19 groups exhibit significantly greater values in tongue texture direction than the control group, with the adenovirus group showing the highest mean value of 40.7 (SD 19.1). In terms of texture contrast, the COVID-19 group has the lowest average value at 12.5 (SD 5.8), while the adenovirus group reaches the highest average at 24.6 (SD 9.9), in contrast to the control group, which averages 17.1 (SD 9.4). The density plot suggested distinct patterns in tongue features among individuals with COVID-19, adenovirus, and those in the control group, demonstrating the potential of these features in differentiating respiratory viral infections (Figure 3).

Figure 3. Extracted tongue image feature density plot.

Diagnostic Performance Results

The tree-based and boosting models achieved over 70% AUCPR performance, with AUC exceeding 80% for general performance. The GBM achieved the highest AUC value of 0.888 and AUCPR value of 0.764. XGBoost came in second with an AUC value of 0.872 and an AUCPR value of 0.751, followed closely by random forest with an AUC value of 0.872 and an AUCPR value of 0.747. However, logistic regression showed a relatively worse performance, with an AUC value of 0.812 and an AUCPR value of 0.668 (Multimedia Appendix 6), and the confusion matrix of the test set is presented in Multimedia Appendix 7.

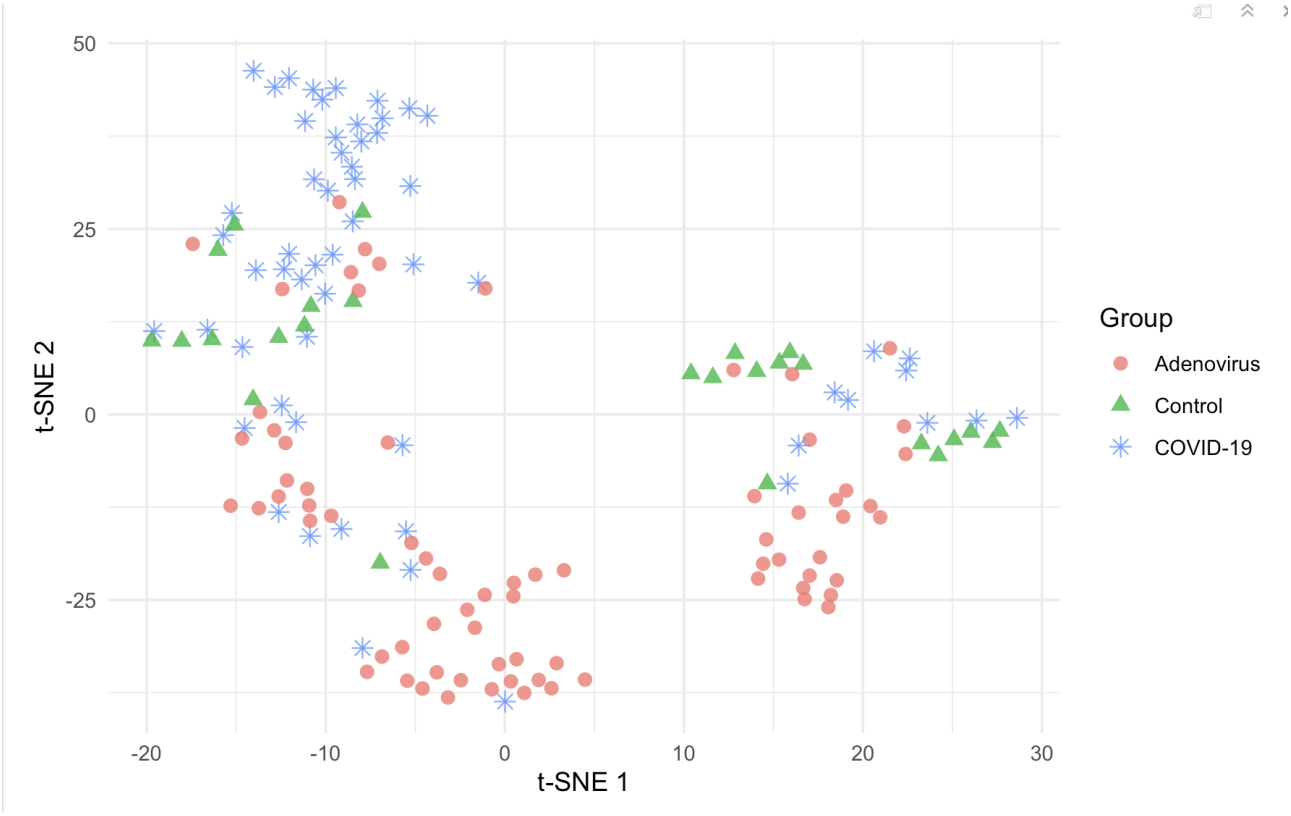
RenderX

Explaining the Rationale Behind the Predicted Models



Based on SHAP values integrating 4 machine learning models, several factors contribute to diagnosing adenovirus and COVID-19, including the color of tongue coating, moisture level, and texture direction. The feature importance plots indicate that the most significant variables are tongue color, moisture level, and texture direction (Multimedia Appendix 8). Specifically, a red tongue coating helps identify adenovirus cases, while a green tongue coating is beneficial for identifying COVID-19 cases (Figure 4). In addition, the t-SNE plot projects these variables into a 2D space and color codes each group. The distribution of patients with COVID-19 and adenovirus differs within the t-SNE space, showing some overlap, while the control group is between the 2 infectious cases (Figure 5).

Discussion

In this study, we developed and validated an AI-based prediction model to analyze tongue images for the differential diagnosis of respiratory infections caused by COVID-19 and human adenoviruses. Our models demonstrated high diagnostic accuracy, with key tongue image features, such as color, coating, moisture, and texture serving as significant discriminators. These findings highlight the potential of noninvasive tongue image analysis as an effective and cost-efficient diagnostic tool, which may facilitate early and accurate differentiation of respiratory viral infections and support clinical decision-making.

In recent years, the concurrent prevalence of respiratory infectious diseases, such as COVID-19 and HAdVs, has made it challenging to establish a differential diagnosis without pathogenic testing, thereby impacting the efficacy of the treatment [29]. Tongue image diagnosis has emerged as an effective, noninvasive method for auxiliary diagnosis that can be conducted in various settings, catering to the global demands of primary health care systems [30]. In this study, we developed machine learning models that use tongue images to predict acute respiratory tract infection (ARTI) pathogens. The accuracy of these models exceeded 80%, with feature importance plots revealing tongue color, moisture level, and tongue texture direction as pivotal variables. We then projected the tongue image features of the 3 groups of participants into a lower-dimensional space by t-SNE plot. The resulting clusters of COVID-19 and adenovirus were notably distinct, suggesting that the tongue image parameters we extracted contribute significantly to the diagnosis of ARIs. This noninvasive, convenient, and rapid approach has the potential to mitigate unnecessary diagnostic procedures and reduce health care costs.

The constructability of a risk warning model using tongue diagnosis data has been validated in research on metabolic diseases and cancers [16,31]. Our study is pioneering in applying AI deep learning techniques to investigate the diagnostic value of tongue images in acute respiratory tract infection diagnosis and can be integrated into clinical practice to aid decision-making and alleviate physician burden. Previous research by Mai and Krauthammer [32] aimed to predict common respiratory viruses in the United States by combining natural language processing tools with machine learning techniques. However, the model's prediction performance of HAdVs was moderate, with an area under the receiver operating characteristic curve (AUROC) of 0.53 [32]. Chang et al [33] used an XGBoost model, incorporating demographic, physical examination, laboratory, and vital sign data, to predict HAdVs in hospitalized children with respiratory symptoms, achieving an AUROC of 0.82. Our model exhibited superior performance, achieving an AUROC of 0.87, following the inclusion of various features in its development. In contrast to models established in previous studies, the model developed in this paper benefited from the usage of noninvasive tongue image data, obviating the need for laboratory examination indicators. By using the YOLOv4 object detection framework for image feature extraction and integrating ensemble learning algorithms (ie, GBM and XGBoost), we have demonstrated the clinical utility of tongue images. All 4 models exhibited discriminative validity over tongue images, indicating that tongue images can serve as a reliable tool for ARTI diagnosis and are robust across different AI deep learning model types. Notably, tree-based models, such

XSL•FO
RenderX

as GBM, XGBoost, and random forest, outperform logistic regression due to their ability to capture complex nonlinear relationships and interactions among features. Tongue image-derived features often display nonlinear patterns that contradict the linear assumptions of logistic regression. In contrast, tree-based models are nonparametric and resistant to multicollinearity, making them ideal for complex datasets derived from image analysis.

Previous research has validated the use of objective tongue image acquisition equipment, methods, and data analysis techniques [34]. Research on AI in TCM tongue diagnosis has predominantly focused on standardizing tongue diagnosis to minimize human errors [34]. Xu et al [35] developed a multitask joint learning model for segmenting and classifying tongue images, using a deep neural network to optimally extract tongue image features. Meng et al [36] proposed a novel feature extraction framework, termed constrained high dispersal neural networks, to extract unbiased features and minimize human labor in TCM tongue image diagnosis. This study used the YOLOv4 framework, which excelled in extracting high-level image features, thereby enhancing the model's capacity to identify intricate patterns and subtle variations [21]. The model was initially pretrained on the VOC 2007 and VOC 2012, which are effective for capturing general low-level visual features but lack domain-specific characteristics relevant to medical imagery, such as tongue images. To overcome the challenge of transferring features from natural datasets to specialized domains, domain-specific fine-tuning was performed using collected samples and synthetic data. Although the limited sample size may restrict the model's ability to capture complex patterns in tongue imagery, the fine-tuned feature extractor achieved approximately 95% classification accuracy across 20 defined groups, demonstrating effective adaptation. This integration, coupled with the fusion of ensemble learning algorithms, harnesses the complementary strengths of clinical and image-derived features, effectively addressing the limitations of each modality in isolation [37]. Consequently, the model gains enhanced discriminative power, leading to more accurate predictions of ARTI.

The analysis of feature importance in machine learning models (GBM, XGBoost, and random forest) revealed that a red tongue coat is most indicative of HAdVs and control group, while the green color is more suggestive of COVID-19 cases. Furthermore, statistical analysis of the tongue images of the 3 groups showed that the COVID-19 group had a higher moisture level and lower contrast rate, suggesting that the patients with COVID-19 are more likely to have a thicker and greasier tongue coating compared to the other 2 groups. Our findings align with the TCM theory. According to TCM, COVID-19 is classified as a "cold-dampness" disease, characterized by a tongue that is pale red or dark and a thick, white greasy coating. HAdVs are considered "warm" diseases in TCM, typically presenting with red and dry tongues. The thickness and dryness of the tongue coating can also indicate the severity of the disease and the extent of fluid damage. Epidemiological studies conducted in China, the United Kingdom, and Ukraine have yielded analogous findings; the predominant tongue colors observed were pale pink and dark red, with the most frequently encountered tongue coating being thin and greasy [38-40]. Therefore, a patient presenting with acute respiratory symptoms and a red tongue devoid of a thick, greasy coating is more likely to have an HAdVs infection. Such observations could guide health care professionals in suggesting additional diagnostic tests and preventive measures, like isolation or improved hygiene, to avert transmission to susceptible household members. Considering its noninvasive nature and rapid assessment capability, AI-assisted tongue image analysis could be particularly valuable as a screening or triage tool in primary care clinics and emergency departments, where timely differentiation of respiratory infections is essential. The advancement of large language models and multimodal AI has facilitated the development of intelligent diagnostic systems that enhance tongue image interpretation and provide real-time decision support. These technologies not only assist clinicians in prioritizing patients for confirmatory testing and early intervention, optimizing health care resource allocation but also enable remote patient monitoring and telemedicine applications.

Hypothetically, the SARS-CoV-2 virus may induce alterations in the expression levels of genes coding for apoptosis and necroptosis of epithelial cells [41,42], resulting in the accumulation of oral epithelial cells and increasing tongue coating thickness. However, these proposed mechanisms remain preliminary and require further experimental validation to clarify their roles in oral manifestations of COVID-19. Supporting the clinical relevance of tongue changes, Wang et al [43] found a correlation between tongue coating thickness in patients with COVID-19 and levels of white blood cells as well as the neutrophil-to-lymphocyte ratio. Conversely, in patients with fever who tested negative for COVID-19, the presence of slimy or greasy tongue fur was associated with the level of C-reactive protein [43]. In addition, studies have indicated that greasy tongue fur is associated with higher blood fibrinogen levels in patients with stroke and with increased activity of glossal epithelial cells and vascular permeability in rodent models [44,45].

It is important to acknowledge several limitations of this study that may impact the generalizability of its findings. Although our predictive models demonstrate the potential of tongue image features for the differential diagnosis of acute respiratory tract infections, their accuracy remains modest, with area under the precision-recall curve (AUPRC) values below 80% across all models (Multimedia Appendix 7). Visualization of the data using t-SNE projected the 3 groups into generally distinct but overlapping clusters in 2D feature space, with considerable overlap, especially between the COVID-19 and adenovirus groups. This overlap is further reflected in our confusion matrix analyses, which consistently show misclassifications between these 2 groups across all classification models. Such overlap between the COVID-19 and adenovirus groups observed in the t-SNE projection may be partly attributable to the similarity of tongue image features shared by these 2 patient populations. In addition, the dimensionality reduction inherent in t-SNE can lead to loss of critical discriminative information, further exacerbating this overlap. Together with the limited sample size used for model development and validation, as well as the exclusion of additional clinical information, such as patient

XSL•FO
RenderX

symptoms and other relevant features, these factors collectively contribute to the modest accuracy of our predictive models. Furthermore, the COVID-19 pandemic's operational constraints necessitated data collection at a single tertiary hospital. Nevertheless, as a national referral center serving Beijing and surrounding provinces, our institution treats patients from geographically diverse regions, which may partially mitigate concerns regarding population representativeness. Future studies should incorporate larger and more diverse cohorts, combined with the integration of comprehensive clinical data, which are warranted to improve the discriminative power and generalizability of the models.

Conclusion

This study illustrates the utility of AI in helping clinicians identify potential pathogens in ARTI at the time of admission. The interpretability and clinical relevance of our models suggest that they may help reduce unnecessary medical costs and diagnostic procedures while maintaining diagnostic accuracy. Moreover, by alleviating clinicians' workloads, this approach has the potential to enhance the overall quality of medical care. Looking forward, further research is warranted to externally validate these predictive models in independent cohorts and to expand the sample size to improve generalizability. In addition, incorporating clinical symptoms and other patient-specific features could further refine model performance and support more comprehensive decision-making in respiratory infection diagnosis.

Abstract

Background: As the older population grows, so does the prevalence of cognitive impairment, emphasizing the importance of early diagnosis. The Mini-Mental State Examination (MMSE) is vital in identifying cognitive impairment. It is known that degraded oral health correlates with MMSE scores ≤26.

Objective: This study aims to explore the potential of using machine learning (ML) technologies using oral health and demographic examination data to predict the probability of having MMSE scores of 30 or ≤26 in Swedish individuals older than 60 years.

Methods: The study had a cross-sectional design. Baseline data from 2 longitudinal oral health and ongoing general health studies involving individuals older than 60 years were entered into ML models, including random forest, support vector machine, and CatBoost (CB) to classify MMSE scores as either 30 or ≤26, distinguishing between MMSE of 30 and MMSE ≤26 groups. Nested cross-validation (nCV) was used to mitigate overfitting. The best performance-giving model was further investigated for feature importance using Shapley additive explanation summary plots to easily visualize the contribution of each feature to the prediction output. The sample consisted of 693 individuals (350 females and 343 males).

Results: All CB, random forest, and support vector machine models achieved high classification accuracies. However, CB exhibited superior performance with an average accuracy of 80.6% on the model using 3 × 3 nCV and surpassed the performance of other models. The Shapley additive explanation summary plot illustrates the impact of factors on the model's predictions, such as age, Plaque Index, probing pocket depth, a feeling of dry mouth, level of education, and use of dental hygiene tools for approximal cleaning.

Conclusions: The oral health parameters and demographic data used as inputs for ML classifiers contain sufficient information to differentiate between MMSE scores ≤26 and 30. This study suggests oral health parameters and ML techniques could offer a potential tool for screening MMSE scores for individuals aged 60 years and older.

KEYWORDS

classification; machine learning; mini-mental state examination; cognitive impairment; oral health

Introduction

The anticipated global population of 8 billion individuals for 2023 has been achieved. The population growth continues to persist, albeit experiencing a decelerated trajectory. Global birth rates are declining, juxtaposed with a consistent upward trajectory in average life expectancy, attributed to advancements in scientific knowledge, improved nutritional standards, advancements in public health infrastructure, and enhanced sanitation practices [1]. An estimate for the year 2050 suggests that individuals aged 60 years and older will constitute 38% of the total population and will continue to increase. While many individuals enjoy several quality years of life, a significant portion of them will also struggle with neurocognitive diseases such as Alzheimer disease (AD) and mild cognitive impairment (MCI) [2]. Until now, diagnosing AD, which is the most common neurocognitive disorder, has required extensive hospital-level efforts, and no curative treatment has been available [3]. Recent research has identified biomarkers in blood that identify proteins associated with AD [4]. At the same time, several approved antibody medications now stop the breakdown of nerve cells caused by phosphorylated Tau and amyloid plaques [5]. This is expected to significantly burden the health care system, as early diagnosis is essential for a good treatment

XSL•FO
RenderX

result. The need for screening methods is expected to be extensive. It is widely recognized that MCI and neurocognitive diseases contribute to deteriorating oral health, with individuals affected by these conditions exhibiting poorer oral health [6,7]. The decline in oral health carries profound implications, causing hardship for affected individuals and placing substantial demands on society and health care systems in terms of both costs and human resources. However, recent research suggests that the deterioration of oral health in individuals with MCI can be delayed by at least 12 months through the introduction of a powered toothbrush [8]. Additionally, severe periodontitis poses a risk factor for dementia [9]. Various instruments are available to assess cognitive function, with one of the most commonly used being the Mini-Mental State Examination (MMSE) test, which is internationally recognized and validated in numerous languages. The MMSE scale ranges from 0 to 30, with higher scores indicating a better cognitive function [10]. Recently, machine learning (ML) has emerged as a valuable aid in enhancing the precision and efficiency of cognitive assessments [11,12], leading to significant progress in the field of cognitive research [13-15]. Various datasets and algorithms can be used to better predict MMSE scores, differentiate between MCI and AD, and improve cognitive test batteries. A comprehensive study used a multifaceted approach, integrating brain cortical characteristics, biological markers, risk factors, positron emission tomography scan measures, and cognitive scores into a joint feature set to predict MMSE scores at 6 and 12 months, achieving mean absolute errors of 1.40 [16]. Researchers have improved predictive accuracy by experimenting with ML algorithms, including logistic regression, decision trees, support vector machine (SVM), XGBoost, and random forests (RF). This approach enhances diagnostic precision and offers valuable insights into disease progression and treatment response [17]. Similarly, previous research has explored integrating MRI data with cognitive tests, such as logical memory, to detect and distinguish individuals with normal cognition from those with MCI. Through deep learning models trained on MRI slices and fusion techniques, the combined model surpassed individual modalities in predictive performance, underscoring the potential of multimodal fusion in cognitive assessment, achieving an accuracy of 90.9% [18]. Earlier research has explored the area of oral health and its relationship with cognitive health. One meta-analysis [19] found that oral health in individuals with dementia was significantly worse than that of the controls. Another systematic literature review [20] came to a similar conclusion, attributing this to both difficulties in self-care due to the consequences of the disease and inflammatory mechanisms. Further, a systematic literature review [21] also indicated an association between oral health and cognitive impairment, implying a bidirectional relationship between these and ratifying a need for higher-level evidence in this area. Another systematic literature review analyzed the effects of oral interventions on cognition and found that dental treatments had a subjective influence on cognition [22]. One study [23] explored the relationship between oral health–related quality of life and cognitive function among individuals in residential care settings. Significant correlations were found between poor oral health and cognitive impairment, including MCI, revealing a relationship between cognitive status and perceived oral health [23]. Another study investigated the use of noninvasive digital biomarkers to quantify oral health and applied ML algorithms to detect cognitive decline within a community setting. Significant findings included notable differences in oral diadochokinesis rates and oral acidity between individuals with cognitive decline and those with normal cognitive function. This further demonstrates that digital oral health biomarkers have the potential to track cognitive function and facilitate early detection of cognitive decline [24].

Despite promising advancements in clinical practice and the possibility of early diagnosis, further research is needed. One significant research gap is the lack of exploration of oral health parameters as potential indicators for estimating MMSE scores. Although oral health has a recognized influence on overall well-being and cognitive function, there have been no empirical studies to explore the integration of oral health metrics into ML-based cognitive assessment models. This opens an opportunity for future studies to expand the scope of cognitive assessments and develop more comprehensive diagnostic frameworks. Many individuals routinely visit dental care facilities for treatment and preventive care. Leveraging existing patient history data alongside current examination findings requires minimal additional effort from dental care staff, and it can be seamlessly integrated with digital medical record systems. Previous research presents diverse evidence on the association between oral and cognitive health. This study builds on this knowledge by investigating different parameters and using a robust and balanced sample of participants in the MMSE 30 and MMSE ≤26 score groups.

Integrating oral health parameters into ML-driven decision support systems for MMSE score estimation could offer insights into the interplay between oral health and cognitive function. By leveraging advanced algorithms and comprehensive datasets encompassing cognitive and oral health data, researchers could uncover novel biomarkers and risk factors for cognitive decline, paving the way for more personalized approaches to cognitive assessment and intervention.

This study aims to explore the potential of using ML technologies using oral health and demographic examination data to predict the probability of having MMSE scores of 30 or ≤26 in Swedish individuals older than 60 years.

The main contributions of this study are as follows:

- The evaluation of the potential of oral health parameters for binary classification of MMSE scores of 30 and ≤26.
- The evaluation of the most deterministic oral health parameters that influence the outcome of the best-performing ML classifier.
- The assessment of RF, SVM, and CatBoost (CB) ML classifiers as indicators of MMSE scores of 30 and ≤26.

Methods

Ethical Considerations

This study used secondary, open-access data from the Swedish National Study on Aging and Care (SNAC-B) and Support Monitoring and Reminder Technology for Mild Dementia

XSL•FO
RenderX

(SMART4MD) projects. No new data were collected specifically for this study. The use of SNAC-B data was approved by the Ethics Committee of Lund University (LU 604‐00). The data for SMART4MD was collected and used under the approval of the Ethical Review Board in Sweden (LU No. 650‐00 and No. 744‐00). Informed consent was obtained from all participants in both studies. All data were fully anonymized prior to access by the authors. No compensation was provided to participants for the purpose of this study. All data were used in accordance with applicable data sharing agreements and stored securely. The study complies with the ethical standards outlined in the Declaration of Helsinki.

Data Description

The formed sample was used in experiments with ML models, including RF, SVM, and CB, aiming to indicate whether the participant's MMSE scores were 30 or ≤26. Data from 2 studies, which recruited participants from the European collaborative study SMART4MD [25] and the SNAC-B [26], formed the sample. SNAC-B is a longitudinal study involving individuals aged 60 years or older. Participants undergo examinations every 6 years, with more frequent assessments every 3 years, starting at the age of 78 years. The cohort ranges from 60 to 96 years of age [26]. The study sample recruited from SMART4MD involved individuals aged 60 years or older, examined every 6 to 12 months over 36 months [27]. Both studies are conducted at a research clinic affiliated with Blekinge Institute of Technology by experienced dentists and dental hygienists and involve comprehensive clinical and demographic data collection. Ethical approval was obtained for both studies, and informed consent was collected from all participants. While both studies are longitudinal in design, only the baseline visit data, meaning the first available observation per participant, were used in this study.

All clinical and demographic features, including oral health variables, were extracted from each participant's first examination. This resulted in a cross-sectional dataset suitable for ML analysis. The final sample included 693 baseline observations (350/693, 51% females and 343/693, 49% males) with an average age of 75 years. The sample was divided into 2 relatively balanced groups: one with MMSE scores of ≤26 and one with an MMSE score of 30. Observations with intermediate scores of 27‐29 were excluded to ensure distinct group separation. There was a total of 339/693 (49%) observations for individuals with ≤26 MMSE scores (165/339, 49% females and 174/339, 51% males) and 354/693 (51%) observations for the MMSE 30 score (185/354, 52% females and 169/354, 48% males). The dataset comprised 693 observations, each with 16 features (Table 1). The oral health features selected for inclusion were limited to those available in both datasets and supported by prior studies linking them to general health or cognitive decline. Examples include the Plaque Index (PI), which reflects hygiene maintenance; dry mouth, often associated with medication use and systemic conditions; and the number of teeth, which may serve as a proxy for long-term oral care and functional ability.

The listed features represent a combination of demographic, behavioral, and clinical oral health indicators obtained from baseline dental examinations. Probing pocket depth (PPD) measurements were categorized based on severity: values of 4 mm typically reflect a mild periodontal status, 5 mm indicate moderate depth, and ≥6 mm signify advanced periodontal disease. Variables such as PPD, PI, and bleeding on probing (BOP) were calculated as the percentage of affected surfaces out of the total examined. Self-reported variables, including dry mouth and hygiene tool use, were assessed through standardized questionnaires. Denture status was recorded separately for full and partial prostheses in both the maxillary and mandibular arches. These variables were selected due to their availability in both datasets and their clinical relevance to cognitive and systemic health in older adults.

MMSE scores are known to vary within individuals over time. Research indicates that changes of up to 3 points may occur without representing a clinically meaningful cognitive change, especially in older populations [28]. To reduce misclassification due to such variability, only individuals with MMSE scores of ≤26 or exactly 30 were included in the dataset. Based on this analogy, the MMSE ≤26 and the MMSE 30 score groups were designated and labeled as "1" and "0," respectively. No normalization, mean-centering, or outlier filtering was performed prior to model training. Tree-based models like RF and CB are scale-invariant, and for consistency, unscaled features were also used with SVM.

Table . List of features used for the study.

Parameter	Description	Index/Categories
Age	Participant age	• Number
Education	Level of education	• Elementary School • Secondary School • Higher education
PI[a]	Number of tooth surfaces in % with dental plaque of the total number of surfaces	• Percentage
PPD[b] 4mm	The number of PPD 4 mm in % of the total number of surfaces	• Percentage
Use of dental hygiene tools for approximal cleaning	How often do you use approximal dental hygiene tools?	• Rarely/never • Once a week • Daily • Several times daily
Gender	Gender	• Male, female
A feeling of dry mouth	Do you experience a sensation of dry mouth?	• Yes, often • Yes sometimes • No never
Number of teeth	Number of teeth	• Number
PPD 5mm	The number of PPD 5 mm in % of the total number of surfaces	• Percentage
Mirror test	Mirror test	• Glides easily • Sliding • Getting stuck
BOP[c]	The number of surfaces with BOP in % of the total number of surfaces.	• Percentage
PPD≥6mm	The number of PPD ≥ 6 mm in % of the total number of surfaces	• Percentage
Mandibular denture	Mandibular denture	• Yes, No

Classification Experiment

Several well-known classifiers, RF, CB, and SVM, were used for the classification experiment. The dataset was split into 2 subgroups: a training set comprising 80% of the data (554/693 samples) and a test set containing 20% (139/693 samples). To ensure an unbiased estimation of model performance and to reduce the risk of overfitting during hyperparameter tuning, nested cross-validation (nCV) was applied within the training data.

The parameter grid for hyperparameter tuning was defined as follows:

- For Random Forest:{'n_estimators': [50, 100, 200],'max_depth': [None, 10, 20], 'min_samples_split': [2,5,10]}
- For SVM: {'C': [0.1, 1, 10],'kernel': ['linear', 'rbf,' 'poly'], 'degree': [2, 3, 4]}
- For CatBoost:{'iterations': [100, 200, 300], 'learning_rate': [0.01, 0.1, 0.2], 'depth': [4, 6, 8], 'l2_leaf_reg': [1, 3, 5]}

nCV is particularly appropriate in ML pipelines that involve hyperparameter optimization or model selection. It separates the parameter tuning step from the performance evaluation step, which prevents information leakage between training and test data and avoids optimistically biased performance estimates. This methodological rigor is especially important in

XSL•FO
RenderX

moderate-sized datasets where variance due to overfitting can significantly affect the results [29-31].

Model performance was assessed using a 10 × 10 nCV framework. The outer 10-fold loop was used to evaluate generalization performance, while the inner loop was used solely for hyperparameter optimization. This design avoids information leakage and produces unbiased performance estimates, allowing for a robust assessment of model performance under varying fold configurations and providing a stable basis for comparison across classifiers.

Performance Evaluation

To evaluate the performance of each ML classifier, multiple metrics were used, including accuracy, precision, recall, and F_1-score. To enhance clinical interpretability, the following definitions were used: true positives (TP) represent correctly identified positive cases; false positives (FPs) refer to negative cases incorrectly classified as positive; true negatives (TN) are correctly identified negative cases; and false negatives (FN) denote positive cases that were incorrectly classified as negative. Box plots, which illustrate the distribution of accuracy scores for the respective models and additional statistical information, were used for the data visualization. Subsequently, the classifier with the highest scores was further analyzed for its feature importance. The examination of the most essential features relied on Shapley Additive Explanation (SHAP) summary plots, providing visualizations of the influence of parameter groups on the output, organized by their importance. This importance is based on SHAP values, offering insights into features' effects on the ML model's decision-making process [32].

Experimental Setup

The experiment was conducted on a Dell Precision 7920 MT desktop, and all models were implemented using Python (version 3.9; Python Software Foundation) with Scikit-learn (version 1.2.2) and CB (version 1.2). Visualization was supported via Seaborn (version 0.12.2).

Results

Experimental Results

The dataset, comprising 693 observations, each containing 16 features in its feature vector, underwent experimentation using 3 different ML models to discriminate between MMSE ≤26 and MMSE 30 score groups. Figure 1 displays the accuracy of each model for all nCV combinations. The box plot analysis reveals that the CB model outperforms the RF and SVM models in accuracy. Specifically, the CB model achieves the highest median accuracy of 0.760, the highest mean accuracy of 0.752, and the highest maximum accuracy of 0.810. Additionally, the CB model shows the smallest variability in accuracy scores, as evidenced by the lowest IQR of 0.020. The RF model demonstrates a solid performance with a median and mean accuracy of 0.740, but it does not reach the same maximum accuracy as the CB model, peaking at 0.780. The RF model also has a moderate IQR of 0.030, indicating some variability in its performance. While still competitive, the SVM model shows the lowest median accuracy of 0.730 and the lowest mean accuracy of 0.721 among the 3 models. It also has a maximum accuracy of 0.760, which is lower than both RF and CB. The IQR of 0.030 is comparable to that of RF, indicating a similar level of performance variability.

The performance of the 3 ML models (CB, RF, and SVM) was evaluated using accuracy, precision, recall, and F_1-score on both the training and test datasets. Table 2 summarizes these results. On the training set, RF achieved the highest scores across all metrics, followed closely by CB. However, on the test set, CB demonstrated the most balanced and generalizable performance, with an accuracy of 80.6%, precision of 77.4%, recall of 78.7%, and an F_1-score of 78.0%. In contrast, RF showed signs of overfitting, indicated by a decline in test precision and accuracy despite maintaining high recall. SVM yielded moderate but consistent results across both datasets. These results suggest that CB is better suited for generalization in this context, likely due to its regularization features. RF, while highly effective on the training set, may have captured dataset-specific patterns that did not generalize well. SVM demonstrated stable but lower overall performance.

Table 3 shows the confusion matrix results associated with all models. The performance of 3 ML models, CB, RF, and SVM, was evaluated on both training and test datasets in terms of TP, FP, TN, and FN. Rather than focusing on raw counts, the interpretation emphasizes overall performance patterns. CB maintained a strong balance between correctly identifying both positive and negative cases. RF achieved high recall but also produced more FPs on the test set, which may limit its clinical precision. SVM showed more balanced errors, though with generally lower performance.

The hyperparameters and nCV combinations associated with each and the best-performing model are as follows:

- CB: 3X3nCV, ('depth': 4, 'iterations': 200, 'l2_leaf_reg': 5, 'learning rate': 0.1).
- RF: 4X7nCV, ('max depth: 20, 'min samples split': 5, 'n estimators': 50).
- SVM: 8X5nCV, ('C': 10, 'degree': 3, 'kernel': 'poly').

Feature Importance

The SHAP summary plot in Figure 2 illustrates the impact of various features on the model's output. Each dot represents a Shapley value for a feature for an individual instance, and the color denotes the feature value, ranging from low (blue) to high (red). The SHAP summary plot reveals that age, PI, dental hygiene devices, education, a feeling of dry mouth, and PPD are critical in influencing the model's predictions. The balance of these features, along with others like BOP and the number of teeth, determines the overall outcome predicted by the model. These findings indicate that age, PI, and PPD are significant predictors, with older age and higher PI correlating with an increased likelihood of having an MMSE score ≤26. Education appears to inversely affect the prediction, suggesting that higher education levels may be associated with better oral health practices. The number of teeth shows an inverse relationship, where having more teeth is linked to a lower risk of MMSE ≤26. Additionally, the presence of dental prosthetics and feelings of dry mouth positively influence the prediction, indicating a higher likelihood of MMSE ≤26. Gender shows a minimal impact, with the female gender slightly reducing the predicted MMSE ≤26 risk.

Figure 2. SHAP summary plot for model features. The plot illustrates the impact of each feature on the model's output. BOP: bleeding on probing; PI: Plaque Index; PPD: probing pocket depth; SHAP: Shapley Additive Explanation.

Discussion

Principal Findings

This study explored the potential of using ML technologies using oral health and demographic examination data to predict the probability of having MMSE scores of 30 or ≤26 in Swedish individuals older than 60 years. The main findings of the study were that all CB, RF, and SVM classifiers achieved high classification accuracies, but the CB classifier outperformed both RF and SVM classifiers with an average accuracy of 80.6%. Acceptable accuracy levels vary across studies [33-35], but it can be argued that all CB, RF, and SVM classifiers demonstrate strong performance, each exceeding 72% accuracy. This indicates that with specific nCV combinations and hyperparameter tuning, all classifiers can indicate whether the individual belongs to ≤26 MMSE scores or higher MMSE score (score=30) groups with varying grades of accuracy [36]. These findings hold the potential to identify individuals in need of support and treatment, benefiting not only them but also health care professionals and systems by optimizing treatment with fewer resources.

The performance evaluation based on the training and test set results is a common indicator of finding the unexpected accuracy relation of ML models [37]. The evaluation of the models reveals distinct differences in performance and generalization capabilities. On the training set, RF showed a well-balanced performance with strong metrics across the board, reflected in its Precision, Recall, Accuracy, and F_1-score and its TP, TN, FP, and FN counts. The classifier CB performs better in the test set regarding the average performance metric, and SVM lagged significantly behind in both training and test sets. However, the general performance evaluation might differ from a clinical point of view when the higher recall is considered a more important parameter. In that case, RF with the highest TP values becomes the best classifier. FP could lead to unnecessary clinical evaluations or interventions, while FN could result in missed diagnoses, delaying treatment for cognitive impairment. When the goal of ML models is early detection and ensuring no cases of cognitive impairment are missed, minimizing FN is essential [38]. However, if the focus of these models is on reducing unnecessary interventions and managing health care resources efficiently, minimizing FP should be prioritized [39]. From a generalizability perspective, SVM shows the lowest performance drop between training and test, and CB indicates a second strong generalizability with a low-performance drop compared with the training and test set results. On the other hand, RF showed a decline in performance between the training and test sets. This suggests that SVM and CB are more suitable than RF for handling new, unseen data. Hyperparameter tuning was conducted through nCV using model-specific grids. For RF, parameters included the number of estimators, tree depth, and minimum samples per split. Despite this rigorous tuning, RF exhibited overfitting, reflected by its high training accuracy and reduced performance on the test set. This behavior suggests that RF, with its tendency to create deep and complex trees, may have captured noise or sample-specific patterns. In contrast, CB's built-in regularization mechanisms, including L2-leaf regularization, contributed to more stable generalization. To address overfitting in future implementations, simpler models or additional regularization techniques such as pruning, reduced tree depth, or feature selection could be explored.

Oral health and demographic factors vary across different regions globally, and this method's applicability is specific to Swedish conditions, which poses a limitation. However, a study from Taiwan [24], using oral health biomarkers and CB for cognitive decline classification predictions, yielded results akin to those presented in this study. In their model [24], crucial features included daily social interaction, oral diadochokinesis, PI, saliva protein, and age. In contrast, this study benefits from a more extensive and balanced dataset, presenting absolute average values rather than weighted results. Additionally, to mitigate overfitting risks, nCV was used to train ML classifiers across various k-fold combinations to mitigate overfitting risks in ML classifiers across various k-fold combinations. Furthermore, these studies collectively highlight oral health and demographic factors that vary across different regions globally, and this method's applicability is specific to Swedish conditions. Additionally, while the use of 10 × 10 nCV ensures an unbiased estimate of generalization performance within the dataset, the importance of validating models on external data is well recognized. Internal validation alone cannot capture the variability introduced by different clinical environments, geographic regions, or data acquisition protocols. External validation on independent cohorts or through integration into routine dental examinations would be required to evaluate robustness. Such efforts would help assess the model's applicability under real-world variability and determine its readiness for broader clinical use.

The implications drawn from the SHAP summary plot underscore critical insights into feature relevance concerning cognitive health assessments via ML models. The clear demarcation between the groups of MMSE scores ≤26 and 30 across influential variables like age suggests that such demographic factors hold substantial weight in predictive analytics. Notably, age emerges as a pivotal factor, with higher age correlating strongly with lower cognitive health scores. This correlation is also highlighted in other studies that consistently demonstrated that MMSE scores tend to be lower for older individuals and decline over time [40]. The SHAP summary plot highlights age, PI, and use of dental hygiene tools as the most influential predictors of MMSE classification. Older age and higher plaque levels were associated with increased likelihood of MMSE ≤26, suggesting that both biological aging and reduced oral hygiene maintenance contribute to cognitive risk [20,41]. In particular, individuals with lower use of interdental hygiene tools exhibited stronger SHAP effects, indicating a potential interaction between age-related decline in motor or cognitive function and oral hygiene behaviors. This aligns with findings that individuals with cognitive impairment often experience challenges in maintaining oral hygiene due to reduced executive functioning and manual dexterity [7,42]. Features such as dry mouth and education also showed moderate predictive strength, consistent with their known associations with polypharmacy and cognitive reserve, respectively [41]. In contrast, features like BOP, gender, and presence of dentures showed minimal SHAP influence, suggesting weaker or less

XSL•FO
RenderX

consistent relationships within this sample. These findings suggest that age-related decline may act synergistically with deteriorating oral hygiene habits, offering further evidence for behaviorally anchored early risk screening in clinical practice.

Given that MCI resides on the border between healthy aging and neurocognitive illness, individuals with MCI may fluctuate between MMSE scores ≤26 and 30 [43]. About 50% of individuals with MCI receive a neurocognitive diagnosis within 3 years, with a 2-step decrease in MMSE score within 12 months indicating disease onset. Recommended thresholds for the MMSE can be expressed as 0 - 22, indicating dementia; 23 - 26, MCI [44]; and 27 - 30, indicating normal cognitive function [7,42]. In this study, the threshold MMSE≤26 was used. This criterion was adopted in the study, resulting in the exclusion of MMSE scores of 27, 28, and 29 from calculations. This limit has been chosen as 2 different studies have found that changes of 2 to 3 points indicate reliable changes in the MMSE test value at the 90% confidence level [28,45]. However, it is important to note that this regulatory threshold may limit the study, potentially leading to missed indications. The exclusion of MMSE scores of 27, 28, and 29 may also affect generalizability. One of the strengths of this study is the use of ML as the methodology. Recent studies in ML have shown significant promise in predicting various disorders, such as dementia [46,47], chronic obstructive pulmonary disease [48], cancer [49], and Parkinson disease [50]. The used tree-based models, CB and RF, and the distance-based model SVM allow comparability in the case of possible effects of outliers in the dataset, where the tree-based models are known to be more resistant to imbalance in the dataset than the distance-based models [51-53]. Despite this study seeking a balanced data set, there is a heterogeneity regarding ages represented in the dataset where some ages might be overrepresented, which can be seen as a limitation in this study. Another limitation is the low number of participants and the recruitment that took place in a small county in southern Sweden, which is an obstacle to making conclusions from a broader perspective that represents more variety in demographic and regional differences. However, in relation to previous research, this study includes a larger number of participants, thereby increasing the generalizability of the findings. Another notable difference concerns the threshold used to distinguish between the MMSE ≤26 and MMSE 30 groups; in this study, a higher threshold was applied. Since the dataset of 693 observations is relatively small and may not be representative of a larger population, it may affect generalizability. In addition, even if the groups are relatively balanced, small differences in group size (339/693, 49% vs 354/693, 51%) can affect model performance and bias. These limitations can be overcome by expanding the data set by including divergent and wider participants' data from larger geographical areas in upcoming studies. Future research may also address the performance of capturing changes over time for monitoring purposes, highlighting the need for longitudinal studies. Although the findings demonstrate strong internal performance, several practical challenges constrain the model's readiness for clinical use. These include variability in oral health assessment protocols, limited interpretability of model outputs for nontechnical users, and the absence of integration pathways with existing clinical information systems. SHAP plots provide valuable transparency but may need adaptation for clinician-facing use. Implementation would require standardization of input data, compatibility with electronic health records, and interdisciplinary development efforts. Further investigation is needed to evaluate clinical usability and workflow alignment.

Other limitations of the study are that only baseline data were used from longitudinal studies, meaning that potential changes over time may be missed. Only 16 parameters were selected, which means that other important parameters that could affect the results may have been omitted. The oral health features used in the models were selected based on their consistent availability across both datasets and their previously reported clinical relevance to cognitive function. These features, such as PI, number of teeth, and dry mouth, may reflect both localized oral conditions and systemic factors, including frailty, polypharmacy, and reduced self-care capacity. Such conditions have been associated with cognitive impairment in older adults. Other potentially relevant features, like microbial profiles or periodontal attachment levels, were not included due to data limitations, but future work could incorporate these variables in extended datasets.

Conclusion

This study suggests that oral health parameters, demographic data, and ML techniques offer a potential tool for screening MMSE scores for individuals aged 60 years and older. The data used as inputs for ML classifiers contains sufficient information to differentiate between MMSE scores ≤26 and 30.

It is important to include both demographic and oral health-related factors in predictive models. Despite some limitations, the study offers valuable insights for future research and potential clinical applications. To ensure the robustness and generalizability of the model, further external validation and adaptation to different clinical settings are required.

Abstract

Background: Cardiovascular and cerebrovascular diseases significantly contribute to global mortality and disability. The shift to outpatient postoperative care, accelerated by the COVID-19 pandemic, emphasizes the need for effective management of postoperative outcomes. The high rates of cardiovascular and cerebrovascular diseases in Korea necessitate focused transitional care during patient discharge periods. However, limited research exists on the postoperative experiences of discharged patients, underscoring the necessity of establishing evidence-based services to optimize transitional care.

Objective: The objective of this paper was to analyze the emotional experiences of patients who underwent cardiovascular and cerebrovascular surgeries using data from Naver, a major South Korean web portal.

Methods: Posts were collected using specific keywords and processed with the Korean Bidirectional Encoder Representations from Transformers (KoBERT) model based on Transformer, which classified sentiments into positive, neutral, and negative categories. Model performance was validated according to precision, recall, F_1-score, and support. Sentiment analysis was conducted within the Transitional Care Model (TCM) framework, divided into 5 domains: health status, care resources, care demand, interaction, and mental state.

Results: The KoBERT model demonstrated high classification performance, achieving a precision of 96%, recall of 94%, and an F_1-score of 94%. Sentiment analysis revealed that compared with cardiovascular surgery patients, cerebrovascular surgery patients experienced higher negative emotions regarding health status, whereas cardiovascular surgery patients expressed more negative sentiments in care demands.

Conclusions: Different patient groups experience distinct emotional and practical challenges postdischarge. Particularly, keywords within the TCM framework highlight that cerebrovascular surgery patients require robust rehabilitation and caregiver support, whereas cardiovascular surgery patients need better cost management. These findings underscore the importance of personalized transitional care strategies tailored for cardiovascular and cerebrovascular diseases. The insights derived from this study can guide health care policymakers in designing more targeted and patient-centered interventions to improve postdischarge care and patient-centered transitional care, ensuring continuous and effective postoperative management.

Introduction

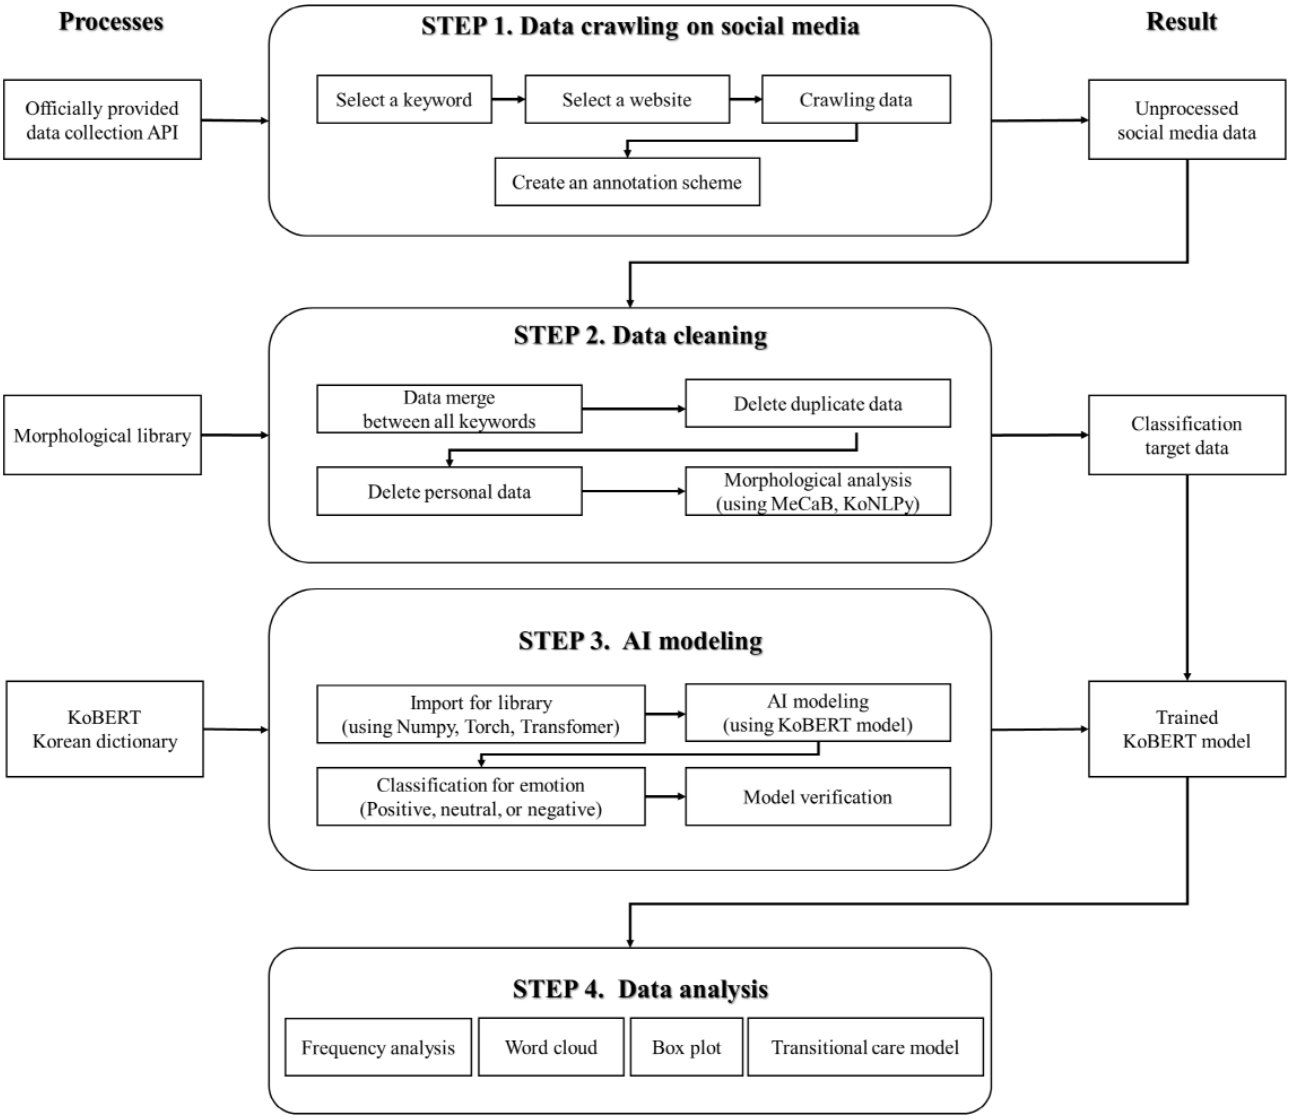
Cardiovascular and cerebrovascular diseases are among the leading causes of mortality worldwide, causing 17.5 million deaths annually. Ischemic heart disease and stroke rank as the second and fourth leading contributors to the global disease burden, respectively. Furthermore, the disability-adjusted life years (ie, years lost due to premature death and years lived with disability) related to ischemic heart disease and stroke are projected to increase progressively [1,2]. In addition, with increases in life expectancy owing to advancements in medical technology and improved health care access, the number of older patients undergoing cardiac and neurological surgeries also continues to increase [3,4]. Although postoperative prognostic monitoring has traditionally been conducted in hospital settings, the COVID-19 pandemic has accelerated a shift toward outpatient treatment for prognosis, facilitated by advancements in surgical techniques and improved success rates [5]. This transition offers several benefits, including reduced medical costs and a quicker return to normal life. However, it also underscores the need for further research on the management of postoperative outcomes in outpatient settings. There have been reports of patients experiencing deterioration or death owing to inadequate management or reduced continuity of care following a transition from inpatient to outpatient treatment [6,7]. Considering these concerns, patients often experience anxiety and uncertainty regarding the appropriateness of postoperative discharge decisions during transitional periods during transitional periods.

These transitional periods refer to the change among health care providers, medical staff, or the health service environment. The period during which patients are discharged from hospitals to their homes or other facilities is critical. During this time, patients face a higher risk of medical complications, management failures, and adverse drug reactions because of potential interruptions in treatment, care, and information flow [8-10]. “Transitional care services” refer to interventions provided to high-risk patients with multiple vulnerabilities to mitigate risk during critical transition periods and ensure continuous care, enabling them to effectively manage and recover from illnesses [8]. This extends beyond medical management and focuses on providing services tailored to the unique lives and needs of patients with specific conditions.

Numerous studies have demonstrated the health-promoting and economic benefits of transitional care services [11]. The Transitional Care Model (TCM) comprises several core components, namely, screening, staffing, relationship maintenance, patient and family caregiver engagement, risk and symptom assessment and management, education and self-management promotion, collaboration, continuity promotion, and coordination fostering [12]. Extensive research shows that TCM provides a validated structure for analyzing postdischarge challenges by integrating components such as health status monitoring, care resource coordination, patient-provider interaction, and mental health support [13]. Many Organisation for Economic Cooperation and Development (OECD) countries, including the United States with its Hospital Readmission Reduction Program, incentivize hospitals to provide transitional care services to reduce readmissions. However, in Korea, transitional care services remain at the pilot stage and have not yet been implemented for the general public. By analyzing the emotional experiences encountered during the transitional period of patients who have undergone hospitalization and surgery for cardiovascular and cerebrovascular diseases, valuable insights may be gained regarding the need for transitional care services in a patient-centered care design and further improvements in the care system.

Recently, artificial intelligence (AI)–driven sentiment analysis has enhanced personalized health care and improved postoperative care. Through sentiment analysis using large language models (LLMs), patient emotions extracted from clinical records and nursing diaries have provided insights into emotional well-being and its impact on recovery from cardiovascular disease [14]. In addition, LLMs have been used to assist health care providers in developing more patient-centered treatment strategies by identifying sentiment-based patterns in medical documentation [15]. The Bidirectional Encoder Representations from Transformers (BERT) model, introduced in 2018, has shown outstanding capabilities in natural language processing and has been applied to various emotional analyses [16]. This has led to a growing body of research that uses the BERT model for emotional analysis in the health care sector. South Korea is among the most rapidly advancing countries in information technology within the OECD, boasting exceptionally high rates of smartphone adoption and social media engagement [17]. Particularly, patients who have undergone brain or cardiac surgery often share their postoperative progress, physical condition, and psychological well-being with fellow patients who have undergone similar procedures. With South Korea’s advanced digital infrastructure and high levels of internet use, an increasing number of discharged patients share status updates through online support groups or online communities. This information is continuously accumulated as unstructured data on various websites, and there is a growing trend of analyzing these posts to study patients’ emotional states and experiences [18]. However, existing research on the postoperative experiences of patients undergoing cardiovascular and cerebrovascular disease surgery remains limited, leading to a lack of empirical evidence necessary for developing effective transitional care strategies. In particular, comprehensive investigations into the challenges and needs of patients during their recovery period are scarce, emphasizing the urgent need for evidence-based, tailored support services. The objectives of this study were as follows: (1) to analyze the emotional states of patients who have undergone cerebrovascular and cardiovascular surgeries, (2) to categorize these emotional states based on TCM, (3) to identify scores and keywords in each field related to the patients, and (4) to provide policy recommendations for the management of surgical patients based on these findings. Toward this goal, the Korean Bidirectional Encoder Representations from Transformers (KoBERT) model was applied for sentiment analysis of postdischarge cardiovascular and cerebrovascular surgery patients. Data were integrated with the TCM framework to categorize patient emotions across 5 key domains, identify disease-specific

XSL•FO
RenderX



emotional trends, and provide practical insights for personalized transitional care and health care policy improvements.

Methods

Study Design

This study investigated the emotional experiences of patients who underwent cerebrovascular or cardiovascular surgery and were subsequently discharged from the hospital. The research methodology used a four-step process: (1) data crawling, (2) data cleaning, (3) AI modeling, and (4) data analysis. Figure 1 shows a schematic of the workflow.

Figure 1. Research framework. API: application programming interface; MeCaB: yet another part-of-speech and morphological analyzer; KoNLPy: Korean natural language processing in Python; AI: artificial intelligence; KoBERT: Korean Bidirectional Encoder Representations from Transformers.

Ethical Considerations

Institutional review board approval was not sought, as the study did not involve human subjects. All websites were publicly accessible, and only archived versions were reviewed. No identifiable private information was accessed or recorded.

Data Collection

This study used data collected from Naver [19], South Korea's premier search engine, and web portals. Naver offers a comprehensive suite of services, including search engines, portals, blogging platforms, discussion forums, and e-commerce solutions, and has the largest user base in Korea. As of November 2024, Naver's search engine usage rate in South Korea stands at 77.4%, significantly higher than that of Google, the second most used search engine, at 34.1%. In addition, Naver grants crawling application programming interface (API) access exclusively to researchers, whereas other search engines and social media platforms have restrictions on API access. As such, only Naver was included in this study [20]. In addition, it was selected for this study because of its diverse user demographics, particularly the broad age range of the blog contributors. Data were collected using Naver's API in Python (Python Software Foundation), targeting posts published over the past decade. The keywords used for data crawling included "stroke," "cerebral hemorrhage," "cerebrovascular," "cardiovascular

XSL•FO
RenderX

disease," "surgery review," "inpatient review," and "discharge review," resulting in a total of 10 distinct subsets. Each subset was limited to a maximum of 1000 posts, yielding a comprehensive corpus of 9393 blog posts for analysis (see Table 1).

Table . Keywords for crawling data.

Patient group and subset		Posts collected (N=9393), n (%)	Crawling keywords	
			Keyword 1	Keyword 2
Cerebrovascular disease				
	1	872 (9.28)	Surgery review	Stroke
	2	990 (10.53)	Surgery review	Cerebral hemorrhage
	3	951 (10.12)	Surgery review	Cerebrovascular
	4	850 (9.05)	Inpatient review	Stroke
	5	970 (10.33)	Inpatient review	Cerebral hemorrhage
	6	930 (9.90)	Discharge review	Stroke
	7	960 (10.22)	Discharge review	Cerebral hemorrhage
	8	910 (9.69)	Discharge review	Cerebrovascular
Cardiovascular disease				
	9	1000 (10.65)	Surgery review	Cardiovascular
	10	960 (10.22)	Discharge review	Cardiovascular

Data Cleaning

The collected data were preprocessed for analysis. All posts were initially consolidated into a single dataset (data merging), and then 787 duplicate posts were subsequently eliminated along with posts related to animals. Redundant content was removed, and personal information (eg, names, phone numbers, and addresses) was redacted. Preprocessing was conducted using a MeCab morphological analyzer from the Korean Natural Language Processing in Python library. MeCab was selected for its high accuracy, efficient part-of-speech recognition, high processing speed, multilingual support, and ease of installation. From the 9393 posts, 575,505 words were extracted for analysis.

Data Training

For the sentiment analysis of crawled posts, this study used the KoBERT model. Briefly, KoBERT is a deep learning model for Korean natural language processing and is based on Google's BERT model. It is widely used in applications such as chatbots, search engines, and machine translations. In this study, the model was trained using the Korean Sentiment Dictionary from the Emotional Dialogue Corpus. This corpus is a comprehensive natural-language sentiment dictionary comprising 15,700 sentences from 1500 Korean speakers and 270,000 sentences encompassing 60 detailed sentences [21]. The Emotional Dialogue Corpus served as a sentiment dictionary for training the KoBERT model. For model training, the dataset was split into 216,000 samples (80%) for the training set and 54,000 samples (20%) for the test set (see Table 2).

The KoBERT model was trained to classify the sentiment of the data (posts) into 3 sentiment score categories: "positive," "neutral," and "negative." Relevant documentation is available on GitHub [22]. We used KoBERT as the base model for sentiment classification. The input text was first tokenized using the MeCab morphological analyzer with a maximum sequence length of 64 tokens. The tokenized input was then processed through the KoBERT transformer encoder, followed by a fully connected classification layer to predict the sentiment as positive, neutral, or negative. For training, we used the Adam optimizer with a learning rate of 5×10^{-5}, a warmup ratio of 0.1, and gradient clipping with a max norm of 1 to stabilize learning. The model was trained for 3 epochs with a batch size of 64. To evaluate computational performance, the training and inference times were measured. The total training time per epoch was approximately 4.15 minutes, while the inference time per batch was approximately 233 ms. A summary table of hyperparameters and a diagram illustrating the model architecture are included for clarity.

Table . Model training and analysis parameters.

Parameter	Value	Description
Model	KoBERT[a]	Korean Bidirectional Encoder Representations from Transformers–based sentiment classification model.
Pretrained dataset	Korean Sentiment Corpus	Used for initial model training.
Optimizer	Adam	Optimizer for gradient descent.
Learning rate	5×10^{-5}	Initial learning rate for model training.
Log_interval	200	Gradient clipping value.
Batch size, n	64	Number of samples per batch
Epochs, n	3	Number of training iterations.
Max_len, n	64	Maximum token length per input text.
Max_Grad_norm	1	Logging interval during training.
Train split, n (%)	216,000 (80)	Rate of train set.
Test split, n (%)	54,000 (20)	Rate of test set.
Evaluation metrics	Precision, recall, and F_1-score	Performance measures for sentiment classification.

[a]KoBERT: Korean Bidirectional Encoder Representations from Transformers.

Data Validation

The performance of the AI deep learning model was assessed according to 4 key metrics: precision, recall, F_1-score, and support. The operational definitions of these metrics are provided in the subsections below.

Precision

Precision indicated the percentage of actual positive samples among cases predicted to be positive by the machine learning (ML) model. Particularly, it referred to the percentage of the actual sentiment classes relative to the predicted sentiment classes. Precision was calculated as follows:

Precision (%)=(tptp+fp)×100

Recall

Recall showed the percentage of sentiment classes predicted by the ML models relative to the actual sentiment classes. Specifically, it is the percentage predicted to show the risk group among the actual sentiment classes. Recall was calculated as follows:

Recall (%)=(tptp+fn)×100

F_1-score

The F_1-score represented the harmonic mean of precision and recall. The mathematical formula was as follows:

F1score%=2tp2tp+fp+fn×100

Support

Support represented the number of occurrences of each class in an actual dataset. It was not included in the calculation of any score but provided additional information about the distribution of classes in the dataset. Support is often used to identify class imbalance.

Data Analysis

Sentiment analysis was performed based on the data collected using the KoBERT model, and a more detailed analysis was conducted using the TCM framework divided into 5 domains. The TCM framework was used as the analytical framework and was restructured from the patient's perspective into the following 5 domains: health status, care resources, care demand, interaction (with medical staff), and mental state. Detailed information is provided in Multimedia Appendix 1. A detailed analysis of the following 4 focus areas was conducted. First, word clouds were generated to analyze keywords related to the emotions of patients discharged after heart and brain surgery. Second, the postdischarge sentiment scores (calculated as percentages) of the patients who underwent cardiovascular and cerebrovascular surgeries were classified into 3 score categories: positive, neutral, or negative. Each category is presented with its minimum, maximum, 95% CI, median, mean, and variance. Third, patient distribution according to the 5 domains of patient-centered TCM was identified. Finally, the "positive" score category for the emotional state was presented as 5 mean scores (%) based on the TCM framework and presented as box plots. These plots displayed the frequency, quartiles, and minimum and maximum values. All analyses were conducted using GraphPad Prism 10.2.2.

Results

Model Verification

The AI KoBERT model used in this study was trained using the Korean Sentiment Dictionary derived from the Emotional Dialogue Corpus. The trained model achieved satisfactory performance. The precision, recall, and F_1-scores exceeded 0.8, indicating a high level of accuracy and reliability in sentiment classification (see Table 3).

XSL•FO
RenderX

Table . Korean Bidirectional Encoder Representations from Transformers (KoBERT) model verification.

Class	Precision	Recall	F_1-score	Support, n
Positive	0.96	0.89	0.92	1217
Neutral	0.93	0.93	0.93	318
Negative	0.98	0.99	0.98	6054
Average	0.96	0.94	0.94	2529

Word Cloud

Data pertaining to cerebrovascular and cardiovascular surgeries were visualized and analyzed using word clouds (Multimedia Appendix 2). For cerebrovascular surgery patients, the prominent keywords were “surgery,” “hospital,” “test,” “receive,” and “symptom.” For cardiovascular surgery patients, the key terms that emerged were “surgery,” “hospital,” “receive,” “eat,” “admission,” and “symptom.”

Sentiment Scores by Patient Type

The patients’ emotional states were categorized as positive, neutral, or negative, and their respective distributions were analyzed. The results revealed a lower proportion of patients with “neutral” emotional state among cerebrovascular surgery patients than among cardiovascular surgery patients (62,896/84,100,74.8% vs 12,456/16,000, 77.9%). Conversely, the proportion of patients with “positive” (16,839/84,100, 20.0% vs 3072/16,000, 19.2%) and “negative” (4364/84,100, 5.2% vs 471/16,000, 2.9%) emotional states was higher among cerebrovascular surgery patients than their cardiovascular surgery counterparts (see Table 4).

Table . Rates of emotions by patient type.

Patient type and emotional state		Min, %	Max, %	Mean (SD), %	Variance	Range
Total						
	Positive	0	68.8	19.9 (11)	121.0	68.8
	Neutral	0	36.4	4.8 (4.9)	23.9	36.4
	Negative	25	100	75.3 (12)	143.9	75.0
Cerebrovascular						
	Positive	0	68.8	20 (11.2)	126.3	68.8
	Neutral	25	100	74.8 (12.3)	150.7	75.0
	Negative	0	36.4	5.2 (5)	25.2	36.4
Cardiovascular						
	Positive	0	53.3	19.2 (9.7)	93.3	53.3
	Neutral	40	100	77.9 (10)	100.8	60.0
	Negative	0	24	2.9 (3.6)	13.3	24.0

Keyword Analysis Related to the Transitional Care Model

We analyzed 575,505 words from 9393 posts. The data were classified into 5 domains within the TCM framework and restructured based on the patient’s perspective (see Table 5). For cerebrovascular surgery patients, the top 3 keywords in each domain were as follows: (1) “health status:” sick (n=1860), symptom (n=1819), and sleep disturbance (n=881); (2) “care resources:” mom (n=1792), transfer (n=1774), and caregiver (n=890); (3) “care demand:” rehab (n=1323), postcare (n=689), and check (n=647); (4) “interaction:” hospital (n=5623), test (n=4215), and therapy (n=3117); and (5) “mental state:” good (n=2406), confirm (n=828), and tough (n=716). For cardiovascular surgery patients, the top 3 keywords in each domain were as follows: (1) “health status:” ache (n=410), symptom (n=297), and sick (n=294); (2) “care resources:” counseling (n=205), visit (n=125), and cost (n=104); (3) “care demand:” medication (n=193), preparation (n=108), and check (n=108); (4) “interaction:” hospital (n=898), procedure (n=321), and doctor (n=223); and (5) “mental state:” void (n=625), good (n=410), and confirm (n=313).

Sentiment Scores by Patient Type

Figure 2 shows the box plots of the distribution of the sentiment scores (%) for the 5 domains within the TCM framework (health status, care resources, care demands, patient-provider interactions, and mental state).

Compared with cardiovascular surgery patients, cerebrovascular surgery patients demonstrated higher mean postdischarge positive sentiment scores in 3 domains: care resources (3,765/18,600, 20.2% vs 292/1600, 18.3%), care demand (4465/22,100, 20.2% vs 1280/7200, 17.7%), and interaction (2107/10,100, 20.8% vs 575/2900, 19.8%). Conversely, cardiovascular surgery patients exhibited higher mean postdischarge positive sentiment scores in 2 domains: health status (267/1400, 19.2% vs 4467/23,300, 19.1%) and mental state (674/3000, 22.4% vs 2034/10,000, 20.3%). With respect to negative sentiment scores, there was a higher level of dissatisfaction with their health status among patients with cerebrovascular disease than among patients with cardiovascular disease (17,594/23,300, 75.5% vs 2199/3000, 73.3%). Meanwhile, compared with their cerebrovascular counterparts, patients with cardiovascular disease expressed more negative emotions regarding care resources (2198/2900, 75.8% vs 13,898/18,600, 74.7%), care demand (5817/7200, 80.7% vs 16,551/22,100, 74.8%), interactions (1236/1600, 77.3% vs 7467/10,100, 73.9%), and mental state (2316/3000, 77.2% vs 7384/10,000, 73.8%).

Discussion

Principal Findings

This study addresses the critical gap in understanding the postoperative experiences of patients who have undergone cardiovascular and cerebrovascular disease surgery. The sentiment analysis revealed significant challenges faced by patients during their recovery, underscoring the need for evidence-based, tailored support services to enhance transitional care strategies. The KoBERT model used for sentiment analysis demonstrated high performance, achieving a precision of 0.96, recall of 0.94, and F_1-score of 0.94.

These results are consistent with those of previous studies that used KoBERT. For instance, a BERT model trained on clinical notes from Korean doctors achieved a precision of 0.99, recall of 0.97, and F_1-score of 0.93. Another KoBERT model trained on sentiments from Korean Internet posts showed precision, recall, and F_1-scores of 0.86 across all metrics. Previous studies have evaluated models using mean squared error, root mean squared error, mean absolute error, and R^2. However, this study focused on classification rather than continuous variables, and thus, these metrics were not used [23].

The performance level of the KoBERT model used in this study is closely similar with that of existing models [24,25], validating its effectiveness in classifying sentiments as positive, neutral, or negative. Furthermore, the model's capability to identify emotional trends in real time during consultations presents opportunities for its expanded use in relevant research fields. The analysis revealed that the proportion of patients who experienced more negative emotions was higher among those who had underwent cerebrovascular surgery (5.2%) than among those who had undergone cardiovascular surgery (2.9%). This finding is consistent with previous research demonstrating that patients with cerebrovascular disease tend to experience higher levels of anxiety and worry relative to those with other diseases [26]. In a study involving 3200 surgical patients, 40.5% experienced negative postoperative emotions, such as depression, anxiety, and fear. The lower levels of negative emotions observed in our study may be attributed to various factors, including advanced medical technology in Korea leading to high surgical success rates, improved patient management owing to high medical accessibility, and a relatively low financial burden owing to comprehensive health insurance coverage [27-29]. However, it is important to note that the data in this study were obtained by crawling internet posts made by patients after surgery. That is, the patients had access to the internet, potentially indicating a lesser severity of illness,

XSL•FO
RenderX

younger age, and relatively good overall physical health. Furthermore, the lower prevalence of negative emotions among cardiovascular surgery patients than among cerebrovascular surgery patients may be explained by the nature of cardiovascular disease treatment in Korea. Most hospitalizations and surgeries related to cardiovascular issues involve ischemic heart disease, which is often treated with percutaneous coronary intervention rather than major surgery. This less invasive approach typically leads to quicker discharge and a lower risk of long-term disability in cardiovascular diseases than in cerebrovascular diseases [30].

TCM is designed to provide continuous care for patients transitioning postoperatively from the hospital to home or another care facility. This study analyzed keywords and sentiment scores (calculated as percentages) across 5 TCM domains classified from the patient's perspective: health status, care resources, care demand, interaction, and mental state. Across all conditions, keywords indicating physical pain and side effects, such as pain, sickness, and severe, were frequently mentioned in relation to health status. Regarding mental state, negative emotional keywords, such as tough, worry, and problems, were frequently mentioned. This highlights the impact of hospitalization and surgery on patients with severe conditions, such as cardiovascular and cerebrovascular diseases, as well as the need for related care. The interaction-related keywords mainly involved medical care and treatment, including hospitals, procedures, and doctors. This highlights the absence of elements crucial for transitional care services in the Korean health care setting, such as coordination, education, consultation, and explanations. Disease-specific differences were also observed, especially in the domains of care resources and demand, indicating that postdischarge care resources and needs varied according to disease type. For patients with cerebrovascular disease, the highlighted keywords were mother, caregiver, transfer, ambulance (care resources), rehabilitation, and postcare (care demand). This indicated a high demand for postsurgery or postdischarge rehabilitation and related transfers. In contrast, for patients with cardiovascular diseases, the keywords were insurance and cost (care resources) and medication and workout (care demand), indicating a high demand for cost-related items. These disease-specific differences in TCM domain keywords reflect varying patient needs during transition periods. This information is crucial and should be incorporated when modeling patient-centered transitional care services.

When comparing the sentiment scores of patient-centered TCM domains for cardiovascular and cerebrovascular diseases, the positive score categories for health status were similar, accounting for 19.1% and 19.2% of the total scores, respectively. However, in the domains of care resources, care demand, and interaction, the cerebrovascular surgery patients exhibited higher positive sentiment scores than did the cardiovascular surgery patients. This disparity may be due to the fact that cerebrovascular diseases often involve longer postsurgery or postdischarge processes and are more likely to involve additional care services such as rehabilitation, leading to more positive keywords being mentioned during the recovery process. Regarding mental state, cardiovascular surgery patients showed a higher positive score than did cerebrovascular surgery patients (22.4% vs 20.3%). This difference may be attributed to the typically shorter hospital stay of cardiovascular surgery patients and the fact that their immediate problems are often resolved through procedures. These factors can potentially contribute to a more positive average sentiment score among cardiovascular surgery patients than among cerebrovascular surgery patients.

For cerebrovascular diseases, the positive sentiment score category related to interaction (20.8%) was notably higher than that related to other areas, with health status scoring the lowest (19.1%). In contrast, for cardiovascular diseases, the positive sentiment score category was the highest for mental state (22.4%), whereas it was the lowest for care demand (17.7%). These findings may be attributed to the nature of cerebrovascular diseases in which prolonged interactions with medical staff, rehabilitation specialists, and caregivers are crucial during the transition period. Conversely, for cardiovascular diseases, despite the recognized importance of postdischarge cardiac rehabilitation, it appears to be underdeveloped, as reflected by lower scores. This finding is consistent with previous findings showing that only 44.2% of stroke patients discharged from university hospitals continue outpatient rehabilitation and that only 17% of cardiovascular surgery patients discharged from regional cardiovascular centers pursue outpatient cardiac rehabilitation [31,32]. This analysis of sentiment scores for each disease type suggests which components of transitional care are lacking and require improvement, as determined based on patients' reported experiences that highlight positive or negative sentiments.

Negative sentiment analysis revealed the highest score for health status (75.5%) for cerebrovascular diseases, surpassing that for cardiovascular diseases. This finding aligns with the lower positive sentiment score in this category, likely because of the high risk of postdischarge sequelae. Postdischarge sequelae are closely associated with physical and mental health challenges and result in increased negative sentiment scores. Conversely, among cardiovascular surgery patients, negative sentiment scores were the highest for care demands (80.7%), followed by those for care resources (75.8%), interactions (77.3%), and mental state (77.2%). These scores were higher than those among cerebrovascular surgery patients. This suggests that although cardiovascular diseases significantly affect patient lives, the relatively underdeveloped infrastructure and resources for postdischarge transitional care services may still contribute to the higher negative scores. Patients experience an ongoing need for care, such as cardiac rehabilitation, which can be burdensome and may exacerbate negative sentiments.

Consequently, the keywords and sentiments analyzed within the TCM framework encompass the experiences of surgery or hospitalization and are not restricted to postdischarge transitional care. Therefore, these results should be interpreted with caution. A combination of quantitative and qualitative research methods is essential to gain a comprehensive understanding of patients' emotional states. Future research can enhance these findings by incorporating focus group interviews with discharged patients and integrating clinical data.

RenderX

Limitations

This study had some limitations. First, access to primary data is restricted by South Korea's Personal Information Protection Act, particularly by the Medical Care Act. Future research can address this limitation by conducting analyses of primary data under strict protocols and anonymization procedures in collaboration with medical research institutions, allowing for the inclusion of detailed clinicodemographic variables. Second, we analyzed posts from patients who shared their health status on the online community. Considering that internet users are likely to have better physical health, information from patients with more severe conditions may have been underrepresented, potentially introducing sample bias. Third, the keywords used as search terms pertained to surgical and inpatient experiences, making it challenging to distinguish between experiences during hospitalization and those during the postdischarge transition period. Fourth, this research classified emotions into only 3 categories. Emotions can be defined in various ways, and we acknowledge the limitations in classifying emotions into more detailed categories due to accuracy concerns. Future research should aim to classify emotions in a more exhaustive manner.

Conclusions

The sentiment analysis results demonstrated that the KoBERT model had comparable performance levels to those of previous models. For sentiment analysis, the TCM components was categorized into 5 patient-centered domains: health status, care resources, care demand, interaction, and mental state. The sentiment analysis revealed that cardiovascular surgery patients expressed fewer negative sentiments than did cerebrovascular surgery patients, likely because of the relatively simpler procedures generally used in treating cardiovascular conditions. Conversely, patients with cerebrovascular disease who typically required long-term rehabilitation had higher negative sentiment scores. Notably, cerebrovascular surgery patients showed high positive sentiment scores in the "interaction" domain (relating to medical staff) but high negative sentiment scores in the "health status" domain. In contrast, cardiovascular surgery patients exhibited high positive sentiment scores for mental states and high negative sentiment scores for care demands. Collectively, these results suggest that a one-size-fits-all approach is not applicable for managing cardiovascular and cerebrovascular diseases. Instead, considering the differences in sentiment scores for each TCM domain, health care providers should provide personalized patient care during the transition from surgery to postdischarge care.

Abstract

Background: Diabetes affects millions worldwide. Primary care physicians provide a significant portion of care, and they often struggle with selecting appropriate medications.

Objective: This study aimed to develop a model that accurately predicts what drug an endocrinologist would prescribe based on the current measurements. The goal was to create a system that would assist nonspecialists in choosing medications, thereby potentially improving diabetes treatment outcomes. Based on the performance of previous studies, we set a performance target of achieving a receiver operating characteristic area under the curve (ROC-AUC) above 0.95.

Methods: A transformer-based encoder-decoder model predicts whether 44 types of diabetes drugs will be prescribed. The model uses sequences of age, sex, history for 12 laboratory tests, and prescribed drug history as inputs. We assessed the model using the electronic health records from 7034 patients with diabetes seeing endocrinologists between 2012 and 2022 at the University of Tokyo Hospital. We assessed model performance trained on data subsets spanning different time periods (2, 5, and 10 years) using micro- and macro-averaged ROC-AUC on a hold-out test set comprising data solely from 2022. The model's performance was compared against LightGBM.

Results: The model trained on data from the past 5 years (2017 - 2021) yielded the best predictive performance, achieving a microaverage (95% CI) ROC-AUC of 0.993 (0.992-0.994) and a macroaverage (95% CI) ROC-AUC of 0.988 (0.980-0.993). The model achieved an ROC-AUC above 0.95 for 43 out of 44 drugs. These results surpassed the predefined performance target and outperformed both previous studies and the LightGBM model's microaverage ROC-AUC of 0.988 (0.985-0.990) in terms of prediction accuracy. Furthermore, training the model with short-term data from the past 5 years yielded high accuracy compared to using data from the past 10 years, suggesting that learning from more recent prescribing patterns might be advantageous.

Conclusions: The proposed model demonstrates the feasibility of accurately predicting the next prescribed drugs. This model, trained from the past prescriptions of endocrinologists, has the potential to provide information that can assist nonspecialists in making diabetes-treatment decisions. Future studies will focus on incorporating important factors such as prescription contraindications and constraints to enhance safety, as well as leveraging large-scale clinical data across multiple hospitals to improve the generalizability of the model.

Introduction

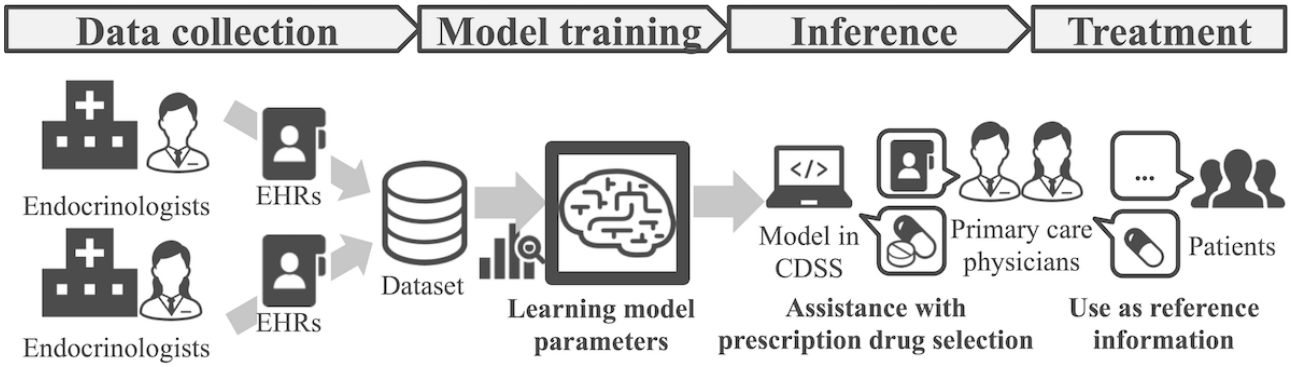
Diabetes affects 529 million people worldwide, with 1 in every 10 adults experiencing the condition [1]. Patients with diabetes receive care from primary care physicians, not endocrinologists, in many areas including the United States, Europe [2], and Japan [3]. This is particularly concerning in the United States, where the endocrinologist shortage is significant: the population-to-endocrinologist ratio within 20 miles was 29,887:1 for adults aged 18 - 64. Rural areas face even greater disparities, with only 55.5% of adults having access to at least 1 endocrinologist within that distance [4]. Japan also faces a similar problem. Japan has 11 million patients with diabetes but only about 7000 specialists, and two-thirds of people with type 2 diabetes (T2D) receive care from primary care physicians [3]. These nonspecialists may struggle to predict a patient's glycemic control. Approximately 60% of surveyed patients with T2D treated by nonspecialists experienced poor glycemic control

XSL•FO
RenderX

(hemoglobin A_{1c} [HbA_{1c}] ≥8%), with around 30% seeing worsened levels the following year, according to a survey on T2D treatment practices by primary care physicians [3].

One of the difficulties in diabetes treatment for primary care physicians is drug selection [5,6]. Medications are prescribed either as monotherapy or in combination. Medications need to be chosen [7] considering insulin secretion and insulin resistance [8], age [9,10], degree of obesity [11], severity of chronic complications [12], liver function, and kidney function [13]. New diabetes treatments continue to be developed, expanding the options for medication selection. For example, in Japan, sodium–glucose cotransporter 2 [14], imeglimin [15], and tirzepatide [16] were introduced in 2014, 2021, and 2023, respectively. The selection of diabetes medications depends on individual patient factors, with guidelines [17] and treatment tendencies [18] that vary from country to country. A tool supporting drug selection could enhance treatment outcomes. It could provide early warning to physicians and potentially improve treatment outcomes for patients who are being examined by nonspecialized physicians.

Clinical decision support systems (CDSS) provide physicians with safety tools for drug selection [19]. By adopting a knowledge-based approach aligned with clinical guidelines, CDSS help to prevent medication errors such as overdosing, incomplete, or unclear orders [20,21]. However, replicating the ability of endocrinologists to select drugs for individual patient conditions in a CDSS is complex and challenging for knowledge-based approaches.



Machine learning (ML) has demonstrated success in predicting patient symptoms, including forecasting the onset of T2D [22] and predicting complications [23]. Several studies have applied ML to the problem of drug selection for patients with diabetes [24]. A study predicting the next prescribed diabetes drugs for 161,497 patients with diabetes using sequential pattern mining demonstrated an accuracy of 89.1% - 90.5% in guessing from 37 drug classes (eg, DPP-4 inhibitor) and 63.5% - 64.9% accuracy in guessing from 43 drugs (eg, algliptin) [25]. Another study predicted 7 drug classes with an ROC-AUC of 90.6% - 94.3% using recurrent neural networks (RNN) [26]. There are also proposed methods for predicting treatment outcomes after selecting diabetes medications [27].

The field of ML has undergone significant advancement since the introduction of the transformer approach in 2017 [28,29]. Transformers enable contextual interactions for natural language processing tasks and have become a core technology across diverse domains [30-32]. The transformer model incorporates an attention mechanism and has shown remarkable performance in tasks involving the extraction of temporal and semantic relationships, leading to success in tasks such as generation and classification [33]. Generally, transformers enhance predictive performance through two types of training: pretraining via self-supervised learning and fine-tuning via supervised learning. For example, large language models like GPT and bidirectional encoder representations from transformers (BERT) were pretrained on a task predicting the next or masked word and then fine-tuned on a task generating responses to an instruction [34]. Several studies in health care have already used this scheme of 2 types of learning. TransformEHR improved performance on the fine-tuned task of predicting the onset of pancreatic cancer and intentional self-harm among patients with posttraumatic stress disorder by pretraining on the task of predicting randomly-masked diseases and outcomes in time series of 6.5 million patients [35]. A deep neural sequence transduction model for electronic health records (BEHRT) [36] was pretrained using an electronic health records (EHR) dataset of 1.6 million patients and was fine-tuned to predict diagnosis codes. Recent transformers have also made advancements in learning by combining different modalities of information such as images, audio, and text. Foresight [37] was trained with structured data such as laboratory results as well as unstructured data such as free text from 1.5 million patients across three EHR datasets. The transformer approach has not previously been applied to the task of selecting diabetes medications. In addition, while efforts have been made to train models with large amounts of data to improve accuracy [38], the impact of the training data period on predictions is largely unexplored.

Diabetes drug selection involves deciding to prescribe one or more drugs from among many candidates. This selection can be handled by ML as a multichoice task. This study aimed to develop an ML tool that accurately predicts the next prescribed drugs using the patient's medical condition and prescription history over the past year. The objective is to enhance diabetes treatment outcomes for nonspecialists through improved support in drug selection (Figure 1). Based on the performance of previous studies [24-26], our goal was to achieve an ROC-AUC above 0.95 when predicting the next prescribed drugs. Drawing on our team's previous work in self-management support for T2D treatment [39] and predicting treatment discontinuations [40,41], we designed this task with the hope of overcoming barriers to nonspecialist diabetes treatment in clinical practice, believing it could significantly improve diabetes treatment outcomes.

Methods

Datasets

All data were collected from the EHRs at the University of Tokyo Hospital, which included 7034 patients who visited the hospital, had diagnostic codes, and were registered to the Japan diabetes comprehensive database project based on an advanced electronic medical record system (J-DREAMS) cohort [42]. The data were recorded in the EHRs between January 1, 2011 and December 31, 2022. The data, including treatment decisions and outcomes, were reflective of care by endocrinologists. Variables extracted from the EHRs included sex, age, 12 kinds of diabetes-related laboratory tests, and drugs. The laboratory tests included numerical values of HbA_{1c}, glucose, triacylglycerol, high density lipoprotein cholesterol, total cholesterol [43], urinary albumin creatinine ratio, creatinine [44], alanine transaminase, aspartate transaminase, and γ-glutamyltransferase [45], and categorical values of proteins [45] and glycogen. Drugs were identified using the list of drug price standards [46] provided by the Ministry of Health, Labour and Welfare of Japan, and 44 types prescribed in 2021 were selected.

Training and Test Data

The records used for training were not used for testing to ensure that the same patients were not included in both groups. A total of 80% (5627/7034) of patients were included in the training group, and the remaining 20% (1407/7034) of patients were included in the testing group.

In order to examine the size of the training data needed to achieve the target prediction accuracy, we extracted three different subsets of training data from the sequences of the 5627 patients in the training group: 2 years from 2020 to 2021 (3013 patients and their 25484 subsequences), 5 years from 2017 to 2021 (4009 patients and their 78,020 subsequences), and 10 years from 2012 to 2021 (4524 patients and their 168,595 subsequences). For testing, we further identified a subset of the testing data that was solely data from 2022 (637 patients and their 2988 subsequences). Thus, there was no overlap in patients or time periods between training and testing. Table 1 shows the characteristics of the patients. The drugs in the table are the top 5 and bottom 5 in terms of number of prescriptions in the 2-year training data. All characteristics are provided in Multimedia Appendix 1.

ML Models

Patients' medical conditions and prescription histories are in general irregularly spaced, reflecting variability in patient care appointment dates, with updates to outpatient EHR occurring before and after clinical visits. We organized the data into Monday-to-Sunday weeks and quantized the data to a single value per week, using the average in the case of multiple measurements and treating weeks with no values as having missing values [47]. This approach allowed the ML model to treat irregularly spaced data spanning Y (a natural number) years as regularly spaced data consisting of (Y×365)/7 (rounded up to the nearest integer) values, that is we treated all data as weekly data. We did not perform preprocessing, including interpolation, on missing values in the regularly spaced data. No normalization, outlier removal, or dimensionality reduction was performed.

We designed a transformer-based encoder-decoder model (Figure 2) that takes as input a time series of drugs prescribed and laboratory tests over the past 1 year, sex, and age. The model approaches drug selection as a multichoice task. With N types of drugs, there are 2^N potential prescription combinations. By setting the number of units in the output layer of the transformer decoder to N, we implemented N binary classifications. The model outputs a set of scores representing the probability of each drug being prescribed on that day and, for each drug and day, a binary prescription decision based on whether the prescription probability is greater than or equal to 0.5.

Figure 2. Architecture of the transformer-based encoder-decoder model for predicting the next-prescribed diabetes medications. EHRs: electronic health records.

We treated age and HbA_{1c} values as numerical data, sex as a categorical label, and prescription history as a set of categorical labels. In addition, a time series representing the presence or absence of missing data, called an attention mask, was simultaneously generated. Each data type was transformed into a uniform-dimensional vector using an embedding layer specific to that data type, which was then handled by the transformer model. Time information was converted to a uniform-dimensional vector using a positional embedding layer with a periodic function and added to the output value of the embedding layers.

The model incorporates two types of attention layers: self-attention in the encoder, designed to extract relationships in time and meaning from the time series of drugs prescribed and laboratory tests, and cross-attention in the decoder, used to predict the next prescribed drugs based on these relationships. Times in the time series that contain missing data are ignored in the self-attention and mutual attention calculation process using the attention mask. This makes it easy to handle without additional processing for missing data completion. The self-attention weights were optimized through self-supervised learning. This involves the task of predicting both the next laboratory test values and drugs prescribed using a time series of past laboratory tests and drugs prescribed. The cross-attention weights were optimized through supervised learning involving the task of predicting a set of scores representing the probability of each drug being prescribed on that day.

The model consisted of four transformer-encoder layers including four multihead self-attention blocks and four transformer-decoder layers including four multihead cross-attention blocks, along with a hidden layer of dimension 256. Compared to the text data handled by the language model, the prescription drug selection data has a smaller vocabulary (number of drug types) and a shorter time series, so these hyperparameters were set to about one-third the size of the BERT model [34]. The parameters were optimized by Adam with a learning rate of 1e-4, a batch size of 256, and 100 epochs. The loss functions for numerical and categorical data were mean squared error and focal loss [48], respectively. All implementations were written in Python 3.11 (Python Software Foundation) and PyTorch 2.2 (Meta AI).

The model was trained using prescription records from endocrinologists at the University of Tokyo Hospital. As a result, the model generates outputs aligned with the treatment approaches of these specialists.

Statistical Methods

We analyzed the characteristics of patients in the dataset using means, SD, and frequency counts. We calculated 95% CI using the bootstrap method where applicable. We performed all statistical analyses using custom Python code.

We compared our model with an established ML method recognized for high accuracy. There were validations on similar T2D prediction tasks favored LightGBM [49,50], making it our chosen reference for comparisons. We compared the predictive

XSL•FO
RenderX

accuracy of the two methods with the three different training dataset for the prescription prediction of 44 drugs using both macro- and microaverages [51] of the receiver operating characteristic area under the curve (ROC-AUC) as metrics. The macroaverage is a measure of the average performance across all classes independently. The method computes the metrics of ROC-AUC for each individual drug, then averages them to obtain an overall score. This analysis method gives equal weight to each drug, regardless of its size or imbalance in the dataset. On the other hand, the microaverage is a measure of the aggregate performance that weights all instances in the dataset equally. This analysis method first aggregates the true positives, false positives, true negatives, and false negatives across all drugs, and then computes each metric using these aggregated values. The microaverage treats every prediction equally, without considering the kinds of drugs.

The predictive performance of each drug was also evaluated using ROC-AUC.

Ethical Considerations

This study was approved by the institutional review board of the University of Tokyo School of Medicine (approval number: 10705-(4)) and was conducted in accordance with the Declaration of Helsinki. This was a retrospective, noninterventional database study without patient involvement. Confidentiality was safeguarded by the University of Tokyo Hospital. According to the Guidelines for Epidemiological Studies of the Ministry of Health, Labour and Welfare of Japan, written informed consent was not required. Information about the current study was available to patients on a website, and patients have the right to cease registration of their data at any time [52].

Results

Prediction Performance for Various Sizes of Training Data

We assessed different sizes of training data (Table 2). The best prediction performance was obtained from training with the 5 years of data from 2017 to 2021. This version achieved a microaverage (95% CI) ROC-AUC of 0.993 (0.992-0.994) and a macroaverage (95% CI) ROC-AUC of 0.988 (0.980-0.993), and we selected it as our model. Performance was similar when trained using the full range of 10 years of data, from 2012 to 2021, producing somewhat worse results. For all sizes of training data, we met the study's objectives of achieving an ROC-AUC above 0.95 from our macro- and microaverage evaluations. The prediction accuracy of LightGBM with the 5 years of data had a microaverage ROC AUC of 0.988 (0.985-0.990), and the transformer outperformed LightGBM.

Table . Overall prediction performance of models for the next-prescribed diabetes drugs, stratified by the training data period. This table compares the overall accuracy of the developed transformer model against a LightGBM model.

	Transformer		LightGBM	
	Microaverage (95% CI)	Macroaverage (95% CI)	Microaverage (95% CI)	Macroaverage (95% CI)
2 years of training data	0.991 (0.990-0.992)	0.981 (0.975-0.988)	0.987 (0.984-0.989)	0.970 (0.941-0.992)
5 years of training data	0.993 (0.992-0.994)	0.988 (0.980-0.993)	0.988 (0.985-0.990)	0.962 (0.916-0.993)
10 years of training data	0.992 (0.990-0.993)	0.987 (0.976-0.994)	0.984 (0.981-0.986)	0.959 (0.921-0.987)

Prediction Performance for Each Drug

We examined the prediction performance for each of the 44 drugs (Table 3). The drugs in the table are the top 5 and bottom 5 in terms of the number of prescriptions in the 2 years of training data. All results are provided in the supplemental file (Multimedia Appendix 2). We achieved an ROC-AUC above our target of 0.95 for 43 of the 44 drugs when trained with the 5 years of data.

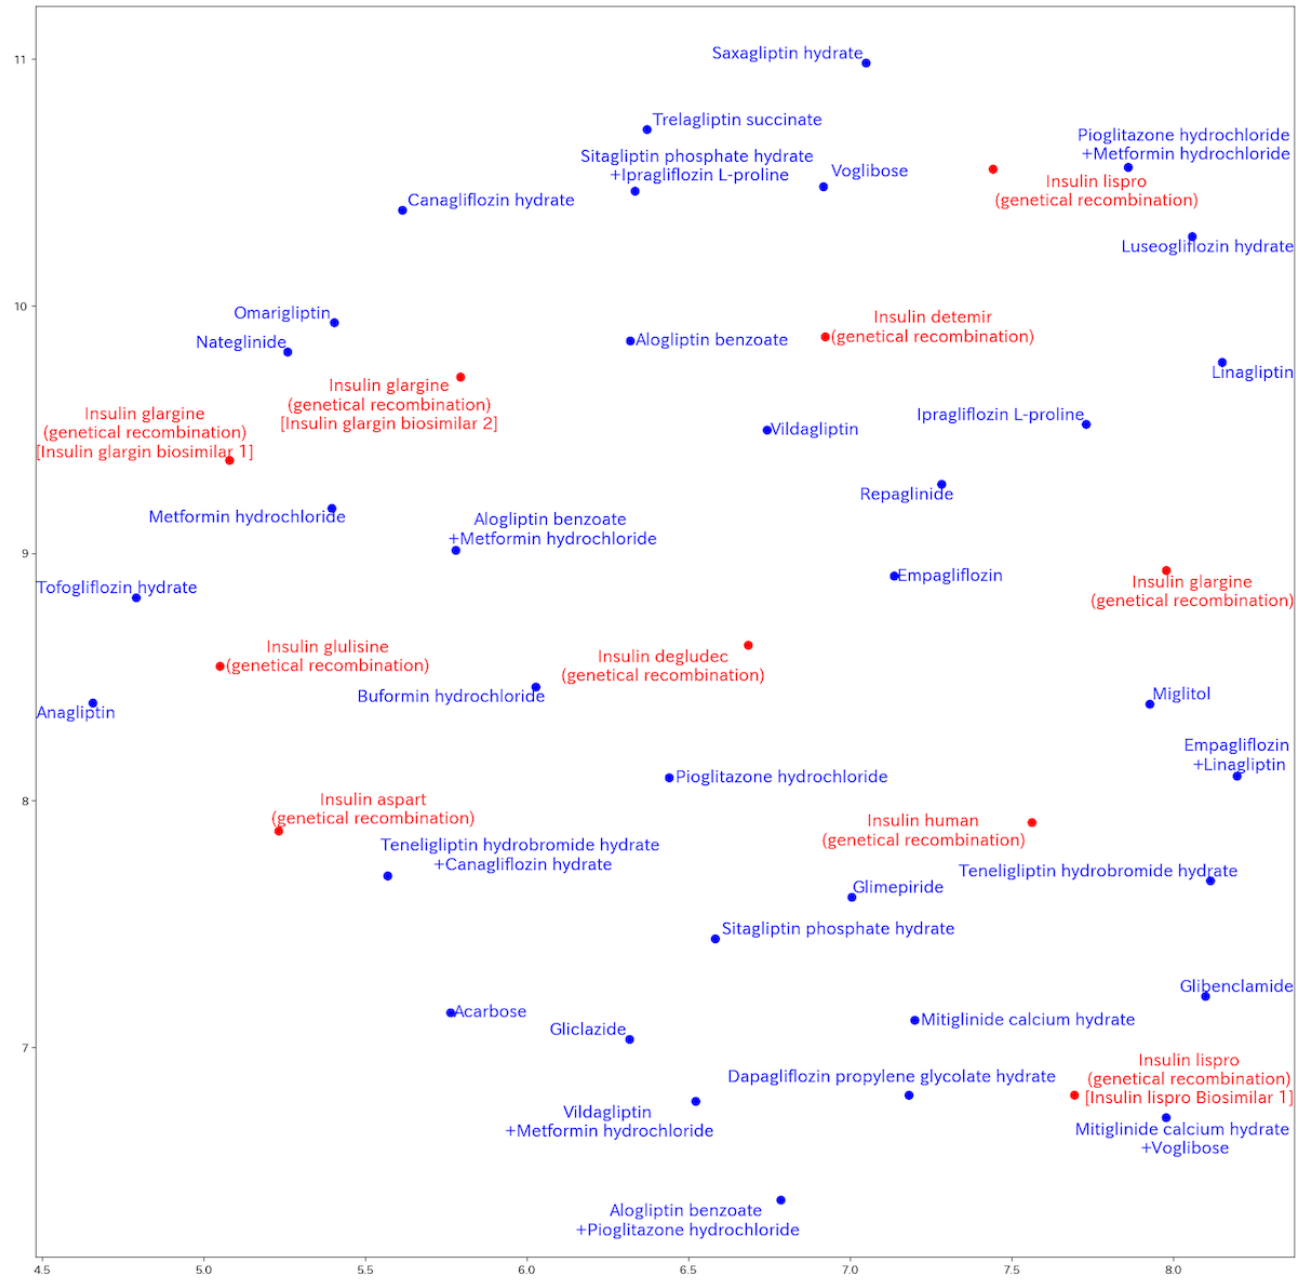
Glibenclamide, n (%)	11 (0.37)	0.999 (0.999-1.000)	0.999 (0.997-1.000)	0.999 (0.999-1.000)	0.999 (0.997-1.000)	0.973 (0.935-0.999)	0.996 (0.994-0.998)



The only drug that did not achieve the target value was "Insulin lispro (genetical recombination) [Insulin lispro Biosimilar 1]." The prescription of this drug began in 2020. Therefore, the same instances of prescription were present in all three training data periods. For this drug, the model trained on just 2 years of data had the highest ROC-AUC.

Interpretability

The proposed model performed as well as other transformer-based models considering the ability for extracting relationships in time and meaning [53]. The embedding vectors obtained through training represent the closeness of relationships between vectors as proximity. The embedding vectors in this experiment were the same 256 dimensions as the transformer hidden size. Projecting onto two dimensions using uniform manifold approximation and projection [54] allows visualization (Figure 3). While we did not observe a strong tendency for clustering, several biosimilar drugs, such as insulin glargine (genetical recombination, ie, insulin glargin biosimilar 1), were positioned close to the biosimilar drug.

XSL•FO
RenderX

Figure 3. Visualization of learned drug embedding vectors using uniform manifold approximation and projection. This plot displays a 2D representation of the relationships between 44 different diabetes drugs, as learned by the transformer model's encoder component. Each point corresponds to a specific diabetes drug. Proximity between points suggests that the model identified similarities in how these drugs were used or in the patient contexts associated with their prescription within the training dataset.

Discussion

Evaluation of the Predictive Accuracy

The proposed model achieved impressive predictive accuracy, with macroaverages (95% CI) of ROC-AUC of 0.988 (0.980-0.993). In previous studies [11,12], the ROC-AUC for drugs was less than 0.95, and our model represents a significant improvement relative to this previous work.

The prediction accuracy was higher when trained with short-term data from 5 years than when trained using data from the past 10 years. We suspect that changes in the treatment environment, such as the introduction of new prescription drugs, are responsible for this difference in prediction accuracy. When training on data from the past N years, the model uniformly learns the prescription selection trends for the past N years. Therefore, when N is large, the model is heavily influenced by the trends of older prescription selections. This suspicion is supported by our results that the prescription drug that did not reach target accuracy, "Insulin lispro (genetical recombination) [Insulin lispro Biosimilar 1]," was only recently approved and prescribed. Introduced in 2020, this drug has remained relatively rare in the dataset, as demonstrated in Table 1. Even when expanding the training data period from 2 to 10 years, the number of prescriptions for this drug has remained stagnant at 59, and its proportion within the overall dataset has decreased from 0.23% to a mere 0.03%. This low frequency and temporal bias in the data have rendered learning this specific drug's patterns challenging. Although ML models generally perform better with more data, for this application it may be better to

XSL•FO
RenderX

gather data from more hospitals rather than a longer time span, since it is desirable to learn more fresh data, including new prescription drugs. Transformer models, known for power-law characteristics, benefit from scale-ups [38], and expanding the study to multiple hospitals could explore potential performance enhancements and test the applicability of the power-law in the medical field.

Physicians select drugs considering insulin secretion and insulin resistance, age, obesity, severity of chronic complications, and liver and kidney function. In this experiment, we used age, sex, 12 kinds of diabetes-related laboratory tests, and past prescription history. By adding comprehensive items likely used in medication selection to the model input, performance may be improved.

Our ultimate goal is to improve the treatment outcomes of diabetes. Merely predicting drug selection alone cannot achieve this goal. Expanding the scope to predict the impact of prescribed drugs could further enhance the model's utility in diabetes treatment.

Limitations

Our study has notable limitations. First, the model uses only age, sex, 12 kinds of diabetes-related laboratory tests, and past prescription history as inputs. It is desirable to fully account for the various constraints and contraindications that physicians consider in real-world clinical practice. For example, when considering patient characteristics, factors such as age (older adults or pediatric), pregnancy, lactation, BMI, type of diabetes, c-peptide, renal and hepatic function, comorbidities, allergies, urinary tract infection history, diabetic ketoacidosis history, cardiac history, and hypoglycemia must be considered. Regarding medications, considerations include adverse effects, drug resistance, and cost. However, despite these limitations, this study demonstrates that it is possible to narrow down treatment options to some extent using a limited set of variables. We believe that this result holds promise for providing primary care physicians with some guidance and direction. Regarding warnings of constraints and contraindications in drug selection, CDSS have traditionally excelled in this [20,21] and can effectively complement this model. In addition, recent advancements in natural language processing within ML models [33,34] have enabled the extraction of important information on constraints and contraindications from fresh sources such as research papers published daily. We believe there is substantial potential for future research to integrate these important factors into ML models, and we intend to work on this improvement.

Second, the data were sourced from a single hospital, limiting generalizability. Potential biases in the results include the race and geography of the patients and the prescribing tendencies of a limited number of endocrinologists at the hospital. ML models tend to learn biases present in the training data, resulting in predictions that reflect those biases. Prediction accuracy is significantly degraded when different biases exist between the training data and the test data. Therefore, in order to generalize the prediction results of the model, a large dataset of data from multiple hospitals containing data on patients with diverse backgrounds is required. However, in reality, it is difficult to build an ideal dataset due to constraints such as privacy protection and data collection costs. As one solution, we believe that it is good to collect training data that resembles the patterns of patients treated by the primary care physicians who are the users of the model, thereby eliminating biase differences between the training data and the test data as much as possible. Specifically, we collect EHRs of patients who have been involved in prescriptions by endocrinologists at multiple hospitals in a specific region, and use this to build the model that selects prescription drugs for patients treated by primary care physicians in the same region. We believe that this approach will reduce the bias differences in regional characteristics between the training data and the test data, and improve generalization performance with realistic data collection. We would like to verify the validity of this solution in the future.

Third, ML reflects majority characteristics, potentially limiting applicability to diverse patient populations. In the dataset used in the experiment, over 40% (297/637) of patients were prescribed metformin hydrochloride, and patient characteristics are biased. There is a risk that truly effective treatments may not be prescribed correctly to a minority of patients. Prediction failure analysis needs to be further scrutinized, including versus patient characteristics. We should examine this issue by comparing prediction accuracy for each patient cluster.

Fourth, this was a backward-looking study, using past data, and the essential next phase is to assess the model's predictive capabilities in clinical practice. There is a need for a careful exploration of the model's effectiveness in real clinical scenarios.

Fifth, while the proposed model requires hyperparameters, we determined these values based on previous studies. Although fine-tuning hyperparameters is generally desirable, transformer models are typically computationally expensive to train, and many previous studies have likewise not fully tuned their parameters. There is potential for performance improvement through hyperparameter tuning, and we intend to investigate this further in future work.

Sixth, the model has poor interpretability. We investigated the proximity relationship between embedding vectors, but no strong tendency was found. It would be better to use other information obtained from the transformer, such as attention weights, to further improve interpretability.

These limitations raise important ethical considerations in the development and application of medical artificial intelligence. Physicians who use the model must be aware of these limitations and exercise appropriate clinical judgment. Obtaining appropriate informed consent from patients is important.

Conclusions

The proposed model addresses the challenge of predicting the next prescribed drugs. This model, trained using past prescriptions of endocrinologists, has the potential to improve treatment outcomes for nonspecialists by assisting them in making prescription decisions. Future efforts should focus on improving accuracy by incorporating disease state information beyond current inputs and validating the model on large clinical datasets across multiple hospitals.

Multimedia Appendix 1
Characteristics of patients with diabetes included in the training and testing datasets. Characteristics are presented separately for the patient groups belonging to the different training datasets defined by period: 2 years (2020-2021), 5 years (2017-2021), 10 years (2012-2021) and the independent test dataset (data exclusively from 2022). Variables shown include patient counts, age, sex distribution, laboratory values, and prescription frequencies of 44 drugs.

Abstract

Background: For the public health community, monitoring recently published articles is crucial for staying informed about the latest research developments. However, identifying publications about studies with specific research designs from the extensive body of public health publications is a challenge with the currently available methods.

Objective: Our objective is to develop a fine-tuned pretrained language model that can accurately identify publications from clinical trials that use a group- or cluster-randomized trial (GRT), individually randomized group-treatment trial (IRGT), or stepped wedge group- or cluster-randomized trial (SWGRT) design within the biomedical literature.

Methods: We fine-tuned the BioMedBERT language model using a dataset of biomedical literature from the Office of Disease Prevention at the National Institute of Health. The model was trained to classify publications into three categories of clinical trials that use nested designs. The model performance was evaluated on unseen data and demonstrated high sensitivity and specificity for each class.

Results: When our proposed model was tested for generalizability with unseen data, it delivered high sensitivity and specificity for each class as follows: negatives (0.95 and 0.93), GRTs (0.94 and 0.90), IRGTs (0.81 and 0.97), and SWGRTs (0.96 and 0.99), respectively.

Conclusions: Our work demonstrates the potential of fine-tuned, domain-specific language models to accurately identify publications reporting on complex and specialized study designs, addressing a critical need in the public health research community. This model offers a valuable tool for the public health community to directly identify publications from clinical trials that use one of the three classes of nested designs.

Introduction

Researchers need to identify publications from trials that use nested designs to access evidence relevant to community-level interventions and make informed decisions about public health strategies, as well as to understand the effectiveness of these interventions in improving health outcomes and reducing health disparities within populations. Additionally, they may require these publications to conduct meta-analyses and systematic reviews.

There are three important classes of nested designs widely used in clinical trials [1,2]. The parallel group- or cluster-randomized trial (GRT) involves the randomization of groups or clusters to study arms with observations taken using members of those groups or clusters [3-8]. This design is widely used to evaluate interventions that are delivered to groups or clusters that modify the physical or social environment, or that cannot be delivered to individuals without the substantial risk of contamination. The stepped wedge group or cluster-randomized trial (SWGRT) involves the randomization of groups or clusters to sequences; all groups or clusters begin in the control arm and transition to the intervention arm on a schedule determined by their sequence so that by the end of the trial, all groups or clusters are in the intervention arm [9]. The individually randomized group-treatment (IRGT) trial involves the random assignment of individuals to study arms but delivery of the intervention in a group-based format or using shared intervention agents [10,11]. All three nested designs have design, analytic, and sample size challenges not found in the traditional randomized clinical trial [1,2].

XSL•FO
RenderX

Currently, most public health researchers, including ourselves, use manual searches to identify GRTs, IRGTs, or SWGRTs, because, so far as we are aware, there are no automated methods for identifying published papers using these designs. However, manual searches can easily miss many qualifying publications due to the complexity of search parameters and the lack of consistent reporting. Document classification using machine learning and natural language processing techniques offers a more promising approach for categorizing documents into predefined groups.

Garcia et al [12] enhanced automatic document classification in the biomedical domain by leveraging Wikipedia knowledge to create bag-of-concepts representations, resulting in performance gains over traditional bag-of-words approaches in both single-label and multi-label classification tasks. Cohen [13] also proposed a biomedical text classifier, which integrates document words, MeSH terms, and normalized biological entity identifiers.

Previous studies have demonstrated the utility of machine learning approaches in identifying randomized controlled trials (RCTs) from biomedical literature databases. Marshal et al [14] used machine learning models, including convolutional neural networks, support vector machines, and ensemble models to identify RCT publications. Al-Jaishi et al [15] addressed the challenge of accurately identifying GRTs reports from bibliographic citations by leveraging static embedding techniques, developing and validating machine learning algorithms for information retrieval.

While these studies have focused on identifying specific types of RCTs, such as conventional RCTs and GRTs, our research aims to extend this approach to the identification of diverse categories of randomized trials, including GRTs, IRGTs, and SWGRTs. To achieve this, we propose a novel approach leveraging fine-tuned language models, specifically the pretrained BioMedBERT model, trained on a dataset of biomedical literature curated by the Office of Disease Prevention at the National Institute of Health.

Large language models represent an ideal choice for the development of biomedical text classifiers due to their capacity to grasp the contextual nuances within the data. Pretrained transformer language models, like bidirectional encoder representations from transformers (BERT) [16-18], have outperformed the existing deep neural network models, including convolutional neural networks and recurrent neural networks. Examples of transformer-based models trained on biomedical data include BioBERT [19], BioLinkBERT [20], BlueBERT [21], and BioMedBERT [22], which are pretrained on biomedical literature and clinical text.

While these pretrained models are readily applicable to common tasks due to their training on biomedical data, classifying scientific literature presents a unique challenge because scientific literature encompasses a diverse range of topics, writing styles, and research fields. Identifying and categorizing clinical trials into highly specialized categories is especially challenging, even for human coders. Leveraging transfer learning and fine-tuning a pretrained language model allows the machine learning platform to learn and adapt to the particular context and vocabulary of these types of documents, enhancing its effectiveness in tasks such as document classification, information extraction, and summarization [18].

To our knowledge, there is currently no transformer-based language model fine-tuned to identify clinical trial publications based on nested designs. In our method, we leverage BioMedBERT [22], a model that has been pretrained from scratch using abstracts from PubMed and full-text articles from PubMedCentral. We fine-tuned BioMedBERT using labeled clinical trials, with a specific focus on distinguishing various types of clinical trial publications, including GRTs, IRGTs, and SWGRTs. The fine-tuning process involved training on a carefully curated dataset comprising a substantial number of GRTs, IRGTs, and SWGRTs. The outcome of this fine-tuning process is a model that provides a high level of sensitivity and specificity in classifying and differentiating various types of randomized trial publications.

Methods

Traditional Machine Learning Models (Baseline Model)

In our study, we initially established a baseline model for classifying publications using traditional machine learning and word embedding techniques to demonstrate the effectiveness of employing a transformer-based model in identifying publications based on nested designs. To create the baseline model, we employed FastText (Facebook AI Research) to generate word embeddings, followed by a logistic regression model. Logistic regression has been widely recognized in the literature as an effective classifier for text data due to its simplicity, interpretability, and robust performance across various domains [23]. To enhance the model's capability to process biomedical text data, we leveraged pretrained FastText embeddings specifically trained on PubMed and MIMIC-III data, known as BioWordVec [24], to extract meaningful features from titles and abstracts of publications. Subsequently, we used these extracted embeddings to train a logistic regression model for the classification of publications.

Evaluation Metrics

There are various metrics available to evaluate the performance of a classifier. While the area under the curve is commonly used in binary classifiers, accuracy can be helpful for balanced evaluation datasets. However, in our case, where the model serves as a multiclass classifier with imbalanced data, the F_1-score emerges as the most reliable metric [25]. Our primary objective was to fine-tune an existing pretrained language model to maximize the F_1-score on a validation dataset.

The F_1-score is the harmonic mean of precision and recall. Precision is the ratio of correctly predicted positive observations to the total predicted positives. It measures the accuracy of the positive predictions made by the model. High precision ensures that when our model predicts an article belongs to a nested design group, it is highly likely to be accurate. This is crucial in applications where precision contributes to the trustworthiness of the classification outcomes, such as systemically classifying research publications. Recall, which is the same as sensitivity,

XSL•FO
RenderX

is vital when the cost of false negatives is high. A high recall ensures that our model effectively captures a comprehensive set of articles within each predefined group.

The F_1-score is particularly useful in situations where there is an imbalance between the classes or when there is an equal importance placed on precision and recall. It is a metric that balances the trade-off between precision and recall, providing a single value that reflects the overall performance of the model.

Our dataset is imbalanced with fewer examples in the IRGT and SWGRT classes, and accuracy alone can be misleading. Precision, recall, and F1-score provide a more nuanced view of a model's effectiveness, especially in identifying the strengths and weaknesses associated with false positives and false negatives.

$$\text{Precision} = \frac{\text{True Positives}}{\text{True Positives} + \text{False Positives}}$$

$$\text{Recall} = \frac{\text{True Positives}}{\text{True Positives} + \text{False Negatives}}$$

$$\text{F1 Score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}$$

Specificity serves as a crucial metric for assessing the number of false positives within a model. It measures the ability of the model to correctly identify negative instances, thus providing insight into the model's performance in avoiding false-positive predictions. Although it was not initially used as an evaluation metric during our experimental phase and model development, it was calculated to provide a comprehensive assessment of performance, particularly in gauging the rate of false positives.

$$\text{Specificity} = \frac{\text{True Negatives}}{\text{True Negatives} + \text{False Positives}}$$

The weighted average considers the class imbalance in the dataset by considering the contribution of each class proportional to the number of instances in that class. In other words, classes with more instances have a greater impact on the overall metric than classes with fewer instances.

$$\text{WeightedAverage} = \sum_{i=1}^{C} m_i \cdot \frac{n_i}{N}$$

Where

m_i is the metric value (eg, precision, recall, F1-score) for class, n_i is the number of instances in class i, C is the number of classes, and *N* is the total number of instances in the dataset

BioMedBERT

We chose BioMedBERT as the initial pretrained model due to its superior performance compared to other existing models on our gold standard data, publications published prior to 2021 that were identified as GRT, IRGT, and SWGRT papers using search queries. BioMedBERT is a pretrained language model developed by Microsoft Research for biomedical text processing using abstracts from PubMed and full-text articles from PubMedCentral [22]. It is a specialized variant of the BERT architecture [16], designed to capture domain-specific nuances in biomedical literature. The architecture of BioMedBERT enables it to learn contextualized representations of words and phrases bidirectionally and understand the contextual relationships within biomedical texts. The BERT model used in our study was downloaded from Hugging Face's Transformers library, configured as a classifier. In this framework, the tokenizer automatically manages special tokens such as [CLS] and [SEP], ensuring proper preprocessing for input sequences.

For the classification task, the [CLS] token's embedding from the final layer of BERT serves as a representation of the input sequence's contextual information. A multilayer perceptron is applied to this embedding to perform the classification. This multilayer perceptron consists of fully connected layers that map the [CLS] token's representation to the output space, followed by the softmax activation for probability distribution over classes.

The pretrained BioMedBERT uses a bidirectional transformer architecture with several layers of self-attention mechanisms. The model embeddings, including word embeddings and positional embeddings, contribute to encoding patterns in biomedical language.

During the pretraining phase, BioMedBERT was initialized with weights obtained from training on a domain-specific corpus: 14 million abstracts, 3.2 billion words, and 21 gigabytes [22]. This large-scale training ensures that the model captures a wide range of biomedical concepts, terminology, and contextual relationships. BERT-BASE [16] with 12 transformer layers and 100 million parameters was used to pretrain BioMedBERT.

A pooling layer was introduced atop the transformer's final layer, known as the embedding layer. This embedding layer underwent pooling to derive a fixed-size representation of the entire input sequence. To capture nonlinearity and intricate patterns within the data, a feedforward layer was incorporated. This layer is linked to the output layer, responsible for computing logits.

Fine-Tuning BioMedBERT

For this study, we fine-tuned BioMedBERT to adapt the model to the specific nuances of our dataset related to publications from clinical trials that use nested designs. By leveraging the contextual information encoded in BioMedBERT, we aimed to enhance the accuracy and efficiency of our machine learning model in identifying and distinguishing various types of clinical trial publications. In particular, our goal was for BioMedBERT to serve as a multiclass classifier that can categorize biomedical publications into four distinct categories: GRT, IRGT, SWGRTs, and the broader category of publications based on studies that used other designs, which we refer to as negatives (Multimedia Appendix 1).

Data

The National Institute of Health Office of Disease Prevention provided a labeled dataset consisting of publications from PubMed, published prior to 2021, with each publication categorized into one of the three classes: GRT, IRGT, and SWGRT. We selected nonclinical trial publications from a list of 120 journals that published most of the nested clinical trial publications; we will refer to those publications as negative publications. The original dataset consisted of 891 GRT publications, 59 IRGT publications, 109 SWGRT publications, and 996 negative publications. The first version of the fine-tuned

XSL•FO
RenderX

language model underwent training on titles and abstracts from this dataset. The best-performing model was subsequently employed to classify unlabeled publications published in 2021. After thorough verification of predictions by domain experts, a complementary set of 299 GRT, 40 IRGT, 65 SWGRT, and 1200 negative examples from 2021 was added to the original training, validation, and test sets.

The new dataset served as the foundation for tuning the model hyperparameters to predict labels for publications published in 2022. With the improved training data, the model demonstrated higher accuracy and F1-score, enabling precise classification of publications from the subsequent year, 2022. The same strategy as above was employed to add 2022 verified data to our training dataset, which resulted in the addition of 461 GRT, 195 IRGT, and 93 SWGRT, and 539 negative publications to the training, validation, and test datasets to prepare the classifier to predict labels for publications published in 2023. The Results section describes the final performance of the model trained and evaluated on this dataset.

Tokenization

To process the textual data, we utilized the Hugging Face Trainer API in conjunction with the BioMedBERT tokenizer. The BioMedBERT tokenizer is trained on a corpus of biomedical text to tokenize and segment text into subwords using the WordPiece algorithm, just like the original BERT tokenizer. Therefore, the tokenizer is tailored to handle biomedical terminology and language patterns [22]. For instance, when tokenizing the title "Comparison of different intervention methods to reduce the incidence of venous thromboembolism: study protocol for a cluster-randomized, crossover trial" from a 2023 publication, the tokens are segmented as follows: ["comparison," "of," "different," "intervention," "methods," "to," "reduce," "the," "incidence," "of,' "venous," "thromboembolism," ":," "study," "protocol," "for," "a," "cluster," "-," "randomized," ",", "crossover," "trial," "."]. The tokenization process was carried out separately for the titles and abstracts of the publications. In order to maintain computational efficiency and manage memory constraints, we imposed a length limit on the tokenized text. Titles were truncated to a maximum length of 30 tokens, which was the maximum title length in the data, while abstracts were truncated to 256 tokens from the start of the text, ensuring that majority of abstracts in our dataset fit within this allocation. Shorter sequences were padded with zeros. Based on the length distribution of titles and abstracts, we adjusted the allocation to align with actual usage patterns, ensuring that all instances remain within the supported range while optimizing model efficiency.

Addressing Class Imbalance

An imbalanced dataset refers to any dataset where there is an unequal distribution among classes, with one or more classes having significantly fewer instances than others. When trained on imbalanced datasets, models may exhibit a bias towards predicting the majority class more frequently, resulting in poor generalization for the minority class. Therefore, selecting the appropriate evaluation metric becomes crucial in such scenarios. A model might achieve high accuracy by predominantly predicting the majority class while displaying poor performance on the minority class. Various strategies exist to address class imbalance, including selecting appropriate performance metrics, such as precision-recall or the F_1-score, to accurately reflect model performance. Techniques like undersampling the majority class, oversampling the minority class, employing synthetic data generation methods like SMOTE (synthetic minority over-sampling technique), leveraging algorithms designed to handle class imbalance robustly, and incorporating cost-sensitive learning by assigning costs to the loss function are among the approaches commonly employed [26-28]. Given the observed class imbalance within the dataset, we implemented a customized loss function to mitigate the impact of this imbalance during the training phase. To achieve this, inverse class weights were calculated based on the number of examples in each class within the training dataset. These weights were then utilized in the weighted categorical cross-entropy loss function, assigning varying levels of importance to each class during model training.

The weighted categorical cross-entropy loss function is defined as follows:

$$\text{Weighted Categorical Cross-Entropy Loss} = -\sum_{i=1}^{N}\sum_{j=1}^{C} w_j \cdot y_{i,j} \cdot \log(P_{i,j})$$

- where C is the number of classes, N is the number of samples in the dataset, yi is the true probability distribution (one-hot encoded vector) for class i, Pi is the predicted probability distribution for class i, and wi is the weight assigned to class i

The inverse class frequency method is used to assign higher weights to classes with fewer examples. The rationale is to give higher weights to classes that are under-represented, making the model more sensitive to minority classes and potentially improving performance on imbalanced datasets.

$$w_i = \frac{\text{Total Number of Examples}}{\text{Number of Examples in class } i}$$

Hyperparameter Tuning

To evaluate the model's performance, we split our dataset into three subsets: a training set, a validation set, and a test set. The test set comprised 20% of the total dataset and was created by stratified random sampling from the labeled data. To assess the generalizability of our model to unseen data and to ensure a robust and unbiased evaluation of our model, a stratified k-fold cross-validation technique was used by splitting the remaining 80% of the dataset into subsets to train and validate the model iteratively, k times. In this technique, the dataset is divided into k folds while maintaining the same class distribution in each fold as the original dataset. We chose k=5 for a 5-fold cross-validation. Each fold maintained the proportion of class labels similar to that in the overall dataset. This helped prevent the model from being biased toward the majority class [29].

We conducted a series of experiments to determine the optimal hyperparameters for our model. These included exploring various values for learning rates, weight decay, batch sizes, and the number of training epochs [22]. Our goal was to identify the combination of hyperparameters that produced the best model performance with the highest F1-score. The initial hyperparameters were selected based on the pretrained

XSL•FO
RenderX

BioMedBERT model, and they were changed during the training process iteratively. The final model hyperparameters include a batch size of 32 and a learning rate of 0.00003098.

A regularization term is added to the loss function during training to penalize large weights and prevent overfitting [29]. The modified loss function with weight decay is calculated as follows:

$$\text{Total Loss} = \text{Original Loss} + \lambda 2 \sum i \parallel \theta i \parallel 2$$

Where original loss is the loss without regularization, λ is the weight decay hyperparameter, and Σi ‖ θi ‖ 2 represents the sum of squared weights across all layers of the model.

The value of the weight decay hyperparameter is a crucial aspect of training. It determines the strength of the regularization effect. Too small a value may not prevent overfitting, while too large a value may penalize weights too much and stop the learning process. Moreover, early stopping was applied to the classifier head to prevent overfitting and improve efficiency with a patience of 5 epochs.

By following these steps, we developed a fine-tuned BioMedBERT model capable of classifying publications into the specified categories. This model was rigorously trained, validated, and optimized to maximize the classification accuracy and F_1-score.

Results

To assess each model for generalizability, we evaluated its performance on the test set containing 20% of the final dataset that was randomly stratified and had not been introduced to the model previously.

Baseline Model Performance

After generating features using a FastText model and training the logistic regression model, we evaluated its performance across all classes. While the model demonstrated good performance on the majority class, indicating its efficacy in capturing prevalent patterns within the dataset, its performance on the minority class, IRGT, and SWGRT is suboptimal. Table 1 presents the baseline model's performance across all classes, while Table 2 depicts the confusion matrix of the baseline model. The weighted average for precision, recall or sensitivity, specificity, and F_1-score is 0.85.

Table . Performance metrics of logistic regression model across all classes.

Class	Accuracy	Precision	Recall or sensitivity	Specificity	F_1-score
Negative	0.85	0.87	0.93	0.90	0.90
GRT[a]		0.83	0.81	0.90	0.82
IRGT[b]		0.65	0.45	0.96	0.53
SWGRT[c]		1	0.70	0.98	0.82

[a]GRT: group- or cluster-randomized trial.

[b]IGRT: individually randomized group-treatment.

[c]SWGRT: stepped wedge group or cluster-randomized trial.

Table . Confusion matrix.

Actual	Predicted			
Classes	Negative	GRT	IRGT	SWGRT
Negative	508	27	12	0
GRT[a]	60	269	2	2
IRGT[b]	17	15	26	0
SWGRT[c]	2	14	0	37

[a]GRT: group- or cluster-randomized trial.

[b]IGRT: individually randomized group-treatment.

[c]SWGRT: stepped wedge group or cluster-randomized trial.

Pretrained Versus Fine-Tuned Performance

The low performance of the pretrained BioMedBERT classifier on all classes justifies the fine-tuning of the transformer-based model. Following the fine-tuning process using a training set that was curated by domain experts iteratively, the model's performance exhibited noticeable enhancement in all performance metrics. The inclusion of domain expertise in the data curation process contributed to refining the model's understanding and, consequently, improving its predictive capabilities.

Table 3 shows the performance of the latest version of the fine-tuned model on our test set, which was not seen by the model during training and validation. The confusion matrix, depicted in Table 4, provides a breakdown of the model's predictions against the actual values. The weighted average for precision, recall or sensitivity, specificity, and F_1-score are 0.94.

XSL•FO
RenderX

Table . Performance metrics of fine-tuned BioMedBERT across all classes.

Class	Accuracy	Precision	Recall or sensitivity	Specificity	F_1-score
Negative	0.94	0.96	0.95	0.93	0.95
GRT[a]		0.95	0.94	0.90	0.94
IRGT[b]		0.69	0.81	0.97	0.75
SWGRT[c]		0.96	0.96	0.99	0.96

[a]GRT: group- or cluster-randomized trial.

[b]IGRT: individually randomized group-treatment.

[c]SWGRT: stepped wedge group or cluster-randomized trial.

Table . Confusion matrix.

Actual	Predicted			
Classes	Negative	GRT	IRGT	SWGRT
Negative	518	12	17	0
GRT[a]	14	311	4	2
IRGT[b]	8	3	47	0
SWGRT[c]	0	2	0	51

[a]GRT: group- or cluster-randomized trial.

[b]IGRT: individually randomized group-treatment.

[c]SWGRT: stepped wedge group or cluster-randomized trial.

Discussion

Principal Results

The model developed in this research used data provided by the Office of Disease Prevention at the National Institute of Health and leveraged a transformer-based pretrained language model, BioMedBERT, to identify publications of clinical trials that used one of three nested designs. The model outperformed the baseline model developed using features generated by BioWordVec and logistic regression. Compared to our baseline model, the recall and specificity for each class demonstrated improvements as follows: 2 points for recall and 3 points for specificity in non-randomized class; 13 points for recall and 0 points for specificity in GRT; 36 points for recall and 1 point for specificity in IRGT; 26 points for recall and 1 point for specificity in SWGRT. The IRGT class exhibited the lowest sensitivity compared to other classes, due to fewer examples in the training data and the inherent difficulty in identifying such publications by only processing titles and abstracts. Even for human curators, labeling these publications is challenging, often necessitating meticulous examination of the whole paper's content. Since the fine-tuned model was trained solely on titles and abstracts, it had limited information available for predicting IRGT publications.

Comparison With Prior Work

While machine learning and natural language processing techniques have been utilized to identify RCTs in the medical literature [15], there have been fewer models specifically designed to identify special categories of group randomized clinical trials. Existing models for biomedical document classification predominantly rely on static embedding techniques, such as Word2Vec or FastText, although recent approaches have increasingly adopted nonstatic embedding methods, particularly transformer-based models like BERT and BioBERT, for more dynamic and context-aware text representations [30-32]. Our model leverages attention mechanisms and dynamic embedding techniques to capture the varying importance of words within the context of each document. By dynamically adjusting the embedding representations based on the context of the input sequence, our model can better capture the nuances and semantic relationships within the text, leading to improved classification performance.

Future Work

Moving forward, future research endeavors may focus on refining the model to distinguish between subcategories within each main category, such as the method, protocol, and results [33]. Tailoring the model to address these distinctions could further enhance its utility in biomedical text classification tasks, facilitating more precise and comprehensive literature analysis.

Conclusions

Our study presents a robust framework leveraging transformer-based language models to effectively identify distinct categories of clinical trial publications within the biomedical literature. Through fine-tuning the pretrained BioMedBERT model, we achieved high accuracy and F_1-score metrics across three categories: GRTs, IRGTs, and SWGRTs. The developed framework outperforms conventional search queries, providing advanced language understanding capabilities for discerning a broader spectrum of publications.

XSL•FO
RenderX

Our findings underscore the significance of transformer-based models in biomedical text classification, offering improved performance compared to traditional machine learning approaches and static embedding techniques. By continually updating and refining our model with new training data, we anticipate ongoing improvements in performance and adaptability over time. This iterative approach ensures the model remains up to date on the latest developments in the biomedical field, contributing to more efficient literature exploration, information retrieval, and knowledge discovery.

Abstract

Background: Anemia is a global public health issue causing symptoms such as fatigue, weakness, and cognitive decline. Furthermore, anemia is associated with various diseases and increases the risk of postoperative complications and mortality. Frequent invasive blood tests for diagnosis also pose additional discomfort and risks to patients.

Objective: This study aims to assess the facial spectral characteristics of patients with anemia and to develop a predictive model for anemia risk using machine learning approaches.

Methods: Between August 2022 and September 2023, we collected facial image data from 78 anemic patients who met the inclusion criteria from the Hematology Department of Shanghai Hospital of Traditional Chinese Medicine. Between March 2023 and September 2023, we collected data from 78 healthy adult participants from Shanghai Jiading Community Health Center and Shanghai Gaohang Community Health Center. A comprehensive statistical analysis was performed to evaluate differences in spectral characteristics between the anemic patients and healthy controls. Then, we used 10 different machine learning algorithms to create a predictive model for anemia. The least absolute shrinkage and selection operator was used to analyze the predictors. We integrated multiple machine learning classification models to identify the optimal model and developed Shapley additive explanations (SHAP) for personalized risk assessment.

Results: The study identified significant differences in facial spectral features between anemic patients and healthy controls. The support vector machine classifier outperformed other classification models, achieving an accuracy of 0.875 (95% CI 0.825-0.925) for distinguishing between the anemia and healthy control groups. In the SHAP interpretation of the model, forehead-570 nm, right cheek-520 nm, right zygomatic-570 nm, jaw-570 nm, and left cheek-610 nm were the features with the highest contributions.

Conclusions: Facial spectral data demonstrated clinical significance in anemia diagnosis, and the early warning model for anemia risk constructed based on spectral information demonstrated a high accuracy rate.

Introduction

Background

Anemia is a condition characterized by a decrease in red blood cell count or hemoglobin concentration below a certain threshold, thereby reducing the blood's oxygen-carrying capacity throughout the body. It serves as an indicator of poor nutritional and health status [1]. A study conducted from 1990 to 2019 reported that more than 1.7 billion people worldwide were anemic [2]. Typical symptoms include fatigue, drowsiness, weakness, tachycardia, shortness of breath, increased heart rate, decreased appetite, hypotension, and dizziness [3]. According

XSL•FO
RenderX

to the results of China's fourth nutritional survey, the prevalence of anemia among Chinese residents is 20.1%, and the global prevalence of anemia in all ages is 22.8% in 2019 [4], indicating it has become an important public health issue. In a survey of 13,175 Chinese adults aged >50 years, the prevalence of anemia is 31%, indicating that anemia is particularly prevalent in China's middle-aged and older adult population [5]. Especially among older adults, anemia has been identified as one of the independent risk factors for poor patient outcomes [6]. Studies have found that older adults with anemia were more than twice as likely to suffer from frailty [7], and the survival rate of older adult patients with anemia was significantly lower than that of the nonanemic older adult population [8]. Hemoglobin (Hb) concentration is a reliable indicator for diagnosing anemia [9]. Specifically, a low hemoglobin concentration is strongly correlated with disability, poor physical performance, and declining cognitive ability and strength in aging individuals [10,11], especially so for the oldest individuals [12]. Anemia is associated with a variety of diseases for which there is a negative impact on the patient's prognosis [13]. Additionally, preoperative anemia has been identified as an independent correlation factor of increased postoperative complications and mortality rates [14]. Anemia is often diagnosed by an invasive blood specimen collection method that patients may find uncomfortable, especially for those who are sensitive and fearful of invasive blood tests. Bateman et al [15] conducted a prospective, multicenter, epidemiological, and observational study with 977 children enrolled and found that blood draws accounted for 73% of daily blood loss, and that 96.5% of the children lost blood as a result of blood draws. In fact, frequent drawing of blood can lead to medical anemia.

Current Research on Noninvasive Hemoglobin Detection

Current noninvasive testing methods being explored include photoelectric volumetric pulse wave, spectroscopy, and hyperspectral techniques. For diagnosis via photoelectric volumetric pulse wave, Acharya et al [16] developed a multimodel stacking regressor and estimate the total Hb using noninvasively acquired photoplethysmogram. Spectroscopic techniques explore material properties through the interaction between matter and electromagnetic waves of different frequencies [17]. Hyperspectral imaging techniques provide a more detailed segmentation in spectral dimensions and contain much more information than red, green, and blue [18]. Color measurement in Chinese medicine color diagnosis by visible reflectance spectroscopy is similar to clinical color diagnosis, reflecting the accuracy, authenticity, and reliability of color diagnosis results [19]. Raman spectroscopy can be used to analyze the distribution of metabolite, lipid, protein, water, and blood content in tissues by detecting the skin[20]. Hyperspectral imaging can estimate Hb concentration and blood oxygen saturation by diffuse reflection of tissues [21]. Spectral imaging of sublingual microcirculation was proven to be able to detect anemia [22]. Research on noninvasive Hb measurement using spectroscopy predominantly focuses on areas such as the palm, fingernails, and conjunctiva. Kesarwani et al [23] proposed a noninvasive palm pallor–based anemia detection system, which utilizes a smartphone app to estimate Hb levels by monitoring changes in palm pallor. The system achieved a sensitivity of 0.93, mean squared error of 0.701, and root mean squared error of 0.698. Liu et al [24] used a fingertip measurement method, constructed partial least squares and back propagation artificial neural network models, and developed a portable prototype for their noninvasive Hb detection system. Mannino et al [25] used the color of patients' nail beds from smartphone photos to estimate Hb levels, defining anemia as 11.0 g dL<threshold. The model for the study had a sensitivity and specificity of 0.92 and 0.76 in the classification of anemia versus healthy individuals. Bevilacqua et al [26] proposed an alternative method for noninvasive Hb estimation based on image analysis of specific regions of the conjunctiva; in total, 77 patients with anemia and healthy individuals were studied and modeled using a binary support vector machine (SVM) classifier with a resulting accuracy of 0.844, specificity of 0.824, and sensitivity of 1.000. Kalantri et al [27] conducted a blind, independent comparison of the presence and absence of pallor in physical features (including conjunctiva, tongue, palms, and nail beds) and a reference standard (Hb estimated by an electronic cell counter). Diagnostic accuracy was measured by calculating likelihood ratios, 95% confidence intervals for different Hb thresholds, and the area under the characteristic curve of the subjects. The area under the characteristic curve was 0.84 and 0.71 for Hb of 7 g/dL and 9 g/dL as cutoffs. Wang et al [28] developed HemaApp, which uses a smartphone camera and different light sources to noninvasively monitor Hb concentration based on photoelectric volumetric pulse wave techniques. HemaApp was evaluated on 31 patients, with a light source passing through the patient's finger for chromatic analysis to estimate the Hb concentration by blood color. Regression analysis of Hb concentration was performed in the paper for different light sources: when white +970 nm LEDs were used, R=0.69; when white +970 nm LEDs + incandescent were used, R=0.74; when white + 880 nm and 970 nm LEDs + incandescent were used, R=0.82.

Facial diagnosis is an important and intuitive method of traditional Chinese medicine (TCM). The facial features of patients with anemia always differ from those of healthy persons, usually showing a pale complexion [27]. Pallor of the conjunctiva, palms, nail beds, or any part of the body is associated with significantly lower Hb concentrations [29]. The continuous development of intelligent diagnostic methods has provided classification models for recognizing facial complexions, which to some extent avoids the subjective limitations of the traditional facial diagnosis that are qualitative and experience-based [30]. An increasing number of experts are integrating color optical theories and modern instrumentation into the modern research field of TCM diagnosis, making the research more scientific and objective, and avoiding biases caused by human factors [31]. However, there is currently a lack of formal studies focusing on noninvasive, spectral Hb monitoring of the facial region [32].

Goals

Based on this, we collected data from patients with anemia and healthy controls, analyzed the spectral reflectance and image features of their faces, and built an anemia classification model based on machine learning (ML) methods. The results showed

XSL•FO
RenderX

that patients with anemia generally have a paler complexion, with the most noticeable differences located in the nose, right cheek, right zygomatic, and jaw.

Methods

General Description of Participants

To control for variables such as age, locale, and gender, we implemented rigorous matching criteria. Between March 2023 and September 2023, we collected data on people who underwent routine physical examinations at the Shanghai Jiading and Gaohang Community Health Centers, from which we randomly selected 78 healthy individuals, consisting of 38 males (49%) and 40 females (51%), aged 45 to 85 years, with a mean age of 68 years. Additionally, from August 2022 to September 2023, we gathered data from patients admitted to the hematology ward at the Shanghai Hospital of Traditional Chinese Medicine, ultimately analyzing 78 patients with anemia consisting of 38 males (49%) and 40 females (51%) aged 45 to 85 years, with a mean age of 67 years. This anemia group contained 26 mild (33%), 26 moderate (33%), and 26 severe cases (33%) of anemia.

Diagnostic Criteria

According to the diagnostic criteria established by Chinese hematologists [33], in China, anemia can be diagnosed in adult males with a Hb level ≤120 g/L and in adult females (nonpregnant) with Hb ≤110 g/L. Within this range, Hb ≥90 g/L is considered mild anemia, 60 g/L≤ Hb ≤89 g/L is considered moderate anemia, and 30 g/L≤Hb ≤59 g/L is considered severe anemia.

Inclusion and Exclusion Criteria

The inclusion criteria for the healthy control group is as follows: (1) the absence of any acute or chronic diseases according to clinical diagnostic criteria (no diagnosis of any acute disease within 3 months, and no diagnosis of any chronic disease within 6 months), (2) no current medication use or other irregularity found in the blood, and (3) regular urine, liver, and kidney functions.

The inclusion criteria for the anemia group is as follows: (1) the patient's Hb value must meet the diagnostic criteria for anemia [33]; (2) the patient exhibits symptoms of anemia, such as pale complexion, lips, or nails, fatigue, weakness, shortness of breath, and resting tachycardia [3,34]; and (3) the patient's age is between 45 and 85 years. Both male and female patients were included.

The exclusion criteria for the anemia group is as follows: (1) the patient requests to withdraw informed consent; (2) the patient is unable to meet the inclusion criteria; (3) presence of severe cardiovascular, cerebrovascular, endocrine, motor, autoimmune, or infectious diseases; (4) presence of mental illnesses or disorders of consciousness and communication; (5) patients undergoing blood transfusion; and (6) pregnant and breastfeeding women, or those preparing for pregnancy.

Observation Methods

Facial spectroscopic data of the healthy controls and patients with anemia were collected using a CS-600CG spectrophotometric colorimeter (Figure 1).

Figure 1. CS-600CG Spectrophotometer

To obtain more comprehensive facial information, we selected 8 points on the subjects' faces: the forehead, glabellum, nose, jaw, right zygomatic, left zygomatic, right cheek, and left cheek. It should be noted that subjects were required to be free of cosmetics and maintain a natural facial complexion during data collection. The following specific steps were taken: (1) calibrate the spectrometer and adjust the parameters to standard values; (2) instruct subjects to keep their faces clean; (3) sterilize the instrument with 75% medical alcohol; (4) position the collection port against the subject's skin and collect data at the following locations in the order specified: forehead, glabellum, nose, jaw, right zygomatic, left zygomatic, right cheek, and left cheek; and (5) verify the consistency of the collected data and minimize excessive variability between each facial area.

XSL•FO
RenderX

Statistical Analysis

We used SPSS (version 25.0; IBM Corp) for statistical analysis. Data satisfying normality were expressed as mean (SD), whereas data not satisfying normality were expressed as median (IQR). The significance level was set at α=.05. To compare the 2 groups, independent samples *t* tests were used for data that were normally distributed and demonstrated homogeneity of variance; otherwise, Mann-Whitney *U* tests were applied. All tests were 2-tailed, and a P<.05 was considered to indicate statistical significance. To compare the 4 groups, 1-way ANOVAs were used for data that were normally distributed and exhibited homogeneity of variance; Kruskal-Wallis tests were applied for data that were not normally distributed or exhibited inhomogeneity of variance. All tests were 2-tailed, and a P<.05 was considered to indicate statistical significance.

Model Selection

After selecting feature factors from all independent variables, we divided patients with anemia and healthy controls into training and test sets. Multiple ML classification models were then applied for a comprehensive analysis to compare the discriminative performance of different models. Additionally, we evaluated and validated the results using the optimized model. A SHAP demonstration model was also developed. The specific steps are as follows:

1. Feature selection: Initially, we conducted the least absolute shrinkage and selection operator (LASSO) regression analysis in R to adjust variable selection and complexity. Subsequently, the results from the LASSO regression analysis were utilized as feature variables for machine learning.

2. Data division: To prevent randomness in modeling results, we classified patients with mild, moderate, and severe anemia according to the diagnostic criteria established by Chinese hematologists. Using average random sampling, we divided the data proportionally for training and validating the classification model: 108 cases (70%) for the training set and 48 cases (30%) for the test set.

3. Comprehensive analysis of multiple classification models: We utilized an open-source version of Python 3.7 for our analysis. Subsequently, we used various functions from the scikit-learn library via Python 3.7, applying LASSO regression to extract different spectral bands as feature bands. We constructed a risk warning model for anemia using 10 ML algorithms: logistic regression, decision tree, SVM, random forest, k-nearest neighbor (KNN), artificial neural network (ANN), Bayesian classifier, extreme gradient boosting (XGBoost), adaptive boosting (AdaBoost), and light gradient boosting machine (LightGBM).

Logistic regression is used for binary and multiclass classification, using maximum likelihood for parameter estimation [35]. Decision tree uses tree diagrams for decision-making, handling classification and regression without data standardization [36]. SVMs find optimal hyperplanes for classification, using kernel tricks for complex issues [37]. Random forest uses multiple trees for better stability and accuracy, ideal for high-dimensional datasets [38]. KNN predicts by nearest categories, which is best for simple, small-scale datasets [39]. ANNs learn complex data relationships through neural connections, great for nonlinear and large datasets [40]. Bayesian classifiers use Bayes' theorem for probabilistic outputs, suitable for medical diagnostics [41]. XGBoost optimizes boosting trees for performance and efficiency, excelling in large or feature-rich datasets [42]. AdaBoost improves classification by adjusting for misclassified samples, using multiple weak classifiers [43]. LightGBM focuses on efficient learning with high precision and speed, and it is optimized for distributed environments [44]. We then trained and tested the above parameterized models, analyzed the importance of the training set and testing set indicators in different models, and selected the optimal one. Python 3.7 was used to construct the area under the receiver operating characteristic curve (AUROC), which is often used to describe tools for diagnostic testing or the identification accuracy of predictive models [45]. Python 3.7 was used to plot precision-recall (PR) curves, which were widely used to evaluate the performance of models. PR and the area under the PR (average precision [AP]) curve can provide a valuable complement to existing model evaluation methods [46]. Python 3.7 was used to plot the decision curve analysis (DCA), essentially the decision analysis. Thus, with these evaluations, it was possible to determine the viability of a given model, as well as which of several models was optimal, with significant advantages in assessing the clinical applicability of the model [47]. Also, we evaluated the performance of the classification models using a range of metrics, including accuracy, sensitivity, specificity, F_1-score, AUROC, positive predictive value (PPV), and negative predictive value (NPV). The formulas for accuracy, sensitivity, specificity, precision, F_1-score, PPV, and NPV are as follows:

(1)Accuracy=TP+TNTP+TN+FP+FN

(2)Sensitivity=TPTP+FN

(3)Specificity=TNTP+FP

(4)Precision=TPTP+FP

(5)F1=2×Precision×SensitivityPrecision+Sensitivity

(6)PPV=TPTP+FP

(7)NPV=TNTN+FN

4. We used SHAP library via Python 3.7 to plot the SHAP interpretation of importance and contribution to the model and interpreted the model results by calculating the contribution of each feature to the prediction results.

Ethical Considerations

The studies involving human participants were reviewed and approved by the Ethics Committee of Shanghai Municipal Hospital of Traditional Chinese Medicine affiliated to Shanghai University of Traditional Chinese Medicine (registration number 2021SHL-KY-03-01) and the institutional review board of Shuguang Hospital affiliated with Shanghai University of Traditional Chinese Medicine (registration number 2018-626-55-03). Informed consent was obtained from all subjects involved in the study. The privacy and confidentiality of patients' personal information were strictly protected throughout the research process. All patient data were anonymized and stored securely.

Results

Participant Characteristics

The baseline characteristics of the first 2 healthy and patient groups are shown in Table 1 and the baseline characteristics of the latter healthy and patient groups classified by severity group are shown in Table 2.

Table . Baseline comparison of 2 groups (n=156).

Characteristics	Healthy controls (n=78)	Patients with anemia (n=78)	*P* value
Gender, n (%)			
Male	38 (49)	38 (49)	1.00
Female	40 (51)	40 (51)	
Age (years), mean (SD)	67.03 (10.62)	68.24 (4.68)	.94

Table . Baseline comparison of 4 groups (n=104).

Characteristics	Healthy controls (n=26)	Anemia patients (n=78)			*P* value
		Mild (n=26)	Moderate (n=26)	Severe (n=26)	
Gender, n (%)					
Male	13 (50)	12 (46)	14 (54)	12 (46)	.94
Female	13 (50)	14 (54)	12 (46)	14 (54)	
Age (years), mean (SD)	67.03 (10.62)	70.35 (11.03)	65.19 (11.14)	65.54 (9.19)	.11

The results indicate that there were no statistically significant differences in gender and age distribution among the 2 or 4 groups (χ^2 test for gender, Kruskal-Wallis test for age).

Statistical Analysis of Facial Spectral Data

The results (Multimedia Appendix 1) showed statistically significant differences in spectral reflectance at specific wavelength ranges between the 2 groups ($P<.05$), including the forehead (400 - 600 nm), glabellum (400 - 700 nm), nose (400 - 700 nm), jaw (400 - 610 nm), right zygomatic (400 - 700 nm), left zygomatic (400 - 470 nm and 500 - 610 nm), and right cheek (400 - 700 nm). Additionally, significant differences were noted at the forehead (400 - 420 nm, 520 - 590 nm, 690 - 700 nm), glabellum (400 - 700 nm), nose (400 - 700 nm), jaw (470 - 500 nm), right zygomatic (400 - 700 nm), left zygomatic (440 - 700 nm), right cheek (400 - 700 nm), and left cheek (400 - 600 nm, 650 - 700 nm) between the 4 groups ($P<.05$).

To directly observe and understand the differences in facial spectral images between the anemia group and the healthy group, we plotted the average spectra at 8 locations for both the anemic and healthy groups, as depicted in Figure 2. The red line represents the average spectral reflectance of the anemic group, while the green line represents that of the healthy control group. It is evident that at the glabellum, nose, right zygomatic, and right cheek locations, the spectral reflectance of the anemic group is significantly higher than that of the healthy control group. Similarly, at the forehead, jaw, left zygomatic, and left cheek locations, the spectral reflectance of the anemic group remained significantly higher, particularly in the 480 - 630 nm range.

Figure 2. Comparison between 2 groups of spectral lines for 8 positions: (**A**) the spectral reflectance of the forehead, (**B**) the spectral reflectance of the glabellum, (**C**) the spectral reflectance of the nose, (**D**) the spectral reflectance of the jaw, (**E**) the spectral reflectance of the right zygomatic, (**F**) the spectral reflectance of the left zygomatic, (**G**) the spectral reflectance of the right cheek, and (**H**) the spectral reflectance of the left cheek.

XSL•FO
RenderX

Furthermore, to directly observe and understand the differences in facial spectral images between the anemia group and the healthy control group, we plotted the average spectra of the healthy control group and the mild, moderate, and severe anemia groups across a total of 4 groups at 8 positions, as shown in Figure 3. The red line represents the average spectral reflectance of the moderate anemia group, the yellow line represents that of the severe anemia group, the blue line represents the spectral reflectance of the mild anemia group, and the green line represents the average spectral reflectance of the healthy control group.

We observed that the spectral reflectance of both the healthy control group and the severe anemia group is significantly different from that of the other groups at all 8 positions. Moreover, a gradual decrease in spectral reflectance is noted from the severe anemia group to the moderate anemia group, then to the mild anemia group, and finally to healthy individuals across the 400 - 630 nm wavelength interval. This gradient of decrease was particularly pronounced at the nose.

Screening of Characteristic Factors for Risk of Patients With Anemia

Using the presence or absence of anemia as the dependent variable, we performed LASSO regression analysis on 217 independent variables exhibiting statistical differences (Figure 4). LASSO can compress variable coefficients to prevent overfitting and address severe collinearity issues [48]. The results showed that (lambda with minimum mean square error=0.009) 217 independent variables were reduced to 20 (20/217, 9%). The selected variables included glabellum-570 nm, right cheek-520 nm, right zygomatic-570 nm, jaw-570 nm, left cheek-610 nm, left cheek-700 nm, nose-700 nm, jaw-490 nm, nose-490 nm, left zygomatic-500 nm, jaw-610 nm, left cheek-420 nm, forehead-420 nm, nose-400 nm, right cheek-640 nm, right zygomatic-670 nm, glabellum-660 nm, glabellum-670 nm, jaw-420 nm, and glabellum-420 nm.

Figure 4. LASSO regression analysis was used to select characteristic factors. (**A**) The use of 10-fold cross-validation to draw vertical lines at selected values, where the optimal lambda produces 20 nonzero coefficients. (**B**) In the LASSO model, the coefficient profiles of 217 features were drawn from the log (λ) sequence. Vertical dotted lines are drawn at the minimum mean square error (λ=0.009) and the standard error of the minimum distance (λ=0.020). LASSO: least absolute shrinkage and selection operator.

Comprehensive Analysis of Classified Multimodel

We included locations and bands that exhibited statistically significant differences as identified in our statistical analyses and used these to construct various models. Specifically, we used logistic regression, decision tree, SVM, random forest, KNN, ANN, Bayesian classifier, XGBoost, AdaBoost, and LightGBM algorithms.

By using both the anemia group and the healthy control group as evaluation test sets, we evaluated the performance of the 10 ML methods, with the results summarized in Table 3.

The SHAP to the Test Model Interpretation

Since the SVM classification produced the best results, to intuitively interpret the selected variables, we used SHAP to illustrate how these variables contribute to the diagnosis of anemia within the SVM algorithm [49]. Figure 6A displays the 20 features extracted by LASSO regression. The vertical axis orders the features according to the sum of SHAP values for all samples, and the horizontal axis represents the SHAP values (the distribution of the feature's impact on the model's output); each point represents a sample, with the sample size stacked vertically. In each feature importance line, the corresponding results for all subjects are plotted with points of different colors, where red points denote high-risk values and blue points denote low-risk values. The results indicate that glabellum-570 nm, right cheek-520 nm, right zygomatic-570 nm, jaw-570 nm, left cheek-700 nm, nose-490 nm, nose-400 nm, glabellum-670 nm, and glabellum-420 nm positively impacted the diagnosis of anemia, while left cheek-610 nm, nose-700 nm, jaw-490 nm, left zygomatic-500 nm, jaw-610 nm, left cheek-420 nm, forehead-420 nm, right zygomatic-670 nm, right cheek-640 nm, glabellum-660 nm, and jaw-420 nm negatively impacted the diagnosis of anemia. Figure 6B shows the ranking of the 20 risk factors assessed by the average absolute SHAP values, with the x-axis representing SHAP values that indicate the importance of the predictive model.

Figure 6. SHAP interprets the model. (**A**) Attributes of characteristics in SHAP. Each line represents a feature, and the abscissa is the SHAP value. Red dots represent higher eigenvalues and blue dots represent lower eigenvalues. (**B**) Feature importance ranking as indicated by SHAP. The matrix diagram describes the importance of each covariate in the development of the final prediction model. SHAP: Shapley additive explanations.

Discussion

Principal Results

The findings of this study revealed that the spectral reflectance at most characteristic facial sites and bands was significantly higher in the anemia group than in the healthy control group, with particularly notable increases at some specific sites and bands. Incorporating facial spectral data into the modeling dataset facilitates the creation of an improved classification model, building upon previous studies.

As depicted in Figure 2, reflectance at forehead 410 - 600 nm is higher in patients with anemia than in healthy controls. For the glabellum, nose, right zygomatic, right cheek, and left cheek, the spectral reflectance of patients with anemia from 400 - 700 nm is higher than that of healthy controls. Reflectance at jaw 430 - 610 nm, left zygomatic 400 - 540 nm, and 510 - 600 nm are higher than that of healthy controls. This study reveals a statistically significant increase in facial spectral reflectance among individuals with anemia compared to healthy controls. Several physiological mechanisms may contribute to the observed increase in reflectance.

First, changes in Hb concentration are a critical factor [50]. Hemoglobin, a light-absorbing component of blood, has a decrease in concentration with anemia, potentially enhancing light reflectance through tissues at specific wavelengths. This is particularly noticeable in the nose region. Second, alterations in blood oxygen saturation could play a role [51]. Reduced oxygen binding to Hb in anemic conditions could diminish the light absorption capacity, thereby increasing reflectance at certain wavelengths. It is feasible to use spectroscopy to detect skin oxygen saturation [52]. Additionally, anemia may induce changes in tissue moisture content, which in turn can modulate the optical behavior of tissues and influence light reflectance. The intensity of the absorption spectrum is proportional to the moisture content of the skin [53].

XSL•FO
RenderX

We used LASSO regression analysis to identify the 217 independent variables that showed statistically significant differences. This approach allowed us to compress variable coefficients and address collinearity issues, ultimately reducing the number of independent variables to 20. The selected variables, such as glabellum-570 nm, right cheek-520 nm, and left cheek-700 nm, highlight specific facial regions and wavelength bands that are associated with anemia risk. These findings suggest that certain spectral characteristics of the face may serve as indicators of anemia, warranting further investigation into the underlying physiological mechanisms.

To comprehensively analyze the classifiers in a multimodel comparison, we used 10 different ML algorithms, including logistic regression, decision tree, SVM, random forest, KNN, ANN, Bayesian classifier, XGBoost, adaptive boosting, and LightGBM. The performance of these models was evaluated using 2 distinct test sets, and the results indicated that the SVM prediction model demonstrated the best overall performance.

Within the SVM algorithm, we used the SHAP method to further explain the selected variables and their contribution to the diagnosis of anemia. The SHAP values provided intuitive insights into the impact of each feature on the model's output. For instance, glabellum-420 nm, 570 nm, and 670 nm; nose-400 nm and 490 nm; jaw-570 nm; right cheek-520 nm; right zygomatic-570 nm; and left cheek-700 nm positively impacted the diagnosis of anemia, while glabellum-660nm; forehead-420nm; jaw-420, 490, and 610 nm; nose-700 nm; right zygomatic-670 nm; left zygomatic-500nm; right cheek-640 nm; and left cheek-420 and 610 nm negatively impacted the diagnosis. These findings suggested that specific spectral characteristics may play a crucial role in distinguishing between anemic and healthy individuals.

Application and Advantages of Noninvasive Spectral Techniques in Anemia Diagnosis

According to the final model of this study, anemia was found to be strongly correlated with facial spectral reflectance at specific locations and bands. Therefore, incorporating facial spectral information into the modeling dataset can create a better classification model based on previous studies.

A plethora of studies have integrated advanced ML algorithms with spectral data, resulting in the development of predictive models that not only diagnose anemia but also predict the risk of disease onset in vulnerable populations. Noninvasive Hb measurement techniques have been developed to assess various sites on the human body, including fingers, palpebral conjunctiva, nail beds, bulbar conjunctiva, and other localized skin [32]. The ability to monitor Hb levels without the need for invasive procedures or complex equipment is expected to greatly enhance health care delivery in various settings, thereby contributing to the global effort to reduce the burden of anemia.

The face is not only the most exposed and conveniently assessable part of the human body but also holds significant importance in TCM diagnostics, where facial diagnosis plays a crucial role.

This study has unique advantages when targeting specific populations and environments. For particular groups, such as patients with anemia with low Hb levels, frequent invasive testing methods can lead to additional blood loss, therefore, using noninvasive spectroscopic detection technology can reduce the risk of blood loss. In specific environmental conditions, such as health check-ups for older individuals in the community, noninvasive spectral detection methods demonstrate their convenience and speed, with lower skill requirements for operators. Furthermore, in environments with a high incidence of infectious diseases, the implementation of noninvasive testing methods can significantly reduce the risk of group infections compared to traditional invasive testing techniques.

Based on the model of this study, strong correlations exist for facial spectral reflectance at specific locations and bands. Consequently, incorporating facial spectral information into the modeling dataset, building upon previous research, allows for the creation of an improved classification model. Given that pallor is often a common symptom of anemia [29,54-56], and the face is the most directly exposed part of the body, it serves as an important diagnostic tool. It is an important and intuitive diagnostic method. Therefore, it is necessary to establish a predictive model for anemia risk based on facial visible light reflection spectra. Future research will explore transitioning from contact spectroscopy to noncontact hyperspectral devices.

Limitations

This study possesses several limitations. First, the sample size is small, necessitating future studies to use larger, multicenter cohorts. Second, the study's focus on the middle-aged and older adult population suggests a need for future research to broaden the age range to enhance generalizability. Last, while facial coloration is influenced by various factors, this study controlled for common medical research variables. For the anemia group, additional physiological and biochemical markers that could affect facial coloration have not been considered. Future studies should aim to exclude the influence of such markers, including bilirubin, to provide a more comprehensive understanding of anemia-related facial spectral reflectance.

Conclusion

Facial spectral data of patients with anemia showed distinctive features and correlations. These indicators were of greater significance for the differential diagnosis of anemia, including specific bands such as the glabellum at 570 nm, the nose at 400 nm, the right zygomatic at 400 nm, the right cheek at 530 nm, the left zygomatic at 400 nm, and the left cheek at 700 nm. They emphasized the subtle differences in light absorption and reflection associated with different degrees of anemia. In conclusion, this study constructed a predictive model based on the ML model, and the SVM model demonstrated superior performance in this study. In addition, we provided a personalized risk assessment for the development of patients with anemia explained by SHAP. This effective computer-aided approach can help first-line clinicians and patients identify and intervene early in the case of anemia. It holds promise for future applications in noninvasive diagnosis and population screening for anemia-related conditions.

Abstract

Background: Agitation and sedation management is critical in intensive care as it affects patient safety. Traditional nursing assessments suffer from low frequency and subjectivity. Automating these assessments can boost intensive care unit (ICU) efficiency, treatment capacity, and patient safety.

Objectives: The aim of this study was to develop a machine-learning based assessment of agitation and sedation.

Methods: Using data from the Taichung Veterans General Hospital ICU database (2020), an ensemble learning model was developed for classifying the levels of agitation and sedation. Different ensemble learning model sequences were compared. In addition, an interpretable artificial intelligence approach, SHAP (Shapley additive explanations), was employed for explanatory analysis.

Results: With 20 features and 121,303 data points, the random forest model achieved high area under the curve values across all models (sedation classification: 0.97; agitation classification: 0.88). The ensemble learning model enhanced agitation sensitivity (0.82) while maintaining high AUC values across all categories (all >0.82). The model explanations aligned with clinical experience.

Conclusions: This study proposes an ICU agitation-sedation assessment automation using machine learning, enhancing efficiency and safety. Ensemble learning improves agitation sensitivity while maintaining accuracy. Real-time monitoring and future digital integration have the potential for advancements in intensive care.

Introduction

Patients admitted to intensive care units (ICUs) often experience various clinical problems, such as pain, agitation, and delirium. Agitation refers to physical restlessness due to treatment discomfort or delirium; this condition cannot be self-controlled [1]. Agitation is common in patients in ICUs; most of these patients (71%) exhibit agitation on approximately 58% of their total inpatient days [2-4]. Agitation can lead to the accidental removal of tubes and catheters, compromising patient safety, extending ICU stays, and causing complications [5]. Throughout the treatment period, nurses must regularly evaluate the levels of agitation and sedation and titrate the dosages of sedatives accordingly for patient care.

Various scales have been developed for measuring sedation effects. Among them, the Richmond Agitation-Sedation Scale (RASS) is the most reliable and effective [6]. This scale was developed by a multidisciplinary team at Virginia Commonwealth University in Richmond. It employs a simple and clearly defined scoring system with distinct standards for

XSL•FO
RenderX

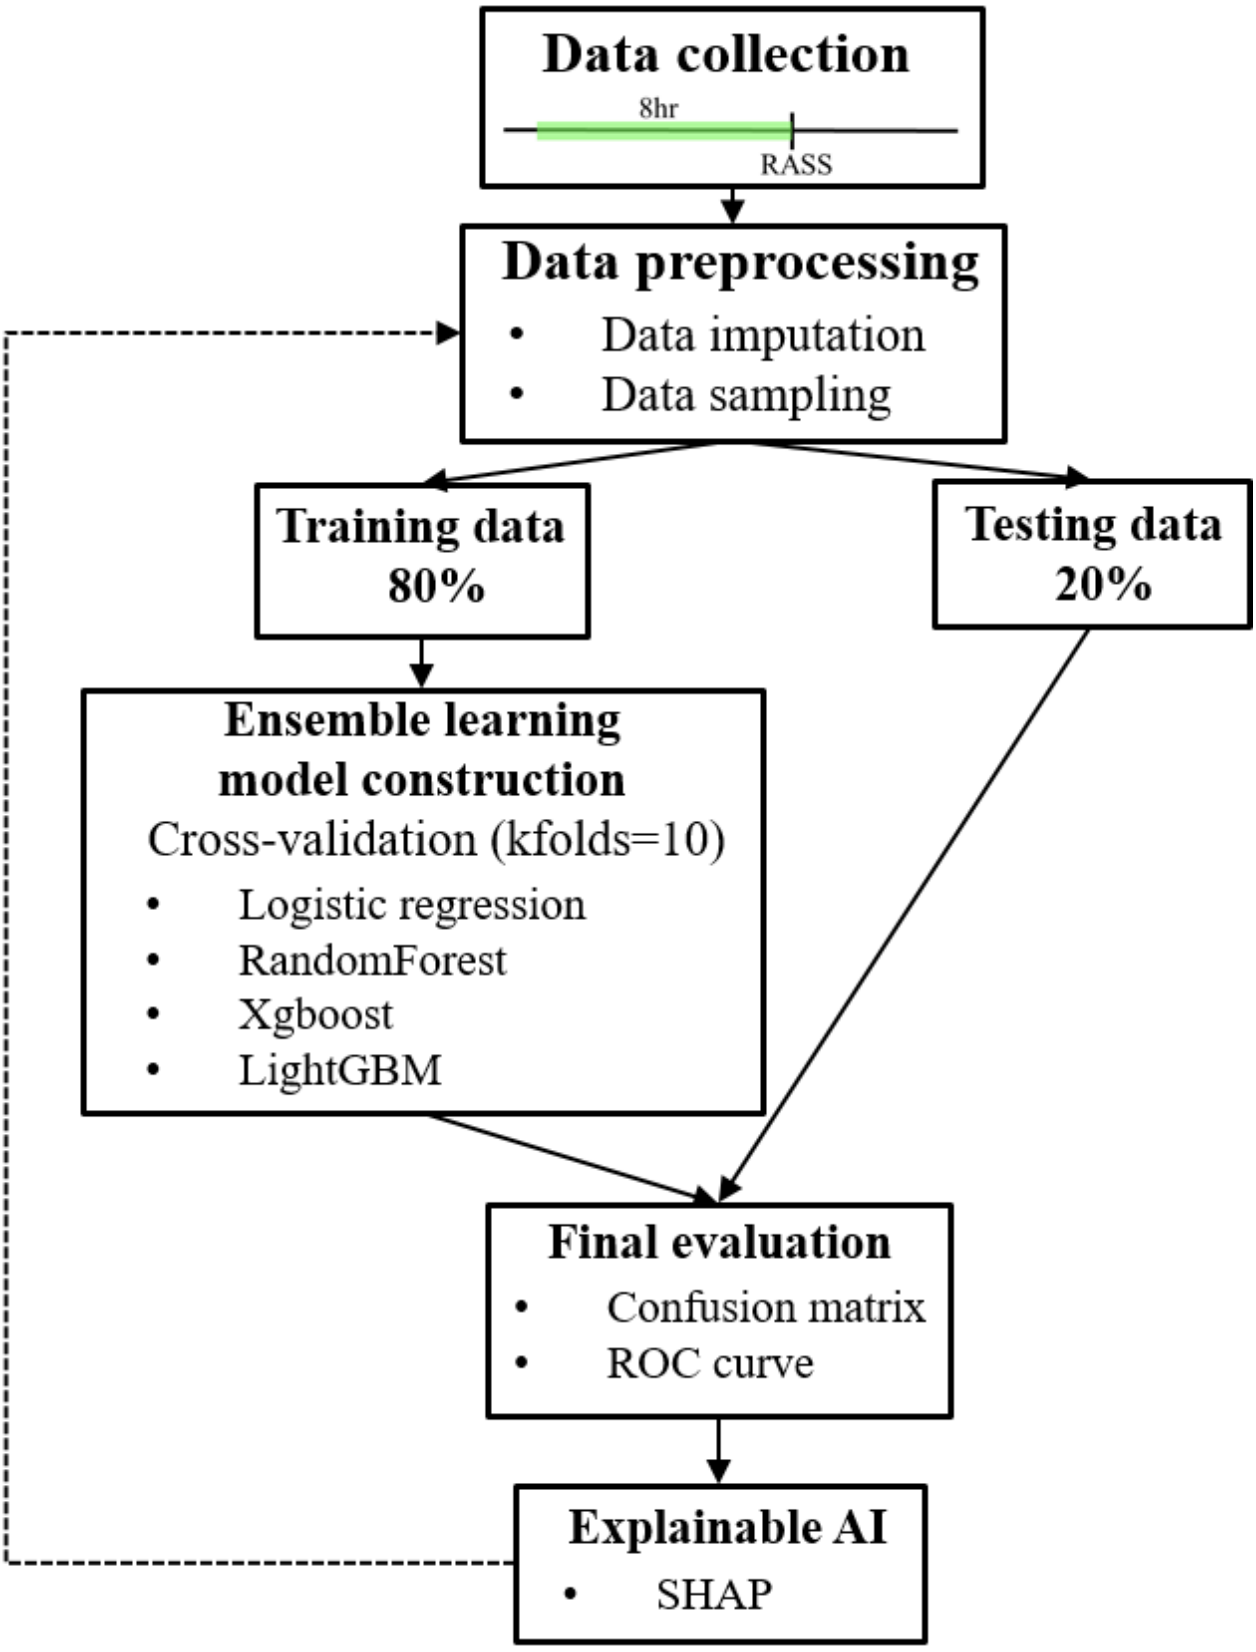
measuring the levels of sedation and agitation. Agitation and sedation levels are represented by positive and negative scores, respectively. The RASS assessment is performed by nurses every few hours, which consumes their significant work time. Reducing the time required for RASS evaluations could increase ICU treatment capacity, thereby improving care quality and patient safety.

However, this scale has some disadvantages, such as low evaluation frequency and high subjectivity, due to variations in patient evaluation standards among medical personnel. Occasionally, nurses may have insufficient knowledge about delirium, which can increase the risk of incorrect evaluations by 20 times [7]. Furthermore, errors in evaluation of patient conditions may result in excessive or insufficient sedation. These issues can be attributed to the subjectivity and uncertainties in the RASS evaluation process, which relies on patients' audiovisual responses, making it is unsuitable for those with severe audiovisual impairment [8]. The RASS facilitates intermittent measurement of agitation levels and assessment of patient behavior; however, unlike activity monitors, it cannot assist in the continuous monitoring of agitation levels [9].

The study's aim was to develop an ensemble learning model for the continuous evaluation of agitation and sedation levels in patients admitted to ICUs. The model is expected to facilitate patient monitoring, provide early warnings about patient behavior, increase assessment frequency, and enable automatic evaluation of patient conditions with treatment suggestions. We believe that this novel design could improve the clinical monitoring of agitation and sedation levels in patients in ICUs, enhance the quality of medical care, and reduce the wastage of medical resources.

Methods

Setting



Taichung Veterans General Hospital (TCVGH) is a 1530-bed medical center in central Taiwan with 7 ICUs comprising a total of 138 beds. We obtained access to the critical care database (AI-111010) of the AI Center of TCVGH. The following data were collected: basic information, disease severity, ventilator use, blood biochemistry, vital signs, catheter types, and medication records.

Research Framework

The study consisted of five major steps: (1) data collection in the ICU, (2) data preprocessing (data imputation and data sampling), (3) ensemble learning model construction, (4) final evaluation, and (5) implementation of explainable AI (Figure 1).

XSL•FO

Data Preprocessing

Data Imputation

Basic information includes patients' age. Predicting RASS in older patients is more challenging. Regarding disease severity, patients' acute physiology and chronic health evaluation (APACHE II) scores may impact their predicted RASS scores [6,10]. Missing data were imputed using average values.

In addition, the use of ventilators was considered. Ventilator modes were categorized into 3 conditions: no ventilator use, noninvasive ventilator use, and invasive ventilator use. Invasive ventilators may cause discomfort, indirectly affecting RASS scores [8,10-12]. Furthermore, PAW (average airway pressure) values, a ventilator parameter, were estimated accordingly. For patients on ventilators, the average value from all ventilator-wearing patients was used to impute missing data, whereas patients without ventilators were assigned normal random values.

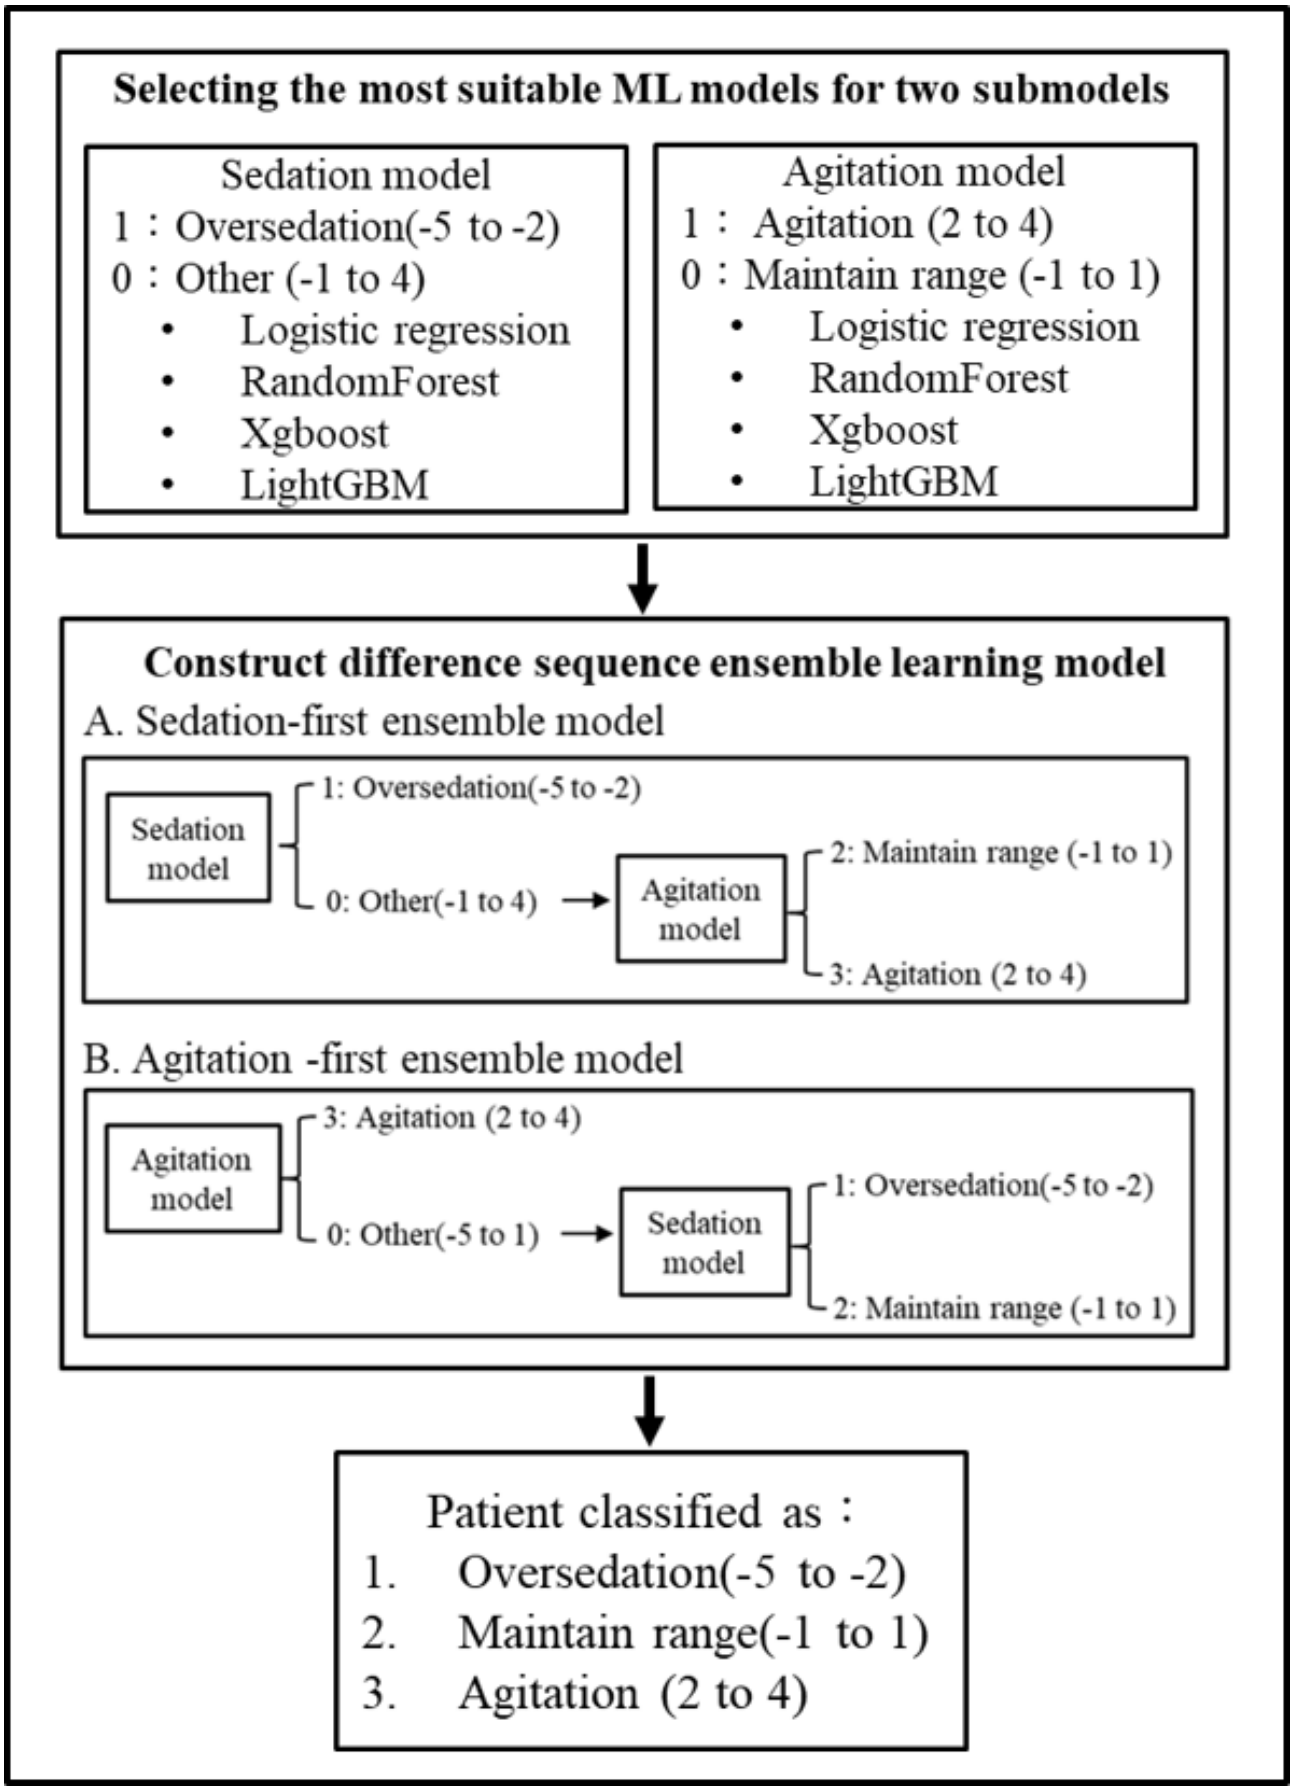
In the category of blood biochemistry, features such as creatinine, lactate, and glucose were included. These were directly associated with patients' physiological conditions [10]. Typically, blood tests were conducted weekly within a 7-day data window. When no blood test data were available within this timeframe, indicating stable patient condition, normal random values were used for imputation.

Vital signs, including blood pressure, pulse rate, and respiratory rate, were indirectly associated with changes in patients' RASS scores [13]. Since vital signs were densely and continuously monitored features, adjacent values were used to fill in missing data directly.

Medication records included the type and dosage of sedatives and analgesics administered to patients, such as benzodiazepine sedatives, muscle relaxants, opioid-related analgesics, antipsychotics, hypnotics, and anesthetics. These drugs can directly or indirectly influence patients' consciousness levels and RASS score changes. Due to the varying recording methods for drug dosage across different types of medications, establishing a consistent standard was challenging. Therefore, in this study, the presence or absence of records indicating the use of muscle relaxants or sedative-hypnotics within the past 8 hours was used as a feature for RASS assessment.

Data Sampling

To address severe data imbalance issues (oversedation: 43,199 cases, maintain range: 77,290 cases, agitation: 814 cases), this study employed data oversampling and undersampling techniques to enhance model learning effectiveness. In addition, discussions with clinical experts were conducted to determine the most suitable sampling approach.



Model Construction

Based on clinical care experience, this study proposed an ensemble learning model that integrates two submodels—sedation and agitation—to classify events into oversedation (RASS -5 to -2), maintain range (clinically expected maintenance RASS -1 to 1), and agitation (RASS 2 to 4).

First, the sedation and agitation models were constructed using 4 ML algorithms: logistic regression, random forest, XGBoost, and LightGBM. The algorithm with the best performance was selected as the foundation for both the sedation and agitation models. Subsequently, the two submodels were combined into 2 sequential ensemble learning models: the sedation-first ensemble model and the agitation-first ensemble model. In the sedation-first model, the sedation model was first used to distinguish "oversedation" from "other," and the remaining categories were then input into the agitation model to further differentiate between "maintain range" and "agitation." Conversely, in the agitation-first model, the agitation model was first applied to separate "agitation" from "other," and the remaining categories were then passed into the sedation model to classify "oversedation" and "maintain range." (Figure 2).

XSL•FO
RenderX

Figure 2. Ensemble model construction consisted of 3 steps: (1) Choose a more suitable ML model, (2) Construct difference sequence ensemble learning model, (3) Classify patient into three categories. ML: machine learning

XSL•FO
RenderX

Final Evaluation

We used confusion matrices and the receiver operating characteristic (ROC) curves as indicators to evaluate model accuracy, precision, recall, F1-score, and area under the curve. The ROC curves helped to compare sensitivity with specificity. Effective models exhibited high sensitivity and specificity, resulting in high area under the curve values.

Explainable AI

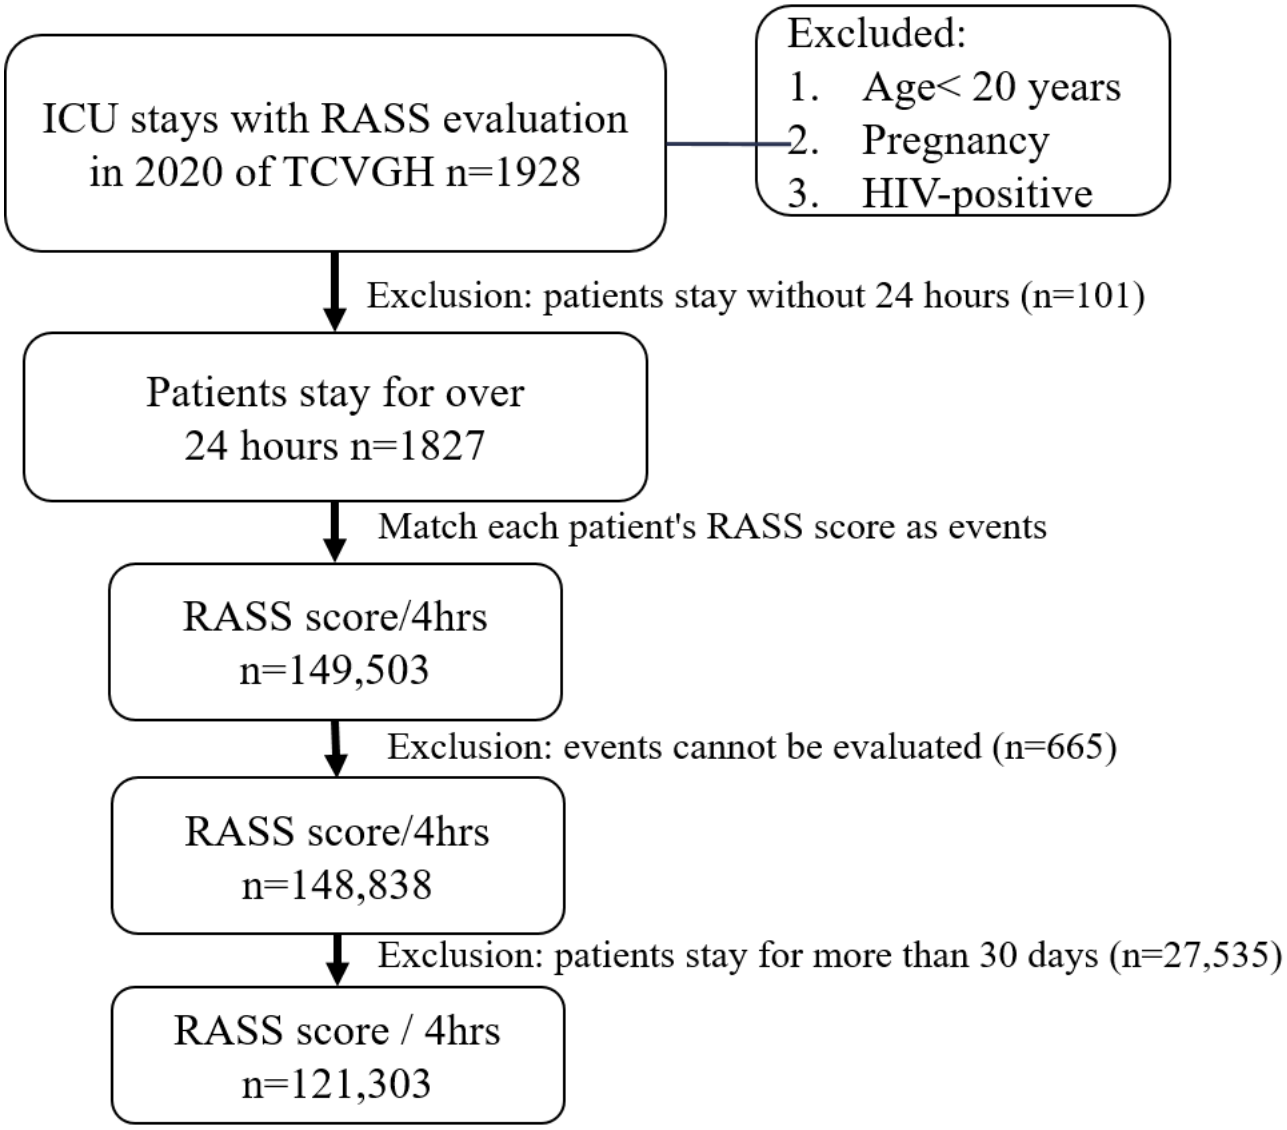
Explainable Artificial Intelligence (XAI) was applied, making the ML system transparent. The top 20 features were selected, and Shapley additive explanations and partial dependence plots were used to visualize their contributions, aiding in understanding the model's decision-making process. Clinical personnel could use this information to offer patient-specific evaluations or decision-making suggestions.

Statistics

This study used statistical methods, including mean (SD) and *t*-test, for numerical data analysis and observation. These methods were used to describe dataset central tendencies, assess variability, and compare group differences. Proportions of each category were also calculated for categorical data. They helped to extract meaningful information and interpret research results.

Ethical Considerations

This study was approved by the TCVGH Institutional Review Board (CE22484A). Informed consent was obtained, with participants given the option to withdraw at any time. For secondary analyses, original consent covered data reuse without additional approval. Data were anonymized to protect privacy, and strict security measures were applied.



Results

Data Collection

This study collected data from adult patients (aged≥20 years) admitted to the ICU at TCVGH between January 1 and December 31, 2020, with an ICU stay lasting more than 24 hours. Every 4-hour RASS assessment (with increased frequency depending on the patient's condition) was considered as a classification event, with events marked as not assessable excluded due to concurrent procedures. Since the average ICU stay did not exceed 30 days, events from ICU stays longer than 30 days were also excluded. A total of 121,306 events were collected, with an average of 108 events per patient (range: 6 to 186). The machine learning (ML) model was trained using data from the 8 hours prior to each event, including ventilator parameters, vital signs, and medication records, along with laboratory biochemical data from the previous week (Figure 3).

XSL•FO
RenderX

Figure 3. Flowchart of subject enrollment. ICU: intensive care unit; RASS: Richmond Agitation–sedation scale; TCVGH: Taichung Veterans General Hospital.

Feature Selection

Based on the literature and clinical experience, the feature selection process in this study involved in-depth discussions with physicians and nurses. During this process, the missing rate of each feature was considered, and features with a missing rate exceeding 20% were excluded. Finally, 23 features were selected, and appropriate imputation methods were applied (Table 1). Categorical features (eg, ventilator modes and medications) were defined based on the presence of recorded events within the past 8 hours. Continuous features such as vital signs and ventilator parameters were calculated as the average values over the past 8 hours, while laboratory test features were based on the most recent record within the past week.

Description of the Study Population

Statistical analysis indicated that nearly all features significantly affect the level of agitation-sedation. Patients with oversedation typically exhibited higher disease severity, lower blood oxygen levels, and a higher proportion of invasive ventilator use. In contrast, patients with agitation showed higher vital sign values and a greater proportion of sedative medication usage (Table 2).

Model Development and Validation

Data Sampling of Agitation Classification

Given the significant class imbalance observed (Table 2), we explored various data sampling methods to enhance the model's sensitivity (recall) for detecting agitated patients. Among these methods, the undersampling approach demonstrated the most notable performance, achieving a sensitivity of 0.82 (Table 3). Consequently, we selected the undersampling method as the data processing strategy.

RenderX

Table . Random forest model performance of different sampling methods for agitation category patients.

Classification	Sampling method (number of patients)	Precision	Recall	F1 score
Agitation Model	Non (n=77288, 814)	0.81	0.26	0.39
	Undersampling (n=642,642)	0.03	0.82	0.06
	SMOTE[a] (n=61834, 61834)	0.28	0.24	0.26

[a]SMOTE: synthetic minority oversampling technique

Performance Comparison of Two Submodels in ML Models

The results of the confusion matrices and ROC curves for the 4 ML models (as shown in Table 4) indicate that the random forest model outperformed the others in both the sedation prediction (accuracy: 0.92, AUC: 0.96) and agitation prediction (accuracy: 0.80, AUC: 0.88). Additionally, the random forest model exhibited superior sensitivity (recall) for detecting agitated patients. Consequently, we selected the random forest model as the foundation for constructing various ensemble learning frameworks to facilitate further analysis and applications.

Table . Four different ML models performance comparison of sedation classification and agitation classification.

Classification and models	Accuracy	Precision	Recall	AUC[a]	Cross-validation Avg-ACC[b] (kfold=10)
Sedation					
Logistic regression	0.72	0.71	0.65	0.71	0.71
Random forest	0.92	0.91	0.91	0.96	0.92
XGBoost[c]	0.92	0.91	0.91	0.94	0.90
LGBM[d]	0.83	0.81	0.83	0.90	0.84
Agitation					
Logistic regression	0.64	0.51	0.61	0.72	0.66
Random forest	0.80	0.03	0.82	0.88	0.77
XGBoost	0.76	0.51	0.76	0.84	0.73
LGBM	0.75	0.51	0.77	0.85	0.75

[a]AUC: area under the curve.

[b]ACC: accuracy.

[c]XGBoost: extreme gradient boosting.

[d]LGBM: light gradient-boosting machine.

Ensemble Learning Model Performance Comparison

The performance results of different sequences of ensemble learning models indicate that prioritizing the identification of agitated patients is more effective in improving sensitivity (recall: 0.82) compared to strategies that first identify oversedated patients. Furthermore, the AUC for all 3 states remained above 0.82 (as shown in Table 5. Given the higher immediate risk associated with agitated patients, the agitation-first ensemble model was selected as the most suitable approach.

XSL•FO

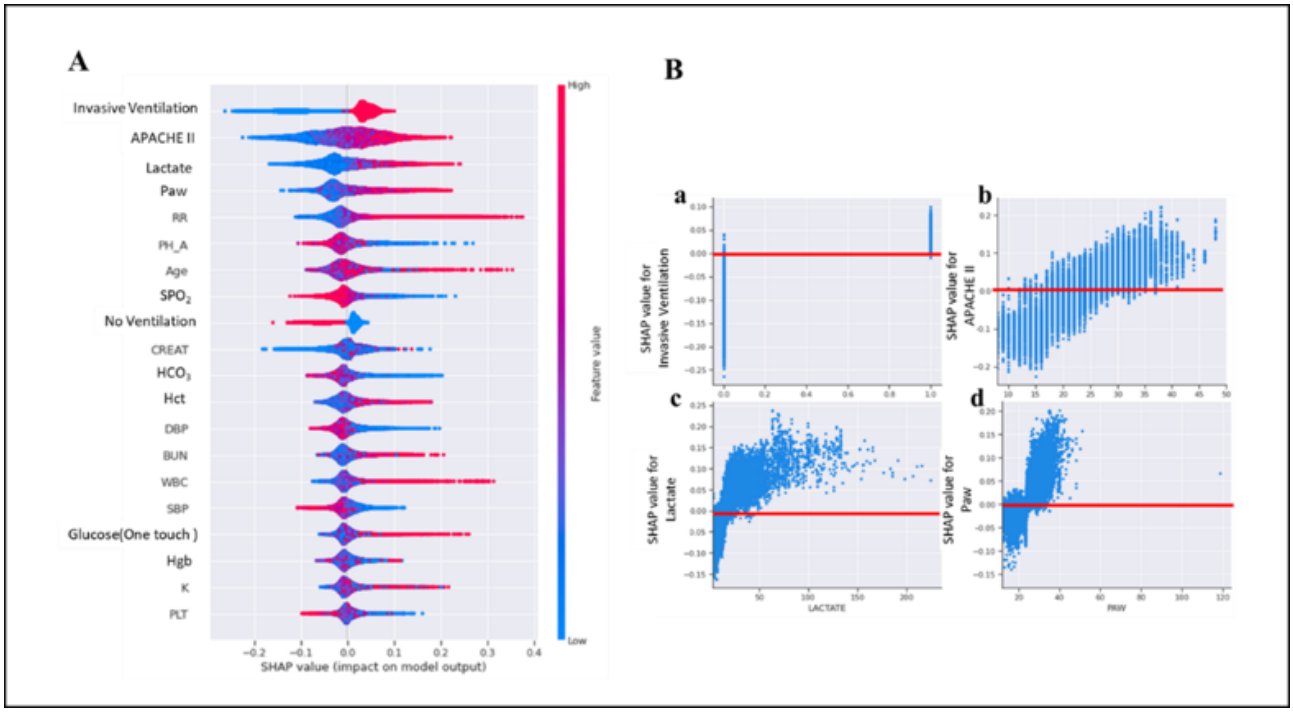
Table . Comparison of performance in classifying the three categories among ensemble learning models with different sequences.

Classification sequence and categories	Accuracy	Precision	Recall	AUC[a]
Sedation-first ensemble model	0.79			
Oversedation		0.91	0.84	0.90
Maintain range		0.92	0.84	0.82
Agitation		0.03	0.76	0.81
Agitation-first ensemble model	0.75			
Oversedation		0.92	0.73	0.85
Maintain range		0.92	0.76	0.82
Agitation		0.03	0.82	0.82

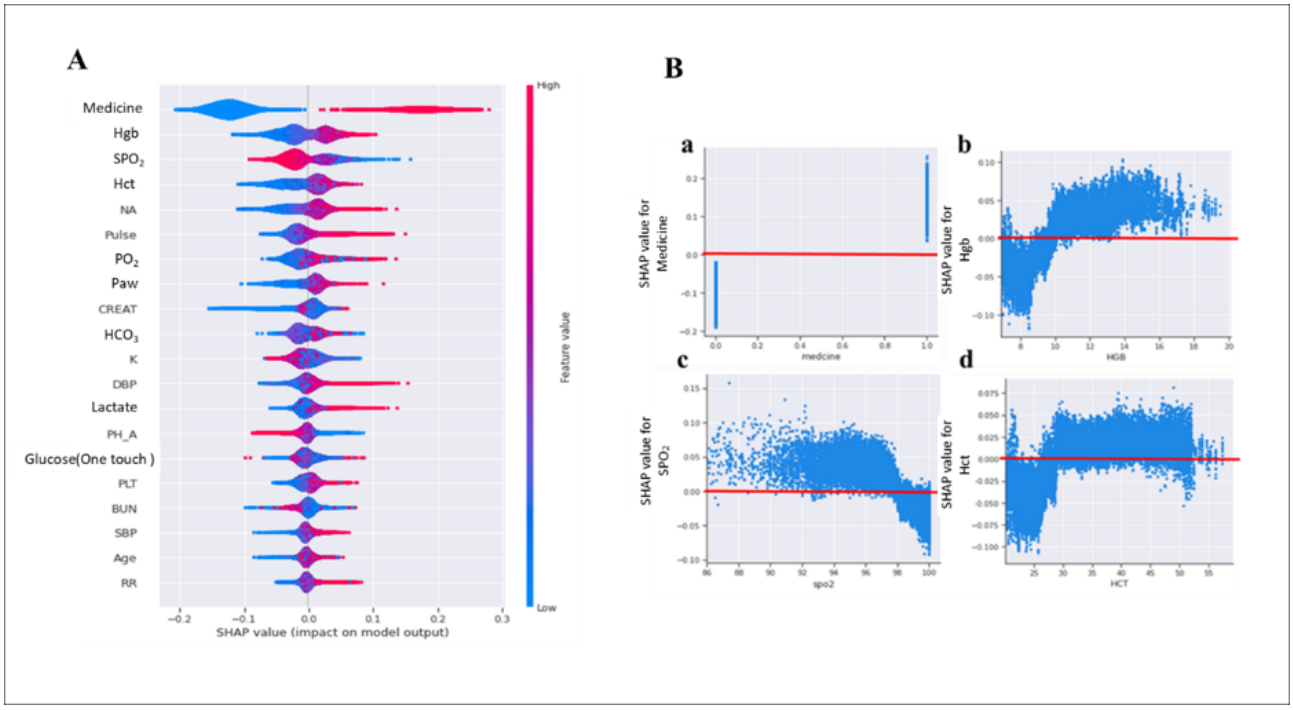
[a]AUC: area under the curve.



Explainable AI (XAI)

The top 4 features that contribute the most to sedation classification are the use of an invasive ventilator (invasive ventilation), APACHE II score, lactate level (LACTATE), and average airway pressure (PAW). A high APACHE II score indicates a high likelihood of oversedation (Figure 4A). The dependency graph of the first 4 features represents how each feature affects the classification results. In most cases, an APACHE II score>29 was positively associated with oversedation (Figure 4B).

Patients who used sedatives were more likely to experience agitation. Patients with a high hemoglobin level were more likely to experience agitation. The dependence plots of the top 4 features indicated that sedative use was positively correlated with agitation. Hemoglobin levels >10 g/dL and≤10 g/dL were positively correlated with agitation and maintained sedation range, respectively (Figure 5).



Overall, patients on mechanical ventilation were mostly sedated, with those in the maintain range exhibiting more stable blood test results and vital signs compared to oversedated or agitated patients.

Discussion

Principal findings

This study successfully developed a model for automating RASS-like agitation-sedation evaluation. Automated agitation-sedation evaluation could be an alternative to RASS and play a crucial role in enhancing ICU efficiency, ultimately improving health care outcomes, care quality, and patient safety.

Machine learning aids ICU personnel in the early detection of high-risk events [14]. Previous studies have used ML to predict mortality rates in ICU patients with acute kidney injury, predict postoperative sepsis mortality rates, and forecast extubation failure in the ICU [15-17]. However, studies on ML for agitation-sedation evaluation in ICU patients are limited.

Zhang et al [18] ensemble 4 machine-learning methods for predicting agitation in ventilated patients under light sedation for 24 hours. However, their ensemble model was limited to predicting agitation in patients with invasive ventilator support under light sedation for 24 hours. Other researchers have proposed using patient body and facial image monitoring for agitation detection [19,20]. However, image monitoring faces challenges such as data acquisition, clinical environment influences, workflow integration, and system installation. Therefore, in addition to the imaging model developed by our research team [21], we have created another model using commonly available feature data in most hospitals, serving as an alternative solution when image monitoring is not feasible.

The study employs 2 ML models for ensemble learning to automate RASS assessment. By using undersampling and adjusting the classification sequence, the sensitivity for detecting agitation is enhanced. Although models with higher sensitivity may reduce the accuracy of classifying over-sedated patients, they perform better in mitigating immediate risks. Traditional methods, which involve manual assessments every 4 hours, result in insufficient monitoring, especially for patients who may experience multiple episodes of agitation within a short period. In contrast, our health care information system can transmit data in real time, perform inference every hour, and adjust inference frequency based on clinical needs, enabling more intensive monitoring. This allows clinicians to track patient conditions and respond promptly to changes continuously.

Understanding algorithmic predictions is crucial in clinical practice. Due to the lack of explanations in the decision-making process, clinicians often distrust black-box models. Explainable artificial intelligence enhances transparency, aiding in the development of reliable decision models [22-24]. Continuous analgesics and sedatives ensure optimal gas exchange between patients and ventilators, making deep sedation important during this period [25]. For patients with stable parameters such as hemoglobin, hematocrit, blood oxygen saturation, and creatinine, the goal is maintaining light sedation (RASS score 0 to −2) [26]. It has been demonstrated that the interpretability of the model aligns with clinical experience.

This study acknowledges its limitations, particularly the imbalance in case numbers due to the high risk of agitation in patients. Especially for agitated individuals, the model's precision of 0.03 suggests there is room for improvement. In future clinical applications, we plan to adjust the decision threshold based on specific needs to balance sensitivity and specificity and reduce false positives. Additionally, the study lacks observations of potential drug overdoses at different sedation levels. Future efforts will focus on integrating this model with digital imaging monitoring and a comprehensive drug dosage system. Real-time monitoring will help identify

XSL•FO
RenderX

patient conditions, guide prescription adjustments, and accelerate recovery, ultimately supporting early intervention, ensuring patient safety, and improving the quality of intensive care.

Conclusions

This study proposes using ML technology to achieve automated RASS-based assessments in ICU settings, enhancing clinical efficiency, and patient safety. Our integrated learning model, combined with the hospital information system, enables real-time data transmission, supports intensive monitoring, and facilitates continuous tracking of patient conditions. The system automatically categorizes patients into three groups, significantly improving sensitivity in detecting agitation categories. This innovative approach not only alleviates the workload of health care professionals but also advances the precision and intelligence of critical care management.

Abstract

Background: Diabetic retinopathy (DR) is the leading cause of preventable blindness worldwide. Machine learning (ML) systems can enhance DR in community-based screening. However, predictive power models for usability and performance are still being determined.

Objective: This study used data from 3 university hospitals in South Korea to conduct a simple and accurate assessment of ML-based risk prediction for the development of DR that can be universally applied to adults with type 2 diabetes mellitus (T2DM).

Methods: DR was predicted using data from 2 independent electronic medical records: a discovery cohort (one hospital, n=14,694) and a validation cohort (2 hospitals, n=1856). The primary outcome was the presence of DR at 3 years. Different ML-based models were selected through hyperparameter tuning in the discovery cohort, and the area under the receiver operating characteristic (ROC) curve was analyzed in both cohorts.

Results: Among 14,694 patients screened for inclusion, 348 (2.37%) were diagnosed with DR. For DR, the extreme gradient boosting (XGBoost) system had an accuracy of 75.13% (95% CI 74.10 - 76.17), a sensitivity of 71.00% (95% CI 66.83 - 75.17), and a specificity of 75.23% (95% CI 74.16 - 76.31) in the original dataset. Among the validation datasets, XGBoost had an accuracy of 65.14%, a sensitivity of 64.96%, and a specificity of 65.15%. The most common feature in the XGBoost model is dyslipidemia, followed by cancer, hypertension, chronic kidney disease, neuropathy, and cardiovascular disease.

Conclusions: This approach shows the potential to enhance patient outcomes by enabling timely interventions in patients with T2DM, improving our understanding of contributing factors, and reducing DR-related complications. The proposed prediction model is expected to be both competitive and cost-effective, particularly for primary care settings in South Korea.

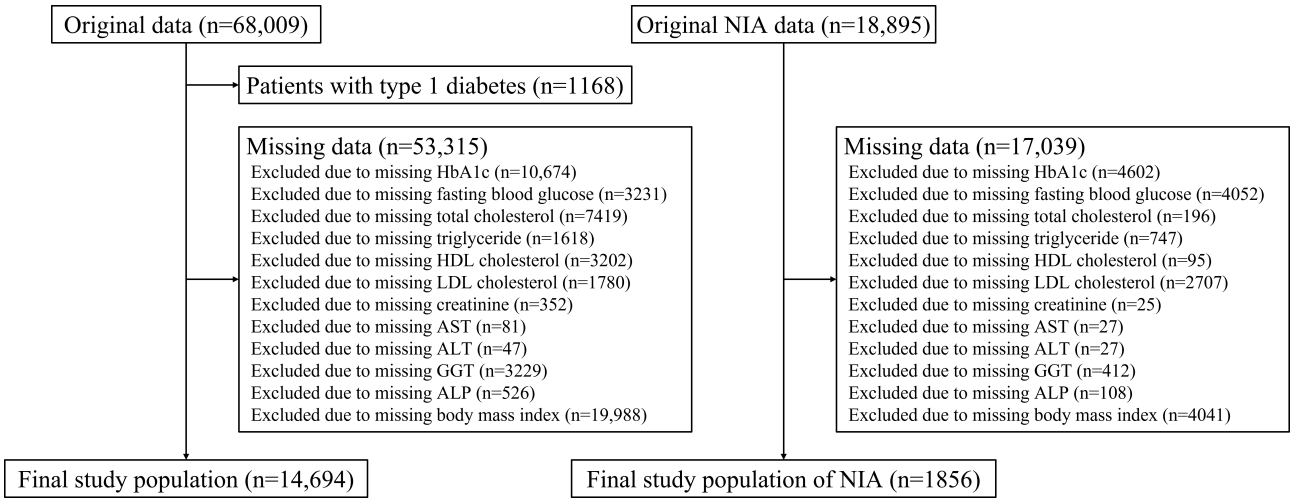
Introduction

The global prevalence of diabetes mellitus (DM) in 2019 was estimated to be 463 million and is expected to reach 700 million by 2045 [1]. Diabetic retinopathy (DR) is the most common complication of DM and a leading cause of preventable blindness in adults [2-4]. The longer the period of diabetes and the lower the blood sugar control, the higher the risk of DR. Particularly, in patients with diabetes for >10 and >15 years, the prevalence of DR was 46.2% and 66.7%, respectively [5]. Additionally, the risk of DR increases by 1.4-fold for each 1% increase in glycated hemoglobin (HbA_{1c}) levels. Moreover,

XSL•FO
RenderX

alongside well-established risk factors, such as poor glycemic control and prolonged diabetes duration, it is important to acknowledge that DR can also manifest in patients with a relatively lower BMI.

DR progression risk factors include both correctable and noncorrectable factors [6,7]. Although DR can be continuously examined and prevented from the beginning, by the time a patient with diabetes experiences symptoms, such as decreased vision due to DR, the disease has already progressed significantly, and serious complications have occurred. Accordingly, the US Centers for Disease Control and Prevention recommends that patients undergo regular tests for DR, even those without symptoms, and receive appropriate management for any identified abnormalities [8,9]. Therefore, patients with diabetes are widely recommended to undergo routine testing annually to prevent DR progression [9].



DR testing requires significant time and effort. However, shortages in trained professionals have been reported. According to a 2022 survey, only 46% of patients with DM in South Korea underwent fundus examination, with examination rates in the mid to high 30% for patients in their 30s to 50s [10]. Effective DR management requires individualized risk models and tools to predict and identify the cause of disease onset. Developing these models can allow for a better prediction of DR risk and improved screening efficiency. DR progression can be prevented using a DR management strategy that focuses on high-risk individuals.

Methods

Study Population and Data Collection

This retrospective study used data from 2 independent longitudinal cohorts as part of an observational study. Data were collected from a hospital between January 1, 2008, and December 31, 2022. Appropriate participants were selected from patients with type 2 diabetes mellitus (T2DM), excluding those with type 1DM (T1DM) and prior cases of DR. Finally, 14,694 patients from a tertiary hospital at Kyung Hee University Medical Center were included in the discovery cohort. Extravalidation data were acquired from a retrospective dataset from Kyung Hee University Hospital at Gangdong and Gachon University Gil Hospital, which included 1856 suitable patients (Figure 1).

Figure 1. Study workflow. ALP: alkaline phosphatase; ALT: alanine transaminase; AST: aspartate transaminase; GGT: γ-glutamyl transferase; HbA_{1c}: glycated hemoglobin; HDL: high-density lipoprotein; LDL: low-density lipoprotein; NIA: National Information Society Agency.

Input Variables

The model encompasses an exhaustive set of 57 variables, including demographic variables such as age, sex, and BMI [11]. Medical history included comorbidities (hypertension and dyslipidemia), macrovascular complications (cardiovascular disease [CVD], dementia, Parkinson disease, and microangiopathic disease), microvascular complications (chronic kidney disease [CKD] and neuropathy), end-stage renal disease, and cancer.

The medication history variables considered the types of drugs used to treat DM (metformin, sulfonylurea, dipeptidyl peptidase-4 inhibitors, meglitinide, thiazolidinedione, α-glucosidase inhibitors, insulin, glucagon-like peptide-1 receptor agonists, and sodium-glucose cotransporter 2 inhibitors), hypertension (angiotensin II receptor blockers, angiotensin-converting enzyme inhibitors, calcium channel blockers, diuretics, and β-blockers), and dyslipidemia (statin, fibrate, and ezetimibe), as well as antiplatelet drugs (aspirin, clopidogrel, cilostazol, and glycoprotein IIb/IIIa antagonists). Blood tests were performed to measure HbA_{1c}, fasting blood glucose, total cholesterol, triglyceride, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, serum creatinine, aspartate aminotransferase, alanine aminotransferase, γ-glutamyl transferase, and alkaline phosphatase. The median and SD of each parameter were used as input variables for the BMI and blood test results. Demographic variables such as age, sex, and BMI were collected at the patient's initial visit to the clinic. Blood tests (HbA_{1c}, fasting blood glucose, and total cholesterol) were conducted during regular follow-up visits, with the last recorded value before the onset of DR used for analysis.

Identification of New DR Cases

New-onset DR in patients with T2DM was identified using the *ICD-10* (*International Statistical Classification of Diseases,*

XSL•FO
RenderX

Tenth Revision) codes for retinopathy (E11.3-E14.3). T2DM was diagnosed as an anchoring event, and subsequent data collection, including DR identification, was based on the patient's first recorded diagnosis of diabetes. As relying solely on electronic health record data to identify conditions has inherent limitations in terms of accuracy, *ICD-10* codes were used to confirm whether the patients were diagnosed with retinopathy. This approach allowed for more reliable identification of retinopathy cases in this cohort.

Data Preprocessing

The data were preprocessed in 3 steps. First, individuals with T1DM were excluded to focus on those with T2DM using electronic health record data and identifying patients with T1DM via the *ICD-10* code (E10). Second, patients with a prior diagnosis of DR were excluded and identified using the *ICD-10* codes for retinopathy (E11.3-E14.3). Thirdly, patients with missing data in categories such as demographics, physical examination results, blood test results, medication history, or comorbidities were excluded from the analysis. Data from physical examinations and blood tests conducted before the onset of DR were analyzed. The most recent values recorded before DR onset were used and averaged across the study period for each patient. Covariates, including medication history and comorbidities, were collected at the patient's first visit and incorporated into the analysis. The final dataset represents variables as means (SD) or numbers (percentages), as appropriate.

Model Training and Validation

The conventional machine learning (ML) methodology for prediction tasks requires splitting the data into training and testing sets. However, the available data on the 3-year incidence of DR are insufficient in the context of this study. Therefore, the model was trained on the complete dataset rather than dividing it for internal validation. A separate external dataset, the National Information Society Agency, was used to assess the model's generalizability. This method was vital for confirming the robustness of the model for new unencountered data.

Model Development

This study applied decision-tree-based ensemble models, including AdaBoost, CatBoost, light gradient-boosting machine (LightGBM), random forest, and extreme gradient boosting (XGBoost). To optimize each model's performance, hyperparameter tuning was conducted using GridSearchCV to achieve the highest area under the receiver operating characteristic (ROC) curve (AUROC) and determine the most practical combination of hyperparameters.

ML Analysis

Tree-based and linear classification models were used to establish AUROC scores to predict the occurrence of DR. After determining the optimal hyperparameters, the model was trained to ensure accurate prediction. Given the class imbalance in the data, a synthetic minority oversampling technique was used to generate synthetic samples. The model's performance was evaluated using various metrics, such as AUROC, accuracy, sensitivity, specificity, and balanced accuracy, which were calculated based on the probability predictions generated by the model. A 10-fold stratified cross-validation was used to assess the model's ability to process new data, and the Youden Index was used within each stratification to pinpoint the optimal threshold [12]. The mean and 95% CIs for each performance metric were calculated to determine the average performance and variability of the model. The model performance was graphically represented by an ROC curve supplemented by the mean ROC curve and SD within that range, illustrating the model performance distribution. The XGBoost model, which provided the highest AUROC score among the various decision-tree models examined, was selected to determine the most crucial features for predicting DR. The significance of each feature was extracted by leveraging the important attributes of the XGBoost model. The top 15 features with the most significant impacts on the model were identified and plotted to visualize their effects on the predictions.

Performance Metrics

Five metrics were used to evaluate the performance of the proposed model: AUROC, accuracy, sensitivity, specificity, and balance accuracy. The AUROC is a resilient performance measure that assesses a model's ability to distinguish between classes across all potential thresholds. Resilience stems from the consideration of both sensitivity and specificity, making it the preferred metric, particularly in scenarios where classes are imbalanced. Accuracy is a simple and intuitive performance metric that denotes the ratio of accurate results (both true positives and negatives) to the total number of cases examined. However, when used alone, the accuracy can be misleading, particularly for unbalanced datasets, thereby necessitating additional performance metrics. The sensitivity and specificity were used to evaluate the ability of the model to correctly identify positive and negative cases, respectively. Sensitivity measures the ability of a model to identify positive cases correctly. By contrast, specificity measures the ability of the model to correctly identify negative cases, indicating its ability to avoid false-positive findings. Finally, balanced accuracy was included to provide a more balanced view of the model performance, particularly when dealing with class imbalances. Balanced accuracy is an excellent alternative to accuracy for unbalanced datasets because it assigns equal weights to sensitivity and specificity. Combining these metrics enabled an assessment of the performance of the model from different perspectives, ensuring a more comprehensive evaluation [13,14].

Software and Libraries

All data preprocessing, model creation, and analyses were performed using Python (version 3.9.16; Python Software Foundation). The libraries used to execute the ML algorithms and manipulate the data included Scikit-learn 1.2.2, NumPy 1.23.5, and Pandas 1.5.3. For data visualization, Matplotlib 3.7.1 and Seaborn 0.12.2 were used.

Ethical Considerations

This study was approved as exempt by the institutional review board of Kyung Hee University Hospital because of the use of deidentified patient data in a secure environment (approval number KHSIRB-22-473(EA)).

Results

Cohort Baseline Characteristics

Among the 14,694 patients in the discovery cohort, the mean age was 62.8 (11.24) years with 7730 (52.61%) males, and the mean BMI was 25.1 (3.58) kg/m^2. The discovery cohort identified 348 (2.37%) patients as having DR. For additional validation, 1856 patients were included, of which 1053 (56.73%) patients were male, and the mean age was 57.7 (11.88) years. A total of 137 patients (7.38%) were identified as having DR within this validation cohort (Table 1 and Figure 1).

Comparisons of Prediction Model Performance

The XGBoost model performed well on the discovery set (AUROC 82.36 [95% CI 80.48 - 84.25]; accuracy 75.13% [95% CI 74.10 - 76.17]; sensitivity 71.00% [95% CI 66.83 - 75.17]; specificity 75.23% [95% CI 74.16 - 76.31]; balanced accuracy 73.12% [95% CI 71.06 - 75.17]; precision 6.51% [95% CI 6.09 - 6.94]; F1-score 11.93% [95% CI 11.18 - 12.68]; and AUPRC 22.08 [95% CI18.04 - 26.13]) (Table 2). When these models were applied to an external validation set, the XGBoost model achieved an AUROC of 71.67 (Table 2). Consequently, with consistent results in both independent datasets, the XGBoost model emerged as the best predictor of DR development within 3 years among patients with T2DM (Figure 2).

Table . Performance metrics of 5 different machine learning algorithms on the original and validation NIA[a] datasets.

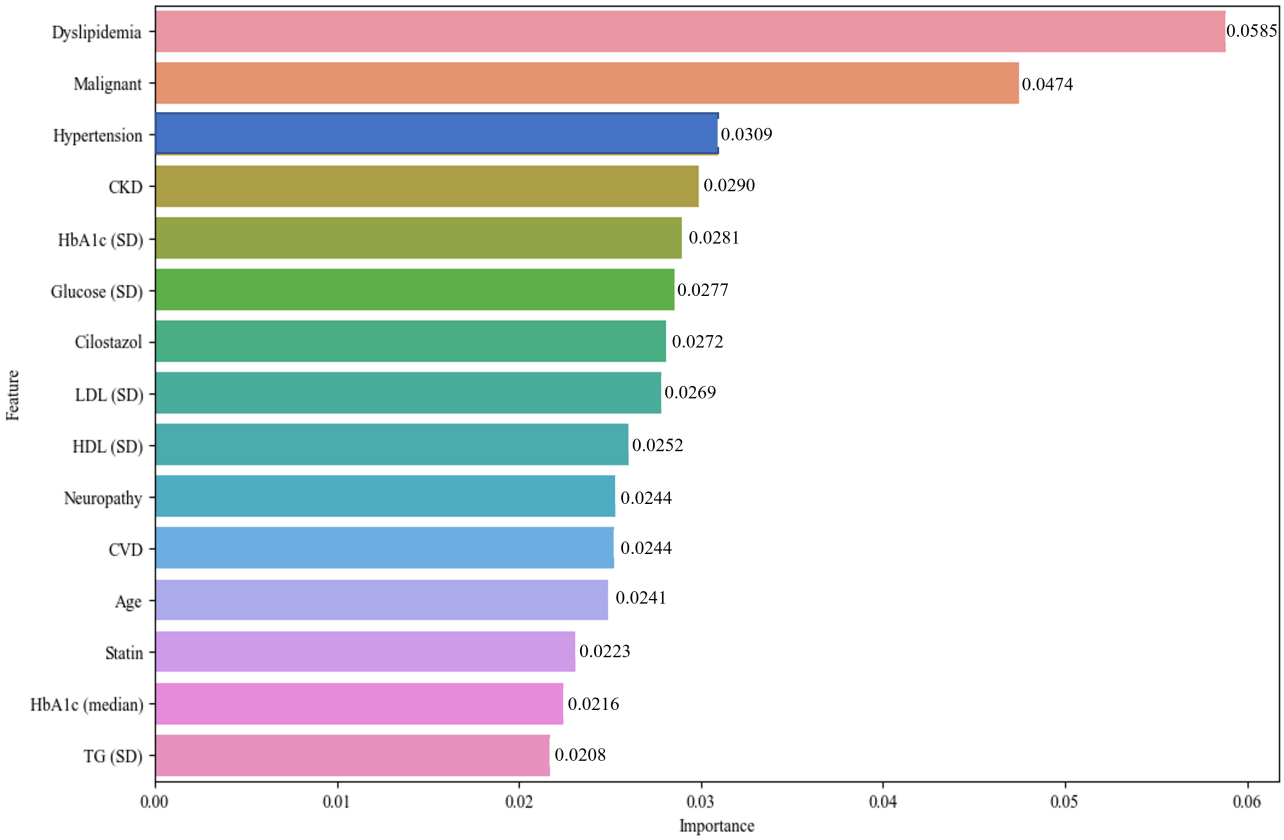
Figure 2. ROC curve of the XGBoost model. Mean ROC curve from 10-fold cross-validation on the original dataset. AUC: area under the ROC curve; ROC: receiver operating characteristic; XGBoost: extreme gradient boosting.



Feature Importance

The XGBoost model identified dyslipidemia (0.0585) as the most significant factor in predicting the development of DR within 3 years in patients with T2DM (Figure 3). Following dyslipidemia, the most critical factors included malignancy (0.0474), hypertension (0.0309), CKD (0.0290), HbA_{1c} variability (SD) (0.0281), glucose variability (SD) (0.0277), cilostazol use (0.0272), low-density lipoprotein variability (SD) (0.0269), high-density lipoprotein variability (SD) (0.0252), neuropathy (0.0244), CVD (0.0244), age (0.0241), statin use (0.0223), median HbA_{1c} (0.0216), and triglyceride variability (SD) (0.0208). These factors were ranked in descending order based on their importance in predicting DR.

Figure 3. Top 15 important features in the XGBoost model. CVD: cardiovascular disease; CKD: chronic kidney disease; DDP: Dipeptidyl Peptidase; HbA_{1c}: glycated hemoglobin; HDL: high-density lopoprotein; LDL: low-density lipoprotein; TG: triglyceride; XGBoost: extreme gradient boosting.

Discussion

Principal Findings

This study used data from 3 university hospitals in South Korea to conduct a simple and accurate assessment of ML-based risk prediction for DR development that can be universally applied to adults with T2DM. The AdaBoost, LightGBM, Random Forest, and XGBoost ensemble models performed well, with AUROC values of 82.36% (95% CI 80.48‐84.25). Dyslipidemia and cancer were the most important factors influencing the predictive model.

Several studies have investigated vision-threatening DR using deep learning (DL) approaches. Gulshan et al [15] used 9963 fundus images, achieving an AUROC of 0.999. Similarly, Ting et al [16] validated a DL system using 71,896 images, reporting an AUROC of 0.958 (95% CI 0.956‐0.961). Li et al [17] also validated a DL system with 35,201 images, obtaining an AUROC of 0.955. These studies reported a more robust performance of DL systems than human testing in various patient populations [15,18]. However, it is important to note that these investigations primarily focused on patients with severe vision-threatening DR, diagnosed through specialized ophthalmological care. Furthermore, a direct end-to-end training approach links the fundus image to the DR grade labels and may overlook critical lesion features due to the inherent black-box nature of DR classification models [19]. This limitation underscores the need for more comprehensive methodologies that can effectively capture and encode relevant lesion characteristics in the context of DR diagnosis.

This study offers the advantage of identifying the strong predictive performance of previously unseen data using a decision tree–based ensemble model that optimizes the combination of hyperparameters. Specifically, the findings suggest that DR can be reliably predicted in patients with T2DM using simple medical information obtained in primary care settings before ophthalmologist consultation and at the onset of visual symptoms. This approach can significantly reduce health care costs by enabling early detection and intervention. Gayathri et al [20] introduced a DR classification system based on various MLs, including multipath convolutional neural networks, random forests, and support vector machines. Similarly, Math et al [21] developed a DR classification system based on adaptive ML and obtained an AUC of 0.963.

This study proposed a new selection method for predicting DR with high accuracy and minimal predictors. The final dataset comprised 15 independent variables, and to identify the most significant risk factors of DR, ensemble models including the AdaBoost, LightGBM, Random Forest, and XGBoost were used to reduce the number of features among the numerous risk factors. The findings indicate that DR exhibited the strongest correlation with dyslipidemia, followed by cancer, hypertension, CKD, neuropathy, and CVD. These results are consistent with previously reported correlations between dyslipidemia [22,23], cancer [24], hypertension [25,26], CKD [27], neuropathy [28], and CVD [29]. This study underscores the importance of these correlations in understanding the multifactorial nature of DR.

XSL•FO
RenderX

It highlights the necessity for comprehensive risk assessments in patients with DM to effectively mitigate the risk of developing DR. In addition, a higher BMI is commonly associated with an increased risk of complications in patients with DM, and studies have shown that DR can develop even in individuals with a BMI of approximately 25, as observed in the study cohort. This suggests that a lower BMI does not necessarily protect against DR and highlights the need for comprehensive risk assessment in all patients with DM, regardless of BMI.

The findings demonstrated that DR in patients with diabetes can be predicted using simple medical information in the primary care setting before the onset of visual impairment and before ophthalmological treatment, thus potentially dramatically reducing medical costs. Furthermore, this study highlights the generalizability of ML systems and their feasibility in scaling up screening programs while maintaining the standards of care. ML systems offer reasonably accurate predictions that can significantly improve settings where additional testing may take weeks or months.

Artificial intelligence (AI)–based technologies support testing for DR, which is an unmet public health concern [30,31]. The results demonstrated that AI-based personalized testing intervals can be incorporated to improve the efficiency, equity, and accessibility of DR testing [32]. In particular, the findings of this study could improve patient outcomes by enabling timely intervention, improving the understanding of contributing variables, and reducing the burden of DR complications in patients with T2DM. The use of AI in the new DR classification is promising and there is optimism regarding future guideline revisions for the use of AI in the management of DR [33].

Limitations

First, as a cohort study conducted in hospitals in urban areas of a single ethnic group, the findings may not represent the entire population. Second, the diagnosis of DR relied on disease codes, which may lead to underestimation. Third, obtaining accurate information was difficult as a retrospective study based on hospital medical records. As no systematic referral tracking exists for the review of electronic medical records, a customized tracking process was implemented within the study. Fourth, the performance of this prediction model cannot be directly compared with existing prediction models. Additionally, the severity of DR was not reflected in the results. Fifth, this study could not confirm a causal relationship between the predictors used in the model and the occurrence of DR. Additional studies are needed to accurately identify the pathophysiological pathways and demonstrate the mechanisms of interaction between variables associated with DR and their impact on DR development. Finally, because the model operates over a wide range of retrospective scenarios, it may not work well if an unexpected situation occurs, such as the outbreak of a new infectious disease such as COVID-19, or if medical records are inconsistent or insufficient. Future studies should use additional models to reduce the dependence of supervised feature selection techniques on a wide range of training data.

This study is the first to apply an ML-based DR prediction system to a nationwide population with diabetes. The results indicate that the implementation of evidence-based, individualized preventive interventions can reduce the burden of DR in Korean patients with diabetes.

Conclusions

This study used a hospital-based cohort to develop an ML-based prediction model to accurately predict the DR risk in a Korean population with T2DM. These results may improve patient outcomes by enabling timely interventions to prevent DR in patients with T2DM, enhancing the understanding of contributing variables, and reducing the burden of DR complications in patients with T2DM. The prediction model proposed in this study is expected to be competitive and cost-effective in preventing DR in patients with T2DM in South Korea and is expected to be widely used, especially in primary care settings.

Acknowledgments

This study will be expanded to include data collected by the National Information Society Agency in South Korea and multicenter research associated with the Korean Diabetes Association and the Korea Disease Control and Prevention Agency. This study was supported by the National Institute of Health Research Project of South Korea (2022-ER1102-01). This research was supported by the Bio&Medical Technology Development Program of the National Research Foundation (NRF) funded by the Korean government (MSIT; RS-2023-00262002). Also, this work was supported by the Institute of Information & communications Technology Planning & Evaluation (IITP) grant funded by the Korea government (MSIT; RS-2022-00143911, AI Excellence Global Innovative Leader Education Program and RS-2024-00509257, Global AI Frontier Lab). Abstract

Background: Unplanned readmissions increase unnecessary health care costs and reduce the quality of care. It is essential to plan the discharge care from the beginning of hospitalization to reduce the risk of readmission. Machine learning–based readmission prediction models can support patients' preemptive discharge care services with improved predictive power.

Objective: This study aimed to develop a readmission early prediction model utilizing nursing data for high-risk discharge patients.

Methods: This retrospective study included the electronic medical records of 12,977 patients with 1 of the top 6 high-risk readmission diseases at a tertiary hospital in Seoul from January 2018 to January 2020. We used demographic, clinical, and nursing data to construct a prediction model. We constructed unplanned readmission prediction models by dividing them into Model 1 and Model 2. Model 1 used early hospitalization data (up to 1 day after admission), and Model 2 used all the data. To improve the performance of the machine learning method, we performed 5-fold cross-validation and utilized adaptive synthetic sampling to address data imbalance. The 6 algorithms of logistic regression, random forest, decision tree, XGBoost, CatBoost, and multiperceptron layer were employed to develop predictive models. The analysis was conducted using Python Language Reference, version 3.11.3. (Python Software Foundation).

Results: In Model 1, among the 6 prediction model algorithms, the random forest model had the best result, with an area under the receiver operating characteristic (AUROC) curve of 0.62. In Model 2, the CatBoost model had the best result, with an AUROC of 0.64. BMI, systolic blood pressure, and age consistently emerged as the most significant predictors of readmission risk across Models 1 and 2. Model 1, which enabled early readmission prediction, showed a higher proportion of nursing data variables among its important predictors compared to Model 2.

Conclusions: Machine learning–based readmission prediction models utilizing nursing data provide basic data for evidence-based clinical decision support for high-risk discharge patients with complex conditions and facilitate early intervention. By integrating nursing data containing diverse patient information, these models can provide more comprehensive risk assessment and improve patient outcomes.

Introduction

Readmission is an unintended outcome that occurs in patients discharged from the hospital. In South Korea, the 30-day readmission rate in tertiary general hospitals in 2020 was approximately 30%, increasing yearly along with readmission cost statistics [1]. According to a Center for Medicare and Medicaid Services report in the United States, readmission rates for patients reach 2 million yearly, with readmissions costing $26 billion [2]. Despite the growing interest and literature on readmissions, unplanned readmission rates still need to be managed.

It is essential to accurately predict and select high-risk discharge patients to reduce readmission costs and improve the quality of medical care. Predictive modeling is an efficient way to stratify patient readmission risk and optimize the allocation of clinical resources by providing preventive interventions to high-risk patients [3]. Traditional statistical methods for creating predictive models have focused on inference, which involves creating a mathematical model of a data-generating process to formalize an understanding of how it works or to test hypotheses. The problem is that as the sample size of the data grows and the number of input variables increases, the possible associations between variables increase, making the model more complex and the statistical inference less accurate [4]. In particular, traditional risk prediction models, such as regression analysis, show limited predictive power [5]. In response to these challenges, machine learning methodologies have emerged as a powerful alternative. These approaches employ diverse algorithms to systematically process complex and voluminous datasets, identifying patterns and generating predictions. This capability proves particularly advantageous when dealing with "big data" characterized by numerous input variables and complex nonlinear interactions [6]. However, it is crucial to note that the application of machine learning in medical contexts presents certain challenges. In the absence of robust predictors and comprehensive domain-specific knowledge, establishing direct correlations between machine learning outcomes and existing medical information can be problematic. Despite these limitations, recent advancements have led to the development of machine learning–based high-prediction models. These models function as advanced predictive analysis technologies, capable of identifying and processing diverse patient information and conditions. Through the analysis of high-dimensional medical data, these sophisticated models generate hierarchical predictive frameworks with enhanced prognostic capabilities. This approach effectively addresses the inherent limitations of conventional statistical methods, thereby facilitating the implementation of personalized treatment strategies tailored to individual patients [7].

Treatment of high-risk discharged patients with high readmission is focused only at discharge, mainly by providing postdischarge care interventions [8]. Additionally, most existing readmission prediction models only utilize medical information data such as the patient's diagnostic tests [9]. Although nursing data in the early stages of a patient's hospitalization include comprehensive and direct information on physical and functional health factors, psychosocial characteristics, and socioeconomic status, studies have yet to be conducted on developing predictive models utilizing the usefulness of this nursing assessment information [10]. Predicting a patient's readmission should be done from the beginning of hospitalization so that a patient-tailored discharge plan can be established and reflected in treatment. It is necessary to actively utilize nursing data containing comprehensive information [11,12].

Therefore, this study aimed to develop a readmission early prediction model utilizing nursing data, including physical, mental, and social information for high-risk discharge patients.

Methods

Study Design and Setting

Our article follows the guidelines of the Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis (TRIPOD) consensus document. This study is a retrospective electronic health record (EHR) data analysis. This retrospective observational study used EHR data collected at a tertiary acute care hospital with over 2500 medical conditions in Seoul, Republic of Korea. To develop a readmission early prediction model for readmission of high-risk discharge patients, we employed a retrospective study design utilizing nursing data.

Data Sources

We extracted medical record data of 12,977 patients at S Hospital in Seoul, Korea, for 25 months from January 2018 to January 2020. As a study to confirm the EHR data from the time of admission to the time of discharge of the patient, the information collected until January 31, 2021, was used to track readmission within 30 days. Data were requested from S University Hospital via the SOBIG data portal using subject inclusion criteria. The big data team extracted and received data from the first hospitalization of adult patients hospitalized for 6 major disease groups (chronic obstructive pulmonary disease, liver disease, diabetes mellitus, lung disease, heart failure, and chronic kidney disease) for 2 years. Hospital S is a high-level general hospital with about 2500 beds, with approximately 2000 to 3000 surgeries per month and more than 10,000 outpatient visits per day. We secured medical records of medical institutions where many patients are frequently hospitalized and readmitted and used them to develop a prediction model.

We used various types of EHR data from the participants, including during hospitalization and follow-up data within 30 days of discharge point. Analysis in this study included general, clinical, and nursing data recorded after the direct assessment of patients.

Data Inclusion and Exclusion Criteria

The data inclusion criteria are as follows: patients were older than 18 years at admission. The disease group selection of the subjects was based on the most recent 2021 HIRA (Health Insurance Review and Assessment Service) data, and the discharged patients from the top 6 main diagnosis groups with high readmission rates were selected. One patient had only one record.

XSL•FO
RenderX

The data exclusion criteria are as follows: patients who died during hospitalization. Data resulting in death were excluded from discharge records.

Data Preprocessing

Data Extraction

Of the initial 12,977 pieces of data, 388 duplicates were excluded, and 10,076 pieces of data were confirmed. Of these, 9536 medical records were analyzed, excluding data from 540 patients who died and data from 2513 patients with diagnoses who did not meet the inclusion criteria. Records with more than 65% missing values or records with missing values in categorical variables were deleted, and the final 9028 medical records were used to develop a prediction model.

To predict early readmissions at the same time as the patient's admission, we built two models, Model 1 using the initial data up to the first day of admission and Model 2 using the data from the entire hospital stay to just before discharge, with different data extraction times.

Data Imputation

Category and continuous variables with missing values were handled differently. For categorical variables, we excluded data by deleting missing values, and for continuous variables, we had about 25% missing values for BMI and ward severity, and less than 5% missing values for all other variables. For BMI, the proportion of missing values was higher than for other variables due to the large number of cases where only weight was entered among the patient's height and weight measurements. For ward severity, there were missing values due to the patient's room change, but there was no difference in predictive power based on missing values when training the model. These missing values were imputed using KNN imputation (K=5). Finally, we constructed a readmission prediction model using 9028 data.

Data Imbalance

The observed readmission rate for all data used in this study was 16.5%. To solve the data imbalance problem when building readmission prediction models, we compared four sampling methods: ADASYN, under-sampling, SMOTE, and random over-sampling. The ADASYN method was ultimately selected among the four sampling methods to resolve the data imbalance issue because the ADASYN method showed the highest possible model performance results.

Ethical Considerations

The ethics review committee of Severance Hospital approved this retrospective data analysis study (DRB approval number 4-2021-1334). Severance Medical Center's guidelines for using EHRs require the data to be provided in Excel format with patient identification information removed. Data analysis was performed based on this data.

Variables

EHR data were analyzed to predict patient readmissions. Readmissions, the primary outcome of interest in the study, were assessed as unplanned readmissions within 30 days [13]. The study aimed to determine a patient's likelihood of readmission to develop an early discharge care plan. To determine the likelihood of patient readmission, we classified the target variable Y as yes (1) or no (0). Predictor variables (X) necessary to confirm the presence or absence of rehospitalization, which is the target variable of the patient, including sex, age, admission days, diagnosis group, number of ICD-10 codes, admission and discharge medications, state of consciousness, BMI, falls and pressure ulcer risk, vital signs, literacy, economic status, functional and emotional evaluation, number of nursing diagnosis records, presence of the caregiver, admission via the emergency room, health behavior habits (smoking, drinking, regular exercise, sleep disorder, and nutritional status), blood test values (levels of sodium, hemoglobin, potassium, aspartate aminotransferase, glucose, and creatinine; and white blood cell counts) were included in the analysis. Utilizing coefficient of variation (CV) values, Model 2 incorporated patient data from admission to discharge to capture data variability.

Among the various variables, the following are included as nursing data: falls and pressure ulcer risks, vital signs, literacy, economic status, functional and emotional evaluation, number of nursing diagnosis records, presence of the caregiver, health behavior habits (eg, smoking, drinking, regular exercise, sleep disorder, and nutritional status), and ward severity. The ward severity score is a score given by the nurse in charge of the ward to each patient by identifying the number of interventions in the areas of hygiene, nutrition, elimination, exercise and activity, education and counselling, emotional support, measurement and observation, communication and alertness, treatment and testing, medication, interdepartmental coordination of patient care, discharge, and power management. The modified Barthel index scale is an ordinal scale that measures an individual's ability to complete activities of daily living. It consists of 10 items and has a total score of 100. However, the organization that collected the data evaluated 11 items by adding an item on the ability to use walking aids other than wheelchairs, and the total score was 105. All of these nursing data variables include information recorded by the nurse during the patient's admission to the hospital to indicate the patient's condition. We built a model to predict unexpected readmissions, divided into Model 1 and Model 2. Model 1 entered possible variables based on data from the first day of hospitalization, and Model 2 selected variables based on data from the entire period of hospitalization. All variables were selected based on prior literature and entered through stepwise feature selection [14,15].

Table 1 displays all the input variables according to Models 1 and 2.

[a]SBP: systolic blood pressure.

[b]CV: coefficient of variation.

[c]DBP: diastolic blood pressure.

[d]Whole blood test: The sum of the normal items of the white blood cell count, hemoglobin, hematocrit, platelet count, and lymphocyte tests among the complete blood count tests.

[e]Chemistry test: The sum of the normal items of blood urea nitrogen, creatinine, aspartate aminotransferase, alanine transaminase, and albumin tests among routine chemistry serum tests.

[f]Electrolyte test: The sum of the normal items of calcium, inorganic P, Na, K, and Cl tests among electrocyte serum tests.

[g]Health behavior habits: smoking history, drinking history, sleep disorder, regular exercise, and nutritional status.

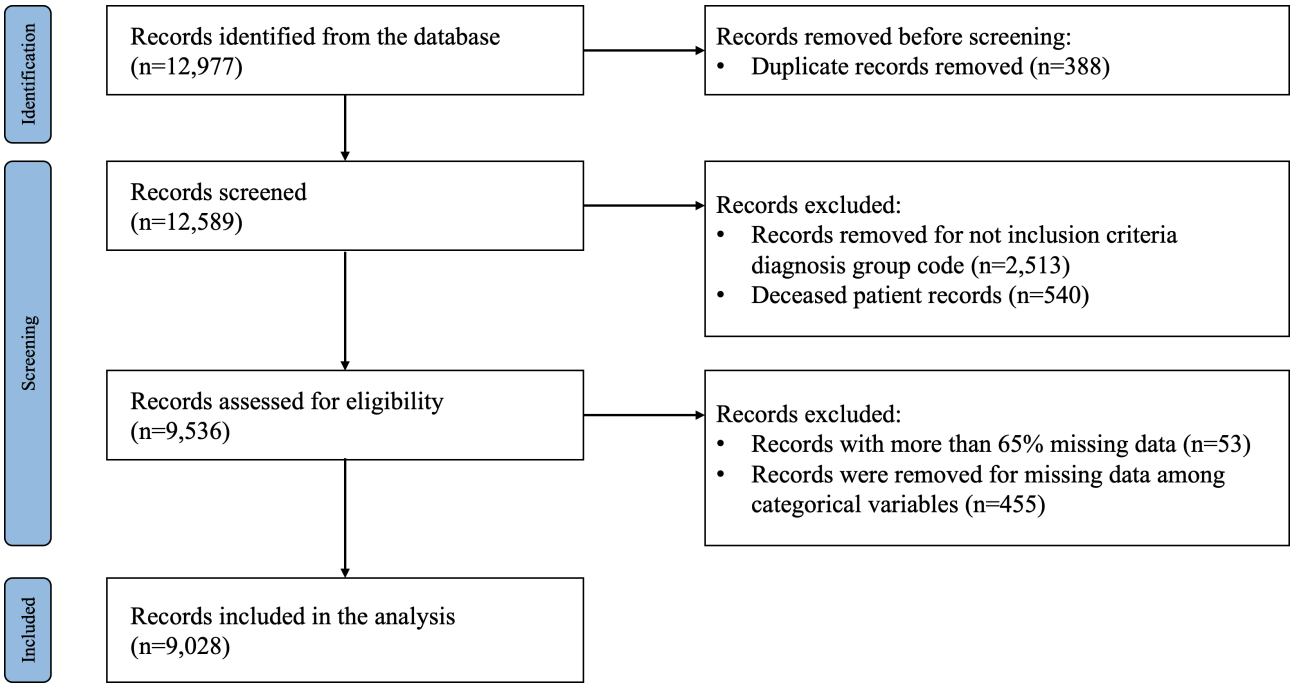
Machine Learning-Based Predictive Models

Machine learning is a field of artificial intelligence that studies the development of computer algorithms and techniques that automatically improve through experience [16]. Machine learning is divided into supervised learning and unsupervised learning and predicts outcomes through supervised learning. There are various types of machine learning. A representative example is a decision tree, a graph representing a selection and its result in the form of a tree. The nodes of the graph represent events or selections, and the edges of the graph represent decision rules or conditions. Each tree consists of nodes and branches. Each node represents an attribute of a group to be classified, and each branch represents a value that the node can take. It is an algorithm suitable for a rehospitalization prediction model that mainly predicts the presence or absence of rehospitalization. The boosting algorithm is a family of algorithms that transform weak learners into strong learners. Boosting is an ensemble learning technique used to reduce bias and variance. A weak learner is defined as a classifier, and a strong learner is a classifier that is randomly correlated with the actual classification. Many algorithms with high accuracy and predictive power are being developed in prediction algorithms. Bagging is applied where the accuracy and stability of machine learning algorithms must be increased, and it can be applied to classification and regression and helps reduce variance and handle overfitting. The random forest algorithm is an algorithm that creates a decision tree using this bagging method. It is an algorithm that can solve the overfitting problem that a single decision tree can have by creating various subdatasets through bootstrapping and having multiple decision trees learn each dataset and collate the results [6]. In this study, we used a supervised learning method through 6 algorithms that are considered most suitable for predicting readmission among machine learning algorithms: logistic regression, decision tree, random forest, CatBoost, XGBoost (extreme gradient boosting), and multilayer perceptron, and developed a readmission prediction model for high-risk patients. The dataset was split into 60% for training, 20% for validation, and 20% for testing, with all models trained 5 times and model performance evaluated using layered 5-fold cross-validation. We performed a grid search to find the most suitable hyperparameters for the model while training and evaluating the model, and then performed model fine tuning.

According to the data inclusion and exclusion criteria and missing value processing, data from 9028 patients were available for analysis. We constructed unexpected readmission prediction models by dividing them into Model 1 and Model 2. Model 1 implemented an early readmission prediction model based on data from the first day of hospitalization to predict readmission early. Model 2 implemented a model to supplement data that should have been included in Model 1 based on all the data. All machine learning–based predictive model development processes were conducted with the participation of artificial intelligence experts, who conducted the procedures together, provided advice, and reviewed them. The analysis in this study was performed using Python Language Reference, version 3.11.3. (Python Software Foundation).

Evaluation of Prediction Performance

After implementing 6 models, we selected the final model and evaluated each model's confusion matrix, accuracy, precision, recall, F1-score, and area under the receiver operating characteristic (AUROC) curve.



We compared techniques using performance measures of different models. Confusion matrices were used to determine accuracy, recall, precision, and F1-score. True positive, true negative, false positive, and false negative were used to determine the performance of each model. True positive refers to cases where the model predicted yes, and the patient was actually readmitted. In contrast, true negative refers to cases where the model predicted no, and the patient was not readmitted. Conversely, false positive refers to cases where the model predicted yes, but the patient was not actually readmitted, and false negative refers to cases where the model predicted no, but the patient was not actually readmitted.

Results

Figure 1 shows the flow of data extraction. Of the initial 12,589 data, we analyzed a final of 9536 medical records, excluding 2513 duplicates and 540 deceased patient data. Of the 9028 participants, 1493 experienced an unplanned readmission within 30 days; the rate of unplanned readmissions within 30 days was 16.5%. Table 2 shows the essential characteristics of the study participants. There were 3186 (35.29%) patients under the age of 60 years, 1194 (13.23%) patients over the age of 80 years, and 4648 (51.48%) patients between the ages of 60 and 80 years. In terms of sex, there were 3309 (36.65%) men and 5719 (63.35%) women in the study, and by diagnosis, 4725 (52.34%) patients had liver disease, followed by 1612 (17.86%) patients with pulmonary disease, 1309 (14.50%) with chronic kidney disease, 1004 (11.12%) with heart failure, 279 (3.09%) with diabetes, and 99 (1.10%) with chronic obstructive pulmonary disease. A total of 3237 (35.86%) patients were admitted unplanned via the emergency department, while 5791 (64.14%) were planned via the outpatient department.

No	7536 (83.47)

[a]COPD: chronic obstructive pulmonary disease

[b]CKD: chronic kidney disease

In this study, we developed 2 prediction models to enable the early prediction of high-risk patient readmissions when admitted to the hospital: one using early hospitalization data and the other using complete data that can compensate for the initial lack of information. Model 1 was a high-risk patient readmission prediction model developed using initial data up to the first day of hospitalization. Model 2 was a prediction model developed based on complete patient hospitalization data. The performance evaluation results of the 5-fold cross-validation test of the 6 candidate model algorithms in Model 1 and Model 2 are shown in Table 3.

XSL•FO

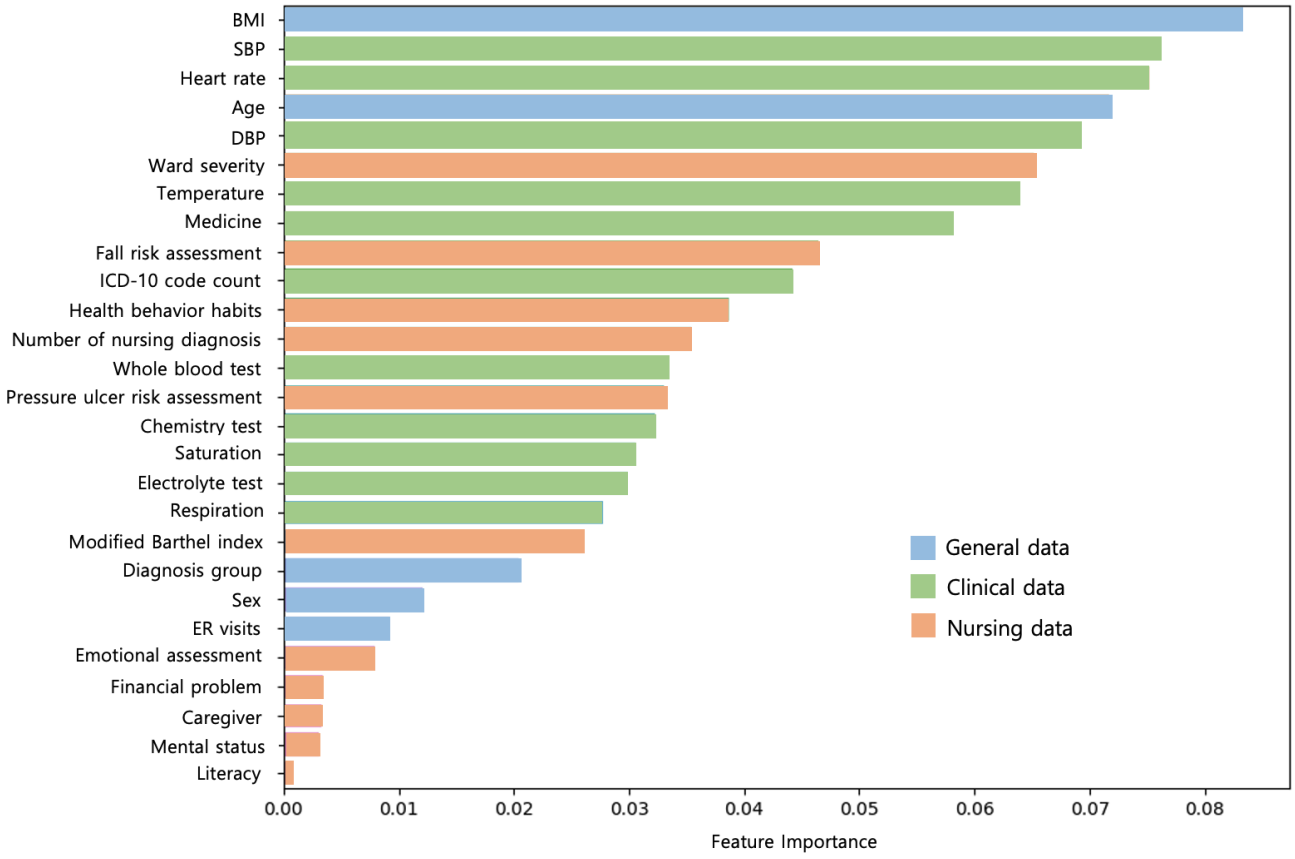
[a]AUROC: area under a receiver operating characteristic.

[b]LR: logistic regression.

[c]DT: decision tree.

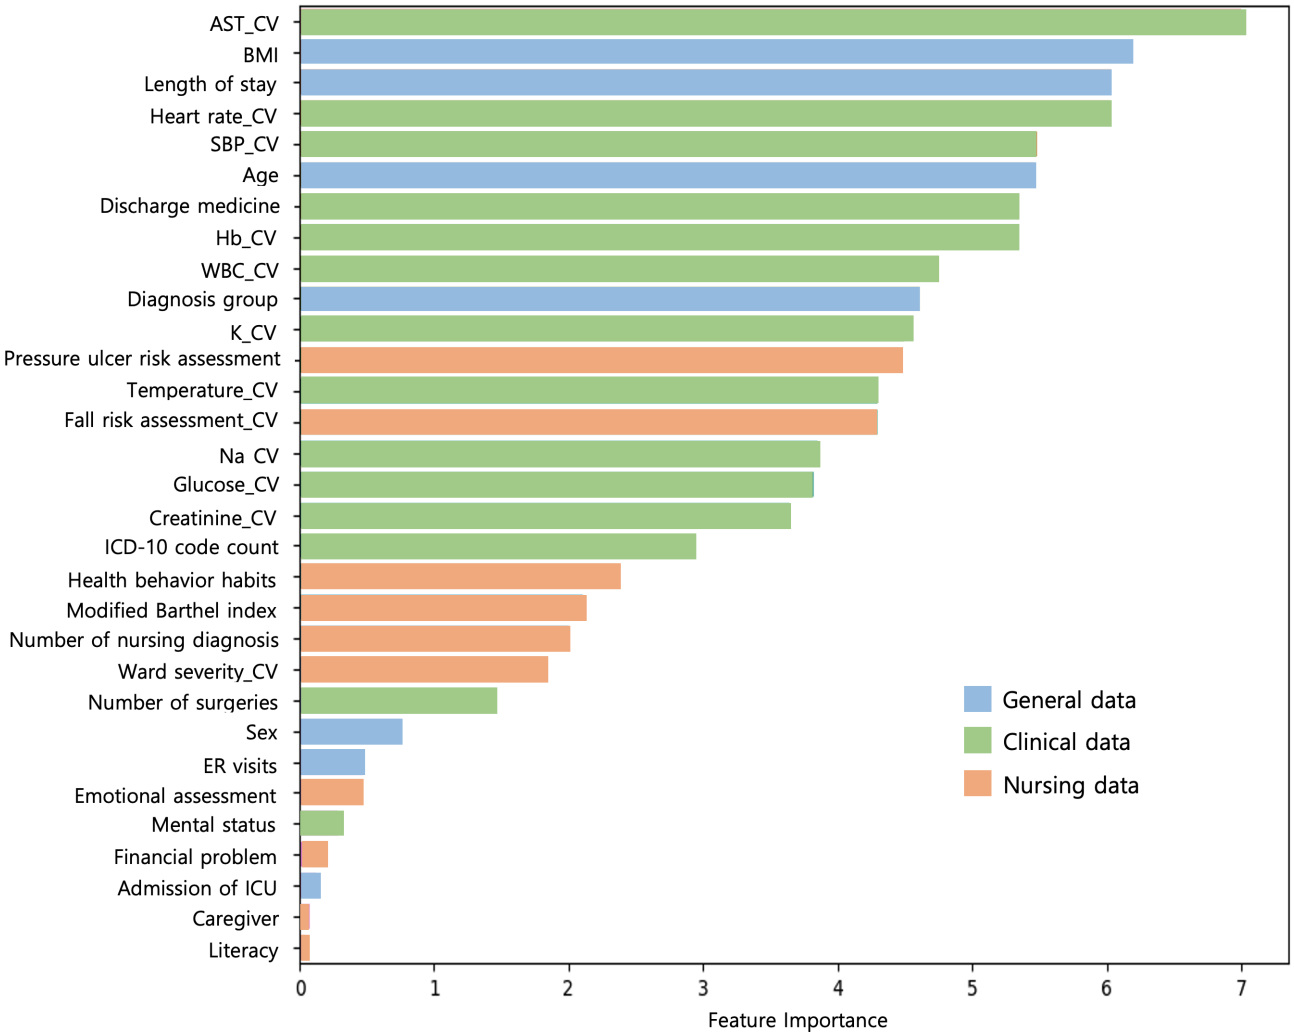
[d]RF: Random forest.



[e]XGBoost: extreme gradient boosting.

[f]MLP: multilayer perceptron.

For Model 1, the random forest model had the highest AUROC curve of 0.62 compared to all other models, while the decision tree model performed the worst with an AUROC curve of 0.55. The feature importance of the best-performing random forest model in Model 1 is shown in Figure 2. In Model 2, the CatBoost model had the highest AUROC curve of 0.64 compared to all other models, while the decision tree model had the lowest performance with an AUROC curve of 0.61. The feature importance of the best-performing CatBoost model in Model 2 is shown in Figure 3. Ultimately, the best-performing prediction models were the random forest model for Model 1 and the CatBoost model for Model 2. Although the random forest model and CatBoost model have the same AUROC curve value, when comparing the performance values of all models including the training data, the random forest model was not overfitted and performed evenly well, so after statistical discussion with AI experts, it was selected as the Model 1 final model.



XSL•FO
RenderX

Figure 2. Feature importance of the random forest model in Model 1. SBP: systolic blood pressure; DBP: diastolic blood pressure; ER: emergency room.

XSL•FO
RenderX

Figure 3. Feature importance of the CatBoost model in Model 2. AST: aspartate transaminase; CV: coefficient of variation; SBP: systolic blood pressure; Hb: hemoglobin; WBC: white blood cell; ER: emergency room; ICU: intensive care unit.

As a result of analyzing the feature importance of Model 1 and Model 2, the three variables of BMI, systolic blood pressure, and age were commonly found to be important predictors of readmission risk. According to Figure 2, Model 1, which enabled the early prediction of readmission, had a higher proportion of nursing data among the important predictors than Model 2. In Model 1, constructed using early hospitalization data, 45% of the nursing data variables (ward severity, fall risk assessment, health behavior habits, number of nursing diagnoses, and pressure ulcer risk assessment) were ranked within the top 50% of important variables. This finding suggests the potential significance of incorporating nursing data in early readmission prediction models.

Discussion

Principal Findings and Comparison With Previous Works

In predicting unplanned readmission within 30 days using data from 9028 high-risk discharged patients, machine learning methods (random forest and CatBoost models) showed better predictive power than traditional logistic regression methods, similar to other previous studies [17,18]. While previous studies have focused on developing a prediction model for a specific condition for a specific group of patients with a specific diagnosis [19], this study is significant in that it is a prediction model development study that focuses on the generalization process of predicting unplanned readmissions within 30 days by incorporating the top 6 diagnosis groups of high-risk discharged patients suggested by the Health Insurance Review and Assessment Service to predict the potential of readmission.

Many interventions aimed at reducing patients' unplanned readmissions are often initiated just before or after inpatient discharge, which has little impact on improving the inpatient quality of care [20]. Providing early interventions related to readmissions during hospitalization with early discharge planning can reduce readmissions [21]. However, most readmission prediction models are built on posthospitalization data, often including information about the patient's physical and diagnostic tests. Because clinically essential variables such as the length of stay, diagnosis codes, laboratory test results, and medications are usually entered just before discharge, readmission prediction models are primarily built on patient data immediately before or after discharge. The most widely used measures of readmission risk in US health care settings are the HOSPITAL score [22] and the LACE index [23], but both have the limitation that they are only available at the end of a hospital stay. When creating a prediction model that

XSL•FO
RenderX

includes all variables, its prediction performance is good. However, it needs to be applied for more time to actual patients, making it challenging to support effective clinical decision-making. In this study, to overcome these limitations, we implemented two patient readmission prediction models, Model 1 and Model 2, to predict the readmission rate from the time of hospitalization and plan discharge care. Model 1, implemented based on the patient's initial hospitalization data, and Model 2, implemented by adding variables that can complement Model 1, can help clinical decision-making by predicting the patient's readmission rate earlier. Model 1, which utilized data from the first day of hospitalization, had an AUROC curve of 0.62 in our study. Although this performance is not exceptionally high, it is consistent with most previous studies that developed readmission prediction models using initial hospitalization data, which reported results of less than an AUROC curve of 0.75 [5,17,24,25]. Importantly, it enables the proactive identification of high-risk patients and the provision of timely and preventive therapeutic interventions early in their hospital stay.

Unplanned readmissions cause a heavy burden on individuals and society through unnecessary health care costs and resource use, and readmission management has been recognized as an essential issue in improving patient quality of care [26]. To reduce the cost of unnecessary readmissions and improve the quality of care for patients, the Korea Health Insurance Review and Assessment Service conducts a national risk-based readmission cost appropriateness assessment, and the US government has implemented the Hospital Readmission Reduction Program (HRRP) since 2012 to encourage the reduction of hospital readmissions by involving patients and caregivers in discharge planning [27]. However, limited health care resources make it challenging to provide discharge interventions to all patients, and screening high-risk patients for early discharge planning is essential. Evidence suggests that focusing interventions on high-risk patients can reduce the risk of hospital readmission within 30 days by 11 - 28% [28-30], and it is essential to utilize nursing data that include holistic information from the patient's initial hospitalization to develop a preventive care plan for high-risk patients. A previous study found the potential importance of utilizing nursing variables to identify risk factors for readmission [31]. The BMI variable at the top of the feature importance of Model 1 is the same as the result that it was highly related to the patient's obesity level, cardiovascular problems, and readmission, similar to the previous study [32]. This study is significant in that it proved that BMI is the most simple and important screening variable related to the patient's readmission in the early stage of hospitalization. In the future, it is necessary to recognize the importance of BMI screening and collect information related to the probability of early patient readmission [32].

Information collected directly about patients' physical, mental, and social aspects by nurses, who interact most closely with patients in the hospital and provide care, is essential in predictive models for the early identification of high-risk discharges. In this study, we developed an early prediction model for unplanned readmissions using nursing data from patients in the early stage of hospitalization. In particular, we found that many nursing data variables were included in the high rankings among the important predictors in Model 1 developed using early hospitalization data. The high representation of nursing variables among the most influential predictors underscores the potential value of integrating nursing-specific information into risk assessment tools for hospital readmission. Further investigation into the specific contributions of these nursing variables may provide valuable insights for enhancing the accuracy and clinical utility of early readmission prediction models. Although most predictions of high-risk discharged patients are based on data at discharge, identifying high-risk patients should ideally be performed early enough to allow for therapeutic interventions during hospitalization, which was attempted in this study.

Limitations

This study has several limitations. First, our prediction model, designed for adults aged over 18 years, does not apply to pediatric patients aged less than 18 years. Second, the model's development was based on data from a single hospital in a specific region. Consequently, its applicability to readmission scenarios in different health care settings or countries may be limited. Furthermore, tracking patient readmissions poses a challenge, especially in cases where patients admitted to our hospital could have subsequent readmissions to different facilities. This potential for cross-hospital readmissions might not be fully captured in our model.

Additionally, as this was a retrospective study utilizing deidentified data, it limited our ability to validate the relationships between our findings and factors identified in other studies. Finally, there were limitations in implementing perfectly standardized data, as the data were manually entered as part of the medical and nursing data.

Clinical Implications

Our readmission prediction model can be used to predict and continuously monitor a patient's risk of readmission during the entire hospital stay. It can be used as an early screening tool to assess the risk associated with a patient's readmission.

Conclusions

This study developed two prediction models, Model 1 using initial hospitalization data and Model 2 reflecting the variability of variables from admission to discharge, for the early prediction of unplanned readmission within 30 days in high-risk discharged patients. Model 1 showed the best performance of the random forest model, with an AUROC curve of 0.95 for the training data and 0.62 for the test data. For Model 2, the CatBoost model performed the best, with an AUROC curve of 0.92 for the training data and an AUROC curve of 0.64 for the test data. The Model 1 and Model 2 predictive models allow us to predict the likelihood of readmission from the beginning of a patient's hospitalization and proactively plan for early discharge. In addition, this study identified various significant predictors of unplanned readmission and identified changes in patients over time. The predictive model was developed and validated using data from 9028 discharged patients and can be applied to adult patients who represent the high-risk discharge population in tertiary care hospitals. However, further research and experimentation are necessary to implement the developed

predictive models in clinical practice within an EHR environment for predicting early readmission and monitoring readmission risk. In particular, additional studies must be conducted to address the limitations of this monocentric study, consider the characteristics of medical data with numerous missing values, and validate the data sources for each variable. Based on this study, future development of a systematic clinical decision support system that utilizes machine learning–based readmission prediction models with nursing data could enable real-time early risk prediction of patient readmission. This approach would facilitate the provision of preventive discharge services for high-risk patients and improve the quality of health care services.

Abstract

Background: Artificial intelligence chatbots are being increasingly used for medical inquiries, particularly in the field of ultrasound medicine. However, their performance varies and is influenced by factors such as language, question type, and topic.

Objective: This study aimed to evaluate the performance of ChatGPT and ERNIE Bot in answering ultrasound-related medical examination questions, providing insights for users and developers.

Methods: We curated 554 questions from ultrasound medicine examinations, covering various question types and topics. The questions were posed in both English and Chinese. Objective questions were scored based on accuracy rates, whereas subjective questions were rated by 5 experienced doctors using a Likert scale. The data were analyzed in Excel.

Results: Of the 554 questions included in this study, single-choice questions comprised the largest share (354/554, 64%), followed by short answers (69/554, 12%) and noun explanations (63/554, 11%). The accuracy rates for objective questions ranged from 8.33% to 80%, with true or false questions scoring highest. Subjective questions received acceptability rates ranging from 47.62% to 75.36%. ERNIE Bot was superior to ChatGPT in many aspects (P<.05). Both models showed a performance decline in English, but ERNIE Bot's decline was less significant. The models performed better in terms of basic knowledge, ultrasound methods, and diseases than in terms of ultrasound signs and diagnosis.

Conclusions: Chatbots can provide valuable ultrasound-related answers, but performance differs by model and is influenced by language, question type, and topic. In general, ERNIE Bot outperforms ChatGPT. Users and developers should understand model performance characteristics and select appropriate models for different questions and languages to optimize chatbot use.

KEYWORDS

chatbots; ChatGPT; ERNIE Bot; performance; accuracy rates; ultrasound; language; examination

Introduction

With the rapid development of artificial intelligence (AI) technology, deep learning models are being increasingly and widely used in various fields, especially in natural language processing and computer vision [1,2]. In the field of natural language processing, several large pretrained models, such as OpenAI's ChatGPT and Baidu's ERNIE Bot [3,4], have demonstrated strong text generation and understanding capabilities. These models acquire rich semantic knowledge and language patterns through pretraining on large-scale corpora, which enables them to handle various complex natural language tasks [5,6]. In recent years, researchers have explored new algorithms and frameworks to optimize the performance of models and improve their accuracy and efficiency in handling complex tasks. In these studies, model selection, training, evaluation, and performance in practical applications have become the focus of research [7,8]. The proportion of medical health–related knowledge obtained through the internet is large, and chatbots are also used to answer various medical questions [9,10]. Researchers have performed many evaluations and studies on chatbots to answer medical questions, including ophthalmology, pediatric, urology, dentistry, and other professional directions, involving myopia, cirrhosis, hypertension, obesity, and other diseases and medical examination questions [11,12].

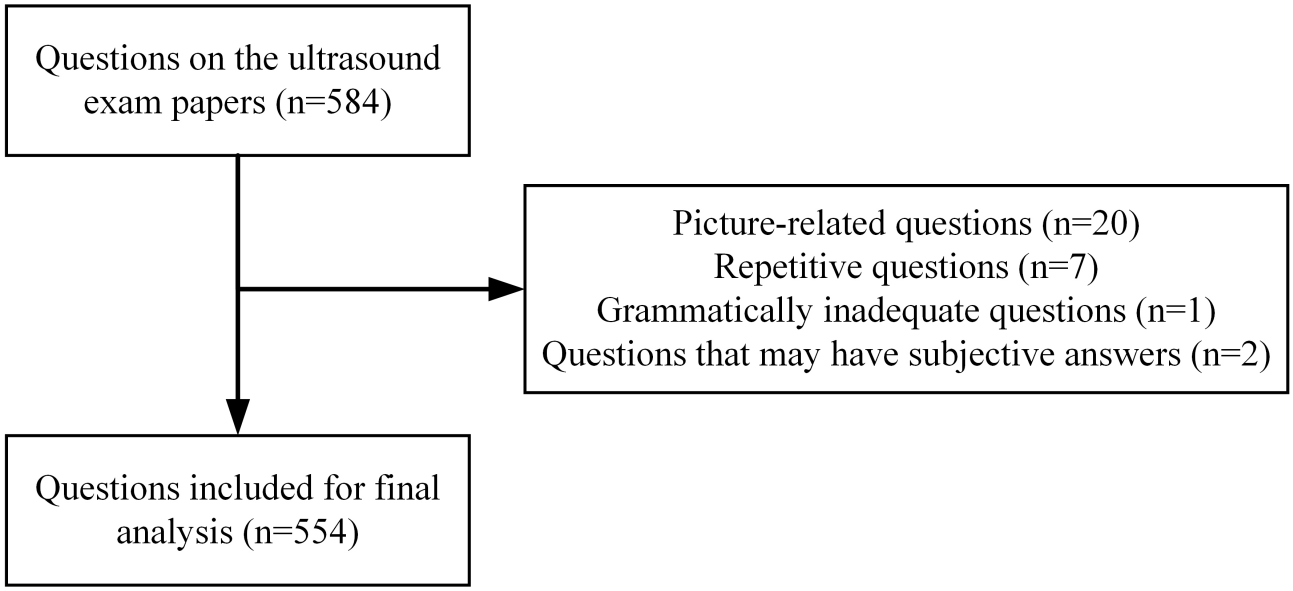
With the rapid development of ultrasound medicine, the demand for ultrasound examination is increasing, and the teaching and popularization of ultrasound is limited. An increasing number of junior ultrasound doctors, students, and patients have begun to use chatbots to obtain ultrasound-related consultation and answers. However, current research shows that chatbot performance is uneven; in some areas or tasks, chatbot performance can reach more than 90% of the accuracy rate or satisfaction, and chatbot performance can even exceed that of some doctors; however, in some tasks, the answer provided is

XSL•FO
RenderX

not valid or even wrong [13,14]. There are performance differences among different models, which are also affected by many factors, such as language, question type, and topic [15]. An in-depth understanding of how models perform in various domains and under various conditions is necessary and valuable for both users and developers [16,17].

ChatGPT is a large-scale language model based on the transformer architecture developed by OpenAI, an American AI research laboratory. It simulates the process of human language generation and understanding through deep learning technology and adopts an autoregressive language modeling method to predict the next word or phrase in the text sequence to generate coherent text [18,19]. ChatGPT training data are derived from massive amounts of text data on the internet, including news reports, academic articles, and social media content. After the data are cleaned and labeled, the data are used to train the parameters of the model so that it can capture the complex patterns and semantic relationships of natural language [20,21]. ChatGPT's powerful language generation and context understanding capabilities enable it to automatically generate relevant and coherent responses based on the input text content, enabling natural interaction with human users and completing multiple linguistic tasks, such as questions and answers, text summaries, and sentiment analysis [6,20,22].

ERNIE Bot is an intelligent question-and-answer system based on deep learning technology created by China's Baidu. Its basic principle is to analyze and understand the questions raised by users by natural language processing technology, convert the questions of users into a form that computers can understand, and extract relevant information from massive amounts of data [23,24]. Natural language generation models are then used to transform the extracted information into a form that humans can understand, generate answers, and return them to the user. ERNIE Bot has a large amount of data, including trillions of web data, billions of search data and image data, billions of daily voice call data, and 550 billion facts in the knowledge graph [25]. ERNIE Bot uses advanced natural language processing algorithms to accurately understand user questions and provide precise answers. Furthermore, it supports personalized customization according to different scenarios and needs and can continue to learn and accumulate knowledge to improve intelligence.



The purpose of this cross-sectional study is (1) to evaluate and compare the performance of ChatGPT and ERNIE Bot in answering questions in ultrasound examination papers; (2) to comprehensively analyze and compare the performance differences of the models in different question types, topics, and input language environments; and (3) to explore the reasons for these differences. This study is expected to provide insight for chatbot users and developers so that we can better understand the performance of various models in different fields. For more complex medical problems and fields, we can attempt to combine the advantages of multiple models to make an objective comprehensive judgment and consider the results. Chatbots can provide better services while constantly improving their own performance.

Methods

Question Curation

We used questions from ultrasound examination papers as a data set. The questions, from the West China Clinical College of Medicine of Sichuan University, covered basic knowledge of ultrasound medicine, the digestive system, the urinary system, superficial organs, blood vessels, and the heart. The question types included single-choice, multiple-choice, true or false questions; noun explanations; and short answers. With a total of 584 questions, we excluded picture-related questions, repetitive questions, questions with poor grammar, and questions with subjective answers from this cross-sectional study. Finally, a total of 554 questions were included, and the flowchart of the questions suitable for inclusion in the study is shown in Figure 1.

Figure 1. Flowchart of the questions included in the study.

XSL•FO
RenderX

Response Generation and Grading

Each question was entered into GPT-3.5 Turbo (GPT-3.5) and ERNIE Bot-3.5 (Bot-3.5) in both English and Chinese, and the responses were recorded. For each input question, the background definition of the question, and the explanation of the question type are given, such as the noun explanation of the undergraduate superficial organ ultrasound examination. An example of the questioning methods for different types of questions is shown in Textbox 1. The subjective questions in this cross-sectional study included noun interpretation questions and short answer questions. All the subjective questions were scored by 5 experts in the field of ultrasound medicine who are fluent in both Chinese and English and have more than 20 years of experience in the fields of ultrasound diagnosis and ultrasound teaching. The experts rated the comprehensive quality of the responses in both languages on a Likert scale [26-28], which is an effective, objective, and fair evaluation method for quantifying and grading answers. The evaluation of subjective responses in this study includes completeness, logical clarity, accuracy, depth and breadth, creativity, and so on. A higher score indicates higher quality (1 point: very poor, the answer content seriously deviates from the requirements of the question, the logic is confused, and there is basically no correct content; 2 points: poor, part of the answer deviates from the requirements of the question, contains some correct content, but the logic is not clear enough, and there are some mistakes or omissions; 3 points: acceptable, the answers basically meet the requirements of the question, the content is relatively complete, the logic is relatively clear, but some details or explanations are not accurate or in depth; 4 points: good, the answer fully meets the requirements of the question, and the content is accurate, complete, and logical; and 5 points: very good, the answers fully meet the requirements of the question, the content is accurate and in depth, comprehensive, logical and rigorous, and even new insights or solutions are proposed). The experiments were completed in October 2024.

Textbox 1. Examples of how to ask questions, including the content of the question, background, and question type description.

Example A

- The following is a single-choice question for the ultrasound examination. Please select the most appropriate one from the options given.
- Which of the following is true about ultrasound?
- Ultrasound is an electromagnetic wave with a strong penetrating force.
- The commonly used frequency range of medical ultrasound is 2.5-12 MHz.
- Ultrasound wave is a wave with a frequency greater than 2000 Hz.
- The form of ultrasound wave propagation in the human body is mainly shear wave.
- Ultrasound is not easily affected by gas and bone.

Example B

- The following is a multiple-choice question for the superficial organ ultrasound examination. Please select two or more of the correct answers from the options given.
- To which layers is the mammary gland subdivided by the fascia layer?
- Skin layer
- Subcutaneous fat layer
- Glandular (parenchymal) layer
- Fat layer in the retromammary space
- Chest wall layer

Example C

- The following is a judgment question for the ultrasound imaging examination. Please judge whether the following description is correct or not.
- An infective endocarditis patient can definitely detect growth on ultrasound.

Example D

- The following is a noun explanation question for the superficial organ ultrasound examination. Please make an appropriate explanation of the following nouns.
- Acoustic impedance

Example E

- The following is a short answer question for the ultrasound examination.
- Please briefly describe the common etiology and typical ultrasound features of cirrhosis.

Statistical Analysis

For statistical analysis purposes, all the questions were grouped into categories: basic knowledge, disease and etiology, ultrasound examination, ultrasound diagnosis, ultrasound signs, case analysis, etc. We used Microsoft Excel to conduct statistical analyses (version 2019; Microsoft Corporation).

Ethical Considerations

Ethics approval was not required since the research did not involve human subjects or animals.

Results

All the questions included in this cross-sectional study are from real ultrasound examination papers, and the proportions of question types and categories are highly representative. The types and categories of all the questions included in this study are shown in Tables 1 and 2. Among the 554 eligible questions included in this study, according to the classification of question types, single-choice answers accounted for the highest proportion (354/554, 64%), followed by short-choice answers (69/554, 12%) and noun explanations (63/554, 11%), and the rest were multiple-choice and true or false questions. According to the classification of topics, the greatest proportion of topics were basic knowledge (181/554, 33%), followed by disease and etiology (106/554, 19%) and ultrasound signs (96/554, 17%), and the rest were ultrasound examination, ultrasound diagnosis, and ultrasound case analysis.

Table . Questions types and categories included in this study.

Categories	Basics, n	Examinations, n	Diagnosis, n	Cases, n	Disease, n	Signs, n	Total, n
Single choice	124	49	41	26	63	51	354
Multiple choice	13	8	6	—[a]	12	9	48
True or false	10	7	3	—	—	—	20
Noun explanation	21	8	3	—	24	7	63
Short answer	13	10	10	—	7	29	69
Total	181	82	63	26	106	96	554

[a]Not applicable.

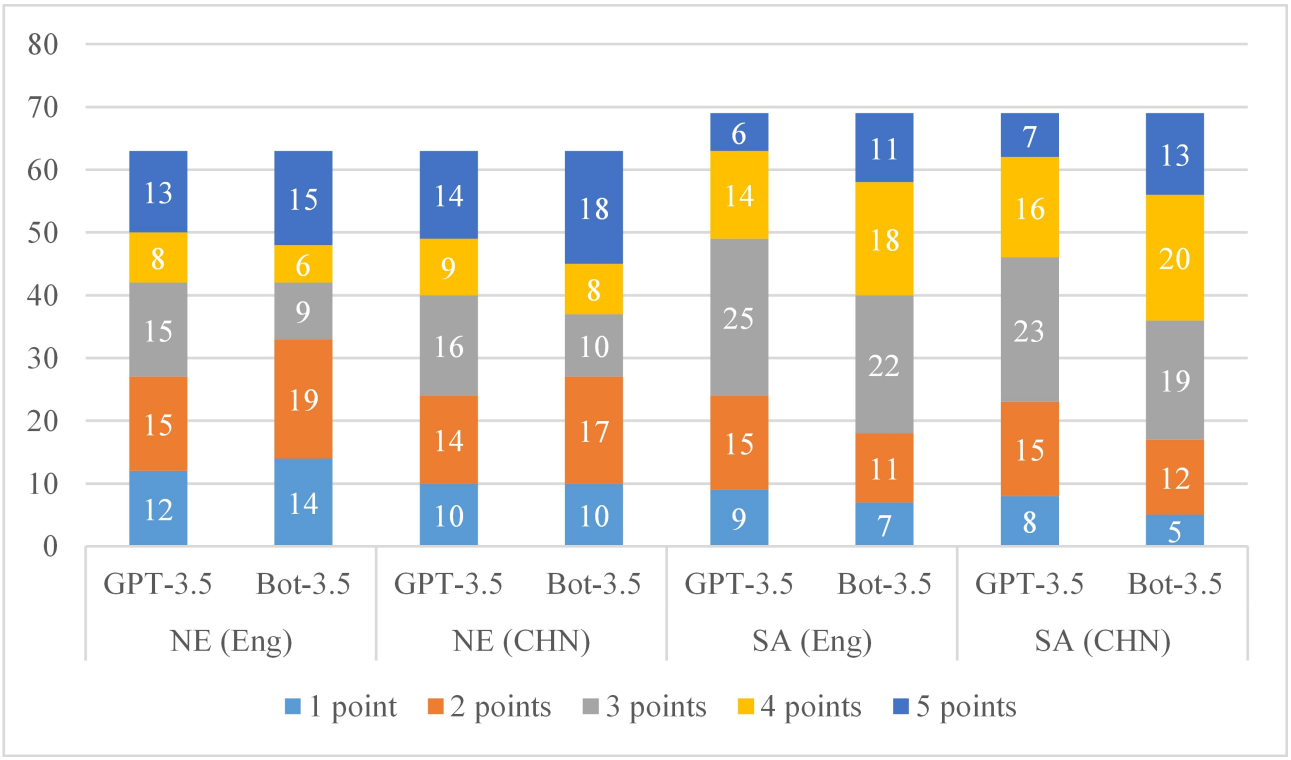
Table . Study results for each question category, stratified by question style (single-choice, multiple-choice, and true or false questions), language (English and Chinese), and artificial intelligence model (GPT-3.5 Turbo [GPT-3.5] and ERNIE Bot-3.5 [Bot-3.5]).

Categories	Model	Basics, %	Examination, %	Diagnosis, %	Cases, %	Disease, %	Signs, %	Total, %
Single choice (English)	GPT-3.5	58.87	59.18	58.54	57.69	50.79	58.82	57.34
Correct (%)	Bot-3.5	57.26	61.22	58.54	61.54	63.49	60.78	59.89
Single choice (Chinese)	GPT-3.5	60.48	61.22	63.41	57.69	53.97	60.78	59.6
Correct (%)	Bot-3.5	58.06	65.31	56.1	65.38	68.25	70.59	62.99
Multiple choice (English)	GPT-3.5	7.69	0	16.67	—[a]	8.33	11.11	8.33
Correct (%)	Bot-3.5	46.15	12.5	16.67	—	25.0	66.67	35.42
Multiple choice (Chinese)	GPT-3.5	7.69	0	16.67	—	16.67	11.11	10.42
Correct (%)	Bot-3.5	53.85	12.5	16.67	—	33.33	66.67	39.58
True or false (English)	GPT-3.5	50	57.14	100	—	—	—	60
Correct (%)	Bot-3.5	60	85.71	100	—	—	—	75
True or false (Chinese)	GPT-3.5	50	71.43	100	—	—	—	65
Correct (%)	Bot-3.5	70	85.71	100	—	—	—	80

[a]Not applicable.

We collected the accuracy rate results of the 2 AI models, GPT-3.5 and Bot-3.5, for single-choice, multiple-choice, and true or false questions in English and Chinese. When the models were asked questions in Chinese (the original language of the test paper), the overall accuracy rate was as follows (GPT-3.5 vs Bot-3.5): single-choice (59.6% vs 62.99%), multiple-choice (10.42% vs 39.58%), and true or false questions (65% vs 80%). When the test paper was translated into English for questioning, the overall accuracy rates were as follows (GPT-3.5 vs Bot-3.5): single-choice (57.34% vs 59.89%), multiple-choice (8.33% vs 35.42%), and true or false questions (60% vs 75%). All translations are performed manually by experts who are proficient in English. It can be clearly seen that Bot-3.5 is superior to GPT-3.5 in all question types and languages. Furthermore, we calculated classified statistics according to the accuracy rates of different categories of questions, and the statistical results are shown in Table 2.

We collected the scores of the GPT-3.5 and Bot-3.5 AI models for noun interpretation and short answers in both Chinese and English. A total of 63 noun explanation questions and 69 short answer questions were included in this cross-sectional study. The scoring criteria were divided into 5 levels—1 point=very poor, 2 points=poor, 3 points=acceptable, 4 points=good, and 5 points=very good. We take the average score of 5 experts, round the average score to the nearest whole number, and finally calculate classification statistics according to the score values. When asked questions in Chinese (the original language of the test paper), the most common scores were as follows (GPT-3.5 vs Bot-3.5): noun explanation (3 points vs 5 points) and short answer (3 points vs 4 points). When the test paper was translated



XSL•FO
RenderX

into English for questions, the most points were scored (GPT-3.5 vs Bot-3.5): noun explanation (2 points vs 2 points) and short answer (3 points vs 4 points). The detailed frequency tables are shown in Table 3 and Figure 2.

Table . Comparison of the distribution of scores stratified by question type (no explanation, short answer), language (English and Chinese), and artificial intelligence model (GPT-3.5 Turbo [GPT-3.5] and ERNIE Bot-3.5 [Bot-3.5]).

Categories and model	1 point	2 points	3 points	4 points	5 points	Total
Noun explanation (English)						
GPT-3.5	12	15	15	8	13	63
Bot-3.5	14	19	9	6	15	63
Noun explanation (Chinese)						
GPT-3.5	10	14	16	9	14	63
Bot-3.5	10	17	10	8	18	63
Short answer (English)						
GPT-3.5	9	15	25	14	6	69
Bot-3.5	7	11	22	18	11	69
Short answer (Chinese)						
GPT-3.5	8	15	23	16	7	69
Bot-3.5	5	12	19	20	13	69

Figure 2. The distribution of scores. Bot-3.5: ERNIE Bot-3.5; CHN: Chinese; Eng: English; GPT-3.5: GPT-3.5 Turbo; NE: noun explanation; SA: short answer.

We conducted a quantitative statistical analysis of noun explanations and short answer scores, including minimum, maximum, IQR, median, mean, sum, and SD scores. We compared the quantitative statistics of the GPT-3.5 and Bot-3.5 scores in the Chinese language environment. For noun interpretation, the maximum, minimum, and median values were equal for GPT-3.5 versus Bot-3.5; other statistics were as follows: IQR 2 - 4 vs 2 - 5, mean 2.86 vs 3.37, sum 180 vs 212, and SD 1.4 vs 1.37. There was a significant difference between the 2 models in terms of the quality of answers to noun interpretation (P<.05). For short answers, the maximum, minimum, and median values were equal (IQR 2 - 4 vs 2.5 - 4, mean 2.93 vs 3.36, sum 202 vs 232, and SD 1.15 vs 1.19), and there was a significant difference between the 2 models in terms of the quality of answers to short answers (P<.05). The statistical results are shown in Table 4.

XSL•FO
RenderX

Table . Quantitative statistical results of noun interpretation and short answer scores for 2 artificial intelligence models (GPT-3.5 Turbo [GPT-3.5] and ERNIE Bot-3.5 [Bot-3.5]).

Categories	Noun explanations (n=63)		Short answers (n=69)	
	GPT-3.5	Bot-3.5	GPT-3.5	Bot-3.5
Minimum	1	1	1	1
Maximum	5	5	5	5
IQR	2 - 4	2 - 5	2 - 4	2.5 - 4
Median	3	3	3	3
Mean	2.86	3.37	2.93	3.36
Sum	180	212	202	232
SD	1.40	1.37	1.15	1.19

To compare and analyze the performance of the 2 AI models (GPT-3.5 and Bot-3.5) in the Chinese language environment when noun explanations and short answers are classified according to different topics, we calculated the number of scores for each type of topic in the Chinese language environment. For noun interpretation, the highest percentage scores were obtained for GPT-3.5 vs Bot-3.5, basic knowledge (4 points vs 4 points), ultrasound examinations (5 points vs 5 points), disease and etiology (1 point vs 2 points), and ultrasound signs (1 point vs 1 point). For short answers, those with the highest percentage of points (3.5 points vs Bot-3.5), basic knowledge (3 points vs 5 points), ultrasound examinations (2 points vs 3 points), ultrasound diagnosis (3 points vs 5 points), disease and etiology (3 points vs 2 points), and ultrasound signs (3 points vs 3 points) were included. The statistical results are shown in Table 5.

Table 5 also shows the differences in scores between the 2 models on different subject categories. Based on the above results, the most important finding is that Bot-3.5 performs better than GPT-3.5 in the Chinese environment, both objectively and subjectively. Bot-3.5 is representative of the localization model, and GPT-3.5 is representative of the internationalization model. The excellent performance of Bot-3.5 is due to its comprehensiveness and depth in the Chinese training data set. The discovery of this performance difference has implications for both users and developers of chatbot systems, and it is necessary for users to have a deeper understanding of the model's data set background, language, and performance to better use them. Developers can also improve and optimize robot models according to performance differences.

5 points		2	1		2	3

Discussion

Preliminary Findings

Since the public release of ChatGPT, its convenience has made AI more accessible than ever before. It has demonstrated its ability to provide answers even to knowledgeable and experienced professors, and its numerous advantages have quickly made it a hot topic and the focus of research. Many technology companies around the world are also developing chatbot systems [4,29,30]. Industries are also exploring how to integrate these AI technologies with their own work and learning to improve quality and efficiency [31,32]. In the medical field, chatbot systems can be used as learning and consulting assistants to answer a variety of medical-related questions, but the accuracy and quality of their information must be carefully evaluated [33,34].

In this cross-sectional study, we analyzed 554 actual examination paper questions from the field of ultrasound medicine and evaluated the performance of an AI chatbot system in answering these medical paper questions. Medical examination papers are often used to evaluate chatbot performance, mainly because of their wide coverage,

XSL•FO
RenderX

representativeness, and reference answers [35-37]. Alessandri et al [35] used the Residency Admission National Examination to evaluate ChatGPT. Humar et al [22] evaluated ChatGPT with questions from the plastic surgery in-service examination. The main advantage of our study is that the questions are from actual ultrasound medical examinations, and its content is broad and representative. The question types included single-choice, multiple-choice, true or false questions; noun explanations; short answers; basic knowledge; ultrasound examination; ultrasound diagnosis; ultrasound case analysis; disease and etiology; and ultrasound signs. We conducted a quantitative comparative analysis of the performance of two of the most representative free chatbots (GPT-3.5 and Bot-3.5). Samaan et al [16] demonstrated that chatbot performance is affected by the language environment. We use both English and Chinese to ask questions and analyze the quality of the answers provided by the 2 models in different linguistic environments.

Regardless of whether the input language is English or Chinese, the GPT-3.5 and Bot-3.5 models perform somewhat well on different types of questions in the field of ultrasound medicine. For objective questions (including single-choice, multipl-choice, and true or false questions in this cross-sectional study), we took the accuracy rate as the evaluation index, and a score of ≥60% is acceptable, which is also the passing score of medical students. The best performance was true or false questions (accuracy rate: 60%-80%), followed by single-choice questions (accuracy rate: 57.34%-62.99%), and the worst performance was multiple-choice questions (accuracy rate: 8.33%-39.58%). For subjective questions (including noun explanations and short answers in this cross-sectional study ≥3 points, considered to be acceptable answers, also the assessment criteria), the performance was better for short answers, with acceptable answers (≥3 points) accounting for 65.22%-75.36%, whereas the performance for noun explanations was lower, with acceptable answers accounting for 47.62%-61.9%.

The reasons behind these differences are worth exploring and analyzing. For objective questions, the difficulty and complexity of the questions may be important factors. Branum and Schiavenato [14] reported that chatbots sometimes provide plausible but incorrect answers to complex clinical questions [38]. True or false questions usually involve only the truth or falsity of a statement and are the least difficult. Although multiple options are provided in a single choice, the answer is unique, and the model needs to identify only the correct answer from a limited number of options, with moderate difficulty. The research results of Lai et al [32] indicate that chatbots have high accuracy in single-choice selection. However, multiple choice requires the model to identify the correctness of multiple options at the same time, which significantly increases the difficulty and complexity of information processing. Mihalache et al [3] demonstrated that substantial progress has not been made in multiple-choice chatbots. Furthermore, the processing of multiple-choice questions in the process of model training may be less common than that of other types of questions, and most of the multiple-choice answers are more flexible. For subjective questions, differences in openness, flexibility, and scoring criteria may be the reasons for differences in performance. Short answer questions often require the model to provide a short paragraph of explanation or description, which allows the model to show more flexibility and depth in its responses. On the other hand, noun interpretation is more focused on the precise interpretation of specific terms, which requires higher accuracy and professionalism of the model. When short answers are graded, the grading criteria may be more flexible, allowing a degree of freedom. Other studies have asked questions about diseases similar to the short-answer questions in this study. Yun et al [33] demonstrated the effectiveness of chatbots when short-answer questions are answered. Noun interpretation, on the other hand, can be more rigorous, requiring the model to provide a precise and professional interpretation [39]. Therefore, the differences in the performance of the models on different question types can be attributed to the differences in the difficulty of the questions, the complexity of information processing, the training data, and the scoring criteria. As a user, it is necessary to understand the performance differences of models of different types in advance, and as a developer, adjusting the distribution of the training data set and optimizing the model are important.

When comparing the performance of the GPT-3.5 and Bot-3.5 AI models in the field of ultrasound medicine, we found some significant differences. Table 2 reported that the accuracy rate of GPT-3.5 for multiple-choice and true or false questions is lower than that of Bot-3.5, suggesting that Bot-3.5 may be more capable of handling problems that require deep understanding and reasoning. Tang and Yang [23] demonstrated that Bot-3.5 shows greater participation and enthusiasm in teaching applications. This difference may be related to the differences in training data and algorithm architecture between the 2 models. Bot-3.5 may have been exposed to more diverse and complex data from the medical field during training to be better able to handle these types of problems. From Tables 4,5 and 5, we further analyze the scores of the 2 models on different question types. In terms of noun interpretation and short answers, Bot-3.5 scores are generally higher than GPT-3.5 scores, especially in the Chinese context. This result suggested that Bot-3.5 may have greater accuracy in understanding and interpreting medical terms and concepts. In addition, from the comparison of the score statistics, we can observe that Bot-3.5 is more concentrated in the score distribution, which implies that it has greater stability and consistency in dealing with similar problems.

When the test paper was translated into English for questioning, the performance of both models declined, but Bot-3.5 maintained its advantage in terms of multiple-choice and true or false questions. This finding reveals the limitations of both models in cross-language processing. Zhu et al [25] compared the performance of large language models developed in different countries, highlighting the necessity for localized models. Although both models claim to support multilingual processing, in practice, the model's ability to process across languages is affected by various aspects, such as architecture, algorithms, or training data, and when the model switches from 1 language to another, it may need to readjust to new language features. This adaptation process can lead to performance degradation, especially when dealing with complex tasks. During the training of the model, there may be differences in the distribution and scale of the Chinese and English data, and if the model is trained

XSL•FO
RenderX

more fully on the Chinese data, it may perform better on the Chinese input. Bot-3.5 was developed and trained in China and has a large Chinese corpus. During the design and training process, Chinese language features were deeply optimized. This optimization allows Bot-3.5 to perform well in terms of Chinese semantic understanding and context grasp.

Biswas et al [26] conducted a categorical assessment analysis of these problems. In terms of noun interpretation and short answer questions, both models scored highly in basic knowledge, ultrasonography, disease, and cause, which may be related to the importance of these topics in the medical field and their richness in the training data. However, in areas such as ultrasound signs and ultrasound diagnosis, both models scored relatively low, which may reflect the complexity and challenge of these topics in the medical field, requiring more in-depth reasoning and understanding of complex issues [40].

Although chatbots are not yet able to provide perfect answers in all aspects of medicine, chatbots have great potential for answering medical questions. Because the performance of chatbots is not static, with the continuous enrichment of training data and the continuous improvement and optimization of algorithms, chatbot performance will continue to improve. The results of this cross-sectional study have implications for both users and developers of chatbot systems. To improve the quality and efficiency of chatbot use, users need to deeply understand the performance and characteristics of different models and carefully study the performance differences and evaluation results of different models on different topics or task types to select the appropriate model according to actual needs [24]. Moreover, users should set clear expectations and establish appropriate evaluation criteria based on the model's actual performance to conduct objective and comprehensive evaluations in practical applications. For complex tasks or tasks requiring high accuracy, users can attempt to combine the advantages of multiple models, adopt the method of ensemble learning, and weight the prediction results of multiple models to obtain more accurate prediction results. Specific feedback and suggestions are provided to developers in appropriate ways and channels when the model is used. For developers, the results of the study can be used to optimize the model for performance issues on a particular topic or task. For example, training data in related fields can be increased, or more advanced training algorithms can be used to improve the performance of the model in the medical field. The user feedback and suggestions are actively collected, and the model is constantly iterated and improved. Everyone needs to recognize that no chatbot is omnipotent. We need to understand it, use it correctly rather than contradict or abuse it, treat it as a judge, let it grow healthily, and create more and better value for human beings.

Limitations

Our study has several limitations. First, the original language of all the questions in this cross-sectional study was Chinese, and the questions were asked in Chinese or translated from Chinese to English, which may not represent the performance of the model in other languages. Second, the sample size of our study was not large and focused only on text-related topics related to ultrasound medicine. Experts also have potential bias in the scoring. The universality of the results of this study in other medical specialties needs further research. Finally, chatbot versions are constantly being updated, and the results of this study may not be representative of the performance of the most recent version of the model at the time of publication [41]. However, GPT-3.5 and Bot-3.5 are the best-performing versions of the current free versions, as well as the largest number of users, and it is meaningful to study the performance comparison of the latest free versions of each model over the same period.

Conclusions

The results show that the AI chatbots represented by GPT-3.5 have a certain ability to answer questions in ultrasound medical examination papers, but there are varying degrees of performance differences across chatbot models, input languages, question types. and topics. For the Chinese ultrasound medical questions in this study, Bot-3.5 was superior to GPT-3.5 in terms of both accuracy and quality in many aspects. These findings suggest that users need to thoroughly understand the performance characteristics of various models and their applicability to different types of problems. For complex problems, multiple models are needed for comprehensive analysis. This finding also suggests that developers need to continuously optimize models to enrich training data, especially in medical specialties. In this way, chatbots can be continuously optimized, their performance consistently improved, and their ability to provide high-quality services enhanced.

Abstract

Background: Cohort studies contain rich clinical data across large and diverse patient populations and are a common source of observational data for clinical research. Because large scale cohort studies are both time and resource intensive, one alternative is to harmonize data from existing cohorts through multicohort studies. However, given differences in variable encoding, accurate variable harmonization is difficult.

Objective: We propose SONAR (Semantic and Distribution-Based Harmonization) as a method for harmonizing variables across cohort studies to facilitate multicohort studies.

Methods: SONAR used semantic learning from variable descriptions and distribution learning from study participant data. Our method learned an embedding vector for each variable and used pairwise cosine similarity to score the similarity between variables. This approach was built off 3 National Institutes of Health cohorts, including the Cardiovascular Health Study, the Multi-Ethnic Study of Atherosclerosis, and the Women's Health Initiative. We also used gold standard labels to further refine the embeddings in a supervised manner.

Results: The method was evaluated using manually curated gold standard labels from the 3 National Institutes of Health cohorts. We evaluated both the intracohort and intercohort variable harmonization performance. The supervised SONAR method outperformed existing benchmark methods for almost all intracohort and intercohort comparisons using area under the curve and top-*k* accuracy metrics. Notably, SONAR was able to significantly improve harmonization of concepts that were difficult for existing semantic methods to harmonize.

Conclusions: SONAR achieves accurate variable harmonization within and between cohort studies by harnessing the complementary strengths of semantic learning and variable distribution learning.

Introduction

Data harmonization, the process that ensures the compatibility of diverse datasets for their cogent integration, is an indispensable tool in today's data-driven research environment [1-3]. The power of data harmonization lies in its capacity to enhance the statistical robustness of studies, thereby enabling the investigation of intricate research questions unattainable within a single dataset's limits. This ability to pool data from existing sources expedites research processes, reduces associated costs, and accelerates the translation of knowledge into practical applications [4,5]. However, despite the advantages of pooling data, the path to effective data harmonization is laden with challenges [6-9]. The most pronounced among these is the discrepancies in how individual datasets document and measure similar concepts [10-12]. Even within datasets, documentation

XSL•FO
RenderX

for analogous concepts is not consistent, thereby further complicating data integration.

Current data harmonization techniques mainly depend on manual curation [10,13,14]. In spite of its widespread use, manual curation is time-intensive, prone to human error, and often constrained in scope, focusing predominantly on a single disease or condition. These drawbacks limit the applicability and efficacy of manual curation in broader, more complex contexts and highlight the need for advanced harmonization methodologies [12,15-17]. Recently, there has been a shift towards automated techniques, like freely available mapping tools [18-20] and algorithms based on corpora or lexicons [21-23]. These tools aim to map terminologies across varied clinical domains. Yet, such methods might still necessitate significant domain expertise and depend on benchmark labels. Furthermore, many of these methods cater to only one kind of medical code, for instance, drug or lab codes.

Another promising approach for data harmonization is through semantic learning. In a study by Zhou et al [24], an automated harmonization algorithm was proposed to cotrain embeddings for electronic health record codes from multiple institutions by combining both electronic health record co-occurrence information and textual information from the code descriptions. As a technique that uses machine learning to infer meaning from data, semantic learning presents a promising avenue for enhancing data harmonization. However, semantic learning's applicability is limited by its demand for extensive, high-quality training data, its sensitivity to noisy or unreliable data, and the complexity involved in manually crafting semantic features.

In this paper, we propose SONAR (Semantic and Distribution-Based Harmonization), an innovative data harmonization approach that synthesizes the strengths of semantic learning with patient data learning. Patient data offers an alternative, unexplored source of learning for data harmonization purposes. The patient-level values for each variable provide information about the underlying concept that a variable measures, separate from the textual information in variable descriptions. By harnessing the context comprehension and inferential power of semantic learning and augmenting it with the capacity of patient data learning to capture concept-specific trends and nuances, we propose a more robust and accurate data harmonization strategy. We demonstrate the implementation and advantages of the proposed approach through its application across 3 major National Institutes of Health cohort studies: the Multi-Ethnic Study of Atherosclerosis (MESA) [25], the Cardiovascular Health Study (CHS) [26], and the Women's Health Initiative (WHI) [27]. Our aspiration is that the method proposed here will provide a valuable foundation for future studies aiming to tackle the multifaceted challenges of data harmonization between heterogeneous datasets.

Methods

Ethical Considerations

The data used in this study were obtained from 3 well-established cohort studies, namely CHS, MESA, and WHI. Ethics approval (IRB17-2059) was granted by the Institutional Review Board of the Harvard Faculty of Medicine. Institutional Review Board approval was secured for access to all studies' retrospective data. De-identified data was accessed through a secure cloud storage platform. Participants were not compensated for the use of their data in this study.

Data Sources

The CHS was a population-based longitudinal study initiated to determine the risk factors for the development and progression of clinically validated cardiovascular disease in adults aged 65 years and older. Beginning in 1989, the study enrolled 5888 participants from 4 US communities: Forsyth County, NC; Sacramento County, CA; Washington County, MD; and Pittsburgh, PA. The cohort consisted of two recruitment waves: the original cohort (1989-1990) and the African American cohort (1992-1993). Comprehensive baseline examinations were conducted, including medical history, physical examinations, laboratory tests, and others, with annual follow-ups to ascertain cardiovascular events [26].

The WHI was a long-term national health study that focused on strategies for preventing heart disease, breast and colorectal cancer, and osteoporotic fractures in postmenopausal women. Launched in 1991, the WHI involved multiple clinical trials and an observational study, enrolling a total of 161,808 women aged 50-79 years across 40 clinical centers throughout the United States. The participants were ethnically diverse, reflecting the demographic composition of the US population. Extensive data on lifestyle, health, and medical history were collected at baseline and at regular intervals throughout the study, creating a rich source of information for a variety of research endeavors [27].

The MESA study was a prospective cohort designed to delve into the prevalence and progression of subclinical cardiovascular disease among community-dwelling adults. MESA assessed a diverse, population-based sample of 6814 asymptomatic men and women aged between 45 and 84 years from 2000 to 2018. The participants were recruited from 6 field centers across the United States, including Wake Forest University, Columbia University, Johns Hopkins University, University of Minnesota, Northwestern University, and University of California – Los Angeles. The MESA cohort was made up of 38% White, 28% African-American, 22% Hispanic, and 12% Asian (primarily Chinese) individuals. Since its inception in July 2000, the study conducted 6 examinations, each occurring every 18 to 24 months [25].

Data Extraction

The process of data extraction necessitated the gathering of documentation for variables within the CHS, MESA, and WHI studies. This information was procured from the Database of Genotypes and Phenotypes (dbGaP) [28]. We used dbGaP metadata to procure the following salient information for each variable within the study: (1) variable accession, (2) variable name, (3) variable description, and (4) dataset accession. While the variable name and variable description were not necessarily unique within or between studies, the variable accession was a unique identifier across all studies. We used the variable description strings as the semantic data in our model. From the

XSL•FO
RenderX

raw variable description strings, we further extracted and removed the temporal period during which the variables were measured by parsing for key temporal terms, such as visit and exam. This data extraction process facilitated a comprehensive understanding of the variables' conceptual characteristics, thereby providing the foundation for the subsequent data harmonization efforts.

We used the dataset accession and variable accession identifiers to access (1) variable metadata and (2) the patient-level data for the set of variables already extracted from dbGaP. To allow for relevant distribution comparisons between variables, we kept only continuous data by filtering variables using the continuous flag in the metadata.

Data Preprocessing

Our study scope was primarily focused on the harmonization of continuous variables at the conceptual level. A "concept" in this context was defined as the underlying notion or theme that a variable represents, independent of the specific unit or time point of measurement. For example, a biomarker such as C-reactive protein, despite being reported in different units across different visits, was treated as having the same concept. Moreover, concepts were sometimes encoded in natural language or questionnaire form, rather than standard medical terms. We focused on conceptual level harmonization for several reasons. Researchers conducting multicohort studies are often interested in identifying all variables corresponding to a concept. Depending on the application, they might be interested in further refining this concept-level harmonization or also harmonizing the variable values across different units or collection time periods. Removing temporal information and units allowed us to focus on the essential meaning or theme underlying the variable, thereby facilitating the primary task of concept-level harmonization, which is manually challenging and resource intensive, paving the way for further data harmonization. Moreover, doing so enhanced comparability across studies, as variables with the same concept were treated as equivalent, irrespective of the units used. During the initial phase of data preprocessing, we streamlined variable descriptions by eliminating temporal information phrases. This practice not only simplified the descriptions but also augmented their comparability.

We also applied filters to variables according to their values. First, we removed variables with incomplete patient data. To preserve a significant portion of variables, we considered incomplete patient data at the subgroup level rather than the individual patient level. We defined patient subgroups using the anchor variables of age, race, and sex. Per the characteristics of the study populations and data availability, we defined 4 age buckets (≤59 years, 60 to 69 years, 70 to 79 years, and ≥80 years). For the categorical anchor variables, we used 2 predefined race categories (White and Black) and 2 predefined sex categories (female and male), yielding a total of 16 possible patient subgroups (calculated as 4×2×2). For each study, we removed variables that had no patient data for one or more subgroups, considering only patient subgroups that were represented in the cohort.

Second, we purged variables that had uniformly zero values across all patients. This removal was necessary as variables without variability do not offer predictive power and thus, contribute little to subsequent analyses. Subsequently, we identified variables within the same study with identical descriptions and treated them as a single entity. Rather than maintaining these as separate variables, we amalgamated their distribution vectors by computing their element-wise mean. This consolidation concurrently reduced redundancy and bolstered the statistical power and robustness of downstream analyses. The underlying principle driving these measures was the emphasis on the core conceptual content encapsulated within variables, a focus that lays the groundwork for a more efficient and meaningful process of data harmonization.

Creation of Gold Standard Labels

To assess the harmonization accuracy of SONAR, we manually created a set of gold standard labels. The process began with the curation of a concept list, consisting of common diseases, laboratory results, and medications, consistent with the goal of harmonization at the conceptual level (details in Multimedia Appendix 1, Section 4). With the concept list in hand, each of the 3 independent reviewers assigned raw variables from all 3 studies to the corresponding concepts based on their descriptions. Not all variables had labels, since the curated concept list was not comprehensive of all underlying concepts present in the studies. To ensure consistency and accuracy, we adopted a consensus-based approach for handling any discrepancies among the reviewers. In cases of disagreements, the reviewers discussed their rationales for their assignments, and through a process of discussion, literature review, and majority vote, they reached a consensus on the appropriate concept assignment. This rigorously prepared set of annotations, backed by consensus, formed our gold standard labels. In particular, each pair of variables corresponding to the same underlying concept formed a gold standard pair (ie, a pair of variables that a harmonization algorithm should map to each other). Such pairs consisted of variables from two different datasets (intercohort) or the same dataset (intracohort), since multiple variables from a single dataset could correspond to the same underlying concept. These labels offered a reliable standard against which we could validate our semantic learning and patient data learning techniques.

SONAR (Semantic and Distribution-Based Harmonization)

The proposed SONAR approach had 4 steps, including semantic learning, distribution learning, concatenation of the two learnings, and supervised training. Underpinning both semantic learning and distribution learning was the idea that variables with similar textual descriptions and patient-level value distributions were more likely to encode the same underlying concept.

Step 1: Semantic Learning

We combined two existing pretrained large language models (LLMs) for semantic learning, CODER (Crosslingual Knowledge-Infused Medical Term Embedding) [29] and SapBERT (Self-Alignment Pretraining for Biomedical Entity

XSL•FO
RenderX

Representations) [30]. CODER, a semantic representation learning tool, is a type of pretrained language model using a contrastive learning framework [30,31]. It is particularly suited to the biomedical terms and descriptions found in clinical studies because it was trained on terms, concepts, and their relations in the Unified Medical Language System (UMLS) [32] knowledge graph. SapBERT is a pretrained, masked learning model also trained on synonyms in the UMLS knowledge graph. Both CODER and SapBERT create embedding vector representations from textual input, which were the variable description strings in our method. Combining CODER and SapBERT, which use different pretraining algorithms and training sets within the same knowledge graph, allowed us to increase the robustness of our semantic embeddings. The advantage of using these existing language models pretrained was a balance between saved training time and specificity to the domain and task. The output of this step was a CODER embedding vector (*VAR_coder*) and a SapBERT embedding vector (*VAR_sapbert*) for each variable. The goal of this process was to transform the variable descriptions into a uniform, computable format that captured their semantic essence.

Step 2: Distribution Learning

In order to conduct comparisons of patient-level values for pairs of variables, we constructed vectors encoding the distributions of variables. For each study, we aggregated patients into the previously defined 16 subgroups, using the anchor variables of age, race, and sex. These anchor variables were present in all studies and clinically relevant to most of the other study variables. It was possible and permissible that the number of anchor groups varied across different cohorts. For instance, in the WHI cohort that consisted only of women, the number of anchor groups was reduced to 8 (4×1×2). Then, we computed the subgroup quartiles (ie, the 25th, 50th, and 75th percentiles), thus yielding a numerical distribution vector for each variable (*VAR_dist*) of up to length 48 (16×3). This process was designed to capture the distribution characteristics of each variable within defined anchor groups, thereby adding a computationally efficient layer of contextual understanding to our harmonization strategy. Moreover, the quartile distribution encoding strategy allowed for greater flexibility in data handling by preserving patient confidentiality.

Step 3: Concatenation

This stage combined the insights gained from semantic learning and distribution learning. Specifically, for each variable, we concatenated its *VAR_coder*, *VAR_sapbert*, and *VAR_dist* vectors into a single *VAR_concat* vector. In order to ensure standardized comparisons with *VAR_concat* vectors of the same length, we kept only the variable distribution dimensions in *VAR_dist* corresponding to anchor groups present in both cohorts in each interdataset harmonization. We kept all available variable distribution dimensions for intradataset harmonization. Prior to concatenation, we also normalized the *VAR_coder*, *VAR_sapbert*, and *VAR_dist* vectors separately to ensure they operated on the same scale. In particular, we took the absolute magnitude of each element in a vector, selected the maximum value among these values, then divided the original vector by the maximum absolute value. After normalization in this manner, the elements in each vector were bound to the −1 to 1 range. This was crucial because it ensured that no vector's magnitude dominated during the concatenation process, thereby preserving the integrity of the information they conveyed. We then concatenated the normalized *VAR_coder*, *VAR_sapbert*, and *VAR_dist* vectors, resulting in a vector for each variable that we denoted as *VAR_concat* with dimension *d*. This concatenated vector, containing both semantic and distribution information, formed the foundation of our automated harmonization strategy.

Step 4: Supervised Training

We further refined the SONAR method through supervised training of a d×d rotation matrix *M* through gradient descent of a loss function (details in Multimedia Appendix 1, Section 1). The supervised embeddings were then the cross product of the unsupervised SONAR embeddings and *M*. Overall, this 4-step process served to capture the nuances and complexities of variable-concept relationships in a computationally efficient and robust manner. The systematic integration of semantic learning with distribution learning offered an innovative approach to data harmonization, promising to enhance accuracy, efficiency, and overall applicability of harmonization strategies.

Evaluation Metrics

We assessed the performance of the proposed SONAR approach both within individual cohorts (intracohort) and between different cohorts (intercohort). We considered the area under the curve (AUC) of the receiver operating characteristic curve as the overall metric for harmonization accuracy. Specifically, for each underlying concept, we first computed the cosine similarity of the embedding vectors for known concept pairs (true positives) and an equal number of randomly selected concept pairs (false positives), where the cosine similarity measured the cosine of the angle between 2 vectors in a multidimensional space, effectively quantifying how similar they are. The AUC was then calculated, summarizing the overall accuracy of our method across varying decision thresholds for a given underlying concept. The overall AUC was the average of the concept-level AUC values. To reduce the effect of outliers within the sampled negative pairs, we averaged the 3 overall AUC values calculated for 3 sets of sampled negative pairs.

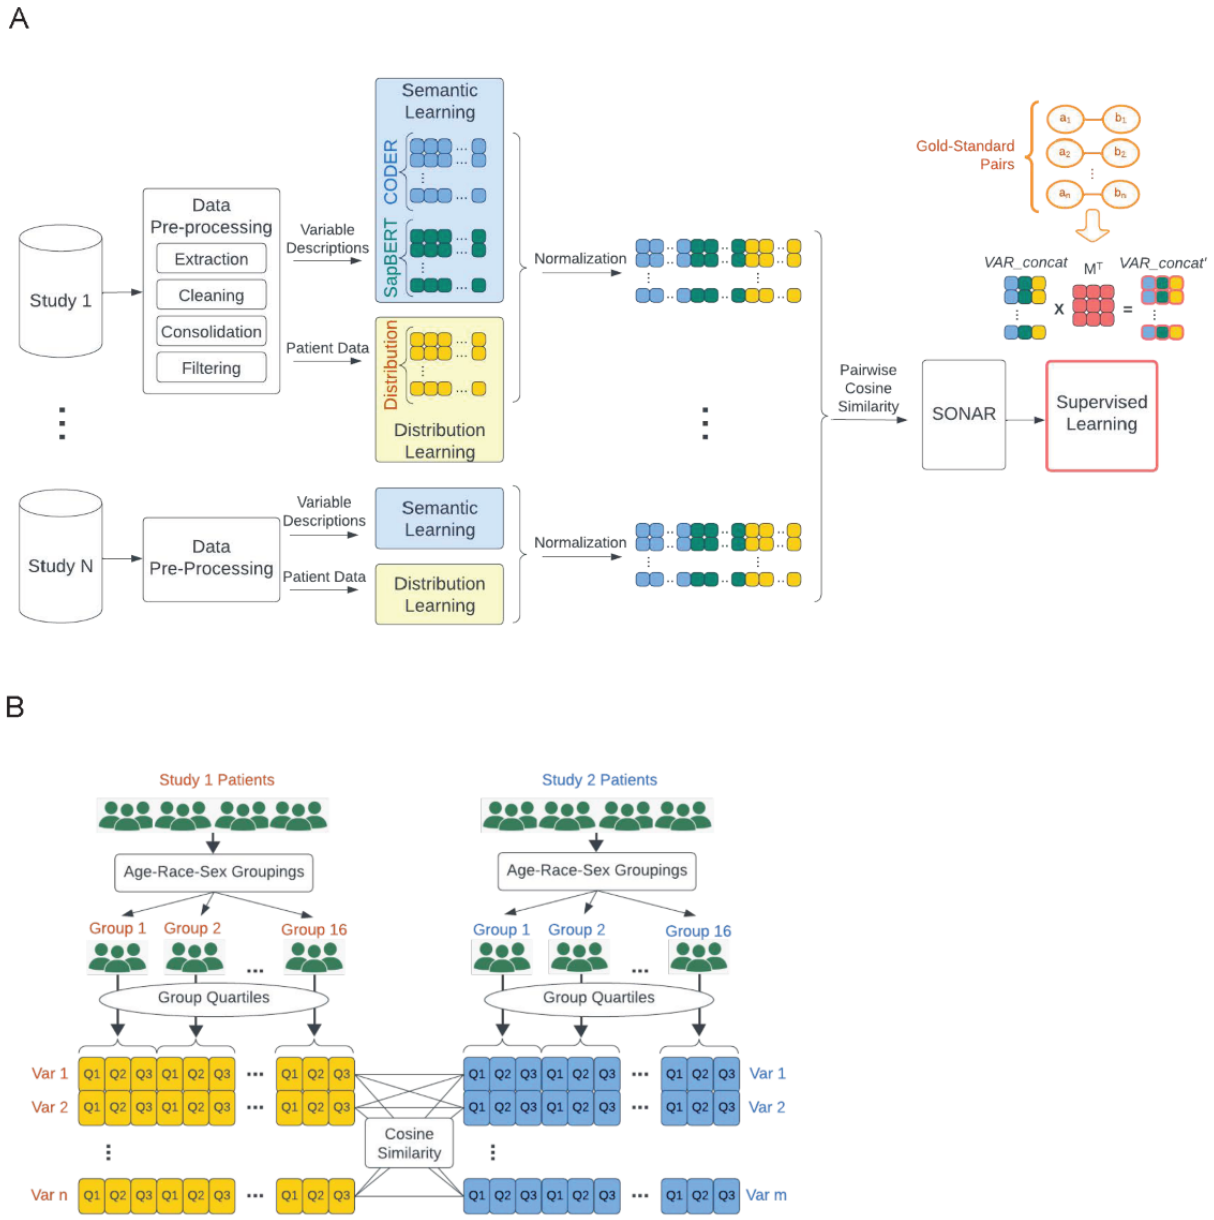
We also evaluated the performance of SONAR on hard concepts, defined to be concepts for which the benchmark SapBERT AUC was below the threshold of 0.900. The hard AUC was the average of the concept-level AUC values for the hard concepts. This was an important metric for demonstrating the added value of distribution learning and more broadly the complementary effects of the two forms of learning.

To further scrutinize the performance of our method, we reported the top-*k* accuracy (acc@*k*) for mapping of codes from Cohort A to Cohort B, where the cohorts were identical for intradataset mapping. For variable a in Cohort A, we let Ba be the set of variables within Cohort B with embeddings that had the largest cosine similarity with variable a, and we let Ga be the set of variables within Cohort B that were in a positive gold standard pair with variable a. Then, the acc@*k* for an underlying concept for the mapping from Cohort A to Cohort B was the

XSL•FO
RenderX

number of codes a such that Ba∩Ga≠0 divided by the total number of gold standard variables in Cohort A corresponding to the underlying concept. The acc@*k* for the mapping from Cohort A to Cohort B was then the average of the acc@*k* across all underlying concepts. This prevented dominance by underlying concepts with many corresponding gold standard variables. To calculate the intracohort acc@*k*, we first computed the intracohort acc@*k* for each underlying concept by averaging the acc@*k* for that underlying concept across all 3 intracohort comparisons (intra-CHS, intra-MESA, and intra-WHI). Underlying concepts were only averaged over the comparisons for which they were relevant, so the intracohort acc@*k* for a concept that had gold standard pairs in only CHS and MESA was be the average of the CHS acc@*k* and the MESA acc@*k* for the concept in question. Then, the intracohort acc@*k* was the average of the acc@k across all underlying concepts. The intercohort acc@*k* was calculated similarly, except across the 6 intercohort mappings (CHS to MESA, CHS to WHI, MESA to CHS, MESA to WHI, WHI to CHS, WHI to MESA). Finally, the overall acc@*k* was calculated across the 9 total mappings for each underlying variable. We obtained acc@*k* values for *k* values of 1, 3, 5, 10, 20 in order to provide additional insight into SONAR's effectiveness at capturing true positives at different thresholds. These rigorous evaluations allowed us to confidently assert the efficacy of our harmonization method in both intracohort and intercohort settings.

For the supervised portion of our method, we used 2-fold cross-validation. We pooled cosine similarity values from both rounds of training before AUC calculations and averaged the 2 resulting cosine similarity values for non–gold standard pairs before acc@*k* calculations. To provide a comprehensive understanding of our method's performance, we compared the AUC and other accuracy metrics obtained by SONAR with those obtained when using semantic learning (BioBERT [Bidirectional Encoder Representations from Transformers for Biomedical Text Mining], CODER, SapBERT) or distribution learning alone. We also obtained metrics for the concatenated semantic portion of SONAR (ie, CODER concatenated with SapBERT) to further highlight the added value of distribution learning. This comparative approach allowed us to illuminate the relative strengths and contributions of the individual components of our method and the added value achieved by their combination.



Results

Data Extraction and Preprocessing

The proposed SONAR approach had 4 steps, including semantic learning, distribution learning, concatenation of the two learnings, and supervised training (Figure 1). We extracted metadata and semantic data from the dbGaP for 14,717 CHS variables, 22,147 MESA variables, and 6207 WHI variables. Filtering for continuous, complete, and nonzero variables using metadata and patient-level data from Service WorkBench, as well as consolidating variables with identical semantic descriptions yielded 2076 CHS variables, 2525 MESA variables, and 1328 WHI variables. Patient data was available for 12 subgroups, 16 subgroups, and 6 subgroups for CHS, MESA, and WHI, respectively. This yielded distribution vectors of length 36, 48, and 18 for intra-CHS, intra-MESA, and intra-WHI harmonization, respectively. Based on overlapping patient subgroups between the cohorts, we used distribution vectors of length 36, 12, and 18 for intercohort CHS-MESA, CHS-WHI, and MESA-WHI harmonization, respectively.

Var: variable.

Gold Standard Labels

We identified a total of 123 concepts with continuous data, consisting of 112 laboratory test concepts, 6 disease concepts, and 5 medication concepts. A total of 531 variables across all cohorts were identified as gold standard representations of these concepts. These yielded 606, 318, and 89 gold standard concept pairs for intradataset harmonization evaluation within the CHS, MESA, and WHI, respectively. For interdataset harmonization evaluation, we had 352, 325, and 133 gold standard concept pairs for CHS-MESA, CHS-WHI, and MESA-WHI, respectively. Detailed numerical summaries of gold standard labels are provided in Table 1.

Intracohort Evaluation

Supervised SONAR achieved a strong performance across all intracohort AUC (Figure 2 and Table S1 in Multimedia Appendix 1) and acc@*k* (Figure 3 and Table S2 in Multimedia Appendix 1) measures, exceeding or meeting all benchmark comparisons. The number of hard concepts for each intracomparison was 13 concepts, 5 concepts, and 5 concepts for intra-CHS, intra-MESA, and intra-WHI, respectively. It is notable that the distribution-only AUC was significantly higher than the semantic-only methods for the intra-CHS and intra-WHI hard concepts, illustrating the advantage of incorporating both semantic and distribution learning in SONAR. While the addition of supervised training only improved overall AUC performance for the intra-WHI comparison, it improved intracohort AUC performance on hard concepts for all 3 intracohort comparisons, exceeding all benchmark methods. The addition of supervised training also improved acc@*k* performance of SONAR across different values of *k*. Across intracohort evaluations, distribution learning provided a clear added value to semantic learning, in spite of a weaker distribution-only performance in comparison to the semantic components of SONAR (CODER only, SapBERT only, CODER + SapBERT). Moreover, there was not a single best semantic learning method between CODER and SapBERT using the various AUC and acc@*k* metrics, providing support for the use of both semantic learning methods in SONAR.

Intercohort Evaluation

Supervised SONAR also achieved a consistently high performance in intercohort harmonization evaluation, exceeding or meeting all benchmark comparisons except for acc@3 and acc@20 (Figure 3). The number of hard concepts for each intracomparison was 4 concepts, 11 concepts, and 5 concepts for the CHS-MESA, CHS-WHI, and MESA-WHI comparisons, respectively. Similar to intracohort harmonization, supervised training improved AUC performance on hard concepts for all 3 comparisons, exceeding all benchmark methods. In contrast with intracohort harmonization, supervised training also improved AUC performance on all concepts to above 0.99 for all 3 intercohort comparisons (Figure 4). Notably, the CODER only and SapBERT only AUC values were higher for intercohort harmonization as compared to intracohort harmonization because identical variable descriptions were allowed for intercohort semantic learning.

Discussion

The SONAR method provides a robust method for concept-level data harmonization across and within longitudinal cohort studies by efficiently constructing variable embeddings from longitudinal cohort study variable descriptions and data. We used a supervised algorithm to refine the concatenated embeddings built from normalized distribution and semantic vectors. When applied to harmonization within and between 3 National Institutes of Health cohort studies, SONAR achieved enhanced performance compared to benchmark methods, with notable improvements over semantic-only and distribution-only methods. These results demonstrate the effectiveness of learning from both semantic and patient-level data. Our method is able to conduct this learning with relatively low training costs by taking advantage of the one-time pretraining of biomedical entity representation–based language models using domain-specific UMLS terms.

There are some limitations to this study. We focused only on continuous variables with complete data, excluding categorical variables and variables with incomplete data. Future studies can expand variable distribution learning to categorical variables and develop methodologies for comparing distribution vectors of differing lengths in the case of variables with incomplete data, allowing for harmonization of a greater range of variables. Moreover, we focused on concept-level variable harmonization, which may be inappropriate for certain applications that require more granular harmonization, such as at the unit level or comparisons between different temporal periods. SONAR already drastically reduces the resources needed for concept-level harmonization, which is a crucial first step for more granular harmonization. Future studies could also automate the manual process of unit and temporal harmonization across variables corresponding to the same concept. Another direction for future research is automating the underlying concept identification process, perhaps by variable clustering using the newest generation of LLMs such as GPT-4. While powerful LLMs like GPT-4 could further improve the semantic learning aspect of our model, future research would need to adapt these generally trained models to the biomedical domain and control for the monetary costs associated with GPT-4 use. Additionally,

XSL•FO
RenderX

although the current implementation of intercohort SONAR involves harmonization of 2 studies, it can be adapted to harmonize 3 or more studies.

SONAR paves the way for multicohort studies through high-quality and efficient variable harmonization. Harmonization at the concept-level is the crucial first step for researchers seeking to identify all variables corresponding to a disease, medication, or laboratory test of interest. Manual curation of or simple keyword searches for such variables are resource intensive and error-prone. The automation provided by SONAR is particularly helpful for harmonization of thousands of variables between large-scale cohort studies with heterogeneous variable encoding of underlying concepts. Multicohort studies that draw upon existing cohort studies are a resource-efficient method for studying risk factors associated with diseases and their pathogenesis. By effectively expanding the study population, multicohort studies also allow for greater statistical power and diversity in the study population, leading to greater generalizability of results and an enhanced ability to study health disparities. Beyond variable harmonization between cohorts, the variable embeddings generated through SONAR can be used for downstream analyses within multicohort studies, including for feature selection and the construction of knowledge graphs.

In conclusion, SONAR provides an approach for investigators to integrate semantic and patient data for multicohort variable harmonization. We demonstrate the robust added value of distribution learning when combined with existing semantic learning methods in variable mapping between cohorts. This innovation will facilitate and expedite multicohort studies by building upon existing data from decades-long cohort studies.

Abstract

Background: The two most commonly used methods to identify frailty are the frailty phenotype and the frailty index. However, both methods have limitations in clinical application. In addition, methods for measuring frailty have not yet been standardized.

Objective: We aimed to develop and validate a classification model for predicting frailty status using vocal biomarkers in community-dwelling older adults, based on voice recordings obtained from the picture description task (PDT).

Methods: We recruited 127 participants aged 50 years and older and collected clinical information through a short form of the Comprehensive Geriatric Assessment scale. Voice recordings were collected with a tablet device during the Korean version of the PDT, and we preprocessed audio data to remove background noise before feature extraction. Three artificial intelligence (AI) models were developed for identifying frailty status: SpeechAI (using speech data only), DemoAI (using demographic data only), and DemoSpeechAI (combining both data types).

Results: Our models were trained and evaluated on the basis of 5-fold cross-validation for 127 participants and compared. The SpeechAI model, using deep learning–based acoustic features, outperformed in terms of accuracy and area under the receiver operating characteristic curve (AUC), 80.4% (95% CI 76.89% - 83.91%) and 0.89 (95% CI 0.86 - 0.92), respectively, while the model using only demographics showed an accuracy of 67.96% (95% CI 67.63% - 68.29%) and an AUC of 0.74 (95% CI 0.73 - 0.75). The SpeechAI model outperformed the model using only demographics significantly in AUC (t_4=8.705 [2-sided]; P<.001). The DemoSpeechAI model, which combined demographics with deep learning–based acoustic features, showed superior performance (accuracy 85.6%, 95% CI 80.03% - 91.17% and AUC 0.93, 95% CI 0.89 - 0.97), but there was no significant difference in AUC between the SpeechAI and DemoSpeechAI models (t_4=1.057 [2-sided]; P=.35). Compared with models using traditional acoustic features from the openSMILE toolkit, the SpeechAI model demonstrated superior performance (AUC 0.89) over traditional methods (logistic regression: AUC 0.62; decision tree: AUC 0.57; random forest: AUC 0.66).

Conclusions: Our findings demonstrate that vocal biomarkers derived from deep learning–based acoustic features can be effectively used to predict frailty status in community-dwelling older adults. The SpeechAI model showed promising accuracy and AUC, outperforming models based solely on demographic data or traditional acoustic features. Furthermore, while the combined DemoSpeechAI model showed slightly improved performance over the SpeechAI model, the difference was not statistically significant. These results suggest that speech-based AI models offer a noninvasive, scalable method for frailty detection, potentially streamlining assessments in clinical and community settings.

Introduction

Global population aging is undergoing a profound transformation as the number of older adults continues to rise at an unprecedented rate. South Korea is undergoing an accelerated aging trend coupled with one of the world's most dwindling birth rates. By 2025, South Korea is predicted to become a superaged society, with the proportion of people aged

XSL•FO
RenderX

≥65 years making up 20% of the population. This demographic shift is expected to continue, with estimates indicating that nearly 44% of South Korea's population will be older than 65 years expected by 2050 [1].

Among the older population, frailty is a very common and significantly important geriatric condition because it affects health-related status, quality of life, place of residence, and mortality [2]. Frailty is a common geriatric syndrome characterized by a decline in physiological reserves and increased vulnerability to stressors. Early diagnosis and management of frailty are important not only for tailoring care plans and predicting adverse health outcomes at the individual level but also for strategizing public health initiatives that meet the distinct requirements of the rapidly growing older population [3].

Although the concept of frailty is universally recognized, methods for measuring frailty have not yet been standardized. The two most commonly used methods to identify frailty are the frailty phenotype and the frailty index [4,5]. However, these two methods have limitations in clinical application as they require measuring the frailty phenotype through a predetermined methodology or collecting various variables, making them not easily adaptable and usable in clinical settings. Another method for assessing frailty is the use of questionnaires [6]. As measuring frailty involves time, cost, and labor, it is necessary to develop a simplified, universally implantable, and convenient methodology to screen for frailty.

A recent study explored the integration of machine learning to enhance frailty detection, demonstrating that the choice of classifier and feature selection significantly impacted model performance, particularly when combining clinical and nonclinical data [7]. Voice biomarkers have been successfully used to identify acute diseases such as COVID-19, cognitive dysfunction, Parkinson disease, and psychiatric disorders [8-11]. Early research on detecting frailty using voice biomarkers often relied on simple methods, such as brief, predetermined vocal tasks [12]. Rosen-Lang et al [13] demonstrated the feasibility of using more sophisticated voice biomarkers for frailty classification, highlighting their potential for improving diagnostic accuracy in this population. Furthermore, the applicability of vocal biomarkers extends beyond frailty detection. Kaufman et al [14] demonstrated that acoustic analysis could effectively predict type 2 diabetes using voice segments, highlighting the versatility of voice biomarkers in noninvasive health diagnostics across various conditions.

The aim of this study was to develop and validate a classification model for predicting frailty status using vocal biomarkers in community-dwelling older people based on the voice recordings obtained from a picture description task (PDT) conducted for 2 minutes via a tablet and modeling with a machine learning algorithm.

Methods

Study Design

In this prospective cross-sectional study for developing and validating an artificial intelligence (AI) model to predict frailty status from vocal biomarkers, we recruited participants aged ≥50 years. We posted research promotion posters at Seoul National University Bundang Hospital to recruit participants. We enrolled those patients or their caregivers who expressed interest after seeing the posters and consented to participate in our study. Exclusion criteria were patients who (1) were diagnosed with dysarthria; (2) had a score of ≥10 on the Korean version of the Short Form Geriatric Depression Scale (SGDS-K) score of ≥10; (3) had a history of uncontrolled sleep disorders, anxiety, or behavioral disorders within 3 months; and (4) were deemed unable to comply with the study at the discretion of the researcher.

Ethical Considerations

This study received ethics review and approval from the Institutional Review Board of Seoul National University Bundang Hospital (approval number B-2107-698-302) for the collection of data from participants in the clinical study. All data used in the study were collected and processed in accordance with the institutional review board guidelines. Informed consent was obtained from all participants for the collection of voice data. Participants were informed that their data would be anonymized or deidentified to protect their privacy and confidentiality.

Data Collection

Voices were recorded in an academic tertiary hospital. The voice recording device, a Galaxy Tablet A7 LTE (SM-T505; Samsung Electronics Co, Ltd), was located between the participant and clinician at a distance of approximately 100 cm. The recordings were performed using an application developed for the PDT by Silvia Health, Inc. The recorded speech signals were digitized at a 48 kHz sampling rate. Audacity (version 3.3.3; Audacity Team) was used to remove noise other than participants' voices.

Development of the Korean Version of the PDT
