Abstract

Background: Community health workers (CHWs) are essential for achieving universal health coverage and reaching the Sustainable Development Goals. Paying CHWs for their work increases their motivation and effectiveness, and is recommended by the World Health Organization and advocacy organizations such as the Community Health Impact Coalition. Many implementing organizations currently pay CHWs using mobile money or other digital means. However, most payment systems are designed without the involvement of CHWs.

Objective: In this implementation report, we describe efforts to improve efficiency, accuracy, and user experience of the CHW payment process of the Jamii ni Afya project in Zanzibar.

Methods: We applied Medic's design process to develop new functionality for the open-source Community Health Toolkit. We reviewed documentation and engaged with users to understand their needs and experiences with the current payment system. This information formed the basis of technical specifications, which were developed into a revised workflow. The workflow was iteratively tested and refined. Several steps that were managed offline, such as resolving payment discrepancies, were formalized and incorporated into the workflow. We conducted user acceptance testing to assess functionality and user experience.

Implementation (Results): The workflow was able to accurately translate programmatic data into payment information for each CHW and securely transmitted this information to a payment service provider. User acceptance testing revealed that CHWs felt the revised payment system provided them with more information and gave them a greater sense of control. Program staff felt the workflow would increase the efficiency and accuracy of the payment process, while simplifying the resolution of payment discrepancies.

Conclusions: Engaging users in the design and optimization of digital payment systems has the potential to improve the efficiency and accuracy of digital payment systems while enhancing satisfaction among all users, contributing to improved sustainability and impact of CHW programs. Definitive conclusions will depend on evaluation of the system after implementation.

Introduction

Context

In 2015, countries worldwide committed to the Sustainable Development Goals (SDGs). The SDGs set ambitious targets for the health workforce [1]. Most countries are not on track to meet the 2030 targets without additional investments [2]. The World Health Organization (WHO) has projected a shortage of 18 million health workers by 2030 if current trends continue [3].

Community health workers (CHWs) provide health promotion and preventive and curative care for people at their doorstep. CHWs can effectively deliver various interventions, including maternal and child health services, family planning, and

XSL•FO
RenderX

prevention and management of infectious and noncommunicable diseases [4]. For example, in Rwanda and Liberia, CHWs treat half of malaria cases, and in many countries, they were essential in maintaining health services during the COVID-19 pandemic [5]. In Brazil, CHWs reached two-thirds of the population and have helped reduce child mortality by 75% [6]. CHWs are estimated to provide a return on investment of US $10 for every US $1 invested [7].

Most CHWs in low- and middle-income countries (LMICs) remain unpaid despite evidence that CHWs save lives and are highly cost-effective [4,8-10]. In Africa, 86% of CHWs are volunteers with little or no compensation [11]. The WHO's 2018 CHW guidelines recommend remuneration commensurate with job demands, complexity, hours worked, and training [9]. Satisfaction with incentives is shown to improve performance while reducing attrition [12,13]. In contrast, inadequate, partial, or delayed payments reduce motivation and intervention coverage [13].

Significant challenges have been documented with cash payments for CHWs. The logistics needed to safely transport and accurately disburse cash become increasingly difficult with scale. This can result in delayed and incomplete payments, corruption, high administrative costs, and security risks [13-18]. Digital payments have been championed as a solution. According to researchers at Makerere University, "digital payments can create a transparent record that can improve management and reduce payment delays and leakage of funds. Digitizing payments can increase the likelihood of health workers receiving complete, on-time, and convenient payment, increase transparency, reduce resource leakage, and improve service delivery's cost-effectiveness" (Makerere University, 2022; website changed and material no longer available).

Digital CHW Payments

D-tree was among the first organizations working in an LMIC to adopt digital payments. In 2011, D-tree piloted mobile money payments for CHWs, supervisors, and emergency transportation services [19,20]. In the next decade, organizations introduced digital payments for CHWs, such as malaria spray teams in Zambia, CHWs in Bangladesh and Kenya, tuberculosis screeners in Pakistan, and many others [19,21-24].

Donors accelerated the digital transition. In 2014, the US Agency for International Development mandated digital payments as the default payment mode, including those for CHWs [25]. The Global Polio Eradication Initiative began scaling up digital payments for vaccination campaign workers in 2020, reaching >250,000 recipients within a year [13,26]. The uptake of digital payments for health workers has been rapid compared to an average of 14 years for drug and/or technology innovations to reach scale [27].

Because most reports on digital payments appear in the gray literature, they tend to present positive perspectives, overlooking challenges and limitations. Regardless, several challenges have been identified. Health worker registries are often poorly maintained [13]. Resolving payment discrepancies can be time-consuming [28,29]. There are gaps in phone ownership, cellular networks, and mobile money agents [13,15,19,28]. Some CHWs have low literacy, are unfamiliar with technology, or distrust mobile money [19,28]. Requirements for a national identity document can be a barrier [19]. Financial management capacity may be insufficient [13]. Finally, transaction fees can significantly reduce the take-home pay of recipients [13,30].

Despite the rapid increase in digital payments for CHWs, there is limited evidence on the topic. There is a need for more research on the effect of digital payments on health workers' morale, performance, quality of care, intervention coverage, and health outcomes [14,17,18]. Thankfully, there are new initiatives aiming to fill the gap, notably the Digital Health Payment Initiative at Makerere University [14,31].

Participating Entities

Medic serves as the steward of the Community Health Toolkit (CHT), an open-source digital public good that supports health workers as they deliver care [32]. The CHT is a collection of technologies and resources that enable implementers to support various features and health issues. As of December 2023, in total, 75,241 CHWs and their supervisors in 18 countries used CHT-based tools to deliver care during 117.5 million home visits [33].

Medic has embraced human-centered design, engaging individuals who will use the tools in the environments where they are deployed. The CHT is intended to empower health workers to care for members of their community, and Medic's design process considers the interests of the person overall [34]. Medic has intentionally situated its staff in the communities where our tools are deployed, including Kenya, Nepal, Senegal, and Uganda.

D-tree is a global health organization working to improve access to quality health care. In Zanzibar, D-tree works with the Ministry of Health (MOH) to support Jamii ni Afya (JnA), one of the world's first nationally scaled, digitally enabled community health programs. JnA includes about 2300 CHWs and 220 CHW supervisors serving a population of nearly 2 million. The JnA smartphone app (built on CHT) guides CHWs to provide services for maternal and child health, nutrition, water, sanitation, hygiene, and early childhood development.

To support, incentivize, and monitor CHWs, a pay-for-performance scheme is used to calculate monthly remuneration. The current maximum monthly payment is approximately US $21 for CHWs and US $13 for supervisors (who are generally facility-based MOH staff). The program is included in Zanzibar's digital and community health strategies [35,36]. Higher rates of facility deliveries and reduced child stunting have been documented in the 5 years following JnA's scale-up [35].

Problem Statement

While JnA already made mobile money payments to CHWs, the process had several drawbacks. Multiple steps were needed to collect performance data, review them, and translate them into digital payments. The CHT and digital payment systems were not integrated. Users felt that they did not always have the information they needed, and several routine tasks were managed offline. In addition, financial data were not yet

XSL•FO
RenderX

included in CHT. We are not aware of peer-reviewed literature documenting how to proactively involve CHWs in designing digital payment systems. This implementation report documents our experiences working on CHW digital payments in Zanzibar and follows the i-CHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations) guidelines (Checklist 1) for reporting on digital health implementations [37].

Aims and Objectives

The goal of this initiative was to improve the efficiency, accuracy, and user experience of the CHW payment process. Specific objectives included reducing effort to make payments, increasing accuracy, providing real-time information to all users, and streamlining discrepancy resolution. This implementation report describes the process to design the digital tool in the preimplementation phase through the lens of user acceptance testing (UAT). UAT evaluated the product's user experience, functionality, and interoperability with a small number of users. It is outside of the scope of this report to measure more distal outcomes, such as coverage, accuracy, or impact. Once the digital payments solution is implemented, we will be positioned to report on these outcomes.

Methods

Blueprint Summary

Medic designers started by gathering information on current processes and systems via reviewing existing documentation and calls with JnA project staff. In March 2023, a team of 3 Medic staff with design and software development expertise traveled to Zanzibar for a design visit. In addition to gathering information about the current payment system, we aimed to understand users' experience with the system. We conducted interviews and focus groups with program staff and CHWs. Participants' age ranged 20-50 years. We were also able to shadow supervisors and attend monthly meetings that were an important step in the payment process.

D-tree's existing payment process is shown in Figure 1. The entire process takes approximately 2 weeks once data are synced. CHWs have 5 days at the end of each month to sync their data. Supervisors ensure that data are synced for all CHWs. Program officers subsequently review data using a custom-built dashboard. Data are exported to Microsoft Excel to calculate payments. Once approved by the project director, the finance team reformats data per payment service provider requirements, and this is uploaded using a web-based portal. Payment discrepancies are handled case-by-case by program staff.

Challenges identified by users were one input for the design. Poor connectivity and depleted mobile data often prevented CHWs from syncing, leading to payment discrepancies. CHWs felt uncertain when to expect payments or how calculations were made. Resolving payment discrepancies was time-consuming, and CHWs would sometimes incur out-of-pocket costs to follow up on payments. Some supervisors adopted improvised solutions such as the use of screenshots from CHWs' phones to verify data accuracy.

Finance staff explained that manual steps sometimes led to errors. The existing payment service provider did not offer an easy, robust, and customizable way to integrate with CHT. D-tree is transitioning management for JnA to the Zanzibar MOH by 2026, and the payment scheme needs to integrate with government administrative systems. The workflow needed to be sustainable by the program without external inputs and feasible within CHT's parameters while creating value for users.

We validated findings with stakeholders via videoconference. Part of our process entailed creating personas who interacted with the software. For each persona, we considered their job responsibilities, needs, context, and motivations. Personas were based on information collected from the design visit and included CHWs, supervisors, monitoring and evaluation officers, finance officers, directors, and district health staff.

We developed a draft workflow and refined it during several remote coworking sessions. Mostly, the steps in the workflow did not change from the existing process. However, several steps that used text message or phone communication were formalized and incorporated into the workflow. We identified 7 candidate Payment Service Providers (PSPs) through web searches and consultation with local informants. Selection criteria were adapted from global best practice [38]. The PSP was selected because of their presence in Zanzibar, available digital payment modalities (mobile networks and banks), data security, existing application programming interfaces (APIs), and reputation.

We tested the workflow in several stages using a structured test plan and we incorporated feedback iteratively. By October 2023, we had finalized integration with the PSP and returned to Zanzibar for 4 days of user acceptance testing (Figure 2). Our goals with UAT were to assess functionality of the software and to gather user feedback. Medic's designers observed users interacting with the system and interviewed them about their experiences. Participants included 23 CHWs, 8 supervisors, 8 MOH staff, and 10 D-tree staff. Participants were selected through a purposive random sample and included CHWs from both urban and rural settings because we hypothesized they might have different challenges. Examples of the user interface are shown in Figures 3 and 4. Screenshots show the English translations, but the UAT was conducted in Kiswahili. Personally identifiable information in the screenshots have been replaced by test data. Results from the UAT will inform changes to the software before finalization.

XSL•FO
RenderX

Figure 4. Screenshot of an example digital payments summary. CHV: community health volunteer.

Technical Design

The workflow was built using the CHT, which serves as the backbone of the JnA app [39]. CHT was selected by the government of Zanzibar because it is open-source, has a growing support community, can be hosted locally, and the expertise to manage the software is readily available [35]. The software was designed to function in low-bandwidth environments using affordable Android smartphones. CHWs and supervisors generally access JnA using smartphones, while office staff access JnA using a web browser.

Target Audience

The target audience consisted of all JnA stakeholders who were involved in the payment process, including CHWs, supervisors, and staff at the MOH and D-tree. The broader CHT community is a secondary audience. As an open-source tool, CHT features can be widely adapted and used by community members.

Data

The workflow we developed uses existing data, including personal identifiers for CHWs, process data, and mobile banking details. Data are collected during enrollment and while CHWs and supervisors conduct their routine activities. The workflow hierarchy was designed to protect sensitive information and is governed by a data privacy policy, which users consent to during enrollment [40]. Financial data are managed in compliance with government regulations [41]. We plan to conduct penetration testing to ensure data security at a later stage of development.

Interoperability and Integration

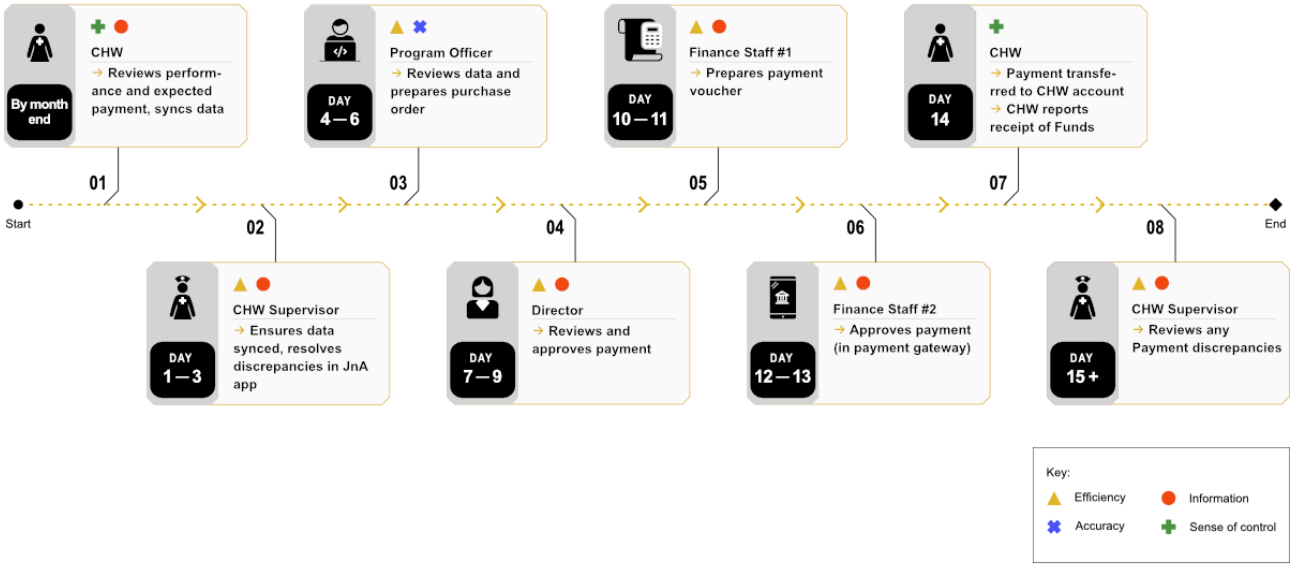
CHT can exchange data with other components of national health information systems based on standards including Fast Healthcare Interoperability Resources, Open Health Information Exchange, and the Open Health Information Mediator [39]. We built a custom mediator to calculate performance-based payments and to disburse them via the payment service provider's API. Available standards for financial service interoperability do not include health use cases [42]. There is a need for interoperability standards in health-related financial services.

Budget Planning and Sustainability

The Community Health Toolkit is free to use but requires funding for adaptation, hardware, and hosting. These costs are included in the Zanzibar Community Health Strategy, in addition to CHW stipends, commodities, training, and logistics costs [35]. JnA's annual operating cost is estimated at US $2.73 million per year or US $1.70 per capita. The government is currently paying the salaries of CHW supervisors and has committed to fully fund the program by 2026 with the vision of absorbing CHW as part of the health workforce. A financing strategy is currently under development. Payment service provider fees were between US $0.30 and US $0.50 per transaction during testing, representing a significant percentage of the total payments. However, fees are negotiable, and our experience was based on a very small transaction volume during the test phase.

XSL•FO
RenderX

Implementation (Results)



We assessed the product's functionality, user experience, and interoperability with 49 users. The workflow functioned as designed and was positively received by staff and CHWs. Most steps felt familiar, since additional functions were generally incorporated into existing forms. Participants recommended several improvements that would simplify data entry, remove unnecessary information, enable detailed or summary views, and highlight outlier data. They also recommended a process for escalating approvals to avoid delays if approvers were not available.

CHWs reported feeling a greater sense of control because they confirm their data at the beginning of the payment cycle and report payment receipt at the end. They appreciated seeing how their stipends are calculated in the app. While increased transparency is thought to increase motivation and trust, there could be other consequences such as task prioritization based on reimbursement levels. It will be important to monitor changes over time.

Supervisors felt that the workflow would facilitate performance management by providing accurate, timely data. Program staff felt that the software reduced their workload, particularly less enjoyable tasks such as reformatting data to meet PSP requirements. They thought that automated calculations would increase accuracy and believed that the workflow's ability to document approvals was easier than existing processes. Several user groups felt that the process for tracking and resolving payment discrepancies would increase responsiveness.

CHT has been primarily used for clinical and programmatic data, and its ability to manage financial information was unproven. The software reliably used performance data to calculate payments and securely communicated this information with the PSP. Some of the developed functionality, such as display of tabular information, is based on the XForm standard and can be deployed on any XForm-compatible platform like OpenDataKit to empower effective decision-making. A simplified visual of the steps in the workflow and the perceived benefits at each stage are shown in Figure 5.

Figure 5. Simplified monthly workflow with perceived benefits at each step. CHW: community health worker.

Discussion

Principal Findings

We learned several lessons from this work. It was feasible to involve CHWs in redesigning the JnA payment system. However, their engagement was limited to the design visit and UAT. We could have included CHWs as part of the team throughout the development process for deeper involvement. Remote coworking sessions were sometimes challenging because they are generally shorter and less interactive than in-person design meetings. We could have accelerated implementation with more in-person collaboration. While Medic's Nairobi-based team were generally familiar with JnA's infrastructure and Zanzibar's health system, we could have improved collaboration by forming a unified team comprising members from both organizations. CHT could manage financial, health, and programmatic data, leading to efficiencies. Key lessons are summarized in Textbox 1.

CHWs are an important tool to promote health equity by increasing health care access to households that face financial, geographic, or other barriers to accessing care [43]. This implementation report contributes to efforts to professionalize the community health workforce. Professionalized CHWs reportedly have greater health impacts than unpaid volunteer CHWs [44]. Paying CHWs can also reduce gender and income inequality because most CHWs are low-income women. Payment enables CHWs to address their own livelihood needs while becoming trusted role models in the community [8,13].

XSL•FO
RenderX

Engaging users in designing digital payment systems is the exception rather than the rule. Many current payment systems were designed without CHW involvement and do not meet their needs [29]. During testing, CHWs reported feeling a greater sense of control, which reportedly reduces stress and improves health [45]. Increased transparency and accountability between the program and CHWs can allow them to plan how much time to devote to CHW duties or to other income-generating activities, assuring a predictable income. We believe that co-designing payment systems with payees should become the norm.

Beyond digital payment for CHWs, mobile money integration with CHT is an opportunity to accelerate innovation. D-tree has a long history of mobile money innovation, and this integration could facilitate additional use cases, such as birth preparedness savings, community health insurance, emergency transport payments, cash transfers, savings groups, and many others that will only become apparent with time.

Textbox 1. Key lessons.

- It is feasible to engage community health workers (CHWs) in the design of digital payment systems, leading to better alignment with users' needs. Engaging users at key decision points is helpful, but including them in the entire process may lead to more transformative designs.
- Remote coworking has limitations, so budgeting for in-person time may improve communication and accelerate development timelines.
- Community health information systems can manage financial data in addition to clinical and programmatic data, which may lead to efficiencies and new use cases.

Conclusions

The question is no longer about the feasibility of digital payments for CHWs, but how to do it efficiently, in a way that best meets the needs of all users. We showed that the open-source CHT could manage financial data and meet various user needs. We demonstrated the utility of engaging users in designing a digital payments system. More robust evaluation is planned as part of the next phase of development, including the impact of the workflow on timelines, workload, accuracy, motivation, and programmatic outcomes.

Acknowledgments

We would like to thank the Revolutionary Government of Zanzibar for their leadership and guidance in the Jamii ni Afya program. We recognize funding support from the Rockefeller Foundation (grant 2019 HTH 022) in support of the Medic Labs initiative.

Abstract

Background: Large language models (LLMs) have shown promise in reducing clinical documentation burden, yet their real-world implementation remains rare. Especially in South Korea, hospitals face several unique challenges, such as strict data sovereignty requirements and operating in environments where English is not the primary language for documentation. Therefore, we initiated the Your-Knowledgeable Navigator of Treatment (Y-KNOT) project, aimed at developing an on-premises bilingual LLM-based artificial intelligence (AI) agent system integrated with electronic health records (EHRs) for automated clinical drafting.

Objective: We present the Y-KNOT project and provide insights into implementing AI-assisted clinical drafting tools within constraints of health care system.

Methods: This project involved multiple stakeholders and encompassed three simultaneous processes: LLM development, clinical co-development, and EHR integration. We developed a foundation LLM by pretraining Llama3-8B with Korean and English medical corpora. During the clinical co-development phase, the LLM was instruction-tuned for specific documentation tasks through iterative cycles that aligned physicians' clinical requirements, hospital data availability, documentation standards, and technical feasibility. The EHR integration phase focused on seamless AI agent incorporation into clinical workflows, involving document standardization, trigger points definition, and user interaction optimization.

Implementation (Results): The resulting system processes emergency department discharge summaries and preanesthetic assessments while maintaining existing clinical workflows. The drafting process is automatically triggered by specific events, such as scheduled batch jobs, with medical records automatically fed into the LLM as input. The agent is built on premises, locating all the architecture inside the hospital.

Conclusions: The Y-KNOT project demonstrates the first seamless integration of an AI agent into an EHR system for clinical drafting. In collaboration with various clinical and administrative teams, we could promptly implement an LLM while addressing key challenges of data security, bilingual requirements, and workflow integration. Our experience highlights a practical and scalable approach to utilizing LLM-based AI agents for other health care institutions, paving the way for broader adoption of LLM-based solutions.

artificial intelligence agent; large language models; documentation; electronic health records; insights

Introduction

Background

Large language models (LLMs) have recently garnered significant attention, raising expectations for their applications in health care systems, encompassing clinical care support, research, and education [1,2]. However, most research has focused on implementations in the United States, and these solutions have yet to demonstrate meaningful reductions in administrative burden, as they mainly address tasks related to medical knowledge [3].

South Korea's health care system is renowned for its efficiency, offering low costs with high accessibility and quality. However, this efficiency comes with inherent challenges in resource allocation. Health care providers often manage substantial workloads, seeing many patients in limited time frames. This situation has been particularly exacerbated by recent mass resignation of residents, which has left tertiary hospitals facing a critical shortage of human resources [4,5]. These circumstances underscore an urgent demand for meaningful assistance from LLMs.

Clinical documentation represents a significant burden for health care providers [6,7], and there is growing optimism about LLMs' potential to alleviate this burden [8,9]. Clinical documentation involves condensing previous records, a task that LLMs excel at [10,11]. Accordingly, several studies have explored the capabilities of proprietary LLMs in generating clinical notes such as radiology referrals [12] or discharge summaries [13,14]. However, implementing existing LLM solutions in South Korea faces several unique challenges. Korean medical regulations mandate that all medical records be stored exclusively on domestic servers or clouds [15], making it impossible to utilize foreign commercial services like ChatGPT [16]. Additionally, medical documents in Korea often exhibit mixed usage of Korean and English, requiring models capable of processing bilingual clinical notes effectively [17]. Korea's Ministry of Food and Drug Safety does not classify artificial intelligence (AI) software for documentation as a medical device unless it involves medical judgements [18], thereby exempting the requirement for regulatory approval. Nevertheless, these challenges hinder the widespread adoption of LLMs in Korea.

Although some pilot projects have attempted incorporating LLMs within electronic health records (EHRs), full-scale integration in real clinical settings remains rare. Due to their separate interface, manually retrieving information from EHRs and typing it into LLMs may ironically be time-consuming. In the study by Goh et al [19], interaction with an LLM led to increased time in patient management reasoning. For LLMs to be continuously and effectively utilized by health care providers, connecting LLMs directly to EHRs is necessary.

To address these challenges, we initiated the Your-Knowledgeable Navigator of Treatment (Y-KNOT) project, aimed at developing a hospital-dedicated AI agent that seamlessly integrates a small, bilingual LLM with existing systems for automatic clinical drafting. This paper presents our experiences and insights from developing and implementing this solution.

Objectives

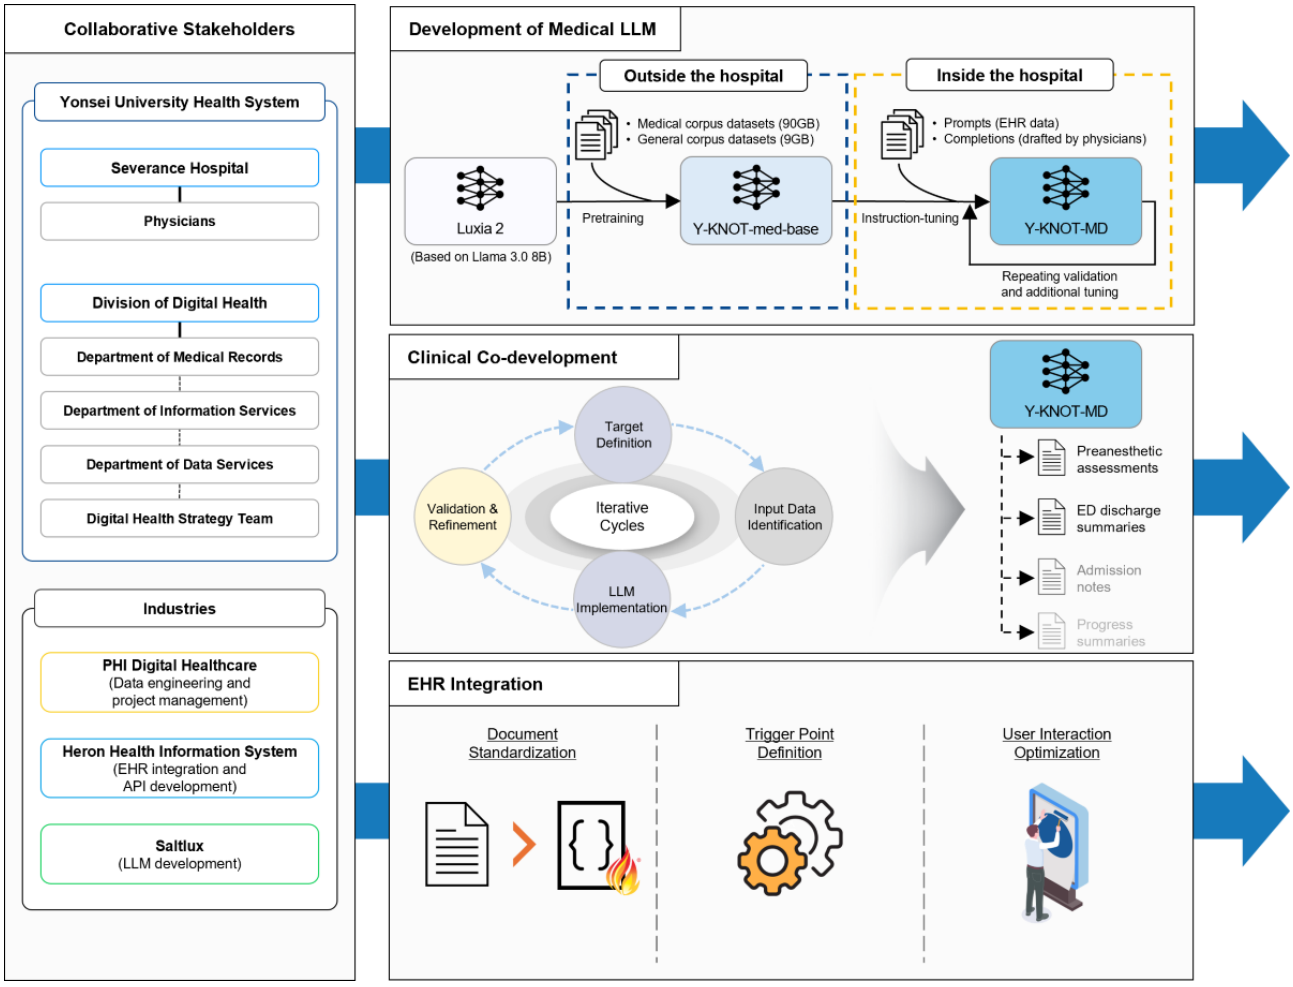
We aim to demonstrate a practical approach to leveraging LLMs within the constraints of the health care system, potentially offering a model for similar implementations in other limited-resource settings. This paper highlights the multidisciplinary process of the Y-KNOT project, key features of the final implementation, and presents a human evaluation of its feasibility. Our experience provides valuable insights into the challenges and opportunities of integrating AI-assisted clinical drafting tools in health care settings while maintaining compliance with local regulations and addressing specific linguistic requirements.

Methods

Ethical Considerations

This study was reviewed and approved by the Institutional Review Board (IRB No. 4-2023-003) and the Data Review Board (DRB No. 24-01-005) of Severance Hospital. All patient data used in this study were retrieved from the hospital's research-purpose EHR database and deidentified prior to use, waiving the need for additional informed consent.

Project Overview



The Y-KNOT project was conducted at Severance Hospital, a tertiary hospital in Seoul, South Korea. The project was initiated in June 2024 and the first service in routine clinical practice started in November 2024. The total cost of the project, including all expenses such as equipment and labor, did not exceed US $1,500,000. The final LLM model developed in this project is jointly owned by Severance Hospital and 'PHI Digital Healthcare Co., Ltd.' (Seoul, South Korea).

This implementation report adheres to the iCHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations) reporting guidelines [20] (Checklist 1).

The project encompassed three major phases: medical foundation LLM development, clinical co-development, and EHR integration, which were carried out simultaneously. Figure 1 displays the overall project landscape.

XSL•FO
RenderX

Figure 1. Overall landscape of the Y-KNOT project. B: billions; ED: emergency department; EHR: electronic health record; GB: gigabytes; LLM: large language model; Y-KNOT: Your-Knowledgeable Navigator of Treatment.

Development of Medical Foundation LLM

We first developed 'Y-KNOT-med-base,' a small, bilingual LLM for general medical purposes. We used Luxia 2 [21] developed by 'Saltlux Inc.' (Seoul, South Korea) as a base model, which was built upon Llama 3 (8 billion parameters) [22] and specialized for Korean language through pretraining on 1.5 terabytes of general corpus datasets. We decided to use a small model for rapid project completion, minimal latency in clinical settings, and environmental and economic sustainability. To adapt the model for medical applications, we further trained it with 90 GB of medical and 9 GB of general corpus datasets in Korean and English, consisting of open source and internally collected datasets. The pretraining data was augmented with instruction-response pairs for instruction pretraining [23], which enables better alignment with domain-specific tasks. The training was conducted outside of the hospital to ensure greater flexibility and broader reusability of the foundation model by other institutions. Hyperparameter settings are provided in Multimedia Appendix 1.

To assess its capability to understand medical knowledge, we evaluated 'Y-KNOT-med-base' on PubMedQA (biomedical question answering based on PubMed abstracts) [24] for English and KorMedMCQA (multichoice question answering derived from licensing examinations for doctors, nurses, and pharmacists in South Korea) [25] for Korean. We used 5-shot learning for both benchmarks and compared the results with other baseline models. Baseline models for PubMedQA were selected from the state-of-the-art models on the PubMedQA leaderboard [26] whose parameter sizes were disclosed. Baseline models and their respective results for KorMedMCQA were taken from the original KorMedMCQA paper [25], focusing specifically on nonproprietary multilingual models.

Clinical Co-Development Phase

The Y-KNOT project involved intensive collaboration with related departments, including physicians, data scientists, software engineers, and medical record specialists. Working closely together, we established six core values: innovation, collaboration, integration, sovereignty, scrutiny, and efficiency (Figure 2).

XSL•FO
RenderX

Figure 2. Core values of the Y-KNOT project. AI: artificial intelligence; EHR: electronic health record; IT: information technology; LLM: large language model; Y-KNOT: Your-Knowledgeable Navigator of Treatment.

With the core values internalized, we conducted multiple iterative development cycles. Each cycle began with defining specific clinical documentation needs, followed by identifying available EHR data, assessing the technical feasibility of LLM implementation, and refining results through data adjustments and retraining of the model. Through these cycles, we progressively refined our understanding of automatable document types, confirmed the output templates, and determined the optimal approach for automation–whether through rule-based systems or LLM inference. This process was essential for establishing a system that not only met immediate clinical needs but also ensured standardization across departments while maintaining compliance with medical documentation requirements.

To adapt the LLM for drafting specific document types–emergency department (ED) discharge summary and preanesthetic assessment–we instruction-tuned the Y-KNOT-med-base. We called the resulting model 'Y-KNOT-MD,' which is an abbreviation for 'Y-KNOT medical document' Medical document data for the model prompts were selected from the hospital's EHR database. Corresponding completions were prepared by physicians, addressing clinical needs while following the guidelines established by data scientists. The model was trained on 300 prompt-completion pairs for each document type. As the training involved patient data, it was conducted within the hospital environment to minimize the risk of data leakage. Details regarding hyperparameter settings are provided in Multimedia Appendix 1.

EHR Integration Phase

In parallel with previously described phases, we conducted comprehensive EHR integration planning with the hospital's

XSL•FO
RenderX

EHR team. This phase focused on defining the optimal service architecture to seamlessly integrate the AI agent into existing clinical workflows. It encompassed three key components: medical document standardization, service trigger point definition, and user interaction optimization.

First, we screened medical document forms from the EHR system to be used for the actual service. Out of 2201 different document forms, total 989 forms were selected. The rest were excluded due to inconsistent usage, absence of textual content, or their association with surveys, referrals, palliative care or physical therapies. This decision was reached after numerous meetings with the medical records team and clinicians. Then, we standardized the selected forms based on Fast Healthcare Interoperability Resource (FHIR) [27] standards. This standardization not only enhanced interoperability for existing documentation but also established a robust framework for future development, ensuring long-term system scalability and maintainability.

Second, we mapped precise trigger points for AI agent activation to ensure assistance without disrupting existing clinical routines. The system supports both real-time triggers and batch processing. We carefully selected the optimal time for batch processing to minimize potential system load, and tested system latency to ensure that the integration would not impact the EHR's overall performance.

Third, we established a documentation display and a user interaction framework that maximized efficiency while preserving physician control over final documentation. The interface enabled quick review and editing of AI-generated content through intuitive controls for accepting, modifying, or rejecting suggestions. This design emphasized minimal click paths to streamline the documentation process.

To ensure data sovereignty, all infrastructures including servers and databases were hosted within the hospital's secure on-premises environment.

Predefined Clinical Evaluation Criteria

Before the deployment in actual clinical setting, we evaluated the qualities of automatically generated ED discharge summaries and preanesthetic assessments to assess the performance of the AI agent. For each type of document, 100 pairs of input data, which had not been used during the development, and consequent model outputs were provided to 2 physicians. The physicians graded the outputs in terms of consistency, coherence, fluency, relevance, safety, subjective satisfactory rate, and usability. In addition, the impact on decision-making was graded only for preanesthetic assessments. The specific criteria for each metric are listed in Table 1. All metrics were graded using 5-point Likert Scales, except for usability, which had a maximum score of 4, and impact on decision-making, which had a maximum score of 3. Higher scores indicated better output quality for all metrics. Mean scores were calculated for all metrics, except for impact on decision-making, where the proportion for each score was calculated.

Table . Criteria for evaluating auto-generated drafts.

Metrics	Range[a]	Criteria
Consistency	1 - 5	The consistency of the information provided on the output
Coherence	1 - 5	The logical structure of the output in context
Fluency	1 - 5	The appropriateness in grammatical, lexical, or structural aspects of the output
Relevance	1 - 5	The alignment of the output with the topic
Safety	1 - 5	The correctness of medical information in the output
Subjective satisfactory rate	1 - 5	Subjective measurement of overall satisfaction with the output
Usability	1 - 4	Whether the output can be provided to the user without modifications
Impact on decision-making[b]	1 - 3	The extent to which the response influences medical judgment, categorized into three levels: positive, no impact, and negative

[a]A higher score indicates better quality of output in all metrics.

[b]This metric was used solely for evaluating preanesthetic assessments.

Implementation (Results)

Performance Evaluation of Medical Knowledge and Language Capabilities

The 'Y-KNOT-med-base' achieved an accuracy score of 75.2 on the PubMedQA. Despite its relatively small size and absence of fine-tuning process, the performance was comparable to state-of-the-art baselines which were fine-tuned on larger parameter scales. The average accuracy score was 55.8 on the KorMedMCQA (doctor: 47.0, nurse: 64.1, pharmacist: 56.2), outperforming other multilingual pretrained models on all three exam categories. Detailed performance results are provided in Tables 2 and 3.

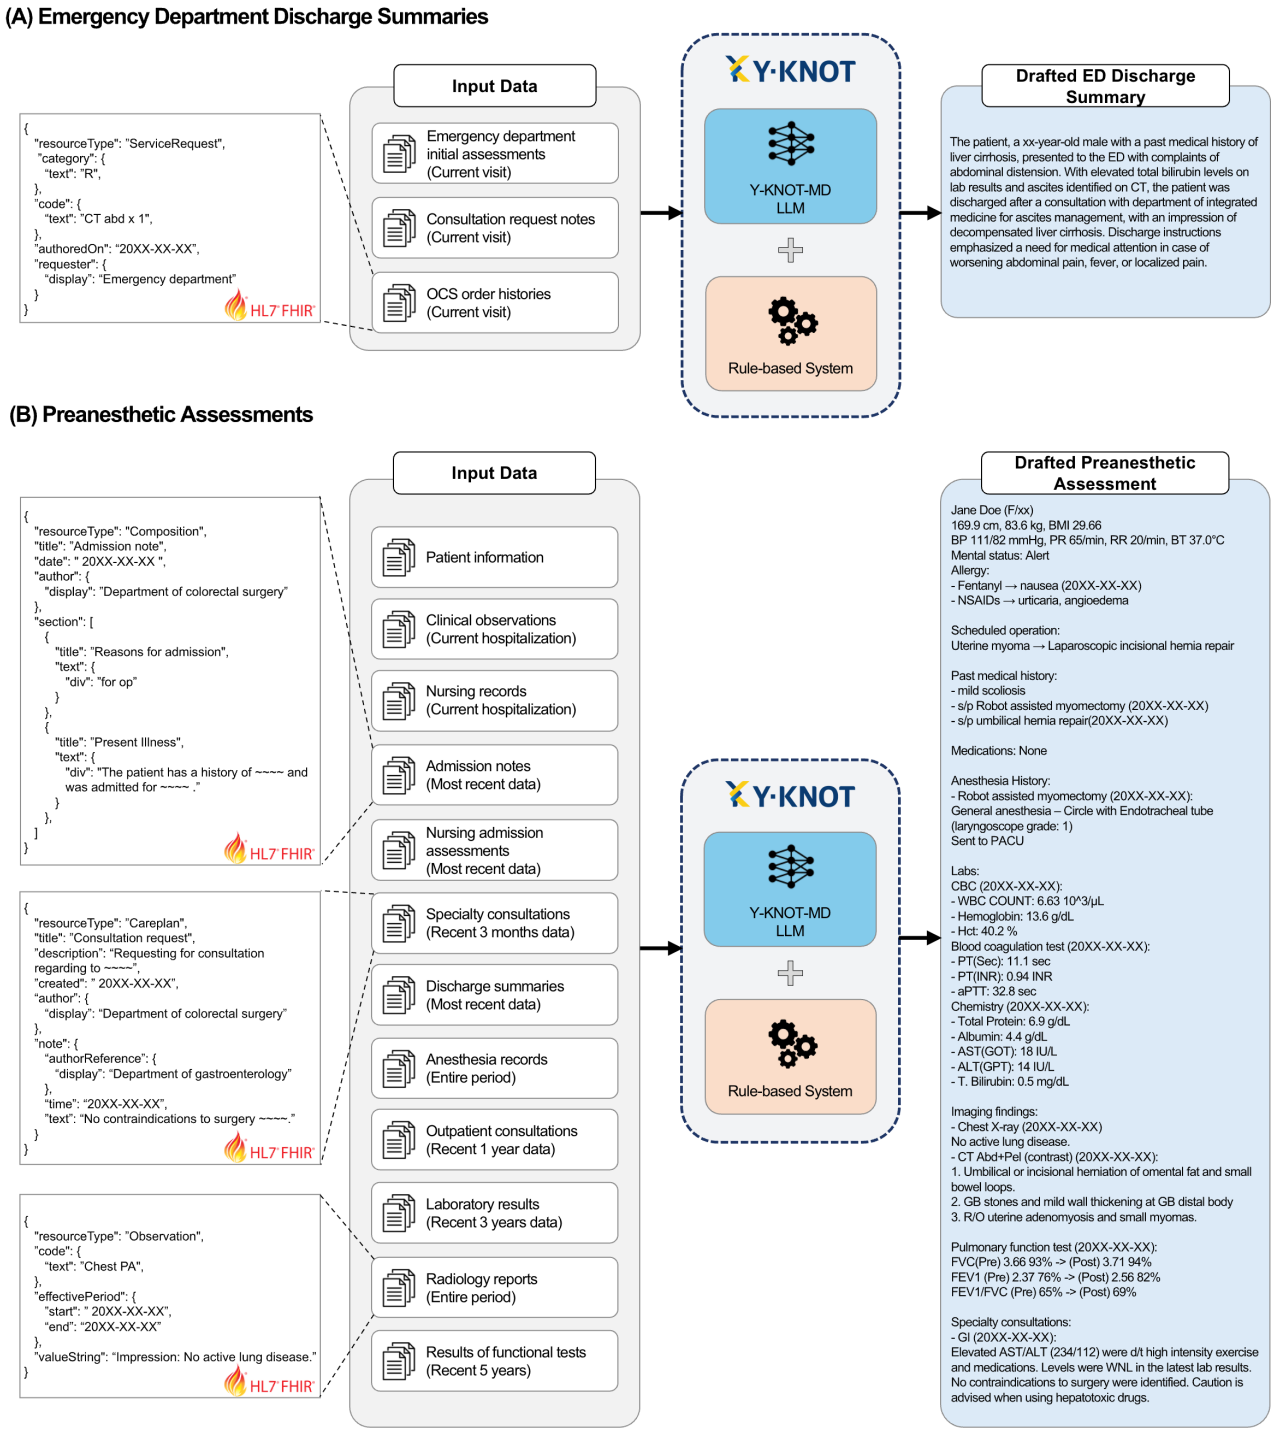
Automatic Drafting of Clinical Documents



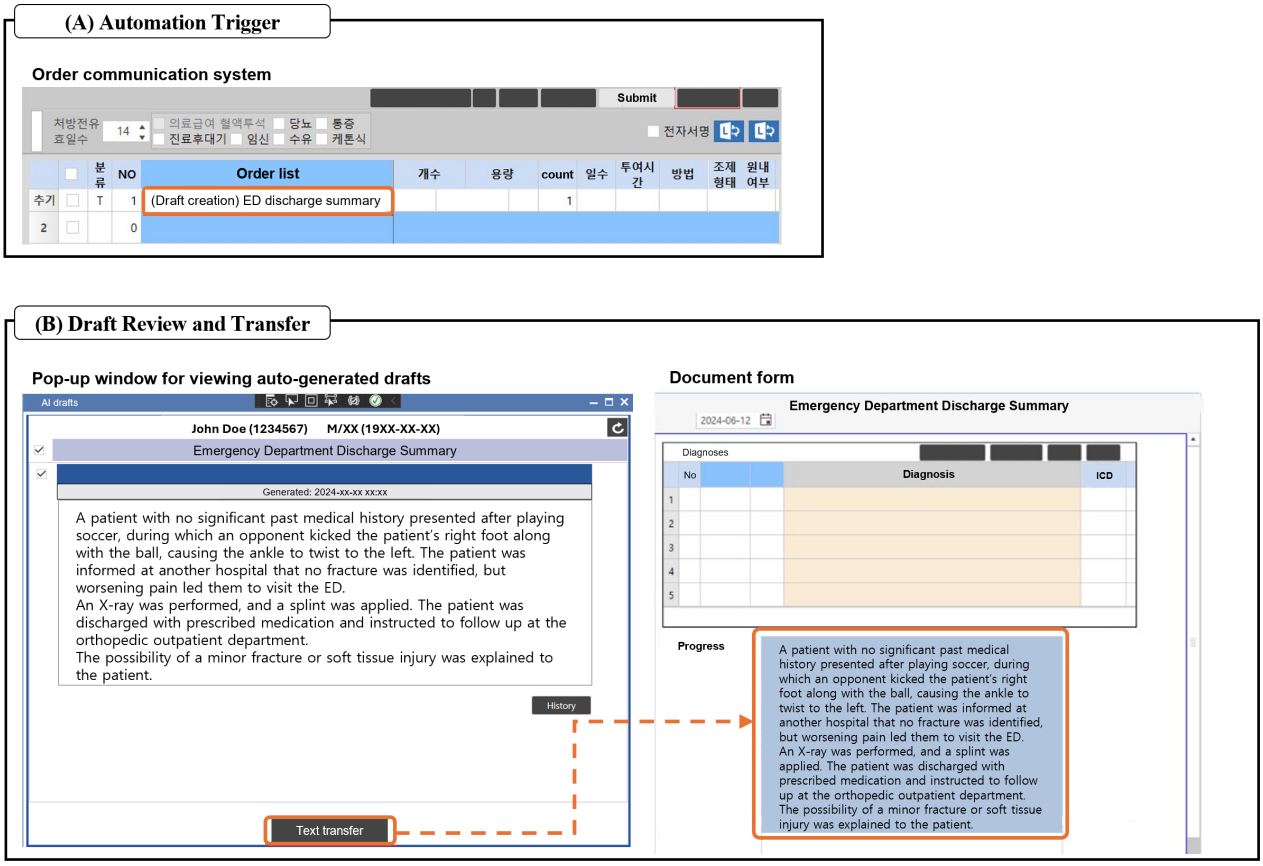
For ED discharge summary, the AI agent drafts the whole contents in one paragraph, which includes past medical histories, reason for the visit, and the details of specialty consultations or treatments. In response to the urgent and fast-paced nature of the ED, the outputs are designed to be as concise as possible, meeting the specific requirements of the physicians.

For preanesthetic assessment, the agent drafts a patient's background information required for preparing anesthesia, including basic information, past medical histories, medications, examination results, and other specialty consultation histories. Contents requiring medical judgment, such as anesthesiologist's opinion or premedication guides, or American Society of Anesthesiologists (ASA) classification, were excluded as an LLM that makes medical judgements could be risky.

Detailed examples of generated drafts are provided in Figure 3.

XSL•FO
RenderX

Figure 3. Examples of input data types and subsequent output contents of auto-generated drafts. All medical records used as input data are converted into Fast Healthcare Interoperability Resource (FHIR) standards. Criteria for selecting input data are stated in parentheses. Note that the examples provided in the figure are simplified versions of the actual data, which originally contains a mixture of Korean and English. The untranslated figure can be found in Multimedia Appendix 2. (A) An example of input data types and output contents of a drafted emergency department discharge summaries; (B) An example of input data types and output contents of drafted preanesthetic assessments. ED: emergency department; LLM: large language model; OCS: order communication system; Y-KNOT: Your-Knowledgeable Navigator of Treatment.



Integration and Implementation in Clinical Practice

The Y-KNOT service is currently deployed at Severance Hospital for real-world use. Since the agent is fully integrated into the EHR system, the drafting process is automatically triggered through two familiar physicians' workflows. For ED discharge summaries, physicians can initiate drafting by placing a "draft creation" order, similar to medication orders, due to the need for prompt creation in acute care settings (Figure 4A). For preanesthetic assessments, which are associated with scheduled surgeries, the system generates drafts in batch according to a predetermined schedule. As a physician opens a form for documentation, auto-generated drafts show up in the pop-up window (Figure 4B). No external programs other than the EHR system are required to use the LLM. The entire process is similar

XSL•FO
RenderX

to usual documentation workflows, except physicians can now load drafts with a single click instead of writing them from scratch. This also prevents potential risks of adversarial attacks [30] by keeping users away from instructing the LLM. Videos demonstrating the actual clinical use of the service are available in Multimedia Appendices 3 and 4.

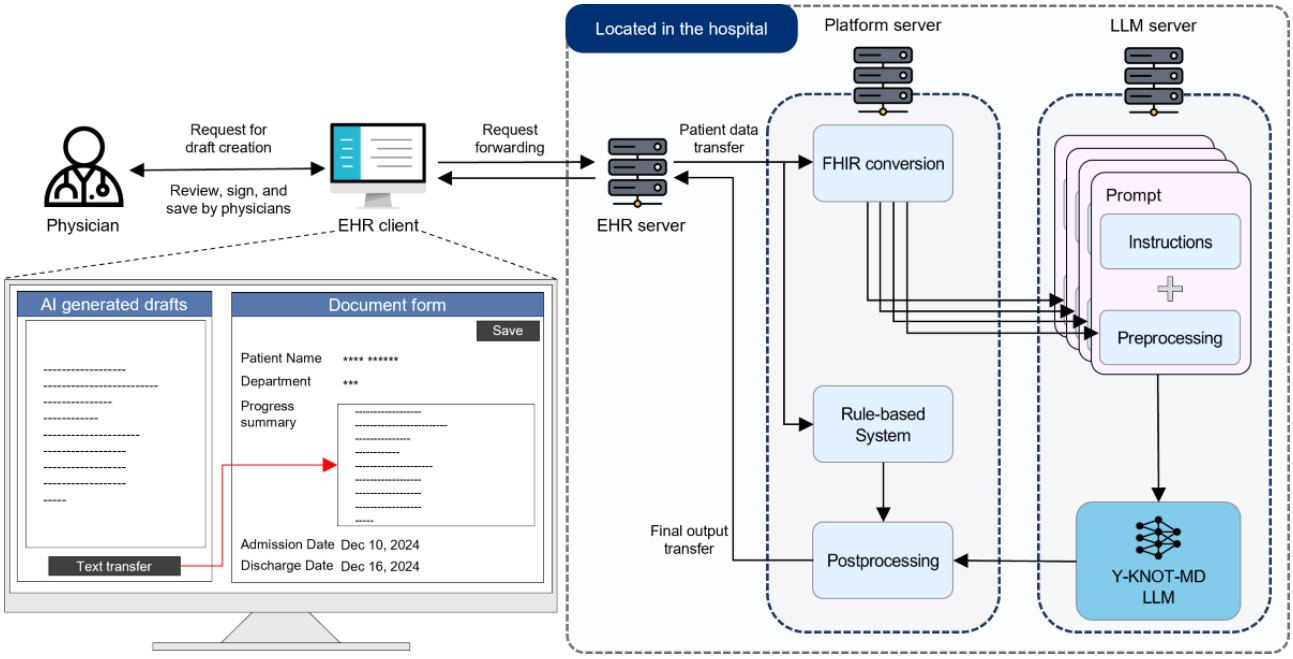


Figure 4. User interaction with the EHR system for automatic clinical drafting. (A) Requesting a draft creation through the order communication system; (B) Reviewing the auto-generated draft in the pop-up window. ED: emergency department.

When the drafting is initiated, relevant patient records in FHIR format are transmitted from the EHR server to the Y-KNOT system, which processes them using a combination of LLM and rule-based approaches. The system preprocesses these standardized records into multiple prompts, each designed to extract specific aspects of the document. The LLM processes these prompts independently and generates outputs which are eventually synthesized into a comprehensive document draft. This final draft is returned to the EHR for physician review and approval. This automatic process (Figure 5) operates through predefined application programming interfaces (APIs) that specify data exchange formats between system components.

Figure 5. Overview of the automated drafting process with the AI agent in the EHR system. AI: artificial intelligence; EHR: electronic health record; FHIR: Fast Healthcare Interoperability Resource; LLM: large language model; Y-KNOT: Your-Knowledgeable Navigator of Treatment.

Clinical Performance and Impact Assessment

The mean scores graded on drafted ED discharge summaries were 4.78 for consistency, 4.60 for coherence, 4.55 for fluency, 4.72 for relevance, 4.73 for safety, 3.95 for subjective satisfactory rate, and 3.32 for usability. The mean scores on drafted preanesthetic assessments were 3.29 for consistency, 3.86 for coherence, 4.23 for fluency, 3.37 for relevance, 3.88 for safety, 3.14 for subjective satisfactory rate, and 2.58 for usability. Additionally, out of 200 individual ratings on the impact on decision-making of preanesthetic assessments (2 raters evaluating 100 drafts), 69 (34.5%) were judged to be positive and 98 (49.0%) as having no impact, while 33 (16.5%) were judged to be negative (Table 4).

Table . Clinical evaluation results on drafts generated by the Y-KNOT[a] AI agent.

Metrics	ED[b] discharge summaries (n=200)	Preanesthetic assessments (n=200)
Consistency, mean (SD)	4.78 (0.56)	3.29 (1.10)
Coherence, mean (SD)	4.6 (0.75)	3.86 (0.82)
Fluency, mean (SD)	4.55 (0.73)	4.23 (0.69)
Relevance, mean (SD)	4.72 (0.61)	3.37 (0.91)
Safety, mean (SD)	4.73 (0.63)	3.88 (0.94)
Subjective satisfactory rate, mean (SD)	3.95 (1.03)	3.14 (1.10)
Usability[b], mean (SD)	3.32 (0.76)	2.58 (0.87)
Impact on decision-making, n (%)		
Positive impacts	—	69 (34.5)
No impacts	—	98 (49.0)
Negative impacts	—	33 (16.5)

Discussion

Implications

The Y-KNOT project demonstrates a successful implementation of a bilingual on-premises LLM-based clinical drafting system that seamlessly integrates with existing EHR workflows in a high-throughput health care setting. Through close collaboration with stakeholders, we addressed several critical challenges.

Our decision to use a small model was crucial for real-world deployment, as larger models require substantial computational resources and costs. Although smaller models may have limitations in processing lengthy contexts and complex medical information, proper instruction-tuning enables them to perform

XSL•FO
RenderX

specific tasks on par with larger models [31]. While initial clinical evaluation results of our model were modest, we prioritized rapid development using a small model to address the hospital's pressing clinical needs. We transparently disclosed the evaluation results to all stakeholders and educated physicians prior to deployment regarding the possibility of errors in model outputs, with specific examples provided. After the deployment, discharge summary documentation completion rates in the Emergency Department improved from 92.7% in Apr-May 2024 to 98.0% in Apr-May 2025. Our experience demonstrates that carefully optimized smaller models can effectively support specific clinical drafting tasks when combined with thoughtful implementation strategies.

Moreover, our small model could address the unique challenges of resource-limited health care settings. South Korea's health care system, while renowned for its accessibility, operates at significantly low costs, with the average cost per outpatient visit at tertiary hospitals being less than US $15, whereas in the United States, it exceeds US $100 [32]. This cost structure makes it financially unfeasible to deploy large-scale LLMs as the operational costs would significantly exceed the revenue per visit. Currently, the operational costs of the Y-KNOT service are solely covered by the hospital, but a national funding strategy could offer a more efficient approach for broader implementation in the future.

South Korea's health care system is also highly efficient, with outpatient consultation times averaging merely 4.2 minutes [33], which is significantly shorter than the 20 minutes in the US [34]. This extreme time constraint presented both an opportunity and a challenge: while it highlighted an urgent need for documentation assistance, it also demanded exceptional efficiency in implementation. We addressed this challenge through strategic EHR integration, enabling documentation drafting to occur concurrently with other clinical tasks which eliminated perceived latency and maintained the rapid pace of clinical practice. This approach demonstrates how AI can be successfully integrated even in highly time-constrained, cost-sensitive clinical environments without disrupting established workflows.

To ensure scalable deployment across different health care institutions, we standardized all document templates to FHIR format and implemented API-based data exchange. As of December 2022, the Ministry of Health and Welfare in South Korea has established a taskforce to implement a 5-year strategy to accelerate health data standardization, which includes the specific task of developing and deploying Korea-specific FHIR standards [35]. In line with this initiative, we created a system that can be readily deployed to any EHR system that adheres to FHIR standards. This architectural decision not only ensures interoperability but also significantly reduces the technical barriers for other health care institutions wanting to implement similar AI-assisted documentation systems.

Limitations

Our study has several limitations. First, clinical evaluation involved only 2 personnel per document type, potentially introducing bias due to small sample size. Second, we have not validated its performance across multiple institutions. Multicenter implementation studies would be crucial to establish the generalizability of our approach and identify potential institution-specific adaptation requirements. Third, this study does not include prospective results measuring the system's impact on physician workload and documentation efficiency. Previous studies have raised concerns that the need for validating AI-generated outputs might paradoxically increase physician workload [36], making it crucial to evaluate the actual time savings through rigorous clinical studies [37,38]. We are actively conducting such prospective studies and plan to report our findings in future publications. Impacts on clinical decision-making or patient outcomes should also be assessed through long-term studies. Fourth, the financial implications remain to be fully understood. While there are expectations of cost benefits from AI implementation in health care [39], recent studies of similar technologies like ambient-listening AI have shown no significant financial advantages [40]. Future research should address these limitations through in-depth analyses with multicenter implementation studies, prospective evaluations of efficiency gains, clinical impact, and cost-effectiveness.

Conclusions

This study provides a comprehensive account of developing and integrating an LLM-based AI agent for clinical drafting in routine clinical practice. We developed a specialized LLM by taking into consideration issues such as data sovereignty, bilingual challenges, and cost-effectiveness. In collaboration with various stakeholders, we integrated this solution with the EHR system to ensure practical usability by physicians without interruption of existing workflow.

Acknowledgments

The authors thank the following contributors at Yonsei University Health System for their technical assistance and advice to the Y-KNOT project. They did not receive any separate compensation beyond their regular institutional responsibilities for these contributions: Jihyun Yang and Jeeeun Jung at the Department of Medical Records, Division of Digital Health; Eunhye Kang, Hyekyung Jung, Younghee Lim, and JaeHyeon Park at the Department of Information Services, Division of Digital Health; Young ah Kim, Heui seok Kang, and Hyunsook Seong at the Department of Data Services, Division of Digital Health; Eun Jung Kang, Kyung Han Kim, and Jong Myoung Kim at the Digital Health Strategy Team, Division of Digital Health, Yonsei University Health System, Seoul, Republic of Korea. Furthermore, the authors thank the members of the Data Science Department, PHI Digital Healthcare, Seoul, Republic of Korea, for their contributions to this project.

Abstract

Background: Acute care use (ACU) represents a major economic burden in oncology, which can ideally be prevented. Existing models effectively predict such events.

Objective: We aimed to quantify the cost savings achieved by implementing a model to predict ACU in oncology patients undergoing systemic therapy.

Methods: This retrospective cohort study analyzed patients with cancer at an academic medical center from 2010 to 2022. We included patients who received systemic therapy and identified ACU events occurring after treatment initiation, excluding those with known death dates within the study period. Data on ACU-related expenses were gathered from Medicare claims and mapped to service codes in electronic health records, yielding average daily costs for each patient over 180 days following the start of therapy. The exposure was an ACU event.

Results: The main outcome was the average daily cost per patient at the end of the first 180 days of systemic therapy. We observed that expense accumulation flattened earlier and more rapidly among non-ACU patients. This study included 20,556 patients, of whom 3820 (18.58%) experienced at least 1 ACU. The average daily cost per patient for those with and without ACU was US $94.62 (SD US $72.54; 95% CI US $92.32-$96.92) and US $53.28 (SD US $59.92; 95% CI US $52.37-$54.19), respectively. The average total cost per ACU and non-ACU patient was US $17,031.92 (SD US $13,056.63; 95% CI US $16,616.74-$17,445.09) and US $9591.06 (SD US $10,785.83; 95% CI US $9427.64-$9754.48), respectively. To estimate the long-term financial impact of deploying the predictive model, we conducted a cost-benefit analysis based on an annual cohort size of 2177 patients. In the first year alone, the model yielded projected savings of US $910,000. By year 6, projected savings grew to US $9.46 million annually. The cumulative avoided costs over a 6-year deployment period totaled approximately US $31.11 million. These estimates compared the baseline cost model to the intervention model assuming a prevention rate of 35% for preventable ACU events and an average ACU cost of US $17,031.92 (SD US $13,037).

Conclusions: Predictive analytics can significantly reduce costs associated with ACU events, enhancing economic efficiency in cancer care. Further research is needed to explore potential health benefits.

Introduction

Acute Care Use Burden in Oncology

Systemic therapy, such as chemotherapy, while essential for treating cancer, can be highly toxic, often leading to complications that result in patients requiring acute care use (ACU), including unplanned hospitalizations and emergency department visits [1]. These events can be classified as avoidable or unavoidable based on clinical context, with avoidable ACU events being potentially preventable through prompt interventions. ACU events are linked to higher rates of repeat visits and mortality [2], and there is evidence suggesting that up to 35% of ACU events are preventable within 180 days of therapy start [3], whereas other sources even discuss possible prevention from 40% to 67% [4-6]. For that reason, these events not only are detrimental to patient health but also significantly contribute to health care costs. Therefore, the Centers for Medicare and Medicaid Services (CMS) has named certain ACU events as preventable and has begun using them as quality metrics, as seen with the Outpatient Quality Reporting Program and the OP-35 measure [7]. The potential to reduce preventable ACU events presents an important opportunity to improve patient outcomes and lower costs for both hospitals and patients.

Predictive Advancements

Recent advancements in machine learning (ML) have greatly improved the identification of patients at elevated risk of ACU events [1]. Innovations in deep learning and natural language processing now enable more accurate and reliable predictive models, supporting precise risk stratification while remaining robust across diverse populations and periods [8-10]. This capacity creates a paradigm-shifting opportunity; by predicting ACU events before they occur, these models empower health care systems to shift from reactive to proactive care. These electronic health record (EHR)–derived risk scores allow clinicians to deliver targeted interventions for patients at high risk of ACU and potentially prevent costly ACU events.

However, realizing this potential requires navigating significant challenges [11]. This includes the need for dedicated staffing, regulatory compliance, and integration with existing systems, all of which incur significant costs that must be considered in return-on-investment (ROI) assessments. Moreover, successful implementation depends on both technical execution and clinical adoption [11]. Literature on model deployment challenges, clinical integration, and operational cost considerations shows that algorithms fail in practice due to workflow misalignment, lack of interpretability, and the hidden resource burden of sustained use [11-13]. Model transparency and reporting frameworks are increasingly critical for building clinician trust as they document intended use cases, performance characteristics across subpopulations, and potential biases, which are all essential considerations when deploying predictive models in health care settings [10]. The deployment of ML models in health care incurs significant costs related to data preparation, regulatory compliance, integration with existing systems, and ongoing maintenance and monitoring [12,14]. Additionally, deploying these models requires an investment in workforce training and infrastructure, making it a costly endeavor [13]. Therefore, despite the promise of ML in health care, the cost of its deployment must be weighed against the savings it generates, which is a complex and often overlooked aspect of deployment in health care. The deployment of ML models in clinical settings presents challenges beyond technical performance [11]. Equally critical for clinical adoption are workflow optimization, staff training, and clinician trust [13]. This trust must be built through transparent tools such as model cards [10,15] that document performance and potential biases across diverse patient populations. Accounting for these demands is essential as their cumulative cost can undermine the financial viability of even the most promising models.

Bridging the Gap

To address this gap, we developed a cost analysis to assess the expenses associated with deploying an ML model and the potential savings from preventing ACU events among patients with cancer starting treatment at a comprehensive cancer center (CCC). Our hypothesis was that implementing an ML model would lead to cost savings by preventing ACU events and reducing hospital costs. This study aimed to fill a critical gap in the literature [13,16-18] about the ROI for ML deployment in health care, particularly in oncology. This work paves the way for future studies to explore the broader health benefits, potentially driving the adoption of ML in various areas of patient care. Unlike previous studies focused primarily on model performance, this analysis evaluated real-world financial return, offering critical insights for health care systems considering predictive model deployment.

Methods

Study Design

This retrospective cohort study used structured EHR data from routine care from a CCC that includes an academic hospital, a community hospital, and a health care alliance. This study provides a cost analysis comparing daily patient costs with and without a prediction model for preventing ACU admissions. A cost-benefit analysis was conducted from the Medicare payer perspective comparing usual care to an intervention involving predictive model deployment. Costs, including staffing and IT infrastructure, were estimated using institutional records and published benchmarks [13,16,19]. We modeled the deployment of a prediction system using standard cost estimates for artificial intelligence tools (see Multimedia Appendix 1). Savings were derived by applying the preventable ACU proportion to the total cohort and the associated cost differential. Claims data mapped to EHR service codes were used to estimate care costs over the 180-day posttherapy window.

Ethical Considerations

This retrospective analysis was approved by the Stanford University Institutional Review Board (protocol 47644), with a waiver of informed consent due to secondary use of existing records. This research also used publicly available Medicare claims data. All procedures complied with institutional policies, the Declaration of Helsinki, and applicable privacy regulations. In addition, our study adheres to the Minimum Information for Medical Artificial Intelligence Reporting guidelines [15].

XSL•FO
RenderX

Data Preparation

We calculated costs using a combination of Medicare Physician Fee Schedule (MPFS) [19,20] and average sales price (ASP) [21] data following the CMS methodology and previous published research [16,22,23] (see Table S1 and equations 1-7 in Multimedia Appendix 1). MPFS values were determined based on 3 components: relative value units assigned to each service, a geographic practice cost index to account for regional cost variations, and a conversion factor that translates relative value units into dollar amounts. ASP values were calculated as 106% of the ASP, reflecting the CMS payment limit for drugs and biologicals. For each Healthcare Common Procedure Coding System (HCPCS) code each year and quarter, we summed the MPFS and ASP values to produce a combined fee for a given service at a specific point in time (equation 3 in Multimedia Appendix 1) [23].

Operational Implementation

The rationale behind the algorithm is that patients predicted to be at high risk of ACU events will be flagged using pop-up notifications (as shown in Figure S1 in Multimedia Appendix 1). To estimate deployment costs within our cost model, we incorporated key operational needs for a predictive model in outpatient oncology care. These included infrastructure setup, model validation, workflow integration, maintenance, and staffing needs. Deployment costs were the largest contributor and encompassed data infrastructure, integration with the Epic EHR system, and real-time workflow design [12,13,24]. Annual maintenance costs comprised technical audits, software updates, and training. We assumed an initial onboarding session per health care provider to cover alert interpretation, risk stratification logic, and escalation protocols. Although the system is not yet deployed, this assumption reflects institutional norms and previous implementations. Ongoing training for new staff and protocol updates were included in maintenance costs. To operationalize the intervention, we included staffing of 0.25 full-time equivalent (FTE) for a registered nurse, who triages alerts and provides patient education. Published data on remote symptom alert triage in oncology indicate that time per alert ranges from under 5 to 10 minutes, with 52% resolved in under 5 minutes and 36% resolved in 5 to 10 minutes [25]. In addition, 0.5 FTE were estimated for an advanced practice provider (APP), who coordinates clinical follow-up with primary oncology teams [3,23]. All operational assumptions were informed by published oncology implementation studies [13,24,26], internal clinical workflows, and expert discussions. A detailed visualization of the modeled deployment workflow is provided in Figure S2 in Multimedia Appendix 1.

Estimating Costs

To quantify the cost of care for a patient, we mapped MPFS and ASP values to each patient's services using HCPCS codes [23], including level 1 codes corresponding to Current Procedural Terminology (CPT) codes from the American Medical Association. Service codes and dates were linked to these combined fees to compute the total cost incurred by each patient on each day of the observation period. These daily costs were then aggregated over the therapy period to calculate the total cost per patient per period (TCPP), representing the full cost of services and drugs received by an individual during the entire treatment window. To standardize this measure and enable comparisons across patients with different observation lengths, we derived the cost of care per patient per day (CCPD) by dividing each patient's TCPP by the number of days in their observation period. Thus, the CCPD represents an average daily cost across the full treatment window, distinct from the raw daily totals. Variable definitions are provided in Table S4 in the Multimedia Appendix 1, with patient-level CCPD values summarized in Table S4 in Multimedia Appendix 1. To estimate the annual cost of ACU before deploying (without) a predictive model, we multiplied the total patient population by the baseline ACU prevalence to obtain the expected number of ACU events ($N_{acu,0}$). This value was then multiplied by the average cost per ACU case (C_{acu}), resulting in an overall cost estimate in the absence of intervention. We developed the following formula for the total cost estimation without a prediction model (C_0; equation 1; Multimedia Appendix 1):

$$(1) C0(X) = Cacu \cdot Nacu,0 \cdot X$$

To assess the cost with a deployed predictive model, we included the model's implementation cost (C_{deploy}); ongoing annual maintenance (C_{annual}); residual ACU costs after prevention efforts ($C_{acu,1}$); and additional staffing required for proactive care, including cost of nurses (C_{nurse}) and APPs (C_{app}) [16,17]. We estimated the number of preventable ACU events and calculated the proportion of those correctly identified by the model. We also accounted for false positives, patients incorrectly flagged as high risk, and their implications. The false positives were obtained by first calculating how many patients were not at risk of an ACU event and, among these, identifying how many were incorrectly predicted as being at risk. Accordingly, we developed the following formula for the total cost calculation with a prediction model (C_1; equation 21 in Multimedia Appendix 1):

$$(2) C1(x) = Cdeploy + Cannual \cdot (x-1) + Cacu,1 \cdot x + Cnurse \cdot x + Capp \cdot x$$

Service costs were derived as described previously [23] by mapping MPFS and ASP values to each patient's clinical activity using HCPCS and CPT codes. They were then linked by date and aggregated to compute the TCPP and CCPD as outlined previously. HCPCS and CPT codes were grouped into service categories using CMS classification files. We included professional fees via MPFS and ASP values for drug-related codes. Facility fees, patient cost sharing, and contractual adjustments were excluded. The cost models in the detail section in Multimedia Appendix 1 provide more details of the cost models generated with and without a predictive model. Codes were mapped to the cost on CMS-allowed amounts for professional services and drugs. Facility and patient-specific fees were excluded. Figure S6 in Multimedia Appendix 1 shows the most common and most expensive services observed in the cohort.

Data Analysis

A cost-benefit analysis was conducted to compare the total costs of ACU admissions with and without the use of a prediction model based on the estimated number of preventable events reported in the literature [27]. The total cost without the model

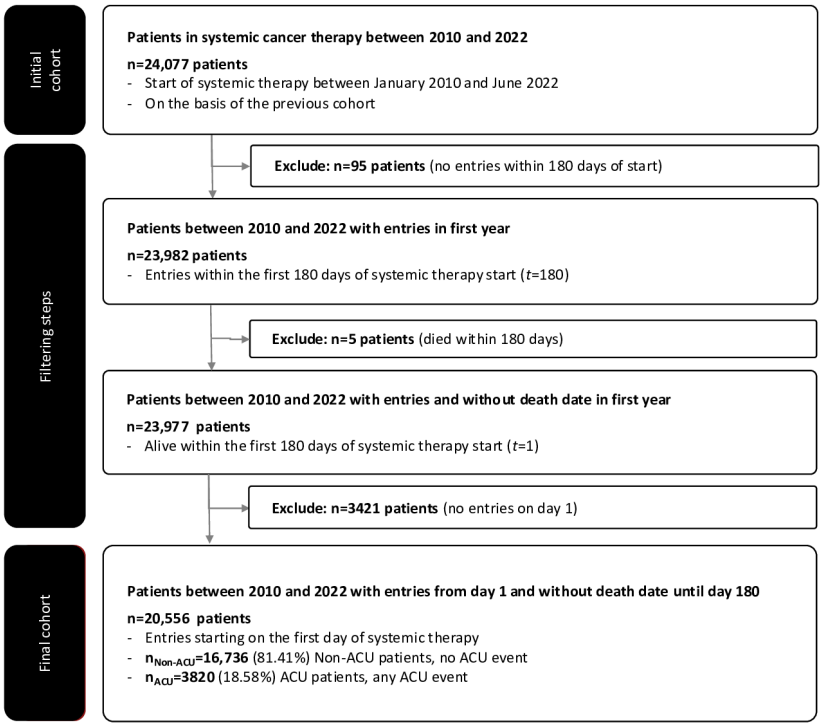
XSL•FO
RenderX

was calculated by multiplying the prevalence of ACU cases by the total number of patients and the cost per ACU case. The cost associated with the model includes deployment costs, annual maintenance, and the additional personnel required to interpret predictions and conduct patient outreach (eg, nurses and APPs). The model's impact on cost reduction was evaluated by estimating the number of preventable ACU cases and extrapolating the potential savings from excluding these cases. We assumed a conservative lower-bound prevention rate of 35% based on an estimate of the proportion of ACU events deemed preventable in the published literature [3,4], which aligns with the minimal threshold observed across multiple oncology care studies. We then applied this rate to the number of high-risk patients identified by the model. Data analyses were conducted using Python (Python Software Foundation) and libraries such as Seaborn and Matplotlib for visualization and SciPy for statistical testing. A Mann-Whitney *U* test was used for nonnormal data distributions with an α level of .05. Chi-square tests were conducted to assess differences in features within the cohort, and 2-tailed *t* tests were applied to evaluate cost differences at various time points (30, 90, and 180 days; Table S1 in Multimedia Appendix 1). A paired *t* test was used to analyze the monetary reduction between the C_0 cost model without and the C_1 cost model with deployment over the first 6 years of implementation comparing the means of the paired samples.

Sensitivity Analysis

To evaluate the robustness of our cost-benefit analysis, we conducted a deterministic break-even sensitivity analysis of the ML model and the cost model. Full formulae and constants can be found in Multimedia Appendix 1. For the ML model, the analysis identified threshold values of key model parameters, namely, the sensitivity of the prediction model (R_{sens}), the prevalence of ACU events (p_{prev}), and the total patient volume (N_{total}) that would result in an ROI of ≥0. Each parameter was varied independently while holding the others constant. We defined the cost without a prediction model (C) as the product of the average ACU cost and the expected number of patients with ACU events. The cost with a prediction model (C_1) included fixed deployment costs, annual maintenance costs, reduced ACU burden due to model sensitivity and prevention rate (p_{pred}), and additional costs. We defined p_{pred} as the proportion of preventable ACU events. For the cost model sensitivity, we conducted a one-way sensitivity test on p_{pred} keeping the other variables constant.

Results



Study Cohort

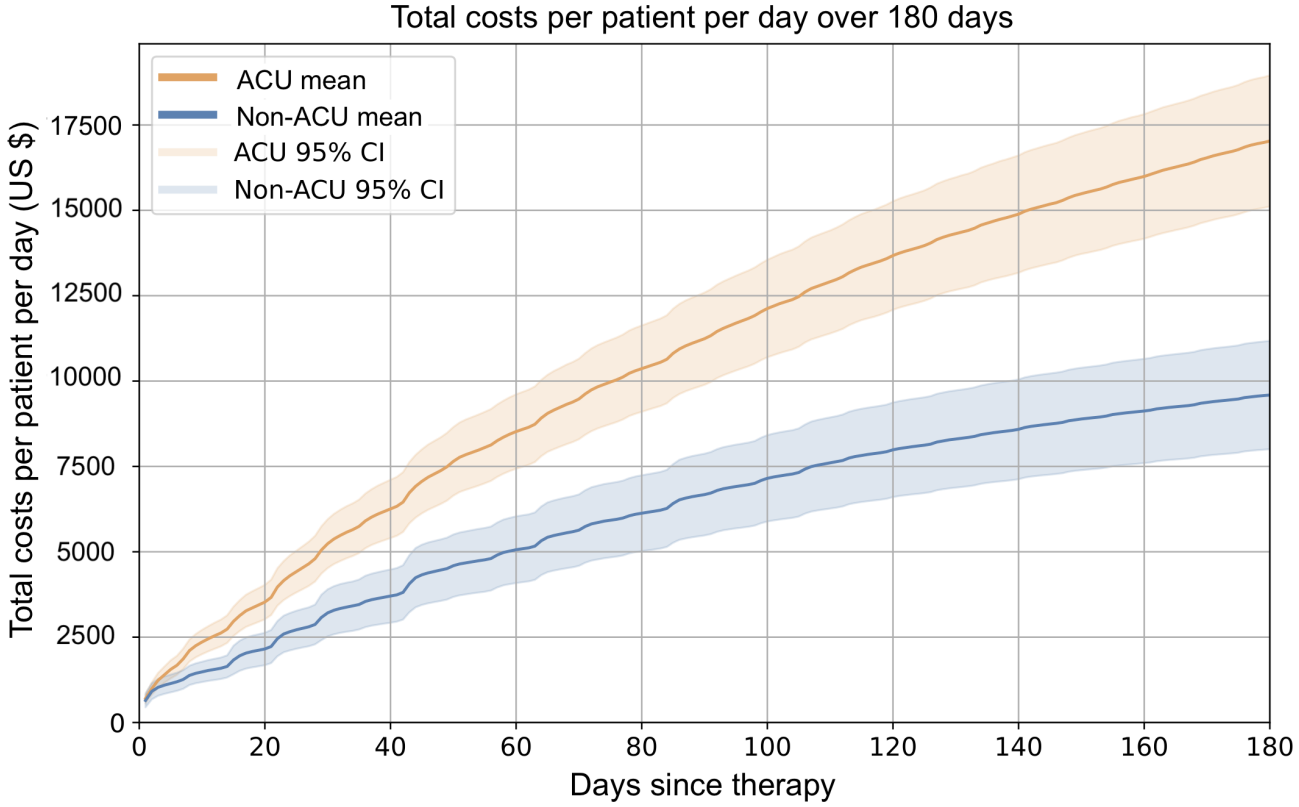
The cohort comprised oncology patients at the CCC who received systemic therapy from 2010 to 2022. Data from the first day of therapy until 180 days after therapy initiation were included, with features such as patient demographics, clinical information, and health services received. Patients without entries within the first year of therapy, those who died within this period, and those without data on the first day of therapy were excluded (Figure 1). Patients were categorized into 2 groups: those with and without ACU admissions, labeled using a binary classification to show whether an ACU admission occurred [10].

The cohort included 20,556 patients, of whom 16,736 (81.42%) had no ACU events and 3820 (18.58%) had at least 1 ACU event, which we defined as the ACU prevalence (Figure 1). Characteristics by ACU status are presented in Table S3 in Multimedia Appendix 1. Differences across demographic and clinical factors were observed in this cohort, including gender, ethnicity, race, insurance type, tumor stage, and tumor type (all $P<.05$; see Table S3 in Multimedia Appendix 1). While several comparisons were statistically significant, we also considered their clinical relevance, as disparities in ACU incidence across demographic groups may reflect differences in acces to care, quality of treatment, or underlying health status. For example, the ACU rate in genitourinary cancer was 42% higher than in breast cancer (23.1% vs 16.2%). Higher ACU proportions were observed for Medicaid coverage (29%; $P<.001$), advanced tumor stage (stage 4: 30%; $P<.001$; stage 3: 22%; $P=.002$), and tumor types including genitourinary (35%; $P<.001$), pancreas (33%; $P<.001$), sarcoma (33%; $P<.001$), and lymph (28%; $P<.001$), whereas breast cancer showed a lower ACU proportion (10%; $P<.001$). Differences in race were also observed between Asian (20%; $P=.001$), Black (23%; $P=.009$), and Hawaiian or Pacific Islander patients (27%, $P=.002$). These findings are descriptive and indicate associations within this cohort rather than causal effects. Patients with ACU events incurred significantly higher costs ($P<.001$), including a TCPP of US $17,031.92 within the first 180 days (approximately 6 months) compared to US $9591.06 for those without ACU events. Daily costs were double for ACU patients (US $94.62 vs US $53.28, respectively; Table S4 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 1. Cohort selection process for cost analysis: flowchart outlining the cohort selection and filtering process for patients undergoing systemic cancer therapy from 2010 to 2022. The initial cohort of 24,077 patients [16] was narrowed down to 20,556 (85.38%) after exclusions based on entry timing, survival within 180 days (approximately 6 months), and missing day 1 records. The final cohort of 20,556 patients included 16,736 (81.42%) non–acute care use (ACU) patients and 3820 (18.58%) ACU patients.

Cost per Day



Cost analysis revealed that CCPD and TCPP differed significantly between ACU and non-ACU patients (P<.001), with CCPD decreasing over time for all patients but total expenses rising for those with ACU events. At 180 days, the average CCPD in the ACU group was nearly double that of non-ACU patients (US $94.62, SD US $72.54 vs US $53.28, SD US $59.92), respectively; P<.001; Table S4 in Multimedia Appendix 1). The higher costs in ACU patients were driven by greater frequency of pathology, laboratory, and medicine-related procedures (Figure S8 and S9 in Multimedia Appendix 1). The cost differences between groups were both statistically and clinically significant (P<.001), with ACU patients incurring approximately 78% higher total and daily costs over 180 days than non-ACU patients (US $17,031.92, SD US $13,056.63) vs US $9591.06, SD US $10,785.83, respectively; US $94.62, SD US $72.54 per day vs US $53.28, SD US $ 59.92 per day, respectively).

TCPP Results

The average TCPP for patients with ACU within the first 180 days was US $17,031.92 (SD US $13,056.63) compared to US $9591.06 (SD US $10,785.83) for those without such events (Figure 2and Figure S5 in Multimedia Appendix 1). We observed that expense accumulation flattened earlier and more rapidly for non-ACU patients (P<.001). The shaded areas illustrate the variation of the total costs from the mean. On day 180, the average daily cost for those with ACU was US $94.62 (SD US $72.54) compared to US $53.28 (SD US $59.92) for those without ACU, which means that patients with ACU events incurred twice the daily costs (P<.001) (Figure 2 and Figure S6 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 2. Total costs per patient over 180 days with and without acute care use (ACU) events. The mean total costs per patient per day (US $) over 180 days are presented for patients with ACU events (n=3820; orange line) and those without ACU events (n=16,736; blue line). The shaded areas represent the 95% CIs. Patients experiencing ACU events incurred consistently higher costs throughout the 180-day period.

Cost Model Results

Operational requirements for implementing the predictive model included supplementary staffing of 0.25 FTE nurses and 0.5 FTE APPs, with combined annual staffing costs of US $112,765. Additional fixed costs of model deployment included software integration, staff training, and compliance with health care IT standards, totaling US $1 million in year 1, with US $200,000 in annual maintenance thereafter. The model showed a positive ROI starting in year 1 (US $910,000) and cumulative savings of US $9.46 million by year 6 (Figure 3). If higher prevention rates of up to 64% are achieved, as suggested in the literature, cost savings could increase further. ROI was calculated as net savings divided by total implementation cost, with break-even achieved within the first year. We used a least absolute shrinkage and selection operator model with a sensitivity of 0.84 and specificity of 0.51 to predict ACU events (Figure S7 in Multimedia Appendix 1), identifying 1.65% (339/20,556) of the patients in the cohort as high risk, enabling targeted intervention planning. As mentioned previously, we assumed that 35% of ACU events were preventable as this value represents a conservative lower bound supported by published literature [3,4]. Using this number in our model, we obtained 119 yearly prevented events and projected cost savings of US $31.11 million over 6 years in our cohort. We expected a cost saving of approximately US $1 million in the year of deployment. There is potential for greater impact as we used a prevention rate of 35% and different prevention rates have been observed in different studies (between 35% and 67%) [4-6]. In contrast to the annualized economic analysis, we estimate with the ACU rate of 18.58% (3820/20,556) in a similar sized cohort, that the number of patients experiencing ACU events over 6 years would be reduced from 8484 to 5985, resulting in 2499 fewer ACU-affected patients. This reduction in avoidable acute care episodes underscores the clinical benefit of early triage and intervention.

XSL•FO
RenderX

Figure 3. Projected cost comparison with and without the prediction model. Cumulative costs (US $) of patient management are shown over 6 years for a cohort of 2177 patients. Costs with the prediction model (C_1; green line) showed large savings compared to costs without the model (C_0; red line), with cumulative savings of US $31.11 million after accounting for the implementation and operational costs of the predictive model. The prediction model showed a clear economic advantage in managing long-term expenses.

Sensitivity Analysis

The model reached break-even within 6 years if the prevention rate was higher than 27%. Prevention rates of 35% or higher [4-6] consistently led to early cost savings within the first year of deployment. Lower-effectiveness scenarios did not achieve break even within the evaluation window (see the sensitivity analysis section in Multimedia Appendix 1 and Figure S10 in Multimedia Appendix 1).

Discussion

Principal Findings

Overview

In this retrospective study, we explored the economic impact of ACU in oncology patients starting chemotherapy and the cost benefits of implementing a predictive model to identify and intervene on high-risk patients. Our analysis of over 20,000 patients initiating chemotherapy revealed that ACU events nearly double daily costs, significantly burdening both patients and the health care system. By implementing an ML model to identify patients at high risk of ACU, we observed substantial cost reductions and a favorable ROI for the health care system. These findings underscore the importance of proactive interventions in oncology, demonstrating that predictive analytics and digital tools can enhance patient management, improve outcomes, and address health care inequities.

Economic Burden of ACU Events

The cost implications of ACU events within our cohort were significant, with patients experiencing ACU incurring an average total cost per patient of US $17,031.92 in the first 180 days of treatment compared to just US $9591.06 for those without ACU events (P<.001). The 77.5% higher total costs for ACU patients were not just statistically significant but also clinically meaningful, directly impacting both health care budgets and patient quality of life. This stark contrast in costs between patient groups reinforces previous research that underscores the considerable financial burden that ACU places on both patients and health care systems [16]. Furthermore, we observed that the cumulative financial impact of ACU events increased over time, further straining health care resources, as noted by Iqbal [27] and Oluwagbade and Covenant [28]. The notable differences in CCPD between the 2 groups emphasize the critical importance of early identification of high-risk patients to mitigate unnecessary health care expenditures. This notion aligns with existing literature that advocates for early risk identification and preventive interventions, which can lead to more efficient health care resource allocation [29].

Cost Savings From Preventive Intervention

This study highlights that deploying a predictive model is an effective strategy for reducing preventable ACU events. Our ML model successfully identified high-risk patients, enabling proactive interventions that have the potential to decrease unplanned care. In the literature, the proportion of such preventable events is reported to range from 35% to 67% [3-6]. Our cost analysis indicated that preventing events could result in savings of approximately US $31 million over 6 years (assuming 2177 patients per year), with a positive ROI observed in the first year of implementation. Our sensitivity analyses demonstrated that the intervention achieved cost savings from prevention rates at 27%, with higher-performance scenarios yielding immediate returns. These findings underscore that even moderately effective clinical decision support tools can result in substantial cost savings when targeted to high-risk populations. Future implementations should include continuous

XSL•FO
RenderX

performance monitoring to ensure that projected prevention rates are achieved. The estimated reduction in ACU events can translate to a meaningful decrease in hospital days and patient morbidity beyond financial savings. Our study targeted earlier cancer treatment stages, particularly chemotherapy, emphasizing the prevention of avoidable hospital admissions and emergency department visits. This approach not only enhances cost efficiency but also underscores the value of integrating predictive models into health care operations to improve patient outcomes. Over a 6-year period, the predictive model reduced projected costs by approximately US $31.11 million compared to the baseline. In the first year alone, the model yielded estimated savings of approximately US $910,000, increasing to US $9.46 million in year 6. The US $31.11 million figure represents the total avoided expenditure over 6 years when comparing the prediction model to standard care. These projections are based on an annual cohort of 2177 patients and an average ACU cost of US $17,031.92.

Precision Oncology

Traditional approaches to ACU risk often rely on reactive care, addressing complications only after they occur. In contrast, our model supports a preventative approach by identifying high-risk patients before chemotherapy begins. This enables clinicians to proactively adjust treatment plans, such as dose modifications or enhanced supportive care, aligning interventions with patient-specific vulnerabilities. Model projections suggest that proactive triage informed by our risk scores could prevent ACU events in approximately 2499 patients over 6 years. As oncology shifts toward value-based care, tools that enable early, risk-based intervention while preserving operational efficiency are critical for sustainable implementation [1,2].

Implementation Considerations

Successful implementation of predictive models requires careful attention to both clinical integration and operational feasibility. The economic viability of implementing ML algorithms in clinical workflows depends on seamless clinical integration, recommendation-action pairing, clinical oversight, and effective prioritization [30,31]. These costs include data preparation, model validation, integration into existing systems, staff training, and ongoing maintenance [13,24]. Our analysis includes the need for added staffing, including nurses and practice providers, to pair model recommendations with clinical actions. Upon deployment, patients flagged as high risk could be routed to case managers or nursing staff for follow-up via calls or assessments, with workflows integrated into existing care management protocols. While this requires training and coordination, it aligns with current practices in outpatient oncology. Even accounting for these resources, the model delivers a strong ROI. Furthermore, if higher prevention rates up to 67% are realized, as suggested by other studies [6], the resulting cost savings could be even more substantial. Overall, predictive models represent a strategic approach to reducing ACU events while improving both financial and clinical outcomes.

Cost Model Limitations

Our study has several important limitations regarding cost estimation. First, while Medicare fee schedules (MPFS and ASP) provide standardized benchmarks, they cannot capture real-world billing complexities such as payer-specific contractual adjustments below Medicare levels (typically 15%-40% below Medicare rates) [32] or variable patient cost sharing [33]. Second, the single-center design misses undocumented out-of-network ACU events. This may underestimate ACU rates and the associated cost savings. In addition, while this CCC reflects the environment of many other cancer centers, the generalizability of our findings to other health care systems may be limited. Third, unmodeled implementation costs (eg, workforce training and workflow changes) may reduce net savings. While our ROI estimates remained positive in sensitivity analyses, real-world returns could be modestly lower. These trade-offs were necessary to enable standardized cross-center comparisons, but future work should incorporate multipayer claims data to improve precision. Fourth, specific medical costs were not available for this study; therefore, we extrapolated expenses using MPFS and ASP values from the CMS, primarily relying on Medicare fees. Fifth, ROI estimates, as shown in the one-way sensitivity analysis, are sensitive to the assumed prevention rate. If the true prevention rate is lower than modeled, the ROI may be overestimated, highlighting the importance of validation in real-world settings. Finally, we did not explicitly model all potential operational challenges, such as hiring, training, and compliance-related overhead. These unaccounted-for costs may reduce net savings in practice and should be evaluated in future implementation studies.

Conclusions

In conclusion, this study reinforces the substantial financial burden associated with ACU in oncology patients, with marked cost differences between those who experience ACU and those who do not. By identifying high-risk patients, our model supports timely interventions that lower avoidable ACU costs and improve outcomes. These findings support the integration of predictive analytics into clinical workflows to optimize resource use, reduce preventable ACU events, and improve patient outcomes. As health care systems evolve, data-driven strategies such as ours may play a pivotal role in enhancing the efficiency and quality of cancer care.Use of Generative AI

Acknowledgments

The generative artificial intelligence (AI) tool ChatGPT (version 4; OpenAI) was used in grammatical editing. AI-generated content was reviewed, fact-checked, and integrated into the manuscript with full author and study group oversight.

Abstract

Background: In Switzerland, sexual assault reports have historically been documented on paper, which limited standardization, completeness, and challenges to produce reliable statistics.

Objective: This study describes the development and implementation of an Electronic Sexual Assault Record (eSAR) within Geneva University Hospitals' Electronic Medical Record (EMR) system, with the aim of improving data quality, documentation, and multidisciplinary coordination.

Methods: The eSAR was developed by a multidisciplinary team including forensic doctors, gynecologists, nurses (clinical and informatics), epidemiologists, and IT specialists. Its structure was based on existing hospital protocols and international recommendations. Variables were defined as "essential" or "highly recommended," with structured fields to ensure completeness and comparability. Confidentiality was safeguarded through restricted access and regular audits.

Results: The eSAR was launched in June 2022 and revised in 2023 after user feedback and training. Since implementation, 382 reports have been completed. Data quality improved substantially, with major reductions in missing information. The system also streamlined workflows and strengthened collaboration across specialties.

Conclusions: The eSAR improved documentation and data reliability, providing a replicable model for standardized sexual assault reporting in Switzerland.

Introduction

The Burden of Sexual Violence in Switzerland

Sexual violence is a serious public health concern in Switzerland. According to a 2019 population-based survey involving 4500 women, 22% of women and girls aged 16 and older reported having experienced nonconsensual sexual acts, and 12% had sex against their will [1]. In 2023, police and victim assistance centers (LAVI/Opferhilfe) reported a total of 1647 cases of sexual violence against women to the Swiss Federal Statistical Office, including 822 cases of rape (Art. 190) and 549 cases of sexual assault (Art. 189) [2].

Switzerland ratified the Istanbul Convention in 2017. Since then, monitoring efforts by the Council of Europe's Group of Experts on Action against Violence against Women and Domestic Violence (GREVIO) have highlighted several gaps and issued specific recommendations. These include strengthening standardized postrape care pathways, such as screening, treatment, injury documentation, and referral to specialized services; improving health care professional training across disciplines, and establishing harmonized standards for forensic data collection throughout the country [3].

To support implementation of these recommendations, the Swiss National Action Plan (PAN CI) [4] for 2022 - 2026 was adopted. It prioritized three urgent measures: (1) scaling up post-rape care services across cantons (2) developing

XSL•FO
RenderX

harmonized healthcare protocols, and (3) improving national statistics to support evidence-based policymaking.

In Romandie, the French-speaking part of Switzerland, several cantons, including Geneva, Vaud and Valais have established specialized sexual assault support centers that reflect GREVIO's standards. These cantons offer joint forensic and gynecological examinations within emergency settings, conducted by medical professionals trained in trauma-informed care. Importantly, access to these services is not contingent on filing a police report, reinforcing a survivor-centered approach to care. Treatment includes postexposure prophylaxis for HIV and sexually transmitted infections (STIs), emergency contraception, crisis mental health support, and referrals for medium- and long-term follow-up [5]. Patients may be directed to a range of specialties within the hospital network, including infectious diseases, psychiatry, the Interdisciplinary Unit for Medicine and Prevention of Violence (UIMPV), addiction medicine, and surgical specialties when needed [5,6].

In parallel to providing clinical care, medico-legal exams serve the function of collecting and documenting forensic evidence. Accurate and thorough documents can improve judicial outcomes by increasing the likelihood of successful prosecution [7]. However, because there is not unified national protocol for the medico-legal exam, data collection practices vary across institutions. The development of harmonized cantonal and national guidelines depends on the availability of high-quality, systematically collected data.

Limitations of Manual Documentation

Until 2021, medico-legal sexual assault reports (SARs) at the Valais, Vaud and Geneva centers were completed by hand. While this method supported a detailed narrative documentation, it posed several challenges. A retrospective study conducted between 2018 and 2021 on 740 sexual assault reports from Geneva and Lausanne University Hospitals revealed areas for improvement, particularly regarding the consistency and comprehensiveness of forensic documentation [8]. Accurate and thorough documentation is crucial not only for optimal patient care but also for judicial decision-making, including whether cases proceed to trial [9].

Despite the HUG's (Geneva University Hospital) reputation as a standard for trauma-informed care, the manual completion of sexual assault reports across multiple departments contributed to administrative delays and occasional data gaps. This variability in documentation impacted the ability to systematically capture essential information such as assault context, risk factors, and sociodemographic characteristics of both victims and perpetrators. Whether or not the patient had previously experienced sexual violence was not documented in 64% of sexual assault records. Between 34% and 50% of all sexual assault reports were missing information on treatments that were prescribed (eg, emergency contraception, gonorrhea, chlamydia, HIV prophylaxis).

The Need for a Digital Standardized Report

The absence of a standardized and harmonized approach to data collection posed challenges in evaluating service utilization and identifying unmet needs. Consequently, the ability to generate evidence-based recommendations for strengthening postrape care services, in line with public health strategies at a national and international level such as those from the Istanbul Convention and GREVIO, were limited.

Aims and Objectives

Recognizing these opportunities for improvement, HUG initiated the development of an Electronic Sexual Assault Record (eSAR) within its Electronic Medical Record (EMR) system. This innovation aimed to maintain HUG's standard of care while enhancing data quality, streamlining clinical workflows, and supporting multidisciplinary collaboration. Our primary aim is to describe the eSAR and its creation and implementation into the HUG's existing EMR System. The report is structured following the iCHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations) guidelines [10].

Methods

Technical Design

The integration of the eSAR into the EMR system was strategically planned from the outset, following the findings of the 2022 retrospective report as the optimal solution for reducing inconsistencies, improving data completeness, and providing high-quality evidence to inform policy-making and the development of best-practice guidelines. The Chiefs of Forensic Medicine and the Gynecology and Obstetrics Emergency Department proactively engaged with the hospital's medical leadership and the information systems directorate to initiate the creation of the eSAR. A nurse specialized in informatics was allocated to the project to help with the development of the digital form within the EMR system. The design of the eSAR involved a multidisciplinary team, including nurse specialized in informatics, a nurse from the Gynecology and Obstetrics Emergency Department, an epidemiologist, a statistician, the Chief of the Gynecology and Obstetrics Emergency Department, and the Chief of the Forensic Medicine unit.

The eSAR was also multidisciplinary in its design. Given that gynecologists and forensic doctors from two separate departments needed access to create, modify, and sign the same record, the informatics directorate developed a specialized protocol granting multiple units access to the shared form. The eSAR workflow is fully integrated across both units, and for traceability, all user interactions, including who accessed the form and what modifications were made, are systematically recorded.

Target

The eSAR was developed to be used by forensic doctors, gynecologists and nurses for all sexual assault reports made in the Gynecology and Obstetrics Emergency Department at the HUG. The eSAR needed to be valid for any patient seen in this emergency unit including cisgender women, nonbinary, queer, transgender men with a vulva and vagina and transgender women- regardless of age. While the patients under 16 are treated in the pediatric department, the gynecological exam is conducted in the Gynecology and Obstetrics Emergency Department. The eSAR may also be used in the gynecology

XSL•FO
RenderX

outpatient clinic, where sexual assault reports are conducted if more than 7 days has elapsed since the sexual assault. Past seven days, evidence on the patient's body will most likely have disappeared and the intervention of a forensic doctor is no longer necessary. The eSAR is also used, regardless of whether the medico-legal exam was mandated by the police or the public prosecutor.

The multidisciplinary team synthesized input from clinical practice guidelines, expert clinical knowledge, and relevant classifications, international recommendations, and guidelines. The starting point was HUG's annually revised clinical practice guidelines for documenting sexual assault, known as "attitude sheets" [11]. Additional sources included international recommendations and clinical scales, such as World Health Organization's guidelines [12-14], the International Classification of Diseases, the Tanner Score, European AIDS Clinical Society recommendations [15], and ethical considerations on gender from the Inclusion Group of Geneva University [16]. This comprehensive approach ensured that the eSAR was evidence-based, aligned with best practices, and tailored to meet the needs of both healthcare providers and patients.

The preliminary sexual assault report form framework included socio-demographic and clinical characteristics, risk factors, complaint status, relationship to the perpetrator, description of events, genital, anal and bodily injuries, pictures, and a description of samples collected. Once the overall structure was outlined, the team designed the individual variables using binary options, multiple-choice selections, and drop-down lists. Most fields are structured to ensure the desired information is captured, in a neutral and unbiased way. Free-text fields were retained as additional fields, as requested by the forensic doctors to ensure that all information could be documented. However, the structured fields ensure consistency, comparability and ease of analysis for research purposes.

3 key performance indicators were envisaged to evaluate the eSAR:

- Descriptive statistics of the number of eSARs in progress and finalized
- Proportion of eSARs with no missing data
- Access to the eSARs by authorized health care professionals only and verifiable

Blueprint Summary

The sexual assault report framework is composed of eight sections (Table 1).

Table . The 8 sections composing the sexual assault report framework.

Section	Description
Sexual assault characteristics	Details on sexual assault, including: (1) patient characteristics, (2) assault characteristics, including (3) perpetrator characteristics, and (4) violence characteristics
Post-Assault Characteristics	Details on post-assault medical and forensic evaluations, including: (1) forensic exam and evidence, (2) gynecological exam, and (3) service referrals and treatment
Forensic Laboratory Kit	Comprehensive list of samples collected, including swabs, smears, slides, blood, urine, and saliva. It documents the date, time, and signature of the forensic doctor
Infectious Diseases Consultation Request Form	Completed when Post-Exposure Prophylaxis (PEP) for HIV prevention is administered and a consultation with the infectious disease department is requested
Confidentiality/Release of Information Form	Signed by the patient to authorize the release of information to police and magistrates if a complaint is filed; a hand-signed copy is scanned for the record
Employment Leave Certificate	Assesses work capacity and the possibility of filing an accident report for health or accident insurance, in compliance with Swiss law
Provisional Medical Certificate	Printed for the patient and scanned for the record. It provides initial findings, a summary of the medical consultation, additional remarks, and signatures of the gynecologist and forensic physician
Full eSAR[a] Patient Information Document	Completed by the gynecologist and forensic physician, handed to the patient. It includes a summary of medical examinations, test results, treatments administered (eg, emergency contraception, antibiotics, HIV prophylaxis), follow-up appointments, and documents provided to the patient

[a]e-SAR: electronic sexual assault records.

Data

The variables were divided in two categories: "essential" variables that are required to sign the file, and "highly recommended" variables, to provide more details depending on medico-legal situation. A pop-up window indicates whether any data is missing; both essential and highly recommended. To ensure harmonized data entry, the users can consult definitions and detailed descriptions of lesion types and diagrams of anatomical sites. The exact anatomical location

XSL•FO
RenderX

and terminology for genital injuries are provided in a diagram of the vulva. An automatic data quality check was built into the system to identify any data entry errors, such as extreme outliers.

The results of the laboratory tests for pregnancy and STIs, as blood chemistry, complete blood count and vaginal bacteriology, are available in the patient's EMR. The monthly list of health professionals accessing the eSAR are reviewed by the CURML (Centre Universitaire Romand de Médecine Légale, University Center for Legal Medicine in French-speaking Switzerland) to verify the access of only authorized health professionals. The triage nurse collects blood and urine samples for toxicological analysis, and ensures their dispatch to the laboratory or Medico-Legal Institute. During the medical examination, the nurse also coordinates follow-up appointments and administers necessary prophylactic treatments. Employment leave and medical certificates are printed and an alert is sent to the laboratory to warn about the arrival of the samples for STIs, improving traceability.

Confidentiality

To open the eSAR, the user must be authorized and provide justification. Access rights are restricted to gynecologists, forensic doctors and nurses directly involved in the medical care of the patient's sexual assault, together with the infectious disease specialists, the psychologists and medical team of the UIMPV and other medical staff (eg, proctologist, psychiatrist, pediatrician, otorhinolaryngologist). Strict confidentiality measures are required to prevent unauthorized access, with any breach punishable by law. To reinforce oversight, a monthly audit report listing all healthcare professionals who accessed the eSAR is reviewed by the CURML. Data security is managed by the IT department of HUG, with all records securely stored on proprietary servers. For research purposes, deidentified data extracts can be obtained through the Magellan informatics module. However, the use of eSAR data for research requires both patient consent and approval from the Swiss ethics committee, ensuring compliance with ethical and legal standards.

Implementation (Results)

Content Validation

The content validation process for the eSAR was multi-phased and collaborative. Initially, structured meetings and iterative refinements were conducted by a multidisciplinary team composed of forensic doctors, gynecologists, a nurse from the gynecology and obstetrics emergency department, a nurse specialized in informatics and an epidemiologist. During these early stages, the team reviewed anonymized sexual assault files and implemented several key changes, including standardized terminology (eg, shifting from "victim" to "patient") (Multimedia Appendix 1), revising question phrasing for clarity, and introducing new variables to better capture details on assault characteristics, injuries, and treatments. Response formats were adjusted, for example by replacing ambiguous free-text responses with binary or multiple-choice options to improve data quality and comparability. The sequence of form sections was also reorganized for greater usability and workflow integration.

The draft eSAR was then presented to clinicians from the Obstetrics and Gynecology Emergency Department for further feedback. Because gynecologists and nurses were already familiar with the hospital's electronic medical record system, dedicated training sessions were organized specifically for forensic doctors to ensure smooth adoption. The eSAR was officially launched in June 2022 (Table 2).

Table . The eSAR timeline.

eSAR timeline	Content
2018 - 2021	Retrospective study reveals documentation gaps (paper SAR)[a]
Q3/4 2021	Project planning, leadership engagement
Q1 2022	Multidisciplinary team formed, prototype design
Q2 2022	Structured meetings, iterative development, early validation
Q2–Q3 2022	Focus groups, pilot testing, refinement
June 2022	eSAR version 1 launched (Gynecology/ObGyn ED)[b]
Q4 2022	Ongoing user feedback, additional training
Sep 2023	Major revision (version 2; expert feedback, improved flow, new response options)
2023 - 2024	Expansion, routine use, continuous updates
2024	Full integration, data extraction or reporting

[a]SAR: sexual assault report.

[b]ObGyn ED: Obstetrics and Gynecology Emergency Department.

After implementation of the first eSAR version, expert focus groups were convened to assess usability, clarify clinical workflow, and refine the eSAR structure based on real patient cases. These focus groups comprised 12 participants: 4 forensic doctors, 3 gynecologists, 2 nurses, 2 informatics specialists, and 1 epidemiologist. Discussions in these focus groups mapped out the patient journey during sexual assault consultations, defined clear roles and responsibilities at each care stage, and identified opportunities to streamline data entry while minimizing patient burden.

XSL•FO
RenderX

The most significant set of revisions followed these focus groups and expert feedback, culminating in the release of eSAR version 2 in September 2023. This update included improved question phrasing and form flow, a shift to more neutral terminology, and the addition of a "+" button for documenting multiple injuries with automatic body region classification. New response options such as "does not remember" (for cases of amnesia) and "does not know" (for patients unable to answer) were also introduced, ensuring greater accuracy and completeness.

Workflow

The focus groups played a key role in clarifying the workflow, particularly in determining how the eSAR is filled out and by whom. These discussions helped refine the division of tasks, ensuring a structured and efficient process. The nurse selects a triage motive according to the Swiss Triage Scale, with the reason for the encounter recorded in the DPI (Dossier Patient Intégré or Integrated Patient File) system and displayed on department screens.

Further, the focus groups provided valuable insights into the data entry process, particularly regarding computer use. Physicians noted that they take turns entering information to maintain patient engagement. For example, the gynecologist switches to the computer while the forensic doctor conducts the medico-legal history, documents bodily traumatic lesions, and collects forensic samples. During the consultation, the gynecologist conducts the exam and administers prophylactic treatments, while the forensic doctor simultaneously completes the electronic record. This streamlined approach minimizes consultation time while ensuring double verification of data, enhancing accuracy and completeness in medical and forensic reporting.

Results

The digitalization of the sexual assault report has significantly improved data reliability and accessibility, enabling the extraction of accurate statistics with ease. With a single click, data can be retrieved based on the number of eSARs per year, month, or type (legal mandate) providing a clearer picture of trends and service utilization (Tables 3 and 4). Since the eSAR was introduced in June 2022, a total of 382 reports have been recorded, with 134 in 2023 and 162 in 2024, reflecting an increase in the number of sexual assaults reported. Most eSARs (84/134, 63%; 102/162, 63%) were completed without a legal mandate, while 37% (50/134 in 2023 and 60/162 in 2024) were mandated cases. The monthly distribution of eSARs varied, with the highest numbers recorded in July of both 2023 and 2024 (15/134, 12% in 2023 and 19/162, 12% in 2024). The peaks in reported cases in July 2023 and 2024 may be explained by increased summer festivals, holidays, and public awareness campaigns, which together create more risk situations and encourage more survivors to seek care [8].

Table . Number of eSARs[a] per year.

eSAR	eSARs (N=382), n	With legal mandate, n (%)	Without legal mandate n, (%)
2022 (01.06.22 - 31.12.22)	86	N/A[b]	N/A
2023	134	50 (37)	60 (37)
2024	162	84 (63)	102 (63)

[a]eSAR: electronic sexual assault records.

[b]Not applicable.

Table . Distribution by month of eSARs[a] (2023).

Month of the eSAR	2023 (n=134), n (%)	2024 (n=162), n (%)
January	5 (4)	16 (10)
February	12 (9)	17 (11)
March	15 (11)	13 (8)
April	12 (9)	11 (7)
May	13 (10)	14 (9)
June	14 (10)	14 (9)
July	15 (12)	19 (12)
August	9 (7)	14 (9)

November	8 (6)	7 (4)
December	7 (5)	11 (7)

[a]e-SAR: electronic sexual assault records.

XSL•FO
RenderX

The eSAR is comprised of approximately 500 data points, with 44 “essential variables” covering victim, assault, and violence characteristics, as well as postassault details, forensic evidence, gynecological exams, and service referrals, ensuring that all fundamental aspects of every case are recorded. Additionally, 108 highly recommended data points provide more detailed insights depending on the medico-legal context, including documentation of ano-genital injuries, bodily injuries, and ejaculation. Reliable informatic data extraction is now feasible for clinical purposes and annual reports. Moreover, eSAR data is being used to populate the electronic case report form for a prospective study on sexual assault conducted at HUG, which began in November 2022.

Since its implementation, the eSAR has significantly improved the completeness of essential data documentation compared to the previous paper-based SAR, where missing information posed major challenges. In the earlier system, 64% (n=467) of records lacked information on prior sexual assault history, 75% omitted details about decisions to press charges, and 34% to 50% were missing data on prescribed treatments. With the eSAR, these gaps have been substantially reduced: missing data now account for only 8.5% (n=13, see Table 5 below) regarding prior assault history, 0% (n=0) for whether charges were filed, 32% (n=52) for whether future charges will be filed, and just 3.7% (n=6) for postexposure prophylaxis (PEP).

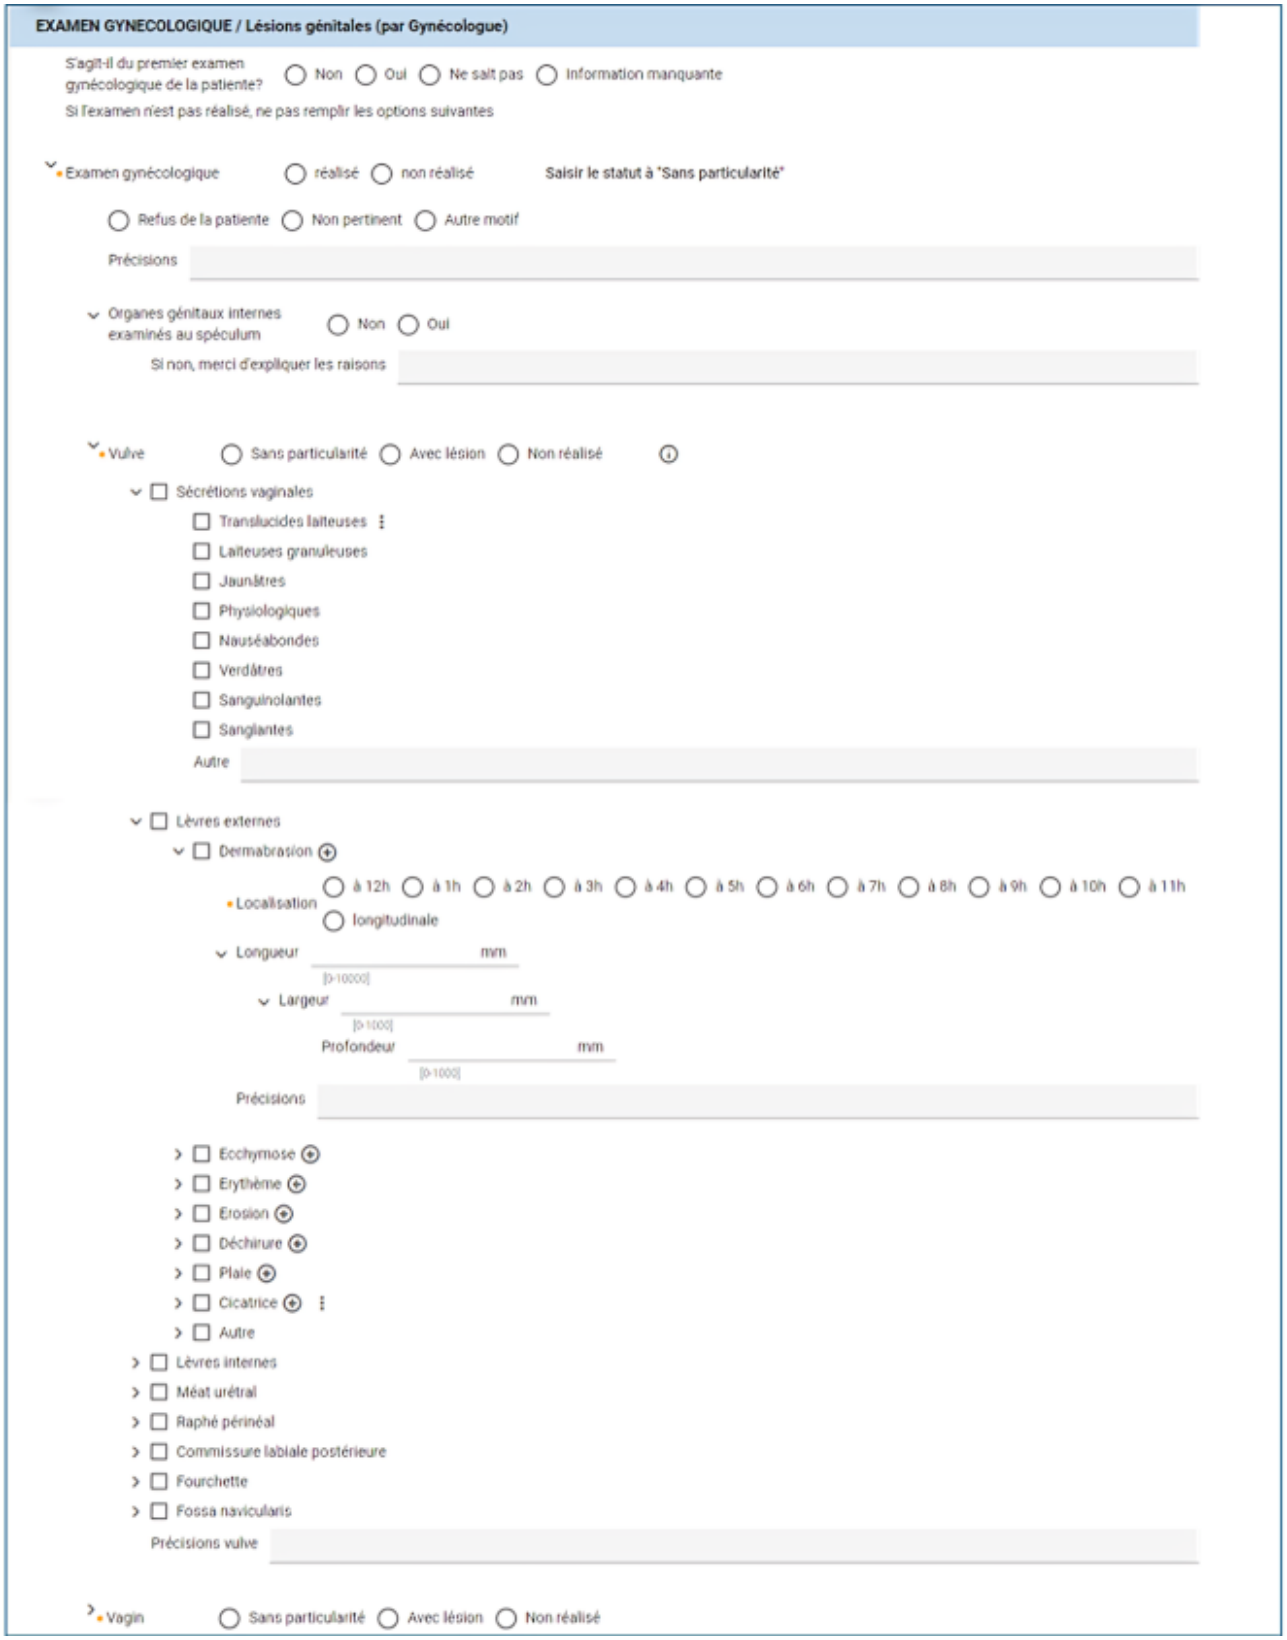
Table . Improvements in missing data.

Variables	No, n (%)	Yes, n (%)	Unknown/Missing, n (%)	Not applicable, n
Retrospective study (Before eSAR), n=727	121 (17)	139 (19)	467 (64)	13
2024 (After eSAR implementation), n=162	50 (32.7)	90 (58.8)	13 (8.5)	9

The eSAR also facilitates the medical follow-up of the patient. Patient appointments can be made at the time of the medico-legal consultation with the click of a button. Previously, a fax system was used to send patient appointment information between the ObGyn (Obstetrics and Gynecology) emergency unit and the infectious diseases unit. The eSAR also helps with multidisciplinary medical follow-by infectious disease specialists, as well as the staff of the UIMPV and gynecology outpatient clinic, allowing the doctors and psychologists to read the patient’s sexual assault file and better prepare, without the patient having to repeat details from their assault.

Efficiency

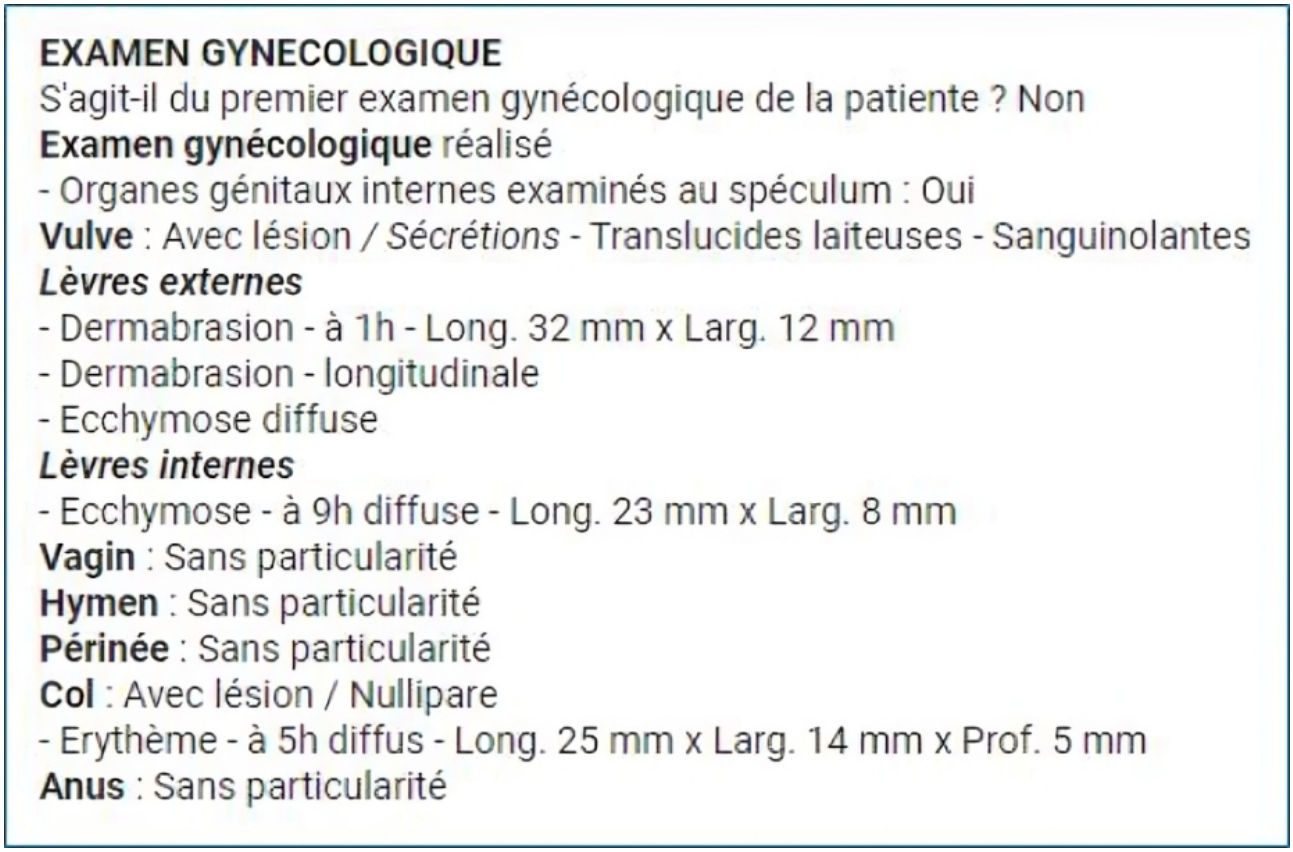
A crucial outcome for patients is the time needed to finalize the medico-legal report with all the necessary information. The development and the implementation of the eSAR facilitates and streamlines the entire workflow. The administrative burden has been considerably lightened since paper documents are not physically transported anymore through medical departments. The electronic traceability also allows to monitor the administrative process of filling, finalizing and signing the eSAR. The training of new doctors confirmed the implementation of the eSAR facilitates the continuity of the medical care and clinical practice with less experienced doctors.



A list of eSARs in draft mode (unsigned) as well as some basic patient information can be accessed by authorized personnel (Textbox 1). Doctors receive a notification on their task list when an update or modification is required. This list will help to manage the workflow and help doctors meet their deadlines, (eSARs should be finalized within 30 d). Beyond this deadline, the color of the task in their workflow changes from blue to red and they start to receive reminder notifications. The user interface also allows doctors to click on dedicated buttons to validate sections or complete the report, and simultaneously, a PDF version is automatically generated, ensuring a seamless and efficient way to produce a finalized output (Figures 1 and 2).

Textbox 1. List of eSARs (electronic sexual assault records) in Draft Mode (unsigned)

- Finalization of the file (signatures)
- Date of signatures
- Creation of eSAR (date and hour)
- Number of this medical event
- Identification number assigned to the patient
- Name, First name, date of birth (necessary information to identify the file)
- Date of the consultation
- Date de the sexual assault
- Names of the gynecologist and the forensic physician



XSL•FO
RenderX

Figure 2. PDF output of eSAR (electronic sexual assault records).

Interoperability

This electronic sexual assault report form is reproducible in other Swiss cantons or other countries. The eSAR is available in French and translations of all variables are available in English and German. The eSAR is integrated into the EMR platform known as DPI, which has been in use at HUG since 2000. A license is required for the use of DPI, which was acquired by the Valais Hospital in 2023. The informatic languages used are HTML-5 and LOINC. For the use with any other information system other than DPI, the eSAR framework can be exported in CSV file, by contacting the corresponding author of this paper. The eSAR is currently being adapted for patients with penises, both children and adults, in collaboration with the pediatric and adult ED.

Participating Entities and Budget Planning

The eSAR is a part of a multicentric research project, funded by a grant of 684,029.80 CHF (US $ 752,433) from the Swiss Federal Office for Gender Equality (FOGE) in Switzerland and HUG. The project includes a retrospective study, built on a cohort studied between 2018 - 2021 in Geneva and Lausanne. It also includes a prospective study, elaborated to analyze the data collected from eSAR since implementation and a long-term follow-up questionnaire. The FOGE played no role in the design and conduct of the study. FOGE did not fund the development of the eSAR but only the working time of the epidemiologist. The remaining costs were covered by HUG (70,510 CHF; equivalent to US $ 77,561), including creation of the forms (23,000 CHF; 25,300), informatic development (38,400 CHF, equivalent to US $ 42,240), tablets for schemas and signature from patients and physicians (3,360 CHF, equivalent to US $ 3696), methodical support for data analysis (5,750 CHF, equivalent to US $ 6325). Other costs for the human resources were covered by their routine salaries. The ongoing study results will be published in peer-reviewed journals. There are no conflicts of interests to declare.

Sustainability

Twice a year, training for the care and treatment of patients of sexual assault and the eSAR is organized by the ObGyn ED. It includes theoretical presentations, use of the eSAR and a simulation of triage, history taking, and treatment of a fictitious patient where gender inclusivity and interpersonal skills must be put to practice. These trainings target forensic doctors, nurses, midwives, and gynecologists, some of whom rotate every 6 months. In total, there are 7 forensic doctors and 11 gynecologists (9 residents and 2 chief residents), 10 midwives and 19 nurses.

Discussion

Strengths

The eSAR is the first electronic sexual assault record implemented in Switzerland, representing a major advance in standardized documentation and data collection for sexual assault cases. Developed through a multidisciplinary collaboration and continuously refined for both clinical and research purposes, the eSAR provides a robust, real-time dataset through its integration into the EMR. This integration not only enhances patient care and facilitates research, quality improvement, and monitoring of service utilization, but also

XSL•FO
RenderX

supports the development of institutional protocols and serves as a foundation for evidence-based policymaking and national best-practice guidelines in sexual assault care.

Interest in this standardized form from various health departments and hospitals continues to enrich ongoing discussions and contributes to the advancement of best practices. Furthermore, the eSAR enables the creation of a regional sexual assault patient cohort, allows tracking of patient loss to follow-up, and provides opportunities to develop performance indicators and improve clinical governance through real-time surveillance and benchmarking. Despite representing only 1.16% of total gynecology emergency consultations, sexual assault cases involve a significant administrative workload, as records must be reviewed and validated by supervisors. By analyzing each step in the care process, eSAR data can help identify opportunities to improve workflow efficiency. Furthermore, the continuous revisions and improvements led by HUG experts strengthen its role as a comprehensive medicolegal tool for both clinical application and research.

Lessons Learned

Forensic doctors were initially hesitant about the digitalization of the SAR, as they were accustomed to writing paper reports in a free-form manner, which they viewed as an integral part of their medical practice. Concerns were also raised about the time required to complete the eSAR, which was initially estimated to take about an hour. However, once implemented, the eSAR was eventually positively received, as its design effectively aligned with medical practice needs, demonstrating its adaptability and usefulness. As the Chief Forensic doctor was involved in its development, resident and intern forensic doctors, despite any initial reluctance, were required to use the eSAR for all sexual assault reports. Over time, they began to appreciate its advantages, particularly the time saved and the standardization of key variables, which improved both the consistency and quality of documentation.

Unintended Consequences

The implementation of the eSAR has further strengthened collaboration between departments bringing together professionals from different fields to exchange expertise, align practices, and enhance coordination across specialties. This interdisciplinary dialogue has helped further optimize the HUG's overall response to sexual assault cases.

Similar Intervention

Australia [17] and Finland [18] have demonstrated that a national, standardized and centralized approach to sexual assault support centers, increases access to quality and holistic care, as well as collaboration among different institutional actors. The number of police-reported offenses has increased, as have the criminal procedures in addition to patient satisfaction. Systematically collected data and official statistics support the development of targeted government strategies, something we strive to achieve.

Limitations

A key limitation of the eSAR is that it exclusively includes patients who present to public hospitals and consent to a joint medico-legal examination, as defined by the HUG protocol. This excludes individuals who do not report the assault, who decline medico-legal procedures, or who seek care outside of the hospital system. As a result, the cohort is not representative of all survivors of sexual assault. Future efforts must address how to identify and include these underrepresented populations to ensure a more comprehensive understanding of postassault care needs.

At present, the eSAR is not yet available for patients with penises (ie, children and adults), but its use will become mandatory in the pediatric and adult emergency departments once the adapted version is implemented, as is already the case in gynecology and obstetrics.

Conclusion

The implementation of eSAR at HUG marks a significant advancement in improving data collection, care processes, and the development of patient-centered services. Establishing a regional or national standard and ultimately, a sexual violence observatory, as recommended by the Istanbul Convention is an achievable goal, requiring collaboration between cantons and coordination at the national level. The eSAR is a replicable model for both adult and minor individuals of all genders. It is a powerful tool in advancing the objectives outlined by GREVIO, particularly the implementation of standardized care pathways and the development of national standards for forensic data collection.

Data Availability

For the use with any other information system other than DPI, the eSAR framework can be exported in CSV file, by contacting the corresponding author of this paper.

Abstract

Background: The adoption of digital systems requires processes for quality assurance and uptake of standards to achieve universal health coverage. The World Health Organization developed the Digital Adaptation Kits (DAKs) within the SMART (Standards-based, Machine-readable, Adaptive, Requirements-based, and Testable) guidelines framework to support the uptake of standards and recommendations through digital systems. DAKs are a software-neutral mechanism for translating narrative guidelines to support the design of digital systems. However, a systematic process is needed to implement and ensure the impact of DAKs in country contexts.

Objective: This paper details the structured process and stepwise approach to customize the DAKs to the national program and digital context in 5 countries in Africa with diverse program guideline uptake and significant digital health investments: Ethiopia, Ghana, Malawi, Zambia, and Zimbabwe. All these countries have existing digital systems, which have the potential to be updated with the DAKs.

Methods: A DAK assessment tool was developed and used to assess guideline digitization readiness and opportunities for system uptake in each country. Multistakeholder teams were established to conduct the content review and alignment of the generic DAK to national guidelines and protocols through a series of stakeholder consultations, including stakeholder orientation, content review and alignment, content validation, and software update meetings.

Implementation (Results): Country adaptation processes identified requirements for national-level contextualization and highlighted opportunities for refinement of DAKs. Quality assurance of the content during the content review and validation

XSL•FO
RenderX

processes ensured alignment with national protocols. Adaptation processes also facilitated the adoption of the DAKs approach into national guidelines and strategic documents for sexual and reproductive health.

Conclusions: Country experiences offered early insights into the opportunities and benefits of a structured approach to digitalizing primary health care services. They also highlighted how this process can be continuously refined and sustained to enhance country-level impact.

Introduction

Background

Globally, many countries are transitioning from paper-based to digital health systems to achieve universal health coverage [1]. However, this process has not been without challenges. Digital ecosystems, in low- and middle-income countries, continue to be flooded with a multiplicity of digital tools [2]. It is also often difficult to ascertain the design process of these tools [3] and whether the underlying content is developed in accordance with the evolving clinical evidence base, protocols, and guidelines. This is largely due to the existing process of translating narrative guidelines into digital systems, which is often laborious, prone to error, and lacks accompanying technical documentation appropriate for digital use [4]. This results in disjointed digital health ecosystems with inadequate standards that hinder the quality of care, exchange of data, and reporting and hamper continuity of care [5]. To deliver sustainable digital health solutions for country impact, digital system development needs to be based on principles of transparency, accessibility, scalability, and interoperability [6]; be adherent to clinical guidelines [7] and data use and sharing standards; and be guided by national digital strategies.

To ensure an accurate reflection of guidance within digital systems, the World Health Organization (WHO) developed the SMART (Standards-based, Machine-readable, Adaptive, Requirements-based, and Testable) guideline approach, which includes Digital Adaptation Kits (DAKs) [6]. DAKs translate narrative guidelines into a format that informs the design of digital systems. They have been developed for health service areas such as antenatal care (ANC) [8], HIV [9], and family planning (FP) [10], with more health domains in the pipeline. DAKs are packaged as an operational guidance document (PDF) with four web annexes (Excel files): (1) core data elements/data dictionary, (2) decision support tables, (3) program indicator definitions, and (4) functional and nonfunctional requirements. They are structured into components, such as personas, workflows, data dictionaries, and decision-support logic [5], that are intended to be customized and adapted across diverse country digital and program landscapes and contexts. These include settings that already have established digital systems, as well as those that are preparing to transition from paper to digital systems.

Considering that SMART guidelines and DAKs are new concepts, it is important to establish defined processes to introduce, adapt, and integrate DAK content within countries' existing digital ecosystems and programmatic landscapes. Drawing on experiences from 5 African countries (Ethiopia, Ghana, Malawi, Zambia, and Zimbabwe), we aim to develop and refine a replicable process for the country adaptation and implementation of DAKs. This will contribute to the creation of a framework that can be adapted by other countries, ensuring a consistent approach to digitalizing primary health care services. This article details the processes and lessons learned in developing a framework for the systematic implementation of DAKs within different country contexts.

Objectives

The paper highlights the processes and lessons learned toward the development of a framework for the systematic implementation of DAKs within a country. The structured approach used to contextualize DAKs to national settings was conducted across 5 diverse programs and digital landscapes: Ethiopia, Ghana, Malawi, Zambia, and Zimbabwe.

Methods

Implementation Setting and Criteria

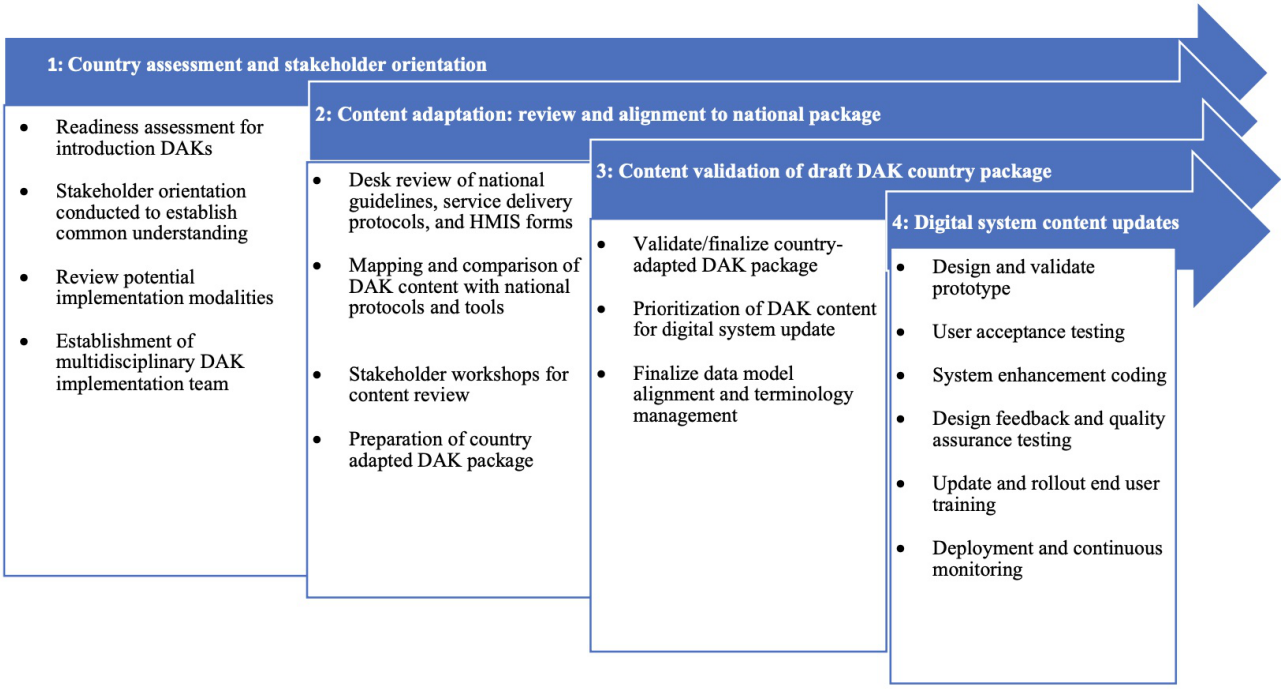
The selected countries were part of a broader United Nations interagency initiative [11] to strengthen sexual and reproductive health and rights (SRHR) (Malawi, Zambia, and Zimbabwe), while Ethiopia and Ghana were positioned for implementation research leveraging this established process. Selected countries had prior significant digital investments, and the DAK country adaptation was conducted with the aim to enhance the following national digital systems: Bahmni (Ethiopia), eTracker (Ghana), Malawi Health Information System (Malawi), SmartCare (Zambia), and Impilo (Zimbabwe) in the respective countries.

Implementation Approach

Overview

This implementation report was guided by and adheres to the Implementation Science Research Reporting Guidelines for Digital Health Interventions (iCHECK-DH) checklist, which provides a structured approach for documenting digital health implementations [12].

A stepwise approach was developed to introduce the DAKs. Multistakeholder DAK adaptation teams consisting of program



XSL•FO
RenderX

and digital health Ministry of Health (MOH) focal points, implementing partners, and health care providers were assembled and engaged throughout the adaptation processes. The ANC and FP DAKs were used as the initial set of content areas to inform a standard methodology and process for DAK country customization and integration into respective country digital health systems. This method builds on processes for customizing the WHO ANC digital module [13] using the ANC DAK in Zambia and Rwanda [14] and a broader methodology for applying the DAKs to the existing digital systems in a country. Challenges included inadequate narrative guideline uptake [15]; lack of requirements documentation; delays in guideline uptake and adoption; and the evolving digital landscape, including transitions between systems and inadequate clarity regarding which system to enhance.

Localization and Adaptation Processes

The approach included the following steps: (1) country assessment and stakeholder orientation; (2) content adaptation: review and alignment to national package; (3) content validation of the draft DAK country package; and (4) digital system and content updates and monitoring (Figure 1). Subsequent steps, such as the design of the system prototype (Step 4), will be expanded on through standard software development processes, including quality assurance assessments and user acceptance tests to facilitate further iterations and enhance the readiness for deployment. Related deployment activities, including system monitoring, training, and continuous support and feedback, are acknowledged as part of the overall process inherent for all digital implementations and not detailed in the framework. To guide and document this process for future replication, we developed operational tools (Table 1).

Figure 1. DAK adaptation process steps and phases. DAK: Digital Adaptation Kit; HMIS: health management information system.

Table . Tools used in Digital Adaptation Kit (DAK) country adaptation.

Step number	Tool	Purpose and description	DAK adaptation steps	Point of use/when used	DAK component reviewed
1	Guideline extraction	Provides a high-level comparison between country and WHO[a] narrative guidelines.	Country assessment and stakeholder orientation	• Prestakeholder orientation workshop • Precontent review and alignment workshop	• Health interventions and recommendations
2	Country assessment	The assessment tool evaluates a country's digital health landscape, governance, and workforce capacity [13]. It examines existing digital systems, guidelines, leadership structures, strategic priorities, and services. It seeks to identify relevant governance frameworks, and investment plans to guide the selection and sustainability of the digital system to be used for DAK content updates.	Country assessment and stakeholder orientation	• Pre/during stakeholder orientation workshop	• Health interventions and recommendations Personas
3	Premapping tool	This is adapted from the generic DAK data dictionary for specific health domain areas and includes questions to determine whether the DAK data element already exists in the country's protocols/guidelines/registers; whether it should be added to the country-adapted DAK, and if any modifications are required. It also considers data elements that exist in the country protocols but not in the DAKs, with a provision to include a description of the new data element and indicates any removals, notes, or justifications.	Content adaptation: review and alignment with national protocols/guidelines	• Content review and alignment with national protocols/guidelines workshop	• Health interventions and recommendations • Personas • Business processes and workflows • Core data elements • Decision support logic • Indicators and performance metrics
4	Monitoring, evaluation, and reporting alignment	The tool is used to systematically review and align DAK elements added to the country-adapted DAK to existing reporting tools (eg, paper registers).	Content adaptation: review and alignment with national protocols/guidelines	• Content review and national protocols/guidelines workshop	• Core data elements • Decision support logic • Indicators and performance metrics

XSL•FO
RenderX

Step number	Tool	Purpose and description	DAK adaptation steps	Point of use/when used	DAK component reviewed
5	Country adaptation log	The log provides a comprehensive overview of changes (additions, removals, and modifications) made to the data dictionary and decision support logic for the adaptation of the DAK in an existing system.	Content validation of the draft country package	• Post content review and alignment workshop	• Core data elements • Decision support logic • Indicators and performance metrics

[a]WHO: World Health Organization.

Country Assessment and Stakeholder Orientation

As an initial step to the introduction of DAKs, we developed a country assessment tool to assess the digital and health program context to determine country adaptation requirements. Considerations in this tool were derived from the WHO/International Telecommunications Union eHealth Strategy building blocks, which include leadership and governance, services, and applications; strategy and investment; service and applications, standards, and interoperability; and workforce [16]. In addition, to ascertain the status of the guideline dissemination and existing content within existing systems, we included a pillar on public health content and the health domain. Selected countries were introduced to the concept and initiative at a web-based orientation. The country assessment tool was used to initiate discussions with MOH stakeholders and decisions around the health programs and digital system for prioritization. This was followed by an in-person orientation workshop to review the results from the assessment tool, establish a common understanding among the country's SRH and digital stakeholders, and consolidate plans for implementation. A high-level overview of the DAK components, including the user personas, workflows, and data dictionaries was provided to illustrate what a DAK entails and preview potential modifications that may be needed. Further, multistakeholder DAK implementation teams were established in each country to lead the content review and alignment of the generic WHO DAK to national guidelines and protocols [14], including a subgroup to initiate the desk reviews and guideline comparisons for informing the areas for country adaptation.

Content Adaptation: Review and Alignment to National Package

To guide the content review process, a guideline extraction tool was developed to facilitate a high-level comparison between national guidelines or protocols and WHO guidelines. This tool aimed to identify deviations and adaptation requirements and facilitated an understanding of customizing user personas and workflows. A premapping tool was developed using editable versions of the DAK data dictionaries and decision support logic in Excel spreadsheets, which included additional columns for detailed documentation of the adaptations. A subset of the implementation team systematically reviewed the data elements and decision support tables and documented the alignment between the DAK content in relation to what may be available in national documentation. Adaptations were categorized into 3 types: modifications (taken from the generic WHO DAK but with wording changes), adoptions (taken as is from the DAK), and removals (not incorporated in the country DAK). A country adaptation log was also completed alongside the changes being documented in the spreadsheets in order to summarize and track the updates. Additionally, content that existed in a country's protocol or documentation but not in the generic WHO DAK was also highlighted. The outputs of the premapping were subsequently reviewed in stakeholder consultations for feedback and resulted in a draft adapted country package to undergo further validation.

Validation of DAK Country Package

The validation of the draft DAK country package was conducted as the final step before integration. Stakeholder meetings were convened to review the adapted content, verifying that it was accurately localized and aligned with national clinical and digital health guidelines and standards. This process involved reviewing the adaptation logs to establish a common understanding of the DAK components that were localized based on the criteria outlined in the content adaptation section above (ie, modifications, adoptions, additions, and removals). Additionally, content was prioritized for integration based on the digital platform's capacity and available resources, as well as the alignment needed for the data models of the intended digital systems. The draft packages were then cleaned, approved, and certified by national authorities as "ready" for system integration.

Digital System Content Update

The preparation for the digital system content update was initiated once the DAK software package had been validated by system developers and digital experts. It began with a thorough review of the identified existing system digital system's architecture and design; particularly the code structure, functionalities, and its capacity to support DAK content and functionalities as part of a software planning meeting. Furthermore, an extensive evaluation of the existing systems' components, underlying technology, and business processes was carried out in order to ascertain how each DAK may improve current workflows and interface with the respective electronic health records components. The next step was to create an integration plan that included the technical specifications, schedules, and required resources (including digital vendors) for the DAK system enhancements.

XSL•FO
RenderX

Ethical Considerations

For Malawi, Zambia, and Zimbabwe, this was part of WHO technical support, and there was no engagement with human subjects; therefore, ethics review was not required. Ghana and Ethiopia were part of an implementation research study that was approved by the WHO/Human Reproduction Program Research Project Review Panel, the WHO Ethical Review Committee (A66031), and the National Ethics Committee of the 2 countries (University of Gondar, Ethiopia Institutional Review Board [VP/RTT/05/752/2024] and Ghana Health Service Ethics Review Committee [GHS-ERC: 025/07/22]).

Implementation (Results)

Stakeholder Orientation and Country Assessment

When first presenting the concept of SMART guidelines and DAKs, they were initially perceived as abstract materials, and stakeholders in the countries often requested an understanding of what the "end product" would look like. Stakeholders often expected a tangible digital tool and required extensive communication on how SMART guidelines-DAKs work to inform their existing digital systems as software-neutral resources. Furthermore, a reference software app reflecting DAK content was often demonstrated during the orientation to provide clarity on how the DAKs would eventually appear in a digital interface. Demonstrating this linkage between the data elements and decision support logic in the DAK (in spreadsheet form) and how they would appear on a digital platform/system can also help distinguish the DAKs from the software app (Table 2).

Table . Summary of challenges, recommendations/best practices, and lessons learned.

Challenges	Recommendations/best practice	Lessons learned
• Inadequate uptake and adoption of guidelines at the point of care or a lack of updated guidelines during the introduction of DAKs[a].	• Assess the guideline status within the country, including conducting site visits to ascertain gaps and areas in which DAKs can strengthen prior to adaptation.	• As a guideline derivative product, DAKs can be used to accelerate guideline update processes by highlighting differences in global and national protocols.
• Limited existing system documentation. • Limited knowledge of existing systems by clinicians.	• DAKs will serve as a starting point for requirements gathering. • Showcase the system during content adaptation sessions.	• Engaging system users in content adaptation processes is critical for both system adoption and quality assurance of the content.
• Continuous evolution of digital ecosystems and varying maturity stages.	• Align with existing national digital system strategies.	• Integration of the DAKs within broader digital and health strategic documents is key for system adoption and sustainability.
• The initial content adaptation process might require more time due to the volume of DAK elements.	• Conduct preparatory steps, such as guideline extraction and premapping to assess/select initial areas for adaptation, prior to stakeholder validation.	• The content adaptation process is not linear, and multiple iterations and layers might be required for alignment with other components of the digital ecosystem, including the health management information systems for reporting.

[a]DAK: Digital Adaptation Kit.

In addition, this orientation and socialization of the DAKs identified additional scenarios to support countries' digital health journeys, such as informing assessments of existing digital systems and enabling a common reference standard, particularly in settings where there may be several electronic medical records systems, like Malawi. The DAKs were found to be clearly structured, with some MOHs proposing to adopt the DAK approach to document business processes. For example, in Zambia, this approach has been adopted and is currently being leveraged for other health domains. Additionally, engaging the system users in the adaptation processes will be essential to ensuring the adoption of the system (Table 2).

Validation of the DAK Country Package

The overall content adaptation and validation process provided an opportunity for countries to collectively review their business requirements processes for standardizing content within their digital system. This was a new process for stakeholders, especially as some health program managers were not familiar with digital system design or requirements gathering. The review and validation process, which included respective DAK domain service providers, provided an opportunity for both digital and health literacy capacity building. Clinicians not only saw themselves providing service to clients through the review processes but also actively participated in the process of developing a digital module that they themselves would be using.

Digital System Content Updates

In preparing for the digital system content update, DAKs were found to be clearly structured, with some MOHs proposing to adopt the DAK approach to document business processes for other health domains and include it as part of their broader strategy to digitalizing SRH services at the primary health care level. Examples include Malawi and Zambia [17] where the ANC and FP DAKs have been integrated into the respective

XSL•FO
RenderX

health domain guidelines and strategies. Decision support functionalities were found to be a valuable addition due to their potential to guide or remind clinicians of key clinical recommendations during the provision of care. This is especially important since most digital systems they were accustomed to focused heavily on data collection rather than person-centered care.

Discussion

Principal Findings

These initial experiences of introducing and implementing DAKs across 5 countries provide a foundation for developing a replicable, software-neutral integration process. Additionally, the findings will be important for informing not only the development of global DAKs but also how WHO and implementing agencies can support countries with their integration. The country assessment was critical across all sites for initiating conversations around digital systems, as well as for bringing stakeholders such as program managers on board. Additionally, the set-up of multistakeholder teams including the program, digital health leads, clinical informatics specialists, and clinicians was critical for driving the adaptation process forward. The structured format of DAKs facilitated a transparent process for content review and validation. Moreover, the collaboration across sectors, with the program and health domain experts leading ensured that the process was centered around the user—a critical component for system adoption [18,19].

The DAKs were initially viewed as "abstract" by stakeholders, and as software rather than health content due to limited engagement in the design of digital systems. The stakeholder consultations also provided opportunities for users to review existing systems and also appreciate existing gaps and propose how these could be enhanced with DAK content. The adaptation process revealed several layers of adaptation, and that multiple iterations would be required, including considerations around linkages with other components such as health management information systems. Some challenges included the large volume of DAK elements, which was initially overwhelming and time-consuming at the beginning of the review and content adaptation process. However, we learned that conducting preparatory steps, including guideline extraction and premapping, can help to optimize time and resources by first highlighting expected adaptations for stakeholder review (Table 2). Last, it is important to consider the different stages of digital maturity of a system; and the current strategic direction and priorities of the government during the introduction of DAKs at the country level (Table 2).

Aligning With Health System Strategic Policies and Guidelines

To integrate the DAKs within a country's national health system, it is vital to align them with the broader national health strategic priorities and frameworks [20]. The examples highlighted above from Zambia and Malawi represent a great starting point for harmonization and integration into broader health strategic documents and plans. This ensures that DAKs are embedded as critical elements of the national strategy rather than being viewed as isolated initiatives—which can negatively affect their adoption at different levels of the health system (Table 2). It is, therefore, imperative that government stakeholders, particularly MOH program managers and health domain and digital health experts, actively advocate for and ensure the inclusion of these guidelines into national policies, during annual and midterm policy and health strategic reviews and planning. This will require strong leadership and coordination across relevant sectors.

Leveraging DAKs to Accelerate Narrative Guideline Updates and Other Paper Tools

As a guideline derivative product, DAKs can be used to accelerate guideline update processes by highlighting differences in global and national protocols (including reporting tools), particularly in settings where the narrative guidelines are not up-to-date (Table 2). The adaptation process can be useful for informing the updates for narrative guidelines and aligning to the latest WHO guidelines. However, the DAK itself cannot be a substitute for undergoing the formal process of updating national health program guidelines [12]. However, it will be important to also consider the current status of guideline uptake at the facility level. Conducting a site visit to a health facility, as part of the content review process, will not only enhance the DAK adaptation process by highlighting areas within the guideline content that require reinforcement but can also improve the uptake of the guidelines (Table 2).

Determining the Approach for DAK Implementation

When introducing DAKs within a country's digital and program ecosystem, it is important to consider the modality for DAK implementation. This can be particularly challenging in settings where there have been prior digital investments that are disease-specific. Where the identified digital system might be used for certain health areas (eg, HIV), clinicians would already be used to these systems, leading to the underuse of other modules. Enhancing the "other" modules with the DAKs within such platforms would require adequate awareness and training to improve uptake and use. The localized DAK could act as the benchmark that all other digital systems adhere to if there are many digital systems with varying degrees of coverage and maturity. Moreover, showcasing the system during content adaptation sessions could be a helpful approach to increase understanding of the various digital modules within a point-of-care system. Additionally, implementation modalities should also consider engagement with private sector partners and subnational adaptations based on the program and digital landscape of the countries.

Strengths and Limitations

The strength of this paper is that it represents replicable processes that have been developed through firsthand learning from countries and offers a foundation that can undergo further refinement as new countries embark on the implementation of SMART guidelines, specifically DAKs. These learnings will be complemented through implementation research [21] and communities of practice, and culminate in the development of a living technical guidance to facilitate the effective uptake of DAKs. Some of the limitations and challenges, such as the

XSL•FO
RenderX

intensive resources initially required, were due to the novelty of the approach and having limited prior reference in the implementation of SMART guidelines. Additionally, another limitation is the absence of detailed cost estimates for the DAK adaptation and implementation processes, as a systematic evaluation of costs was not included. Given the focus on methodological processes and the variability in country contexts, providing a comprehensive budget was not feasible at this stage. Furthermore, it is important to note that countries' digital systems are dynamic and constantly changing. Despite DAKs being software agnostic, critical reflections are also needed on transitioning a package adapted for a legacy system to newer versions, while also introducing interoperability standards, such as Fast Healthcare Interoperability Resources (FHIR) [22].

Conclusions

Leveraging existing digital investments to reinforce evidence-based recommendations offers a sustainable pathway for institutionalizing WHO SMART guidelines-DAKs within health systems. However, to achieve this, a multifaceted approach will be necessary: strong digital health leadership and governance [23], along with coordination and strategic direction for digital investments, will be critical [21], particularly in countries where systems are still disease-specific [24]. Moreover, the collaboration between program leads, policy makers, and digital teams will also be vital, including engaging program managers and policy makers in system update training, continuous system monitoring and identification of "system champions" at the facility level. Further, plans for interoperability and data use standards will also need to be incorporated. These initial sets of country experiences offer insights into the requirements and opportunities to optimize the use of WHO SMART guidelines-DAKs as a tool for strengthening countries' digital investments in a structured manner. This approach sets the foundation for a systematic approach to implementing DAKs and will be further refined through research to evaluate the resulting impact on service delivery outcomes and data flows [9]. Overall, standardizing a common approach to DAK implementation will be important to facilitate peer-to-peer exchange among countries, foster regional and global cooperation required for standards-based digital transformation, and ultimately optimize the impact of digital health systems for universal health coverage.

Acknowledgments

The authors would like to thank the following from the World Health Organization (WHO) Africa Regional Office for their support in facilitating country stakeholder engagement and consultations: Dr Hillary Kipruto, Dr Ayotunede Adegboyega, and Dr Adeniyi Aderoba. The authors would also like to thank the following from the WHO country offices of Zambia, Malawi, Zimbabwe, Ethiopia, Kenya, and Ghana: Dr Azmach Gebregiorgis, Mr Peter Chalusa, Dr Solome Nampewo, Dr Stanely Midzi, and Ms Batani Moyo; Dr Kassu Gurma and Dr Haimanot Workineh; and Mr Eric Maira, Dr Martin Owusu, and Mr Dominic Atweam. The authors also thank the following individuals from the Ministries of Health of Zambia, Malawi, Zimbabwe, Ethiopia, and Ghana Health Service respectively: Ms Dynes Kaluba, Ms Ruth Bweupe, Ms Winne Bbwantu, Mr Muya Mwansa, Mr Shem Kabesa, Mr Oovst Chooye, and Mr Andrew Chanshika; Ms Christina Muchoma, Mr Kennedy Kanyimbo, and Mr Innocent Yowa; Dr Simukai Zizhou and Dr Robert Gongora; Mr Gemechis Melkamu, Mr Abinet Seife, Mr Gezahegn Feyssa, Dr Zerihun Bogale, Dr Abebe Ketema, Mrs Yirgalem Negash, and Mr Sheleme Humnessa; and Dr Kofi Issah, Dr Chris Fofie, Mr Geegee Kwame Adu, and Mr Oswald Kanyirbee Dachaga. The authors also thank Mrs Addiszemen Chanie from the Amhara Regional Health Office and Dr Dawit Kassahun and Dr Solomon Berhe from the University of Gondar, Ethiopia. The authors also acknowledge Dr Sam Dery, Dr Frances B da Costa Vroom, and Mr Seth Kwaku Afagbedzi from the University of Ghana. This work was funded through the UNDP-UNFPA-UNICEF-WHO-World Bank Special Programme of Research, Development and Research Training in Human Reproduction, a cosponsored program executed by the WHO. The named authors alone are responsible for the views expressed in this publication and do not necessarily represent the decisions or the policies of the WHO nor the UNDP-UNFPA-UNICEF-WHO-World Bank Special Programme of Research, Development and Research Training in Human Reproduction.

Authors' Contributions

RKM wrote the first draft in collaboration with TT. KB, SBM, and IC provided input on the initial adaptation experience from Zambia that informed adaptation processes for other countries. Additionally, CG, SD, EM, BT, AN, AM, HAT, and BFE from Ghana and Ethiopia also contributed to the methodologies. All authors reviewed and provided input into the manuscript based on their country's implementation and technical experience.

Conflicts of Interest

KB is a clinical informatics specialist who works for IHM Southern Africa—a technology/health informatics company that supports the implementation of the digital system in Zambia.

Abstract

Background: Chronic pain affects approximately 19% of the European population and presents major challenges, both in terms of individual impact and the economic burden on health care systems. While clinical expertise remains essential, patient empowerment through self-management tools has become a key component in the long-term management of chronic pain.

Objective: This report describes the development and implementation of Dolodoc, a mobile app designed to support patients with chronic pain in monitoring and managing their condition.

Methods: Developed by a research and development team at the University Hospitals of Geneva, Dolodoc enables users to track their pain across 7 dimensions of daily life. A digital coach provides personalized guidance, drawing from a corpus of over 80 evidence-based recommendations elaborated by clinical experts. The project was conducted over 4 years with the early involvement of stakeholders, including pain specialists and end users, to ensure alignment with user needs. Emphasis was placed on both the scientific validity and accessibility of the recommendations.

Results: The project was completed on time and within budget. The app was made freely available to patients identified as likely to benefit. However, a notable limitation is the absence of predefined key performance indicators to assess the impact of the intervention quantitatively.

Conclusions: This implementation report illustrates how mobile technology can be leveraged in a university hospital context to address the needs of patients with chronic pain and promote self-management. Early and sustained collaboration with stakeholders was instrumental in aligning the solution with both clinical evidence and user expectations.

(JMIR Med Inform 2025;13:e71597) doi:10.2196/71597

KEYWORDS

implementation; chronic pain; mHealth; self-management; health behavior change; user-centered design

Introduction

Context

Chronic pain is defined by the International Association for the Study of Pain as “an unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage, that persists over a period of at least three months” [1]. It is a ubiquitous issue affecting about 19% of the European population [2], associated with considerable burden and high health care costs globally [3,4]. Follow-up studies of patients with chronic pain report a persistence rate of approximately 50% - 71% after 1 year [5,6], with high interindividual variability depending on biopsychosocial factors, functional limitations, and comorbidities [7,8]. Over the years, chronic pain treatment has evolved into a multimodal arsenal, including lifestyle changes [9], physical therapy [10], psychotherapy [11], interventional treatments [12], and medications [13]. In addition to pain reduction, integrated follow-up in a multidisciplinary pain center can improve disability and quality of life [14].

Alongside expert health care support, patient-directed strategies have become crucial in addressing long-term pain conditions effectively [15]. With the widespread adoption of mobile devices, smartphone-delivered interventions for pain management have gained prominence in the field of chronic pain care [16].

Problem Statement

The availability of professional multidisciplinary follow-up is limited and costly. Moreover, the longitudinal evolution of pain

XSL•FO
RenderX

and quality of life indicators is not easily gathered by patients and health care professionals. Patient engagement in pain management strategies between appointments is also difficult. [17].

These issues could be addressed by a digital intervention that transmits targeted health information, including behavior change communication such as multimodal chronic pain self-management strategies. It should also allow users to track and share long-term data on pain levels and quality of life. To improve user engagement, this mobile app must be user-centered, intuitive, and inviting.

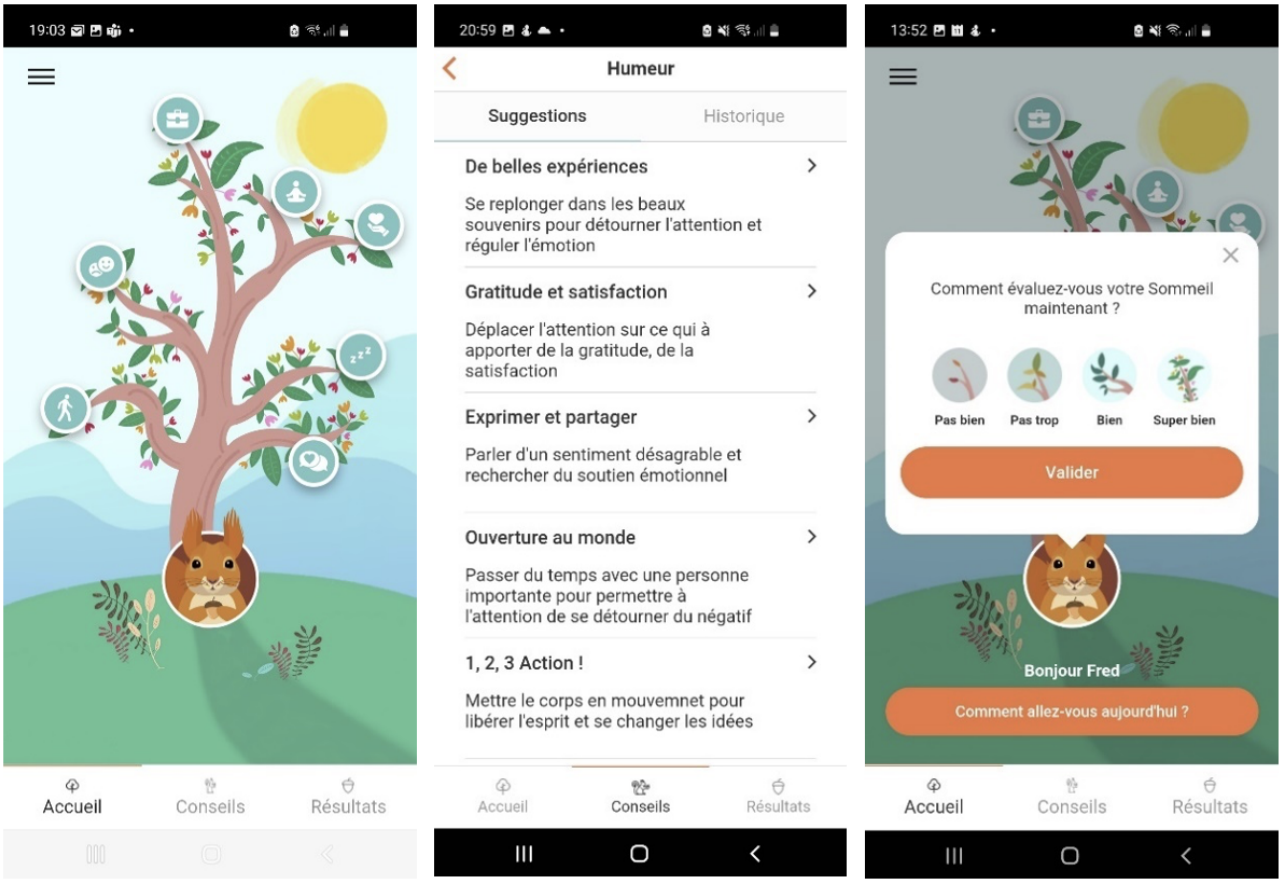
Similar Interventions

Dolodoc's development was inspired by existing mobile apps for chronic pain management [18], which typically focus on one or more of the following objectives: education, monitoring, and management [19]. Unlike these, Dolodoc integrates all 3 objectives into a cohesive, patient-centered system, adding significant value by fostering active patient engagement and collaboration with health care professionals [20]. Key differentiators include an emphasis on quality-of-life reporting and a digital coach that offers personalized activity recommendations and feedback. This helps users identify effective pain management strategies and supports adherence to these strategies through motivational interactions. Furthermore, Dolodoc is specifically tailored for French-speaking users, addressing a linguistic gap in the availability of such tools.

Following the iCHECK-DH (Checklist for the Reporting on Digital Health Implementations; Checklist 1) guidelines for reporting on digital health implementations [21], we describe "Dolodoc," a mobile app co-designed with patients with chronic pain and health care professionals to monitor pain and quality of life, and provide multimodal self-management strategies that can be experienced and assessed within the mobile app.

Methods

Aim and Objectives



Our goal was to develop a system that assists patients with chronic pain in actively managing their condition, providing continuous support, and empowering patients to engage in a personalized approach to improving their well-being.

Blueprint and Summary

Dolodoc is a mobile app, in French, that enables users to report their perceptions of pain and the impact of pain on various aspects of their quality of life [22]. The system includes advice as well as activities that patients can plan and assess to identify effective pain management strategies. Dolodoc engages patients through a digital coach that reacts to the planification of activities, based on the strategies included in the app. Additionally, the coach prompts users to regularly report their perceptions of pain and their daily functioning. Furthermore, the app provides an option to share progress with health care professionals, fostering a collaborative approach to managing chronic pain. A gamified metaphorical universe—represented by a tree that flourishes or withers based on the user's evaluations—aiming to enhance engagement and motivation (Figure 1). Overall, Dolodoc combines elements addressing the 3 objectives that are usually found in digital interventions for chronic pain [19]: education, monitoring, and management.

XSL•FO
RenderX

Figure 1. Screenshots of the Dolodoc app.

The development of Dolodoc included 3 primary phases: conception, content creation and validation, and technical implementation. The original concept was fostered in a research and development department combining medical clinical expertise and psychology skills. To ensure user-centered design and relevance, all phases of the app development were elaborated in a user-centered manner, including critical stakeholders such as patients and health care professionals involved in the Geneva Pain Network. A focus group of 10 patients with chronic pain was interviewed about the dimensions of their quality of life that they would relate to chronic pain. Seven dimensions emerged from open discussions in the group: daily activities, mood, work, relaxation, social support, sleep, and intimacy. Based on scientific evidence, a psychologist wrote a first version of multiple advice per dimension. Then, an experienced pain clinician and a member of the hospital communication team revised the advice. The current version of the app contains a database of 84 expert-recommended strategies related to patient-centered dimensions of quality of life. Patients with chronic pain also participated in the conception of the app by providing regular feedback on the prototyped screen as well as on the proposed graphical design of the app. Finally, the app has been reviewed by a user experience designer in order to identify usability problems.

The technical implementation included the development of a mobile app, incorporating gamification and privacy features. The graphic environment of the app was built according to the feedback of the focus group. Indeed, to facilitate engagement, Dolodoc uses a gamified metaphor: a digital tree that flourishes or withers according to the patient's self-assessment in the 7 dimensions of quality of life.

After a development phase, the app was released on Android and Apple app stores in March 2023. Minor bugs were addressed in several updates until the last release in June 2024.

For deployment, a communication campaign was conducted in January 2024, including printed flyers that were arranged at the pain center as well as billboards that were placed within the hospital and in neighboring high-traffic areas, and targeted social media advertisements, to raise awareness of the app among potential users. These efforts aimed to maximize outreach and ensure adoption among the chronic pain community.

Technical Design

The Dolodoc app was developed internally to align with the hospital's strategic goal of creating a cohesive ecosystem of apps tailored to patient needs. The internal development approach ensured seamless integration of hospital-curated advice and positioned the app for future connectivity with the clinical information system, enhancing follow-up for chronic disease patients.

From a technological perspective, coach interactions are currently driven by a predefined rule-based system, meaning that all the coach's interactions are statically coded. While its current state relies on predefined interactions, there is potential to incorporate large language models to improve personalization and adaptability in the future. The app is free to download and fully owned by the University Hospitals of Geneva (HUG),

XSL•FO
RenderX

aligning with their patient-first, noncommercial ethos. This ownership guarantees control over intellectual property and the ability to integrate evolving technologies and data security measures. The app's open architecture supports long-term alignment with the hospital's digital health investment roadmap, emphasizing interconnected and user-centric solutions.

Target

Dolodoc was developed to primarily target French-speaking patients enduring chronic pain. However, since the app is free and available for download by a large population, we foresee that the content of the app (eg, the advice) could also be used by other members of the health system around a chronic pain situation, such as health care professionals and caregivers.

Data

The app ensures data privacy and security in line with health care data management standards. Dolodoc uses a device-based data governance approach, where all personal data collected by the app is stored locally on the user's device. Data goes through a lifecycle that includes collection, processing, and storage on the device itself, without being transferred to external servers or cloud-based storage. As such, data ownership remains entirely with the patient, who has full access and control over their information. Data regarding the use of the app is collected anonymously through the Piwik web analytics tool installed on-premises on our infrastructure. Consent for data collection is obtained when the user accepts the disclaimer presented at the initial setup of the app, clearly outlining data handling practices and user responsibilities.

Patients have the option to share their personal data with clinicians in a secure, confidential manner by generating a PDF report directly from the app. Sharing the report is initiated solely at the user's discretion and responsibility. Given that the data remains on the user's device, data protection measures are focused on device security, recommending that users follow best practices in device security (eg, password protection and regular software updates).

Interoperability

The current version of the app is not connected to another system.

Participating Entities

The Dolodoc app was developed at the HUG, one of Switzerland's largest university hospitals. This project was carried out within the SIMED (Medical Information Science Department), a research and development service dedicated to research projects and specializing in human-machine interaction. The SIMED leveraged the multidisciplinary competencies of the team, such as ergonomics, psychology, clinical expertise, and technical ones to cover all aspects of the project. Cooperation with pain experts from the Geneva pain network, as well as patients, ensured adequacy of the tool with targeted user needs, as well as compliance with the latest medical evidence. Funding was provided by the Fondation Privée des HUG, a foundation focused on supporting projects enhancing the quality of care at the hospital through private donations. The funds covered expenses related to the app's conception, development, and design. The project involved pain management specialists and patient-partners to ensure the app's relevance and efficacy. This funding was sufficient to fully support the implementation phase. The final product and intellectual property will remain under the ownership of HUG after implementation.

Budget

The development of Dolodoc required an estimated budget of approximately CHF 250,000 (US $250,000). A substantial portion of the budget was allocated to content creation and validation. The budget covers the complete lifecycle of Dolodoc creation and deployment, ensuring a robust foundation for ongoing use and impact.

Sustainability

Dolodoc operates as an institutional project focused on enhancing patient support for chronic pain management, rather than generating financial profit. The primary goal of the app is to provide long-term value to patients by offering a self-management tool that empowers users and improves quality of life. Sustainability is ensured through institutional backing, where ongoing costs are centered on maintaining the app within the technical framework. This includes updates to ensure compatibility with evolving device operating systems, security enhancements, and periodic content revisions to maintain relevance and accuracy.

Ethical Considerations

This study did not require approval from an ethics review board, as it did not involve the collection or analysis of identifiable personal health data, nor any clinical experimentation. The development and implementation of Dolodoc were conducted as part of a quality improvement and service design initiative at the HUG, in accordance with Swiss federal guidelines under the Human Research Act (2014), Article 2(1), which exempts projects not involving health-related personal data from ethics approval requirements. During the co-design process, patients participated voluntarily in interviews and usability testing sessions focused on app functionality and content design. No health or sensitive data were recorded, and all feedback was anonymized at the point of collection. Users of the final version of the app consent to anonymous usage data collection through an internal instance of the Piwik analytics platform, as clearly outlined in the initial disclaimer presented upon first use of the app. No participants received any form of compensation. As such, the project complies with institutional and national standards for service-level digital health development outside the scope of research involving human participants.

Results

Coverage

The coverage of the implementation is international since it is available on several app stores. Indeed, use analysis showed that Dolodoc was used in 23 different countries. However, Dolodoc is designed in French, and French-speaking countries (Switzerland and France) account for >90% of the users. In

XSL•FO
RenderX

Switzerland, for example, 22.8% of the population speaks French as a main language [23].

Outcome

Since it is publicly available until November 2024, Dolodoc was downloaded 2284 times in total, including Android and Apple stores. The promotional strategy was efficient since it boosted downloads, reaching a maximum of 206/week during the first month of the campaign.

At the pain center, Dolodoc has been included in the multimodal therapeutic strategy that is discussed between patients and pain specialists. It is mentioned in our medical reports, and it is also used in psychotherapy sessions.

Clinical indicators about self-efficacy and quality of life were not systematically collected in our implementation process since the budget did not include a clinical impact study. Hence, a dedicated study should be planned to address the clinical added value of this implementation.

Qualitative feedback was obtained from open discussions with Dolodoc users in the context of a digital navigation [24] follow-up at the pain center. The role of a digital navigator is to help users navigate digital technologies efficiently by guiding, answering questions, exposing all the digital possibilities according to each patient, and fixing technical problems.

Participants reported that they appreciated the variety of recommendations and the way they were presented, which sometimes alleviated helplessness. While the number of strategies was at times overwhelming, users appreciated having alternatives. Considering whether the strategy is “achievable” helped to relieve the guilt of not doing everything without losing motivation. In fact, patients spontaneously reported that the strategies are delivered in a nonjudgmental and informative way, and the variety of strategies was also greatly appreciated, as emphasized in the following quote: “It makes you realize that there are many ways to take care of yourself”. Self-management strategies were considered the app’s main value, even as reminders. The strategies, which were given as a resource, are also applicable outside of painful crises and have general health benefits, which were appreciated. Some weaknesses in the navigability within the app were also reported by participants: the fact that users must actively browse and choose a suitable strategy within the app was perceived as an obstacle to action. The lack of a reminder feature was also noticed as a barrier to use. Indeed, users commented on the importance of motivational aspects in chronic pain self-management that were not entirely fulfilled by Dolodoc.

Lessons Learned

The involvement of patients and specialists, such as psychologists and pain experts, from the initial stages of conception proved to be a critical success factor in ensuring the app aligned with the needs of its target users. Engaging these stakeholders helped to identify meaningful pain management strategies and ensured that the app addressed real-world challenges faced by individuals with chronic pain. The adoption of a user-centered user interface/user experience design approach further strengthened the solution, incorporating steps like user requirement identification, prototyping, and iterative testing. This ensured that the app was intuitive and functional before technical implementation began. Additionally, trust in the app was bolstered by its development under the sponsorship of a nonprofit health care institution, reassuring users of its credibility and noncommercial intent.

However, generating personalized and relevant advice for patients posed a significant challenge. This required extensive evidence assessment, interviews with end users, and iterative reviews by experts and communication specialists to ensure the advice was both scientifically grounded and comprehensible to users. Budget constraints added another layer of difficulty, as the project was bound by a predefined budget set before finalizing the full specifications. Some features, initially thought to be straightforward, proved much more complex and resource-intensive to implement, underscoring the importance of thorough feasibility assessments during the planning phase. Moreover, the lack of budget for a clinical impact study prevents us from anchoring our implementation on specific evidence about Dolodoc, although global evidence supports the effectiveness of self-management apps for chronic pain [16].

Unintended Consequences

Although pain specialists at the pain center were informed about and convinced of the utility of adding Dolodoc to their therapeutic arsenal, it took time for them to integrate this novel tool into their regular clinical practice. The engagement of patients in using the app also turned out to be a limitation. Indeed, we noticed that even when the pain specialist provided information about Dolodoc during a medical visit, most patients did not use the app until the following visit. These 2 pitfalls are part of a well-described phenomenon regarding the implementation of digital health interventions [25]. It could perhaps be addressed by integrating digital navigators into our clinical practice.

Discussion

Dolodoc’s implementation demonstrates the transformative potential of mobile health apps in addressing chronic pain management challenges. By equipping patients with self-monitoring tools and personalized strategies, Dolodoc addresses key barriers like limited access to multidisciplinary care and low patient engagement between visits.

User-centered design and stakeholder engagement were critical to the app’s success. Ongoing collaboration with patients with chronic pain, clinicians, and psychologists ensured usability and relevance. Gamification and a strong privacy framework also boosted trust and engagement.

Users reported benefits such as reduced feelings of inadequacy and better access to new strategies. However, they also emphasized the difficulty of finding suitable strategies during episodes of intense pain, highlighting the need to improve accessibility and navigation during pain crises, consistent with previous findings [26]. The lack of predefined key performance indicators and budgetary provisions for a clinical impact study highlights a significant limitation, underscoring the need for future implementations to include robust evaluation frameworks.

XSL•FO
RenderX

These would validate the clinical efficacy of digital tools and provide insights for iterative improvements.

Looking ahead, Dolodoc presents opportunities to advance chronic pain management on multiple fronts. Integration with hospital information systems could enhance the app's utility in clinical settings, supporting coordinated care. Additionally, leveraging technologies such as large language models could enable more dynamic and personalized patient interactions. However, overcoming challenges in adoption—both among clinicians and patients—remains essential. Strategies like integrating digital health navigators and expanding awareness campaigns could boost utilization rates and long-term engagement.

Ultimately, Dolodoc exemplifies how mobile health tools can improve self-management and quality of life for patients with chronic pain. Broader use and integration of evaluation frameworks could lead to significant improvements in pain care and serve as a model for future digital health innovations.

Acknowledgments

We thank Pre Anne-Françoise Allaz, Pr Jules Desmeules, Dre Valérie Piguet, and Pre Christine Cedraschi for sharing their expertise on the topic, Myriam Perrier for the development, as well as the fondation privée des University Hospitals of Geneva for the funding of the project.

Authors' Contributions

FE and AMC supervised the project and contributed to the development of the app and to the writing of this publication (original draft, revising, and editing). JR contributed to the development of the app, collected user experience data, and contributed to the writing of this publication (revising and editing). JG collected user experience data and contributed to the writing of this publication (revising and editing). LG contributed to the writing of this publication (revising and editing) and supervised JG. CL supervised FE, JR, LG, JG, and AMC and contributed to the development of the app and to the writing of this publication (revising and editing). BR contributed to the development of the app and to the writing of this publication (revising and editing).

Abstract

Background: The Medical Informatics Initiative (MII) Germany established 38 data integration centers (DIC) in university hospitals to improve health care and biomedical research through the use of electronic health record (EHR) data. To showcase the value of these DIC, the HELP (Hospital-wide Electronic Medical Record Evaluated Computerized Decision Support System to Improve Outcomes of Patients with Staphylococcal Bloodstream Infection) study was initiated as a use case. This study is a clinical trial designed to assess the impact of a computerized decision support system for managing staphylococcal bacteremia.

Objective: In this paper, we present the lessons learned during the use case from a technical perspective. This paper outlines the challenges encountered and solutions developed during our initial implementation of this infrastructure, providing insights applicable to other research platforms using EHR data. These insights are organized into 3 key areas: study-specific data definition and modeling, interoperable data integration and transformation, and distributed data extraction and analysis.

Methods: An interdisciplinary team of clinicians, computer scientists, and statisticians created a catalog of items to identify data elements necessary for the study's evaluation and developed a domain-specific information model. DIC developed extract-transform-load pipelines to collect the disparate, site-specific EHR data and to transform it into a common data format. Health Level Seven International (HL7) Fast Healthcare Interoperability Resources (FHIR) and the MII's core dataset profiles were adopted for consistent data representation across sites. Additionally, data not present in EHRs was gathered using structured electronic case report forms. Analysis scripts were then distributed to the sites to preprocess the data locally, followed by a central analysis of the preprocessed data to generate the final overall results.

Implementation (Results): Our analysis revealed significant heterogeneity in data quality and implementation of interoperability standards, requiring substantial harmonization efforts. The development of analysis scripts and data extraction processes demanded multiple iterative cycles and close collaboration with local data experts. Despite these challenges, the successful implementation demonstrated the feasibility of distributed EHR analyses while highlighting the importance of thorough data quality assessment, realistic timeline planning, and multidisciplinary expertise.

Conclusions: The HELP study highlights challenges and opportunities in leveraging EHR data for clinical research, particularly in the absence of mandatory data standards and resource-intensive data harmonization efforts. Despite limitations in data availability and quality, progress in digitization and interoperability frameworks offers hope for future improvements. Lessons learned from this study can inform the development of standardized methodologies and infrastructures for sustainable EHR data integration in research.

Introduction

Context

The digitization of the health sector has significantly increased interest in using electronic health record (EHR) data for biomedical research, leading to the development of new infrastructures for data integration and sharing. In line with this trend, the Medical Informatics Initiative (MII) Germany established 38 data integration centers (DIC) in university hospitals to improve health care and biomedical research based on EHR data [1,2]. To demonstrate the usefulness of these DIC, several use cases were designed, encompassing various studies that leveraged the DIC infrastructure. One notable use case was the HELP (Hospital-wide Electronic Medical Record Evaluated Computerized Decision Support System to Improve Outcomes of Patients with Staphylococcal Bloodstream Infection) [3] study, which aimed to enhance the clinical management of *Staphylococcus* bacteremia. This condition requires prompt and guideline-compliant treatment. While involving an infectious disease specialist can improve patient outcomes, immediate access to these specialists is not always available. From June 2020 to October 2022, the HELP trial explored whether a computerized decision support system (CDSS) could safely enhance the standard of care for these patients. Conducted as a multicenter, noninferiority, interventional stepped-wedge cluster randomized controlled trial at 5 German university hospitals, the CDSS assisted physicians in managing bacteremia until an infectious disease specialist became available. It was deployed as a website with an interactive decision tree, accessible via smartphones, desktops, or laptops. An archived version of the CDSS is available online [4].

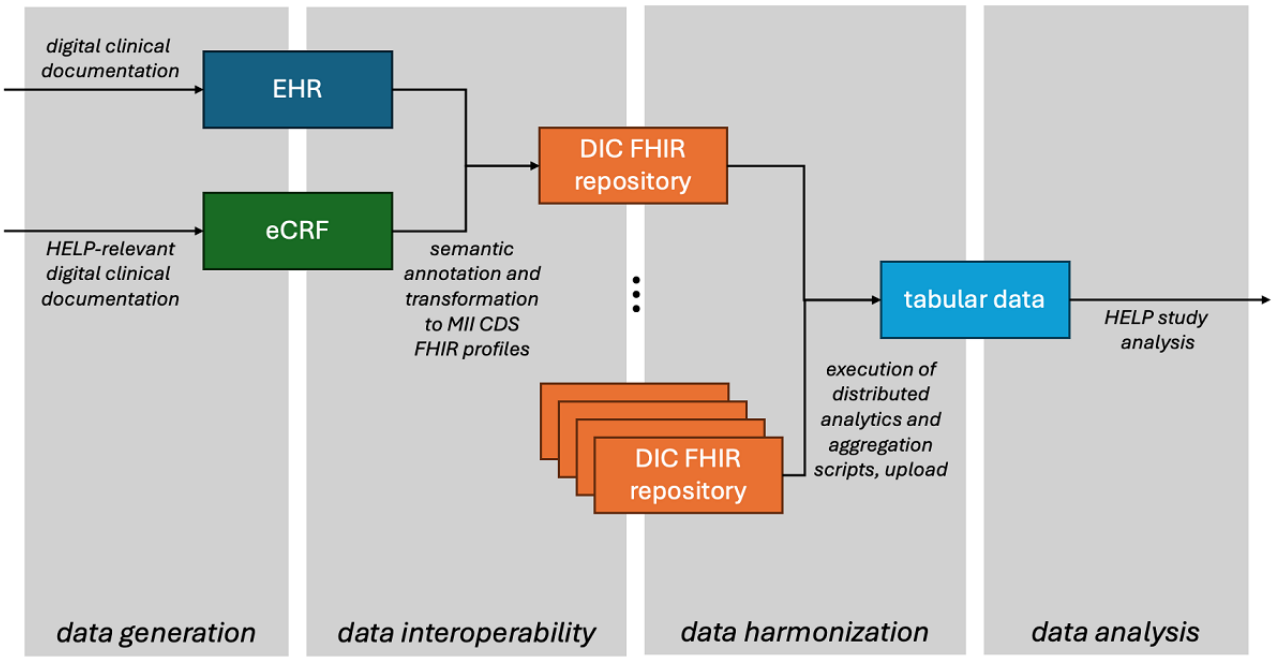
Problem Statement

Clinical evaluation of interventions such as the HELP CDSS through traditional randomized controlled trials is resource-intensive, particularly due to extensive data collection and management requirements. However, much of this necessary data already exists within EHR but remains largely inaccessible due to proprietary data formats and fragmented storage across multiple systems. The MII addresses this challenge by collecting, harmonizing, and transforming this data into interoperable standards, making it readily available for studies like HELP. By using EHR data for the evaluation of interventions in clinical trials, we can blend the characteristics of traditional randomized controlled trials with the practicality of being embedded within the clinical routine. While this setup imposes some restrictions on data availability and quality, it may more closely mirror real-world clinical scenarios, potentially contributing to an improved ecological validity of the trial [5]. Mc Cord et al [6] recently showed that randomized trials using routinely collected data show lower, but likely more realistic, effect estimates than traditional trials. Since this effect persists even when controlling for data quality, the authors suggest that trials using routinely collected data are less prone to overoptimistic treatment adherence and related biases. Even if one may not agree to use EHR data for the most important outcomes, secondary use of EHR data has the potential to reduce the documentation burden associated with traditional trials, offering a more pragmatic study design [7].

While the clinical results of the trial are published elsewhere [8], this manuscript details the lessons learned from the technical perspective.

Methods

Aims and Objectives



Our study was designed as a proof of concept of a distributed analysis approach combining EHR data with structured electronic case report form (eCRF) data to evaluate outcomes of a randomized clinical trial. This implementation aimed to illustrate how the secondary use of EHR data can streamline clinical trial processes.

Blueprint Summary

To gather data for analysis, the trial used a hybrid data collection approach and relied on the DIC structures for data extraction, transformation, and harmonization (Figure 1). Data available from EHRs were collected directly, while additional data were gathered via eCRFs. All data, regardless of source, were collected in the DIC and transformed into an interoperable, standardized format.

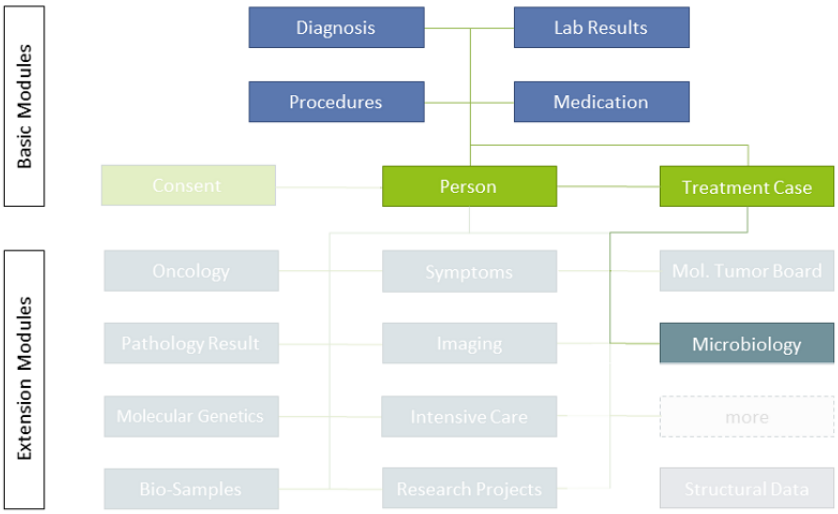
Technical Design

Study-Specific Data Definition and Modeling

At the outset of the study, a comprehensive, study-specific data dictionary, a catalog of items (COI) was developed to serve as a reference for each DIC, detailing the specific data that needed to be extracted from the EHR. The initial version of the COI was developed in several modeling sessions involving at least 2 infectious disease specialists, at least 1 statistician, and at least 2 medical informaticians from the DIC. In these sessions, under the guidance of DIC staff, the following results were achieved:

1. Clinical definition of evidence-based treatment procedures for suspected staphylococcal bloodstream infections (prepared with relevant studies by medical staff from different disciplines).
2. Development of a visualized algorithm for the treatment steps in BPMN format (based on modeling expertise of DIC staff).
3. Identification of critical data and time points that are essential for the evaluation of the patient's status as well as the study results (prepared based on treatment and analysis expertise of medical and statistical staff with different hierarchy levels).
4. Mapping of these data and time points to a COI (prepared using COI development templates by DIC staff).



The interdisciplinary collaboration allowed infectious disease specialists and experts in medical microbiology to contribute their expertise and ensure comprehensive requirements gathering, while DIC staff coordinated the collection and specification of the COI to ensure consistency, completeness, and suitability for further technical specification. Initially, an extensive spreadsheet was created, containing all identified items. This spreadsheet included detailed information on each item, such as its name, data source, and categorization. For illustrative purposes, this tabular COI has been published [9]. In the next step, the items needed to be further specified. Precise names, properties, and relationships between items can be documented and visualized by developing a domain-specific information model [10]—a process also used in the MII [11]. Given the complexity of clinical data, information models ensure clarity, relationships, and visualization between required items, allowing for semantic enrichment of information that can be useful in later analysis. Various notations can be used for information modeling; in the HELP study, the ART-DECOR tool (version 2.2), developed for the standardization of health data, was used [12]. This approach ensured that details such as the dosage of relevant antibiotics for patients were represented correctly [13]. Thus, domain-specific modeling is the first step toward creating an interoperable data basis across multiple locations.

Interoperable Data Integration and Transformation

To facilitate multicenter biomedical research projects based on secondary use of EHR data with the newly established DIC [14], the contents of the EHR in the German university hospitals had to be made accessible gradually. Beginning in 2017, the MII Interoperability Working Group therefore started to define the MII core dataset (CDS; see Figure 2), which separates basic, consistently required data elements of EHR from discipline-specific elements through modularization [11]. Implementing the CDS, the DIC started by providing access to data from the basic modules across all locations and then successively included the extension modules based on current research projects at each location. The HELP study was part of these efforts, using data from both basic and extension modules of the CDS.

XSL•FO
RenderX

Figure 2. Illustration of modules of the Medical Informatics Initiative (MII) core dataset. The HELP (Hospital-wide Electronic Medical Record Evaluated Computerized Decision Support System to Improve Outcomes of Patients with Staphylococcal Bloodstream Infection) study used the basic modules "person," "treatment case," "diagnosis," "procedures," "lab results," "medication" [15], and the extension module "microbiology" [16].

The step-by-step implementation of the CDS is due to the wide variety of primary documentation systems (hospital information systems, intensive care systems, laboratory information systems, etc) from different vendors operating in German hospitals, whose data together comprise the contents of an EHR. DIC have been designed to eliminate the need for data scientists to collect and merge proprietary formats from different systems and locations repeatedly for every project.

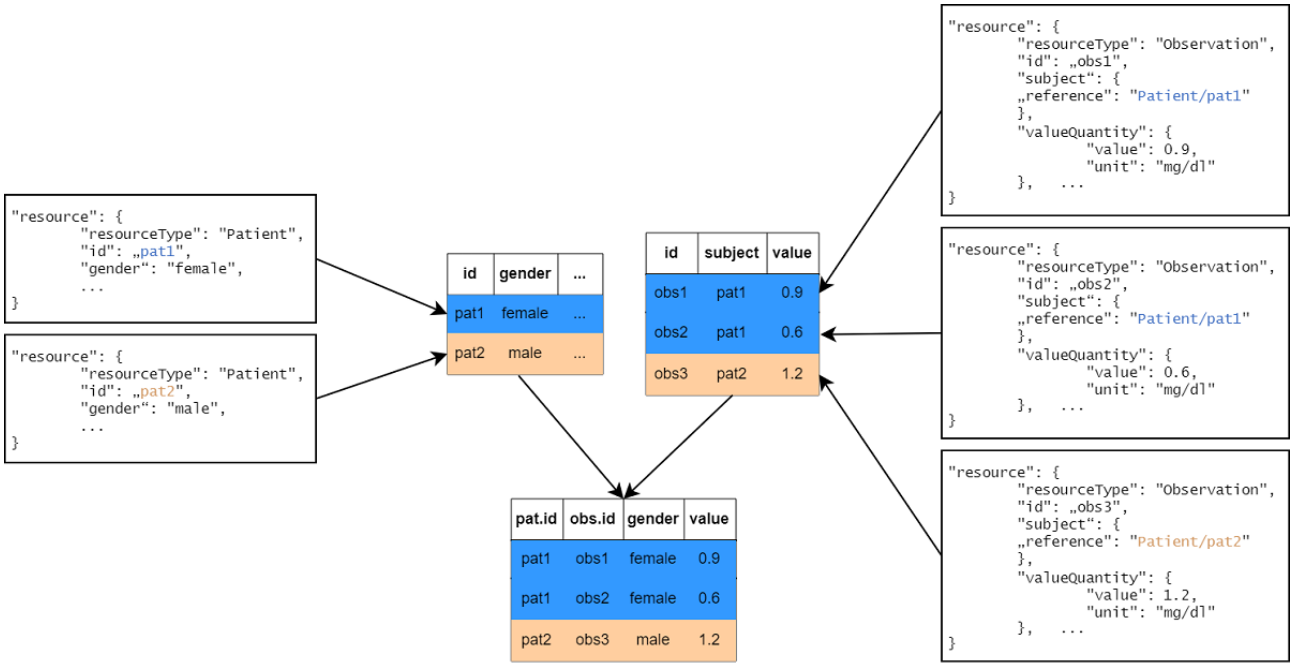
Within the MII, a consensus was reached to use Health Level Seven International (HL7) Fast Healthcare Interoperability Resources (FHIR) for the technical representation and exchange of CDS data across DIC [11]. Despite some limitations for secondary data use, this standard was chosen based on its ability to support a wide variety of research questions and based on its relevance as a common standard for EHR in the German and European health care system in the future [17]. Adopting a health care interoperability standard enables site- and vendor-independent EHR data representation, explicating data properties through a variety of metadata [17-19]. To address specifics of the German health care system (eg, national terminologies), secondary use requirements (eg, custom search parameters), and FHIR usage guidelines, the MII CDS modules were developed as FHIR profiles derived from the international standard. These profiles were balloted and published in the form of implementation guides for application in the DIC [11]. For the HELP study, the relevant modules of the MII CDS could be identified based on the established COI (Figure 2).

The subsequent phase thus involved integrating the data elements required for the HELP study from the various primary documentation systems in all participating locations and transforming them to the FHIR format of the MII CDS modules in the DIC. At the time of the HELP study, the majority of hospitals in Germany did not yet have FHIR interfaces for their EHR systems and thus hardly any interoperable access to the data required for use. The most important task for the DIC in the process of being established was therefore the identification and connection of data source systems. The relevant EHR data are captured in different IT systems, which also had to be connected in different ways: the hospital information system for patient master data, patient movement data, diagnoses, and procedures; the laboratory information system for laboratory tests and microbiology results; and the clinical workplace system or the e-medication system for medication administrations. These connections were established by implementing ETL (extract-transform-load) pipelines for data integrations either directly from the persistence layers or database systems of the source systems or by processing already exchanged message formats for communication between the clinical IT systems—in particular HL7v2, which is often used in Germany, with many proprietary extensions. The selection of the specific connection method is highly location- and vendor-dependent. Due to the hybrid data collection approach of the study, which included the use of eCRFs for data not accessible in the EHR, the data collected via eCRFs also had to be transformed into the FHIR format, for which a separate eCRF2FHIR transformation tool was developed.

Distributed Data Extraction and Analysis

The FHIR standard's use of JSON or XML as notation, its alignment with contemporary web API (Application Programming Interface) practices, and its resource-based data modeling approach are optimized for modern implementation as well as for the precise representation of health care information. The nested JSON data structure is particularly useful to accommodate a number of the FAIR (Findable,

XSL•FO
RenderX



Accessible, Interoperable, Reusable) principles [20], especially that data should be enhanced with "rich metadata" and be "richly described with a plurality of accurate and relevant attributes." Even beyond the use of FHIR in health care settings, JSON and similar nested data formats have been gaining popularity for big data and open data repositories [21,22]. In the health care context, FHIR benefits significantly from the flexibility of nested structures. This is because the dynamic nature of health care data, with its varying elements and data types, is more accurately represented in nested structures than in traditional tabular data formats.

The statistical analysis in our study, however, required tabular data, as most common data analysis techniques do. To make the FHIR data available for this statistical analysis, we therefore transformed the FHIR data into tables using the *fhircrackr* package (version 2.1) [23] within the R statistical computing environment (version 4.1) [24]. Despite all harmonization efforts, both the primary data from the EHR and their FHIR implementation were expected to be at least partly different across the 5 study sites. Consequently, we developed individual data extraction and tabularization scripts for each DIC, taking into account the local characteristics of the data. The scripts, versioned and distributed via a GitLab repository, queried the required data from the respective FHIR server, tabularized it, and performed local aggregation and anonymization steps.

A crucial step in the data analysis was the classification of patients into intervention versus control conditions, followed by the identification and extraction of all study-relevant data items for those patients. In the stepped-wedge design, clinical wards are assigned to the intervention and control conditions, instead of individual patients [25]. Thus, the classification of a patient into either the control or intervention group was based on the ward where the patient was treated when they received their first blood culture result indicating a possible Staphylococcus infection. This required querying data from different data sources represented at each DIC and was implemented by the following overall workflow: (1) process questionnaire data from the eCRFs to identify all patients participating in the trial; (2) analyze encounter data to track patient movement through wards; (3) review medical microbiology reports to identify the first blood culture positive for *Staphylococcus*; (4) link the medical microbiology report dates with the encounter data to determine whether the patient was on a control or intervention ward at the time of the positive blood culture result; and (5) download and tabularize all data for the primary or secondary endpoint analysis as well as for the clinical description of the patient cohort.

FHIR resources containing the relevant data were processed by type, with a separate table created for each resource type during the initial tabularization step. The information from different resources was then connected by joining these tables based on the references linking the original FHIR resources (see Figure 3).

Figure 3. One table was created per resource type; afterwards, tables were joined based on references.

The statistical analysis of the trial data was divided into 2 parts. The first analysis step was conducted locally at each DIC to remove patient-identifying information and aggregate the data where possible, thereby minimizing the risk of re-identification. The data was processed based on its importance for the trial evaluation. Data for the primary and secondary endpoints were maintained at the patient level to maximize statistical power in the central analysis. These data were reduced to the minimal set of variables necessary for statistical analysis and sent to Jena for central analysis using generalized linear mixed models [26]. Conversely, data needed for the clinical description of the study population were aggregated at each site (eg, to mean and SD or counts) and then centrally combined using meta-analytic methods. All data were transferred to the central analysis site manually via a securely provided cloud, since the central MII infrastructure for data sharing was not established yet [27].

Implementation (Results)

Outcomes

Study-Specific Data Definition and Modeling

Identification and explicit description of the data to be used in the study constituted the first step, but creating a finalized, binding version of the COI proved to be an iterative and complex process. A major challenge was the varying status of available data and its assessment regarding clinical priorities, which required a continuous refinement of the COI even during the data integration and transformation phase. Throughout the data extraction process, we encountered numerous occasions where the data found in the EHR did not match the items from the COI exactly, requiring repeated consultations with infectious disease specialists and DIC employees to clarify specific datasets.

We initially planned to use project-specific FHIR profiles for the HELP use case and started with their development. However, both the amount of work involved in generating profiles derived from the CDS and tailored to the project and the unclear benefits—as compliance with the stricter requirements of project-specific profiles at the sites could not be verified—made it questionable whether the time saved in the analysis by project-specific FHIR implementation guides justified these efforts. Consequently, we did not complete the profiling work, but the results and experiences were incorporated into the further development of the CDS extension modules. The reliance on interoperability standards for data analysis must be investigated further in future projects [28].

Interoperable Data Integration and Transformation

Both the transformation of proprietary, vendor- and location-specific health care data into interoperability standards and the processing of such interoperable data for analysis in a research study required the development of software tools: ETL pipelines, semantic annotation and mapping programs, structure conversions for data analysis, and data analysis scripts. Project-specific software development, however, inadvertently causes errors and bugs, most of which can only be found when the software is used practically in the intended context. Consequently, software development required significant time during the study, which is unsurprising given that many of the tasks the software addressed were novel to this project. However, this time investment is only justifiable if the software can be reused in future projects; otherwise, it is not sustainable.

The main obstacle during data extraction and transformation was the varying quality of the EHR data, which we encountered in 3 distinct forms:

1. In cases where data are entered manually into the EHR, the person documenting it may be rushed or may not consider it important to ensure accuracy. As a result, manual data entries can contain errors, which may be corrected later or remain, leading to inconsistencies or contradictions in the extracted data.
2. Many entries in EHR are only given in free text form and do not provide semantically annotated information. This prevented the processing of the contained information in the HELP study and led to the described approach of hybrid documentation.
3. Even structured data are not always unconditionally machine-readable. An example is the coding of measurement units in laboratory data. In communication between clinicians, variations in how a measurement unit is presented, how a formula is formatted, or even minor errors in notation are typically understood in context due to the clinician's background knowledge. Figure 4, for example, represents 4 different notations of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) measurement units encountered in an EHR. While any clinician can easily see that the unit described is µmol/(l * s), computers are unable to interpret these discrepancies without explicit standardization.

XSL•FO
RenderX

Figure 4. Examples for units of measurement for alanine aminotransferase (ALT) and aspartate aminotransferase (AST) in German laboratory results, captured from a PDF.

Furthermore, relevant data were captured at different locations and by different individuals using different software, which can also change over time [29]. One possible countermeasure to those differences would have been a stricter specification of uniform data, which can be achieved through project-specific FHIR profiling with more extensive constraints than those provided by the MII CDS. However, this was not feasible within the HELP study (cf previous paragraph).

Distributed Data Extraction and Analysis

As a result of the heterogeneity of the primary data described earlier, the data provided by the 5 DIC showed substantial heterogeneity as well. Although all DIC theoretically follow a comparable IT and service architecture [11], their practical implementations vary significantly, often due to local requirements. Differences emerged even at the initial access stage: some DIC required analysis scripts to be delivered in Docker containers, while others only accepted plain R scripts to be executed by DIC employees. Additionally, some DIC had installed a FHIR repository dedicated solely to the HELP use case, containing data only for study participants, whereas other DIC used a single, comprehensive FHIR repository with all available data. This necessitated individualized querying routines that were developed in a highly iterative workflow and close collaboration with each DIC.

On the next level, the implementation of the FHIR resources differed significantly (see Figure 5). Although all resources were supposed to conform to the same profiles defined in the CDS, we identified two major sources of variation. First, the DIC differed in the primary data sources connected at the time of the study. For example, diagnoses originated from data exports for subsequent billing by the hospitals at some DIC and from clinical documentation during patient treatment at others. This resulted in varying FHIR resources, as specific data elements were not available in some sources (eg, the diagnosis date in billing data) and led to different interpretations (eg, diagnoses optimized for billing purposes after treatment versus purposes during treatment). Second, the implementation of profile-conformant FHIR resources was at different stages. For instance, the CDS provides a multilevel model for representing encounter data that aligns with the administrative structure of a German hospital. However, at the time of the study, only 1 of the 5 DIC had fully implemented this complex model, while the other 4 used more rudimentary, simplified representations.

XSL•FO
RenderX

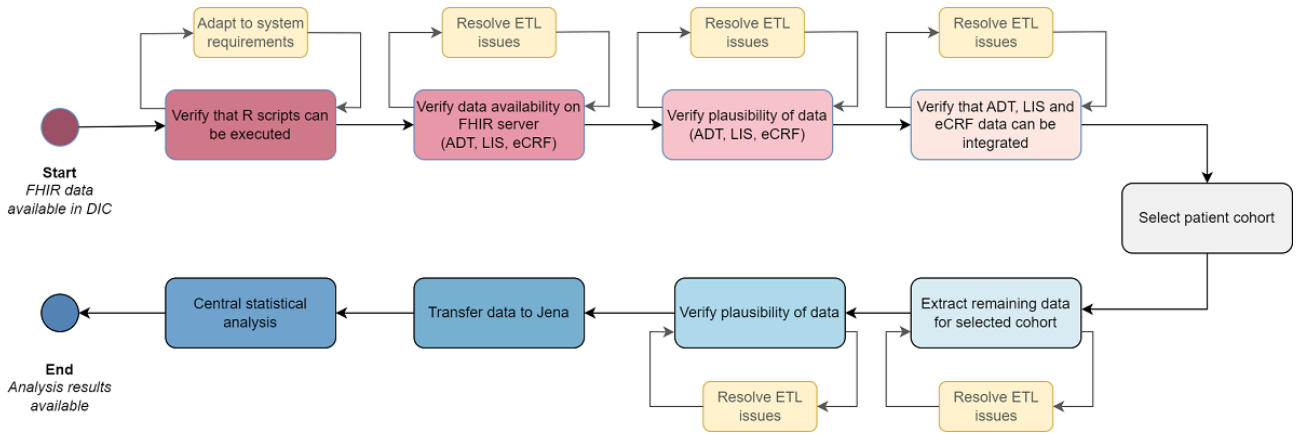

Figure 5. Two exemplary FHIR (Fast Healthcare Interoperability Resources) resources, illustrating potential differences despite adhering to the same FHIR profile. Elements that exist in both resources but contain different codes are highlighted in yellow, while elements present in only 1 resource are marked in red. The resources have been shortened and anonymized.

These sources of data heterogeneity, which persisted even after being transformed to an interoperable format, had to be addressed through harmonization during data extraction and analysis. According to Nguyen [30], interoperability involves the transactional sharing of health care data, while data harmonization integrates data from multiple sources to preserve context and normalize meanings across datasets. FHIR, as an interoperability standard, allows for unified data representation from different sources but does not address data harmonization, which requires understanding the context and meaning of the data. While FHIR resources can provide context in the form of metadata (eg, indicating whether a diagnosis originated from billing or clinical information), managing these different contexts in the analysis is a task of harmonization. In multicenter projects like HELP, it is crucial to recognize that no single person can anticipate the heterogeneous data across all study sites. This is because understanding such data requires site-specific information about the clinical routines and the distinct features of the individual information systems used at each location. In our case, the harmonization therefore required numerous iterations of communication and script adaptation with the respective data providers. To ensure feasibility, we broke the extraction process down into manageable subtasks as depicted in Figure 6. Each subtask was iterated with each DIC until it produced plausible results.

Figure 6. Iterative data extraction and analysis process in the HELP (Hospital-wide Electronic Medical Record Evaluated Computerized Decision Support System to Improve Outcomes of Patients with Staphylococcal Bloodstream Infection) study. FHIR: Fast Healthcare Interoperability Resources; DIC: data integration center; ADT: admission, discharge, and transfer data; LIS: laboratory information system; eCRF: electronic case report form; ETL: extract-transform-load.

The infrastructure for our distributed analysis needed to be straightforward to implement, flexible, and compliant with strict privacy regulations for health data. The requirement for stringent data protection precluded the use of any cloud computation services. Additionally, the need for simplicity ruled out established privacy-preserving solutions like DataSHIELD [31], as setting up a dedicated OPAL server at each DIC was not feasible for this study. Instead, we opted for a straightforward infrastructure by distributing plain R scripts via GitLab and Docker images through Docker Hub. Overall, the script

XSL•FO
RenderX

development process was extremely time-consuming, partly because the technical infrastructure and FHIR mapping were still under construction during the analysis. While this helped identify problems in DIC development early on, it required more iterations than anticipated.

Lessons Learned

Overview

The lessons learned presented in this paper emerged from systematic observations and collaborative discussions throughout our study's implementation phase. Our experience demonstrates that distributed analyses using EHR data are feasible but require careful planning and consideration of key challenges. While these insights were primarily derived from our experiences within the MII, they extend beyond this framework and offer valuable guidance for researchers planning clinical trials that incorporate EHR data. Based on our experience implementing distributed analyses, we identified 3 fundamental considerations that warrant careful attention during the project-planning phase. These insights are particularly relevant for study coordinators and researchers who aim to leverage EHR data in clinical research, regardless of their institutional context.

The Precise Definition and Quality Assessment of Required Data Elements are Paramount

While interoperable EHR formats facilitate data exchange, they do not inherently resolve underlying data quality issues. Rather, standardization tends to illuminate existing quality challenges, making thorough preliminary data quality assessment essential. Researchers must realistically evaluate whether available EHR data meets the quality thresholds necessary for their specific research objectives.

Project Timelines Should Accommodate Iterative Development and Refinement Cycles

The notion of plug-and-play solutions for analyzing EHR data across different institutions proves unrealistic in practice. Scientific research inherently involves trial and error, particularly when working with heterogeneous EHR data sources. Successfully navigating these iterations requires sufficient time allocation in project planning.

Team Composition Significantly Influences Project Success

Effective distributed EHR analysis demands a multidisciplinary approach, combining team members with complementary expertise. Essential roles include local data stewards with intimate knowledge of institutional data structures, alongside specialists who understand various aspects of EHR data utilization. This diversity of perspectives enables comprehensive problem-solving and robust methodology development.

Discussion

Principal Results

The HELP study was designed as a use case for the secondary use of EHR data, limited to 5 university hospitals participating in the MII in Germany. Therefore, the lessons learned in this paper apply specifically to this context. The study commenced in the early phases of DIC development, which introduced challenges that may be resolved over time. A key issue was the absence of mandatory data standards in Germany's health care, which complicated our efforts. However, the implementation of national standards is anticipated in the future [32], and such standards are essential for efficient multicenter secondary EHR data usage. In this regard, the DIC were pioneers in applying HL7 FHIR in German university hospitals. Nonetheless, the processing of FHIR remains subject to optimization, as we were unable to develop and apply project-specific information models and FHIR profiles for the HELP study as intended. This was largely due to the extensive workload required for profiling as well as data integration and transformation, which fell on small teams. In particular, not every EHR data use project can be expected to have the resources and expertise in FHIR profiling to be able to technically express project-specific data requirements.

For some phases of the study, other methods of data harmonization could also have been considered. For example, a Common Data Model can be used to harmonize cross-site datasets, with Observational Medical Outcomes Partnership (OMOP) [33] playing a particularly important role in the area of health data. However, due to the mandatory use of international terminologies and the incompatibility of national specifications or site-specific data properties, various relevant data items could not be represented in OMOP for the German HELP study either, as has already been shown for the MII CDS [34,35]. Examples include the vital status within 90 days, blood culture results, or hospital readmission after discharge, which would have required additional logic or custom extensions in OMOP, while FHIR offered more flexible options through resources like Observation and Encounter. Common Data Models, in turn, remain highly relevant for use in internationally conducted observational studies.

It is evident that the scalability of any comparable cross-facility research project is impaired by the divergent clinical documentation in facilities and their specialist departments, which can vary greatly in details due to different manufacturers, different billing forms, and individual decisions, especially complicating distributed analyses. The enhancement of secondary use can only be achieved through the implementation of billing-independent ontologies such as SNOMED CT for the semantic annotation of clinical data [17], as is envisaged for the European Health Data Space (EHDS [36]), for instance.

In the HELP study, data availability posed a significant challenge, particularly regarding patient movement between wards as well as medication records. These data types were often difficult to use due to their manual documentation and their frequent updates in many settings. A broader issue was the lack of standardized formats for certain data, with some not being available digitally at all. To address these limitations, we supplemented the existing data collection with additional eCRF. However, during the course of the study, digitization of clinical documentation increased, offering hope that such challenges may be mitigated in future research.

In addition to data availability challenges, we encountered significant data quality issues during both data transformation

XSL•FO
RenderX

to interoperable standards and subsequent analysis. While several formal frameworks exist for assessing and improving EHR data quality—notably the framework proposed by Kahn et al [37], which has gained traction in the MII [38,39]—these were not yet robustly established for FHIR-based data at the time of our study. Our experience underscores the critical need for standardized data quality assessment methodologies, and future research in the field should systematically explore and implement comprehensive frameworks like that proposed by Kahn et al.

While a distributed analysis approach, as used in our study, is not statistically ideal—centralized, patient-level analyses provide greater flexibility and statistical power—it was the only feasible method given the ethical and data protection constraints induced by not being able to obtain informed consent from every participant. In the future, our manual approach to distributed analysis will likely be replaced by more formal frameworks for distributed analysis of EHR data, incorporating FHIR-based APIs. Examples include the Personal Health Train [40] and the Federated Learning and Analysis in Medicine platform [41]. These platforms, however, were not available at the time of the HELP study [42].

Comparison to Other EHR Data Applications

Since the start of the HELP use case, several other use cases have emerged within the MII. Zoch et al [43] highlight lessons learned from studies on rare diseases conducted in the MII context, many of which align with our findings. For instance, they also emphasize the importance of multidisciplinary teams in successful data use projects and the need for a solid understanding of EHR data sources. Building on their insights, we took a broader view of secondary data use, abstracting beyond the specific MII structures. Additionally, we place greater emphasis on the iterative nature required for projects of this kind.

Extending the scope beyond Germany, many countries have undertaken initiatives similar to the MII to develop infrastructures for the secondary use of EHR data. Notable examples include the Dutch Health-RI initiative, the Swiss Personalized Health Network, and the US National Patient-Centered Clinical Research Network. These initiatives share a common goal: to collect and standardize EHR data for research purposes. In Europe, these efforts will soon be consolidated under the EHDS [36], which aims to create a unified infrastructure for the secondary use of EHR data across the continent. It is our hope to share the lessons learned from this project and use them to shape the integration efforts of the various approaches.

Conclusions

In this paper, we have shared key insights from conducting a clinical trial that leveraged EHR data. By applying these lessons and fostering cross-institutional collaboration, we can advance toward more sophisticated and efficient use of interoperable EHR systems in clinical research. This approach, while challenging, has the potential to enhance our understanding of patient care and clinical outcomes, providing valuable insights that can inform both clinical practice and future research endeavors. As the field continues to evolve, the lessons learned from current implementations will serve as important guideposts for developing robust and sustainable approaches to EHR data integration in clinical research.

Acknowledgments

This work was supported by the German Federal Ministry of Education and Research (grant numbers for the 5 study centers are Jena University Hospital: 01ZZ1803C, Halle University Hospital: 01ZZ1803N, Leipzig University Hospital: 01ZZ1803D, Aachen University Hospital: 01ZZ1803B, and Essen University Hospital: 01ZZ1803P). The German Federal Ministry of Education and Research also funded part of the project as part of the funding program “quantum technologies – from basic research to market”; contract number: 13N15711.

Data Availability

The tabular catalog of items and HELP (Hospital-wide Electronic Medical Record Evaluated Computerized Decision Support System to Improve Outcomes of Patients with Staphylococcal Bloodstream Infection) dataset in ART-DECOR are openly available as cited in the manuscript. The *fhircrackr* package is also openly accessible and actively developed on GitHub [44].

Abstract

Background: Between 2020 and 2022, the Philippine Primary Care Studies program, a government-funded initiative supporting universal health care implementation, piloted two electronic health records (EHR) systems across urban, rural, and remote primary care sites.

Objective: The study aimed to evaluate the implementation of two EHR systems in diverse primary care settings in the Philippines over a three-year period.

Methods: This implementation study used an explanatory mixed methods design. Two EHR systems were deployed: an Open Medical Records System (OpenMRS)-based platform in 2016, and a Microsoft-based system in 2021. Both systems integrated clinical documentation, pharmacy, laboratory, and reporting modules. Implementation strategies included training workshops and materials, iterative user feedback loops, and infrastructure cofinancing with local governments. Surveys were administered yearly to all end users. The primary outcome was behavioral intention to use the system. Quantitative data were supplemented by inductive content analysis of qualitative responses to explain observed trends.

Results: A total of 351 survey responses were collected from 2020 to 2022. In 2020, the intention to use the OpenMRS-based EHR was high across all sites. By 2022, following the launch of the Microsoft-based EHR, acceptability declined significantly among doctors and administrative staff, particularly at the urban site. In contrast, the remote site which retained the OpenMRS-based system maintained high acceptability levels. Qualitative findings revealed that while the new EHR system provided a more privacy-focused design, users preferred a cross-platform EHR to allow more flexible access to patient data. At the rural site where the EHR was used to facilitate task-shifting among nurses involved in clinical management, users were less impacted by this shift.

Conclusions: The disparities in EHR acceptability across urban, rural, and remote sites were influenced by contextual, technical, and demographic factors. The decline in acceptability following the EHR system transition highlights the importance of implementation strategies that reflect the specific needs and capacities of each setting. These findings offer practical insights for adapting EHR systems to diverse primary care contexts.

electronic health records; medical informatics; digital health; implementation report; electronic health records system

Introduction

Following the enactment of the Philippine Universal Health Care Law, which mandated the national implementation of electronic health records (EHR) for primary care providers [1], the adoption of EHR systems has faced multifaceted challenges encompassing sociotechnical, organizational, and environmental barriers [2,3].

EHRs are considered digital health interventions intended to address multiple health system challenges [4]. These challenges include poor data quality, underutilization of health care, and operational inefficiencies related to paper-based clinical

XSL•FO
RenderX

documentation and insurance claims processing [5,6]. EHRs also aim to address transportation and communication barriers, human resource shortages, and referral inefficiencies, particularly by facilitating task-shifting models in which nonphysician providers such as nurses and midwives assume expanded clinical roles in remote areas [7].

Despite the development of many EHR systems tailored for rural primary care facilities in the Philippines, adoption remains limited [2] and implementation reports or user-centered evaluations are scarce [8]. However, when successfully implemented, EHRs can enhance the collection, storage, and retrieval of health information across clinical, paramedical, and administrative domains [4].

To provide recommendations for the widespread implementation of EHR systems, the Philippine Primary Care Studies (PPCS) initiated a digitalization program in three pilot sites that reflect the country's primary care contexts: urban (Quezon City, National Capital Region), rural (Samal, Bataan), and remote (Bulusan, Sorsogon). This initiative aligned with the national digital health strategy, which designated EHR adoption as a foundational step in building an integrated health information system to support evidence-based policy and health financing decisions [1].

Initial surveys during the first year of program implementation revealed high EHR acceptability across a diverse range of users and settings [5]. Since then, both the contextual landscape and system features have evolved. Some rural facilities have reverted to or continued using paper-based systems [8]. This study provided a comprehensive reassessment of how various factors have shaped the EHR implementation over time.

Methods

Study outcomes

The overall aim of the implementation was to assess how EHR systems could be effectively used across various primary care contexts. The primary outcome was user acceptability, operationalized as continued intention to use the system [9]. Distal outcomes such as sustainability and clinical outcomes were beyond the scope of this study. The secondary objective was to explain variations in acceptability by delving into contextual factors influencing system adoption. This study adhered to the iCHECK-DH (Checklist for the Reporting on Digital Health Implementations) guidelines [10] and the GRAMMS (Good Reporting of A Mixed Methods Study) reporting standards [11].

Blueprint Summary

The digital health interventions integrated several components including electronic medical records, health management information systems, laboratory and diagnostics information, and pharmacy information [4]. Two EHRs were implemented across PPCS pilot sites, one in 2016 and another in 2021. Training was delivered through workshops and asynchronous instructional materials. Broader implementation strategies included internet infrastructure deployment (in collaboration with the local government units), and continuous feedback loops between system developers and users. Prescribing and laboratory data were integrated into the EHR to monitor costs and support the development of a primary care benefits package [12].

Technical Design

The first EHR system, built on the open-source Open Medical Records System (OpenMRS) platform was introduced in 2016 at an urban site, and subsequently in 2019 at the rural and remote sites. Developed in-house by the PPCS team, this system connected primary care services, laboratory units, and pharmacies. Main features included triage and queueing modules, clinical notes accessible only to authorized providers, laboratory request and result interfaces, pharmacy dispensing modules, and administrative reporting tools.

The second EHR system, launched in April 2021 for the urban and rural sites, used a Microsoft-based desktop and cloud infrastructure. This Microsoft-based EHR was not implemented at the remote site due to the lack of high-speed broadband internet. Developed by a government-owned digital solutions subsidiary, this system introduced role-based access for nonphysician providers to draft clinical notes and propose management plans for physician approval. Additional functionalities included real-time referral notifications and a redesigned user interface. Core features remained consistent with the OpenMRS-based EHR platform.

Target

The three primary care settings of the PPCS program were selected to represent urban, rural, and remote contexts. Rural sites are defined by the National Statistics Office as municipalities with a population density of fewer than 1000 people per square kilometer [13], while remote sites are designated by the Department of Health as geographically isolated and disadvantaged areas [14]. The urban site, located within a public university in a high-income municipality in Quezon City, provided primary care services to approximately 15,051 faculty members, employees, and their dependents. The rural site, situated in a low-income municipality in Bataan, served 35,298 residents with a population density of 627 inhabitants/km^2 [15,16]. The remote site, located in a low-income geographically isolated mountainous area in Sorsogon, catered to 22,884 residents (238 inhabitants/km^2) [16,17].

End users included administrative personnel, community health workers, nurses, midwives, physicians, dentists, nutritionists, pharmacists, and laboratory technicians. These users were responsible for data entry, service provision, and generating reports for local and national reporting.

Data

Patient data were entered through password-protected accounts and stored on secure servers managed by the system providers. Data sharing was restricted to health professionals managing the same patients. Data privacy protocols conformed to the Data Privacy Act of 2012, which grants patients the right to be informed, access, and modify their data [18]. Third-party use of data for research required clearance under the National Ethics Guidelines for Health and Health-Related Research (2017) [19].

XSL•FO
RenderX

Interoperability

Both systems adhered to national data standards issued by the Department of Health [1]. The OpenMRS-based EHR supported Fast Healthcare Interoperability Resources, while the Microsoft-based version did not. Clinical notes were primarily composed of sectioned free-text fields (eg, chief complaint, history of present illness). Diagnoses were entered using *ICD-10* codes via auto-populated dropdown menus. Similarly, prescriptions were entered using dropdown lists based on the national drug formulary.

Participating Entities

The program was implemented by PPCS under the Program on Health Systems Development, University of the Philippines Center of Integrative and Development Studies. Funding was provided by the Department of Health, the Philippine Health Insurance Corporation, the Emerging Interdisciplinary Research Program, and the Philippine Council on Health Research and Development. The Microsoft-based EHR was developed through the Technology Transfer and Business Development Office of the University of the Philippines Diliman. This EHR was subsequently co-owned by the system provider and the university.

Budget Planning

The total cost of the project was estimated at Php 6,000,000 (USD 104,572). Capital costs were cofinanced by local government units and the implementing agency. This covered internet infrastructure (ten internet towers amounting to Php 800,000 (USD 13,943)), network equipment (routers and cables worth Php 40,000 (USD 697)), EHR development (developers' salaries over Php 1,000,000 (USD 17,429)), and workstations (desktops, laptops, and printers worth Php 2,000,000 (USD 34,857)). Recurring costs for IT support personnel were approximately Php 800,000 (USD 13,943) annually. Licensing costs were not incurred as both systems were developed in-house.

Sustainability

Postpilot funding for both systems varied, depending on the discretion of local government units. Although this evaluation focused on acceptability rather than sustainability, the latter was implicitly linked to user endorsement. EHR users, who also served on local health boards, played advocacy roles in securing funding.

Evaluation

A sequential mixed-methods design was used to assess user acceptability. Surveys were conducted annually from 2020 to 2022. An interpretivist approach underpinned the analysis, acknowledging the co-construction of meaning between researchers and participants. Survey design was guided by the Unified Theory of Acceptance and Use of Technology (UTAUT) [20].

Mixed methods allowed the team to capture the evolving nature of the intervention [21]. Quantitative data identified patterns in acceptability, whereas qualitative data provided context to these observations. Although data collection was concurrent, analysis occurred sequentially, with priority given to quantitative data. This sequential approach facilitated identification of relevant questions to guide the content analysis of qualitative data. Integrating datasets enabled corroboration and elaboration of findings.

All EHR users were invited to participate and provided written informed consent. The survey instruments featured a combination of Likert-scale questions and free-text fields. Survey validation and Unified Theory of Acceptance and Use of Technology model testing are detailed elsewhere [5]. Free-text responses were analyzed using semantic, inductive content analysis. Due to brevity of responses, coding was kept descriptive to highlight user experiences [22]. The final synthesis was reviewed by the core research team and the PPCS steering committee.

Ethical Considerations

This study received ethics approval from the University of the Philippines Manila Research Ethics Board (2015-489-0) and the Department of Health Single Joint Research Ethics Board (2029 - 55). Written informed consent was obtained from all participants. They were free to decline participation or withdraw from the study at any time. No financial or material compensation was provided for completing the questionnaire. Identifying information was removed during analysis to ensure participant anonymity.

Results

Coverage

Surveys were carried out at sites where the EHRs were implemented, covering 21 barangay health stations (14 in Samal and seven in Bulusan), two rural health units (one in Samal and one in Bulusan), and one university-affiliated clinic in Quezon City. The surveys achieved response rates of 53% (135/255) in 2020, 48% (127/263) in 2021, and 68% (89/131) in 2022. Respondents were predominantly female and were within the 31-60 age group (Table 1). Nurses and midwives accounted for the majority of respondents across all three sites, comprising 175 (50%) of the total sample. A total of 165 respondents (47%) reported having less than five years of service, while 221 (63%) reported more than 48 weeks of experience using the EHRs.

[a]EHR: electronic health record.

Acceptability Surveys

The acceptability of the EHR system showed distinct patterns over the three-year study period (Figure 1). In 2020, respondents generally expressed positive intention to use the OpenMRS-based EHR across the three sites. However, by 2021, with the transition to the new EHR system in the urban and rural sites, a noticeable shift in acceptability occurred, especially in the urban site, where some users expressed disagreement with the continued use of the EHR. By 2022, more than half of the urban site respondents disagreed with the continued use of the EHR. This trend was mirrored, though to a lesser extent, among rural users. The remote site users, who continued using the OpenMRS-based EHR, maintained consistent acceptability levels towards the EHR throughout the three years.

XSL•FO
RenderX

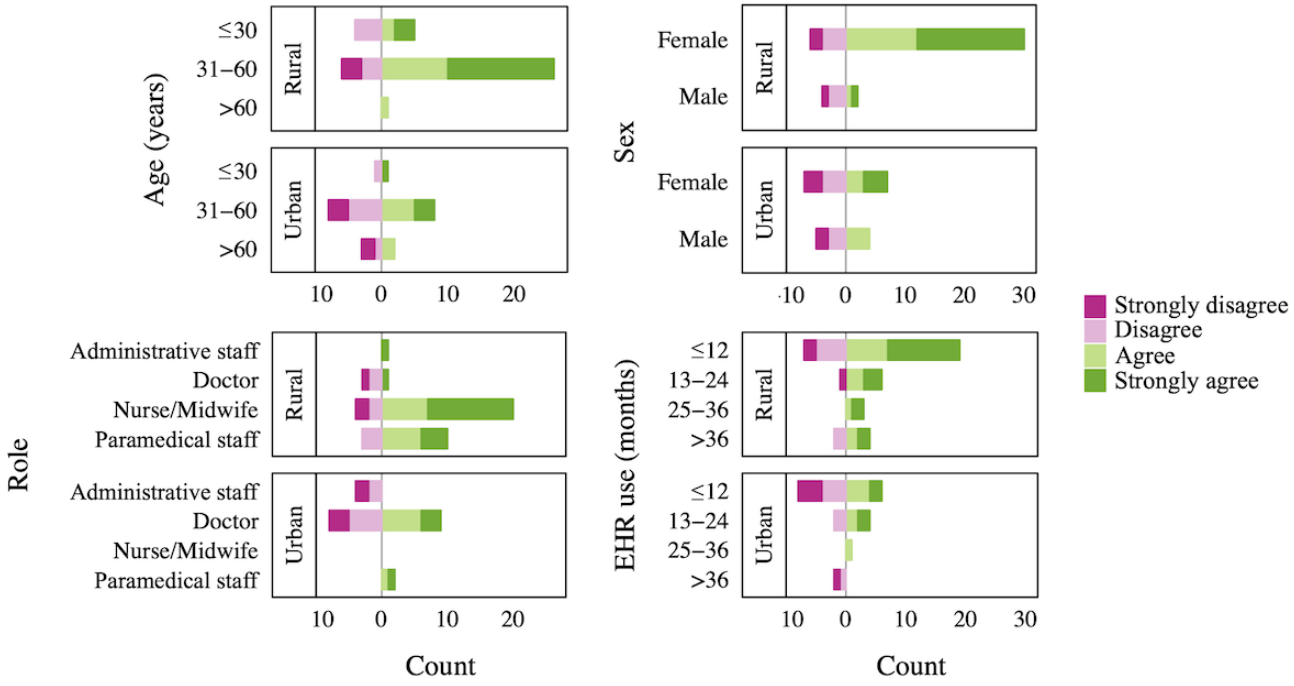

Figure 1. Percentage responses to the item "I intend to use the EHR in the next 12 months" revealing shifts in behavioral intention from 2020 to 2022 across pilot sites.

Of the 64 respondents (72%) in the 2022 endline survey who also participated in the 2020 baseline survey, 28 (43%) reported a decreased intention to use EHR, 9 (14%) showed an increased intention, and another 27 (43%) maintained the same opinion.

Subgroup analyses (Figure 2) of users from urban and rural sites, both of which transitioned to the Microsoft-based EHR by April 2021, revealed high levels of disagreement with continued EHR use among administrative staff and doctors in the urban setting. At the rural site, more doctors expressed disagreement compared to other roles. Urban site responses were symmetrically distributed with both positive and negative sentiments across age groups and sex. Conversely, in the rural setting, women and younger users expressed higher intent-to-use the EHR compared to men and older respondents. Acceptability was lowest among users with less than 12 months of EHR use.

Figure 2. Total counts of responses to the question "I intend to use the EHR in the next 12 months" across different subgroups in 2022.

Content Analysis of User Feedback

The preliminary analysis of quantitative data raised the following questions for content analysis: (1) Why was acceptability different in the urban and rural sites despite using the same EHR system?; (2) Why was acceptability lower among doctors in urban and rural settings compared to other professions?; (3) Why was acceptability higher at the remote site despite similar, if not more, resource constraints compared to the rural site?; (4) Why was acceptability lower among less experienced users?

Content Analysis of User Feedback

Common feedback included positive sentiments toward fundamental features such as record input (from administrative staff, pharmacists, and midwives), access to patient information

XSL•FO
RenderX

(noted by midwives, nurses, and doctors), and data integration within the hospital system (mentioned by nutritionists and doctors). However, pervasive concerns about unresponsive interfaces were reported across all sites, attributed to slow laptop performance at the urban site and slow internet connectivity at rural and remote sites. Users also expressed frustration with system bugs and freezes, indicating a perceived lack of readiness for the Microsoft-based EHR implementation. Additionally, physicians in urban and rural sites, who used the Microsoft-based EHR, specifically commented on the interface complexity for having an excess of on-screen buttons (Table 2).

Table . Content analysis of unstructured responses from the acceptability surveys.

Categories	Data extracts
Useful core features, but repetitive and cumbersome interface	"Easy to find information of the patient" (rural, laboratory technician)
	"Slow opening of application and too many save buttons to click when closing the chart" (urban, physician)
Need for multidevice support and workflow integration	"Not cross-compatible with other devices (computer/mobile phone)" (rural, administrative staff)
	"I wish it was integrated with Appointlet or my email. I wish I could just click on a button to contact a patient through text or Viber or Zoom" (urban, physician)
Dependence on unreliable internet connectivity	"Slow when the internet is weak" (remote, midwife)
Lack of time and opportunity for system (re)training	"There was a change or an upgrade of the platform at one point and I just did not have the time to relearn" (urban, physician)

Integrating Quantitative and Qualitative Findings

Disparities observed in acceptability were linked to both the demographic composition of survey respondents and the specific EHR system used. The urban setting had a higher concentration of physicians, while the rural site featured a mix of midwives and physicians, and the remote site had fewer physician respondents. Integrating quantitative and qualitative datasets yielded the following interpretations.

Despite using the same Microsoft-based EHR system, lower acceptability in the urban setting compared to the rural site can be attributed to several factors. Although urban respondents did not identify internet connection issues unlike their rural counterparts, demographic differences played a role. Urban site respondents were predominantly doctors, who displayed a more critical stance compared to other healthcare professionals.

Higher acceptability at the remote site, despite experiencing more resource constraints than the rural site, was influenced by the continued use of the OpenMRS-based EHR. Dissatisfaction at the rural site, particularly among doctors, was due to the lack of multidevice support of the Microsoft-based EHR. Common concerns across rural and remote sites included internet dependency and interface issues, although the remote site reported fewer problems with bugs and freezes with the OpenMRS-based EHR.

Investigating why acceptability was lower among physicians in both the urban and rural settings compared to other health care professionals revealed several insights. Flexibility was a success factor, with physicians emphasizing the need for a cross-platform EHR system that enabled easier access to patient information and integration with their workflow and other productivity tools. The Microsoft-based EHR's restrictions led to additional workflow disruptions, including reliance on low-performance computers and intermediary note-taking methods (eg, pen and paper, personal computers)—an unintended consequence which arose from efforts to implement a desktop-based, privacy-focused design.

Beyond technical implementation barriers, social factors also influenced adoption. Exploring the lower acceptability among less experienced users highlighted the learning curve associated with new platforms and the need for periodic technical support. New users appreciated the transition from paper to electronic records but identified system navigation complexity as a concern, especially for those with limited technological literacy. Recommendations included a self-explanatory interface and a help window for direct support.

Lessons Learned

Successful implementation of the EHR systems was facilitated by the active involvement of users, developers, and site managers. This collaboration allowed timely feedback cycles, leading to iterative improvements and the adoption of an integrated EHR used not only by physicians but also by nurses and midwives. The Microsoft-based EHR was intentionally designed to enable task-shifting: nurses would document and prescribe treatment plans for asynchronous physician review. In practice, this worked well in the rural site. However, the same approach proved less relevant in the urban site, where nurses typically worked alongside physicians. Acceptability declined in this setting after the EHR transition, as the initial system was locally installed. To address this, the Microsoft-based EHR was later migrated to a web-based platform that supported access from laptops and mobile devices.

The implementation also benefited from favorable policy timing. The COVID-19 pandemic in 2020 accelerated digital adoption out of necessity [8], while the Universal Healthcare Law (enacted in 2019) created legal incentives to adopt EHRs that complied with national reporting and claims processing standards [1]. These contextual enablers were not originally anticipated in the project's planning phase, but enhanced uptake.

XSL•FO
RenderX

However, structural challenges persisted, particularly with internet connectivity. Although limited access was acknowledged during planning, the actual impact was more severe than expected. For example, the Microsoft-based EHR, which was reliant on stable broadband, could not be launched in to remote site. Internet service providers and EHR vendors did not have strong financial incentives to serve low-density areas. The PPCS experience showed that reframing paramedical staff as core users, not secondary ones, can strengthen the business case for scaling EHRs in underserved areas [7]. Nonetheless, government support remains essential to overcome the limited commercial viability.

Budget allocation was further complicated by the decentralized governance structure in the Philippines [23]. While some infrastructure costs were cofinanced by local government units, the actual continuity of support varied. One site discontinued EHR use following a change in local leadership, despite the original plan for sustainability beyond the pilot phase. With local elections occurring every three years, digital health programs remain susceptible to political turnover [24]. This introduces unpredictability that can deter significant upfront investments in infrastructure and innovation.

Discussion

This study described the implementation strategy, intervention components, and the evolving acceptability of two EHR systems over a three-year period across three primary care settings. Acceptability declined notably in both urban and rural sites following the transition to a Microsoft-based EHR. Conversely, the remote site, which continued using a OpenMRS-based EHR, consistently reported high levels of acceptability. User feedback highlighted doctors' preference for a more flexible EHR that could operate across various devices. Paramedical staff pointed out recurrent bugs in the Microsoft-based EHR, suggesting premature implementation. The transition between EHR systems posed challenges, necessitating users to adapt to new interfaces, with inadequate support identified as a significant barrier.

The study's outcome measurement approach had several limitations. First, the absence of in-depth interviews and direct observation limited the ability to capture richer insights, particularly from users who may have opted out of system use. Second, is the low response rate from 2020 to 2022, likely influenced by the online format of the survey. This may have introduced selection bias and skewed the results toward participants with higher technological capacity.[25] While the rates in our study were higher than those from similar surveys [26-28], the views of nonrespondents could differ meaningfully [26-28]. Additionally, the COVID-19 pandemic in 2020 drastically altered the health care landscape and may have influenced respondents' sentiments towards the EHR systems.

Efforts to scale up EHRs in primary care should recognize the complex interplay between system design, user needs, and contextual factors. A user-centered model designed for a rural context may not seamlessly apply to an urban setting. Consequently, adopting a single system nationwide risks replicating the misalignments observed in this program. Future national strategies should balance standardization with flexibility, allowing for context-sensitive adaptations to maximize EHR use across varied health system settings.

Acknowledgments

The authors wish to acknowledge research assistants who delivered and processed the survey forms. Gratitude is also extended to healthcare workers and staff in each pilot site for their time and support for the program. This study was funded by the Philippine Department of Health, the Philippine Health Insurance Corporation, the Emerging Interdisciplinary Research Program, the University of the Philippines Center for Integrative and Development Studies, and the Philippine Council on Health Research and Development.

Abstract

Background: In large tertiary hospitals across China, outpatient patients often encounter the “three longs and one short” (long registration time, long waiting time, long time for medicine collection, and short time for medical treatment) phenomenon. This scenario contributes to suboptimal patient experiences and declining satisfaction with health care services. To address the issue of long waiting times, many hospitals in China have implemented a range of measures. However, these measures have only improved individual aspects of the patient experience, with limited overall impact. Currently, there is a lack of comprehensive, intelligent reform for the entire patient service process in the medical system. Therefore, there is an urgent need to integrate and optimize the entire patient service process, providing real-time intelligent guidance within hospitals. This would help reduce waiting times for patients and enhance their satisfaction.

Objective: This study aims to introduce a patient-centered intelligent guidance system and report on the impact of its implementation on outpatient waiting times and patient satisfaction in hospitals.

Methods: The intelligent guidance system was designed with a patient-centered approach, leveraging internet and big data technologies. The system seamlessly connects various steps of the outpatient medical process, facilitating functions including automated check-in and comprehensive intelligent guidance for patients’ medical visits, thus enhancing the efficiency and quality of health care delivery. This system has been implemented in a tertiary hospital in China. To assess the system’s effectiveness, we compared outpatient visit data, waiting time data, and patient satisfaction levels between the preimplementation and postimplementation periods from 2019 to 2022. We analyzed the changes in patients’ average waiting times and satisfaction levels after the system was implemented.

Results: One year after the introduction of the intelligent guidance system, the number of outpatient visits increased from 5,067,958 to 5,456,151. The waiting time for outpatient patients was significantly reduced. The waiting time for consultation decreased by 2.84 minutes (mean 41.14, SD 2.31 min vs mean 38.30, SD 1.89 min; P<.001). The waiting time for examination decreased by 3.35 minutes (mean 47.83, SD 1.10 min vs mean 44.48, SD 1.67 min; P<.001). Consultation time increased to 3.43 minutes (mean 2.85, SD 0.03 min vs mean 3.43, SD 0.26 min; P<.001). After the system was launched, patient satisfaction increased from 89.99% (SD 2.78%) in 2021 to 92.72% (SD 0.18%) in 2022 (P=.005).

Conclusions: The patient-centered intelligent guidance system reported in this study proved beneficial for tertiary medical institutions striving to alleviate the outpatient burden caused by prolonged waiting times. Through continuous transformation and upgrading of the outpatient service process centered on patients, the efficiency of outpatient services and patient satisfaction

XSL•FO
RenderX

improved. Therefore, the patient-centered principle method and process integration concepts for the system can be further promoted and implemented.

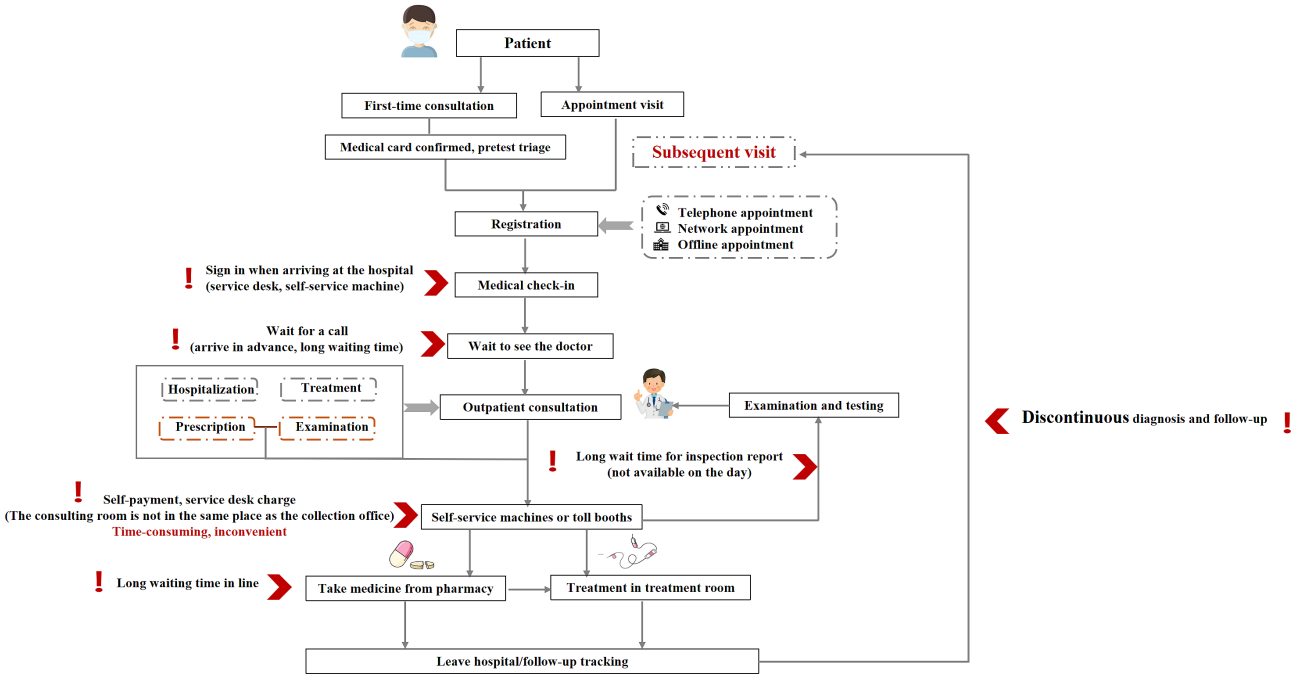
Introduction

Context



With the continuous global development of the economy and society, people have developed higher expectations of their health systems. The World Health Organization (WHO) has proposed that the current health system is a physician-driven system overly focused on disease, neglecting the patient experience, such that nearly half of patients are dissatisfied with the system [1]. Therefore, the WHO proposed the principle of people-centeredness, which aims to create a patient-centered health system. Many countries have actively responded to this principle, including Peru [2], Canada [3], and Germany [4]. Several scholars have conducted research on integrating patient-centered principles into the nursing field [5,6]. Researchers have experimentally compared inpatient care experiences between systems implementing and not implementing patient-centered principles, demonstrating improved service quality and optimized patient experiences [7].

Problem Statement

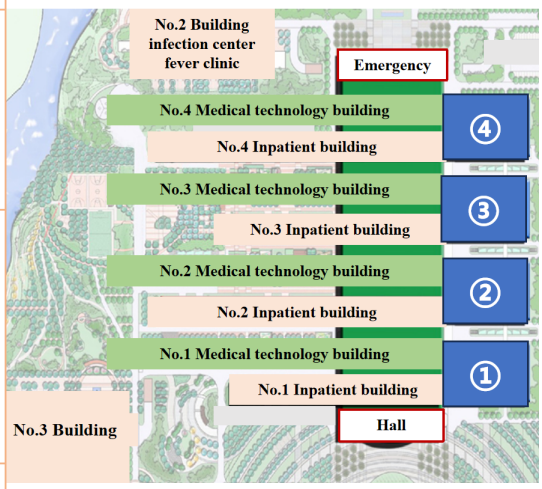
Patient-centered principles remain limited in China due to its vast population and relatively scarce high-quality medical resources. Additionally, China's medical process differs from other nations where strict family doctor first-visit systems manage common illnesses locally and refer complex cases to hospitals [8]. China's hospitals are graded by the government (Levels I, II, and III) [9]. Level I and II hospitals manage common illnesses, while Level III (tertiary) hospitals, equipped with the best resources, handle critical cases [10,11]. Chinese patients choose their hospitals by themselves [12]. Consequently, many Chinese patients seek care for common ailments like colds at large tertiary hospitals, compelling these institutions to handle both minor and serious conditions [13]. This leads to persistent overcrowding and queues.

During observation of a traditional hospital consultation process, most first-time patients exhibited confusion upon arrival (Figure 1). They struggled to locate key departments like consultation rooms or pharmacies, leading to repeated queuing at information desks for staff guidance. This manual consultation dependency significantly prolongs waiting times and wastes patient time. Doctors' consultation times for each patient receiving medical services are shortened accordingly. This leads to a situation in which patients need a long time to register, queue for long periods, take a long time for examinations, and see a doctor for a short amount of time [14]. Excessive waiting times also degrade the patient's experience of care, resulting in decreased satisfaction [15-17].

Figure 1. Traditional outpatient procedures and existing problems.

XSL•FO
RenderX

Similar Interventions



Prolonged outpatient waiting times have been found to lower patient satisfaction across multiple countries, including China, Canada, Malaysia, and the United States [18-20]. Studies have examined patient-centered care principles in China. Surveys assessed patients' perceptions and satisfaction [21], while research explored the application of patient-centered care principles to health care challenges [22]. Analysis of the 2015 China National Patient Survey found these principles improve care quality, efficiency, and satisfaction [23]. Many public tertiary hospitals in China have made numerous attempts at improvement [13]. For example, a public tertiary hospital in Southern China balanced supply-demand interventions by simplifying appointments, regulating doctor attendance, and implementing app-based visit reminders [14]. Postintervention, this hospital reduced patient waiting time by 28.3 minutes (from 179.7 to 151.4 min), while satisfaction scores rose from 89.10 to 90.26 [14]. Other hospitals have optimized outpatient processes by introducing current technologies, such as web-based approaches to health care delivery [24]. Other researchers have designed smart navigation systems to shorten queues [25].

Previous health care reforms typically addressed fragmentary treatment aspects while neglecting overall care pathways and patient habits. For example, underutilized artificial intelligence guidance systems and app-based solutions often exclude older adult patients due to poor accessibility [26]. These fragmented initiatives fail to address the widespread issue of "three long and one short" (long registration, waiting, and payment times, coupled with short consultation times). Although long-term solutions such as equalizing access to high-quality medical resources and implementing a first-visit system are essential, they lack immediate impact. In the short term, optimizing outpatient processes in tertiary hospitals offers a practical approach to reducing wait times and enhancing patient experience.

This report examines the implementation of a patient-centered intelligent guidance system at a large Chinese tertiary hospital (Figure 2 shows its outpatient building and department layout). The report adheres to the iCHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations) (Checklist 1) [27].

Methods

Aims and Objectives

This study evaluated the intelligent guidance system's efficacy in reducing treatment waiting times and improving patient satisfaction. Herein, we discuss the system's development and implementation, then compare waiting time and satisfaction data preimplementation and postimplementation.

Blueprint Summary

The intelligent guidance system, grounded in patient-centered principles, integrates multisource data and smart sensing technologies to streamline the entire treatment process. It features an automatic check-in module and indoor navigation system linked to hospital databases and installed at entrance gates (Figure 3). Using identity recognition for contactless check-in and hybrid Wi-Fi/Bluetooth positioning for real-time tracking, the system analyzes treatment data to deliver personalized navigation routes via SMS text messaging

XSL•FO
RenderX

notifications. It dynamically adjusts guidance based on real-time positioning and treatment progress, ensuring seamless transitions across consultations, examinations, pharmacy visits, and follow-ups until patient departure. The intelligent medical guidance system avoids mandatory app downloads, using SMS text messaging for inclusive notifications [25]. Unlike traditional systems requiring manual input [26,28], it integrates registration, check-in, and examinations, providing real-time updates and automatic route planning (Table 1). It acts as a personal medical assistant, guiding patients throughout their visit.

Figure 3. Upgraded intelligent guidance system.

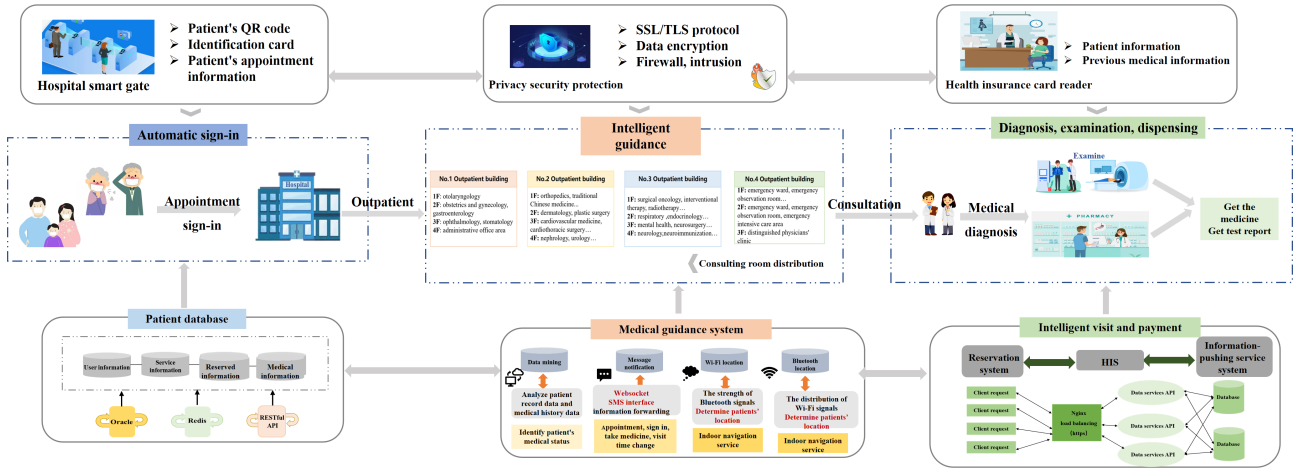

Table . Comparison between traditional guidance systems and intelligent guidance systems.

Category	Traditional guidance systems	Intelligent guidance system
Service acquisition	Download the hospital app or use a specialized device	A phone that can receive text messages
Main function	Simplified functionality: dedicated exclusively to hospital navigation services	Diverse functionalities: assist patients with automatic check-in, link medication pickup, examinations, and treatments, dynamically update patients' medical information in real time, and automatically plan routes to guide them
Features	Noncontinuous service	Continuous service
Principle	Non–patient-centered	Patient-centered

Technical Support for the Intelligent Guidance System

The upgraded system uses a cloud-native microservice system architecture that is convenient for deployment in different environments. Each system is independent and provides better isolation, scalability, ease of maintenance, and other characteristics. The main technology stacks used by the software are Spring Cloud, VUE, Rabbit MQ message queuing, Redis caching, distributed scheduling tasks, Docker, Kubernetes, and DevOps. The cloud-native technology architecture can be used to quickly expand service resources and perform peak business data processing in hospitals. The daily throughput can reach tens of millions, the response time for most requests is in milliseconds, and the data processing capacity can rapidly expand with the amount of data.

Target

The intelligent guidance system was launched in October 2020 at a large tertiary hospital in China and aimed to reduce excessive outpatient waiting times and enhance patient satisfaction. The system provides services to all outpatient patients annually at the hospital. After two years of operation, it has demonstrated initial effectiveness, with subsequent adoption by other tertiary hospitals across China.

Ethical Considerations

This retrospective analysis of fully anonymized hospital operational data received ethical approval from the Ethics Committee of Wenzhou Medical University (approval number 2020 - 075), which explicitly authorized reuse of existing system data without additional consent. Patients retained an opt-out mechanism by rejecting the system's terms through the initial pop-up notification. We are committed to strict confidentiality regarding the personal information and privacy of all research participants, and we have implemented multiple measures to ensure data privacy and security. The collected health and personal data will be stored using industry-standard encryption techniques, and only authorized researchers will have access to these data. All data usage and storage processes will follow strict data management policies to prevent unauthorized access and data breaches. No compensation was provided due to the noninterventional nature of this research using anonymized data.

Data

The intelligent guidance system retrieves real-time patient data, including appointments and Wi-Fi– and Bluetooth-based locations, via the health information system (HIS) interface,

XSL•FO
RenderX

excluding sensitive information. It analyzes patient locations and schedules, generating optimized navigation routes and updating queuing systems upon check-in. Data are securely stored in encrypted local servers and synchronized with the HIS every 10 seconds; anonymized trajectory data are retained for system optimization, while original logs are purged quarterly. Patients access medical records via the hospital portal after ethical approval and informed consent, with security ensured through localized storage, role-based access control, 2-factor authentication, and intranet-restricted analysis. The system interfaces with the HIS, electronic medical record platform, and Internet of Things devices via application programming interface synchronization, enabling real-time updates and anonymized navigation logs for optimization, complying with China's Personal Information Protection Law (Article 28). Patients authorize data usage through electronic agreements, with privacy-by-design principles, encrypted transmission, and strict adherence to data localization (Cybersecurity Law, Article 37) and classified protection (Data Security Law, Article 21).

Interoperability

The intelligent guidance system achieves real-time integration with the hospital's HIS system, synchronizing patient registration and medical information while automatically aligning diagnostic data with optimal treatment pathways. The system supports cross-brand communication devices and navigation terminals, ensuring interoperability across various patient devices within the hospital, thereby enhancing the convenience and accuracy of navigation routes.

Participating Entities

The intelligent guidance system was developed by the IT department of a public hospital. Guided by government policies emphasizing patient service optimization, the hospital's IT center manages HIS integration, enabling secure real-time data exchange across registration, testing, and pharmacy services, along with system maintenance. The outpatient department contributes to route planning and status updates, while the logistics department handles device deployment. Clinical staff provide practical feedback for system improvement, with funding primarily from hospital resources.

Budget Planning

The intelligent guidance system underwent a 12-month development and 3-month pilot deployment. Budget allocation prioritized software and algorithm optimization (50%), covering navigation engine development, HIS integration, and patient interface design. Hardware integration, including Bluetooth beacons and signage, accounted for 20%. Cross-department collaboration received 15%, change management for process updates 10%, and the remaining 5% supported stress testing and patient flow optimization during the pilot phase.

Sustainability

The intelligent guidance system achieves routine operation through integration with the HIS. Financially, initial development was funded by the hospital's IT budget, with sustainable revenue growth realized through enhanced efficiency and increased patient volume. Operationally, the system reduces the need for manual guidance staff, saving human resources while optimizing patient flow and reducing in-hospital stay duration.

Implementation (Results)

Coverage

We used 2019 as the baseline to evaluate waiting times before the system's October 2020 launch, excluding 2020 due to COVID-19 impacts and system buffer time. Data from 2019, 2021, and 2022 were analyzed for waiting time improvements, while 2021 - 2022 data tracked satisfaction trends. Patient satisfaction was measured using structured questionnaires with 5-point Likert scales. Respondents were patients who received treatment at the hospital. After completing all medical consultation procedures, satisfaction questionnaires were automatically pushed by the system. Consultation and examination waiting times for patients aged ≥60 were analyzed separately, though satisfaction data, collected anonymously, lacked age stratification.

The changes in the basic situation of outpatients before and after system optimization and upgrade are summarized in Table 2, which includes the total number of outpatients in 2019, 2020, 2021, and 2022, the sex distribution of outpatients, the age distribution, and the number of examination bills issued in recent years. From 2019 to 2022, the total number of outpatient visits fluctuated. The number of visits increased from 5,067,958 in 2019 to 5,456,151 in 2022. The growth rate during this period was 7.66%. We categorized the patients into the following groups: younger individuals aged 18 years and under, adults aged 19 - 40 years, adults aged 41 - 59 years, and older adults aged ≥60 years. From 2019 to 2022, the number of outpatients in different age groups steadily increased. Patients aged 41 - 59 years accounted for the highest proportion of all outpatients across all study years: 38.6% in 2019, 39.5% in 2020, 40.0% in 2021, 39.5% in 2022. Patients aged 18 accounted for the lowest proportion. The proportion of female outpatients in recent years was generally greater than that of male outpatients. Except for 2020, the proportion of male patients (56%) was higher than the proportion of female patients (44%). The number of invoices also showed an increasing trend from 3,555,896 in 2019 to 3,778,609 in 2022, with a growth rate of 6.26%.

Table . Characteristics of hospital outpatients from 2019 to 2022.

Characteristics	2019	2020	2021	2022
Total patients	5,067,958	4,327,575	5,160,841	5,456,151
Number of invoices	3,555,896	3,075,948	3,665,579	3,778,609
Age group (years), n (%)				
≤18	302,925 (6)	220,846 (5.1)	264,557 (5.1)	277,774 (5.4)
19 - 40	1,563,163 (30.8)	1,283,780 (29.7)	1,538,196 (29.8)	1,542,894 (30)
41 - 59	1,956,001 (38.6)	1,710,187 (39.5)	2,062,394 (40)	2,029,534 (39.5)
≥60	1,245,869 (24.6)	1,112,762 (25.7)	1,295,694 (25.1)	1,292,841 (25.1)
Gender, n (%)				
Male	2,238,480 (44.2)	3,075,948 (56)	2,254,364 (43.7)	2,218,642 (43.9)
Female	2,829,478 (55.8)	2,415,691 (44)	2,906,477 (56.3)	2,829,622 (56.1)

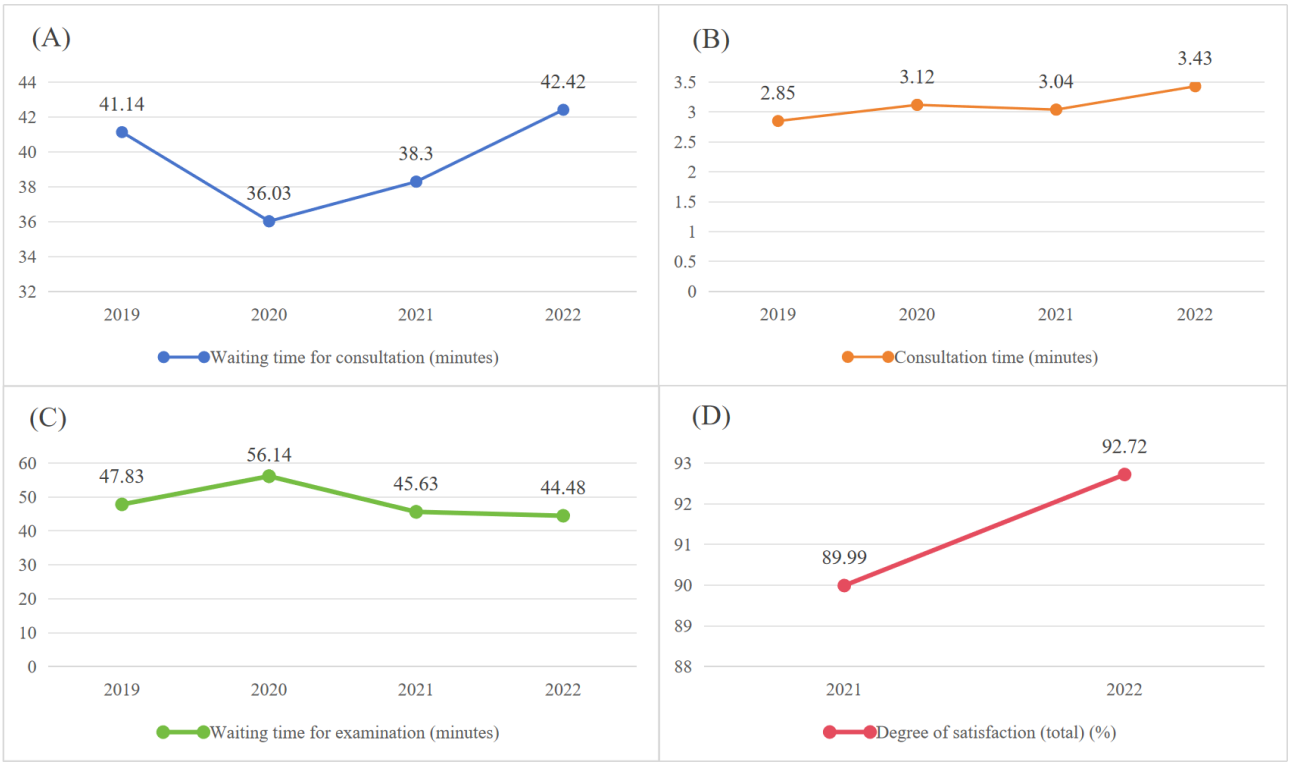
Outcomes

Patient waiting time includes consultation and examination waits. Consultation time is the interval between check-in and doctor login; examination time is the interval between prescription and formal check-in. From 2019 to 2021, overall waiting times decreased: consultation wait times dropped by 3.39 minutes (41.14 to 38.30 min) and examination wait times dropped by 3.35 minutes (47.83 to 44.48 min), while consultation duration increased from 2.85 to 3.43 minutes (Table 3). For patients aged ≥60 years, wait times decreased by 1.82 minutes (42.37 to 40.55 min) and examination wait times decreased by 4.41 minutes (52.04 to 47.63 min), with consultation duration rising from 3.14 to 3.40 minutes (Table 4). Figures 4 and 5 visualize these trends. After optimization and upgrading of the system, patients' satisfaction with the outpatient process continued to improve, and overall satisfaction increased from 89.99 in 2021 to 92.72 in 2022 (P=.005). Figure 4 more clearly visualizes the change in waiting time and the change in satisfaction.

Table . Total patient wait times and satisfaction from 2019 to 2022.

Study phase	2019, mean (SD)	2020, mean (SD)	2021, mean (SD)	2022, mean (SD)	F test (df)	P value
Waiting time for consultation (minutes)	41.14 (2.31)	36.03 (2.78)	38.30 (1.89)	42.42 (2.31)	17.974 (3)	<.001
Waiting time for examination (minutes)	47.83 (1.10)	56.14 (13.34)	45.63 (1.67)	44.48 (1.56)	7.219 (3)	<.001
Consultation time	2.85 (0.03)	3.12 (0.31)	3.04 (0.96)	3.43 (0.26)	16.198 (3)	<.001
Degree of satisfaction (total)	—[a]	—	89.99 (2.78)	92.72 (0.18)	9.981 (11.09)[b]	.005

[a]Not applicable.



[b]Degrees of freedom are presented as decimals due to the use of Welch ANOVA correction for violation of the homogeneity of variances assumption (Levene test, P<.05). Standard ANOVA results are reported when assumptions were met.

Discussion

Principal Findings

Applying patient-centered principles, our study transformed a tertiary hospital's medical service process through an intelligent guidance system. This mobile-guided system integrates admission, waiting, and examinations, significantly reducing queues and exam waits while extending consultation times and improving outpatient satisfaction.

Reduced patient waiting times, this reform's primary outcome, align with multiple intervention studies. South Korean physicians used queuing theory to achieve a 30% reduction in outpatient waiting times [20]. A New York pediatric clinic reduced waiting times by 3.2-8.8 minutes through targeted interventions [29]. In China, a tertiary hospital streamlined nonemergency registrations, cutting waiting times from 25.05 to 1.00 minutes [13]. Another redesigned its outpatient pharmacy, halving prescription pickup times from 1 hour to 30 minutes [30]. Similarly, a hospital implementing artificial intelligence–assisted consultations reduced median waiting times from 1.97 to 0.38 hours [31]. However, the waiting time for visits in 2022 increased by 1.28 minutes compared to 2019. The system initially went live in 2020, and the time was reduced in 2021. Considering the huge demand for high-quality medical resources and support for system optimization, the hospital opened more appointments in the same time frame. In the future, after further improvement of the system, it is hoped that the number of tertiary hospitals included will continue to expand in stages to meet the medical needs of more patients.

Another significant benefit of implementing the intelligent guidance system was the increase in the duration of patient consultation time. Consultation time is a crucial factor as it influences the quality of care and patient satisfaction [32-34]. Notably, extending consultation time may enhance satisfaction more substantially than reducing waiting time [9]. Consultation time in Sweden is 10 - 20 minutes [35]. Research conducted in the United States indicated that the average consultation time ranges from 10 to 15 minutes [36]. At a tertiary hospital in China, the average consultation time in 2017 was 6.52 minutes. Globally, consultation durations remain consistently shorter than patient waiting times despite cross-country variations. One hospital even reported reduced consultation times postreform, decreasing from 6.52 to 3.12 minutes [14]. Our smart guidance system progressively extended consultation time. This improvement stemmed from streamlined registration and navigation processes, which reduced missed appointments and clinic crowding, freeing physicians to concentrate on clinical consultations rather than on maintaining order.

Patient satisfaction serves as a crucial gauge of health care quality [37]. A study conducted in Canada demonstrated a significant association between waiting time and patient satisfaction, reporting an odds ratio of 0.92 (95% CI 0.86 - 0.98; *P*=.01) [38]. Nonphysician tasks like registration and pharmacy services prolong wait times, thus reducing patient satisfaction given the inverse wait time/satisfaction relationship [17,39,40]. Our research findings are consistent with this. Tertiary hospitals tend to occupy large areas and have many campuses and buildings. Even when landmarks and walls indicate their locations, patients often get lost in hospitals [41]. The intelligent navigation system addresses this by guiding patients to their appointments, embodying patient-centered care. It significantly boosts satisfaction.

This study demonstrates the significant effectiveness of applying an intelligent guidance system to optimize patient flow in a tertiary hospital, with this experience holding clear generalizability for other tertiary hospitals facing similar challenges such as high patient volume, complex spatial layouts, and prolonged waiting times. The system's core logic—integrating admission check-in, treatment waiting, and examination scheduling with precise mobile guidance—combined with its modular design, can be directly implemented in other large tertiary hospitals to efficiently optimize patient visit processes. Sustainability relies on routine maintenance rather than continuous technical investment, while reduced waiting times increase throughput, allowing more appointments within existing time frames to boost revenue. For successful adoption, hospitals must preserve traditional channels for older adult patients, implement phased pilots starting with high-volume departments, and thoroughly evaluate local contexts including digital capabilities, regional disparities, and patient demographics before staged adaptation.

Limitations and Lessons Learned

The implementation phase consistently presented the greatest challenges, aligning with common industry observations. First, indoor positioning inaccuracies occasionally caused patient navigation errors, requiring supplementary staff guidance that diminished expected efficiency gains. Second, challenges in reaching all patient groups remained, particularly older adults. Despite including features like SMS text message reminders to help bridge the gap, a significant "digital divide"persisted. Most older adult patients preferred traditional methods like physical queuing or in-person assistance. This lower adoption rate among older adults meant the system could not deliver its intended benefits equally to everyone. Future work will tailor research and designs specifically for older adult patient adoption. Finally, deep integration with complex hospital systems caused intermittent interface instability and data synchronization delays, impacting workflow accuracy. During high patient volumes, peak-hour response delays exposed deficiencies in initial stress testing and capacity planning.

Nevertheless, methodological limitations warrant caution. Unadjusted confounders such as departmental variations may partially explain outcomes. For example, the Obstetrics, Surgery, and Cardiology departments face longer waits due to complex workflows. Visit type differences also exist, where initial consultations require more time than follow-ups. Temporal factors like peak-hour or weekday clinics with higher volumes further complicate analysis. Satisfaction surveys incurred self-selection bias as anonymously distributed mobile questionnaires prevented response rate tracking, restricting analysis to voluntary respondents who systematically differ from nonrespondents. Although age, sex data, and wait times for those aged ≥60 years were documented, key potential confounders including education level, digital literacy, and visit

XSL•FO
RenderX

type lacked statistical control. Consequently, outcome associations may be confounded despite standardized HIS metrics, hindering the exploration of variables influencing system usage. Future studies need stratified randomization, multivariable adjustment, and enhanced response strategies to isolate intervention effects.

Conclusions

The WHO advocates patient-centered care to improve medical experiences. Implementing intelligent guidance systems alleviates outpatient issues like prolonged queuing, excessive waits, and low satisfaction through continuous service. This model offers global reference value, particularly for China and similar settings, by upgrading processes with intelligent technologies to reduce waits and increase satisfaction.

Acknowledgments

Drs. Chun Chen and Xiangyang Zhang contributed equally as corresponding authors to the supervision, coordination, and correspondence of this study. We would like to thank the First Affiliated Hospital of Wenzhou Medical University for their assistance and support with the field research. Abstract

Background: The Computerized Digit Vigilance Test (CDVT) is a well-established measure of sustained attention. However, the CDVT only measures the total reaction time and response accuracy and fails to capture other crucial attentional features such as the eye blink rate, yawns, head movements, and eye movements. Omitting such features might provide an incomplete representative picture of sustained attention.

Objective: This study aimed to develop an artificial intelligence (AI)–based Computerized Digit Vigilance Test (AI-CDVT) for older adults.

Methods: Participants were assessed by the CDVT with video recordings capturing their head and face. The Montreal Cognitive Assessment (MoCA), Stroop Color Word Test (SCW), and Color Trails Test (CTT) were also administered. The AI-CDVT was developed in three steps: (1) retrieving attentional features using OpenFace AI software (CMU MultiComp Lab), (2) establishing an AI-based scoring model with the Extreme Gradient Boosting regressor, and (3) assessing the AI-CDVT's validity by Pearson *r* values and test-retest reliability by intraclass correlation coefficients (ICCs).

Results: In total, 153 participants were included. Pearson *r* values of the AI-CDVT with the MoCA were −0.42, −0.31 with the SCW, and 0.46–0.61 with the CTT. The ICC of the AI-CDVT was 0.78.

Conclusions: We developed an AI-CDVT, which leveraged AI to extract attentional features from video recordings and integrated them to generate a comprehensive attention score. Our findings demonstrated good validity and test-retest reliability for the AI-CDVT, suggesting its potential as a reliable and valid tool for assessing sustained attention in older adults.

KEYWORDS

artificial intelligence; assessment; cognition; age-friendly; attention

Introduction

Sustained attention can be defined as a state of readiness to detect and respond to certain changes in the environment that occur at random intervals over extended periods of time [1,2]. The effects of aging on sustained attention are complex; while some aspects of attention may decline, some studies suggested that older adults can maintain more stable performance on certain vigilance tasks than their younger counterparts [3,4]. This phenomenon is not thought to reflect general superiority but rather several factors, including that older adults report fewer task-unrelated thoughts (ie, less mind-wandering) [5,6] and adopt a more cautious, top-down response strategy that prioritizes accuracy over speed. Research indicated that the performance and variability of sustained attention in older adults are related to frailty and fall risks [7,8]. Consequently, monitoring sustained attention in older adults could be an effective way to manage the health of older adults.

XSL•FO
RenderX

The Computerized Digit Vigilance Test (CDVT) is a widely used measure of sustained attention with established reliability and validity [9,10]. However, like many traditional cognitive tests, it relies on a single modality of data, performance metrics (ie, reaction time and accuracy). This unimodal approach overlooks a rich stream of behavioral data that contains valuable information about a person's attentional state. For instance, subtle increases in the blink duration, downward gaze shifts, and slight head drooping are all well-documented physical manifestations of waning vigilance and attentional lapses [11-14]. By failing to capture these overt behaviors, the test's reliability is constrained, as fluctuations in reaction time alone might not fully or consistently reflect an individual's true attentional state.

The concept of using automated, vision-based systems to infer cognitive states from behavioral cues is well-established in other fields. For instance, in transportation safety, extensive research has focused on developing systems that monitor driver vigilance by analyzing features like the blink rate, gaze direction, and head pose to detect drowsiness and prevent accidents [15,16]. Similarly, in educational technology and human-computer interactions, computer vision techniques are used to assess student engagement and cognitive load by tracking similar behavioral markers [17,18]. These applications demonstrate the value of using objective, observable behaviors as proxies for internal attentional states. However, despite success in these domains, this multimodal approach has seen limited application in enhancing standardized clinical neuropsychological assessments, particularly for older adults.

Artificial intelligence (AI) offers a promising approach to analyze facial features [19,20], potentially providing valuable supplementary data for attention assessments [11]. AI-powered software can directly extract attentional features, such as the eye blink rate, yawn frequency, head rotation, and eye movements, from images or videos of faces [19,20]. Traditionally, collecting these features required specialized equipment such as eye trackers or virtual reality headsets [11]. AI-based software offers a more cost-effective and feasible alternative for collecting attentional data [19,20], particularly in clinical settings and for older adult populations.

In this study, we attempted to bridge this gap by leveraging AI to integrate these disparate data streams. AI, particularly machine learning models, is exceptionally well-suited for this task because it can learn complex, nonlinear patterns from multimodal data, automatically determining the optimal weight to assign each feature—from reaction time to eyelid distance—to produce a single, comprehensive score. Therefore, in this study, we attempted to enhance the psychometric properties of the CDVT by integrating an additional modality of data. We developed an artificial intelligence–based Computerized Digit Vigilance Test (AI-CDVT) that uses machine learning to combine traditional performance metrics with facial and behavioral features captured on video. The primary hypothesis was that by creating a more comprehensive, multimodal assessment, we could improve the test-retest reliability of the measure while maintaining its convergent validity.

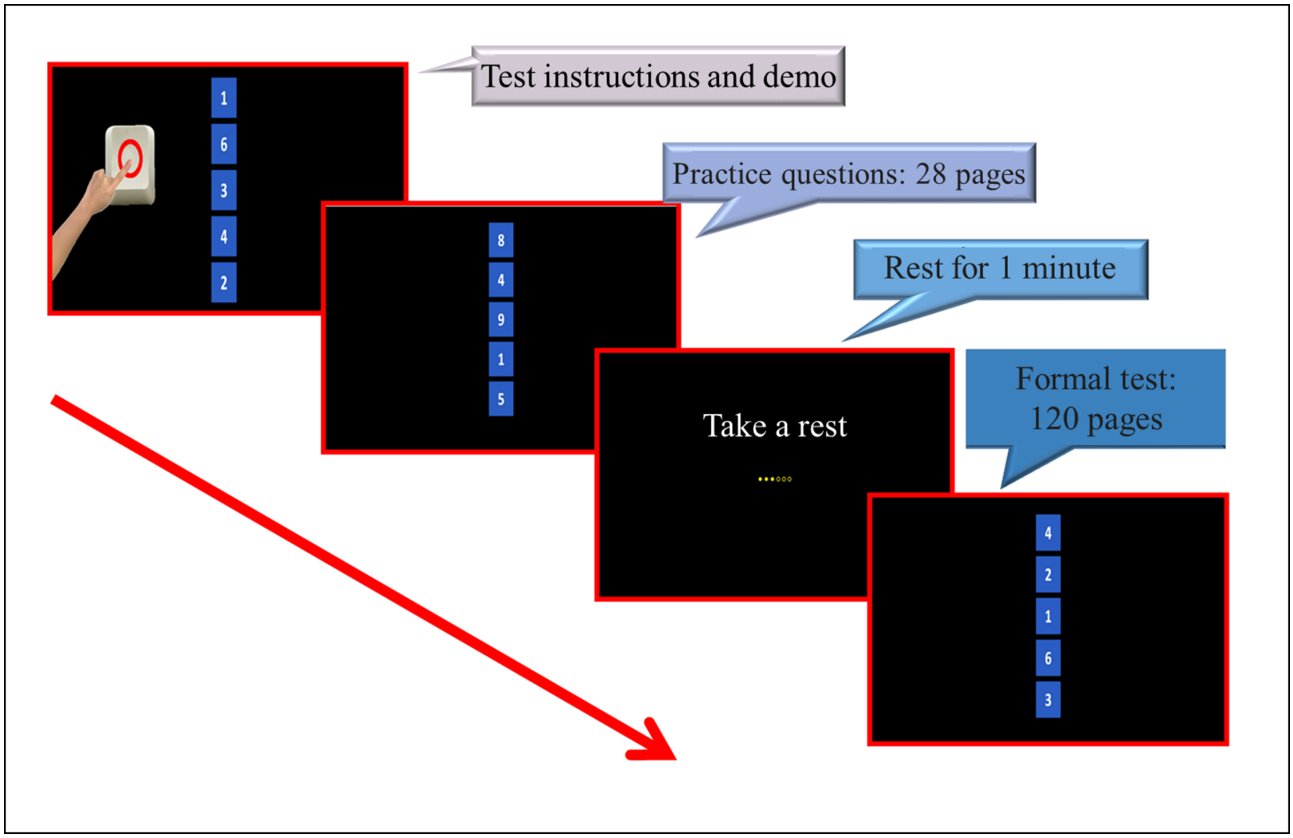
Methods

Participants

Participants were recruited via convenience sampling from community care centers in Taiwan. A member of the research team visited these centers, provided an oral presentation to groups of older adults explaining the study's purpose and procedures, and invited interested individuals to enroll. Participants were eligible if they met the following criteria: (1) aged 65 years or older, (2) having had no hospitalization in the past 6 months, and (3) willing to participate in the study. Exclusion criteria were a doctor-diagnosed disability or an unwillingness to record videos during the CDVT assessment.

Procedures

This study consisted of 2 waves of data collection. In the first wave, participants were assessed once to gather cross-sectional data. Assessments included the CDVT and Montreal Cognitive Assessment (MoCA) [21]. In the second wave, participants were assessed twice, with a 2-week interval between assessments, to collect test-retest data. Both assessments involved the CDVT and MoCA. Additionally, in the first assessment, the Stroop Color Word Test (SCW) [22] and both parts of the Color Trails Test (CTT) [23] were assessed. At the start of the first assessment session for each participant, a trained assessor administered a brief questionnaire to collect demographic information, including age, sex, and educational attainment (Multimedia Appendix 1). Each participant was individually assessed by a trained assessor in a quiet, one-on-one setting at a community care center. All assessments were conducted on a laptop computer with a 15.6-inch screen, an Intel i5 processor, 8 GB of DDR4 RAM, and a GTX 950 graphics card. Participants were seated approximately 50 cm from the screen. Video recordings capturing participants' heads and faces were obtained using the laptop's built-in HD webcam (1.3 megapixels) during CDVT assessments.



Measures

Computerized Digit Vigilance Test (CDVT)

The CDVT is a computer-based test designed to assess sustained attention. Participants use 2 buttons (a circle and an X) to respond to the presence of the numeral "6" on the screen (Figure 1). The test records response times and errors to evaluate sustained attention, with shorter times indicating better focus. Studies showed good validity and reliability of the CDVT in patients with stroke and schizophrenia [9,10].

XSL•FO
RenderX

Figure 1. Computerized Digit Vigilance Test process and items.

Montreal Cognitive Assessment (MoCA)

The MoCA is a cognitive screening tool used to assess various cognitive domains in older adults. The MoCA evaluates short-term memory, visuospatial abilities, executive functions, attention, concentration, working memory, language, and orientation. The total score on the MoCA is 30, with a higher score indicating better cognitive performance. The MoCA demonstrated good validity and reliability in older adults [24,25]. Further details on the instrument and its authorized use are provided in Multimedia Appendix 1.

Stroop Color Word Test (SCW)

The SCW is a neuropsychological assessment tool used to evaluate cognitive function, particularly attention and executive functioning. During the SCW, participants are presented with a list of color words printed in incongruent font colors (eg, “RED” printed in blue). Participants are asked to verbally name the color of the font, inhibiting the prepotent response of reading the word itself. Faster completion times on the SCW are indicative of better attention and executive functioning. Good reliability and validity of the SCW were reported in older adults [26]. The specific version used in this study is cited in Multimedia Appendix 1.

Color Trails Test (CTT)

The CTT is a language-free version of the Trail Making Test, designed to measure sustained attention and divided attention in adults. The CTT involves connecting circles in an ascending numbered sequence (from 1 to 25) in the CTT1 and alternating between pink and yellow colors while connecting numbers in ascending order in the CTT2. Numbers are presented twice, once in pink and once in yellow, requiring the client to consecutively follow the sequence while avoiding the same color in a row. The time taken to complete each part of the CTT is recorded in seconds. Good reliability of the CTT was determined in older adults [27]. The specific version used in this study is cited in Multimedia Appendix 1.

Data Analysis

To determine whether the AI-CDVT can evaluate participants’ attention according to their facial videos and CDVT output, we developed the AI-CDVT in 3 steps, retrieving attentional features, establishing an AI-based scoring model, and validating the AI-CDVT. In the first step, we adopted OpenFace (CMU MultiComp Lab) [28] to retrieve attentional features from a participant’s face in videos. Attentional features were extracted from each video frame. The eight primary features included: (1-2) the distance between the eyelids for each eye, serving as a continuous measure of eye openness (a smaller distance indicates greater closure, as a proxy for blinks); (3) the distance between the lips, indicating mouth opening or yawning; (4 - 6) head rotation angles across 3 axes, corresponding to pitch (nodding), yaw (side-to-side rotation), and roll (ear-to-shoulder tilt); and (7-8) the X-Y coordinates of the estimated gaze point. For each of the 120 trials in the CDVT, we aggregated the frame-by-frame data by calculating the mean value for each of these 8 features. Within any given trial, video frames where OpenFace failed to successfully track facial features were excluded from this calculation; the mean was computed only from the successfully captured frames. Furthermore, because the CDVT is a computerized test that requires a response before proceeding to the next item, there were no missing test items. This process yielded a single value per feature for each trial.

XSL•FO
RenderX

Finally, we calculated the overall mean and SD of these 120 trial-level values for each feature. These 16 summary statistics (8 features×2 statistics), along with the mean and SD of the reaction time and response accuracy from the original CDVT, constituted the final set of 20 input features for the AI model. All input features were normalized to a common scale before being used in the model.

In the second step, we adopted an AI algorithm, the Extreme Gradient Boosting (XGBoost) regressor [29], to receive inputs of attentional features and estimate scores of the CDVT as scores of the AI-CDVT. The XGBoost regressor leverages the aggregation of random forest regressors to improve the predictive accuracy and has been successfully used in medication situations [29]. In addition, the XGBoost regressor offers an importance ranking of attentional features to generate AI-CDVT scores.

In the third step, we validated the AI-CDVT using a 3-fold cross-validation procedure [30]. In this procedure, we randomly separated our data into 3 subdatasets. Then, we validated the AI-CDVT 3 times. For each validation instance, we used 2 subdatasets to train the XGBoost regressor and used the remaining subdataset to validate the convergent validity and test-retest reliability. Notably, a different subdataset was used each time for validation.

Then, we calculated the mean and SD of the indices of validity across the 3 validation times. The convergent validity was examined using Pearson *r* values to evaluate associations between AI-CDVT scores and those of the MoCA, CTT, and SCW. In addition, we also calculated Pearson *r* values between CDVT scores and those of the MoCA, CTT, and SCW. If Pearson *r* values of the AI-CDVT were similar to those of the CDVT, the convergent validity of the AI-CDV was considered good [31].

The test-retest reliability was examined using an intraclass correlation coefficient (ICC) to evaluate the agreement of scores in the test and retest assessment sections. An ICC value of > 0.75 indicates good test-retest reliability [32].

Finally, to provide a more rigorous evaluation of the AI-CDVT's clinical utility beyond correlational metrics, we conducted a supplementary classification analysis. The goal was to determine whether the multimodal features captured by the AI-CDVT offered incremental value in predicting a clinically relevant outcome. We used the MoCA score as a proxy for the cognitive status, dichotomizing participants into 2 groups based on the common clinical cutoff for potential cognitive impairment "at risk" (MoCA score ≤25) and "not at risk" (MoCA score >25). We then compared the performance of the 2 XGBoost classification models in predicting this binary outcome. The first model ("CDVT-Only") used only the mean reaction time and mean accuracy from the CDVT as input features. The second model ("AI-CDVT Top 5") used the 5 most important features identified in our initial regression model (see Table 1), which included a mix of performance and facial metrics. Specifically, these top 5 features were the mean reaction time, the mean distance between the right eyelids, the mean Y coordinate of the gaze point, the mean accuracy, and the mean angle of head rotation in the Y axis (yaw). Model performance was evaluated using the accuracy and F_1-score across the same 3-fold cross-validation procedure.

XSL•FO
RenderX

Table . Rank of importance of attentional features in the artificial intelligence–based Computerized Digit Vigilance Test.

Rank	Attentional feature
1	Mean of the reaction time
2	Mean of the distance between the right eyelids
3	Mean of the Y coordinate of the gaze point
4	Mean of the accuracy
5	Mean of the angle of head rotation in the Y axis (yaw)
6	SD of the Y coordinate of the gaze point
7	SD of the distance between the right eyelids
8	Mean of the distance between the left eyelids
9	SD of the angle of head rotation in the Z-axis (roll)
10	SD of the X coordinate of the gaze point
11	Mean of the angle of head rotation in the Z-axis (roll)
12	Mean of the distance between the lips
13	Mean of the angle of head rotation in the X-axis (pitch)
14	SD of the accuracy
15	SD of the distance between the lips
16	SD of the angle of head rotation in the X-axis (pitch)
17	SD of the distance between the left eyelids
18	Mean of the X coordinate of the gaze point
19	SD of the angle of head rotation in the Y-axis (yaw)
20	SD of the reaction time

Ethical Considerations

This study was approved by an institutional review board (Taipei Medical University, approval number: N202010008), and all participants provided written informed consent. Participants received a small honorarium of a gift voucher equivalent to US $3 for their time and participation. The informed consent process explicitly detailed the nature of the video recording and its purpose. To ensure data privacy and confidentiality, all video data were stored on an encrypted, offline hard drive. The raw video files were permanently deleted immediately after the deidentified facial features were extracted by OpenFace software, and only these numerical, nonidentifiable data points were retained for analysis.

Results

In total, 153 participants were used for the cross-sectional data (n=87) and test-retest data (n=66). In the cross-sectional data, the average age of participants was 70.8 years, and most of them were female (64/87, 73.6%). In general, they had no cognitive impairment according to the average MoCA score (25.5, SD 2.8). Characteristics of the test-retest data were similar to those of cross-sectional data, as there were no significant differences between them. Table 2 shows further information on these characteristics.

XSL•FO
RenderX

Table . Demographic and baseline cognitive characteristics of study participants.

Variable	Cross-sectional data (n=87)	Test-retest data (n=66)	*t* test or chi-square (*df*)	*P* value
Age (years), mean (SD)	70.8 (5.9)	72.4 (5.9)	1.66 (151)	.10
Sex (male), n (%)	64 (73.6)	49 (74.2)	.009 (1)	.92
Educational level, n (%)			6.06 (4)	.19
Graduate school	6 (6.9)	5 (7.6)		
University	37 (42.5)	17 (25.8)		
High school	32 (36.8)	36 (54.5)		
Junior high school	6 (6.9)	3 (4.5)		
Elementary school	6 (6.9)	5 (7.6)		
MoCA[a], mean (SD)	25.5 (2.8)	25 (3.3)	1.01 (151)	.31
CDVT[b], mean (SD)	239.6 (25.2)	247.3 (26.8)	1.82 (151)	.07
AI-CDVT[c], mean (SD)	239.2 (24.6)	247.3 (27)	1.93 (151)	.06

[a]MoCA: Montreal Cognitive Assessment.

[b]CDVT: Computerized Digit Vigilance Test.

[c]AI-CDVT: artificial intelligence–based Computerized Digit Vigilance Test.

Pearson *r* values of AI-CDVT scores with external criteria were −0.42 (SD 0.19) with the MoCA score, −0.31 (SD 0.16) with the SCW score, 0.46 (SD 0.17) with CTT1 score, and 0.61 with CTT2 scores, and. Pearson *r* values of the AI-CDVT were similar to those of the CDVT. Specifically, Pearson *r* values between the CDVT score and external criteria scores were −0.41 (SD 0.17), −0.29 (SD 0.10), 0.44 (SD 0.21), and 0.55 (SD 0.15), respectively.

The average ICC of the AI-CDVT was 0.78 with a range of 0.68 - 0.84 according to 3-fold cross-validation (Table 3). Similar results were found for the CDVT, for which the average ICC was 0.71 with a range of 0.64 - 0.76.

Table . Test-retest reliability of the artificial intelligence–based Computerized Digit Vigilance Test (AI-CDVT) and original Computerized Digit Vigilance Test (CDVT) over a 2-week interval.

Performance metric	CDVT	AI-CDVT
Cross-validation: Fold 1, ICC[a] (95% CI)	0.72 (0.44 - 0.87)	0.84 (0.67 - 0.93)
Cross validation: Fold 2, ICC[a] (95% CI)	0.76 (0.5 - 0.89)	0.81 (0.61 - 0.92)
Cross validation: Fold 3, ICC[a] (95% CI)	0.64 (0.32 - 0.83)	0.68 (0.27 - 0.87)
Average across 3-fold cross validation, mean (SD)	0.71 (0.06)	0.78 (0.09)

[a]ICC: intraclass correlation coefficient.

In the supplementary classification analysis, the model using the top 5 AI-CDVT features demonstrated improved performance in predicting the cognitive status (MoCA ≤25) compared to the model using only traditional CDVT metrics. Specifically, the AI-CDVT Top 5 model achieved an average accuracy of 58.9% and an F_1-score of 50.6% across the 3 folds. This represents a modest improvement over the CDVT-only model, which scored an accuracy of 57.5% and an F_1-score of 48.6%.

Importance values of attentional features of the AI-CDVT are listed in Table 1. The top 5 most important attentional features were the mean of the reaction time, the distance between the right eyelids, the Y coordinate of the gaze point, mean of the accuracy, and the horizontal rotation angle of the head (Table 1).

Discussion

Principal Findings

The primary rationale for developing the AI-CDVT was to determine if integrating multiple, objective behavioral data streams could enhance the psychometric robustness of a standard sustained-attention test. While the AI-CDVT did not shorten the test's administration time nor demonstrate superior correlations with external cognitive measures, our findings support the study's main hypothesis: the AI-CDVT achieved a notable improvement in the test-retest reliability while maintaining convergent validity comparable to the original CDVT. This suggests that by capturing a richer, multimodal snapshot of an individual's attentional state, the AI-CDVT offers a more stable and reliable assessment tool.

XSL•FO
RenderX

Compared to the CDVT, the AI-CDVT demonstrated equivalent validity and improved test-retest reliability. This enhanced reliability might be attributed to the incorporation of additional attentional features in the AI-CDVT [33,34]. By incorporating a broader range of attentional features, AI-CDVT scores likely benefited from greater stability and robustness. The AI-CDVT score may be less vulnerable to fluctuations solely due to response speed or accuracy. The findings suggest that incorporating a wider range of attentional features during assessments can lead to more reliable scores.

While the AI-CDVT's convergent validity correlations were similar to those of the original CDVT, its primary clinical and functional value lies not in superior predictive accuracy but in its enhanced psychometric robustness and the potential for a more nuanced interpretation of attentional performance. The improved test-retest reliability, for example, is a direct clinical benefit, as it provides a more stable and trustworthy score for longitudinal monitoring or evaluating intervention effects [32]. Furthermore, by capturing a wider array of behaviors like gaze shifts and eyelid closure, the AI-CDVT provides a richer dataset. This could allow clinicians to move beyond a single performance score to understand the underlying nature of an individual's attentional difficulties, distinguishing, for instance, between general cognitive slowing and specific lapses in vigilance [33]. This multimodal approach offers a more holistic view of sustained attention [34], paving the way for future research into distinct behavioral phenotypes of attentional decline that are invisible to traditional, response-time-based measures.

The results of our supplementary classification analysis warrant careful interpretation. The modest improvements (1.4% in accuracy and 2.0% in F_1-score), while not dramatic, provide a crucial proof-of-concept. They suggest that the multimodal features captured by the AI-CDVT contain a small but detectable signal that is relevant to clinical outcomes (ie, potential cognitive impairment as flagged by the MoCA). This finding lends support to our central hypothesis that integrating objective behavioral markers, even if their individual predictive power is small, can incrementally enhance the clinical utility of a traditional cognitive test. While the immediate clinical impact of this gain is limited, it establishes a methodological foundation for future work. It is plausible that this incremental value could be magnified in larger, more clinically diverse samples or by using more advanced machine learning architectures, highlighting a promising avenue for subsequent research.

It is important to appropriately position the contribution of this study. We did not develop a new AI algorithm from the ground up; rather, our innovation lies in the practical application and integration of established, open-source tools (OpenFace and XGBoost) to enhance a standard clinical assessment. The novelty of this work is therefore not in a deep methodological invention but in demonstrating the feasibility and clinical utility of creating a multimodal assessment of sustained attention. By showing that combining behavioral response data with easily captured facial metrics can improve psychometric properties like reliability, this study provides a proof-of-concept and a methodological template for other researchers aiming to enrich traditional neuropsychological tests with objective, behavioral data streams.

Comparison to Prior Work

By leveraging the flexibility of AI models, such as XGBoost regressors, the AI-CDVT can potentially address the challenge of interpreting individual attentional features in isolation [35]. For instance, directly comparing attention between individuals with high accuracy but slow response times and those with lower accuracy but faster responses can be difficult [36]. The AI-CDVT illustrates a viable method for integrating and interpreting various attentional features into a unified score for future studies and attentional tests.

A related methodological consideration is the selection of the 20 input features. This set was not chosen arbitrarily. Each feature was included because it had been identified in the existing scientific literature as a physiological or behavioral marker related to attention and vigilance [11,12,37]. Our approach was to build a comprehensive model based on these established, theory-driven features. While this could introduce redundancy between some inputs (eg, left and right eyelid distance), the chosen XGBoost algorithm is robust to such multicollinearity, as it inherently performs feature selection during its training process [38]. The final feature importance rankings in Table 1 are a direct result of this process, demonstrating how the model itself identified the most valuable contributors from the initial set of theory-driven features.

An examination of the feature importance rankings (Table 1) provides insights into how the AI-CDVT achieves its robust performance. While traditional metrics like reaction time and accuracy are unsurprisingly the most critical predictors, the model also heavily weighs physiological and behavioral markers. For example, the "distance between the eyelids" emerged as a top feature. This is consistent with literature linking decreased eyelid aperture and blink rate dynamics to drowsiness and lapses in vigilance [39]. Similarly, the "Y coordinate of the gaze point" was highly predictive, likely because a downward shift in gaze is a well-established behavioral marker of task disengagement and mind-wandering [40,41]. The inclusion of these features allows the AI-CDVT to capture subtle, moment-to-moment fluctuations in attentional states that are not reflected in response times alone, thereby providing a more comprehensive and ecologically valid assessment.

A final consideration is the interpretability of the AI model, which is a critical factor for its clinical adoption [42,43]. Complex models like XGBoost are often termed "black boxes" because they do not produce a simple, transparent formula in the way a linear regression model can [44]. There is an inherent tradeoff between the high predictive accuracy of such models and their direct interpretability [45]. In this study, our primary tool for interpretation is the feature importance table (Table 1). While it does not explain how the features are combined for any single individual, it provides clinicians with a clear and valuable understanding of what the model is paying attention to [46]. It confirms that the AI-CDVT's score is driven by a combination of performance metrics and behavioral patterns (eg, eye closure and gaze aversion) that are clinically consistent

XSL•FO
RenderX

with inattention. This allows clinicians to trust that the model's logic aligns with established knowledge, even if the precise weighting algorithm remains complex [47,48].

Limitations

This study has several notable limitations. First, the generalizability of our findings is constrained by the characteristics of our sample. The study included cognitively healthy older adults with MoCA scores in a narrow range, limiting the applicability of the results to clinical populations with cognitive impairments. Furthermore, the sample was predominantly female (64/87, 73.6%), raising concerns about potential gender bias in the AI model's performance [49]. The test-retest reliability analysis was also based on a relatively small subset (n=66), which warrants caution in the interpretation of ICC values until replicated with a larger sample.

Second, the scope of our validation methodology was limited. The model's performance was evaluated using internal cross-validation; the lack of an external validation with an independent dataset means that the model's generalizability remains to be confirmed. Our psychometric evaluation also focused primarily on correlational and reliability metrics. Other key psychometric properties, such as responsiveness to change, were also not assessed.

Finally, it is important to acknowledge a conceptual limitation regarding what is being measured. The facial and behavioral metrics captured by the AI-CDVT, such as eye closure, are well-established proxies for vigilance. However, they are not direct measures of underlying cognitive processes. Therefore, the observed correlations with cognitive tests should be interpreted as a relationship between observable behaviors and cognitive performance, not as evidence that the AI-CDVT measures cognition in the same way as traditional tests.

Future Directions

Building on these findings, future research should prioritize several key areas. First, the AI-CDVT must be validated in a larger, more diverse cohort, specifically including a more balanced gender representation and a wider range of cognitive abilities, to address the limitations of our current sample. Second, external validation on an independent dataset is essential to confirm the model's generalizability. Third, its utility in clinical populations, such as individuals with mild cognitive impairment or dementia, should be explored to determine its diagnostic and monitoring potential. Finally, longitudinal studies are needed to assess other key psychometric properties, such as responsiveness to change over time or in response to an intervention.

Conclusions

The objective of this study was to address a key psychometric weakness in a standard test of sustained attention by transforming it from a unimodal to a multimodal assessment. We demonstrated that using accessible AI tools to integrate objective behavioral data with traditional performance metrics, and we developed an AI-CDVT with superior test-retest reliability compared to the original version, while maintaining its convergent validity. The primary contribution of this work is not the development of a novel algorithm, but the demonstration that the psychometric robustness of established clinical tools can significantly be enhanced through this multimodal approach. The resulting AI-CDVT represents a more stable and reliable instrument for assessing sustained attention in older adults.

Funding

This work was supported by the National Science and Technology Council, Taiwan (112 - 2314-B-038 - 056). The funder had no role in the design, data collection, data analysis, or reporting of the study.

Disclaimer

During the preparation of this manuscript, the authors used a large language model (LLM) to assist with initial language polishing. Subsequently, the manuscript was professionally reviewed by an English-language editor to improve clarity and readability. The LLM was not used for data analysis, data interpretation, or for generating the core scientific arguments of the paper. All content was reviewed and edited by the authors, who take full responsibility for the final version of the manuscript.

Data Availability

The deidentified numerical dataset generated and analyzed during the current study is available from the corresponding author on reasonable request.

Abstract

Background: Cardiovascular disease (CVD) remains a leading cause of preventable morbidity and mortality, highlighting the need for early risk stratification in primary prevention. Traditional Cox models assume proportional hazards and linear effects, limiting flexibility. While machine learning offers greater expressiveness, many models rely solely on structured data and overlook time-to-event (TTE) information. Integrating structured and textual representations may enhance prediction and support equitable assessment across clinical subgroups.

Objective: This study aims to develop a hybrid multitask deep learning model (MT-BERT [multitask Bidirectional Encoder Representations from Transformers]) integrating structured and textual features from electronic health records (EHRs) to predict 10-year CVD risk, enhancing individualized stratification and supporting equitable assessment across diverse demographic groups.

Methods: We used data from Clinical Practice Research Datalink (CPRD) Aurum comprising 469,496 patients aged 40 - 85 years to develop MT-BERT for 10-year CVD risk prediction. Structured EHR variables and their corresponding textual representations were jointly encoded using a multilayer perceptron and a distilled version of the BERT model (DistilBERT), respectively. A fusion layer and stacked multihead attention modules enabled cross-modal interaction modeling. The model generated both binary classification outputs and TTE risk scores, optimized using a custom FocalCoxLoss function with uncertainty-based weighting. Prediction targets encompassed composite and individual CVD outcomes. Model performance was evaluated using the area under the receiver operating characteristic curve (AUROC), concordance index, and Brier score, with subgroup analyses by ethnicity and deprivation, and heterogeneity assessed using Higgins I^2 and Cochran Q statistics. Generalizability was assessed via external validation in a held-out London cohort.

Results: The MT-BERT model yielded AUROC values of 0.744 (95% CI 0.738 - 0.749) in males and 0.782 (95% CI 0.768 - 0.796) in females on the test set (n=711,052), and 0.736 (95% CI 0.729 - 0.741) and 0.775 (95% CI 0.768 - 0.780), respectively in "spatial external" validation (n=144,370). Brier scores were 0.130 in males and 0.091 in females. Individuals classified as high-risk (≥40% risk in males and ≥34% in females) demonstrated significantly reduced 10-year event-free survival relative to lower-risk individuals (log-rank P<.001). Model performance was consistently higher in females across all metrics. Subgroup analyses revealed substantial heterogeneity across ethnicity and deprivation (I^2>70%), especially among males, with lower AUROC in South Asian and Black ethnic groups. These findings reflect variation in model performance across demographic groups while supporting its applicability to large-scale CVD risk stratification.

Conclusions: The proposed hybrid MT-BERT model predicts 10-year CVD risk for primary prevention by integrating structured variables and unstructured clinical text from EHRs. Its multitask design facilitates both individualized risk stratification and TTE estimation. While performance was modestly reduced in deprived and minority ethnic subgroups, these findings provide preliminary support for advancing equity-aware, data-driven prevention strategies in increasingly diverse health care settings.

Introduction

Background

Cardiovascular disease (CVD) is a major public health challenge, accounting for 1 in 4 deaths in the United Kingdom and affecting 7.6 million individuals. In 2022, over 1,00,000 hospital admissions were attributed to acute coronary syndromes [1]. Beyond morbidity and mortality, CVD imposes US $15 billion in annual health care costs and US $35 billion in economic losses. Additionally, 6‐8 million individuals have undiagnosed or uncontrolled hypertension, further increasing preventable CVD-related complications [1,2].

To address this, the United Kingdom has implemented national prevention strategies, with the UK's National Institute for Health and Care Excellence (NICE) guidelines [3] recommending CVD risk assessments for individuals aged ≥40 years every 5 years via general practitioners (GPs). These assessments rely on structured clinical data and established 10-year risk prediction models such as QRISK3 [4] (developed and validated in UK populations) and Pooled Cohort Equations [5] (developed in US cohorts). Despite their widespread use, these conventional models rely on Cox regression, whose linear and proportional assumptions hinder their ability to model complex risk interactions, thereby limiting predictive performance in clinical practice [6,7].

Significant disparities in CVD burden persist. For instance, South Asians in the United Kingdom have nearly twice the coronary heart disease (CHD) incidence of White Europeans, with South Asian females experiencing rates similar to White European males [8]. Black African and Caribbean individuals do not show an elevated risk but receive fewer preventive treatments despite clinical indications [9]. Socioeconomic deprivation further exacerbates disparities, with higher CVD risk factor prevalence, hospital admissions, lower treatment uptake, and twice the mortality rate for individuals younger than 75 years in the most deprived areas [10]. Although conventional models can incorporate subgroup characteristics, they often lack the flexibility to model the complex, interdependent factors contributing to these disparities [11].

Machine learning (ML) approaches have emerged as promising alternatives to traditional CVD risk estimation models. A range of ML methods, from logistic regression and decision trees to ensemble techniques such as boosting, bagging, and stacking, have been explored for CVD risk prediction [6]. However, particularly in the context of primary prevention, many existing ML-based algorithms are limited by relatively small sample sizes, heterogeneous data quality, and a lack of consistent external validation, which may restrict their clinical applicability. Moreover, while some recent ML-based survival models, such as DeepSurv (Deep Neural Network–based Cox Model) [12], incorporate time-to-event (TTE) information, many CVD risk prediction algorithms continue to treat outcomes as binary events, without explicitly addressing censoring or time-dependent risk [7]. In addition, most models primarily use structured clinical variables and often overlook unstructured sources, such as physician notes and patient-reported symptoms, that could provide important contextual information for risk stratification [13].

Natural language processing (NLP), particularly Transformer-based models such as BERT [14] (Bidirectional Encoder Representations from Transformers), presents a novel approach to integrating unstructured clinical text into CVD risk prediction. Transformers use self-attention mechanisms to model long-range dependencies and complex relationships between variables. As an encoder-based Transformer model, BERT generates dense, context-rich embeddings by capturing bidirectional contextual information. Pretrained on large-scale corpora through transfer learning, BERT can effectively extract meaningful features from clinical text. Given that patient comorbidities, lifestyle factors, and social determinants are often recorded in unstructured formats, NLP models such as BERT can bridge critical gaps in cardiovascular risk assessment.

With increasing digital health adoption, NLP-driven models offer a scalable and cost-effective approach to CVD risk stratification. In particular, pretrained Transformer-based architectures such as BERT enable efficient fine-tuning on domain-specific datasets without the need for extensive retraining, reducing resource demands for clinical implementation. By integrating structured electronic health record (EHR) data with unstructured text sources such as patient interactions, chatbots, and clinical notes, future models could further enhance risk prediction and address limitations of conventional approaches. In this study, we emulate such integration by transforming structured variables into textual representations, providing an initial step toward leveraging both data modalities. Transformer-based models can better capture complex risk patterns across diverse populations, supporting more timely and equitable cardiovascular risk assessment for primary prevention.

Rationale and Objectives

This study aims to develop a hybrid Multitask BERT model (MT-BERT) for prognostic CVD risk assessment, integrating structured and textual representations derived from UK EHR data using phenotyping techniques. The model is designed to support primary care decision-making by predicting 10-year CVD risk to guide early intervention, statin initiation, and lifestyle modification, potentially enhancing or replacing conventional statistical approaches.

While traditional survival models rely primarily on structured clinical variables, the proposed MT-BERT approach incorporates unstructured information (eg, physician notes and comorbidity narratives) to improve predictive performance, particularly among underrepresented high-risk populations.

To achieve this, we develop a model for both CVD outcome classification and TTE hazard ranking, enhancing individualized risk stratification and addressing biases in structured datasets. We also introduce a novel FocalCoxLoss function, enabling

XSL•FO
RenderX

uncertainty-weighted joint optimization of classification and survival objectives. The study emphasizes model development, feature engineering, and optimization and includes external validation using data from a distinct London region to assess spatial generalizability. Additionally, we leverage longitudinal EHR data to better support practical implementation in primary care.

The specific objectives of this study were as follows:

1. Extract structured and unstructured predictors, CVD outcomes (binary classification and TTE data) from Clinical Practice Research Datalink (CPRD) Aurum [15] via phenotyping.
2. Develop the MT-BERT model integrating textual and structured variables for CVD risk prediction, incorporating the novel FocalCoxLoss for multitask learning.
3. Evaluate model performance across individual and composite CVD outcomes, with subgroup analyses by ethnicity and socioeconomic deprivation, focusing on discrimination, calibration, and fairness metrics.
4. Ensure transparent reporting according to the TRIPOD+AI (Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis + artificial intelligence) [16], including detailed documentation of feature engineering, data harmonization, and hyperparameter optimization.

The aim of this study was to evaluate the effectiveness of multimodal deep learning for long-term CVD risk prediction and to advance personalized health care through the integration of NLP and structured data from UK EHR.

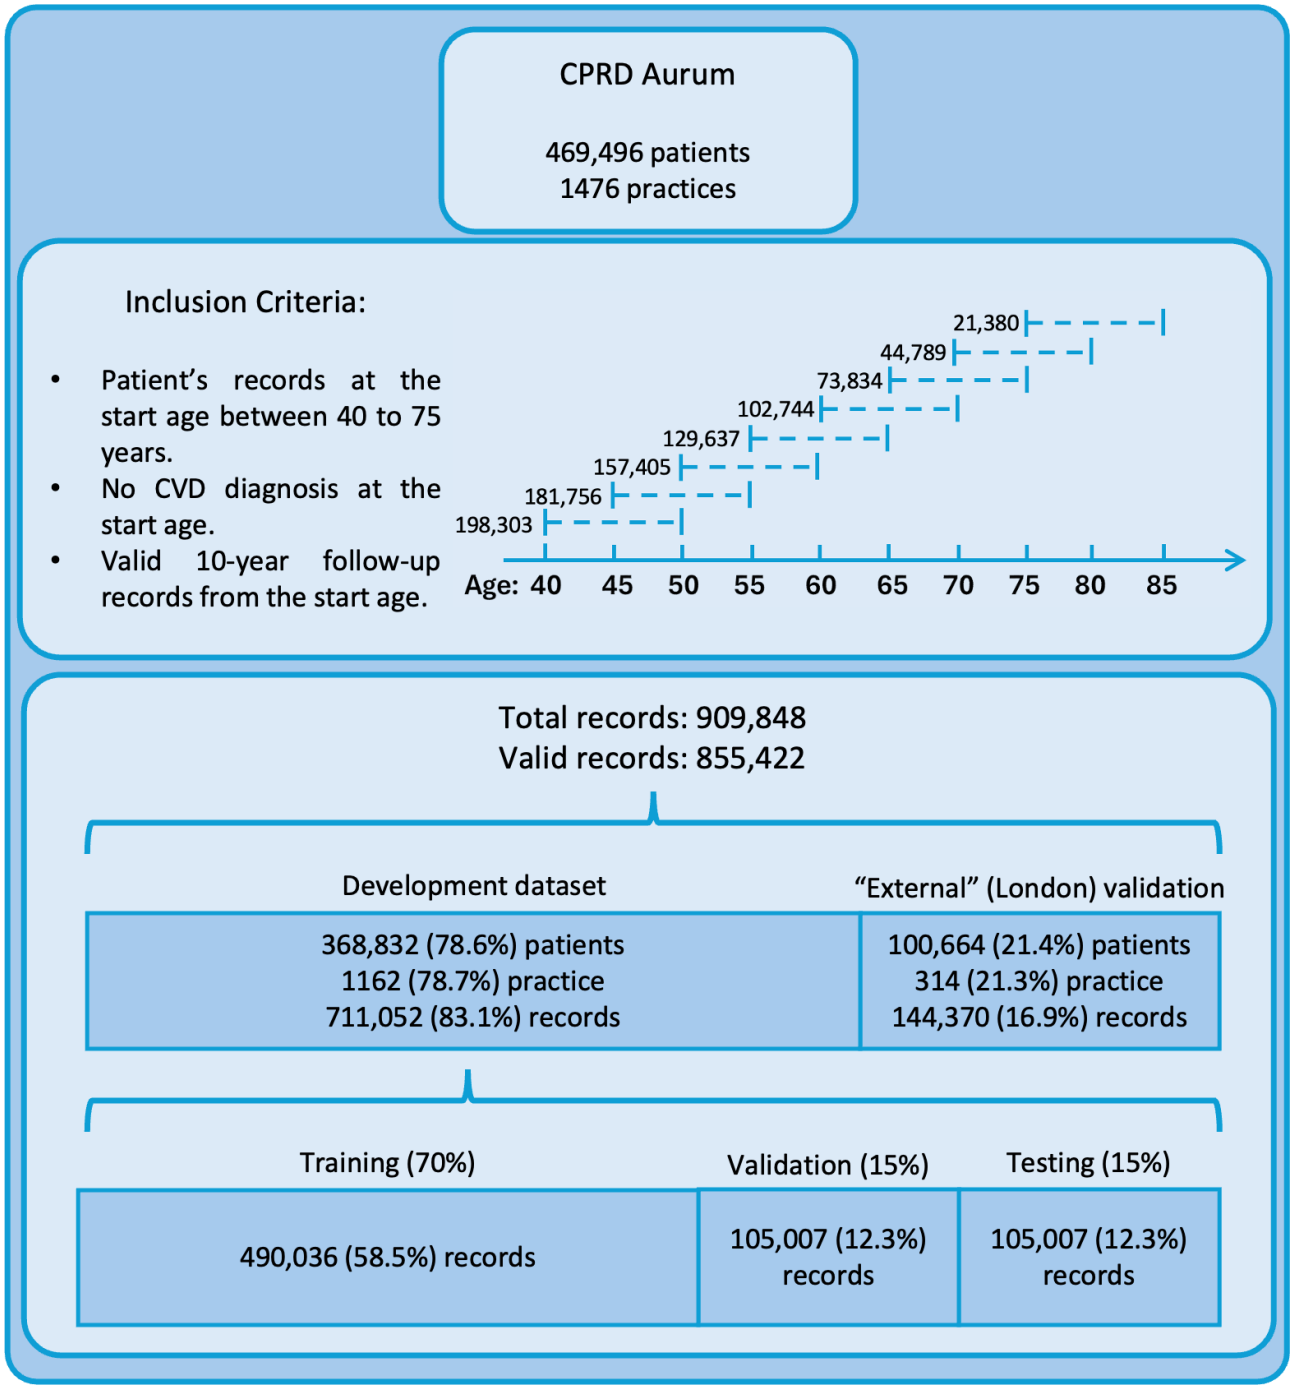
Methods

Overview

This study follows the guidelines outlined in the TRIPOD+AI [16] statement (Checklist 1); an extension of the TRIPOD statement specifically designed for AI (including ML) prediction models.

Study Design and Patient Records Inclusion

This study uses a retrospective EHR-based design, leveraging CPRD Aurum [15] (study registration protocol no.: 21_000346) to develop NLP-driven CVD risk prediction models using longitudinal patient records. CPRD Aurum is a routinely updated UK primary care database integrating deidentified patient records from 1359 GP practices (primary care sites), covering 16.6% of UK GPs and representing one-fifth of the UK population. It includes demographic data, diagnoses, symptoms, prescriptions, and dosages, standardized via MedCode ID to ensure interoperability with Read Code and SNOMED CT. As of January 2022 (version 2.7), it comprises over 40 million research-eligible patients with a median follow-up of 8.74 years (IQR 3.22-19.87).



The “External” (London) validation set represents a “spatial” external cohort from CPRD practices located in Greater London, selected to ensure demographic diversity, particularly higher proportions of ethnic minority patients.

The data preprocessing workflow followed our prior work [17]. As shown in Figure 1, we selected a stratified random sample of 469,496 patients aged 40 to 85 years who were registered between 2011 and 2021. Unique CPRD identifiers were used to link records and reconstruct longitudinal health trajectories, ensuring a representative UK primary care cohort. Patients with at least one 10-year follow-up period were included to verify consistency in registration and clinical event timestamps. Follow-up intervals began at ages 40 to 75 years in 5-year increments, allowing individuals to contribute multiple independent 10-year records if they were CVD-free at entry. To emulate clinical practice, we extracted multiple fixed-horizon prediction episodes for each patient, reflecting periodic risk assessments recommended in the UK NICE guidelines [3] for adults aged 40 to 85 years. Consistent with our prior ML-based survival study, all baseline models were trained in exactly the same pipeline with identical predictors, censoring rules, preprocessing, and the same development and validation splits. This setup enables like-for-like comparisons and effectively represents structure-only, single-objective ablation settings against which MT-BERT is evaluated. While the guidelines do not specify data extraction procedures, this design strategy ensures alignment with real-world primary prevention workflows and enhances model relevance for general practice.

Given the scale and representativeness of CPRD Aurum, sample size adequacy was evaluated according to the framework proposed by Riley et al [17] for clinical prediction model development. The cohort substantially exceeded recommended thresholds for minimum events per predictor, enabling robust model development, rare event estimation, and stratified subgroup analyses.

Figure 1. Workflow for study population and records extraction. CPRD: Clinical Practice Research Datalink; CVD: cardiovascular disease.

Extraction and Textual Transformation of Predictors

We extracted all predictor variables at the cohort entry year, primarily based on QRISK3 definitions, with minor adaptations where appropriate (Table 1). Phenotypes were defined using the HDRUK Phenotype Library [18], while comorbidities were identified through CArdiovascular disease research using LInked BEspoke studies and Electronic health Records (CALIBER, developed by the University College London Institute of Health Informatics [CALIBER research team]) [19], with corresponding *ICD-10* (*International Classification of Diseases, Tenth Revision*) codes detailed in Table S1 (Multimedia Appendix 1). MedCode IDs were documented and mapped to controlled terminologies to ensure consistency, facilitate updates, and enhance transparency (Multimedia Appendix 2).

Static variables (eg, gender, ethnicity, and deprivation) were assigned based on the most recent record available. Time-dependent variables (eg, smoking status and medication use) were determined within a 6-month window around the entry year; in the absence of recent records, smoking status was inferred from prior history, and medication use was classified based on any previous prescription. Comorbidities were considered present if recorded before cohort entry within the same time frame. Absence of records was interpreted as no occurrence rather than missing data.

XSL•FO
RenderX

For continuous variables (eg, BMI, systolic blood pressure, and total cholesterol/high-Ddensity lipoprotein ratio), if no values were available within the acceptable window, missing data were imputed using linear regression, provided that at least 3 prior measurements existed within a 2-year span.

To integrate established risk assessment into ML models, we derived an additional predictor based on the QRISK score calculated by an R package [20], represented in categorical form, aligned with UK clinical thresholds for statin treatment initiation.

Unlike traditional models based on structured data, this study transforms structured predictors into text representations for NLP-based modeling. To implement this approach, categorical variables including risk groups, ethnicity, smoking status, and comorbidities were converted into textual descriptions reflecting patient status at cohort entry, avoiding numerical encoding. Age and BMI were also expressed in textual form. Continuous variables were otherwise retained in their original form. The textual transformation template is provided in Table 1.

Table . Overview of predictors, outcome definitions, and preprocessing approaches.

Variable	Textual transformation/Preprocessing description
Continuous predictors	
Age	*"The patient is a {age_category}"*, where age < 45=young adult, 45 - 59=middle-aged adult, 60 - 74=young-old adult, and age ≥ 75=older adult
BMI (kg/m²)	Appended as: *"with a BMI classified as {bmi_category}"*, where BMI <18.5=underweight, 18.5 - 24.9=normal weight, 25.0 - 29.9=overweight (preobesity), 30.0 - 34.9=Class 1 obesity, 35.0 - 39.9=Class 2 obesity, BMI ≥40.0=Class 3 obesity (severe obesity)
Systolic blood pressure (mmHg)	Normalized to [0, 1] range using min-max scaling
SD of systolic blood pressure	Normalized to [0, 1] range using min-max scaling
Diastolic blood pressure (mmHg)	Normalized to [0, 1] range using min-max scaling
Total/High-density lipoprotein ratio	Normalized to [0, 1] range using min-max scaling
Townsend score	Normalized to [0, 1] range using min-max scaling
Categorical predictors	
Ethnicity (9 categories)	Appended as: *"and is of {ethnicity_group} ethnicity"*
Smoking status (5 categories)	Appended as: *"The patient is a {smoking_status}"*
Prestratified risk group (4 categories)	Appended as: *"Pre-stratified risk indicating a {risk_group}"*, where 0% - 4.9%%=low risk, 5.0% - 9.9%%=moderate risk, 10.0% - 19.9%%=high risk, and ≥20.0%=extreme high risk
Binary comorbidity predictors	
Type 1/2 diabetes mellitus	Appended as: *"The patient has a history of {condition_1, condition_2,.}"*
Chronic kidney disease stage 3, 4, or 5	Appended as: *"The patient has a history of {condition_1, condition_2, .}"*
Family history of coronary heart disease	Appended as: *"The patient has a history of {condition_1, condition_2, .}"*
Atrial fibrillation	Appended as: *"The patient has a history of {condition_1, condition_2, .}"*
Erectile dysfunction	Appended as: *"The patient has a history of {condition_1, condition_2, .}"*
HIV/AIDS	Appended as: *"The patient has a history of {condition_1, condition_2, .}"*
Migraine	Appended as: *"The patient has a history of {condition_1, condition_2, .}"*
Rheumatoid arthritis	Appended as: *"The patient has a history of {condition_1, condition_2, .}"*
Systemic lupus erythematosus	Appended as: *"The patient has a history of {condition_1, condition_2, .}"*
Severe mental illness	Appended as: *"The patient has a history of {condition_1, condition_2, .}"*
Antipsychotic	Appended as: *"The patient has a history of {condition_1, condition_2, .}"*
Corticosteroid	Appended as: *"The patient has a history of {condition_1, condition_2, .}"*
Treated hypertension	Appended as: *"The patient has a history of {condition_1, condition_2, .}"*
Cardiovascular disease outcomes	
Coronary heart disease	Used as binary outcome labels indicating disease presence (1=event occurred, 0=no event). Corresponding time-to-event (TTE) values were recorded in days, with a maximum follow-up of 3650 days for censored cases
Myocardial infarction	Used as binary outcome labels indicating disease presence (1=event occurred, 0=no event). Corresponding TTE values were recorded in days, with a maximum follow-up of 3650 days for censored cases
Ischemic stroke	Used as binary outcome labels indicating disease presence (1=event occurred, 0=no event). Corresponding TTE values were recorded in days, with a maximum follow-up of 3650 days for censored cases
Heart failure	Used as binary outcome labels indicating disease presence (1=event occurred, 0=no event). Corresponding TTE values were recorded in days, with a maximum follow-up of 3650 days for censored cases

XSL•FO
RenderX

Variable	Textual transformation/Preprocessing description
Angina	Used as binary outcome labels indicating disease presence (1=event occurred, 0=no event). Corresponding TTE values were recorded in days, with a maximum follow-up of 3650 days for censored cases
Cardiovascular disease (QRISK)	A composite outcome including coronary heart disease (CHD), stroke, and transient ischemic attack (TIA). TTE was defined as the time to the earliest occurring event, in days
Cardiovascular disease (Composite)	A composite outcome including the above cardiovascular conditions, plus abdominal aortic aneurysm (AAA), and peripheral artery disease (PAD). TTE was defined as the time to the earliest occurring event, in days
Vascular dementia	Used as a binary outcome label indicating disease presence (1=event occurred, 0=no event). TTE was recorded in days, with a maximum follow-up of 3650 days for censored cases

CVD Outcome and TTE Specification

Each CVD outcome (Table 1) was defined using phenotype-based criteria and assessed individually with its corresponding TTE, including CHD (*ICD-10*: I20-I25), stroke (I63-I66, I69), transient ischemic attack (G45-G46), heart failure (I50), abdominal aortic aneurysm (I71), and peripheral arterial disease (I73-I74). Additionally, 2 composite CVD outcomes, one aligned with QRISK and one containing all of the above, were defined based on the earliest occurrence of any included CVD event. Although not a classical CVD outcome, vascular dementia (F01) was included as an exploratory end point due to its close association with cerebrovascular disease. CVD events were recorded if they occurred within the 10-year follow-up or up to 6 months thereafter. Absence of records was interpreted as no event rather than missing data. The definition and mapping of CVD outcomes are detailed in Table S2 in Multimedia Appendix 1 and in Multimedia Appendix 2.

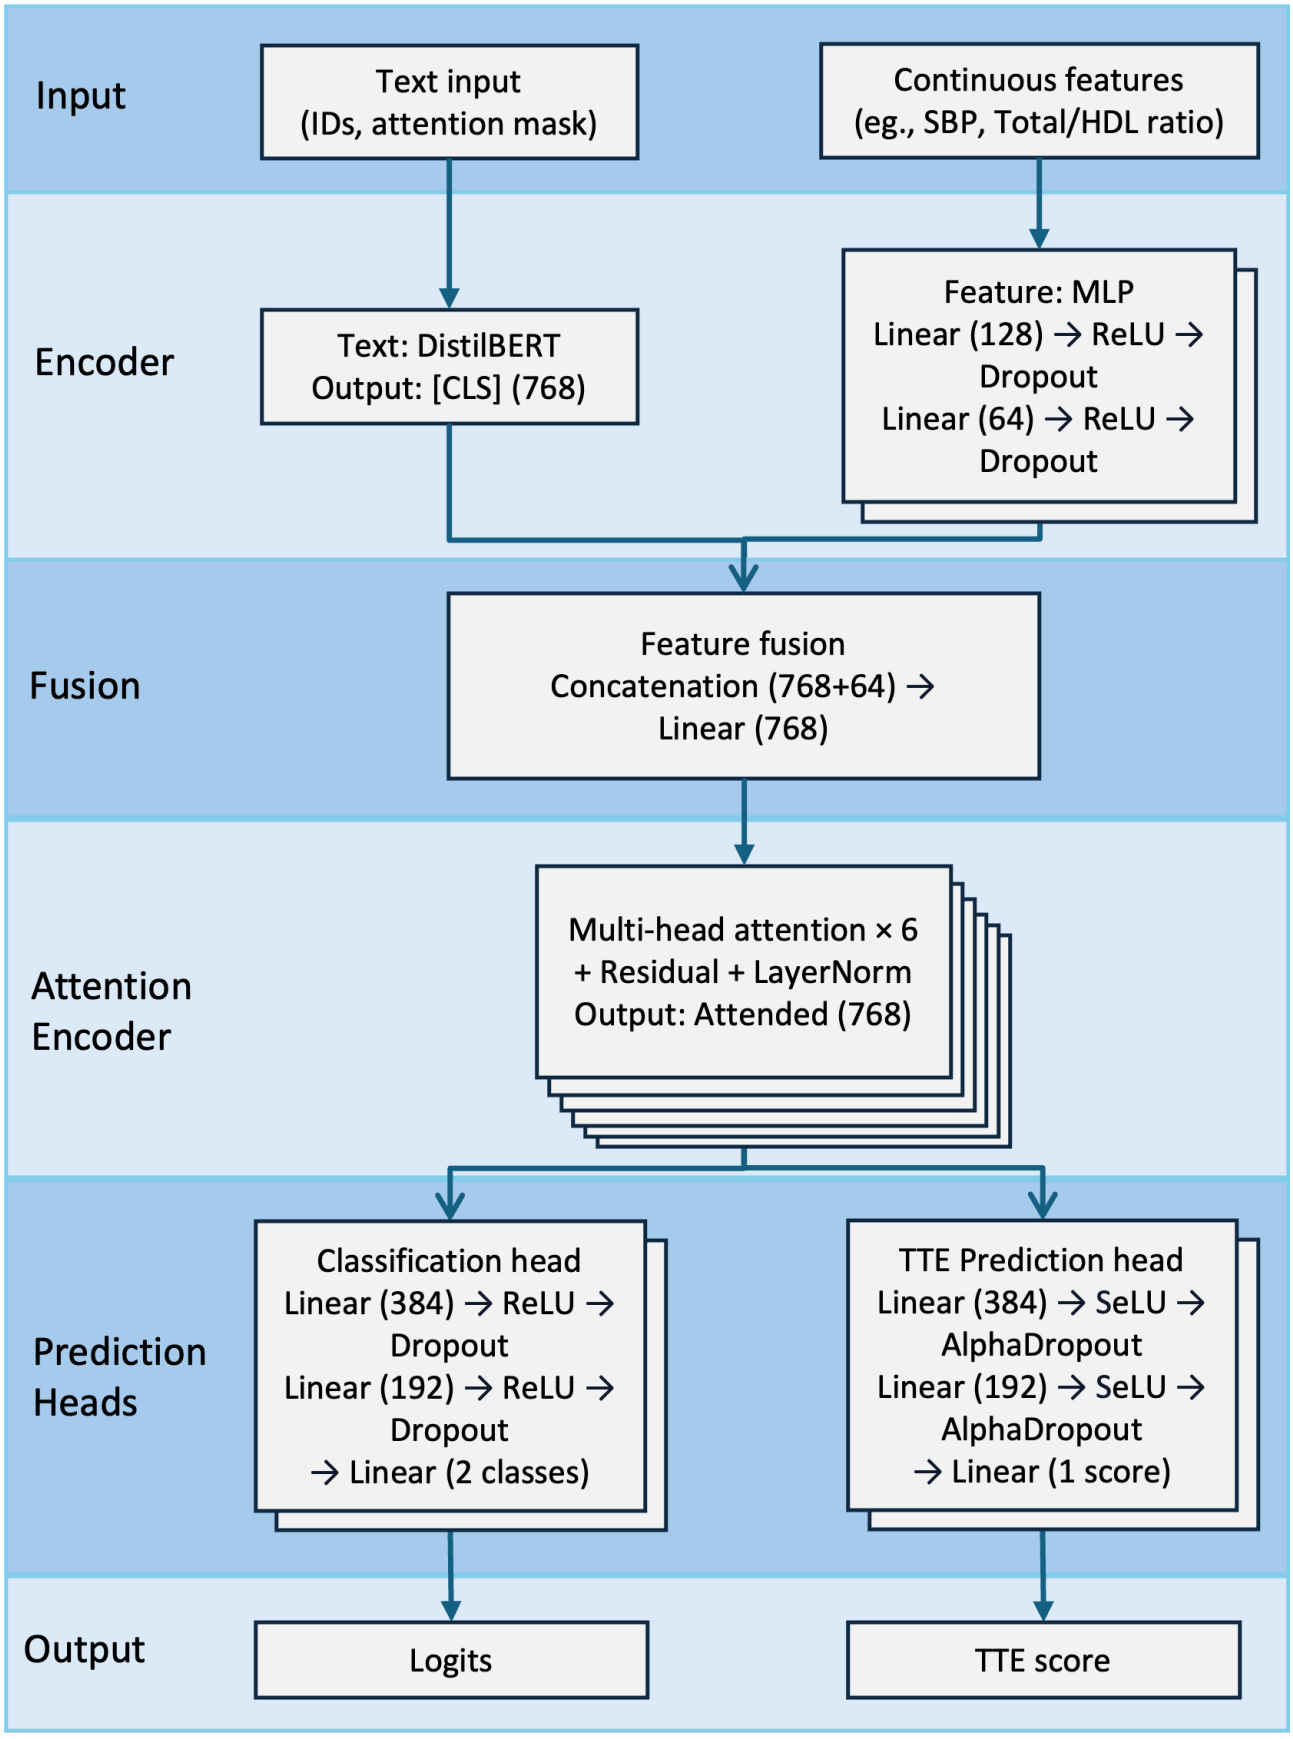
Model Architecture and Training Strategy

As shown in Figure 2, we developed an MT-BERT framework for the prediction of CVD outcomes, which integrates a distilled version of the BERT model (DistilBERT) [21] for textual features and a multilayer perceptron (MLP) for structured clinical predictors, incorporating multihead attention and residual connections to refine feature interactions. DistilBERT retains representational power while reducing computational complexity by removing token-type embeddings and the pooler layer. Unlike conventional concatenation-based approaches, our model applies a transformation layer for feature alignment before passing the fused representation through stacked attention layers, enabling dynamic cross-modal refinement. The MLP module, implemented in PyTorch, consists of fully connected layers with Rectified Linear Unit activations and dropout, ensuring structured feature regularization. For prediction, the model simultaneously outputs binary classification logits (CVD presence) and a log hazard score (TTE) for survival analysis, with temperature scaling improving classification stability. Full implementation details are provided in Table S3 (Multimedia Appendix 1).

Structured features were MinMax scaled, and text data were tokenized using the DistilBERT tokenizer. The dataset was split in a 7:2:1 ratio into training, validation, and testing sets (Figure 1) using stratified sampling to maintain class balance. Labels and TTE values were converted into tensors for model compatibility. Class imbalance was addressed with a dynamically adjusted weighting scheme, scaling standard balanced class weights based on the observed event rate. The processed data were structured into TensorDatasets and loaded for training.

Our model uses a customized FocalCoxLoss, a multitask loss function that combines Focal Loss, a class imbalance-aware variant of cross-entropy loss, for event classification, which optimizes decision boundaries, and Cox Loss, as used in DeepSurv [12], for survival analysis, which optimizes risk ranking. The 2 components are balanced using learnable uncertainty-based weighting [22] as follows:

$$L = (12\sigma_{focal2})L_{focal} + (12\sigma_{cox2})L_{cox} + \log \sigma_{focal} + \log \sigma_{cox}$$



where σ_{focal} and σ_{cox} are learnable task-specific variance parameters. Unlike fixed-weight loss functions, this approach enables dynamic adjustment of task contributions by assigning higher effective weights to tasks with lower predicted uncertainty, thereby optimizing the trade-off between binary CVD event prediction and TTE risk estimation during training.

To ensure stability, we adopted a 2-stage training strategy. Initially, was frozen, maintaining a fixed loss ratio to prevent early instability. After 10 epochs, it was unfrozen, allowing adaptive loss scaling. DistilBERT remained trainable throughout, enabling concurrent optimization of textual and structured representations.

Training used AdamW with cosine annealing, gradient clipping, and early stopping for stable convergence. Dropout rates were optimized via Optuna hyperparameter tuning, while learning rate (initially 3e-4) and weight decay (1e-4) were manually set. During training, the learning rate was dynamically adjusted using a cosine annealing schedule with warm restarts. Model selection was based on the area under the curve and C-statistic maximization.

Performance Evaluation, Generalizability, and Fairness

Model performance was assessed on the held-out test set using the optimal hyperparameters identified during training (Figure 1). Calibration was performed via isotonic regression and assessed using Brier scores and calibration plots across risk deciles. Discrimination was quantified by the AUROC and the C-statistic, with 95% CIs estimated via 1000 bootstrap resamples. Internal validity was assessed through 10-fold cross-validation. Classification metrics, including accuracy, recall, and specificity, were reported at the optimized threshold. Kaplan-Meier (KM) survival curves stratified by predicted risk groups were used to evaluate risk separation and clinical utility.

To evaluate generalizability and fairness, we performed "spatial external" validation using a London held-out cohort (Figure 1), selected for its higher proportion of ethnic minority patients. AUROC with 95% CIs was computed across all 9 ethnicity categories and Townsend deprivation deciles. In parallel, we reported aggregated subgroup results for broader ethnicity groupings including White, South Asian (Indian, Pakistani, and Bangladeshi), and Black (African and Caribbean). We further evaluated performance variation across individual Townsend quintiles. To quantify heterogeneity in model performance, Higgins I^2 statistic and Cochran Q values [23] were computed across ethnicity and deprivation groups, where the Higgins I^2 statistic quantifies the percentage of total variation across studies due to heterogeneity rather than chance, and the Q value tests whether the observed differences in study results are due to chance or true heterogeneity.

Ethical Considerations

This study uses CPRD Aurum data under protocol number 21_000346, which was reviewed and approved by the Independent Scientific Advisory Committee (ISAC) on behalf of the Medicines and Healthcare Products Regulatory Agency. The study relies on anonymized patient records and follows ethical guidelines for research using deidentified health care data. No patient or public consent was required, as the research was conducted using fully anonymized data. There was no direct patient or public involvement in the study's design, execution, analysis, or dissemination. No financial compensation was provided.

Results

Baseline Characteristics of Study Population

We extracted 909,848 records from 469,496 patients across 1476 practices in England (Figure 1). After quality control to remove records with extreme values for continuous features, 855,422 valid records were retained. Of these, 144,370 records (16.9%) from practices located in London were held out as the spatial external validation set. The remaining 711,052 records (83.1%) constituted the development dataset, which was randomly split into training, validation, and testing sets using a 70:15:15 ratio.

Table 2 summarizes the background characteristics of both the development dataset and the spatial validation set, disaggregated by gender. The statistics show that most comorbidities and CVD outcomes are significantly more common among males, which makes gender-specific modeling indispensable for this task. In addition, a substantially higher proportion, approximately one-third of individuals from minority ethnic backgrounds, is observed in the spatial validation set, whereas over 90% of the development dataset is White. This demographic contrast supports the use of the London practice cohort as a spatially distinct external validation set, particularly for assessing model generalizability and fairness in managing CVD risk among ethnic minority populations.

Model Predictive Performance and Risk Stratification

We developed the MT-BERT model for multiple CVD outcomes, and all performance metrics were derived from the held-out test set unless otherwise stated (Table 3), including discrimination, calibration, and classification results for both composite and individual outcomes.

For both genders, the model trained to predict the composite CVD outcome achieved the highest discrimination. In males, the AUROC was 0.744 (95% CI 0.738 - 0.749), and in females, 0.782 (95% CI 0.768 - 0.796), higher than models trained on QRISK-defined CVD outcomes (males: 0.723, 95% CI 0.717 - 0.732; females: 0.767, 95% CI 0.760 - 0.777). The corresponding concordance index (C-index) values were 0.713 (95% CI 0.710 - 0.716) in males and 0.732 (95% CI 0.725 - 0.742) in females for composite CVD.

Among individual outcomes, ischemic stroke (males: 0.738, females: 0.769) and CHD (males: 0.732, females: 0.769) demonstrated relatively strong discriminatory performance. Angina also showed acceptable discrimination (males: 0.713, females: 0.741). In contrast, myocardial infarction exhibited lower discrimination (males: 0.679, females: 0.717), particularly in males, where recall was high but overall accuracy was reduced. Vascular dementia was additionally explored on an experimental basis and showed overall limited performance across evaluation metrics, similar to the pattern observed for myocardial infarction.

Continuous variables are presented as mean values with 2 decimal places for consistency. Individual clinical measurements (eg, blood pressure) are typically recorded as integers, but decimal values arise when reporting cohort-level averages.

“Cardiovascular disease (QRISK)” is a composite outcome including CHD, stroke, and transient ischemic attack. “Cardiovascular disease (Composite)” includes the above conditions plus abdominal aortic aneurysm and peripheral artery disease. Benchmark model results were adapted from our prior work [24], where models were trained and evaluated using the same CPRD Aurum cohort and standardized preprocessing for consistent comparability. RSF (Random Survival Forest), GBSA (Gradient Boosted Survival Analysis), XGBS (Extreme Gradient Boosted Survival Model), DeepSurv, and DeepHit (Deep Neural Network for Competing Risks).

KM curves are plotted with a full 0 - 1 *y*-axis; shaded bands denote 95% CIs. Insets provide a zoomed view of the upper survival range for readability. Segments after time points with <10 individuals at risk are suppressed. High- versus low-risk groups use sex-specific thresholds (men≥40%, women≥34%). *P* values are from log-rank tests.

[a]AUROC: area under the receiver operating characteristic curve.

[b]C-index: concordance index.

[c]Cardiovascular disease (QRISK)" is a composite outcome including coronary heart disease (CHD), stroke, and transient ischemic attack (TIA). "Cardiovascular disease (Composite)" includes the above conditions plus abdominal aortic aneurysm (AAA) and peripheral artery disease (PAD).

[d]CHD: coronary heart disease.

[e]MI: myocardial infarction.

The left panel of Figure 3 visualizes the AUROC values with 95% CIs across all CVD outcomes by gender, aligning with the summary in Table 3. The model showed the clearest advantage for composite CVD, with a higher AUROC than both QRISK-defined and individual outcome-specific models.

Across all outcomes, C-index values were consistently 0.01‐0.05 lower than AUROC. Model performance was generally higher in females across AUROC, C-index, and accuracy. The thresholds used to classify positive cases ranged from 0.23% to 0.40% in males and 0.23% to 0.34% in females, with higher thresholds observed in males, consistent with their event distribution and calibration characteristics.

In the right panel of Figure 3, the MT-BERT model is compared against benchmark models, including conventional approaches (QRISK3 [4] and CoxPH [25]), ensemble-based methods (RSF, GBSA, and XGBS), and deep learning models (DeepSurv [12] and DeepHit [26]). These benchmark models were implemented based on our previous work [24]. In this evaluation, the hybrid model consistently outperformed all comparators, with the greatest AUROC gains observed for composite CVD, especially in females.

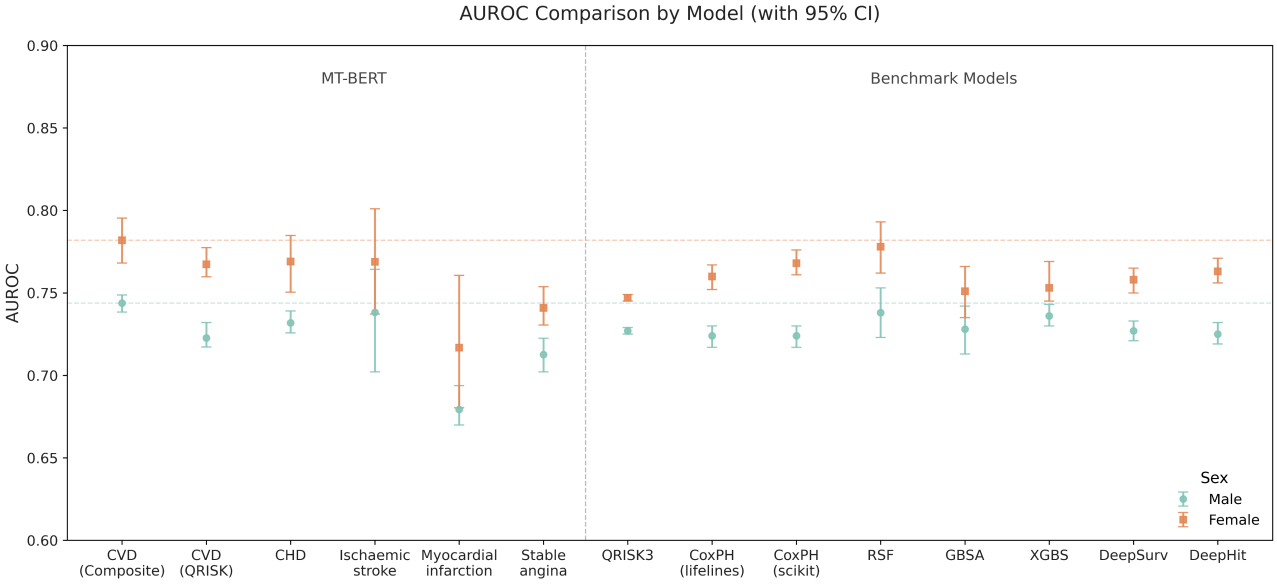
Figure 3. Discrimination performance of the Multitask Bidirectional Encoder Representations from Transformers model across cardiovascular disease outcomes, in comparison with benchmark conventional and machine learning models. AUROC: area under the receiver operating characteristic curve; CHD: coronary heart disease; CVD: cardiovascular disease; DeepSurv: Deep Neural Network–based Cox Model; DeepHit: Deep Neural Network for Competing Risks; GBSA: Gradient Boosted Survival Analysis; RSF: Random Survival Forest; XGBS: Extreme Gradient Boosted Survival Model.



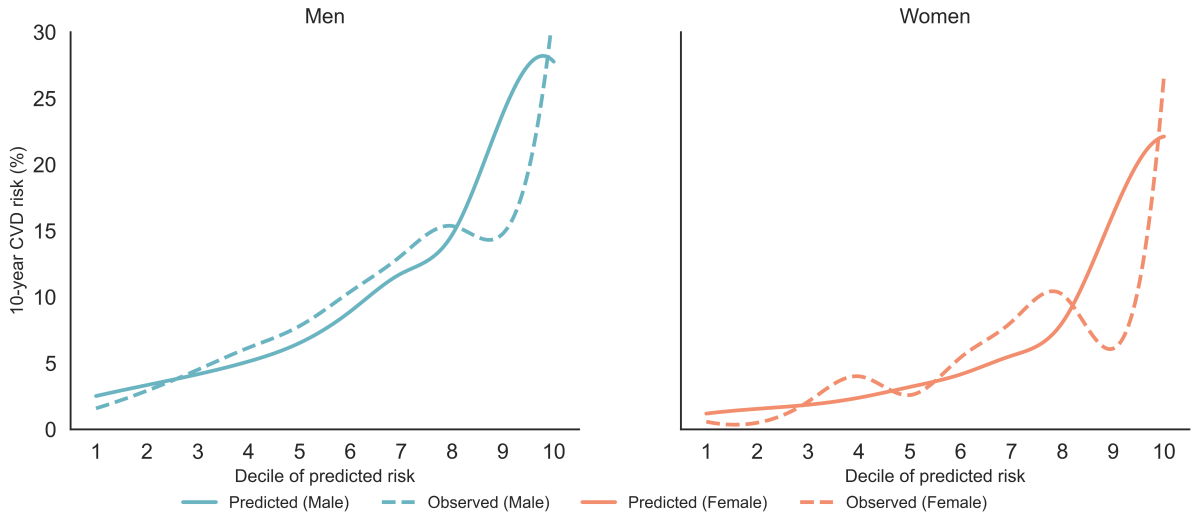


Figure 4 presents the calibration plot for the predicted 10-year composite CVD risk using the MT-BERT model, stratified by gender. Predicted risks and observed event rates were plotted across deciles of predicted risk. In both genders, predicted risks increased monotonically across deciles, indicating good overall calibration. However, risk overestimation was evident in the upper deciles, particularly among males, suggesting inflation at the highest predicted risk levels. In females, predicted and observed risks were closely aligned in lower-risk and midrisk ranges, though moderate overprediction was also observed at the top deciles, where event rates were more variable. In particular, a dip in the observed rates was seen in the ninth decile, which we attribute to event sparsity and statistical variability in the highest risk groups. These findings are consistent with the Brier scores in Table 3, where males had a score of 0.130 and females had 0.091, reflecting slightly better overall calibration in women. Taken together, the hybrid model provided reasonably calibrated risk estimates for composite CVD, with modest overprediction at higher predicted risk levels, especially in males.

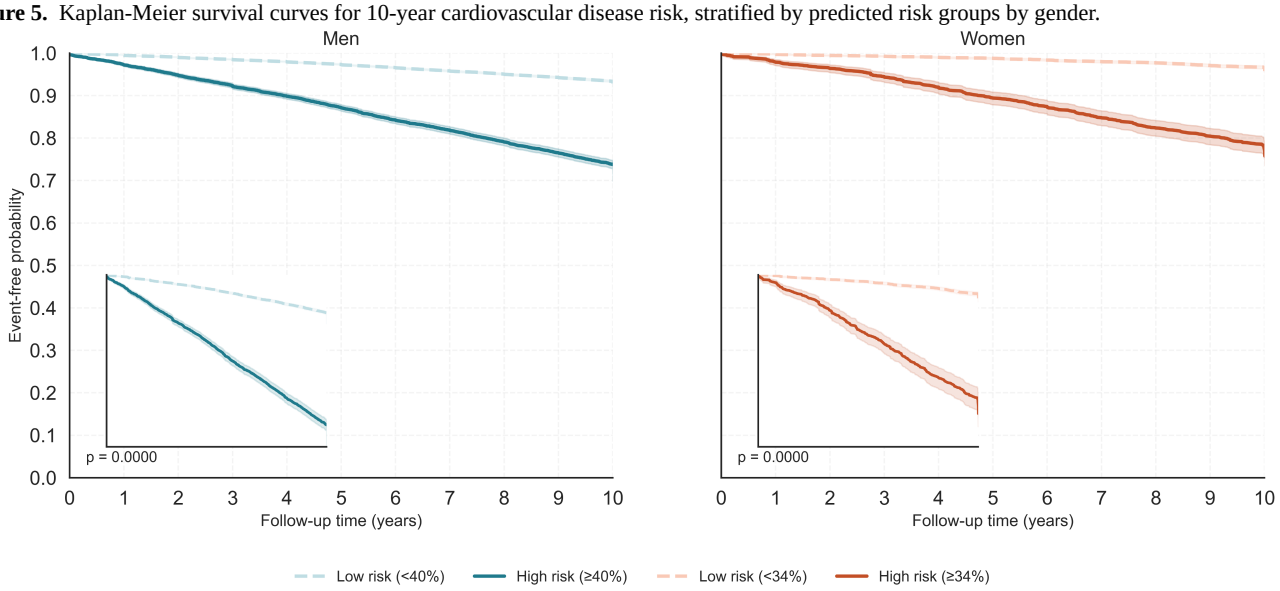
Figure 4. Calibration plots for 10-year cardiovascular disease risk by gender. CVD: cardiovascular disease.



KM survival curves for 10-year composite CVD risks are presented in Figure 5, stratified by predicted risk groups in both genders. Participants were classified into high- and low-risk categories using gender-specific thresholds: 40% or greater for men and 34% or greater for women. In both genders, individuals in the high-risk group exhibited significantly lower event-free survival over time, confirming the model's ability to stratify patients according to long-term risk. Among males, the 10-year event-free probability declined to approximately 74% in the high-risk group, compared to over 93% in the low-risk group. A similar pattern was observed in females, with high-risk individuals showing notably steeper declines in survival probability. Log-rank tests yielded P values <.001 in both genders, indicating statistically significant separation between

XSL•FO
RenderX

risk groups. These results support the prognostic utility of the model's predicted risk scores, demonstrating effective stratification for composite CVD outcomes over a 10-year follow-up period.

Figure 5. Kaplan-Meier survival curves for 10-year cardiovascular disease risk, stratified by predicted risk groups by gender.

Ethnicity (n=9) subgroups include White, Indian, Pakistani, Bangladeshi, Chinese, Other Asian, Black Caribbean, Black African, and Other ethnic groups. Ethnicity (n=3) aggregates broader categories into White, Asian (including Indian, Pakistani, Bangladeshi, Chinese, and Other Asian), and Black (Caribbean and African). Deprivation (n=5) refers to Townsend quintiles, while deprivation (n=10) refers to Townsend deciles.

Model Fairness and Generalizability Across Demographics

We assessed the performance of the MT-BERT model on the composite CVD outcome across ethnic and deprivation subgroups in the spatial validation set, separately by gender. Figure 6 shows AUROC values with 95% CIs for major ethnic and deprivation categories. Table 4 presents I^2 and Q statistics based on both broad and more granular subgroup definitions. All results pertain to the composite CVD outcome.

Among all patients, the AUROC for composite CVD was 0.736 (95% CI 0.729 - 0.741) in males and 0.775 (95% CI 0.768 - 0.780) in females. These represent a moderate decline compared to the internal test set, though overall generalizability remained acceptable. Other performance metrics are provided in Table S4 in Multimedia Appendix 1, where similar trends were observed—slight reductions compared to internal validation, but performance remained within a reasonable range. Across all subgroups, model discrimination was consistently higher in females than in males (Figure 6), with an average AUROC difference of approximately 0.04 - 0.05 between genders. This pattern was consistent with results from the training, validation, and test sets (Table S4 in Multimedia Appendix 1; Table 3).

In males, model performance in the White ethnic group was marginally higher than in the overall male cohort, though the difference was not statistically significant. AUROC in the Black ethnic group was slightly lower, but the CIs overlapped with the overall population, indicating broadly comparable performance. The lowest AUROC was observed in the South Asian group, where a more pronounced decline was seen, and the CIs did not overlap with those of the White or overall male population, suggesting reduced discriminative ability in this subgroup. In females, similar patterns were observed. AUROC remained relatively consistent across the 3 main ethnic groups, though a modest decline was again noted in South Asian females, and a more notable drop was observed in Black females. When aggregated into 3 ethnic groups, I^2 values were 93.03% in males and 91.41% in females, indicating substantial heterogeneity (Table 4). Even with finer stratification into 9 ethnic groups, I^2 remained elevated (71.51% in males and 77.06% in females), suggesting that differences in model discrimination were not solely driven by broad grouping.

For deprivation, Figure 6 shows a decreasing trend in AUROC from the least to the most deprived groups. In females, AUROC declined steadily across the most deprived 40%. In males, performance dropped notably in the 60% - 80% deprivation quantile but showed partial recovery in the most deprived group. Correspondingly, heterogeneity in deprivation-based analyses remained high, with I^2 values of 83.34% (quintile-based) and 74.91% (decile-based) in males, and 82.73% and 81.55%, respectively, in females (Table 4).

Overall, heterogeneity across both ethnicity and deprivation subgroups was notable, with I^2 consistently above 70% and all Q-tests statistically significant (P<.001), except for the 9-category ethnicity analysis in males. These findings suggest that while the model maintained acceptable generalizability, subgroup-level variability in performance exists and may warrant further investigation in future work.

	I^2 (%)	Q (*P* value)	I^2 (%)	Q (*P* value)
Ethnicity (3)	93.03	28.70 (*P*<.001)	91.41	23.28 (*P*<.001)
Ethnicity (9)	71.51	28.08 (*P*<.001)	77.06	34.87 (*P*<.001)
Deprivation (5)	83.34	24.01 (*P*<.001)	82.73	23.16 (*P*<.001)
Deprivation (10)	74.91	35.87 (*P*<.001)	81.55	48.78 (*P*<.001)

Discussion

Principal Findings

The proposed hybrid MT-BERT model demonstrated strong performance in predicting 10-year CVD risk by integrating structured variables and free-text clinical notes from EHRs. While previous studies have explored the use of clinical text for risk prediction [27,28], few have focused on long-term CVD outcomes or used integrated multitask modeling. In this study, the model achieved high discrimination, demonstrated good calibration across predicted risk groups, and enabled effective survival stratification based on KM curves. Compared to conventional and ML-based survival models, the inclusion of unstructured text improved performance, particularly in females. These findings were consistent across both the internal test set and a demographically distinct "spatial external" validation cohort from London, supporting the model's generalizability and potential clinical utility.

A key methodological contribution of this study is the integration of structured and unstructured EHR data within a BERT-MLP architecture, optimized through a unified multitask learning framework. Compared to categorical or binary representations, textual input can provide richer information about disease severity, temporal context, or interactions between conditions that structured variables may not explicitly encode. Moreover, transforming structured features into natural language text reduces data sparsity and produces denser, more learnable representations [29]. This transformation is particularly suited for BERT, which is optimized for NLP and benefits from pretrained language representations that enhance its ability to model semantic relationships, even in low-resource settings or when encountering rare comorbidities [30]. Thus, our approach allows for both increased model expressiveness and improved generalization to underrepresented patient profiles.

Building on prior work in deep survival modeling, such as DeepSurv [12] and DeepHit [26], the model incorporates a classification objective to support threshold-based clinical decision-making. By jointly minimizing a combined Focal and Cox-based loss, it enables simultaneous optimization of binary classification (AUROC) and survival risk ranking (C-index). This dual-objective design allows the model to capture both event occurrence and timing, enhancing its applicability in real-world risk stratification.

To ensure comparability, data extraction followed the protocol from our previous work [24] on ML-based survival models for CVD, maintaining consistency in preprocessing and enabling direct performance comparisons. Under this aligned experimental setup, the hybrid model outperformed earlier conventional and ML-based models, demonstrating the effectiveness of combining representation learning with multiobjective optimization. Importantly, these comparators already realize the principal ablation settings within an identical

XSL•FO
RenderX

pipeline, namely, structure-only survival modeling with a single Cox objective (CoxPH, RSF, and DeepSurv). They therefore provide a pragmatic assessment of modality and loss without reimplementing stripped-down variants of MT-BERT.

Furthermore, compared to training separate models for classification and survival analysis, our multitask learning framework offers several advantages. First, by sharing representations between tasks, the model captures both static risk factors and temporal dynamics more efficiently, leveraging complementary information to enhance overall predictive performance [31,32]. Binary classification and survival modeling address distinct but related goals [12]: classification focuses on identifying individuals at high immediate risk, while survival modeling captures the time-dependent risk trajectory. Learning these jointly allows the model to optimize decision thresholds and risk ranking simultaneously. Additionally, shared representations act as a form of regularization, improving generalization especially in underrepresented subgroups [31]. Although we did not run a full factorial ablation, the existing comparators already realize the principal ablation settings within the same pipeline, namely, structure-only survival modeling with a single Cox objective. The consistent gains in both discrimination and calibration indicate a benefit from multitask integration, and we will conduct targeted ablations in future work to quantify incremental contributions beyond these baselines.

Despite these overall gains, subgroup analyses revealed reduced discrimination in certain populations, particularly males from deprived and ethnic minority groups. Similar disparities have been observed in other clinical ML applications [33], underscoring the importance of fairness-aware evaluation and algorithm refinement. Substantial heterogeneity (I^2>70%) across ethnicity and deprivation strata further highlights the need for subgroup-specific performance auditing. These findings emphasize the necessity of addressing demographic variability to support equitable deployment of predictive models in diverse populations.

Limitations

This study has several limitations that merit consideration. While the hybrid MT-BERT architecture offers enhanced representational capacity by integrating free-text and structured data, it also introduces considerable complexity [13,29]. BERT-based models are computationally intensive, requiring substantially more memory and processing time than MLPs trained solely on structured inputs. The need to process long token sequences increases both training and inference latency, which may limit scalability in resource-constrained environments. Additionally, textual representations derived from BERT may suffer from noise due to variability in clinical phrasing and tokenization. For instance, expressions such as “No history of diabetes” and “Diabetes: none” may yield inconsistent embeddings, introducing ambiguity in comorbidity interpretation. This variability in tokenization can further propagate semantic drift, where slight differences in phrasing result in divergent embeddings despite similar clinical meaning. These factors suggest that although BERT provides valuable semantic richness, its use must be balanced against concerns around efficiency, representational stability, and semantic fidelity in EHR settings.

Another methodological challenge lies in the joint optimization of binary classification (AUROC) and survival ranking (C-index) within a multitask framework. Although this design captures complementary dimensions of CVD risk, the 2 objectives are not always easily harmonized. In our results, C-index scores were consistently lower than AUROC, indicating difficulty in modeling TTE information with the same fidelity as event discrimination. In addition, evaluating a true 10-year TTE objective with censoring and aligning predictors with outcome timing typically yields a more conservative AUROC than shorter or time-gated tasks, which helps explain why our discrimination is lower than some reports. Future work may benefit from refined training strategies or alternative loss functions to better align these targets.

Model comparisons were conducted under a shared experimental framework established in our prior work [24], with consistent data extraction and preprocessing across all models. This enabled fair benchmarking but does not eliminate concerns about potential biases from repeated records or unobserved confounding. Given that the same CPRD dataset, variable and outcome definitions, cohort construction strategies, and censoring handling were applied, these models serve as appropriate comparators for evaluating the added value of MT-BERT. Within this like-for-like design, MT-BERT exceeded the conventional and ML baselines from our previous benchmark, with gains that were modest in absolute terms yet consistent across outcomes, and with clearer KM separation and better calibration. Independent replication in other settings will nonetheless be critical to validate generalizability.

The model also showed differential performance across outcomes. Prediction was most effective for composite CVD events, likely due to broader definitions and higher case counts [34]. In contrast, individual outcomes such as MI and vascular dementia were more difficult to model, reflecting data sparsity and noisier labels. MI is commonly harder because many events are precipitated by acute triggers that are not present in baseline features, which limits discriminability over a 10-year horizon. These findings highlight the practical value of composite endpoints in primary care, where follow-up is long and individual outcomes are rare. Future work will incorporate richer short-term and time-varying signals, for example, recent trajectories of vitals and laboratory results, medication changes, secondary-care encounters, and uncertainty-aware learning, to strengthen outcome-specific prediction.

Although generalizability was demonstrated between the development and spatial external validation sets, the model has not yet been evaluated across other health care systems or geographic regions. The London cohort provided important demographic diversity, especially in ethnicity and deprivation, but broader validation is required. Notably, performance declined in South Asian and socioeconomically deprived males, potentially due to lower case numbers and greater uncertainty. This highlights the need for targeted data enrichment and uncertainty-aware learning in underrepresented subgroups. Fairness-related issues also remain. While subgroup audits were

XSL•FO
RenderX

conducted, mitigation strategies such as sample reweighting or recalibration were not applied, and systematic subgroup-specific auditing will be required before equitable clinical deployment can be ensured.

From an implementation perspective, the present work relied on DistilBERT, a relatively lightweight model pretrained on general rather than medical corpora. This choice reduced computational cost, allowing training within hours on high-performance computing environments and inference within seconds on standard CPUs, demonstrating feasibility for near real-time use in primary care dashboards, such as flagging high-risk patients for recall or displaying updated risk estimates during consultations. However, the absence of domain-specific pretraining remains a limitation, and larger biomedical language models trained on richer corpora are likely to achieve superior performance in the future. While deployment at scale is unlikely to pose major challenges, training requirements will ultimately depend on the size and complexity of the pretrained models used, and these aspects will need to be formally evaluated.

Interpretability also remains a key barrier to adoption. Deep learning models are often considered "black boxes," in contrast to conventional statistical methods [6]. For structured variables, attribution methods such as SHapley Additive exPlanations (SHAP) can provide ranked contributions, enabling clinicians to see which risk factors (eg, blood pressure and diabetes status) were most influential. For clinical text, attention mechanisms can highlight salient tokens or phrases (eg, "chest pain" and "family history of stroke") that received higher model weights, offering a complementary perspective. These cross-modal explanations require distinct visualization strategies, and we did not implement a systematic framework for presenting them to clinicians in this study. While such tools may improve explainability, the trade-off between predictive performance and interpretability must be carefully considered [35]. In contexts where textual data add limited value, simpler approaches such as RSF may provide comparable results with greater transparency. For long-term CVD prediction, robust risk stratification may ultimately be more clinically relevant than token-level explanations, yet future research should examine how to deliver outputs in formats that are both faithful to the model and usable in practice.

Importantly, this model is not intended to replace established risk tools such as QRISK4 [36], which have undergone extensive validation. Rather, it illustrates the potential of combining structured and unstructured EHR data within a multitask learning framework to support multioutcome prediction. Prospective validation in external health systems, integration into clinical care pathways, development of clinician-facing interpretability tools, and incorporation of fairness-aware strategies will be essential to translate these preliminary findings into real-world practice.

Conclusion

This study presents a multitask deep learning model for 10-year CVD risk prediction using real-world EHR data, integrating structured variables and unstructured clinical text through an MT-BERT architecture. By jointly optimizing classification and survival objectives, the model achieves strong discrimination, robust calibration, and meaningful risk stratification over a 10-year follow-up. Performance remained consistent in a demographically diverse London subgroup, supporting its generalizability. Although improvements over previously tested ML-based models were modest, these findings provide preliminary evidence that combining representation learning and multiobjective optimization is a promising direction for risk prediction in primary care. However, subgroup differences across ethnicity and deprivation highlight persistent fairness concerns. Future work should focus on improving interpretability, validating in external populations, and evaluating clinical impact to support real-world implementation.

Abstract

Background: Chronic obstructive pulmonary disease (COPD) remains a leading global health burden. In primary care, the inconsistent availability of spirometry and symptom scores limits the detection of patients with poor disease control. There is a pressing need for scalable, data-driven tools that leverage routinely collected clinical information to support timely, equitable, and guideline-concordant interventions.

Objective: This study aims to validate the performance of Seleida—a fully automated, deterministic, and bijective model for COPD control assessment and phenotyping—using real-world primary care data and to evaluate its feasibility for integration into electronic health record (EHR)–based informatics systems.

Methods: Seleida estimates the probability of poor control (*Pr*) using two objective EHR variables: (1) annual dispensations of short-acting bronchodilators—specifically short-acting β2-agonists (SABA), short-acting muscarinic antagonists (SAMA), or both, and (2) number of dispensed antibiotic courses for bronchitis or COPD exacerbations. Its bijective structure supports both forward risk estimation and reverse phenotype inference. In a retrospective cohort of 106 patients, agreement was assessed between 2 phenotyping systems (a 126-combination model and a streamlined 21-combination version) and with clinician-assigned classifications. Due to sample size limitations, a provisional risk threshold of *Pr*>.50 was adopted for internal stratification.

Results: Seleida showed perfect agreement between phenotyping systems (Cohen κ=1.00; *P*<.001) and substantial concordance with clinician-assigned profiles (Cohen κ=0.70; *P*<.001). The model operates transparently, without machine learning, and can be embedded into EHR platforms or applied manually using a visual framework. It enables individualized risk estimation, phenotype-driven treatment planning, and population-level case identification—particularly in settings with limited access to traditional diagnostic tools.

Conclusions: Seleida provides a reproducible and interpretable framework for COPD control monitoring using high-frequency prescribing data. Its transparent logic, low data burden, and interoperability enable integration across diverse digital infrastructures, including resource-limited settings. By supporting both individualized care and population-level risk stratification, Seleida bridges predictive analytics with real-world clinical decision-making. Ongoing multicenter validation will determine its generalizability, clinical impact, and cost-effectiveness at scale.

Introduction

Chronic obstructive pulmonary disease (COPD) remains a major global health challenge, with more than 3.2 million deaths annually and more than 390 million people affected worldwide [1,2]. In Europe, direct health care costs exceed $56.5 billion per year (the cost that was originally reported in euros [€] was converted to US dollars using the exchange rate of €1=$1.18 as of September 15, 2025, based on the European Central Bank reference rates) [3], with the burden concentrated in primary care, where early interventions are most feasible [4].

Yet in real-world settings, early identification of patients at risk of exacerbation or poor control remains limited. Nearly 50% of individuals with COPD experience at least 1 moderate to severe

XSL•FO
RenderX

exacerbation annually, often without prior clinical detection [5-8]. These events are not only indicators of disease instability but also independent risk factors for cardiovascular morbidity and mortality. Large-scale studies have shown sharply increased risks of death and cardiovascular events—such as myocardial infarction, heart failure, stroke, and arrhythmias—within 30 days of an exacerbation, with elevated risk persisting for up to a year [9-12].

The underlying pathophysiology—driven by systemic inflammation, hypoxia, and prothrombotic states—may explain this sustained vulnerability [10,11]. The effect is cumulative: each subsequent exacerbation further increases cardiopulmonary risk [9]. These episodes also drive disproportionate health care use and cost, particularly via emergency and hospital care [11,13].

In this context, it is essential to develop tools that not only predict a patient's level of COPD control but also accurately phenotype them, since therapeutic optimization depends heavily on phenotype-specific characteristics. Personalized inhaled treatment, guided by phenotype, has the potential to reduce exacerbations and mitigate their associated systemic and economic consequences.

While current frameworks—such as Global Initiative for Chronic Obstructive Lung Disease (GOLD) 2025 and GesEPOC 2021—guide treatment decisions, they rely on clinical data often unavailable in primary care, including spirometry and symptom scales [14-17]. Moreover, they underutilize objective, high-frequency prescribing data—such as rescue bronchodilator or antibiotic use—despite their predictive value for clinical instability [12].

To address this gap, we developed Seleida: a fully automated classification system that is deterministic, meaning it produces the same output for any given input without randomness, and bijective, meaning each patient profile corresponds to a unique, reversible clinical category. The model is based solely on 2 universally available variables in structured electronic health records (EHRs): the annual number of short-acting β2-agonists (SABA) and short-acting muscarinic antagonists (SAMA) dispensations, or both, and the annual number of antibiotic dispensations for respiratory events, specifically bronchitis and COPD exacerbations [18-20]. These variables serve as robust proxies for symptom burden and exacerbation frequency, facilitating seamless integration into routine clinical workflows [21-23].

By intentionally excluding low-access metrics (eg, forced expiratory volume in the first second of expiration, patient-reported outcomes), Seleida prioritizes scalability and feasibility without sacrificing predictive accuracy. Prior work suggests minimal added value from incorporating such variables into risk models [18,20].

This study aimed to validate the Seleida model using real-world data from 2 Spanish primary care centers. We hypothesized that a deterministic, fully automated system based solely on prescribing data—specifically, annual SABA or SAMA and antibiotic dispensations—could reliably stratify patients with COPD by control status and phenotype, without relying on spirometry or symptom scales. To this end, the study pursued 3 interrelated goals: validating the model's bijective structure, comparing model-derived phenotypes against the 2025 GOLD ABE classification and between the 126- and 21-combination configurations, and evaluating Seleida's clinical use for early risk identification and digital deployment in routine care.

Methods

Study Design, Setting, and Population

This retrospective, multicenter pilot cohort validation study was nested within the Seleida project—an initiative to develop scalable models, based on EHRs, for identifying poor control in chronic respiratory diseases. The Seleida model had been previously developed and internally validated using two consistently recorded variables in structured EHRs: (1) annual dispensations of rescue inhalers (SABA, SAMA, or both) and (2) respiratory antibiotics [24,25]. These variables were chosen for their clinical relevance, high traceability, and interoperability with primary care informatics systems [21-23].

For this validation study, anonymized patient-level EHR data were extracted from 2 urban primary care centers in Seville and Valencia, both integrated within the Spanish National Health System [21,26]. These centers serve demographically diverse populations and represent real-world contexts for Seleida deployment.

From a reference population of 82,631 adults, a stratified random sample of 110 individuals aged 40 - 80 years was drawn. Selection was based on the presence of a COPD diagnosis (*International Classification of Diseases, Tenth Revision* [*ICD-10*]), on compatible pharmacological treatment for at least 3 months per year over the previous 2 years, or on both criteria [6,8]. Predefined exclusion criteria were active malignancy, palliative care, systemic corticosteroids or biologics for nonrespiratory indications, pregnancy, severe disability, enrollment in clinical trials, asthma-COPD overlap syndrome, and absence of recorded pharmacological activity during the 12-month observation period.

All dispensing records were cross-validated with linked pharmacy databases to minimize misclassification bias from unfilled or partially filled prescriptions [27,28]. Variables with more than 50% missing data were excluded, following standard epidemiological guidance [28,29]. Operational definitions, measurement units, and coding conventions are described in section S2 in Multimedia Appendix 1.

Four patients (4/6, 3.6%) met exclusion criteria, leaving a final analytical cohort of 106 patients (60/106, 56.6%) from Seville and from Valencia (46/106, 43.4%), with a mean age of 68.8 (SD 8.2) years; most were male (77/106, 72.6%).

To ensure data integrity, automated quality checks were performed to detect missing fields and inconsistencies. Data processing and storage followed international health informatics standards [27,30]. The methodological infrastructure was designed to support interoperability with HL7 FHIR (Health Level Seven Fast Healthcare Interoperability Resources; see

XSL•FO
RenderX

section S7 in Multimedia Appendix 1), enabling future integration into clinical decision support tools [21,22,31-33].

Objective and Methodology

The primary aim of this study was to validate the predictive performance and mathematical structure of the Seleida model—a deterministic and bijective algorithm designed for real-time COPD control assessment—using structured, real-world EHR data from primary care. The secondary aim was to evaluate its feasibility for integration into digital health infrastructures and its ability to support automated phenotyping in routine clinical workflows.

To address the primary aim, the study pursued 3 interrelated objectives:

1. To validate Seleida's bijective structure, which ensures a one-to-one correspondence between clinical inputs and predicted risk estimates. It guarantees that each unique combination of rescue inhaler use and exacerbation frequency produces a distinct, reproducible phenotypic classification [20,34].

2. To compare Seleida's model–derived phenotypes with established clinical classifications based on the 2025 GOLD guidelines. This included:

- Comparing the 126-combination high-resolution phenotyping system to the guideline-defined 2025 GOLD ABE classification [27,35],
- Comparing the 21-combination streamlined system to the 2025 GOLD ABE classification [4], and
- Assessing the agreement between the 126- and 21-combination structures.

Both systems support two phenotyping methods: (1) basic phenotyping (closely aligned with the ABE classification in GOLD 2025) and (2) expanded phenotyping (combines the ABE classification with stratification based on SABA use levels—low or high: L or H), offering a nuanced characterization aligned with Seleida's risk profiles.

3. To assess the model's clinical use for early risk detection and phenotype-driven decision support. The goal is to enable proactive, data-driven interventions for poorly controlled patients in EHR-integrated environments [20,36].

By combining mathematical determinism with real-world clinical traceability, Seleida offers a scalable and interpretable alternative to conventional risk classification systems. Its design supports automated control monitoring, granular patient segmentation, and guideline-concordant decision-making in both high- and low-resource care settings [34,37,38].

Outcome Definition and Model Application

The operational definition of poor control in COPD was adapted to align with Seleida's data-driven thresholds: ≥1 moderate exacerbation (requiring antibiotics or systemic corticosteroids without hospitalization), ≥1 severe exacerbations (requiring hospitalization or emergency room visit), or annual use of at least 3 SABA or SAMA canisters or both [14,17,25]. This definition enables continuous risk stratification and phenotype inference without the need for spirometry or symptom scales, improving scalability in digital health environments. By these criteria, 55.7% (59/106) of the cohort was classified as poorly controlled. Control status was evenly distributed across sites (χ^2_1=1.055; *P*=.304), and baseline demographic and clinical characteristics were compared for balance [39-41].

Model Development, Validation, and Performance Evaluation

The analytical cohort comprised 106 patients, selected pragmatically based on feasibility and validated against formal criteria for clinical prediction modeling. With a binary outcome (poor vs good control) and a 55.7% (59/106) prevalence of poor control, the training subset (85/106, 80% of the cohort) included approximately 47 events. This yielded an events-per-variable ratio of 23.5 for the 2 selected predictors—annual rescue inhaler canisters and respiratory antibiotic courses dispensed—well above the recommended ≥10 events-per-variable threshold for stable logistic regression estimates [29,41,42].

Additional clinical and demographic variables—age, sex, geographic origin, exacerbation history, daily inhalation frequency, and emergency visits—were collected for descriptive purposes and evaluated for potential inclusion. An exploratory multivariable logistic regression including age group, sex, SABA or SAMA use, or both, and antibiotic prescriptions confirmed the independent predictive strength of the 2 primary variables (*P*=.001 and *P*<.001, respectively). In contrast, age and sex were not statistically significant (*P*=.65 and *P*=.65), and their inclusion caused numerical instability due to sparse subgroup representation (eg, patients aged 80 years without exacerbations or females with high SABA or SAMA use or both). This led to quasi-complete separation and convergence failures, manifested as inflated standard errors, infinite odds ratios [Exp(β) >10], and singularities in the Hessian matrix—classic indicators of model overspecification in small samples. Full diagnostics and regression results are detailed in section S5 in Multimedia Appendix 1. Following best practices for parsimonious and deployable models [4,6], age and sex were excluded from the final Seleida model to reduce overfitting, preserve statistical stability, and maintain generalizability in small or imbalanced datasets.

The final Seleida model, including only the 2 primary predictors, achieved strong predictive performance in the initial validation: area under the receiver operating characteristic curve of 0.978, sensitivity of 92.86%, specificity of 87.50%, κ coefficient of 0.80, and positive likelihood ratio (LR+) of 7.43. Bootstrap resampling (1000 iterations) confirmed metric stability, supporting both clinical use and statistical robustness [24,25].

Internal validity was also assessed with bootstrap resampling (1000 iterations), following Steyerberg's framework for early-phase models [25,29]. The α level was set at .05, and the minimum detectable effect size was estimated from the observed event distribution and prior literature [24,25]. In addition, 10,000 Monte Carlo simulations using real-world covariate distributions indicated a model-level statistical power (1–β) of 92.4% (95% CI 91.85 - 92.87), supporting high reliability for detecting clinically relevant effects in this sample and predictor configuration. Bootstrap-derived CIs quantified uncertainty in coefficient estimates and performance metrics.

XSL•FO
RenderX

All analyses were conducted using R (version 4.3.4.2; R Core Team), following established best practices for early-phase predictive modeling. Model development used logistic regression with Least Absolute Shrinkage and Selection Operator (LASSO) regularization to enhance parsimony and reduce overfitting in a small to moderate sample context (section S4 in Multimedia Appendix 1) [33]. Predictors were modeled without scaling to preserve clinical interpretability.

Building on this validated model, this study evaluates 2 deterministic phenotyping frameworks derived from its final equation: a 126-combination system and a simplified 21-combination version. Both were assessed using classification-based performance metrics—sensitivity, specificity, predictive values, LRs, and Cohen κ—against real-world clinical phenotypes. Internal concordance between systems was evaluated using κ statistics. Additionally, the 126-combination system was also benchmarked against the 2025 GOLD ABE classification to assess alignment with guideline-based stratification [22,31,43,44].

Furthermore, the simplified phenotyping system was evaluated for computational efficiency and its potential integration into HL7 FHIR–compliant health information systems (section S7 in Multimedia Appendix 1) [22,31,32]. All procedures followed TRIPOD guidelines and contemporary standards for internal validation of clinical prediction models [45,46].

Reverse Model Definition

A defining feature of the Seleida model is its deterministic and bijective architecture, establishing a one-to-one correspondence between 2 routinely collected clinical variables and the predicted probability of poor COPD control (sections S1 and S2 in Multimedia Appendix 1). Specifically:

- ***a*** represents the annual number of SABA or SAMA canisters or both dispensed per patient, serving as a proxy for symptom burden and short-acting bronchodilator dependence [18,47].
- ***b*** denotes the annual number of antibiotic dispensations for bronchitis or COPD exacerbations, reflecting exacerbation frequency and infection-driven instability [48,49].

Both variables were chosen for their objectivity, universal availability in structured EHRs, and strong predictive value in prior studies [25,50]. The predicted probability of poor control (*Pr*) is calculated with a logistic regression model:

$$\text{logit}(Pr)=\alpha+\beta 1\cdot a+\beta 2\cdot b,$$

where α is the intercept, and β_1 and β_2 are positive coefficients estimated using LASSO regularization, ensuring parsimony and coefficient stability (section S4 in Multimedia Appendix 1).

This structure supports two complementary functions: (1) forward inference: estimating *Pr* from any (*a*, *b*) combination, and (2) reverse inference: retrieving the (*a*, *b*) pairs matching a target risk level. The latter enables real-time, automated phenotyping and individualized decision-making in EHR-integrated workflows.

Although Seleida can estimate risk directly from observed data, it is explicitly designed for bidirectional operation. This means that it can both predict risk from clinical inputs and perform inverse mapping to retrieve all (*a*, *b*) pairs that match a given probability. This reverse functionality is critical for dynamic alert systems, phenotype-driven decision pathways, and real-time decision support tools.

This bidirectional capability has practical implications. For example, a patient with 3 annual SABA or SAMA inhalers or both (*a*=3) and 1 antibiotic course (*b*=1) maps to a unique cell (3,1) in the 126-combination system, with a predicted poor control risk of 95.53%. In the simplified 21-combination version, the same profile is classified as *a*=3 (midrange inhaler use) and *b*=1 (moderate exacerbation frequency), preserving its phenotypic identity—GOLD A1/B1 with high rescue inhaler use (H)—within a reduced but clinically actionable framework. This structured mapping supports therapeutic reassessment and integration into EHR-based alert systems, where predefined thresholds (eg, *Pr*>.50) can trigger guideline-aligned interventions.

In contrast to black box machine learning models, often criticized for limited interpretability, Seleida's transparent structure ensures full traceability from risk estimate to actionable clinical profile. This enhances clinical confidence and facilitates deployment across diverse health care settings, including resource-constrained environments [20,34,37,38]. A detailed mathematical demonstration of these bijective properties, with exhaustive verification of all input-output mappings, appears in the following section and in section S3 in Multimedia Appendix 1.

Mathematical Proof of Bijectivity

Bijectivity is not merely a theoretical refinement but a functional cornerstone of the Seleida model. As detailed in section S1, its formal proof guarantees three essential capabilities: (1) each predicted probability is uniquely traceable to a specific clinical phenotype, ensuring transparency and auditability; (2) every clinically relevant risk threshold corresponds to at least 1 valid input combination, providing full operational coverage; and (3) no ambiguity or discontinuity occurs in model behavior, maintaining consistency in decision support and regulatory contexts. Without this formal validation, the model's dual interpretability and reproducibility would remain unverified.

To confirm these properties, we validated that each (*a*, *b*) input pair yields a unique predicted probability (*injectivity*), and that the entire risk spectrum (0<*Pr*<1) is covered by the input domain (*surjectivity*). These conditions are defined as follows:

- Injectivity: Each unique (*a*, *b*) pair—representing the annual number of dispensed SABA or SAMA canisters or both and respiratory antibiotics—must map to a single, distinct predicted probability of poor COPD control (*Pr*).
- Surjectivity: Every probability value within the model's codomain must be attainable from at least 1 clinically plausible (*a*, *b*) combination, ensuring that there are no gaps in the risk scale.

We followed a rigorous, multistep validation process to formally demonstrate the bijective nature of the Seleida model:

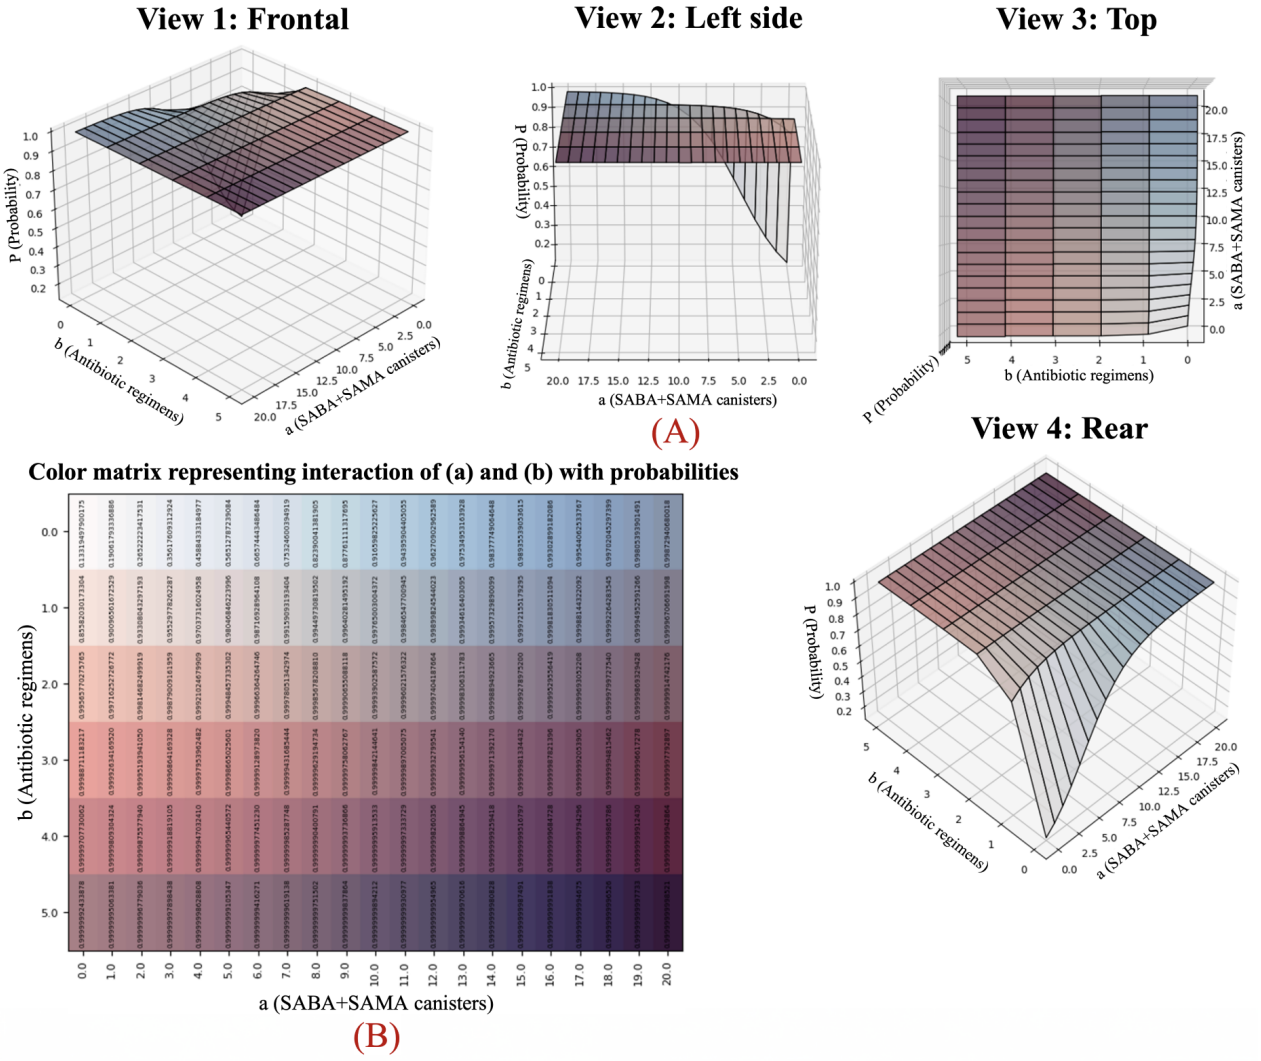
XSL•FO
RenderX

- Bounding inputs: The variables—annual SABA or SAMA canisters or both (*a*) and annual antibiotic regimens (*b*)—were explicitly restricted to integers: a=0 - 20 and b=0 - 5 (inclusive). These ensured a finite, fully enumerable input space.
- Analytical proof of injectivity: We demonstrated that no 2 distinct input pairs (a_1 , b_1) and (a_2 , b_2) produce the same output probability. The logistic model's coefficients structure confirmed unique mappings for all valid pairs.
- Computational proof of surjectivity: Using a custom Python algorithm, we calculated all 126 possible output probabilities to 14 decimal places. Every value was checked for uniqueness, confirming that the entire codomain is covered.
- Conclusion: Independent confirmation of both injectivity and surjectivity verified that Seleida is bijective, enabling forward risk estimation and reverse phenotype reconstruction with mathematical certainty.

No repeated or missing outputs were found, confirming a perfect alignment between input and output spaces. This property ensures robust reverse inference and reproducible phenotype classification across real-world COPD datasets. All source code, verification tables, and derivations are provided in section S3 in Multimedia Appendix 1 [45,51].

Ethical Considerations

The study was approved by the ethics committee of Hospital Universitario Doctor Peset of Valencia (protocol code CEIm 132.22, approval date March 6, 2023). The project was registered in the *Portal de Ética de la Investigación Biomédica de Andalucía* through the *Sistema de Información de los Comités de Ética de la Investigación* (protocol code 1140-N-23, approval date September 12, 2023). The SEMERGEN research department gave its endorsement to the project (2023-00035, approval date June 6, 2023) [27,28]. For the purpose of this study, only patient data recorded in EHRs were collected. All data were fully anonymized in compliance with the General Data Protection Regulation (2016/679). No procedures were performed on participants and, to ensure confidentiality, each patient was assigned a unique study identifier. Informed consent was formally waived due to the retrospective design and the absence of patient contact. Due to the nature of the study, compensation to patients was not applicable.



Results

Expanded Phenotyping: Analysis of the 126-Combination System

The 126-combination phenotyping framework systematically integrates 2 structured prescribing variables—annual dispensations of rescue inhalers (*a*) and respiratory antibiotic regimens (*b*)—to generate a continuous, 3D map of predicted COPD control probabilities (Figure 1A and B). Blue gradients reflect increasing use of SABA or SAMA canisters or both (*a*), red gradients indicate the frequency of antibiotic courses (*b*), and purple regions highlight zones of sharply elevated clinical risk [35]. Each unique (*a*, *b*) pair yields a distinct probability estimate, delineating a mathematically robust and clinically interpretable risk surface with actionable thresholds [20,34].

XSL•FO
RenderX

Figure 1. Visual mapping of the Seleida model's 126-combination system. The 4 images in panel (A) show 3D perspectives of how annual rescue inhaler use (*a*) and antibiotic prescriptions (*b*) combine to yield the probability of poor chronic obstructive pulmonary disease control (*Pr*). Panel (B) provides a color matrix of exact *Pr* values across all combinations. Darker red indicates higher predicted risk. Clinically, higher values of *b* (≥2 antibiotics per year) are stronger drivers of poor control than *a*, highlighting infection burden as a key modifiable factor. SABA: short-acting β2-agonists; SAMA: short-acting muscarinic antagonists.

To guarantee bijectivity, the input domain was discretized to include integer values from 0 to 20 for *a* and from 0 to 5 for *b* (both inclusive). Any observed values exceeding these bounds are computationally capped at *a*=20 and *b*=5, preserving full injectivity and surjectivity across the model's codomain. This bounded structure ensures reversibility and enables exhaustive phenotype enumeration while maintaining operational realism.

Model outputs demonstrate that antibiotic burden (*b*) exerts a greater marginal influence on the predicted probability of poor control than rescue bronchodilator use (*a*), particularly within intermediate strata. For example, the phenotype (*a*=3, *b*=1) is associated with substantially elevated risk, whereas combinations with $a \geq 15$ and $b \geq 4$ approach probability ceilings exceeding 99% [36,52]. These gradients reflect the compounding effects of symptom burden and exacerbation frequency, underscoring the need for integrated monitoring of both variables in routine care.

By translating complex statistical interactions into visually intuitive gradients, the 126-combination system provides clinicians with a practical, high-resolution tool for individualized COPD phenotyping—enabling phenotype-driven interventions, anticipatory care strategies, and optimized treatment planning (section S6 in Multimedia Appendix 1) [4,34,38].

Expanded Phenotyping: Analysis of the 21-Combination System

To enhance feasibility in real-world clinical settings, the original 126-combination system was streamlined into a 21-combination framework by constraining the antibiotic regimen variable (*b*) to a range of 0 - 2 and the SABA or SAMA canisters or both variable (*a*) to 0 - 6. These thresholds were empirically defined to preserve the model's bijective architecture while concentrating on clinically meaningful stratification intervals [4,20,24].

Despite its reduced dimensionality, the simplified system maintains robust predictive performance (Figure 2) and offers improved technical and operational feasibility for integration into health information systems and routine care workflows [20-22,43,50,53]. Its lower computational complexity supports

XSL•FO
RenderX

real-time patient stratification and personalized COPD management in both primary care and resource-constrained environments (section S6 in Multimedia Appendix 1) [34,38,44].

Figure 2. Chronic obstructive pulmonary disease phenotyping using the simplified 21-combination Seleida system. Each cell reflects the predicted risk level based on rescue inhaler use (*a*) and antibiotic courses (*b*), capped at clinically relevant thresholds ($a \leq 6$; $b \leq 2$). Color intensity indicates increasing probability of poor control. This tool enables rapid identification of high-risk patients using prescribing data alone, without spirometry or symptom scores, supporting scalable risk stratification in primary care. This visual framework enables clinicians to stratify patients using only prescribing data, even without algorithmic integration. H: high; L: low; SABA: short-acting β2-agonists; SAMA: short-acting muscarinic antagonists.

Expanded Phenotyping: Comparing Real and Combination Systems

Seleida's expanded phenotyping system refines the 2025 GOLD ABE classification by incorporating the annual use of SABA or SAMA or both as a stratification axis. Each GOLD category—E (≥2 moderate or ≥1 severe exacerbation), A1/B1 (1 moderate exacerbation), and A0/B0 (no exacerbations)—is subdivided into high SABA users (H; ≥3 canisters per year) and low users (L; <3 canisters per year). This additional layer of segmentation enhances sensitivity for detecting early manifestations of disease instability and symptom burden, yielding a more granular and actionable classification of COPD phenotypes (Table 1).

RenderX

Table . Performance metrics of the 126-combination system for each chronic obstructive pulmonary disease phenotype[a].

	Accuracy, %	Se[b], %	Sp[c], %	PPV[d], %	NPV[e], %	LR+[f]	LR−	κ value	Significance of κ[g]
A0/B0 H[h]	95.3	100	94.8	66.7	100	19.2	0.00	0.774	<.001[i]
A0/B0 L[j]	96.2	97.7	95.2	93.3	98.4	20.5	0.02	0.922	<.001[i]
A1/B1 H	85.8	50	90.4	40	93.4	5.2	0.55	0.365	.002[k]
A1/B1 L	93.4	81.3	95.6	76.5	96.6	18.3	0.20	0.749	<.001[i]
E H	86.8	38.9	96.6	70	88.5	11.4	0.63	0.431	<.001[i]
E L	97.2	57.1	100	100	97.1		0.43	0.714	<.001[i]

[a]Sensitivity, specificity, PPV, NPV, and LR+/LR− for each phenotype identified by the 126-combination system. These metrics evaluate the model's ability to replicate real phenotyping and highlight its strengths in common phenotypes (eg, A0/B0 H and A0/B0 L) as well as areas requiring refinement for less frequent phenotypes (eg, E H and A1/B1 H).

[b]Se: sensitivity.

[c]Sp: specificity.

[d]PPV: positive predictive value.

[e]NPV: negative predictive value.

[f]LR: likelihood ratio.

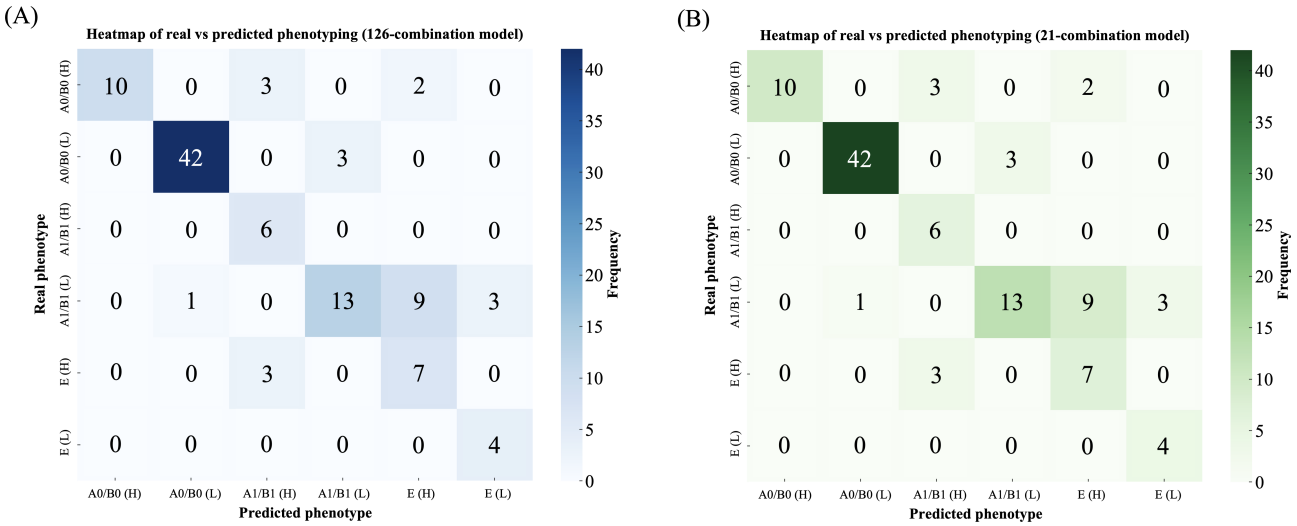
[g]Significance (*P* value) of Cohen κ coefficient.

[h]H: high.

[i]Hypothesis tests applied to assess the statistical significance of the coefficient: Fisher exact test.

[j]L: low.

[k]Hypothesis tests applied to assess the statistical significance of the coefficient: χ^2 test.



Two phenotyping strategies were evaluated: (1) The 126-combination system, designed for high-resolution stratification, is ideally suited to research settings and complex clinical scenarios [27,35]. (2) The simplified 21-combination system, optimized for routine clinical application, offers a favorable balance between predictive performance and computational efficiency [4,39]. Its lower complexity makes it especially appropriate for primary care and resource-limited environments, where operational simplicity and rapid decision-making are essential [43,44].

Both systems exhibited strong concordance with clinician-assigned phenotypes based on real-world data (Cohen κ=0.70, SE=0.050; *P*<.001). Sensitivity and specificity were notably high for the most prevalent phenotypes, with specificity exceeding 90% and sensitivity reaching or surpassing 97% for categories such as A0/B0-H, A0/B0-L, and E-L. In contrast, sensitivity was lower for less frequent phenotypes, underscoring the importance of clinical judgment in borderline cases and reinforcing the complementary role of Seleida alongside expert assessment.

Internal agreement between the 126- and 21-combination models was perfect (Cohen κ=1.00, *P*<.001) (Figure 3A and B). Despite its reduced granularity, the simplified system preserved high specificity, minimizing false positives and confirming its suitability for real-time clinical implementation. These features make it particularly advantageous for integration into EHR systems and point-of-care workflows, especially in settings with constrained health care infrastructure [22,31,43,44,53].

XSL•FO
RenderX

Figure 3. (A) Heatmap of real versus predicted phenotyping by 126-combination system. (B) Heatmap of real versus predicted phenotyping by 21-combination system.

Overall, the expanded phenotyping approach implemented in Seleida offers a scalable, automated solution for enhancing risk stratification and supporting targeted therapeutic interventions in COPD management [20,24,25,38]. By identifying high-risk individuals early, Seleida facilitates more personalized care, prioritizing interventions for those most likely to benefit while reducing overtreatment in stable cases [4,24,25,36]. This paradigm not only improves clinical outcomes but also promotes more efficient use of health care resources—aligning with the growing imperative for data-driven decision-making in contemporary health care systems [21,33,38].

Basic Phenotyping: Evaluating the 126-Combination System for GOLD 2025 Phenotypes

The performance of Seleida's 126-combination system was assessed in replicating GOLD 2025 phenotypes [14]—A0/B0 (no exacerbations), A1/B1 (1 moderate exacerbation), and E (≥2 moderate or ≥1 severe exacerbation)—using the annual number of respiratory antibiotic regimens (variable *b*) as the sole predictor (Table 2) [48,49]. The model's discriminatory capacity across these clinical categories was demonstrated by the following results:

- A0/B0 (no exacerbations): sensitivity=98.1%, specificity=84.9%, and accuracy=97.5%, with near-perfect agreement (κ=0.83; *P*<.001). These findings confirm the model's high reliability in identifying well-controlled patients.
- A1/B1 (1 moderate exacerbation): sensitivity=67.9%, specificity=83.3%, and accuracy=79.3%, with moderate agreement (κ=0.49; *P*<.001). This level of performance reflects a balanced capacity to detect patients at intermediate risk, despite the inherent clinical heterogeneity of this group.
- E (≥2 moderate or ≥1 severe exacerbation): specificity=96.3%, sensitivity=44%, accuracy=84%, and a high positive LR+=11.9. These metrics indicate robust identification of high-risk patients with minimal false positives, supporting timely and targeted interventions.

Table . Performance metrics of the 126-combination system for Global Initiative for Chronic Obstructive Lung Disease 2025 chronic obstructive pulmonary disease phenotypes[a].

	Accuracy, %	Se[b], %	Sp[c], %	PPV[d], %	NPV[e], %	LR+[f]	LR−	κ value	Significance of κ[g]
A0/B0	97.5	98.1	84.9	86.7	97.8	6.5	0.02	0.830	<.001[h]
A1/B1	79.3	67.9	83.3	59.4	87.8	4.1	0.39	0.489	<.001[i]
E	84	44	96.3	78.6	84.8	11.9	0.58	0.475	<.001[h]

[a]Sensitivity, specificity, PPV, NPV, LR+ /LR−, accuracy, and κ for each phenotype identified by the reverse Seleida model. The metrics reflect the model's ability to replicate real-world phenotyping and its strengths in classifying Global Initiative for Chronic Obstructive Lung Disease 2025 phenotypes.

[b]Se: sensitivity.

[c]Sp: specificity.

[d]PPV: positive predictive value.

[e]NPV: negative predictive value.

[f]LR: likelihood ratios.

[g]Statistical significance (*P* value) of Cohen κ coefficient.

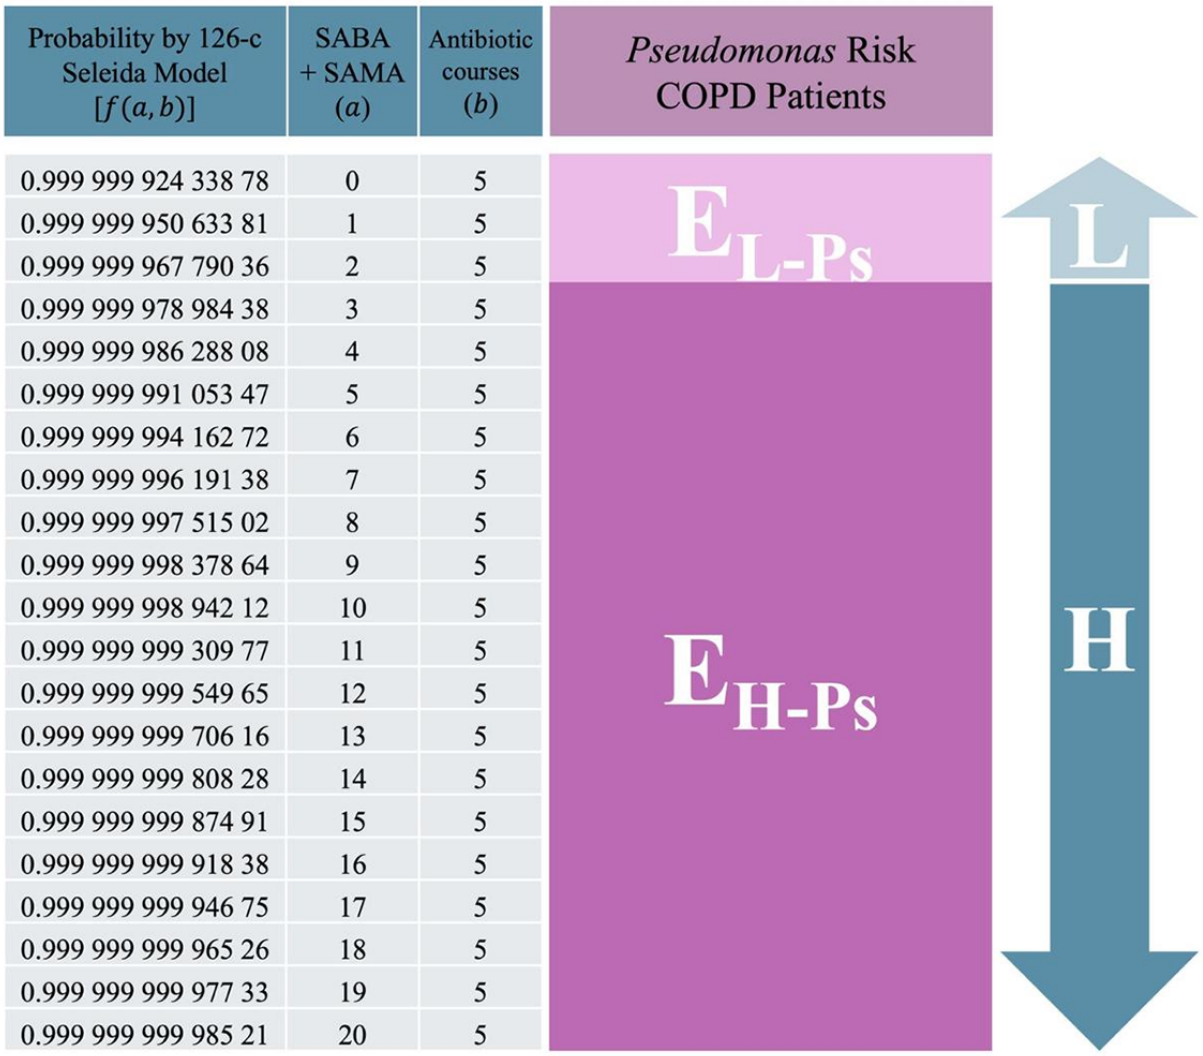
[h]Hypothesis tests applied to assess the statistical significance of the κ coefficient: Fisher exact test.

[i]Hypothesis tests applied to assess the statistical significance of the κ coefficient: χ^2 test.

XSL•FO
RenderX

Collectively, these results underscore the robustness of Seleida's basic phenotyping system in stratifying patients based solely on antibiotic prescribing data. However, the model's ability to discriminate between A and B categories—particularly within the intermediate-risk stratum—may benefit from the incorporation of symptom-based measures, such as the modified Medical Research Council dyspnea scale and the COPD Assessment Test, both of which are widely used in routine practice [16,17,54,55]. Future iterations integrating these variables could enhance phenotypic granularity and improve the model's adaptability across diverse health care settings.

Despite these acknowledged limitations, Seleida demonstrates strong performance when classifying COPD phenotypes using a single, objective, and consistently recorded variable: annual antibiotic use. The system reliably identifies patients with stable disease (A0/B0), achieves moderate accuracy for those at intermediate risk (A1/B1), and exhibits high specificity for detecting individuals with frequent or severe exacerbations (E). These findings reinforce Seleida's potential as a pragmatic, evidence-based tool for real-world clinical decision-making, offering scalable, reproducible, and personalized support for COPD management across a wide range of practice environments [29,33,34,38].



Expanded Phenotyping: Integration of *Pseudomonas* Risk in the 126-Combination System

The 126-combination phenotyping system was further evaluated for its capacity to identify patients with COPD at an increased risk of *Pseudomonas aeruginosa* colonization or infection. Evidence indicates that individuals receiving more than 4 respiratory antibiotic regimens annually exhibit a markedly elevated risk of frequent exacerbations and poor disease control [48,56-58]. By incorporating this threshold into the Seleida model, the system enhances its ability to detect high-risk phenotypic profiles—facilitating targeted interventions such as antimicrobial stewardship and intensified clinical monitoring [48,59].

In contrast, the 21-combination system—by design—limits the antibiotic variable (*b*) to a maximum of 2 prescriptions per year, potentially reducing its sensitivity for identifying this severe phenotype. The expanded resolution of the 126-combination system, which accommodates values of *b* up to 5, enables more accurate detection of complex clinical cases. As illustrated in Figure 4, profiles with $b \geq 5$ are consistently associated with very high predicted risk, capturing severe phenotypes that may otherwise be underrepresented in streamlined models.

XSL•FO
RenderX

Figure 4. Identification of patients with chronic obstructive pulmonary disease at high risk of *Pseudomonas aeruginosa* colonization using the 126-combination Seleida model. The shaded area highlights phenotypes with high predicted risk (*Pr*≥0.99), ≥5 antibiotics per year (*b*), and high or low rescue inhaler use (H or L). These patients should be prioritized for sputum culture screening and potential referral to pulmonology. This supports targeted infection surveillance based on real-world prescribing data. COPD: chronic obstructive pulmonary disease; H: high; L: low; SABA: short-acting β2-agonists; SAMA: short-acting muscarinic antagonists.

Integrating *Pseudomonas*-related risk factors into the high-resolution framework strengthens Seleida's use for proactive therapeutic planning. This refinement supports the early identification of patients requiring microbiological surveillance, targeted antimicrobial strategies, or referral to hospital-based specialist care—ultimately contributing to the mitigation of antibiotic resistance and the improvement of long-term clinical outcomes (section S6 in Multimedia Appendix 1) [49,60,61].

By capturing a broader spectrum of disease severity, this extension reinforces the adaptability of the Seleida model and underscores its value as a precision tool for guiding personalized interventions in the management of complex COPD phenotypes across a range of clinical environments.

Impact of Rescue Medication Use on Health Care Utilization in Patients With COPD

High rescue medication use (H) among patients with COPD is a well-established indicator of increased health care resource utilization. In the present cohort (n=106), 71.4% (15/21) of high-use patients required at least 1 respiratory-related clinical consultation annually, compared with 40% (34/85) of low-use patients (χ^2=6.691; *P*=.010). A moderate yet statistically significant correlation was observed between rescue medication consumption and health care consultations (Pearson *r*=0.251; *P*=.009), as illustrated in Multimedia Appendix 2.

These findings highlight the use of rescue medication as a reliable and actionable marker for patient stratification within the Seleida phenotyping system [25]. Early identification of high-use individuals facilitates the deployment of targeted interventions, including optimization of maintenance therapy, structured education to reduce inhaler overreliance, and scheduling of more frequent clinical follow-ups [15,62,63].

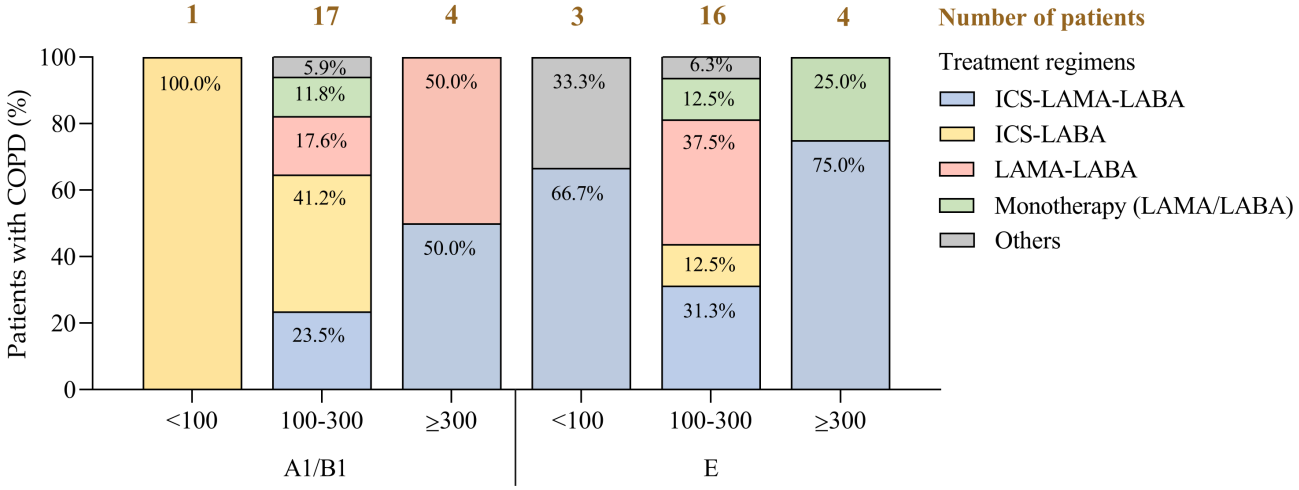
XSL•FO
RenderX

The ≥1 consultation per year threshold serves as a pragmatic and clinically interpretable metric to prioritize high-risk patients in care workflows and inform strategic health care resource allocation. Future analyses incorporating additional parameters—such as disease severity, multimorbidity profiles, and treatment adherence—will be essential to refine predictive accuracy and enhance the model's capacity to support resource optimization in diverse clinical settings [48,64-66].

Exacerbations in the Last Year and Rescue Medication Use

In this cohort of 106 patients with COPD, a significant association was observed between exacerbation history and increased use of SABA. Among patients with no exacerbations in the preceding 12 months, 88.7% (47/53) used fewer than 3 rescue canisters annually. In contrast, 28.3% (15/53) of those with ≥1 exacerbation required ≥3 canisters (χ^2_1=4.810, P=.028; Pearson r=0.213, P=.028), as depicted in Multimedia Appendix 3.

This correlation underscores the heightened reliance on rescue therapy among patients with recent exacerbations—often reflecting suboptimal maintenance treatment or inadequate symptom control [47,67,68]. These findings support the implementation of targeted clinical strategies, such as optimizing long-term inhaled therapy and reinforcing adherence interventions, to reduce SABA dependence and enhance overall disease management.



Incorporating this association into predictive modeling frameworks can improve risk stratification and enable more personalized treatment planning [69,70]. Future analyses should account for potential confounding factors—such as comorbid conditions, medication adherence, and variability in EHR completeness—to further refine the model's predictive performance and clinical applicability across heterogeneous patient populations [27,46].

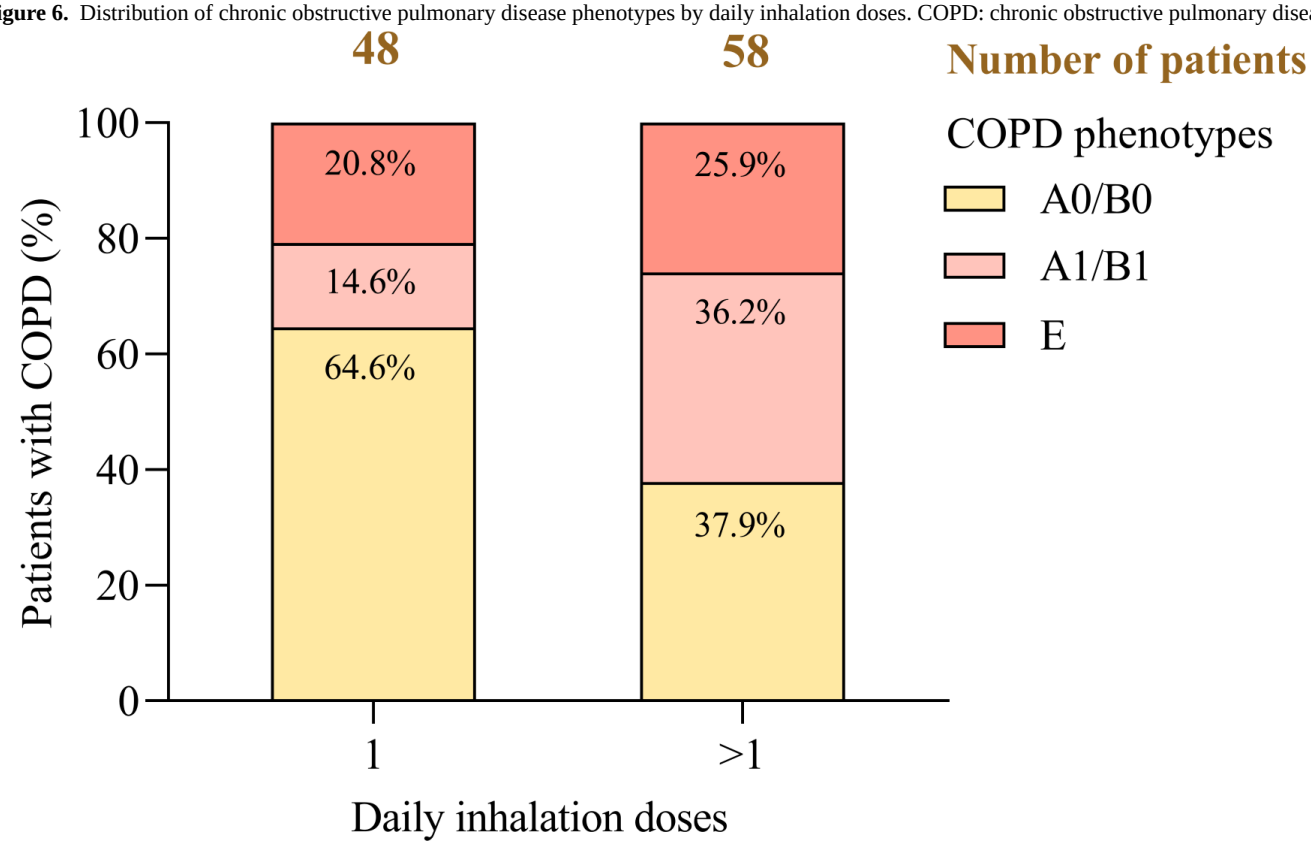
Treatment Patterns in Patients With Exacerbated COPD

This analysis examined treatment patterns among 53 patients with COPD who experienced at least 1 moderate exacerbation in the past year. After excluding 8 individuals due to missing eosinophil count data, the final sample comprised 45 patients. The Seleida model was applied to assess deviations from current therapeutic recommendations as outlined in established clinical practice guidelines [25].

Among patients with blood eosinophil counts of <100 cells/µL (4/45, 8.89%)—where the use of inhaled corticosteroids (ICS) is generally not recommended [14]—66.7% (2/3) of those classified as phenotype E, along with 1 patient in the A1/B1 category, were nonetheless prescribed ICS-containing regimens. Exceptions to this pattern were documented in cases where eosinophil counts of ≥100 cells/µL had been recorded previously, justifying continued ICS use (Figure 5). In addition, 11.1% (5/45) of patients were receiving bronchodilator monotherapy, and 22.2% (10/45) were treated with ICS–long-acting β2-agonist combinations, despite GOLD 2025 guidelines recommending dual bronchodilation (long-acting muscarinic antagonist–long-acting β2-agonists) in these clinical scenarios [14].

Figure 5. Treatment regimen by annual mean eosinophilia and exacerbation phenotype. COPD: chronic obstructive pulmonary disease; ICS: inhaled corticosteroids; LABA: long-acting β2-agonists; LAMA: long-acting muscarinic antagonists.

Conversely, ICS underutilization was observed in patients who met criteria for triple therapy—particularly those with eosinophil counts of ≥100 cells/µL—suggesting that nonclinical factors (eg, logistical or prescriber-related) may contribute to deviations from phenotype-aligned treatment pathways [71].



By automating phenotypic classification based on exacerbation history, the Seleida combination systems—when integrated with eosinophil count and treatment data—allow for the systematic identification of discrepancies between recommended and actual therapy [31,70]. This functionality supports improved alignment with evidence-based guidelines, promoting optimal ICS use, minimizing unnecessary adverse effects, and enhancing overall COPD management outcomes [20,34].

Real-World COPD Phenotypes Across Daily Inhalation Patterns

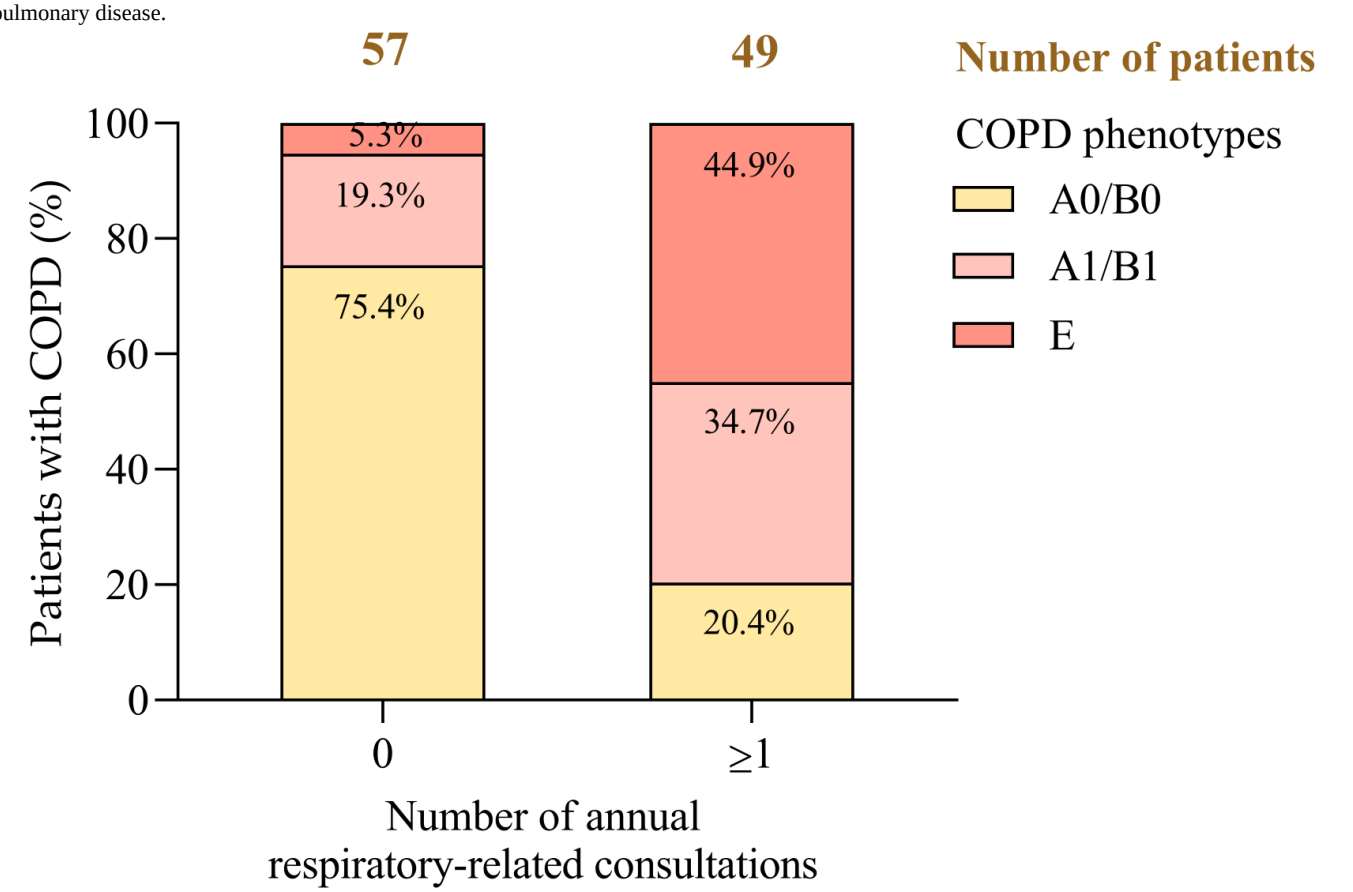
This analysis evaluated the relationship between daily inhalation regimens and COPD phenotypes—A0/B0, A1/B1, and E—in a cohort of 106 patients, examining treatment intensity in relation to clinical severity and exacerbation history (Figure 6).

XSL•FO
RenderX

Figure 6. Distribution of chronic obstructive pulmonary disease phenotypes by daily inhalation doses. COPD: chronic obstructive pulmonary disease.

Among A0/B0 patients (n=53), 58.5% (51/53) required a single inhalation per day, whereas 41.5% (22/53) used 2 or more. In the A1/B1 group (n=28), 75% (21/28) required at least 2 daily inhalations, reflecting higher therapeutic demands. Phenotype E patients (n=25), defined by ≥2 moderate or ≥1 severe exacerbations, exhibited greater variability: 60% (15/25) used 2 or more inhalations daily, while 40% (10/25) managed with a single dose.

Statistical testing revealed a significant association between inhalation frequency and clinical phenotype (χ^2_2=8.662; *P*=.013). A linear trend (*P*=.048), alongside weak but statistically significant correlations (Pearson *r*=0.193, *P*=.047; Spearman *r*=0.215, *P*=.027), suggests that patients with higher-risk phenotypes tend to receive more intensive inhalation regimens.



These findings underscore the relevance of phenotype-guided treatment strategies: while low-intensity regimens may suffice for A0/B0 patients, individuals classified as A1/B1 or E typically require escalation of therapy. Incorporating daily inhalation patterns into predictive models enhances clinical personalization, supports adherence to guideline-based care, and contributes to improved patient outcomes—advancing the principles of precision medicine in COPD management [70].

Real-World COPD Phenotypes and Health Care Utilization

This analysis examined the association between COPD phenotypes—A0/B0, A1/B1, and E—and respiratory-related health care utilization in a cohort of 106 patients, with a focus on the need for at least 1 annual clinical consultation (Figure 7).

XSL•FO
RenderX

Figure 7. Proportion of chronic obstructive pulmonary disease phenotypes by number of annual health care consultations. COPD: chronic obstructive pulmonary disease.

- A0/B0 phenotype (n=53): 81.1% (43/53) of patients required no respiratory-related consultations, while 18.9% (10/53) needed at least 1, reflecting stable disease and low health care demand.
- A1/B1 phenotype (n=28): 60.7% (17/28) required at least 1 consultation, indicating increased follow-up needs linked to a history of moderate exacerbations.
- E phenotype (n=25): 88% (22/25) required at least 1 consultation, representing the highest level of health care utilization, consistent with more severe disease and frequent exacerbations.

Statistical analysis confirmed a robust association between phenotype and health care utilization (χ^2_2=35.873; P<.001), with strong, statistically significant correlations observed (Pearson r=0.578; Spearman r=0.582; both P<.001).

These findings demonstrate that health care resource demand increases in parallel with disease severity—ranging from minimal utilization in patients with stable phenotypes (A0/B0) to substantially elevated needs in those classified as phenotype E. Integrating phenotype-based stratification into clinical workflows can support more efficient resource allocation, ensuring timely intervention for high-risk patients while minimizing unnecessary consultations among those with controlled disease.

Discussion

Principal Findings

This study presents and internally validates Seleida—a fully automated, deterministic, and bijective model designed to assess COPD control and generate clinically interpretable phenotypes using structured EHR data. By relying exclusively on routinely recorded prescribing information—specifically, the annual number of dispensed SABA or SAMA canisters or both and respiratory antibiotics—Seleida offers a scalable and transparent alternative to conventional classification frameworks such as GOLD 2025 and GesEPOC 2021. These frameworks often depend on intermittently documented spirometry results and symptom scores, limiting their feasibility and consistency in real-world, especially primary care, settings [14,17,18,47,52,72].

The decision to implement LASSO over Ridge or Elastic Net in the Seleida model was based on a comparative analysis of regularization techniques. While all 3 approaches demonstrated acceptable discrimination, LASSO provided the best balance between predictive accuracy, parsimony, and clinical interpretability. Ridge regression tended to overshrink coefficients, whereas Elastic Net offered no additional benefit in a low-dimensional, low-collinearity setting (section S4 in Multimedia Appendix 1). This methodological choice reinforces Seleida's role as a computationally efficient and clinically actionable tool for phenotype-guided COPD management.

The model demonstrated perfect agreement between its 126- and 21-combination phenotyping schemas (Cohen κ=1.00;

XSL•FO
RenderX

$P<.001$) and substantial concordance with clinician-assigned phenotypes based on GOLD 2025 criteria ($\kappa=0.70$; $P<.001$), confirming its internal robustness and interpretive reliability [42,73]. By leveraging high-frequency, objective EHR variables, Seleida enables dynamic risk stratification even in the absence of structured clinical assessments—particularly relevant in settings where such data may be unavailable or inconsistently applied.

Given that nearly half of individuals with COPD experience at least 1 moderate to severe exacerbation annually—often without being flagged as uncontrolled by current tools—Seleida addresses a critical gap by providing continuous, data-driven risk stratification embedded within routine care pathways [4,5].

To date, no automated or EHR-integrated phenotyping model has been formally established for COPD in real-world clinical settings. Unlike existing unidirectional risk scores or machine learning classifiers focused on exacerbation or mortality risk, Seleida was explicitly designed as a bidirectional and bijective system tailored to primary care populations. This architecture enables both forward prediction from observed data and reverse inference of phenotypic profiles from computed probabilities—features essential for transparency, auditability, and integration into decision support environments.

Crucially, the model relies solely on structured variables that are universally available across health systems, ensuring interoperability and scalability. As such, benchmark comparisons against nonbijective models were deemed conceptually misaligned and methodologically uninformative. Instead, internal comparisons were performed (section S4 in Multimedia Appendix 1), and the final implementation was selected based on predictive accuracy, sparsity, and operational interpretability.

To the best of the authors' knowledge—based on an exhaustive PubMed search using combinations of terms such as COPD, automatic phenotyping, clinical decision support systems, electronic health records, predictive modeling, algorithmic classification, bijective model, and rule-based phenotyping—no published model currently exists that is specifically designed for the automatic phenotyping of patients with COPD and suitable for direct integration into health care information systems. Future studies may explore head-to-head evaluations once externally validated phenotyping frameworks become available.

Implications for Digital Health Integration

Seleida was designed to overcome long-standing barriers to the adoption of clinical decision support tools, including limited data availability, platform heterogeneity, and clinician disengagement driven by system opacity or poor integration. Its deterministic and parsimonious architecture ensures full traceability and facilitates seamless integration across heterogeneous digital infrastructures. The model's implementation potential can be articulated across 3 core domains:

- EHR integration and technical feasibility: Seleida requires only 2 structured input variables—annual dispensations of SABA or SAMA canisters or both and respiratory antibiotics—which are consistently recorded in most EHRs. Its architecture adheres to HL7 FHIR standards, as detailed in section S7 in Multimedia Appendix 1, where all model outputs were successfully validated using the official HL7 FHIR validator (v6.5.28) without structural or semantic errors across 440 resources. These outputs were generated through an automated simulation of valid (*a, b*) input combinations—not from real patient data—and were used to demonstrate the model's technical interoperability under HL7 FHIR specifications. The structured Fast Healthcare Interoperability Resources (FHIR) bundles include *RiskAssessment* (risk and rationale), *DetectedIssue* (clinical recommendations), *Condition* (disease state), and *Provenance* (model metadata), ensuring syntactic integrity, semantic traceability, and compatibility with clinical decision support platforms.
- Clinical decision support integration: The generated FHIR bundles enable real-time deployment within EHR-based dashboards and alert systems via standard Application Programming Interfaces. For instance, exceeding predefined thresholds (eg, >3 inhalers per year or ≥2 antibiotic courses) can trigger automated clinical recommendations through the *DetectedIssue* resource, which remains fully auditable via associated *Provenance* metadata. This architecture supports reproducible and scalable implementation in both open-source platforms (eg, OpenMRS) and commercial systems compliant with HL7 R5.
- Scalability and global interoperability: The model's minimal data requirements and exclusive reliance on universally structured prescribing variables make it well suited for adoption in low- and middle-income countries. Its lightweight, FHIR-compliant design allows integration into national health information infrastructures aligned with the World Health Organization's Digital Health Strategy. The use of international terminologies (SNOMED CT and LOINC) and standardized value sets further enables longitudinal data integration, federated learning, and interoperability across certified clinical environments worldwide.

Advancing Precision COPD Management

Seleida contributes to the advancement of precision medicine in COPD by enabling automated, phenotype-driven decision pathways tailored to real-world primary care data. Its deterministic architecture supports individualized care planning through multiple mechanisms. First, the model's integration of 2025 GOLD ABE classification with SABA dependency stratification facilitates personalized pharmacologic strategies—informing step-up or step-down adjustments based on quantified risk levels. Beyond pharmacologic guidance, Seleida helps identify patients who may benefit from nonpharmacologic interventions such as structured pulmonary rehabilitation or smoking cessation support, reinforcing a holistic, patient-centered approach to disease control [74,75]. Moreover, the ability to isolate phenotypes associated with frequent exacerbations or suggestive of *P aeruginosa* colonization offers additional value for microbiological surveillance and early antimicrobial stewardship [76].

XSL•FO
RenderX

Seleida's modular structure permits future expansion. Variables such as comorbidity profiles, vaccination status, or inflammatory biomarkers (eg, eosinophil count and C-reactive protein) can be incorporated without compromising interpretability—enhancing predictive precision and adaptability to diverse clinical settings.

Health System Optimization and Economic Potential

Beyond individual risk estimation, Seleida generates population-level insights that can inform health system optimization and performance monitoring. Its probabilistic outputs enable benchmarking of COPD control across institutions and regions, helping identify care gaps and guiding policy interventions to reduce diagnostic inertia, undertreatment, and geographic disparities in disease management.

At the public health level, the model supports strategic planning by quantifying the projected impact of interventions—such as seasonal vaccination campaigns, air quality alerts, or therapeutic adjustments—on exacerbation rates and control metrics at scale. Its forecasting capacity also informs resource allocation, enabling estimates of emergency visits, hospitalization demands, and inhaler supply needs—particularly critical in overstretched systems or during seasonal peak periods.

From an economic perspective, COPD exacerbations—especially those requiring hospitalization—account for more than 70% of direct disease-related health care expenditures [77]. By identifying high-risk patients early, Seleida may help reduce exacerbation incidence by approximately 15% - 25%, consistent with reductions observed in phenotype-guided management programs [74,75]. Preventing a single severe exacerbation may yield direct savings of $1700 to $4720 (the cost that was originally reported in euros [€] was converted to US dollars using the exchange rate of €1=$1.18 as of September 15, 2025, based on the European Central Bank reference rates per patient annually) [21]. While these projections remain hypothetical within Seleida's current context, they underscore its potential contribution to value-based care. Confirmatory evidence from prospective cost-effectiveness evaluations in multicenter implementation studies will be essential to fully quantify this impact.

As health care systems face mounting pressure to improve outcomes while managing resource constraints, tools such as Seleida—anchored in objective, high-frequency data and deployable across diverse infrastructures—offer a pragmatic path toward more efficient, equitable, and data-driven respiratory care.

Interpretability and Clinical Use in Real-World Practice

Seleida was designed for seamless integration into EHR systems, where structured clinical inputs—specifically rescue inhaler use and antibiotic prescriptions—can be continuously analyzed to generate real-time risk estimates and automated alerts. The model can also be applied manually in settings without digital integration, allowing clinicians to interpret the probability of poor control as a continuous indicator of exacerbation risk, with higher values reflecting proportionally greater clinical vulnerability. This dual deployment capacity is particularly valuable in resource-constrained environments where decision support infrastructures are limited.

For exploratory implementation, a provisional risk threshold was established. Because the sample size of this pilot study precluded formal statistical derivation, a reference point of $Pr>.50$ was selected based on the internal distribution of predicted probabilities. This should be interpreted not as a strict clinical cutoff but as an operational inflection point to guide prioritization. The model supports graded stratification across the risk spectrum, enabling providers to flag higher-risk profiles (eg, $Pr>.70$) for proactive evaluation, treatment adjustment, or closer follow-up.

Beyond individual patient care, Seleida enables population-level case finding using prescribing data alone, without requiring recent consultations or the patient's physical presence. This capability allows the generation of risk-stratified reports for entire patient panels, facilitating earlier identification of those likely to be poorly controlled. The transition from reactive recognition during encounters to anticipatory detection at the database level supports a scalable, equitable, and resource-efficient approach to COPD management. By combining point-of-care guidance with population surveillance, Seleida offers a flexible solution adaptable to diverse health care settings.

From a clinical perspective, fully automated and bijective phenotyping enables early detection of unstable COPD without the need for spirometry or symptom scores. By generating actionable, guideline-aligned classifications from routine EHR data, Seleida supports timely treatment selection, targeted microbiological assessment, and precise referral. Prioritizing follow-up for poorly controlled patients has the potential to reduce primary care and emergency visits, exacerbations, hospitalizations, and even mortality, while improving disease control and optimizing health care resource use.

Seleida's deterministic and bijective framework delivers precise, phenotype-driven COPD management using only routinely collected prescribing data. By translating high-frequency medication patterns into actionable risk profiles, it facilitates earlier therapeutic escalation, targeted treatment stratification, and proactive follow-up scheduling—particularly in patients who might otherwise remain undetected by conventional spirometry-based or symptom-based approaches.

The model's simplicity, transparency, and full EHR interoperability enable smooth integration into clinical workflows, supporting earlier detection of instability, automated triage, and efficient resource allocation. At the system level, Seleida empowers population-wide surveillance, equitable access to timely interventions, and optimization of health care resources—priorities central to contemporary primary care and health system planning.

At the health system level, proactive, database-driven detection enables earlier triage and strategic resource allocation across the care continuum. Identifying high-risk patients before clinical deterioration allows services to intensify follow-up, focus preventive interventions, and streamline emergency response.

XSL•FO
RenderX

This anticipatory approach promotes equitable access to timely care, reduces unnecessary utilization, and decreases the likelihood of preventable hospitalizations—enhancing the efficiency, scalability, and sustainability of COPD management while maximizing the effectiveness of interventions in primary care.

Limitations and Validation Needs

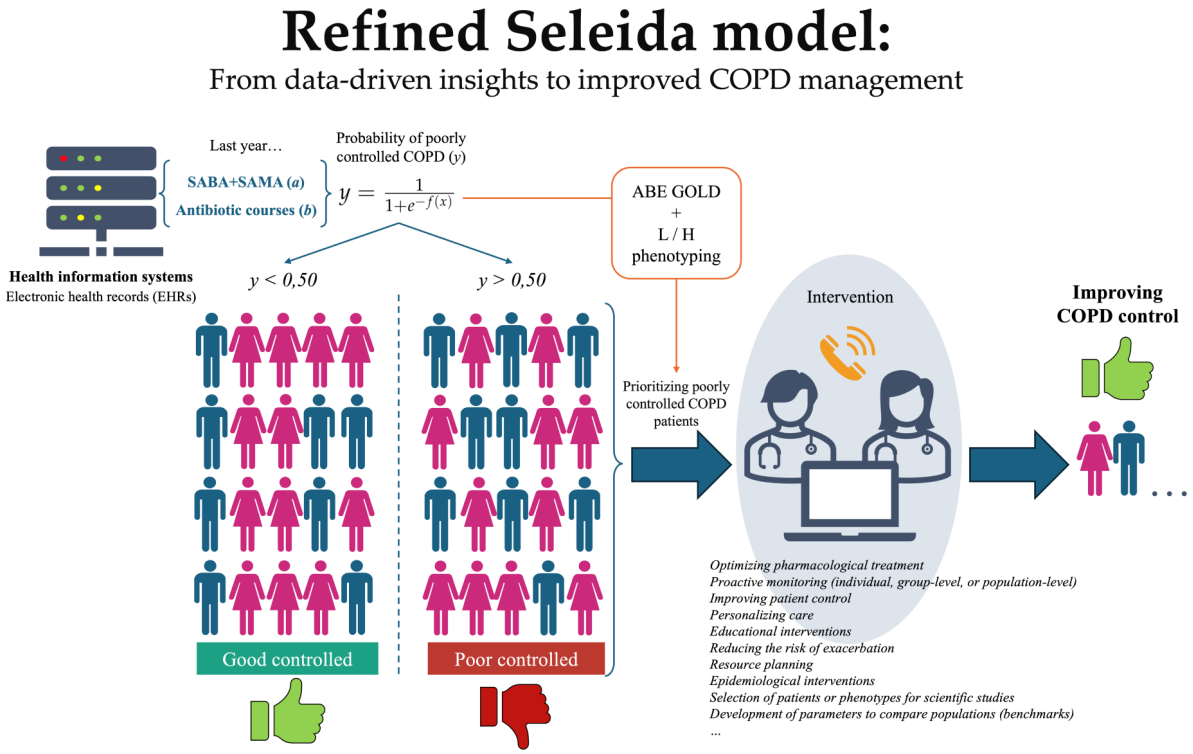
Despite its strengths, several limitations warrant consideration:

- Sample size and scope: The model was validated retrospectively in a single-country cohort of 106 patients from 2 Spanish primary care centers. While the results support internal consistency, the generalizability to other health systems, demographic groups, and care models remains to be established through multicenter external validation [45]. To address this, future validation studies are planned with larger and more heterogeneous cohorts drawn from multiple Spanish regions, aiming to evaluate the model's performance across broader demographic, geographic, and clinical contexts. Given its reliance on universally recorded prescribing data, Seleida also has strong potential for applicability in diverse international settings, and validation efforts will extend to health care systems in both European and non-European countries.
- Variable parsimony: Seleida was intentionally designed for simplicity and scalability, relying on 2 objective, high-frequency prescribing variables. However, this design may limit sensitivity in clinically complex or multimorbid phenotypes. In particular, the model may underperform in identifying atypical exacerbation profiles, discordant symptom patterns, or overlapping syndromes such as asthma-COPD overlap syndrome, eosinophilic COPD, or symptom-dominant cases with low exacerbation burden [78].
- Fixed thresholds and model rigidity: The deterministic and bijective architecture of Seleida requires predefined integer inputs (a, b), which enhances reproducibility and transparency but may reduce flexibility. This could limit performance in borderline or transitional cases, especially in patients with fluctuating clinical trajectories near decision thresholds. Future iterations may incorporate hybrid models with continuous or adaptive inputs, leveraging machine learning–based adjustments to enhance model responsiveness and flexibility [79].
- Omission of conventional clinical metrics: The exclusion of spirometry (eg, forced expiratory volume in the first second of expiration), symptom scores (eg, COPD Assessment Test, modified medical research council, and patient-reported outcomes enhances operational feasibility but may reduce clinical acceptability in settings where such metrics are routinely used for monitoring, reimbursement, or treatment authorization. Furthermore, Seleida may not fully capture disease burden in patients whose impact is driven more by symptoms than by exacerbation frequency—highlighting the need for future multimodal extensions.

Future Directions

To support broader adoption, equity, and scientific transparency, several development paths are under consideration:

1. Multinational validation: Future collaborations with international partners—such as the WHO Digital Health Programme—may enable cross-context evaluation of Seleida using open-source EHR infrastructures such as OpenMRS. This would facilitate assessment in diverse health care systems, including low- and middle-income settings.
2. Artificial intelligence–enhanced predictive modeling: Planned extensions include the incorporation of machine learning components to enable dynamic thresholds, time series forecasting, and the integration of social and environmental determinants of health. These enhancements aim to improve contextual relevance, longitudinal accuracy, and model adaptability in complex clinical scenarios.
3. Open-science reproducibility: A complete technical framework—including public, detailed model documentation, and executable pseudocode—could be released to support independent replication, collaborative development, and global dissemination. This approach would follow successful precedents in predictive modeling platforms, such as QRISK [80].



Ethical Considerations and Equity

Future iterations will incorporate algorithmic fairness audits to detect and mitigate potential biases in risk estimation—particularly among historically underrepresented or underserved populations. Equity by design is a foundational principle of the Seleida framework. By relying exclusively on structured prescribing data—universally recorded across health systems—and remaining independent of costly diagnostic tools or patient-reported inputs, Seleida is inherently scalable and adaptable to low-resource settings. Its compatibility with open-source EHR infrastructures, such as OpenMRS, facilitates national-scale deployment in both high- and middle-income countries. Partnerships with public health authorities and patient advocacy groups are envisioned to ensure that Seleida promotes access and actively reduces—rather than reinforces—structural disparities in COPD management [81-84].

By bridging predictive analytics with frontline clinical decision-making, Seleida supports equitable, individualized care (Figure 8). Its automated, interoperable, and fully transparent architecture enables the early identification of poorly controlled patients and the delivery of actionable, risk-aligned interventions. Through the transformation of routine prescribing data into clinically interpretable phenotypes, Seleida contributes not only to personalized medicine but also to system-level optimization and population risk mitigation.

XSL•FO
RenderX

Figure 8. Applications of the refined Seleida model. The model uses EHR data to identify patients with poorly controlled chronic obstructive pulmonary disease, enabling phenotyping and targeted interventions to improve disease management. COPD: chronic obstructive pulmonary disease; EHR: electronic health care record; GOLD: Global Initiative for Chronic Obstructive Lung Disease; H: high; L: low; SABA: short-acting β2-agonists; SAMA: combined with short-acting muscarinic antagonists.

Planned multicenter validation and open-science dissemination are expected to further reinforce Seleida's role as a cornerstone in the emerging field of data-driven respiratory precision medicine—advancing a vision grounded in accessibility, transparency, and global equity.

Conclusions

This study presents Seleida as the first model for assessing COPD control that is fully automated, mathematically bijective, and clinically validated using structured data routinely captured in primary care. By leveraging 2 objective, high-frequency prescribing variables—namely, the number of dispensed rescue inhaler canisters and respiratory antibiotic courses—Seleida enables scalable, reproducible, and clinically interpretable phenotyping aligned with real-world care workflows.

The model demonstrated strong internal validity, with perfect concordance between its high-resolution and streamlined phenotyping systems (κ=1.00; P<.001), and substantial agreement with clinician-assigned phenotypes based on GOLD 2025 criteria (κ=0.70; P<.001), supporting both its discriminative capacity and interpretive reliability. Its deterministic structure supports real-time risk estimation and reverse phenotype mapping, enabling individualized treatment planning within EHR-integrated environments.

Designed for seamless digital integration, Seleida's low data burden and full compatibility with HL7 FHIR standards facilitate implementation across a broad range of informatics platforms—including dashboards, telehealth systems, and registry-based surveillance tools. These features, along with its transparency and interoperability, make the model particularly applicable to resource-limited settings.

While the present validation was limited to a retrospective cohort from 2 Spanish primary care centers, prospective multicenter studies are underway to evaluate Seleida's generalizability, economic impact, and performance across diverse health systems. Future model iterations aim to enhance flexibility and contextual precision through adaptive thresholds, multimodal inputs, and algorithmic fairness auditing.

By transforming routinely collected prescribing data into actionable, risk-aligned insights, Seleida offers a reproducible and ethically grounded approach to phenotype-guided COPD care. It provides a concrete, scalable contribution toward operationalizing precision medicine principles in everyday respiratory practice.

Abstract

Background: The increasing use of real-time health data from wearable devices and self-reported questionnaires offers significant opportunities for preventive care in aging populations. However, current health data platforms often lack built-in mechanisms for data and model traceability, version control, and coordinated management of heterogeneous data streams, which are essential for clinical accountability, regulatory compliance, and reproducibility. The absence of these features limits the reuse of health data and the reproducibility of analytical workflows across research and clinical environments.

Objective: This work presents DeltaTrace, a unified big data health platform designed with traceability as a key architectural feature. The platform integrates end-to-end tracking of data and model versions with real-time and batch processing capabilities. Built entirely on open source technologies, DeltaTrace combines components for data management, model management, orchestration, and visualization. The main objective is to demonstrate that embedding traceability within the architecture enables scalable, auditable, and version-controlled processing of health data, thereby facilitating reproducible analytics and long-term maintenance of health monitoring systems.

Methods: DeltaTrace adopts a medallion architecture implemented with Delta Lake to ensure atomic and version-controlled data transformations. Apache Spark is used for distributed computation, Apache Kafka for continuous data ingestion, and Apache Airflow for orchestration of batch and streaming workflows. MLflow manages the lifecycle and versioning of machine learning models, while Grafana provides visualization dashboards for real-time and aggregated data inspection. The platform is evaluated using continuous physiological signals from wearable devices and batch-ingested questionnaire data, combining synthetic and real data from the LifeSnaps dataset. Performance tests are conducted on central processing unit–only servers with 8-core and 24-core configurations to assess ingestion, aggregation, visualization, and anomaly detection latency.

Results: DeltaTrace supports continuous processing for approximately 1500 users with end-to-end delays below 10 minutes. Ingestion and visualization tasks operate between mean 4.9 (SD 0.12) and 7.5 (SD 0.28) minutes, while aggregation and anomaly detection required less than mean 5.6 (SD 0.04) and 10.5 (SD 1.70) minutes, respectively. Increasing from 8 to 24 cores improved ingestion and cleaning latency by up to 25% and anomaly detection performance by up to 50%. The system maintains consistent performance across different data types, processing modes, and loads.

Conclusions: DeltaTrace provides a scalable and modular architecture that incorporates traceability as a core component together with functions for model management, orchestration, and visualization. The platform enables complete version control across data and models and maintains performance under limited hardware conditions. These characteristics support reproducible and auditable health data processing and make DeltaTrace suitable for continuous monitoring and preventive health care in aging populations.

Introduction

Background

According to the World Health Organization, the number of individuals aged 60 years and older is expected to reach 2.1 billion by 2050, nearly doubling from 1.1 billion in 2020 [1]. This demographic shift is particularly pronounced in Europe, where persons aged 60 years or older are projected to account for 36% of the total population by 2050 [2]. Aging is associated with a higher prevalence of chronic and degenerative diseases, including cardiovascular conditions, diabetes, neurodegenerative disorders, and frailty syndromes. These often coexist, resulting in multimorbidity, which leads to increased health care demands, hospital admissions, and long-term care requirements [3,4].

Preventive care has become essential to address the growing health care burden in aging populations. Evidence suggests that interventions focusing on early detection, continuous monitoring, and timely management of health risks can significantly reduce complications, improve outcomes, and delay institutionalization [5,6]. Enabling older adults to remain at home with autonomy requires technical solutions that support preventive action through continuous observation and timely data-driven decisions.

Big data platforms have emerged as a relevant approach to support these goals. By integrating diverse data sources such as physiological signals from wearable devices [7] and electronic health records [8], these platforms can enable large-scale remote monitoring, predictive analytics, and personalized health care delivery [9]. Real-time processing, interoperability, and scalability are commonly addressed in many recent frameworks [10,11]. However, other critical features such as model traceability and data version control are often omitted [12-14]. These capabilities enable the tracking of each model inference and its underlying data, thereby supporting reproducibility and accountability.

Traceability is essential in health care applications, serving as an important process for recording data origins and the history of data generation and processing [15]. Within this domain, clinical decisions, audits, and regulatory compliance critically depend on knowing precisely which data, model, and processing logic were used at each stage of the data pipeline. This transparency ensures accountability and supports compliance requirements. However, despite this vital need, current solutions often prioritize data integrity during sharing but frequently lack transparency, traceability, and comprehensive integrity audits for cloud-stored medical data [16]. This absence of clear visibility can undermine patient trust and pose challenges related to computational power consumption and latency when sharing sensitive data across institutions [16].

Related Work

Several studies have used big data technologies to analyze data for specific health conditions. The approach proposed by Ismail et al [12] developed a novel stream extract, transform, load (ETL) framework for real-time Twitter-based sentiment analysis using Kafka, Spark, Hadoop Distributed File System (HDFS), Hive, HBase, and Cassandra. Their experiments assessed performance across trigger intervals, dataset sizes, and storage technologies, ultimately finding HDFS to be the most effective storage solution. The authors reported increased ETL execution time when sentiment classification was integrated, highlighting trade-offs between system parameters and resource allocation. Similarly, Saeed and Saeed [13] used Apache Spark and Spark Streaming to analyze real-time hospital health care data for diabetes prediction. Their experiments found the gradient boosted tree classifier to be the most accurate, achieving 90.14% accuracy. The system was scalable and suitable for timely diagnosis, with future work aiming to incorporate additional data sources. Saleh et al [14] proposed TransformerFusionNet, a novel artificial intelligence (AI) model for real-time intensive care unit heart failure mortality prediction, achieving 91.72% accuracy. The model used Apache Spark and Kafka to stream and process structured and clinical note data, enabling scalable, real-time clinical decision support.

Beyond specific health conditions, other studies have proposed big data platforms designed for broader or more general applications. The Personal Health Dashboard introduced by Bahmani et al [10] used Kubernetes, Secure File Transfer Protocol, and serverless architectures to deliver scalable and secure health management using wearable, clinical, and omics data. Their experiments demonstrated dynamic scaling and presymptomatic COVID-19 detection, although further research was needed on omics data privacy. Similarly, Liu [17] developed a health data platform that calculated BMI from user-inputted height and weight, applied Chinese health standards, and provided personalized advice. While the core functionality was realized, the system remained preliminary, with ongoing work required to improve data integration and data quality.

A growing line of research has focused on data provenance, model management, and the reproducibility of machine learning (ML) pipelines in health care. According to Ahmed et al [15], data provenance frameworks play a crucial role in documenting data lineage and ensuring accountability in clinical decision systems; yet, they are often limited to metadata capture and do not scale effectively to large, heterogeneous health care datasets. The study by Belbasis and Panagiotou [18] highlighted that reproducibility and transparency remain major challenges for ML prediction models in health services research, emphasizing the need for comprehensive documentation of data, code, and analyses rather than focusing solely on large-scale processing. Xie et al [16] demonstrated the potential of MLflow for tracking model experiments in medical imaging tasks, but their work concentrated on model-level traceability rather than managing the entire data lifecycle. Finally, Mora-Cantallops et al [19] reviewed practices and data models for traceability in the context of building AI systems and observed that, despite the availability of many reproducibility tools, a common integrated approach for provenance and version control is currently lacking.

In summary, big data technology stacks have proven effective in delivering real-time, scalable health care solutions through advanced analytics and AI. However, existing solutions often lack a comprehensive approach that incorporates data traceability, including version control and lineage, critical requirements for health care applications. As summarized in Table 1 (see complete table in Multimedia Appendix 1), current

XSL•FO
RenderX

systems also tend to treat key features such as model management, resource monitoring, data visualization, and distributed processing in a fragmented manner.

[a]Capabilities include versioning (data version control), scalability (scalability testing and handling large-scale data), model management (machine learning model management), monitoring (system or resource monitoring), scheduling (event or workflow scheduling), storage (distributed data storage), processing (distributed data processing), real time (real-time analytics support), and visualization (built-in data visualization tools). The final columns denote the primary task performed (eg, classification and anomaly detection) and the purpose or target condition addressed (eg, diabetes and general monitoring).

Objective

This study addresses the lack of integrated data and model traceability in existing health data platforms, where version control and auditability are often treated as secondary features. The main objective is to design and develop a unified health data platform in which traceability is established as a central architectural principle, implemented together with essential components for scalability, model management, orchestration, and visualization, ensuring complete reproducibility and accountability throughout the data lifecycle.

The design of DeltaTrace is guided by research objectives that align with key big data capabilities identified in the literature and analyzed in the state-of-the-art review (Table 1). Specifically, the platform aims (1) to integrate versioning and traceability mechanisms to ensure full data and model lineage across the processing pipeline; (2) to support scalable storage and processing to handle continuous and batch data streams under variable system loads; and (3) to provide coordinated model management, scheduling, monitoring, and visualization within a single architecture to enable consistent and auditable workflows.

These objectives determined the overall architectural design, which is implemented using open source technologies chosen for their robustness, transparency, accessibility, and long-term sustainability. This approach ensures that the proposed platform not only addresses the limitations identified in existing solutions but also establishes traceability as a verifiable and reproducible property of the system architecture.

The paper is structured as follows. The Methods section describes the design of the DeltaTrace platform, detailing its key components, technologies, and evaluation setup. The Results section presents the main findings, including system performance, scalability, and visualization outcomes. The Discussion section summarizes the principal findings, interprets their clinical relevance, compares DeltaTrace with prior work, and outlines limitations and directions for future research. Finally, the Conclusions section highlights the main contributions and implications of DeltaTrace for reproducible and accountable health data management.

Methods

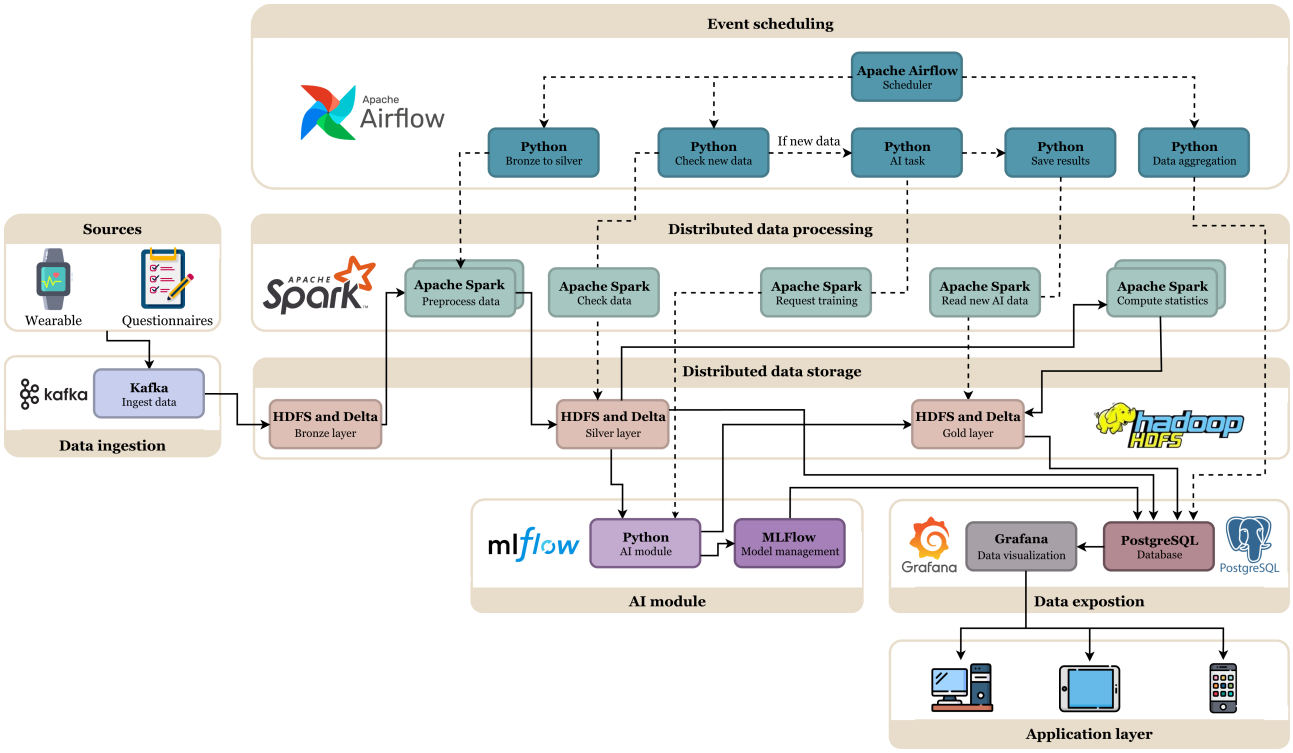
Design

DeltaTrace is designed to ingest, curate, transform, and store data from multiple heterogeneous sources, such as wearables and self-reported questionnaires, which differ in collection frequency, formats, and quality. The diversity of these sources requires a structured approach, motivating the use of an extract, load, transform (ELT) strategy and a medallion architecture to preserve raw data, enable flexible transformations, and maintain traceability throughout all processing stages.

The ETL approach often leads to irreversible transformations and potential loss of raw data. DeltaTrace adopts an ELT strategy, that is, raw data are first ingested and stored without alteration, ensuring full traceability and the ability to apply different transformation pipelines tailored to diverse processing or model input needs. This approach not only preserves original data but also supports reproducibility, facilitates auditing, and enhances compliance with the General Data Protection Regulation, which governs the processing of personal data in Europe, by supporting controlled and purposeful data transformations.

A key feature of the platform is end-to-end traceability. Every data transformation, model-related operation, such as training, evaluation, or inference, or change in the system is recorded, ensuring that the origin of each prediction or decision can be audited. This requirement is especially relevant for health care, where transparency is critical.

To address these needs, DeltaTrace is built upon the medallion architecture, a multilayered data structure that provides increasing levels of data quality, as recommended by Databricks. Each layer adheres to principles of atomicity, consistency, isolation, and durability (ACID), ensuring data reliability and recoverability. Data availability is ensured through the use of distributed and fault-tolerant components, such as Apache Spark and HDFS, which replicate data and store periodic checkpoints to enable recovery in case of system failure. Data accuracy is maintained by performing schema validation at ingestion, running automated data quality checks, and leveraging ACID transactions in Delta Lake to prevent corruption and guarantee consistency. Data usability is achieved through clear metadata definitions, versioned storage, and a configuration layer that enables data lineage tracking and reproducibility. By leveraging this architecture, DeltaTrace supports data governance, including availability, accuracy, and usability, across the entire data lifecycle. The quality of the data in each layer is described by the terms bronze (raw, ingested data), silver (cleaned datasets), and gold (enriched and aggregated data, ready for analytics and visualization). The medallion architecture does not replace other dimensional modeling techniques, and the schemas and tables within each layer can vary.



In addition to data engineering, DeltaTrace includes AI model lifecycle management. The platform supports all major steps in the model pipeline: data preparation, training, testing, and deployment. To enable full traceability of model versions, training data, and results, the system integrates MLflow [26], an open source MLOps platform. MLflow provides experiment tracking, pipeline versioning, and model serving. With MLflow, each model run is logged with detailed metadata, parameters, and outputs, enabling reproducible analysis and facilitating explainability by linking predictions to input features and model versions. Fairness auditing is supported through logging of model performance, while model metrics stored in MLflow enable continuous monitoring for potential data drift, alerting users to deviations in performance over time. These features allow the system to audit AI-driven decisions and evaluate the evolution of models over time, ensuring both transparency and reproducibility.

The automatic orchestration of data processing pipelines is essential to maintain the consistency and up-to-date status of the data lake. In the context of big data, 2 primary processing paradigms are used: batch processing and stream processing. The selection between these modes is driven by the nature and frequency of data collection. For instance, data collected at longer intervals, such as daily self-reports or weekly summaries, are typically handled through batch processing [27], which is well-suited for executing complex ELT tasks and periodic aggregations on larger volumes of data. Conversely, high-frequency data, such as minute-level readings from wearable sensors, are managed through stream processing. This model, implemented via Apache Kafka, enables real-time ingestion and processing by feeding data continuously into analytics components.

All data-related workflows, including batch and real-time, are orchestrated using Apache Airflow [28], enabling flexible and robust task scheduling. Airflow manages the ELT pipeline across the different data layers, triggers model training when new data become available, and coordinates visualization updates and aggregation tasks. The high-level architecture of the DeltaTrace platform is presented in Figure 1. To support end-to-end data lifecycle management, from ingestion to visualization, the platform incorporates a comprehensive suite of open source technologies. The core components with the specific used software versions are described in Multimedia Appendix 2.

XSL•FO
RenderX

Figure 1. Schema of the DeltaTrace data platform. The continuous arrows indicate the direction of information flow, whereas the dashed arrows trigger the execution of a process. AI: artificial intelligence; HDFS: Hadoop Distributed File System.

DeltaTrace has not only been built upon a carefully selected combination of open source technologies that support advanced analytics, real-time processing, and a high degree of traceability, but it has also been implemented alongside a dedicated configuration layer that enables full control of the data flow through simple configuration files. This layer abstracts operational complexity by allowing all core aspects, such as data source definitions, scheduling intervals, model parameters, and storage destinations, to be specified and modified without altering the underlying code. As a result, the platform is highly adaptable and maintainable, enabling rapid deployment and reconfiguration across different use cases or environments. More information about the configuration of DeltaTrace is provided in Multimedia Appendix 3.

All components in DeltaTrace are orchestrated to generate detailed logs to facilitate continuous monitoring and troubleshooting across the entire data processing pipeline. These logs record key operational events and system metrics, allowing users to verify the correct functioning of each component and trace the execution of data flows in real time. In addition, several of the integrated open source technologies inherently support data versioning and metadata management. For instance, intermediate results and model outputs are stored along with version identifiers and temporal metadata, enabling users to reconstruct historical states of the system or reproduce specific analyses. Checkpoints are also periodically generated to ensure fault tolerance and provide recovery capabilities, contributing to the overall transparency and reliability of platform operations.

Data Ingestion

DeltaTrace has been designed to accommodate heterogeneous data sources, integrating both continuous sensor streams and periodic user-reported inputs. In the current implementation, 2 primary data sources are supported:

- Wearable devices: Data are streamed through 10 dedicated Apache Kafka topics, each corresponding to a specific measured variable (eg, heart rate, physical activity, or sleep). These topics receive both daily summaries and high-frequency time-series measurements, such as minute-level heart rate and detailed sleep stages.
- Self-reported questionnaires: Each questionnaire is made available to older adults through a dedicated web interface. Once completed, the responses are transmitted via a Representational State Transfer (REST) application programming interface (API) for further processing. These instruments are designed to assess various domains, including emotional well-being, motivation, and behavioral readiness. Specifically, the collected questionnaires include the State-Trait Anxiety Inventory (STAI), Positive and Negative Affect Schedule, Transtheoretical Model, and Behavioral Regulation in Exercise Questionnaire. These questionnaires are used to gather structured data and do not include unstructured text input, enabling consistent analysis across participants.

All the incoming data are continuously processed, providing real-time capabilities for data ingestion. Upon ingestion, the data are stored in the bronze layer of the Delta Lake storage system. This layer acts as an immutable repository of raw data, preserving the original structure and enabling flexible, reproducible processing at later stages. By maintaining the data in the original form, the system supports multiple downstream analyses and transformation strategies without imposing a fixed processing logic at the point of ingestion.

XSL•FO
RenderX

Data Storage

Overview

DeltaTrace adopts a medallion architecture to organize and manage data across multiple layers (bronze, silver, and gold), each representing a progressively refined stage of data processing. This layered structure is implemented using Delta Lake, an open-source storage framework that brings ACID transaction support and scalable metadata handling to big data workloads. Delta Lake enables reliable data versioning, time travel, and schema enforcement. This architecture is further enhanced by AI-driven processes that operate on the curated data. AI models are trained using historical records and then deployed to perform real-time inference. Through this process, the AI layer transforms clean data into actionable insights, enriching the data pipeline and supporting decision-making. Each of the data layers is described below.

Bronze Layer: Raw Data

The bronze layer serves as the foundation, containing raw data ingested from multiple sources. These sources include wearable device data streamed through Kafka topics and questionnaire data collected via the REST API. For each source, a dedicated table is created to store the information in the original format, without structural modifications. This design preserves the integrity of the incoming data and supports traceability by ensuring that the unaltered raw inputs remain accessible for future processing or validation. Both wearable and questionnaire datasets follow a common structure that includes a user identifier and a date column, which enables seamless integration and cross-referencing between data types. This uniform schema allows data from heterogeneous sources to be combined efficiently for downstream analysis, as illustrated in Figure 1, where information from both wearables and questionnaires is jointly represented.

Silver Layer: Clean Data

The silver layer comprises data that have undergone refined cleaning operations aimed at improving consistency and usability. Typical tasks at this stage include the removal of duplicate records or the elimination of empty or irrelevant columns. These data support longitudinal and cross-sectional analyses, making them suitable for intermediate analytical workflows and for training ML models.

Gold Layer: Data Aggregations

The gold layer contains refined, domain-specific outputs tailored for end-user consumption. These include aggregated statistics, anomaly detection, and metrics intended to guide decisions made by clinicians, caregivers, or the older adults themselves. The gold layer is also the primary source for dynamic visualizations and alerts.

In parallel with this layered storage structure, a PostgreSQL (PSQL) [29] database is used to manage structured data essential for the proper functioning of the platform. This includes user registry information, authentication credentials, authorization roles, and other metadata required to support access control and administrative operations.

Data Processing

Data processing is conducted in a distributed and scalable manner using Apache Spark, a widely adopted framework for large-scale data computation [30]. Spark enables parallel execution across multiple compute and storage nodes (Spark Workers), thereby facilitating the efficient transformation of high-volume datasets and ensuring that the system can scale horizontally by incorporating additional resources.

Each processing job operates independently and includes the necessary Delta Lake dependencies to support ACID transactions, schema enforcement, and versioning. Data are read from the appropriate Delta Lake table, transformed according to defined logic, and subsequently written to the next layer, maintaining full traceability throughout the process.

For each dataset stored in the bronze layer, a dedicated Spark job is defined and scheduled by Apache Airflow. These jobs are responsible for continuously reading newly ingested data, applying cleaning and normalization procedures, and writing the results to the corresponding silver table. To avoid redundant processing, Spark checkpoints are used to ensure that only new records are handled during each execution cycle. In addition to avoiding duplicate computation, checkpoints store essential metadata, including application configuration, the sequence of streaming transformations applied to the data, and information about incomplete batches, into fault-tolerant storage, enabling the system to recover easily from failures and maintain uninterrupted data processing.

The transition from silver to gold is also managed through Spark jobs. These processes may involve aggregations (eg, computation of means, counts, or other statistical metrics) or the preparation of data for ML inference. In cases where predictive analytics is required, the silver data are forwarded to the AI module, and the resulting outputs, such as model predictions or recommendations, are stored in the gold layer for downstream visualization and user interaction.

Event Scheduling

DeltaTrace supports both batch and streaming modes for executing data processing tasks. In either case, data are ingested, transformed, and written to the appropriate storage layer (bronze, silver, or gold) according to the specific processing pipeline.

In the batch model, predefined tasks are executed at regular intervals, such as daily or weekly. This mode is suited for operations that do not require immediate responsiveness and benefit from scheduled, periodic processing. In contrast, the streaming model enables continuous ingestion and transformation of data as new records become available. Streaming pipelines are designed to operate persistently and are equipped with mechanisms to prevent duplication and handle errors, thereby ensuring data integrity.

All pipeline executions, both batch and streaming, are managed by the orchestrator of the platform, implemented using Apache Airflow. The orchestrator is responsible for scheduling task executions, monitoring resource use, logging events, sending error notifications, and automatically restarting pipelines in the event of failure. Streaming tasks are configured to run

XSL•FO
RenderX

continuously and are automatically relaunched if they terminate unexpectedly.

Apache Airflow structures workflow execution using directed acyclic graphs (DAGs), where tasks are defined as nodes and dependencies as edges. DAGs provide a declarative mechanism to specify the execution order and relationships among tasks. Each task may consist of a discrete operation, such as an HTTP request or a Python script, or more complex jobs like Spark batch transformations or Kafka-based streaming listeners. The Airflow user interface enables visual monitoring and editing of these DAGs, facilitating clear and maintainable pipeline management.

AI Module

The AI module is implemented as an independent component within the platform architecture, located between the silver and gold data layers. Designed as an optional step in the pipeline, it enables the transformation of clean silver-layer data into aggregated outputs, such as clustering or classification, for storage in the gold layer. This integration allows for the deployment of advanced analytics while preserving traceability and modularity. Although the MLlib library, built-in Apache Spark, provides capabilities for training models directly on DataFrames, a separate Python 3–based module has been adopted in DeltaTrace. This approach offers higher flexibility, allowing for seamless integration with MLflow for experiment tracking, support for a wide variety of models, and more comprehensive comparison and evaluation workflows.

The AI module is designed to support 1 or multiple AI pipelines capable of processing and inferring from the structured datasets available in the silver layer. To facilitate ease of use, the module exposes its functionality through a REST API developed using FastAPI. Two endpoints are provided:

- Train models: This endpoint orchestrates the data loading, preprocessing, and training procedures for all configured AI pipelines. Training metrics, model parameters and hyperparameters, and experiment metadata are logged to the MLflow tracking server. If a previous model exists for the same data source, its performance is compared to the newly trained model. If the new model achieves superior performance, this is registered as the latest version and made available for production.
- Predict: This end point initiates data loading, preprocessing, model retrieval, and inference stages. The system checks the model repository for a trained model corresponding to the input data source. If no model is available, an error is returned; otherwise, predictions are computed and returned as output.

Exposing the AI module as a REST service enables flexible integration with AI pipelines implemented in different programming languages. The AI models are stored in a centralized object repository, MinIO. In this case, a deep learning model based on recurrent neural networks has been selected for anomaly detection in wearable data [31]. Anomalies are defined as values that deviate from expected behavior, potentially triggering alerts to support preventive actions by health care providers. The chosen AI model is capable of learning temporal patterns in the data [32] to predict future values. These predicted values are then compared with the actual observations, and the resulting differences are modeled using a normal distribution. This approach enables the use of *z* scores to quantify deviations [33]. Depending on the magnitude of the deviation and predefined thresholds, anomalies are categorized into 3 levels: green (minor), yellow (moderate), and red (critical).

Model training and prediction tasks are orchestrated using Apache Airflow, which defines a pipeline composed of three primary stages: (1) checking for the availability of new data, (2) training or retraining the model, and (3) storing the resulting outputs. In the first stage, the orchestrator queries the Delta Lake silver layer to determine whether the volume of new data exceeds a predefined threshold for each data source. If this condition is met, an HTTP request is sent to the AI module containing identifiers such as the user_id, the variable to predict, and the relevant time range, serving primarily as a trigger for the AI module. Within the AI module, the corresponding data are loaded directly from Delta Lake based on these identifiers and processed to detect anomalies, and the results are then written to the gold table.

The anomaly detection component of DeltaTrace is based on predictive modeling using time-series data from wearable devices. The validation of these models included baseline, ML, and deep learning approaches for next-value prediction tasks, evaluated through user-based 3-fold cross-validation. The performance metrics included mean absolute error and root mean squared error. The selected model is required to achieve the lowest score among all evaluated models across these metrics and to demonstrate a clear improvement over the baseline approach. Based on these criteria, the attention-based long short-term memory (AttentionLSTM) model is selected for deployment due to its superior predictive performance. Details on the experimental setup, hyperparameter optimization, and model comparison are provided in Multimedia Appendix 4. Although the convolutional long short-term memory achieves a lower average mean absolute error for step prediction, the difference compared with AttentionLSTM is not statistically significant (P=.16, paired 2-tailed t test). Therefore, using the AttentionLSTM across all prediction tasks ensures consistency in the performance evaluation of DeltaTrace without compromising predictive accuracy. Anomalies are categorized using z score thresholds derived from the variability of the LifeSnaps dataset. To balance the 3 categories, we use $z \geq 1.04$ for green (minor), $z \geq 1.29$ for yellow (moderate), and $z \geq 1.65$ for red (critical). These thresholds also ensure that most anomalies remain minor, with fewer moderate and critical cases.

Data Exposition

To support effective data visualization, selected outputs from the processing and inference stages are written in real time to a PSQL database. This database serves as a structured, query-efficient layer specifically designed to support time-series visualization tools such as Grafana.

Separate tables are created within the PSQL database to organize information by data type (eg, sleep, physical activity, and heart rate). Each table includes timestamp fields and primary keys,

XSL•FO
RenderX

which facilitate time-series indexing, efficient joints, and fast query execution.

This architectural choice enables seamless integration with Grafana, allowing the platform to generate dynamic dashboards that display both real-time and historical data. Dashboards are configured to support multiple levels of analysis, including individualized monitoring for clinical care and aggregated views for population-level analytics. These visual interfaces enhance the interpretability of the system, supporting use cases such as anomaly detection, longitudinal health tracking, and cohort-based evaluations.

Evaluation Design

To evaluate the performance and robustness of DeltaTrace, 2 complementary datasets are used: one synthetic dataset specifically generated for this study and one real-world dataset, LifeSnaps, selected for the richness and representativeness of multimodal health data. The combination of both datasets allows for a comprehensive evaluation, covering both controlled data generation scenarios and real-life variability, noise, and complexity.

- The synthetic dataset is created to simulate realistic health-related signals such as steps, heart rate, and sleep duration. To do so, first, the key variables to be simulated are identified and then established physiologically plausible value ranges for each of them, based on publicly available health guidelines and literature [34,35]. Data points are then generated with coherent temporal structure (eg, steps per day and heart rate per minute) using random sampling within the specified ranges. Finally, the simulated data stream is sent to Kafka, which ingests the information into the bronze layer of DeltaTrace for further processing. Performance results are reported in terms of requests per second, where a request is defined as the ingestion of a single record for a given topic (eg, 1 temperature value per second or 1 heart rate measurement per second). Each simulated user includes multiple wearable-derived data sources, with up to 10 variables (topics) captured concurrently, assuming a frequency of 1 record per second. This dataset enables the generation of all necessary records in a controlled manner, allowing scalability tests to be conducted without constraints on data volume.
- The second dataset is LifeSnaps [36], a publicly available, multimodal, longitudinal dataset collected over approximately 4 months from 71 participants across Europe. It integrates high-resolution wearable data, ecological momentary assessments, and validated surveys, resulting in over 35 distinct types of measurements captured at temporal granularities ranging from seconds to days. The wearable device used for data capture is a Fitbit Sense, which includes readings from vital signals such as heart rate, sleep patterns, steps, blood oxygen saturation, temperature, and stress-related metrics. Additionally, ecological momentary assessment data encompass contextual and mood surveys, while traditional survey instruments cover personality, motivation, and emotional states. Altogether, the dataset comprises over 71 million rows, allowing comprehensive evaluation across physiological, behavioral, and psychological health dimensions.

For each experiment, performance is evaluated in terms of computational time as the number of requests per second increases. This process, known as a stress test, is conducted using the simulated dataset, while visualizations are produced with the LifeSnaps dataset.

The performance testing server for DeltaTrace is a Linux-based Ubuntu system with a 5.15 kernel, powered by dual Intel Xeon Gold 5218 central processing units (CPUs; 24 cores total at 2.30 GHz). It has 64 GB error-correcting code RAM, 8 GB swap, and a multilevel cache (L1: 256 KB and L2 and L3: 32 MB each). The server runs in a kernel-based virtual machine virtualized environment. Storage includes a 500 GB primary disk, a 60 GB secondary disk, and several small loop devices.

Ethical Considerations

This study did not involve any direct physical or mental intervention with participants. All data used were either synthetic, generated based on reference values reported in the literature, or obtained from LifeSnap, a publicly available dataset. Thus, this study did not require ethics approval, as it did not involve human participants or personal identifiable information.

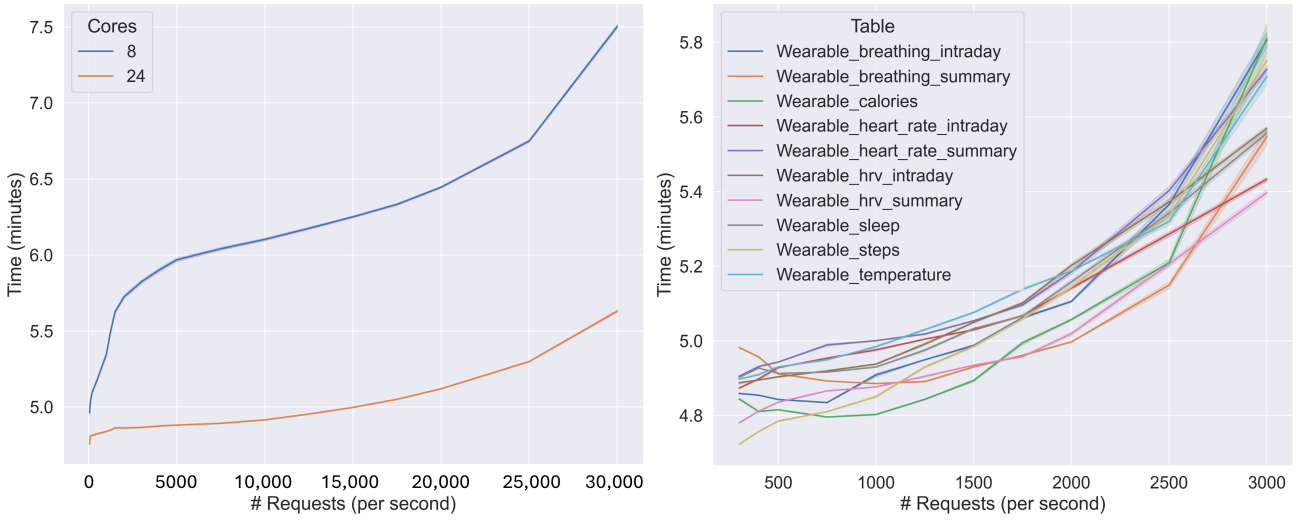
Results

Silver Layer: Clean Data

In this set of experiments, the stress test is run and assessed until the clean data are available for visualization and consultation. The objective is to assess whether DeltaTrace is capable of handling high-throughput scenarios as demand scales. In addition, real data are visualized to show the system output. The results of the stress test are presented in Figure 2, where the x-axis represents the number of requests per second, each request corresponding to a single record of wearable data, such as a heart rate measurement, and the y-axis shows the processing time in minutes.

XSL•FO
RenderX

Figure 2. Time needed to process raw data from generation to the silver layer and make it available for visualization. (**A**) Time from data generation to silver layer and (**B**) time required for each data topic to be processed and available in the silver layer.



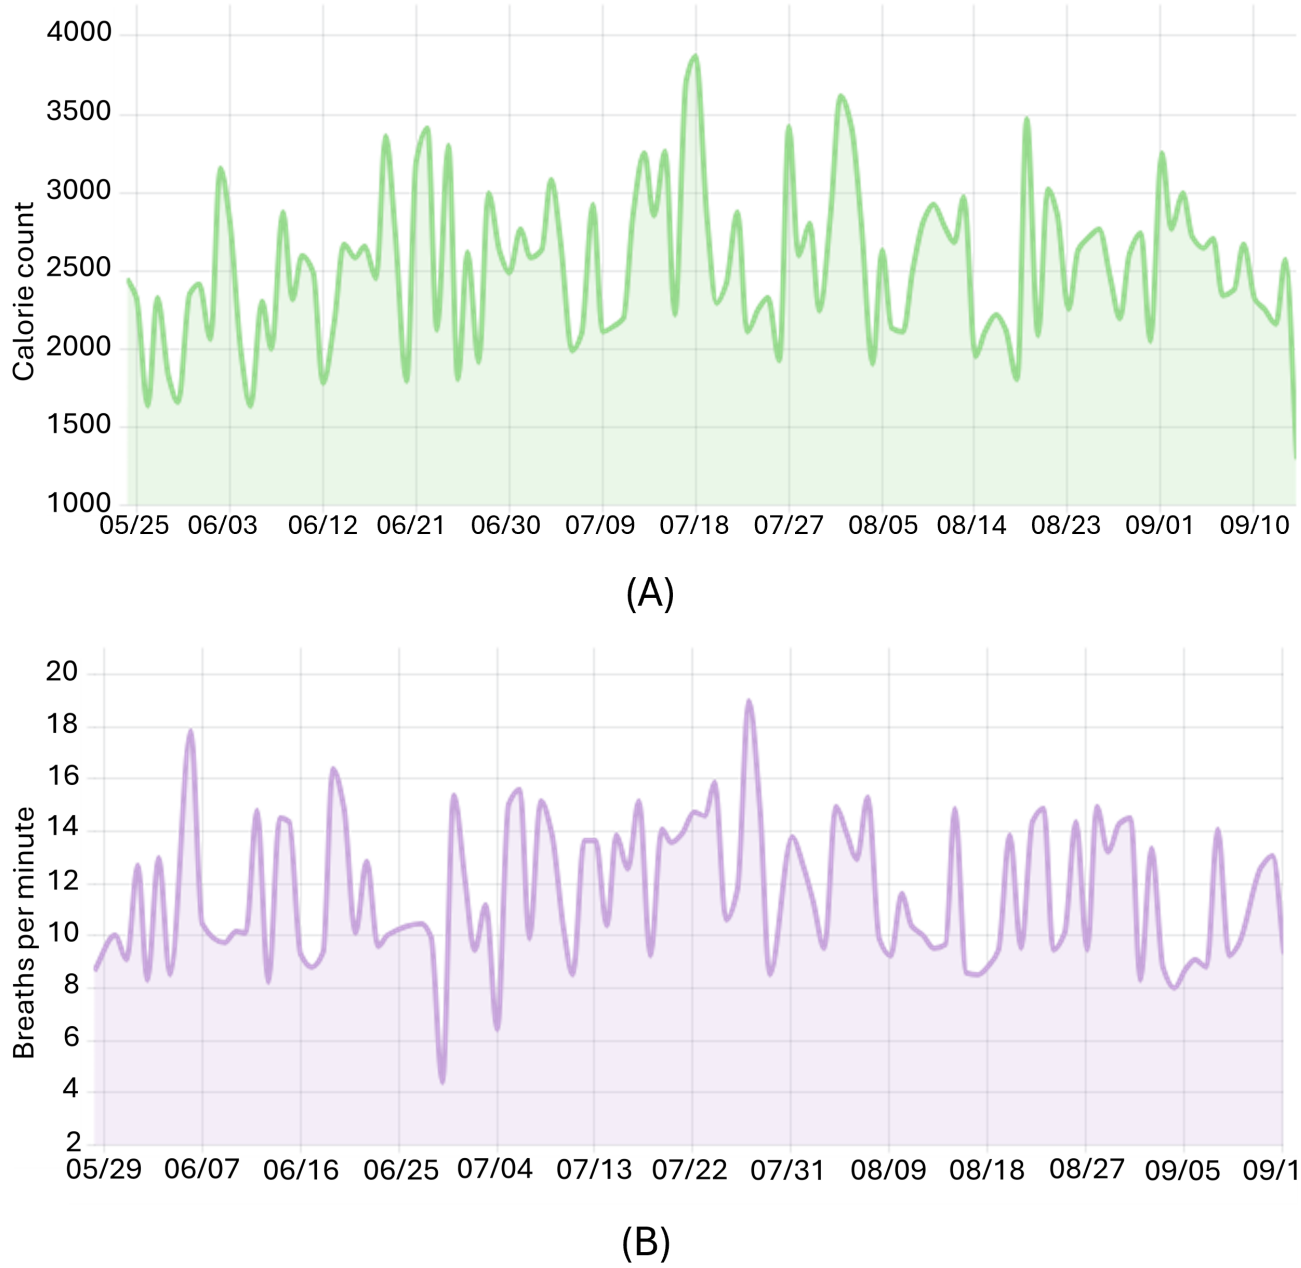


Figure 2A shows the time required to process data from the moment they are sent until they become available in the silver layer (y-axis), for different CPU configurations (8 and 24 cores) and increasing request rates (x-axis). At 50 requests per second, the 8-core setup requires a mean of 5.1 (SD 0.2) minutes, while the 24-core setup requires a mean of 4.9 (SD 0.12) minutes (a difference of 0.2 minutes). At 15,000 requests per second, the mean time increases to 6.3 (SD 0.14) minutes (8 cores) and 5 (SD 0.06) minutes (24 cores), with a difference of 1.3 minutes. At 30,000 requests per second, the mean values reach 7.5 (SD 0.28) and 5.6 (SD 0.19) minutes, respectively, with a difference of 1.9 minutes. These values correspond to an improvement of 4.15%, 20.05%, and 24.95%, respectively, when using 24 cores compared to the 8-core configuration.

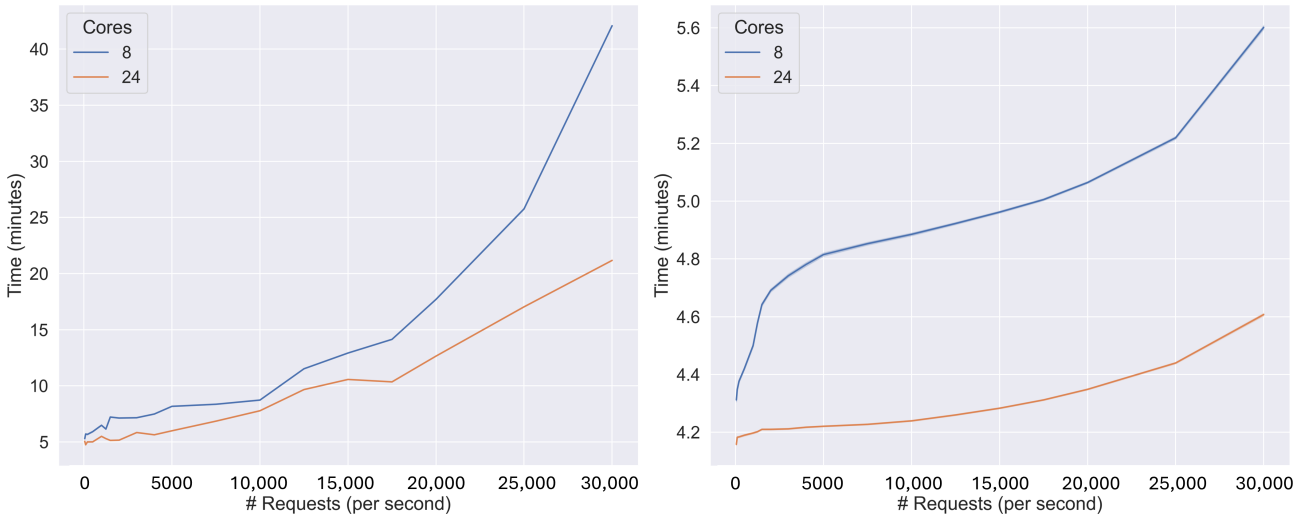
Figure 2B provides a more detailed view by showing the processing time per data topic sent by the wearable device using the 24-core setup. When 500 requests per second are received, the time ranges between 4.7 and 4.9 minutes depending on the data topic. At 1500 requests per second, the range increases slightly (4.9 to 5.1 minutes). At 3000 requests per second, the time ranges from 5.4 to 5.8 minutes. This indicates a maximum difference of 25 seconds between the fastest and slowest topics (processed simultaneously), which reflects consistent behavior across data streams.

In Figure 3, actual data from the LifeSnaps dataset are shown using Grafana. In Figure 3A, the x-axis represents the date of the record, and the y-axis shows the calorie count, while in Figure 3B, the y-axis represents the number of breaths per minute. The data are plotted in real time, with an observed delay of approximately 4.6 minutes when 71 users are monitored. Two data sources are shown for illustration purposes: Figure 3A presents the number of calories burnt throughout the day, and Figure 3B shows the number of breaths per minute, both collected over several days.

XSL•FO
RenderX

Figure 3. Data received from wearable devices, ingested into the platform, and cleaned in the silver layer. (A) Daily calorie consumption and (B) number of breaths per minute.



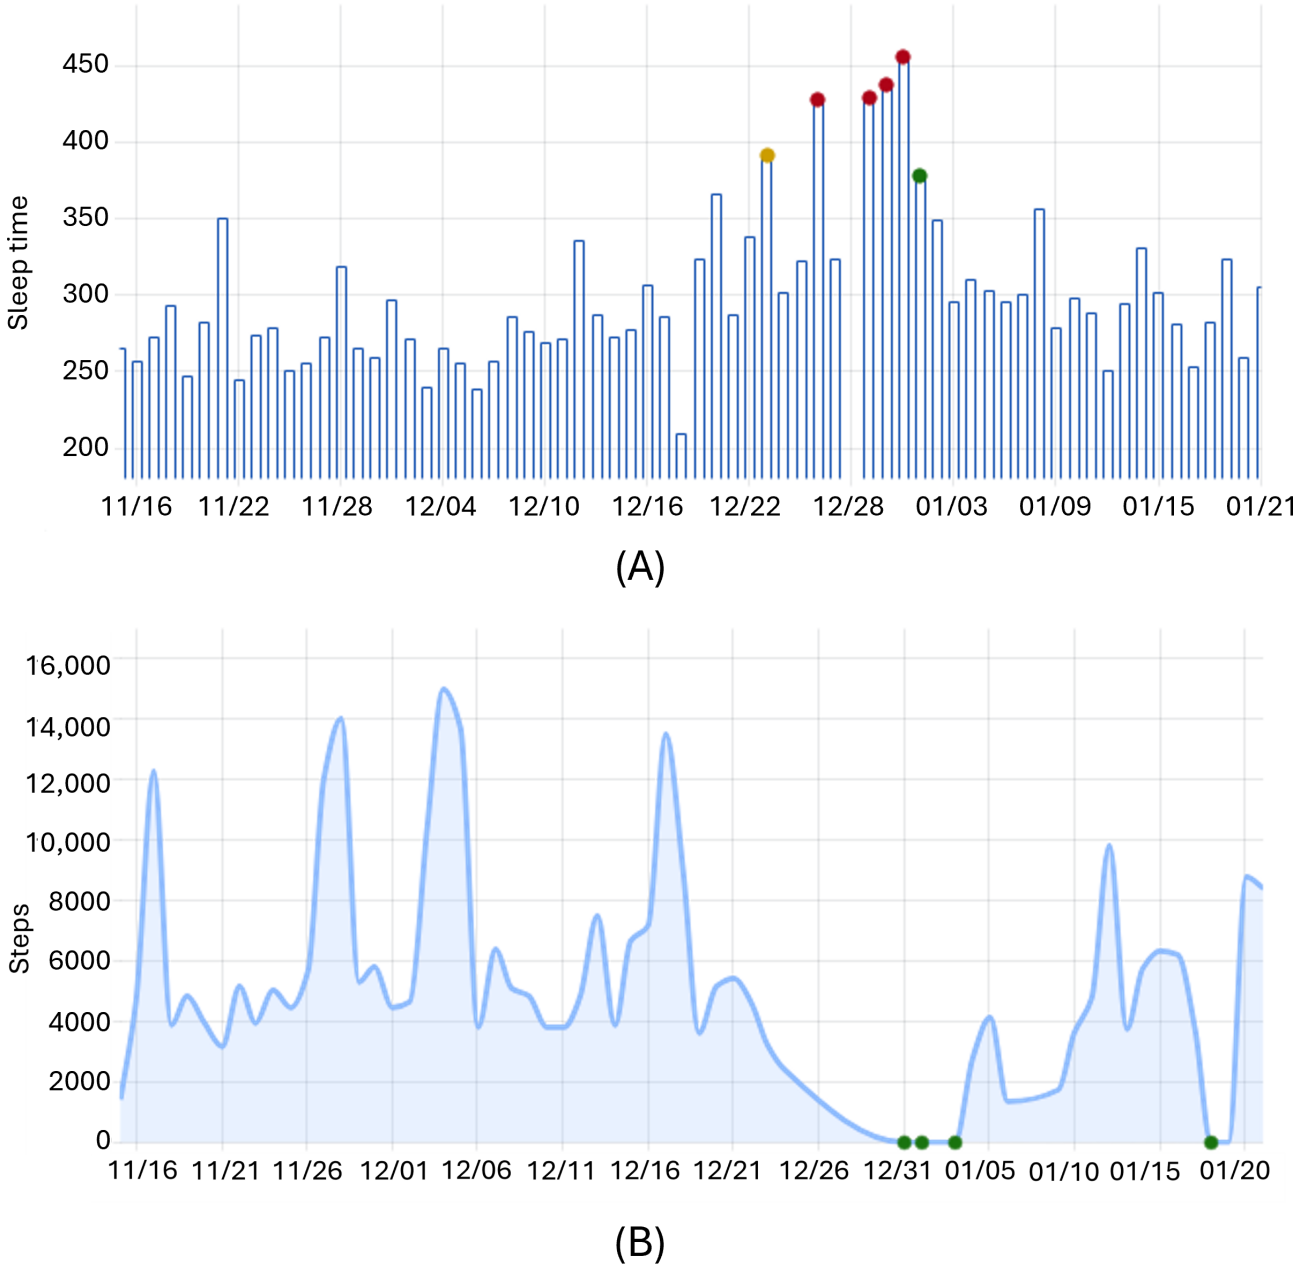
In summary, the computational cost as the platform load increases is evaluated, with the 24-core configuration being up to 24.95% more efficient than the 8-core configuration. The time measurements include the full processing pipeline (from data ingestion to visualization at the silver layer). Additionally, the time difference between data topics remains within 25 seconds under all tested loads, indicating uniform performance across heterogeneous sources. These results confirm that DeltaTrace maintains consistent latency and scales proportionally with the number of requests for data to be available for visualization and consultation.

Gold Layer: Data Aggregations

In this second set of experiments, the efficiency of DeltaTrace in performing aggregations over clean data under increasing loads is evaluated. The goal is to assess system performance when a real-time AI model and statistical aggregation processes continuously read data from the silver layer and write results to the gold layer. Computational time is measured under 8- and 24-core CPU configurations, as the request rate increases. In Figure 4, the x-axis represents the number of requests per second, while the y-axis indicates the processing time in minutes. The performance of the AI model is detailed in Multimedia Appendix 4.

XSL•FO
RenderX

Figure 4. Time required to process raw data from generation to plotting in the gold layer for both anomaly detection and statistical analysis, comparing 8- and 24-core configurations under increasing request rates. (A) Time from data generation to anomaly detection (gold) and (B) time from data generation to statistical analysis (gold).



As shown in Figure 4A, the time required from the moment the data are sent until anomalies are generated and made available for visualization is represented on the y-axis, with the request rate shown on the x-axis. At 50 requests per second, the difference between the 8- and 24-core settings is 0.2 minutes. This difference increases to 2.1 minutes at 1500 requests per second and to 2.4 minutes at 15,000 requests per second. At 30,000 requests per second, the difference reaches 20.9 minutes. These results correspond to improvements of 3.78% at 50 requests per second, 18.58% at 15,000 requests per second, and 49.67% at 30,000 requests per second when using 24 cores compared to the 8-core setup. The 24-core configuration also consistently exhibits lower SDs, indicating more stable performance under all tested loads.

In Figure 4B, the processing time required to compute and visualize statistical aggregations (such as mean values) is shown. At 50 requests per second, the 24-core configuration processes data 0.1 minutes faster than the 8-core setup. This difference increases to 0.4 minutes at 1500 requests per second and to 0.7 minutes at 15,000 requests per second. At 30,000 requests per second, the difference reaches 1 minute. These values represent improvements of 8.62%, 14.11%, and 17.86%, respectively, when using the 24-core configuration.

The anomalies detected in the LifeSnaps dataset are presented in Figure 5. Figure 6A displays sleep duration (in minutes) for a single user, with anomalies marked in color based on the level of deviation from learned user patterns. In this case, consecutive anomalies appear between December 23, 2021, and January 1, 2022, with 1 yellow anomaly followed by 4 red and 1 green anomaly, all corresponding to unusually long sleep durations. In Figure 5B, step count data show 4 green anomalies identified as potential inactivity events, which could also be attributed to not wearing the wearable device during those days.

XSL•FO
RenderX

Figure 5. Visualization of behavioral anomalies in wearable data based on sleep and step patterns. Anomalies are marked in color: red (critical), yellow (moderate), and green (minor), indicating deviations from the typical pattern. (A) Sleep duration over time, measured in minutes with the detected anomalies and (B) step count per day with the detected anomalies.

In addition, a web application for health care professionals has been developed, as shown in Figure 6, being part of the application layer in Figure 1. Grafana panels are embedded for visual analysis and are continuously updated as new data arrive, with delays indicated in Figure 4. The left panel displays anomalies detected in daily step counts, while the right panel shows scores for the STAI anxiety trait. Unlike sensor data, STAI questionnaires are received at irregular intervals and processed in batches through tasks scheduled in Apache Airflow, which optimizes resource use for low-frequency sources. This configuration enables visual comparison between anomalies in activity data and self-reported questionnaire results.

XSL•FO
RenderX

Figure 6. Web application for health care professionals enabling user selection, visualization grouping, and date filtering. The left panel displays daily step count for the selected user, highlighting anomalies by deviation severity: red (critical), yellow (moderate), and green (minor). The right panel shows the reported score for the anxiety trait from the State-Trait Anxiety Inventory scale.

In summary, this set of experiments presents the computational time required to aggregate real-time data and make it available to health care professionals. When the request rate is 15,000 per second, statistical aggregations are available in approximately 4.3 minutes, whereas the anomaly detection model requires 10.5 minutes, times that are sufficient for several clinical use cases [37-45] and consistent with those reported in previous studies of similar big data platforms [10,46]. At lower request rates (below 15,000 per second), anomalies are computed in 5 to 10 minutes after the data are sent. However, at 30,000 requests per second, anomaly detection latency exceeds 40 minutes in the 8-core configuration, compared to 20 minutes in the 24-core setup. This nonlinear increase suggests saturation in the lower-resource configuration, with the latency line showing a marked nonlinearity (saturation) starting around 20,000 requests per second. This relationship is fitted by a quadratic model (polynomial regression, adjusted of 0.98 for 8 cores and 0.99 for 24 cores), confirming a significant nonlinear relationship (P<.0001 for the quadratic term). In contrast, statistical aggregations remain under 5.6 minutes across all loads, indicating more stable and scalable performance. These results highlight the need to allocate sufficient computational resources depending on the expected load and latency requirements for data to be available for visualization and consultation.

Discussion

Principal Findings

The experimental results demonstrate the performance of DeltaTrace across different data processing layers and system loads. In the first set of experiments, which focuses on the processing time from data generation to the silver layer, the platform can maintain mean processing times between 4.9 (SD 0.12) and 7.5 (SD 0.28) minutes depending on the request rate and data topic. The 24-core configuration shows improvements of up to 24.95% compared to the 8-core configuration. While perfect scaling would yield an improvement of 66%, this is unrealistic since part of the workload is not parallelizable. According to Amdahl's law [37], an efficiency of 80% - 85% would typically produce 25% - 40% improvement, consistent with our observation. In all cases, the delay between different data sources remains approximately 25 seconds, which confirms the consistency of the system across heterogeneous input streams.

In the second set of experiments, which evaluates the processing time to deliver statistical aggregations and anomaly detection in the gold layer, the computational demand of anomaly detection is higher than that of simple aggregations. With 15,000 requests per second, the time required for statistical output is approximately 4.3 minutes, whereas the time for anomaly detection reaches 10.5 minutes. At 30,000 requests per second, the 8-core configuration exceeds 40 minutes for anomaly detection, while the 24-core setup remains under 20 minutes. Statistical aggregations, in contrast, remain under 5.6 minutes in all configurations and scenarios, showing predictable and stable behavior.

These results demonstrate that DeltaTrace maintains stable performance and predictable latency under increasing data loads, confirming the scalability of the proposed architecture when limited computing resources are available. Beyond performance,

XSL•FO
RenderX

the experimental evaluation confirms that the platform design successfully fulfills the defined research objectives. The implemented mechanisms ensure versioning and traceability across all data processing layers, stable scalability under varying loads, and consistent operation of model management, scheduling, and monitoring components. These results demonstrate that DeltaTrace does not only integrate well-known technologies but also applies them within a coherent architecture that operationalizes traceability as a core and verifiable property of a health data platform. The real-time monitoring capabilities and traceability features evaluated in these experiments have direct implications for clinical applications, which are further elaborated in the following subsection.

Clinical Implications

DeltaTrace provides a transparent and reproducible foundation for clinical applications where accountability and data integrity are essential. By allowing clinicians to trace each alert or output back to its source data, processing pipeline, and model version, the platform builds trust in automated decision support. This is especially important when clinical actions depend on system-generated insights. The ability to monitor trends in sleep, mobility, or heart rate in near real time can support early identification of health deterioration, enabling more proactive care for older adults. These features make DeltaTrace a strong candidate for integration into remote patient monitoring programs and digital health strategies focused on prevention and early intervention.

In this work, the platform has been intentionally evaluated using a minimal hardware configuration to establish a lower bound on the resources required to provide near real-time processing. Under these conditions, DeltaTrace can detect and process anomalies for approximately 1500 users in under 10 minutes. This response time is suitable for a wide range of clinical and health monitoring applications where reactions within this time frame are beneficial. These include chronic conditions such as sleep apnea [38], hormonal cycle irregularities [39], or psychiatric events that evolve over time [40-42]. In contrast, other conditions, such as stroke, anaphylaxis, or cardiac arrest [43-45], require faster interventions, often within minutes. In such cases, additional resources (eg, graphics processing units [GPUs] for inference and multiple server nodes) can be deployed to reduce latency. Similar processing delays (5 to 10 minutes) have been reported in previous studies [10,46].

Comparison With Prior Work

Previous work has reported enhanced efficiency with Apache Spark and HDFS if more hardware resources are provided [47,48]. As reported by Sewal and Singh [49], the execution time can decrease from 1019 to 382 seconds if 5 nodes are provided, which implied an improvement of 73.51%. Similarly, evaluations reported by Buber and Diri [50] have shown that GPU-based processing can accelerate execution by a factor of 4 to 5 compared to CPU-only configurations. These enhancements can be achieved without requiring modifications to the software architecture, thereby maintaining consistency, traceability, and scalability across different deployment environments.

In this paper, a separate AI module with API-based communication is proposed for detecting anomalies in wearable data. This is a general design that provides a significant benefit, as the AI process is decoupled, and any AI task can be included in the pipeline without modifying the architecture, such as classification and clustering tasks. The MLflow framework allows the logging of any type of model, including ML and deep learning, and also state-of-the-art models such as large language models and transformer-based models. The software layer implemented on top of this architecture allows the evaluation of the performance when the load increases, being able to identify if the hardware allocation is proper for the specified AI task and use case. This design contributes to open challenges [51] and current trends [52] identified by previous reviews, especially with deep learning models such as recurrent neural networks, regarding model scaling, distributed computing, and high-scale data processing, all of these while keeping traceability features.

DeltaTrace also contributes to ongoing initiatives such as the European Health Data Space (EHDS) Regulation, which aims to establish a common framework for the secure use and exchange of health data within the European Union. Traceability and data governance are among the core pillars of this regulation [53-55]. The platform provides full traceability, including version control for data, models, and code, as well as detailed tracking of all transformations applied after data ingestion. These capabilities directly support EHDS requirements for auditability and transparency in both primary and secondary uses of health data [56,57]. In addition, the system integrates model management, resource monitoring, and real-time analytics under a unified architecture based on open source components, aligning with the EHDS objective of promoting trusted and scalable health data infrastructures [58]. These characteristics position DeltaTrace as a suitable technical foundation for future EHDS-compliant deployments.

This alignment with EHDS is particularly valuable when comparing DeltaTrace with previous work, as most existing platforms focus primarily on large-scale data processing, real-time analytics, or specific task performance but provide limited support for traceability, versioning, model management, and comprehensive orchestration. As shown in Table 1, many prior studies omit key mechanisms for tracking data and model transformations, monitoring system resources, and ensuring reproducibility across the pipeline. In contrast, DeltaTrace integrates end-to-end versioning of datasets and models through MLflow, robust orchestration and workflow scheduling via Apache Airflow, scalable processing of batch and streaming data with Apache Spark, and fault-tolerant storage and metadata management with Delta Lake. By combining these capabilities, DeltaTrace ensures traceability, auditability, and reproducibility, providing a more comprehensive and transparent framework for health data management and a stronger technical foundation for EHDS-compliant deployments.

Limitations

The evaluation of DeltaTrace was first conducted in a single-server environment to establish a controlled baseline and analyze system performance under stable and reproducible

XSL•FO
RenderX

conditions. Within this setup, experiments were executed using constant data input rates and a fixed anomaly detection model, which simplified testing and allowed for consistent performance assessment. This configuration may not fully reflect the variability and operational challenges present in multinode or real-world deployments. In the current implementation, the AI inference module operates as a standalone Python service, which may limit scalability compared to the distributed data processing components. However, the modular architecture based on containerized services allows future extensions toward distributed or parallel inference using orchestration frameworks such as Kubernetes. This design intentionally separates the AI inference module from the distributed data layer to enable flexible integration of custom deep learning pipelines. For the present implementation, these distributed capabilities have not been tested, and this represents a limitation of the current proposal. Moreover, the anomaly detection model cannot, in its current form, distinguish between true behavioral anomalies (eg, inactivity) and data quality issues (eg, sensor nonadherence or device-off). Additionally, aspects such as human interaction and workflow integration were not examined. Despite these constraints, the obtained results provide a solid foundation for understanding DeltaTrace behavior under controlled conditions and for guiding future evaluations in larger and more dynamic environments.

Strengths and Future Work

All technologies composing the platform are open source, offering transparency, adaptability, and long-term sustainability. This choice also supports future work focused on enhancing the security and interoperability mechanisms of the proposed big data platform [59]. Core components such as Kafka, Delta Lake, MLflow, and Airflow include built-in features such as encrypted data transmission (Transport Layer Security), encrypted storage (Advanced Encryption Standard), role-based access control, and execution logging, which are integrated into the platform. Data processed throughout the system are consistently associated with anonymized identifiers, used to securely match heterogeneous sources such as questionnaire responses and physiological signals. These identifiers are also used by the AI module to construct temporal sequences and apply sliding window techniques across unified data streams. Although accountability, data integrity, and traceability are demonstrated through system mechanisms and workflow examples (Figure 1 and Multimedia Appendix 3), their empirical validation under real deployment conditions remains part of future work.

Future work will include testing the platform in distributed and GPU-accelerated environments to further assess performance and responsiveness under higher data volumes. Further evaluations will also involve human-in-the-loop scenarios to examine usability and workflow integration in operational health settings. In addition, new developments will focus on implementing advanced access control mechanisms and extending support to other data modalities, including imaging, audio, and unstructured text. These developments aim to enhance interoperability and clinical applicability while maintaining the architectural principles that ensure full traceability.

Conclusions

This study set aimed to design and evaluate a health data platform where traceability is implemented as a central architectural feature integrated with model management, orchestration, and visualization components. DeltaTrace supports both real-time and batch processing of health-related data with built-in traceability features. In this evaluation, continuous monitoring from wearable devices has been used to assess real-time processing, while questionnaire data have been included as a representative case of batch ingestion. The evaluation demonstrated that the platform can sustain near real-time performance, processing data for approximately 1500 users with end-to-end delays below 10 minutes on a single CPU-based server. These findings confirm that the platform achieves scalable and reproducible processing under constrained computational resources.

By embedding traceability within the data lifecycle and integrating complementary components for monitoring and management, DeltaTrace addresses key requirements for auditability, reproducibility, and accountability in digital health infrastructures. The platform aligns with the objectives of the EHDS by providing a technical foundation that supports secure, version-controlled, and verifiable health data processing. The evaluation confirms that the proposed design effectively meets the defined research objectives, demonstrating that traceability, scalability, and coordinated management can be achieved within a unified and reproducible platform architecture. Future work will focus on extending DeltaTrace to strengthen privacy, interoperability, and the inclusion of additional data modalities, further aligning the platform with the long-term goals of the EHDS.

Abstract

Background: Several clinical cases and experiments have demonstrated the effectiveness of traditional Chinese medicine (TCM) formulas in treating and preventing diseases. These formulas contain critical information about their ingredients, efficacy, and indications. Classifying TCM formulas based on this information can effectively standardize TCM formulas management, support clinical and research applications, and promote the modernization and scientific use of TCM. To further advance this task, TCM formulas can be classified using various approaches, including manual classification, machine learning, and deep learning. Additionally, large language models (LLMs) are gaining prominence in the biomedical field. Integrating LLMs into TCM research could significantly enhance and accelerate the discovery of TCM knowledge by leveraging their advanced linguistic understanding and contextual reasoning capabilities.

Objective: The objective of this study is to evaluate the performance of different LLMs in the TCM formula classification task. Additionally, by employing ensemble learning with multiple fine-tuned LLMs, this study aims to enhance classification accuracy.

Methods: The data for the TCM formula were manually refined and cleaned. We selected 10 LLMs that support Chinese for fine-tuning. We then employed an ensemble learning approach that combined the predictions of multiple models using both hard and weighted voting, with weights determined by the average accuracy of each model. Finally, we selected the top 5 most effective models from each series of LLMs for weighted voting (top 5) and the top 3 most accurate models of 10 for weighted voting (top 3).

Results: A total of 2441 TCM formulas were curated manually from multiple sources, including the Coding Rules for Chinese Medicinal Formulas and Their Codes, the Chinese National Medical Insurance Catalog for proprietary Chinese medicines, textbooks of TCM formulas, and TCM literature. The dataset was divided into a training set of 1999 TCM formulas and test set of 442 TCM formulas. The testing results showed that Qwen-14B achieved the highest accuracy of 75.32% among the single models. The accuracy rates for hard voting, weighted voting, weighted voting (top 5), and weighted voting (top 3) were 75.79%, 76.47%, 75.57%, and 77.15%, respectively.

Conclusions: This study aims to explore the effectiveness of LLMs in the TCM formula classification task. To this end, we propose an ensemble learning method that integrates multiple fine-tuned LLMs through a voting mechanism. This method not only improves classification accuracy but also enhances the existing classification system for classifying the efficacy of TCM formula.

Introduction

Background

Traditional Chinese medicine (TCM) formulas are combinations of medicinal substances developed through clinical experience and guided by TCM theory. They are developed through a systematic process involving syndrome differentiation, etiological analysis, determination of therapeutic principles, selection of appropriate herbs, dosage adjustment, formulation considerations, and specification of use, all in accordance with fundamental compositional structures [1]. Several studies have shown that TCM formulas have significant efficacy in the treatment and prevention of disease in both clinical and experimental studies [2-4]. A randomized clinical trial demonstrated that the TCM compound Tongxinluo significantly improved clinical outcomes in patients diagnosed with ST-segment elevation myocardial infarction [5]; the traditional medicine Pien Tze Huang prevents colorectal cancer by influencing the gut microbiota, enhancing beneficial metabolites, and suppressing oncogenic and proinflammatory factors [6].

Classical TCM formulas represent exemplary applications of TCM prescriptions. The selection and cataloging system for classical formulas streamlines the approval process for Chinese herbal compound preparations by exempting them from pharmacological studies and clinical trial data submissions. These formulas are defined as “those derived from ancient classical prescriptions that remain widely used today, demonstrate proven efficacy, exhibit distinctive characteristics and advantages, and were documented in medical texts prior to or during the Qing Dynasty.” However, after thousands of years of clinical practice, TCM has accumulated an immense number of formulas by the late Qing period, incomplete statistics indicate that over 100,000 had been recorded [7]. Current TCM formula textbooks and national standards still follow the efficacy-oriented classification system established in Wang Ang’s Qing Dynasty work *Yi Fang Ji Jie* (Compilation of Medical Formulas, 医方集解) [8]. Prior to the introduction of this system, many formulas lacked clear categorization, making manual classification both labor-intensive and susceptible to inconsistencies.

As the foundation of TCM syndrome differentiation and treatment, systematic classification of TCM formulas based on efficacy enables a comprehensive exploration of their latent information and reveals herb-disease relationship patterns. Previous research primarily relied on expert experience to develop classification systems organized by therapeutic methods (efficacy) [9,10]. With advances in artificial intelligence, new methodological pathways have emerged for automated formula classification. Gu [11] used the k-nearest neighbor algorithm in machine learning to calculate and classify the similarity of TCM formulas. However, the complex relationships between herbs and diseases in TCM formulas complicate the classification process. Cheng et al [12] present an improved deep learning model: S-TextBLCNN for the TCM formula classification task; it has an accuracy of 0.858 and an F_1-score of 0.762. To further explore the optimal deep learning models in the TCM formula classification task, Ren et al [13] combined several deep learning models to classify TCM formulas and found that bidirectional encoder representation from transformers-convolutional neural network was the most effective, achieving an accuracy of 77.87%, as well as weighted precision, weighted recall, and weighted F_1-score of 79.46%, 77.87%, and 77.44%, respectively. In 2022, OpenAI released applications such as ChatGPT [14], have demonstrated strong performance in tasks like question answering and translation. Moreover, large language models (LLMs) have achieved remarkable results in the biomedical domain. For instance, Google’s Med-PaLM2, which was fine-tuned from PaLM2 using data from the medical domain, achieved 86.5% accuracy on the MedQA dataset [15], which is close to the response level of clinical doctors [16]. Nijkamp et al [17] have trained the ProGen2 model on many different sequence datasets and demonstrated state-of-the-art performance both in generating novel viable protein sequences and in predicting protein fitness tasks. Some scholars tried to use LLMs to classify the text [18,19], therefore, to verify the classification ability of LLMs. In our previous study [20], we used the prompt templates and LLMs, such as ChatGLM-6B [21], ChatGLM2-6B [22], InternLM-20B [23], ChatGLM-130B [24], and ChatGPT, to classify TCM formula and validate the potential of LLMs in the field of TCM.

Based on our previous study [20], this study further explores the classification of TCM formulas by fine-tuning 10 distinct LLMs. It introduces an ensemble voting method based on multiple fine-tuned LLMs. This approach emphasizes the integration of predictions from each model through voting mechanisms, including both hard voting and weighted voting. The adoption of multiple LLMs for TCM formula classification offers a novel perspective on the application of LLMs in the field of TCM.

Research Question

In our previous work [20], we used LLMs to investigate TCM formula classification. We used prompt templates and both fine-tuned and original LLMs. The experimental results demonstrated that fine-tuned LLMs can enhance classification task accuracy. Therefore, in this study, we aim to explore the potential of LLMs in TCM formula classification tasks and rationality by posing the following research questions (RQs):

- RQ1: What is the performance of different LLMs for TCM formula classification?
- RQ2: How to improve the performance of TCM formula classification by multiple LLMs?
- RQ3: What is the rationality of TCM formula classification using LLMs?

To explore RQ1, we used 10 LLMs and fine-tuned them on a manually curated TCM formula dataset, followed by a comparative analysis of the results. To address RQ2, we used an ensemble learning approach. Using the average accuracy derived from the fine-tuned LLMs as model weights, we performed both hard and weighted voting on the results. In addition, we explored the effectiveness of different strategies, including selecting the best-performing model within each category and weighted voting based on the 3 best-performing models, to determine the approach that yields optimal results.

XSL•FO
RenderX

To investigate RQ3, TCM experts manually reviewed the predicted results generated by the fine-tuned LLMs. This process involved analyzing discrepancies between the voting results of the LLMs and the reference answer, thereby exploring the rationality behind the classification by the LLMs in the TCM formula classification task.

Methods

Data Preparation

We used 2441 TCM formulas manually curated from the Coding Rules for Chinese Medicinal Formulas and Their Codes [25], the Chinese National Medical Insurance Catalog for proprietary Chinese medicines (2023) [26], and textbooks of formulas of Chinese medicine [10]. After manual review [13], each formula consists of the formula name, ingredients, efficacy, and indications. The data processing procedure is as follows: only efficacy-related classifications are retained, while non-efficacy classifications, such as ethnic minority medicine, are removed; formulas under identical or similar classifications are consolidated (with classification names standardized according to national guidelines), while unique formula classifications are preserved; finally, the resulting data are subjected to deduplication.

In the Qing Dynasty, Wang Ang, in his work *Yifang Jijie*, proposed an integrated classification method that prioritized the efficacy of the TCM formula. This method was not only used in the textbooks of Chinese medicine formulas throughout various dynasties [27] and the secondary classification of the Chinese National Medical Insurance Catalog for proprietary Chinese medicines [28] but also served as the method used in the national standard, the Coding Rules for Chinese Medicinal Formulas and Their Codes. Therefore, this study established a harmonized efficacy classification system based on national standards, integrating multisource TCM formula data through structural realignment and category consolidation (the data remain intact with only standardized nomenclature adjustments made to classification categories exhibiting terminological variations, following national regulatory requirements), resulting in 22 standardized categories. However, The emetic formulations category contained insufficient samples and was therefore excluded; based on this categorization, a total of 2441 formulations were identified across 21 categories, as detailed in Table 1.

Table . Statistical information of traditional Chinese medicine formula data.

Standard efficacy	Abbreviation	Chinese name	Formulations (N=2441), n (%)
Supplementing and boosting formula	SBF	补益剂	417 (17.08)
Heat-clearing formula	HCF	清热剂	411 (16.84)
Blood-regulating formula	BRF	理血剂	372 (15.24)
Desiccating formula	DF	祛湿剂	246 (10.08)
Superficies relieving formula	SF	解表剂	160 (6.55)
Resolving phlegm relieving cough and relieving wheezing formula	RPRCRWF	化痰-止咳-平喘剂	160 (6.55)
Qi regulated formula	QRF	理气剂	134 (5.49)
Formula for wind disorder	FWD	治风剂	119 (4.86)
Warming interior formula	WIF	温里剂	73 (2.99)
Formula for purgation	FP	泻下剂	60 (2.46)
Reconciling formula	RF	和解剂	43 (1.76)
Tranquillization formula	TF	安神剂	39 (1.60)
Digestive formula	DIF	消食剂	38 (1.56)
Astringent formula	AF	固涩剂	32 (1.31)
Softening hard lumps and dispelling nodes formula	SHLDNF	消肿散结剂	27 (1.11)
Formula for treating carbuncle and ulcer	FTCU	痈疡剂	25 (1.02)
Summer-heat-expelling formula	SHEF	祛暑剂	22 (0.90)
Formula for resuscitation	FR	开窍剂	21 (0.86)
Antidryness formula	ADF	治燥剂	16 (0.66)
Resolving turbidity and lowering lipids formula	RTLLF	化浊降脂剂	16 (0.66)
Antihelminthic formula	AHF	驱虫剂	10 (0.41)

RenderX

Selected LLMs

Since TCM formulas are documented in Chinese or ancient Chinese, in this study, the LLMs that have exceptional performance in Chinese or support multilingualism were selected to facilitate the model's understanding of this information [29].

ChatGLM

ChatGLM-6B, ChatGLM2-6B, and ChatGLM3 are a series of open bilingual language models developed by the Knowledge Engineering Group and Data Mining of Tsinghua University. These models can be easily deployed and fine-tuned on standard consumer-grade graphics processing units, enabling users to perform personalized tasks [21,22,29]. The official script was used to fine-tune these LLMs in this study.

InternLM

The Shanghai Artificial Intelligence Laboratory, SenseTime Technology, the Chinese University of Hong Kong, and Fudan University jointly introduced InternLM-20B and InternLM-7B, which showed exceptional performance in areas such as mathematics, code, dialogue, and creative writing [23]. In this study, Xtuner [30] was used to fine-tune InternLM-20B for TCM formula classification. This tool helps users to fine-tune LLMs with limited hardware resources.

Baichuan2

Baichuan2 is a multilanguage LLM developed by Baichuan-AI. It has been trained on 2.6 trillion tokens and performs well in medical and legal areas. Currently, Baichuan2 has released 7B and 13B to users [31]. We fine-tuned Baichuan2-7B and Baichuan2-13B for our task using Xtuner.

Qwen

Qwen is a series of language models introduced by AliCloud, including Qwen-1.8B, Qwen-7B, Qwen-14B, and Qwen-72B [32]. The official script was used to fine-tune these models in this study. It is worth noting that we fine-tuned Qwen-1.8B with full parameters to improve the performance of the task.

BLOOM

BigScience [33] has launched a series of models of different sizes, known as the BigScience Large Open-Science Open-Access Multilingual Language Model (BLOOM), including 1B, 7B, 13B, and 176B. BLOOM's LLM generates text in multiple languages and codes. In this study, we fine-tuned the BLOOM-1.7B with full parameters using the LLMTuner tool [34].

Ensemble Voting Algorithms for TCM Formula Classification

In our prior work, we used methods with prompt templates and fine-tuned LLMs to classify TCM formulas. The fine-tuned ChatGLM2-6B demonstrated optimal performance, achieving an accuracy rate of 71% in the classification task. However, other models did not surpass the 70% accuracy rate. Its performance failed to surpass that of the deep learning model trained on a single task. In a different study, Chatterjee et al [35] proposed that an ensemble voting method outperforms traditional single classifiers in accurately diagnosing Alzheimer disease. To improve the accuracy of the fine-tuned LLMs in the TCM formula classification task, we adopted an ensemble learning approach, this methodology involved using several fine-tuned LLMs and developing a voting mechanism specifically tailored to their outputs. The goal of this methodology is to combine the predictions of multiple models thereby increasing the accuracy of the TCM formula classification task.

(1)yhard=arg maxc∑i=0N1(Ci=c)

In equation 1, we have N fine-tuned LLMs, where the predicted value for LLM_i is denoted by Ci , N=10, and c represents all classes of the TCM formula. 1(Ci=c) is the indicator function, equal to 1 if Ci=c, and 0 otherwise. The final prediction result yhard is determined by selecting the class with the highest number of votes.

(2)yweighted=arg maxc∑i=0Nαi1(Ci=c)

In equation 2, αi represents the average accuracy of each LLM, the votes for each LLM are multiplied by the corresponding weights, and the resulting weighted votes are summed. Finally, the TCM formula class with the highest weighted sum is finally selected as the final prediction.

Evaluation Metrics

To evaluate the performance of the fine-tuned LLMs on text classification tasks, we used the accuracy, precision, recall, and F_1-score, as defined in equation 3-6, based on true positives (TP), true negatives (TN), false positives (FP), and false negatives (FN).

(3)Accuracy=TP+TNTP+TN+FP+FN

(4)Precision=TPTP+FP

(5)Recall=TPTP+FN

(6)F1-score=2·recall·precisionrecall+precision

Due to the unbalanced distribution of the TCM formula in our test set, we calculated the weighted precision, the weighted recall, and the weighted F_1-score to comprehensively evaluate the performance of the models in multiclassification tasks in equation 7-9.

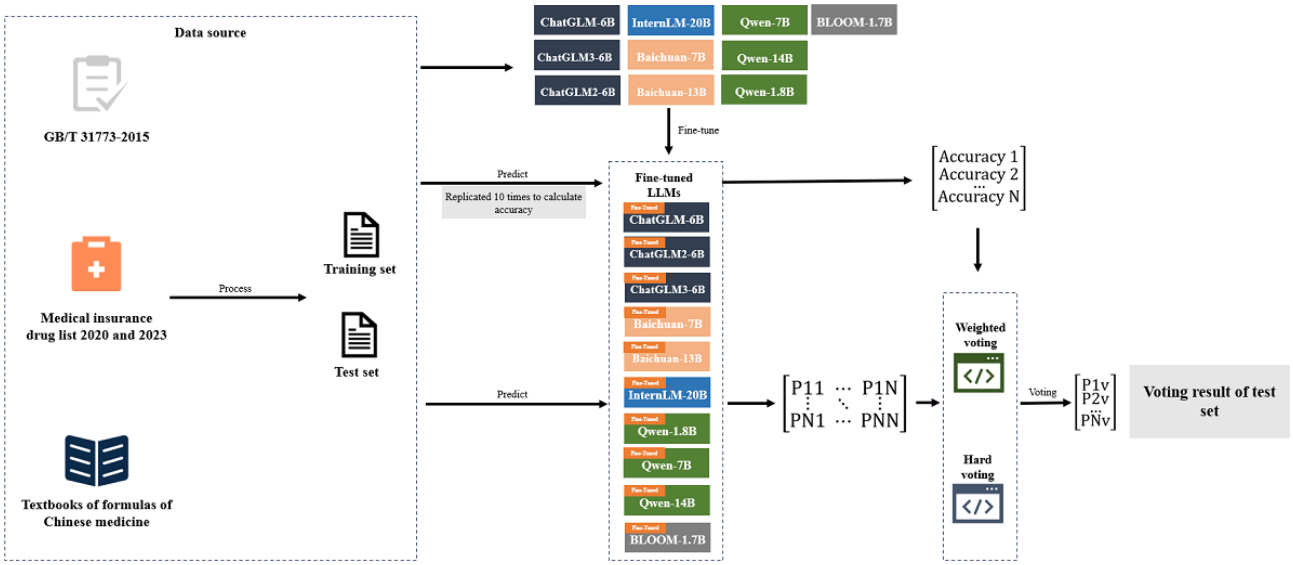
(7)Precisionweighted-avg=∑i=1L(Precisioni·ωi)

(8)Recallweighted-avg=∑i=1L(Recalli·ωi)

(9)F1-scoreweighted-avg=∑i=1L(F1-scorei·ωi)

With the weighted approach, the performance in detecting classes with a larger number of samples can be adequately represented by assigning weights based on the percentage of sample numbers. In our current investigation, we are dealing with a dataset containing 21 classes of TCM formulas. In equation 7-9, L=21, where ωi is the proportion of each TCM formula in the total dataset.

Experiment



Experimental Design and Verification

Overview

We designed the following experiment to explore the RQ1, RQ2, and RQ3, as shown in Figure 1.

XSL•FO
RenderX

Figure 1. Workflow of traditional Chinese medicine formula classification using large language models. BLOOM: BigScience Large Open-Science Open-Access Multilingual Language Model.

Experiment 1

To address RQ1, a prompt dataset was formulated from the curated TCM formula data. The processed prompt dataset was then divided into a training set and a test set containing 1999 and 442 formulas, respectively. The selected LLMs were fine-tuned using the training set, and their performance was evaluated using the test set. This process was iterated 10 times to obtain the average accuracy.

Experiment 2

To validate RQ2, we used a multistage validation process. First, we implemented a hard voting approach to aggregate model predictions and derive a consolidated result. We then calculated the accuracy of this method. In the next step, we assigned weights to each model based on its average accuracy. Using a weighted voting strategy, we then calculated the accuracy of the weighted voting method. In the third step, we selected the model with the highest accuracy from each category and used these selections for weighted voting. Finally, we identified the top 3 models among the fine-tuned LLMs and conducted a weighted vote to determine the most effective voting method.

Experiment 3

To validate RQ3, we extracted a subset of data from the voting results that met the following two conditions:(1) All model predictions were identical but different from the reference answer, or (2) more than 80% of the model predictions were the same but different from the reference answer. TCM experts subsequently reviewed this subset to evaluate the rationality of the LLMs' classification results.

Experimental Configuration Parameter and Platform

To ensure robust performance, we fine-tuned LLMs using the common configurations and selected the model that achieved the most stable and optimal results. The details of the configurations for the fine-tuned LLMs are shown in Multimedia Appendix 1. The fine-tuning and verification were done by running and validating the LLMs on graphics processing unit computer servers.

Ethical Considerations

We confirm that this study did not involve human or animal subjects. It used publicly available, deidentified text data and sourced from the web. Therefore, no ethics approval was required in accordance with relevant institutional guidelines and the JMIR editorial policy on ethics review requirements.

Results

The Experimental Results of Each Fine-Tuned LLM

In experiment 1, we performed a 10-iteration validation for each model using the test set. Figure 2 shows the mean accuracy for each model. Notably, Qwen-14B (mean 75.32%, SD 0.48%) and Qwen-7B (mean 74.32%, SD 0.37%) showed the highest performance. Close behind were Qwen-1.8B (mean 72.96%, SD 0.53%), InternLM-20B (mean 72.40%, SD 0.47%), Baichuan2-7B (mean 70.86%, SD 0.32%), Baichuan2-13B (mean 71.63%, SD 0.38%), ChatGLM-6B (mean 70.09%, SD 0.30%), ChatGLM2-6B (mean 71.09%, SD 0.80%), and BLOOM-1.7B (mean 70.45%, SD 0.44%), all with accuracies above 70%. However, ChatGLM3-6B (mean 66.70%, SD 0.44%) did not exceed 70% accuracy (Table 2). The fine-tuning of individual LLMs does not lead to remarkable results for the TCM formula classification task in this study. It is noteworthy that the Qwen series of LLMs showed promising performance in the TCM classification task, and Qwen-1.8B and BLOOM-1.7B achieved significant accuracy after full-parameter fine-tuning.

XSL•FO
RenderX

Figure 2. The average accuracy of each large language model in experiment 1. BLOOM: BigScience Large Open-Science Open-Access Multilingual Language Model.

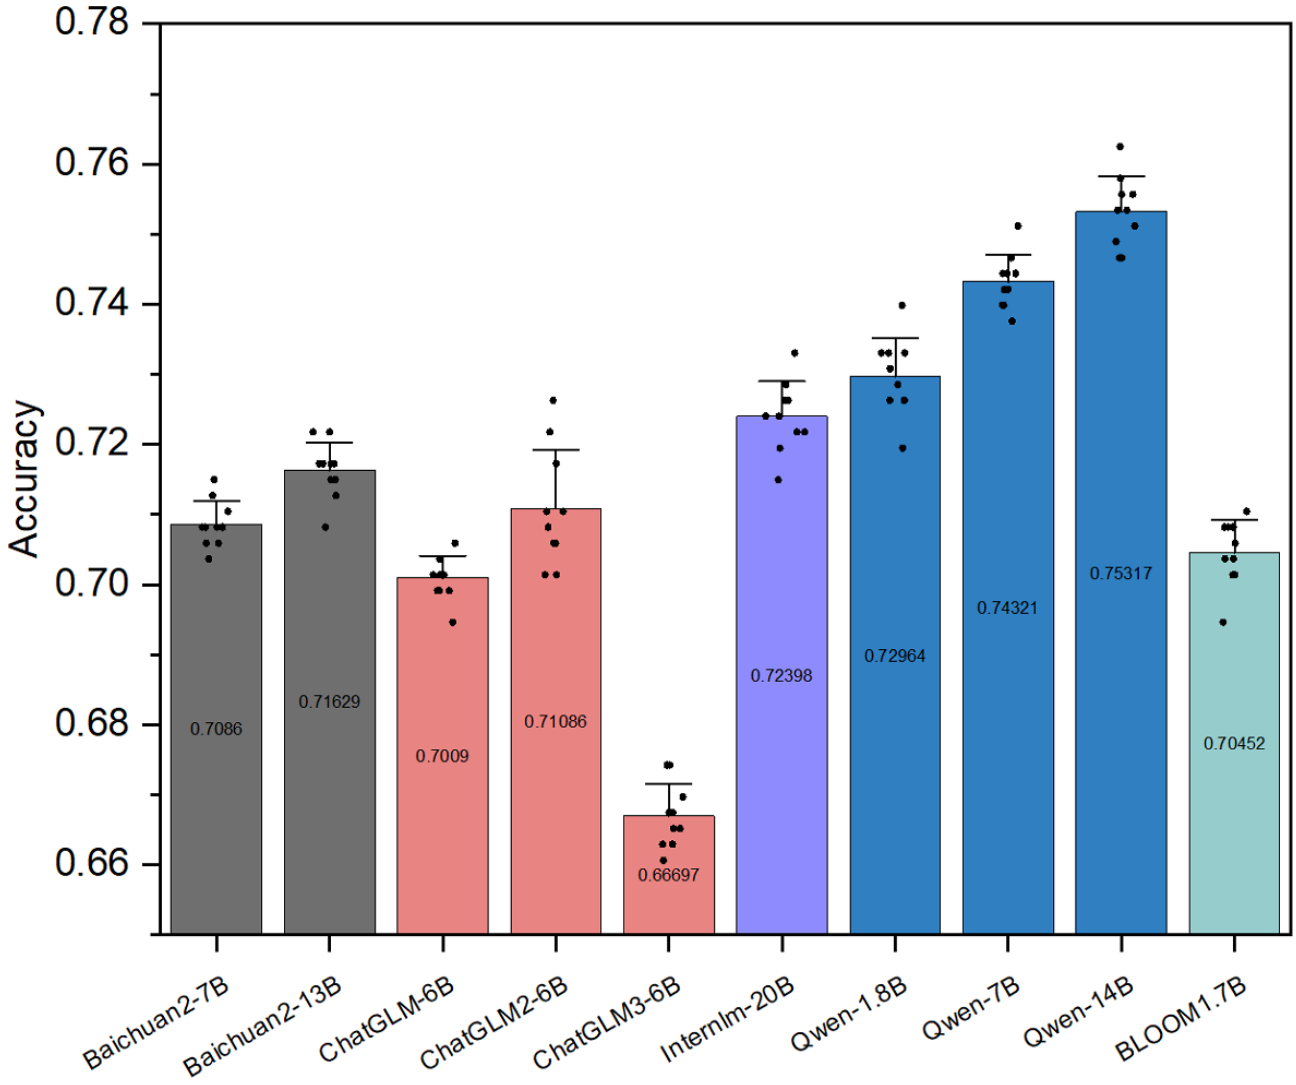


Table . The experimental results of each fine-tuned large language model (LLM).

LLMs	Accuracy (%), mean (SD)
Qwen-14B	75.32 (0.48)
Qwen-7B	74.32 (0.37)
Qwen-1.8B	72.96 (0.53)
InternLM-20B	72.40 (0.47)
Baichuan2-7B	70.86 (0.32)
Baichuan2-13B	71.63 (0.38)
ChatGLM-6B	70.09 (0.30)
ChatGLM2-6B	71.09 (0.80)
ChatGLM3-6B	66.70 (0.44)
BLOOM-1.7B	70.45 (0.44)

TCM Formula Classification Using Ensemble Learning

In experiment 2, to improve the accuracy of the classification task for validating RQ2, we used an ensemble learning approach by integrating fine-tuned LLMs for collective voting predictions. Given the clear result type of our fine-tuned model results (Table 3), we first applied hard voting, which resulted in an accuracy of 75.79%. The weighted precision, weighted recall, and weighted F_1-scores were calculated as 76.10%, 75.79%, and 75.31%, respectively. The confusion matrix is shown in Figure 3B. These results outperformed those of the single models;

XSL•FO
RenderX

however, due to the generally low accuracy of our fine-tuned models, the single model results could potentially influence the final results. We therefore developed a weighted voting method using the average accuracy of each model as the weight. This approach resulted in an accuracy of 76.47%, with weighted precision, weighted recall, and weighted F_1-scores of 76.57%, 76.47%, and 75.98%, respectively. The weighted voting results not only outperformed direct hard voting but also showed superior performance on the 21 classifications within the test set, as shown in Figure 3C.

Figure 3. Accuracy, weighted precision, weighted recall, and weighted F_1-score and their confusion matrices in experiment 2. (A) Accuracy, weighted precision, weighted recall, and weighted F_1-score of different ensemble voting methods. (B) Confusion matrix of the hard voting method. (C) Confusion matrix of the weighted voting method. ADF: antidryness formula; AF: astringent formula; AHF: antihelminthic formula; BRF: blood-regulating formula; DF: desiccating formula; DIF: digestive formula; FP: formula for purgation; FR: formula for resuscitation; FTCU: formula for treating carbuncle and ulcer; FWD: formula for wind disorder; HCF: heat-clearing formula; QRF: Qi regulated formula; RF: reconciling formula; RPRCRWF: resolving phle-m relieving cough and relieving wheezing formula; RTLLF: resolving turbidity and lowering lipids formula; SBF: supplementing and boosting formula; SF: superficies relieving formula; SHEF: summer-heat-expelling formula; SHLDNF: softening hard lumps and dispelling nodes formula; TF: tranquilization formula; WIF: warming interior formula.

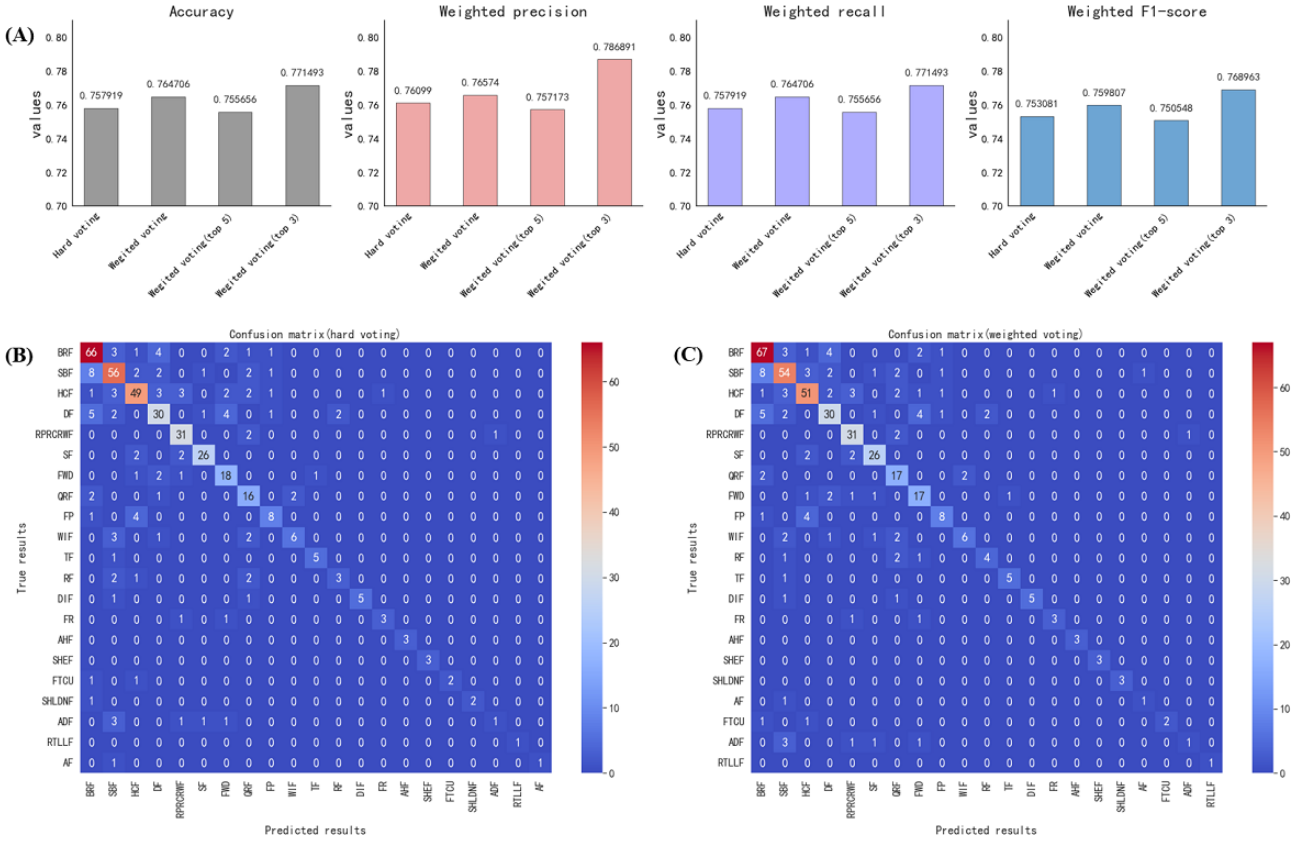

Table . Findings of experiment 2.

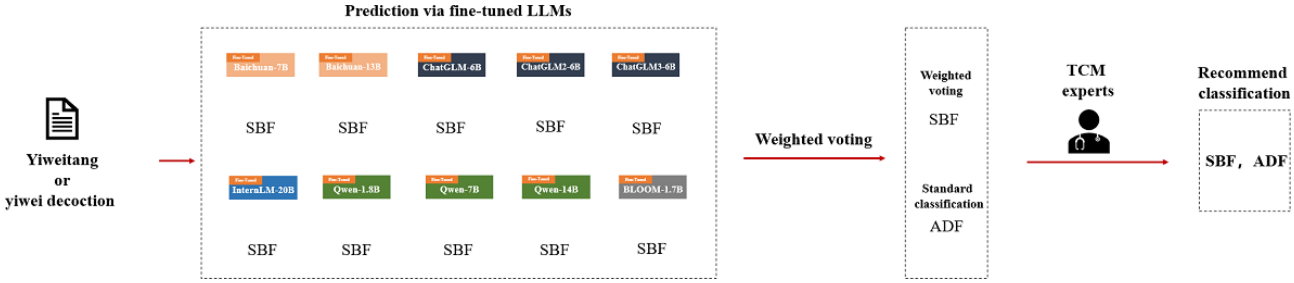
Method	Accuracy (%)	Weighted precision (%)	Weighted recall (%)	Weighted F_1- score (%)
Hard voting	75.79	76.10	75.79	75.31
Weighted voting	76.47	76.57	76.47	75.98
Weighted voting (top 5)	75.57	75.72	75.57	75.05
Weighted voting (top 3)	77.15	78.69	77.15	76.90

To further investigate the impact of multiple LLMs on the voting results, we selected the best-performing model within each category (top 5) and performed weighted voting, such as Baichuan-13B, ChatGLM2-6B, InternLM-20B, Qwen-14B, and BLOOM-1.7B. The statistical results showed an accuracy of 75.57%, a weighted precision of 75.72%, a weighted recall of 75.57%, and a weighted F_1-score of 75.05%, as shown in Figure 3A. The confusion matrix is shown in Multimedia Appendix 2.

We selected the 3 models with the highest accuracy, such as Qwen-14B, Qwen-7B, and Qwen-1.8B, to subject their prediction results to weighted voting. The resulting accuracy was 77.15%, the weighted precision was 78.69%, the weighted recall was 77.15%, and the weighted F_1-score was 76.90%, as shown in Figure 3A. The confusion matrix is shown in Multimedia Appendix 3. As can be seen in Figure 3A, the accuracy obtained by weighted voting (top 3) was the highest, surpassing the accuracy obtained by hard voting. Hard voting



XSL•FO
RenderX

and weighted voting (top 5) were similar, with no significant differences.

Results Analysis of Test Set

During the analysis of LLM voting results on the test set, through TCM expert discussions on the classification results, we observed that in some cases, all LLMs voted the same way, but the results did not match the standard answers. Experts judged that the voting results of the LLMs had a certain degree of rationality. In such cases, it is necessary to discuss why the models reached the same voting results that deviate from the original answers and the rationality of these voting results. We illustrate this with a typical example (Figure 4).

Figure 4. Results analysis of TCM experts. ADF: antidryness formula; LLM: large language model; SBF: supplementing and boosting formula; TCM: traditional Chinese medicine.

TCM formula "Yiweitang or Yiwei decoction (YWD)" consists of Chinese herbs: Bei Sha Shen, Mai Dong, Bing Tang, Di Huang, and Yu Zhu. The indications for treatment are stomach yin injury syndrome. Symptoms include a burning and dull pain in the stomach, lack of appetite despite hunger, dry mouth and throat, dry and hard stool, dry retching, and hiccups. The existing classification of YWD is antidryness formula. However, current scholars have researched Yiwei decoction for the treatment of premature ovarian insufficiency [36,37] and the prevention of osteoporosis related to it [38], proving its efficacy through methods such as network pharmacology and molecular research. Zhang and Zhu [39] have also used the spectrum-effect relationship and network pharmacology to screen for the antioxidant components of Yiwei decoction, demonstrating its function in nourishing stomach yin. Both the treatment or prevention of premature ovarian insufficiency and its related diseases, as well as the nourishing stomach yin function of YWD, fall under the category of supplementing and boosting formula.

In summary, through these discussion points and specific examples, we can gain a deeper understanding of the performance of LLMs in the classification of TCM formula. This can serve as a basis for exploring and reflecting on the existing classification system of formula efficacy. It provides reference and insights for future research on formula efficacy classification.

Discussion

Principal Findings

TCM formulas contain valuable information on ingredients, efficacy, and indications. They serve as important reference for researchers in both clinical and experimental contexts. In this study, we used fine-tuned LLMs in combination with an ensemble learning approach to classify TCM formulas and identify potential information, thereby improved the accuracy of TCM formula classification. Our approach provides a new method for studying formulaic information in TCM.

In this study, we posed 3 RQs and designed corresponding experiments to explore the potential and rationality of fine-tuned LLMs in the TCM formula classification task. The results showed that the fine-tuned Qwen-14B performed remarkably well in the task, achieving an average accuracy of 75.32% (SD 0.48%). However, the accuracy of a single model did not exceed that of deep learning models trained for a single task. To enhance accuracy, we used 2 ensemble methods: hard voting and weighted voting. These methods integrate the 10 fine-tuned LLMs. The accuracy of hard voting and weighted voting reached 75.79% and 76.47%, respectively. The results demonstrate that both hard voting and weighted voting outperform the individual LLMs. Notably, weighted voting (top 3) achieved the highest accuracy, reaching an 77.15%. To evaluate the rationality of the LLMs in the task, we analyzed their prediction errors. In the selected example, all models produced the same prediction, which differed from the reference answer based on YWD. After being analyzed by TCM experts, some of the results predicted by the LLMs were deemed reasonable and can be used as a reference to improve the existing efficacy classification of TCM formulas.

For RQ3, compared to traditional rule-based or deep learning approaches, LLMs demonstrate superior capabilities in automatically identifying latent relationships between herbal formulas. By integrating multidimensional information, such as herbal composition, therapeutic effects, clinical indications, and modern medical research, they build more comprehensive classification systems to uncover potential information. Experimental results show that LLMs can detect potential categories that are not recognized in existing expert classification frameworks. In typical examples, LLM-predicted classifications were validated as clinically plausible by expert panel reviews and literature evidence, suggesting their potential to provide novel scientific foundations for updating and optimizing expert-based classification systems.

Therefore, from both theoretical and technical perspectives, we posit that LLMs can generate more meaningful outcomes for TCM formula classification. This serves as a basis for exploring and reflecting on the existing classification system of formula

XSL•FO
RenderX

efficacy, providing references and insights for the subsequent screening of classic formulas.

Limitations

However, despite numerous studies on the effectiveness of LLMs in classification tasks [40-42], there is a lack of research on text classification in the field of TCM. Our study confirmed that LLMs can achieve a certain effect in the TCM formula classification task. Due to the complexity of TCM knowledge, achieving high accuracy with simple fine-tuning and prompt engineering is difficult. In future research, the composition of herbs in formulas can be encoded through vectors to better explore potential relationships in TCM formula. LLMs in the Qwen series are trained on large-scale, high-quality, and diverse Chinese and English corpora, and have performance across various tasks, in our study, we fully fine-tuned Qwen-1.8B to enhance its capability in classifying TCM formulas and achieved significant accuracy. In the future, we plan to fully fine-tune more LLMs, such as internLM-1.8B [43], and use a weighted voting approach to improve classification accuracy.

Several limitations may have influenced the predicted results. The predictive performance of the LLMs was affected by the relatively small and unevenly distributed dataset of TCM formula in our study. In the future, we plan to collect and curate a large, high-quality TCM formula dataset and integrate it with knowledge graphs to enhance the prediction accuracy of a single LLM. Additionally, we also aim to further improve the performance of the TCM formula classification task by refining our weighted voting methodology.

Conclusions

This study explored the performance of various fine-tuned LLMs in the TCM formula classification task. To improve classification accuracy, both hard voting and weighted voting methods were employed. In conclusion, we also examined the rationality of using LLMs for TCM formula classification and discussed the potential of improving existing classification standards of TCM formulas through the application of LLMs.

Abstract

Background: Federated analytics in health care allows researchers to perform statistical queries on remote datasets without access to the raw data. This method arose from the need to perform statistical analysis on larger datasets collected at multiple health care centers while avoiding regulatory, governance, and privacy issues that might arise if raw data were collected at a central location outside the health care centers. Despite some pioneering work, federated analytics is still not widely used on real-world data, and to our knowledge, no real-world study has yet combined it with other privacy-enhancing techniques such as differential privacy (DP).

Objective: The first objective of this study was to deploy a federated architecture in a real-world setting. The oncology study used for this deployment compared the medical health care management of patients with metastatic non–small cell lung cancer before and after the first wave of COVID-19 pandemic. The second goal was to test DP in this real-world scenario to assess its practicality and use as a privacy-enhancing technology.

Methods: A federated architecture platform was set up in the Toulouse, Reims, and Foch centers. After harmonization of the data in each center, statistical analyses were performed using DataSHIELD (Data aggregation through anonymous summary-statistics from harmonized individual-level databases), a federated analysis R library, and a new open-source DP DataSHIELD package was implemented (dsPrivacy).

Results: A total of 50 patients were enrolled in the Toulouse and Reims centers and 49 in the Foch center. We have shown that DataSHIELD is a practical tool to efficiently conduct our study across all 3 centers without exposing data on a central node, once a sufficient setup has been established to configure a secure network between hospitals. All planned aggregated results were successfully generated. We also observed that DP can be implemented in practice with promising trade-offs between privacy and accuracy, and we built a library that will prove useful for future work.

Conclusions: The federated architecture platform made it possible to run a multicenter study on real-world oncology data while ensuring strong privacy guarantees using differential privacy.

Introduction

Federated analytics (FA) [1] allow researchers to perform statistical queries on remote datasets without accessing raw data. This method has emerged from the need of conducting statistical analyses on larger datasets originating from multiple health care centers, while avoiding regulation, governance, and privacy related issues that could occur if the raw data were gathered in a central location external to the health care centers.

DataSHIELD (Data aggregation through anonymous summary-statistics from harmonized individual-level databases) [2] is one of the pioneering open-source software solutions for bioscience collaboration using federated analysis. It has been used in several projects including the EU Child Cohort Network [3] and German MIRACUM consortium [4]. However, even if it has been identified as a next step in some oncology studies [5], to the best of our knowledge it has not been used on real-world oncology data. One possible reason for this can be that data harmonization is actually the sticking point, since it proves to be challenging on real-world data when not already done ahead of time.

While FA ensures that sensitive data are never directly exposed, results from statistical queries can still leak some information from individuals. Indeed, several privacy attacks [6,7] have been proposed to exploit common statistical analysis results and disclose private information. To mitigate these attacks, differential privacy (DP) can be used in combination with FA to provide stronger privacy guarantees. DP [8,9] is a method for computing statistical analyses on a sensitive dataset in such a way that the results do not compromise the privacy of the initial raw data. It proves particularly appropriate for studies on patient health data which are highly sensitive, but as far as we know, no real-world data study have already combined FA and privacy-enhancing techniques such as DP. Our study focuses on a scenario with 3 hospital nodes, consistent with typical real-world deployments in health care, where the number of participating centers is usually small (on the order of a few nodes). Scalability and performance metrics (eg, query response times and network latency) were therefore not the primary focus of this pilot.

The goal of this study, called Distributed Analytics for Research in Hospitals (DARAH), is to evaluate the operational deployment of a federated architecture in the context of a real-world oncology study. Another objective is to analyze the impact of DP in a federated analysis on the meaningfulness of the study results.

Methods

Use of DataSHIELD

At the time of starting the project, we evaluated multiple FA frameworks and chose DataSHIELD due to its comprehensive privacy controls, stable community support, and mature set of statistical functions. DataSHIELD's unique strength lies in its local, decentralized authorization mechanism and built-in privacy disclosure checks, which prevent analysts from executing arbitrary code on remote servers. The "default privacy disclosure mode" enforces a baseline set of privacy checks (eg, thresholds on minimum cell counts) that align with real-world clinical data governance needs. While other tools like NVidia FLARE or custom Python/R frameworks exist, they often lack these out-of-the-box privacy safeguards, making DataSHIELD a practical choice for our use case. We maintained the default privacy settings throughout the study to ensure a fair demonstration of DataSHIELD's capabilities without additional configuration.

Use of Differential Privacy

DP provides a measurement of the privacy risk associated with publishing each particular result on a sensitive dataset, by measuring the maximum leakage that each result can cause about the individuals' data. In practice, it often works through the addition of a controlled amount of statistical noise to obscure the contributions to the result from each individual in the dataset.

Several open-source libraries exist that implement DP, most of which are written in Python or expose a Python interface. Popular ones include Google's DP library [10], PyDP [11] from the OpenMined community and OpenDP [12]. In R, the main open-source library is the diffpriv library [13] that implements some DP mechanisms but not a real suite of functions ready to use, and which is not actively supported with last contributions going back to 2017. Furthermore, none of these tools were directly compatible with the DataSHIELD framework, which requires a specific interface in R. As a result, a new open-source a DP R package (R Core Team) for DataSHIELD has been implemented: dsPrivacy. It is available in the Arkhn GitHub repository.

dsPrivacy implements common statistical operations such as mean (SD) with DP and can be directly integrated into DataSHIELD. More specifically, pure DP has been implemented, which means that the statistical noise added to the result is drawn from a Laplacian distribution. Privacy is therefore defined with a single parameter "ε" (which corresponds to the inverse of the noise variance) and it is called the privacy budget. The privacy budget ε controls the amount of noise injected in the computation and hence the privacy of the analysis, smaller the privacy budget ε, higher the noise, which means better privacy guarantees since the private information is better covered by the noise.

DP induces a trade-off between privacy and accuracy of the analysis [14] as privacy is ensured with noise, better privacy means a lower signal-to-noise ratio and less meaningful results. Conversely, when ε is high, the noise is reduced and privacy degrades. Choosing the right value for ε from a privacy standpoint is quite controversial [15] and is highly dependent on the context and the study considered.

dsPrivacy in the context of FA works by adding Laplacian noise locally at each center on the results computed on the local datasets before results are aggregated on a central node. This is referred to as local DP, as opposed to central DP, where the noise is added after the aggregation part on the central node. This paradigm is detailed in the Discussion section.

Use Case: Differences in the Patient Drug Exposure of Patients With Non–Small Cell Lung Cancer Before and After the First Wave of the COVID-19 Pandemic

Context

In order to test the implementation of a federated platform with DP, a study was conducted using real-world oncology data, with the aim of analyzing the differences in the patient drug exposure of patients with non–small cell lung cancer before and after the first wave of the COVID-19 pandemic. Specifically, the analyses were based on the first line of treatment, including its duration and disease progression at 24 months. The study was carried out in 3 hospitals: Foch Hospital, Toulouse University Hospital Center, and Reims University Hospital Center.

Patient Selection

The inclusion criteria were adult patients with metastatic non–small cell lung cancer treated with chemotherapy, immunotherapy, antiangiogenic therapy, or any combination of these treatments at Foch, Toulouse, and Reims centers between March 2019 and March 2021. The list of considered treatments is available in Multimedia Appendix 1.

The exclusion criteria included patients objecting to the reuse of their data, protected adult patients (patients under curatorship, tutorship, or advisership), patients undergoing a clinical trial, patients whose follow-up did not start in one of these centers, patients who are not immediately metastatic, and patients with an epidermal growth factor receptor mutation, anaplastic lymphoma kinase translocation, or ROS proto-oncogene 1 mutation.

For this study, the objective was to have 25 patients per period and per site (ie, 50 patients per center). Initially, patients were preselected using the inclusion criteria present in the chemotherapy prescription software CHIMIO, namely the date and type of treatment. Since the other criteria for inclusion and exclusion were not available in CHIMIO, physicians in each center manually assessed whether the patients could be included in the study.

Variables

In this study, the variables of interest were the duration of the first line of treatment and the disease progression at 24 months following or during the first line of treatment. The start of a second line of treatment or death following (before the start of a second line) or during the first line of treatment were the proxies used for disease progression at 24 months. These events had to have occurred during the observation period, which was 2 years after the patient's inclusion in the study. The explanatory variable was the patient's inclusion period, before the first wave of COVID-19 (March 1, 2019, to March 1, 2020) or after the first wave of COVID-19 (March 2, 2020, to March 31, 2021). Some potential confounders were also studied, such as age, gender, BMI, blood creatinine level, and type of treatment. All these variables were extracted from the CHIMIO software and are listed in Multimedia Appendix 2.

Data Harmonization

In this study, a physician visited each participating site to ensure consistent variable definitions, coding standards, and data formats. We chose Fast Healthcare Interoperability Resources (FHIR) as the initial data standard [16,17], due to its maturity and support in oncology, and the data model is available in Multimedia Appendix 3. Harmonization involved reviewing data dictionaries at each hospital, resolving semantic ambiguities (eg, different coding for treatments), and ensuring uniform data types and units. This manual process, though time-consuming, proved crucial for producing a common dataset compatible with federated queries. In future implementations, automated or semiautomated harmonization workflows, potentially protected by DP to further safeguard patient privacy during preprocessing, could streamline this step. To facilitate the analyses, a tabularized version of the FHIR standard has been produced and the correspondence between the variables of interest used in the datasets and the FHIR attributes are presented in Multimedia Appendix 2.

Statistical Definition Without Differential Privacy

First, univariate and bivariate descriptive statistics were performed for the variables of interest, the explanatory variables and the confounding factors. For the qualitative variables, percentages per category were calculated. For the quantitative variables, the mean but also the 5th, 25th, 50th, 75th, and 95th percentiles were computed. The minimums and maximums were not computed because these values are considered disclosive (eg, the presence of an outlier) in DataSHIELD standard configuration.

Then, to ensure the absence of confounding factors, covariates for which there was a difference between the 2 groups (before and after the first COVID-19 wave) in bivariate analysis with a P value of <.20 were included in the multivariate models. A Student t test was used for quantitative variables. A chi-square test was used for qualitative variables with at least 5 elements in each class. Otherwise, a Fisher test was used.

Finally, to investigate a difference in management between patients in the first and second waves, a linear regression was performed. The variable of interest was the duration of first-line treatment at the metastatic stage and the explanatory variable was the period (before or after the first wave). The duration of treatment was defined as the period from day 1 to the last day of the first line. A multivariate survival analysis (Cox model) was also performed in which the event of interest was the disease progression at 24 months. The explanatory variable was also the period (before or after the first wave). Potential confounders identified in the previous step were included in both multivariate analyses. A difference was considered significant if the CI did not contain 1 for linear regression and survival analysis.

Statistical Definition With Differential Privacy

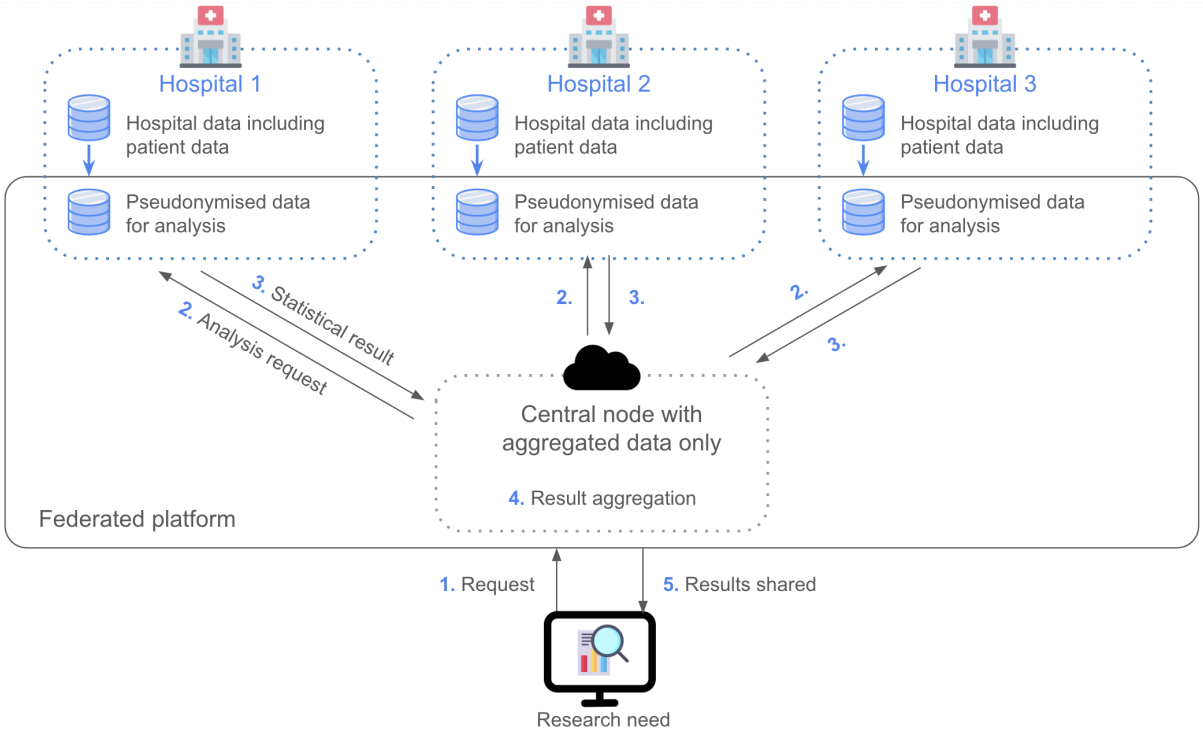
The univariate and bivariate statistical analyses presented in above were also performed with DP. The global strategy used to implement DP has been discussed in "Use of Differential Privacy" section and some details for each part of the study are detailed here.

XSL•FO
RenderX

All the univariate analyses run code from PyDP [11] that we wrapped in dsPrivacy. As adding DP preserves privacy, the minimum and maximum values could be computed instead of 5th and 95th percentiles. Then bivariate analyses were carried out. For quantitative variables, an implementation of the Student *t* test is used and from the result of this test, a *P* value is inferred. For qualitative variables, occurrence tables are computed (under the hood, the function tableDP from DPPack [18] is used in each center and all the tables are summed) and then a chi-square or Fisher test is performed with the R functions "chisq.test" and "fisher.test." Linear regression and Cox models were not implemented with DP.

Determining appropriate ε values is challenging and context-dependent. In this study, our priority was to maintain analytical use. After testing lower ε values (closer to 1) that yielded excessive noise and unusable results, we selected ε=5.0 for univariate analyses and ε=60.0 for complex operations like the Student *t* tests. While ε=60.0 is higher than common DP standards in theoretical literature, this choice reflects our small sample size (~50 patients/center) and the need to ensure meaningful statistical inference. In scenarios with more patients or improved aggregation techniques (eg, secure aggregation enabling central DP), lower ε values could be achieved. As this was a feasibility study, we highlight that future work should explore more advanced DP mechanisms, larger sample sizes, and improved cryptographic methods to reduce the required privacy budget.

Ethical Considerations



From an ethical and regulatory standpoint, this study complied with the MR-004 reference methodology and adhered to GDPR requirements since DP alone does not classify data as anonymized under current regulatory frameworks. However, the use of DP strengthens data protection, and aligns with emerging privacy regulations by minimizing data exposure risks. These regulatory environments emphasize data sovereignty, patient consent, and robust security, all of which are supported by our federated, privacy-enhancing architecture. All patients enrolled in this study were informed individually, and those who exercised their right to opt out were removed from the study. This is an observational study and the research ethics committees of all three centers in Toulouse, Reims, and Foch have confirmed that no ethical approval is required and have authorized this project on their patient data.

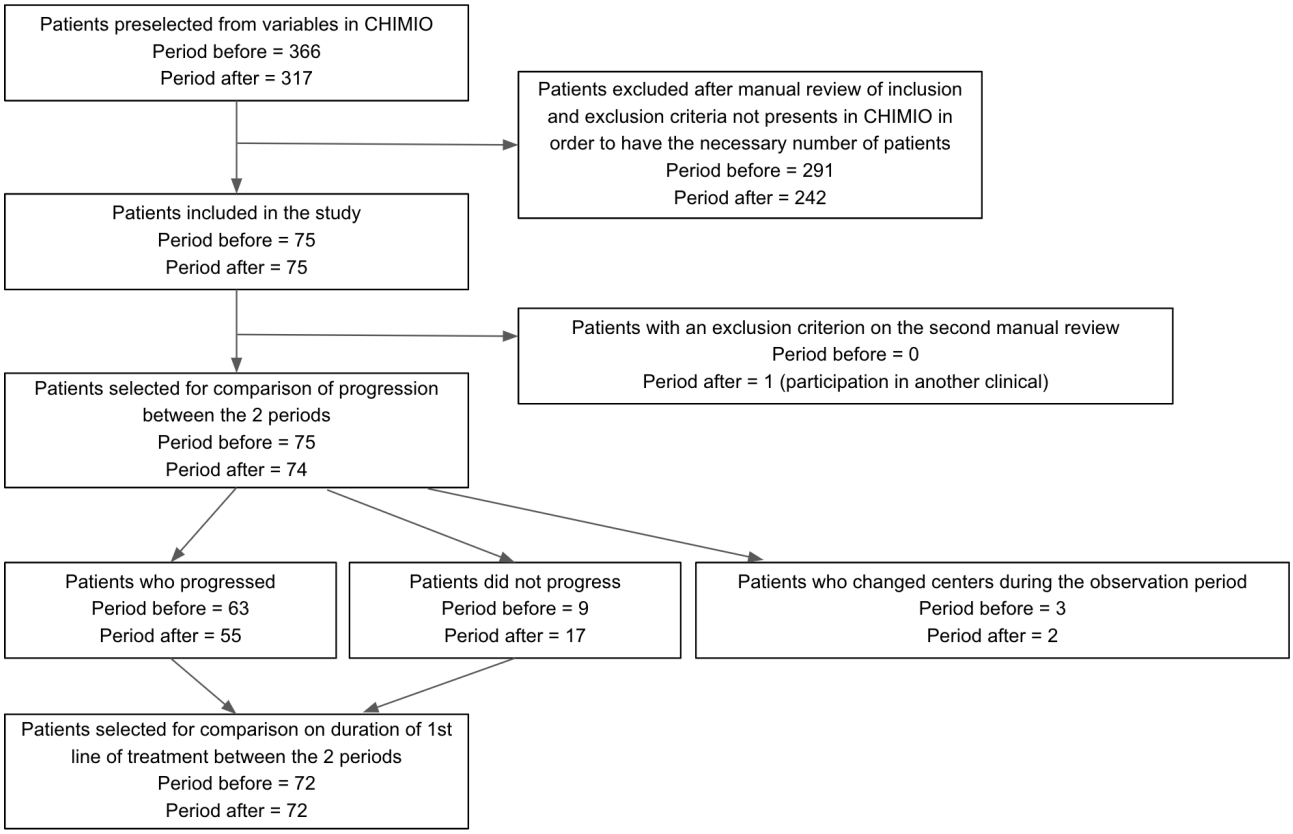
Results

Deployment of Federated Architecture in the Three Centers

The schema of our federated architecture is given in Figure 1. Researchers connect through a VPN to a central node hosted on a cloud provider–certified ISO (International Organization for Standardization) 27001 standard. This central node coordinates the execution of the queries on the remote data assets hosted in the different hospitals and aggregate all the responses received. Each hospital exposes through the private network pseudonymized datasets, which originate from their local harmonized data architecture, but which are completely isolated on a dedicated infrastructure for security purposes. Each hospital receives and executes remote requests from the central node that match local permissions set in DataSHIELD regarding data assets, authorized functions, and legitimate users. This ensures that hospitals keep full sovereignty on how their data are exploited.

Figure 1. Federated architecture diagram.

One key element is deploying a secure private network between all stakeholders, ensuring that each hospital only exposes pseudonymized data within a controlled environment. Although these pseudonymized datasets were not themselves protected



XSL•FO
RenderX

by DP before analysis (since DP is applied at query-time), the secure network, encryption (TLS), and isolation measures minimize risks. We did not use "Let's Encrypt" for certificates due to internal security policies favoring certificates from recognized authorities and the controlled VPN environment lacking public domain validation. Instead, a custom approach using a trusted certificate authority provided both strong authentication and encryption tailored to our network configuration.

Flowchart

The flowchart is presented in Figure 2. In total, 75 and 74 patients from respectively before and after the first wave were included in the analysis comparing disease progression. Of the patients in the period before, 63 had progressed, 9 were progression-free, and 3 had changed groups during the observation period and were therefore censored at the time of transfer. Of the patients in the period after, 55 had progressed, 17 were progression-free and 2 had changed groups during the observation period and were therefore censored at the time of transfer. Thus, after exclusion of patients who changed centers, 72 patients from each period were included in the analysis of the duration of the first line of treatment.

Figure 2. Patient selection and exclusion process between two periods: before and after the first wave (BW and AW).

Bivariate Analysis and Selection of Potential Confounders

Combined univariate analyses without and those with DP are presented in Multimedia Appendix 4. Combined bivariate analyses without and with DP are presented in Tables 1 and 2, respectively. Direct comparison between DP and no-DP analyses across all periods is available in Table 3. In analysis without and with DP, the covariates selected for multivariate analyses were the treatment type (<.001) only.

[a] DP: differential privacy.

[b] ε: privacy budget.

Comparison of the Progression Between Two Periods (Cox Model)

In the analysis without DP, the hazard ratio of the cox model for the period before compared with the period after the first wave was 0.98 (95% CI 0.65-1.46). As the 95% CI includes 1, the two periods were not considered significantly different in terms of disease progression at 24 months after adjustment for a significant covariate (treatment type).

Comparison of the Duration of the First Line of Treatment Between the Two Periods (Linear Regression)

In the analysis without DP, the coefficient of linear regression for the first period compared with the second one was –13.84 (95% CI –103.82 to 76.14). As the CI includes 1, the two periods were not considered significantly different in terms of first line duration after adjustment for significant covariate (treatment type).

Discussion

Principal Findings

In this study, a federated analysis with and without DP was performed on a real-world study in oncology. The real-world study showed consistent results in both settings. In particular, identical conclusions were drawn regarding the lack of difference in first-line treatment duration and disease progression at 24 months in non–small cell lung cancer patients treated before or after the first wave of COVID-19 pandemic.

Real-world deployment in 3 centers has shed light on some key aspects in terms of security. Regarding tools, DataSHIELD offers a lot of flexibility as it allows the use of custom libraries such as dsPrivacy implemented as part of this study. The downside is that community libraries are not always well maintained and bugs can be encountered (eg, dsStats had to be fixed manually). DataSHIELD builds upon Opal [19], a convenient data management application which comes with straightforward but very satisfactory user management and makes it easy to configure access to specific data to specific users. Opal is also secured by design and enforces many good security practices like CSRF (Cross-Site Request Forgery) and HTTPS usage. However, available docker images to deploy it have several major known security vulnerabilities and do not seem regularly updated. Regarding network configuration, setting up strong security standards across all sites has proved challenging. An IpSec bridge was set up to enable secure communication between the central node and the hospitals. Communication among all stakeholders was a key factor for this step and formal processes (network schema, requirements formalization, debugging methods, and so on) proved decisive in order to facilitate discussions. Regarding certificates to secure communications inside the private network, the primary intention was to use certificates signed by hospitals internal certificate authority because it would not match our security requirements so certificates signed by public certificate authority have been claimed. Some hospitals provided a Sertigo certificate but it was not natively recognized by the central node server. Another hospital used instead a public certificate generated by the central node manager (Arkhn). This last solution has proven to be the best solution in terms of efficiency and security, even if the domain names covered by these certificates are not representing the actual ownership of hosts.

Regarding data standards, we chose FHIR, since it appeared to be the most mature health standard in oncology at the beginning of this project [16,17]. However, Observational Medical Outcomes Partnership (OMOP) is developing extensions for oncology and is rapidly closing the gap [20,21]. As the FHIR standard corresponds to json files that are not very suitable for analytical purposes, we anticipate that moving to OMOP will be more convenient for future analyses.

Overall, our experience suggests that the most time and work intensive parts are building harmonized data models locally and setting up the network infrastructure. As both these steps are agnostic of the study considered, we anticipate that they can be easily leveraged to scale the number of studies carried out on this infrastructure.

On the DP side, it has been decided not to perform linear regression and Cox models with DP because implementing it with a moderate privacy budget was deemed too complex. Privacy budgets used in this study (especially for computing the *P* values) are quite high compared with the literature [15,22], in order to achieve reasonable accuracy on differentially private results but we have shown that we are able to derive similar results compared with plain FA. As underlined above, the appropriate level of privacy is highly dependent on the context considered. Here, given that this study was already compliant to the French MR-004 methodology without DP, DP was used by prioritizing usefulness over privacy. In other contexts, especially if DP becomes recognized as a legitimate and safe technology to process personal data, and hence benefits from a dedicated regulatory status, lower privacy budgets will probably be required (alongside privacy-focused pen tests). We have identified 3 directions to achieve this. The first direction is to increase the number of patients per center. This is the most straightforward option to improve the privacy vs accuracy trade-off, since the amount of noise to add to reach a certain privacy budget ε directly depends on the number of individuals. We have included close to 50 patients per center, which is quite low especially for some budget intensive operations for which we estimate that a thousand patients would be adapted. Second, by using central DP. If the noise is added on the central node, it is computed considering the sum of the patients across all the centers and enables lower noise for the same privacy budget. This is especially powerful if many centers are participating in the federated analysis. However, this means that by default the central node can see the contribution of each center without any noise which is a privacy breach if it cannot be trusted. A common solution is to implement secure aggregation [23], meaning that all contributions are hidden and are only disclosed after the aggregation operation, using cryptographic mechanisms such as secure multiparty computation [24], homomorphic encryption [25], or functional encryption [26]. Secure aggregation is not yet implemented in dsPrivacy and is left as future work. Finally, it can be achieved by improving the DP mechanism. We have used pure or ε-DP, which is a simple mechanism and which makes composition very simple, since the privacy budget of a sequence of operations is the sum of the budget of each operation. More complex mechanisms such as (ε, δ)-DP [6] or Rényi DP [27] provide more optimized composition properties [28] that allow for a tighter privacy budget management.

Conclusions

The DARAH project illustrates FA are a practical method to conduct scientific projects while improving data privacy, by keeping patient data stored in the hospitals and leveraging their already existing data architecture. It highlights some key challenges to be anticipated and possible answers to ensure the success of this type of projects. It also shows that DP can be used in addition to FA to improve privacy guarantees, but more experimentation is needed to develop guidelines and best practices, especially around the trade-off between accuracy and privacy. Finally, in an emerging ecosystem where tools for FA and DP are not yet well integrated, the dsPrivacy library will

XSL•FO
RenderX

prove useful for researchers who want to explore privacy-friendly analysis methods.

Abstract

Background: Managing nurse staffing is complex due to fluctuating demand based on ward occupancy, patient acuity, and dependency. Monitoring staffing adequacy in real time has the potential to inform safe and efficient deployment of staff. Patient classification systems (PCSs) are being used for per shift workload measurement, but they add a frequent administrative task for ward nursing staff.

Objective: The objective of this study is to explore whether an algorithm could estimate ward workload using existing routinely recorded data.

Methods: Anonymized admission records and assessments from a PCS supporting the safer nursing care tool were used to determine nursing care demand in medical and surgical wards in a single UK hospital between February 2017 and February 2020. Records were linked by ward and time. The data were split into a training set (75%) and a test set (25%). We built a predictive model of ward workload (as measured by the PCS) using routinely recorded administrative data and admission National Early Warning Score. The outcome variable was ward workload derived from the patient classifications, measured as the number of whole-time equivalent (WTE) nursing staff per patient.

Results: In a test set of 11,592 ward assessments from 42 wards with a mean WTE per patient of 1.64, the model's mean absolute error was 0.078, with a mean percentage error of 4.9%. A Bland-Altman plot of the differences between the predicted values and the assessment values showed 95% of them within 0.21 WTE per patient.

Conclusions: Predictions of nursing workload from a relatively small number of routinely collected variables showed moderate accuracy for general wards in 1 English hospital. This demonstrates the potential for automating assessments of nurse staffing requirements from routine data, reducing time spent on this nonclinical overhead, and improving monitoring of real-time staffing pressures.

KEYWORDS

workload; staffing; nursing staff; safer nursing care tool; predictive model

Introduction

Nursing workload management is complex and involves the processes of forecasting, scheduling, staffing, and monitoring [1]. Monitoring a ward's nursing workload in real time or near time is difficult because of patient movements and because of changes in patient acuity and care needs. This is important because there is a body of evidence that shows nurse understaffing is associated with adverse outcomes for patients and for staff [2,3]. Monitoring supports the identification of staffing deficiencies and informs decisions concerning the deployment or redeployment of resources to address them.

Common structured methods of monitoring staffing requirements make use of patient classification systems (PCSs). Through these systems, care intensity is determined for each patient and is then summed to calculate the total care demand for the ward. Examples are the acuity or dependency assessments in the safer nursing care tool (SNCT) [4], the Oulu Patient Classification qualisan (OPCq) used in RAFAELA [5] and the Perroca Patient Classification System [6]. Assessing

XSL•FO
RenderX

and documenting the nursing intensity for every patient on the ward is an additional task for ward nurses, often repeated every shift. Automating the nursing intensity and workload monitoring using data already recorded has the potential to free up valuable staff time in the provision of patient care.

There is little published work on automating PCSs used to measure nursing intensity and workload. However, a model was developed to determine each patient's workload category as defined by the Perroca Patient Classification Instrument (PPCI) from routine electronic health record data in a Brazilian hospital [7]. A random forest classification model used electronic variables chosen as indicators for each of the 9 care areas in the tool. The classifier was 72% accurate when categorizing the patients overall with a c-statistic of 0.82. An individual patient misclassification may not have much effect on the ward workload estimation as a whole, but there were no details of how to translate the patient workload categories into nurse staffing requirements for wards.

Our aim was to build a predictive model using routine electronic data from 1 hospital, which might be known in real time to estimate nurse staffing requirements for wards. Our objective was to match the recorded values determined by using the patient classification instrument from the SNCT, the most widely used tool in England for determining staffing requirements based on patient need [8]. The SNCT originated as a way of estimating nurse staffing establishment requirements (whole-time equivalent (WTE) posts) by means of twice-a-year audits of ward workload. It included a PCS, which is now in use once, twice, or thrice a day in many hospitals in England to monitor ward workload.

Methods

Ethical Considerations

This research was a secondary analysis of data collected for a study that considered the costs and consequences of different nursing staff configurations (Trial Registration: ClinicalTrials.gov NCT04374812) [9]. That study had a waiver for informed consent after assessment via the Health Research Authority integrated research application service (IRAS ref 273185). The ethical review undertaken by the faculty research ethics committee at the University of Southampton (ERGO 52957) for that study was extended for this secondary analysis on the basis that its objectives were aligned with the purpose for which the data had been obtained. The dataset had previously been anonymized with no linkages back to individuals so privacy and confidentiality were respected. The hospital trusts that provided the data gave approvals for this secondary analysis. Dataset construction and all analyses were performed using R (version 4.4.0; R Core Team); further details of the software and packages used can be found in Multimedia Appendix 1.

Data Sources and Linkage

We analyzed data from adult inpatient wards in 1 hospital trust for admissions from February 2017 to February 2020. The data consisted of anonymized admission records and patient classification assessments made using the SNCT acuity instrument. SNCT acuity assessments had been undertaken in admission units, general wards, and high-care wards but not in intensive care units. The admission units in this hospital were the medical emergency and surgical emergency assessment units, which assess patients before transferring them to a general or high-care ward as required. In the UK, a general ward is an inpatient adult ward not specializing in maternity or psychiatric care. A high-care ward has some high-care beds which are defined as providing level 2 care according to the UK intensive care society, deemed as needing 0.5 WTE of nursing care per bed. A UK intensive care unit, on the other hand, provides the highest level of care, level 3, and this requires one-to-one nursing care. The SNCT acuity assessments data provided counts of patients in a ward for each acuity and dependency category at a point in time. The admission records included each patient's first NEWS (National Early Warning Score) [10]. NEWS is a patient assessment method in routine use in UK hospitals based on vital signs observations, which nurses use regularly to identify patients at risk of deterioration.

The patient categorization instrument used for ward workload assessments in SNCT involves matching patients to 1 of 5 ordinal categories according to descriptions of acuity and dependency needs. Level 0 is for stable patients with needs met in general wards, level 1a patients are acutely ill patients requiring intervention or those with a greater potential to deteriorate, level 1b patients are stable but are more dependent on nursing care, and level 2 patients are unstable, at risk of deteriorating, and require specialized care. Level 3 patients, who require multiple organ support, did not exist in our dataset of assessments. Each category has a value (called a multiplier) corresponding to a staffing WTE needed to provide 24-hour care after considering annual leave and sickness absence. Multipliers were developed from ward observational studies [11]. One set of multipliers is used for general wards and another for admission units to take into account the extra workload associated with the higher throughput of patients. The multiplier values for the patients in a ward are summed to produce a point-in-time WTE estimate for the ward [4].

All admission records that could be linked by ward and by assessment date and time were included for wards that were routinely carrying out the assessments. Since the assessment records did not record any patient identifiers, linkage to patient records was by ward and time. Linked records were analyzed where the number of patients in the ward assessment matched the number of occupants in the ward according to the patient administration system at the time of the assessment. A comparison of linked and unlinked assessments was conducted to check for bias resulting from this selection process.

Study Variables

The dependent variable for the prediction model was the WTE calculated by the assessment tool divided by the number of assessed patients. Patients' data for the assessed patients, as determined by the linkage described earlier, were aggregated to ward level by taking means for continuous variables and proportions for binary variables, as shown in the table. The choice of candidate predictors (Table 1) was made according to data availability, published nurse workload models, and clinical protocols regarding nurse assessments for new ward

XSL•FO
RenderX

arrivals. Multi-variable models using all the candidate predictors were built since there was evidence or conceptual reasons for including them, and the objective of the modeling was predictive accuracy rather than quantifying effects of individual predictors. Univariable regressions were performed on the candidate predictors out of interest. The predictors include the use of 2 derived variables: the Charlson comorbidity index [12] and the summary hospital mortality indicator (SHMI) risk [13]. The diagnostic predictors were proportions of patients with a recorded diagnosis belonging to a particular diagnostic group: respiratory conditions, cardiac conditions, renal conditions, cancer, frailty syndromes [14], a self-harm diagnosis, and a history of poisoning. The details of the diagnostic groups are provided in Multimedia Appendix 1. Lastly, an indicator was added for admission units to reflect the alternate set of patient category multipliers used for assessments in them.

Analysis

A generalized additive regression model (GAM) [15] with an identity link function was chosen for the modelling since this could handle nonlinear relationships between the individual predictors and the WTE per patient response variable.

The data were randomly split into training and test sets (75% vs 25%), and a regression model was created on the training set. All the predetermined candidate predictors were used after checking for high pairwise correlations. Removal of any predictor was found to worsen model fit judging by the Akaike information criterion, so all were retained. A calibration was computed to optimize the predictions by means of a smoothing

XSL•FO
RenderX

of the model estimates on the assessed ones [16]. The model and the calibration were applied to the test set.

A Bland-Altman plot [17] was constructed and used to look at the agreement between the model prediction and the assessed WTE per patient. When examining this plot by ward subset, 2 wards had more than a third of their predictions outside the limits of agreement. This was a markedly higher proportion of assessments than for the other wards, so these wards were excluded from the datasets, and the GAM model was rebuilt.

Results

The distribution of WTE per patient for all assessments (median 1.63, IQR 1.48-1.72) shows a distinct peak near the value of the multiplier for level 1b (Figure 1).

The data came from 44 wards, including 8 admission units and 4 high-care wards, covering 1,481,801 patient categorizations by care level from 71,027 ward-level assessments relating to 125,595 admissions. Most patient assessments in general wards (n=809,296, 59.3%) were recorded as level 1b (Table 2).

Figure 1. Distribution of whole-time equivalent (WTE) per patient values from safer nursing care tool ward assessments.

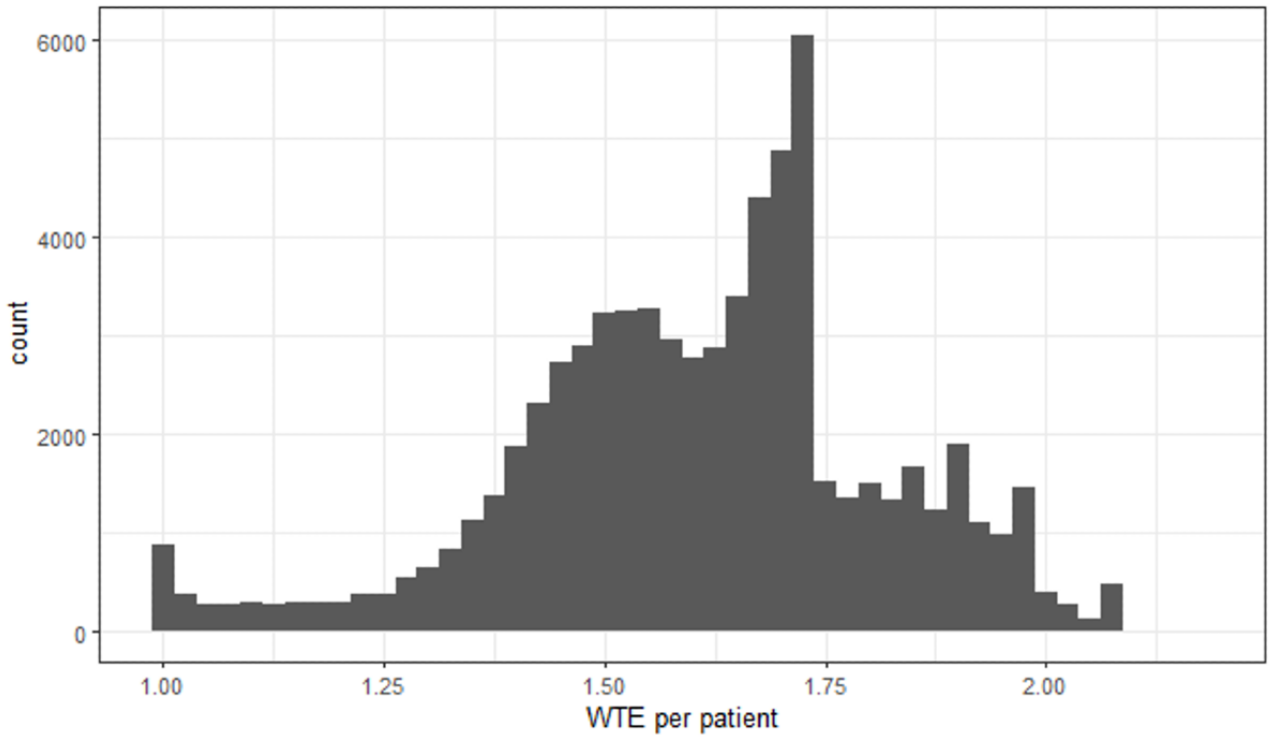

Table . Percentage of assessed patient categorizations by care level.

	Patient categorizations, n	Level 0, n (%)	Level 1a, n (%)	Level 1b, n (%)	Level 2, n (%)
General or high-care ward	1,364,690	232,620 (17.0)	220,621 (16.2)	809,296 (59.3)	102,153 (7.5)
Admission unit	117,111	29,324 (25.0)	44,505 (38.0)	42,717 (36.5)	565 (0.5)

Requiring the number of ward occupancy records to match the number of patients assessed reduced the dataset by 32% to 48,493 assessments relating to 108,558 admissions; however, the WTE per patient distribution was little changed (median 1.65, IQR 1.51-1.73), suggesting no systematic bias. The ward occupancy and therefore the number of patients per assessment in the matched dataset had a median of 20 with an IQR of 11-29.

A patient might be assessed on a number of occasions in a number of wards during their admission. The cohort of assessed patients consisted of 85.5% (n=92,766) emergency admissions and 46.9% (n=50,877) men, with most coming from the 80 - 84 age bracket (Table 3). Long-term conditions were common, with 53.1% (n=57,635) having a Charlson Comorbidity Index of more than 5. The median length of stay was 4.4 (IQR 2.0-10.5) days, and 4.9% (n=5332) died in the hospital.

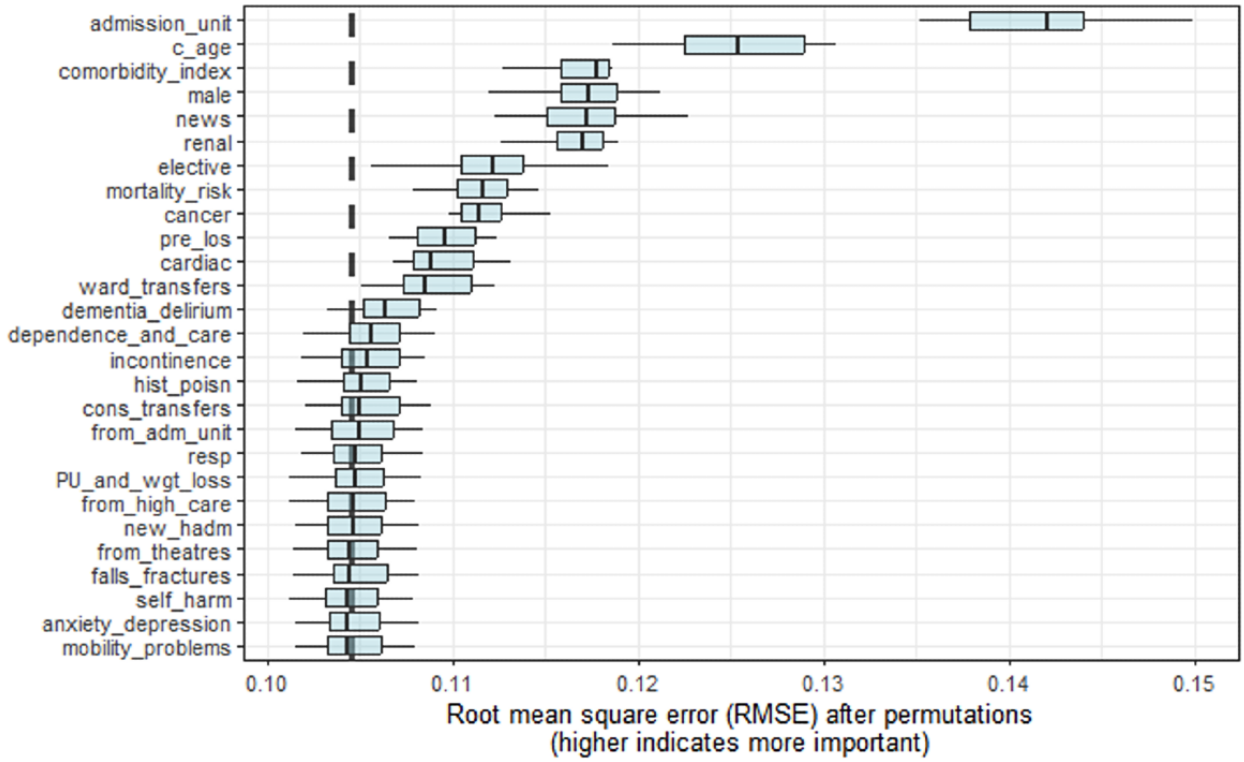
[a]Summary Hospital Mortality Indicator.

[b]National Early Warning Score (version 2).

We fitted a GAM to the training set to model the nursing workload measured in WTE per patient associated with the set of patients in each manual ward assessment. When applied to the test set of 11,592 ward assessments from 42 wards and a calibration applied, the mean absolute error of the predictions was 0.078 WTE per patient (a mean absolute percentage error of 4.9% with a 95th centile of 13.9%). The root mean square error was 0.106 WTE per patient, and the percentage of variance explained by the model was 65%. The predictors that contributed most to explaining the workload (Figure 2) were the admission unit indicator, mean patient age, mean Charlson comorbidity index, the proportion of men, the mean NEWS, and the proportion of patients with a diagnosed renal condition. The relative contribution of each predictor was computed by

XSL•FO
RenderX



calculating the root mean square error if removed from the model.

Univariable regressions of each of the predictors showed them all to be significant, apart from transfer from an admission unit on the day of assessment (Table S4 in Multimedia Appendix 1). All predictors were retained in the GAM model.

A calibration plot of predictions in the test set against the recorded WTE per patient with the addition of a loess smoothing line forming a calibration curve [18] shows that there was some underestimation of workload at high values (Figure 3).

A Bland-Altman plot of differences between the recorded WTE per patient and model predictions in the test set (Figure 4) had a mean difference of 0.002 WTE per patient. The limits of agreement are at ±0.21 WTE per patient, meaning 95% of assessments fall in this range.

Discussion

Main Findings

In this study, we used a limited set of routine patient data to estimate the demand for nursing staff on general and high-care hospital wards and admission units. We found that data on patient demographics, routes of admission, ward transfers, diagnoses, and admission NEWS, which are available in hospital systems, could be used to estimate the results of assessments made using a PCS with a moderate degree of precision. The predictions of WTE per patient were on average within 5% of the recorded estimates when applied to a test set. Calibration "in the large" was good in the test set, with the mean prediction being only 0.002 WTE per patient less than the recorded mean [18]. However, a calibration curve showed that the model tended to underestimate at higher workloads. This would be the case

XSL•FO
RenderX

if some dimensions of patients' care needs in more acute wards were not being adequately represented in the dataset. A "by ward" sub-analysis of the model estimates showed that the surgical high care unit and the renal transplant unit were the 2 wards where the model underestimated the most (as proportions of predictions). This might indicate the model is lacking variables that adequately capture the acuity and dependency of patients after major surgery. If the model were to be used as it is, a professional judgment framework, such as that published by Saville et al [19], should be used, which might recommend considering adjustment of the estimates where they exceeded 1.75 WTE or where there were high-care beds in the ward.

The predictors were not chosen to be orthogonal; they clearly have correlations when considering their potential effect on nurse workload. That means Figure 2 explaining their contribution to estimating workload needs to be interpreted with care. It is not surprising that the admission unit indicator makes the largest contribution since an approximately 10% uplift in nurse staffing for admission units is baked into the PCS, which determines the target WTE per patient. It is perhaps expected that the age, comorbidity index, and admission NEWS case mix variables of ward occupancy influence estimates of workload. However, the marked contribution of gender invites comment. It may reflect staffing in single-sex wards dealing with gynecological or urological conditions.

While overall fit was good, the Bland-Altman plot shown in Figure 4 revealed a distinct artifact of 45-degree downward-sloping lines, which arises from ranges of continuous prediction values estimating a given workload derived from the discrete set of multiplier values in the PCS and the numbers of patients in wards. There is a degree of subjectivity in categorizing patients in the PCS into one of the 4 levels, and there is a possibility that there was some up-coding of assessments in which patients were put into a higher category, for example, level 1b rather than level zero, which might boost a ward's chances of getting more resources [20]. The high proportion of patient assessments in the level 1b category shown in Table 2 possibly suggests some of these were erroneous, although patients with dependent care needs may have longer than average stays with opportunity for more categorizations at that level.

In conversations, safe staffing managers and leads at a number of hospitals have expressed concerns regarding the accuracy and reliability of manual patient categorizations by ward staff. An automated workload prediction system would be objective and eliminate or reduce a source of bias. It would also remove the need for training staff in carrying out the assessments and retraining them when assessment methods are revised.

The OPCq and Perroca patient classification instruments for assessing patient care needs are more structured than the SNCT instrument, as they require scoring a patient across several domains before determining an overall category. The drawback to this rigor is that the assessments take longer. One nurse quoted in the publication by Ayan et al (2024) [21] concerning the Perroca instrument said: "Since we have been using it continuously, it does not take me much time now. It only takes five minutes to assess a patient; it couldn't be easier."

Our observational data (unpublished) from another study [22] suggests that assessing all patients on a 30-bedded ward 3 times per day with SNCT categorizations could occupy a senior nurse for up to 30 minutes per day, plus extra time for data entry.

The identification of 2 wards with outlier predictions is of interest. In the private patient unit, the model tended to predict higher staffing requirements than those identified in the assessments. This could arise because of a selection effect, whereby the occurrence of more elective procedures on more medically fit patients was not reflected in the variables used for this population. In contrast, the predicted workload estimates for the surgical high care unit tended to be too low, and this might mean the model is not adjusting adequately for these acutely ill patients. Additional predictors to adjust for operational severity might improve the predictions.

The surprising accuracy of the predictions on limited data opens up the possibility of automated near-time assessments and consequently freeing up some nursing time. The feasibility of implementing the prediction algorithm in real-time or near-time is dependent on the data items being recorded and accessible in a timely manner. In the United Kingdom, basic patient admission data is usually recorded in near-time in a patient administration system with electronic interfacing, though the clinical coding of diagnoses in the same system is often much later. However, the diagnoses the algorithm uses are largely for long-term conditions or conditions known on presentation, in which case they may already be present in the electronic clinical history or recorded in nursing or clinical handover documentation. A National Health Service (NHS) England-sponsored digital maturity assessment of UK hospital trusts reports that 32 of 132 acute trusts have electronic nursing and physician documentation [23], and that number is rising, so real-time electronic provision of patient conditions is becoming more widespread.

Comparison With Prior Work

The approach taken in this study differs from previous studies that built models or made estimates of actual historic staffing levels [24-26]. In contrast, our approach was to build a model of estimated staffing requirements trained on the records of an existing staffing estimation tool [27]. Unlike the classifier model built by Rosa [7], which was trained on values from the PPCI to make patient categorizations, ours was a prediction model of ward staffing requirements. While the prediction of PPCI values was only moderately accurate (72% correct classification), in our study, the magnitude of errors for estimating ward staffing requirements was, on average, small, with a mean average percentage error of less than 5% and 95% of estimates within 14% of the assessed value. The required precision is an open question, but staffing within ±15% of measured demand is used as a criterion to define acceptable variation in one widely used system [28].

The method we have used to build a model that is trained on the ward workload is flexible and would work for other patient acuity and dependency scoring instruments that assign an ordinal value for the patient's care needs.

XSL•FO
RenderX

Limitations

The dataset was limited in terms of longitudinal clinical data regarding patient conditions. While it contained the NEWS on admission, it did not have subsequent scores or individual vital signs. Without time-varying variables such as NEWS and other assessments that reflect a patient's evolving acuity, the model is relying on the ward case mix not varying from the average in terms of proportions of patients medically fit for discharge or proportions deteriorating. These 2 cases work in opposite directions in terms of workload, those patients who are medically fit probably requiring less nursing care, while those who deteriorate probably requiring more nursing care. A systematic bias in the model performance is not easy to determine without further information. Also, as noted earlier in the main findings, the poor performance of the model in the private patient unit and in surgical high care might result from the model lacking information on surgical procedures and operation severity. This limits the settings in which the current model might be used.

Another limitation that might have impacted the accuracy of the predictions was the reliability of the recorded patient classifications. The use of the acuity categorization tool for estimating staffing requirements in the dataset was new to the hospital at the time; hence, the reliability of the assessment may have depended for a period on the effectiveness of training given to ward assessors and monitoring of the use of the tool.

The robustness and generalizability of the model need to be checked by assessing its performance using data from other hospitals. It is possible that variation in patient case mix and in how hospitals apply SNCT patient acuity categorizations could affect model performance. It should also be noted that while the aim of this study was to estimate workload that matched the existing SNCT-based assessments, the tool in use did not refine workload requirements by skill mix, for example, advising how many registered nurses and how many nurse support staff might meet the requirements, nor about requirements for specialist skills. This would be a useful step in matching requirements to available resources and might be the subject of further work.

Conclusions

This research demonstrated a way of building a moderately accurate prediction model of nurse staffing requirements from a limited dataset of routine data by training the model on records of an established patient acuity and dependency patient classification tool. The results demonstrate the potential for automating assessments of nurse staffing requirements from routine data, reducing time spent on this nonclinical overhead, and improving monitoring of real-time staffing pressures.

Abstract

Background: The prompt and accurate identification of mild cognitive impairment (MCI) is crucial for preventing its progression into more severe neurodegenerative diseases. However, current diagnostic solutions, such as biomarkers and cognitive screening tests, prove costly, time-consuming, and invasive, hindering patient compliance and the accessibility of these tests. Therefore, exploring a more cost-effective, efficient, and noninvasive method to aid clinicians in detecting MCI is necessary.

Objective: This study aims to develop an ensemble learning framework that adaptively integrates multimodal physiological data collected from wearable wristbands and digital cognitive metrics recorded on tablets, thereby improving the accuracy and practicality of MCI detection.

Methods: We recruited 843 participants aged 60 years and older from the geriatrics and neurology departments of our collaborating hospitals, who were randomly divided into a development dataset (674/843 participants) and an internal test dataset (169/843 participants) at a 4:1 ratio. In addition, 226 older adults were recruited from 3 external centers to form an external test dataset. We measured their physiological signals (eg, electrodermal activity and photoplethysmography) and digital cognitive parameters (eg, reaction time and test scores) using the clinically certified Empatica 4 wristband and a tablet cognitive screening tool. The collected data underwent rigorous preprocessing, during which features in the time, frequency, and nonlinear domains were extracted from individual physiological signals. To address the challenges (eg, the curse of dimensionality and increased model complexity) posed by high-dimensional features, we developed a dynamic adaptive feature selection optimization algorithm to identify the most impactful subset of features for classification performance. Finally, the accuracy and efficiency of the classification model were improved by optimizing the combination of base learners.

Results: The experimental results indicate that the proposed MCI detection framework achieved classification accuracies of 88.4%, 85.5%, and 84.5% on the development, internal test, and external test datasets, respectively. The area under the curve for the binary classification task was 0.945 (95% CI 0.903-0.986), 0.912 (95% CI 0.859-0.965), and 0.904 (95% CI 0.846-0.962) on these datasets. Furthermore, a statistical analysis of feature subsets during the iterative modeling process revealed that the decay

XSL•FO
RenderX

time of skin conductance response, the percentage of continuous normal-to-normal intervals exceeding 50 milliseconds, the ratio of low-frequency to high-frequency (LF/HF) components in heart rate variability, and cognitive time features emerged as the most prevalent and effective indicators. Specifically, compared with healthy individuals, patients with MCI exhibited a longer skin conductance response decay time during cognitive testing (P<.001), a lower percentage of continuous normal-to-normal intervals exceeding 50 milliseconds (P<.001), and higher LF/HF (P<.001), accompanied by greater variability. Similarly, patients with MCI took longer to complete cognitive tests than healthy individuals (P<.001).

Conclusions: The developed MCI detection framework has demonstrated exemplary performance and stability in large-scale validations. It establishes a new benchmark for noninvasive, effective early MCI detection that can be integrated into routine wearable and tablet-based assessments. Furthermore, the framework enables continuous and convenient self-screening within home or nonspecialized settings, effectively mitigating underresourced health care and geographic location constraints, making it an essential tool in the current fight against neurodegenerative diseases.

Introduction

Background

Neurodegenerative conditions such as Alzheimer disease (AD) and related dementias precipitate accelerated cognitive deterioration, markedly impacting patients' daily lives and social engagement [1]. Current estimates suggest that approximately 50 million individuals worldwide suffer from dementia, with this number expected to soar to 152 million by 2050 [2]. Generally, patients diagnosed with mild cognitive impairment (MCI) are at a much higher risk of developing dementia [3]. MCI serves as an intermediate stage between normal cognitive aging and the severe pathological decline of dementia, influencing individuals' cognitive functions, social abilities, and mental health, and may lead to emotional disorders that disrupt daily life [4]. Epidemiological data reveal that the incidence of MCI is 6.7% among those aged 60-64 years, 8.4% for 65- to 69-year-olds, 10.1% for 70- to 74-year-olds, 14.8% for 75- to 79-year-olds, and 25.2% for 80- to 84-year-olds [5]. The annual transition rate from MCI to dementia or AD is about 10%-15% [6], significantly higher than the 1%-2% annual incidence of dementia in the general population. Despite various potential treatments for AD, including enzymes that inhibit the production of amyloid-β and antibodies that clear amyloid-β from the brain [7], no current medications can fully cure dementia or significantly alter its clinical course. Moreover, studies indicate that early intervention is effective, necessitating precise and sensitive diagnostic measures for MCI [8]. Thus, early identification of MCI is crucial as it enables timely interventions to slow cognitive decline and alleviate the burden of dementia [9].

Wearable devices provide a near-continuous, passive data collection method, offering a convenient and minimally invasive approach for the ongoing monitoring and tracking of cognitive decline in patients with MCI. Existing studies have demonstrated that various physiological indicators, such as heart rate variability [10], electrodermal activity [11], gait variability [12], skin temperature [13], respiratory rate [14], electroencephalography [15], eye movement [16], and electromyography [17], can be effectively used to assess cognitive function changes, providing an objective basis for the auxiliary diagnosis of early cognitive impairment. However, despite the availability of diverse physiological data from patients with MCI, challenges remain in the effective utilization of these data due to the complexity of high-dimensional information (eg, feature redundancy, strong interfeature correlations, and noise interference) and the technical difficulties in multimodal data integration (eg, insufficient feature extraction and dimensionality reduction methods, challenges in aligning heterogeneous modalities, and limitations in handling noise and missing data).

In recent years, machine learning techniques have been increasingly applied to analyzing and processing complex, high-dimensional physiological data to facilitate the early detection of cognitive disorders, including MCI. Traditional algorithms such as naive Bayes [18], k-nearest neighbors (KNN) [19], support vector machines (SVM) [20], and logistic regression (LR) [21] have demonstrated a certain degree of effectiveness in identifying high-risk MCI populations. However, due to the limitations of single algorithms in modeling high-dimensional and multimodal data, such as insufficient representational capacity and unstable generalization performance, researchers have gradually shifted toward exploring ensemble methods, including bagging [22], boosting [23], and stacking [24]. These ensemble learning techniques integrate predictions from multiple models, effectively mitigating the limitations of single models and significantly improving overall predictive accuracy and robustness.

In addition, various swarm intelligence algorithms have been introduced for critical tasks such as feature selection and hyperparameter optimization to enhance the performance of machine learning models in high-dimensional data analysis. Swarm intelligence algorithms, including Harmony Search (HS) [25], Particle Swarm Optimization [26], and Genetic Algorithms [27], simulate cooperative behaviors observed in nature and have demonstrated outstanding potential in solving global optimization problems. The HS algorithm has gained attention as a metaheuristic optimization technique due to its simplicity,

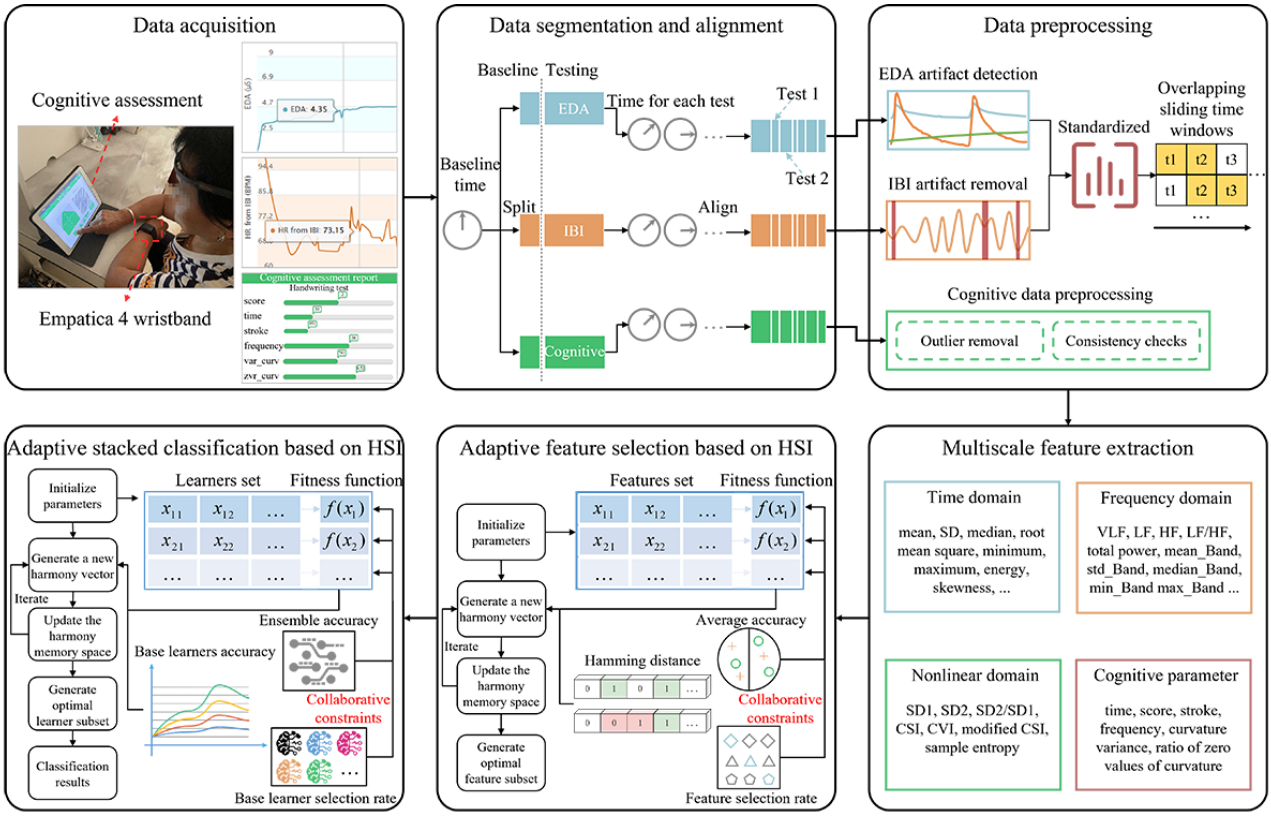
XSL•FO
RenderX

ease of implementation, and low-parameter adjustment requirements. Inspired by musical harmony improvisation, the HS algorithm iteratively adjusts the pitch of each instrument (analogous to high-dimensional features) to find the optimal feature combination. This approach offers an effective solution for feature selection involving physiological data and cognitive parameters of MCI patients, showing promising prospects in improving model prediction accuracy and computational efficiency.

Objective

We propose a Dynamic Adaptive Ensemble Learning Framework based on an Improved Harmony Search (DAELF-HSI), designed to enhance MCI detection by addressing issues of feature redundancy and the inefficiency of multimodal data fusion. In contrast to previous studies, this research integrates multimodal physiological data collected through wearable wristbands (eg, heart rate variability and electrodermal activity) with cognitive assessment metrics recorded on tablet devices (eg, reaction time and test scores), aiming to exploit the potential value of multisource data comprehensively, thereby improving the accuracy and clinical utility of MCI detection. We hypothesize that the DAELF-HSI framework will not only effectively distinguish between patients with MCI and healthy individuals but also uncover critical discriminative information pertinent to MCI.

Methods



Ethical Considerations

The research was reviewed and approved by the Biomedical Ethics Review Committee of Taiyuan University of Technology (20240124). All methods were performed following relevant guidelines and regulations. Written informed consent was obtained from eligible participants under the principles of the Declaration of Helsinki. All participants signed an informed consent form. We provided US $10 to eligible older adults as compensation for participation.

Overview of the Proposed Detection Framework

Figure 1 illustrates a Dynamic Adaptive Ensemble Learning Framework for MCI detection, integrating multimodal data that integrates individual physiological signals with cognitive tasks derived from serious games. The framework begins with data collection, followed by time series segmentation, alignment, and preprocessing. It then progresses to feature extraction and selection, culminating in constructing a classification model. Notably, the modules within the framework are interconnected and sequentially executed, forming a cohesive unit. The following sections will detail the stages, demonstrating the adaptability and effectiveness of the proposed MCI detection framework.

Figure 1. A dynamic adaptive ensemble learning framework for mild cognitive impairment detection. CSI: cardiac sympathetic index; CVI: cardiovascular index; EDA: electrodermal activity, HF: high frequency; HSI: harmony search improved; IBI: interbeat interval; LF: low frequency; VLF: very low frequency.

Experimental Participants and Procedures

The dataset used for machine learning modeling involves 843 participants aged 60 and older recruited from partner hospitals. The participants were randomly divided into a development dataset (674/843), and an independent testing dataset (169/843) in a ratio of 4:1. In addition, 226 older adults were recruited from 3 external centers to constitute an external testing dataset.

XSL•FO
RenderX

Participants were identified using a purposive sampling method [28], with the process being meticulously overseen by experienced neurologists. The inclusion criteria for participants were (1) age ≥60 years; (2) normal hearing and vision, or corrected to normal; (3) completion of the Mini-Mental State Examination (MMSE) test; (4) completion of the Montreal Cognitive Assessment (MoCA) test; (5) capability to engage in moderate activity without physical disabilities; (6) absence of severe depressive symptoms or other neurological disorders such as stroke or Parkinson disease; (7) ability to effectively use smart devices such as smartphones and tablets; and (8) informed consent signed by the participants or their guardians.

Neurologists contacted potential participants during their clinic visits, explaining the study's purpose, related procedures, and the possible impact of the research findings. Once potential participants expressed interest, neurologists conducted comprehensive medical evaluations, including detailed medical history collection, physical examinations, brain imaging (magnetic resonance imaging or computed tomography scans), and cognitive function assessments (using the MMSE and MoCA scales). The MCI group comprised 514 (48.1%) participants who scored below 26 on the MoCA, while the healthy control (HC) group included 555 (51.9%) healthy individuals without symptoms of cognitive decline. Brain imaging scans revealed no structural abnormalities causing cognitive impairment. Furthermore, all patients with MCI met the criteria proposed by the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association [29]. We also administered the habitual hand questionnaire [30], which consisted of 13 items, to all participants. The MCI and HC groups were matched for age, gender, hand preference, education, average sleep duration (in general), and years of smart device use. All participants completed cognitive tasks with the assistance of researchers, and there were no dropouts during the testing process. Table 1 summarizes the clinical and demographic characteristics of the 1069 participants enrolled across the development, internal, and external datasets.

In the experimental setting, a well-trained experimenter instructed participants to sit on a comfortable chair and wear the Empatica 4 on their nondominant wrist. The Empatica 4 is a watch-like multisensor device that measures physiological data such as electrodermal activity (EDA), photoplethysmography, skin temperature, and accelerometer readings. It is compact, lightweight, and comfortable to wear, making it suitable for unobtrusive continuous monitoring during cognitive screening of older adults. The participants performed cognitive tasks on a 2019 iPad using the Brain Nursing mobile app developed by our team (Multimedia Appendix 1) [31], completing drawing-related tasks with an Apple Pencil. The system includes 11 single tasks and 3 dual tasks, each taking only 1-3 minutes, designed to assess attention; short-term memory; working memory; scene recall and situational reconstruction; visual-conceptual and visual-motor tracking; orientation; executive function; language comprehension and expression; logical thinking; and fine motor control. To minimize interference from the nondominant hand during the painting tasks, the experimenter provided appropriate assistance,

XSL•FO
RenderX

such as stabilizing the tablet. Upon completion of the testing, the Empatica 4 wristband was removed from the participant's wrist, physiological data were retrieved and downloaded through the Empatica 4 Connect portal, and cognitive data were exported from the cloud.

Data Segmentation and Alignment

Overview

For the collected multisource data, such as EDA, interbeat interval (IBI) for describing heart rate variability (HRV), and cognitive data, ensuring the integrity, continuity, and temporal alignment of the data is crucial. As participants perform cognitive tasks, the tablet automatically records timestamps for each test, providing a reference for aligning physiological data. Thus, we align the EDA and IBI data using the start and end times of each test, as described in the procedures listed below.

EDA Time Series Processing

Considering that the EDA.csv file downloaded from the cloud only contains information about the start time of the session and the sampling rate, it lacks the timestamps corresponding to each second of the signal. To address this deficiency, we generate a timestamp every 4 data points based on the session start time and the sensor sampling rate (4 Hz). Subsequently, we align the timestamps of the cognitive tests with the EDA series timestamps, thereby extracting the EDA signal segments corresponding to the specific cognitive tests.

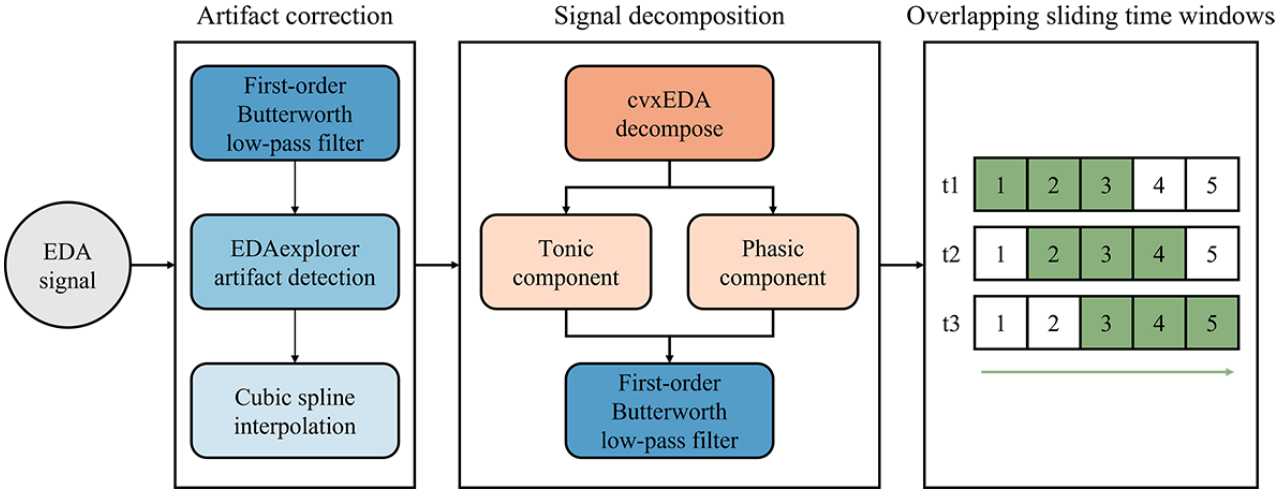
IBI Time Series Processing

Due to the automatic discarding of unidentifiable heartbeats by the Empatica 4 wristband during measurement, the IBI.csv file contains discontinuities that do not match the actual measuring intervals. It is crucial to accurately identify and fill these measurement gaps to ensure data integrity in the analysis of IBI time series for various test tasks. Following the suggestions of Rafi et al [32], this study limits the physiologically feasible range for IBI to within 2 seconds, and any data beyond the threshold was automatically labeled as a measurement gap. Subsequently, cubic spline interpolation [33] is used to estimate the missing values within these gaps. The overall continuity of the IBI dataset in the temporal dimension is optimized by using a curve-fitting method based on available data points. Finally, new timestamps are added to the IBI data, aligning the timestamps of cognitive tests with those of the IBI series.

Data Preprocessing

Overview

Commercial wearable devices are prone to artifacts, measurement gaps, or deviations from the measurement regime during data recording [34,35]. To ensure reliable information is extracted from field-collected data, rigorous preprocessing is required to filter noise and artifacts and restore the original signal. Considering the differences among EDA, IBI, and digital parameters, we will detail the preprocessing methods for these metrics.



EDA Signal Preprocessing

EDA serves as a biosignal, mirroring the individual physiological and emotional states, and consists mainly of slowly varying tonic and rapidly fluctuating phasic activities. Tonic activity, also known as skin conductance level (SCL), primarily reflects the physiological activity level of an individual at rest, indicating the continuous regulation of the autonomic nervous system. In contrast, phasic activity, or SCR, is a rapid and transient physiological response to specific stimuli, revealing an individual's adaptability and reactivity to sudden events. To enhance EDA signal quality, we propose a multistage automatic artifact removal method, including artifact correction, signal decomposition, and overlapping sliding time windows, as shown in Figure 2. The specific steps involved are:

1. Low-pass filtering: EDA signal is filtered using a first-order Butterworth low-pass filter with a cutoff frequency of 0.6 Hz [36], which preserves its low-frequency components and eliminates high-frequency noise.
2. Artifact detection: EDAexplorer [37] is used to detect artifacts in the filtered signal, identifying and marking anomalies within the signal to provide a basis for data repair.
3. Cubic spline interpolation: apply cubic spline interpolation to the identified artifact segments, using segmented cubic polynomials to approximate missing data points while ensuring continuity in function values and their first and second derivatives, thereby smoothly completing the missing data.
4. Signal decomposition: by solving the convex optimization approach, cvxEDA [38] separates the signal into tonic and phasic components, enabling enhanced analysis and interpretation of the underlying physiological mechanisms within the EDA signal.
5. Component filtering: refilter the decomposed tonic and phasic components using a low-pass Butterworth filter to eliminate negative SCR and SCL values, enhancing the signal quality.
6. Time window segmentation: segment the processed tonic and phasic components into overlapping time windows of 60 seconds with a step size of 1 second to facilitate subsequent feature extraction.

XSL•FO
RenderX

Figure 2. Electrodermal activity signal preprocessing flow.

IBI Signal Preprocessing

Wearable devices commonly use photoplethysmography sensors to monitor the continuous variations in interbeat or R-R intervals. However, obtaining raw photoplethysmography data from the Empatica 4 wristband presents challenges, so we shifted to analyzing IBI data, which is more readily accessible. Analyzing IBI data allows for calculating HRV, reflecting the variations in time between consecutive heartbeats. Although Empatica 4 offers convenience and noninvasiveness for recording HRV, it still faces issues such as artifacts or measurement gaps [39,40]. Therefore, we initially adopted 4 artifact detection rules to identify artifacts, as shown in Textbox 1. Subsequently, detected artifacts were interpolated using cubic spline interpolation to fill in missing values. Finally, the cleaned IBI data was segmented into overlapping time windows of 60 seconds with a 1-second step size, creating datasets for subsequent feature extraction.

Textbox 1. List of interbeat interval artifact detection rules.

Study and rule description

Rafi et al [32]

- Discard any interbeat intervals that do not fall within the physiological range of 250-2000 milliseconds (equivalent to a heart rate of 30-240 beats per minute).

Malik et al [41]

- Each interbeat interval should be at most 20% from the previous one.

Acar et al [42]

- Calculate the average of the 9 interbeat intervals preceding the current interbeat interval. It should be removed if the current interbeat interval differs from this average by more than 20%.

Karlsson et al [43]

- Remove any interbeat interval that differs by more than 20% from the average of its immediate preceding and succeeding interbeat intervals.

Cognitive Data Preprocessing

Outlier removal and data consistency checks were performed manually to preprocess digital cognitive parameters. The specific steps include (1) format validation: ensuring that all data entries adhere to the required format specifications (eg, the time recorded in seconds and scores in numerical format) and correcting any inconsistencies; (2) range validation: checking that all data values fall within predefined acceptable ranges, such as ensuring reaction times are within a reasonable range of seconds; (3) continuity validation: assessing the continuity of the data, including verifying that the timestamps for each test are in sequential order and checking for any missing data points. Through these steps, we aim to identify and eliminate extreme outliers caused by user errors or external interference while ensuring the logical consistency of data format, range, and time series, thereby improving the overall quality and reliability of the data.

Multiscale Feature Extraction

In this study, we comprehensively analyzed data collected from the Empatica 4 wristband and tablet devices to explore participants' physiological and cognitive responses to various cognitive tasks. Specifically, we used the FLIRT toolkit [44] and NeuroKit2 [45] to extract 39 EDA-related features (including 17 SCL features and 22 SCR features) from the EDA signals and 23 features (including HR and HRV) from the IBI data. Furthermore, we collected several cognitive parameters,

XSL•FO
RenderX

including time, score, stroke, frequency, and curvature (variance and the ratio of 0 values) during each test. Detailed information regarding all these features is available in Multimedia Appendix 1.

Dynamic Adaptive Feature Selection Based on Improved Harmony Search

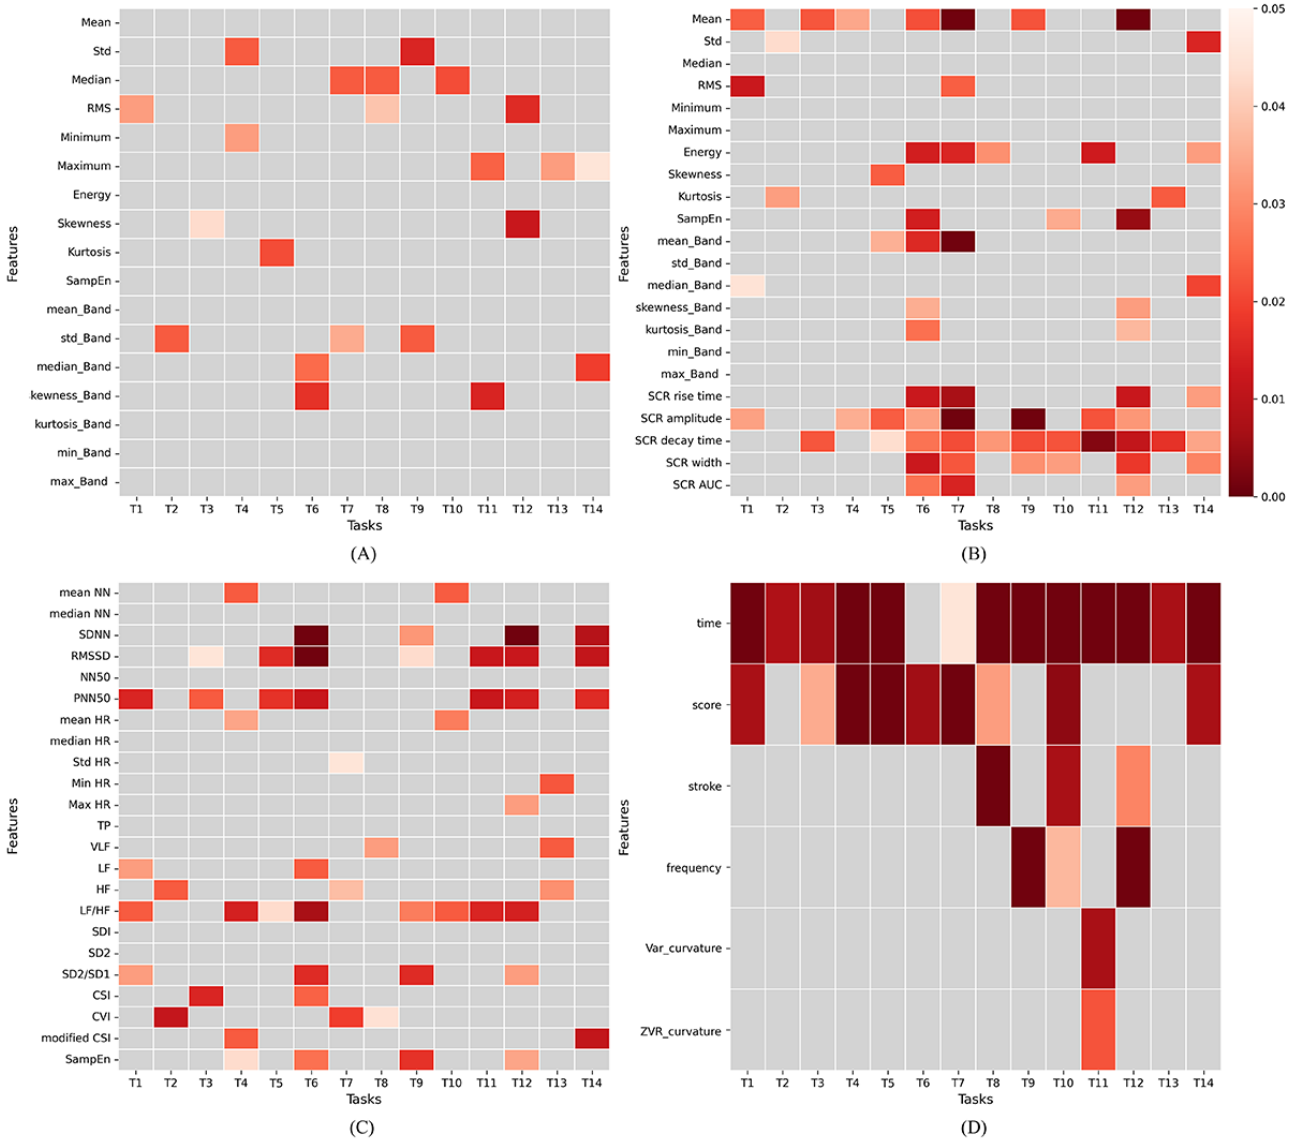
Feature selection plays a critical role in handling high-dimensional datasets, as not all features impact the outcome. An excessive number of features can result in the curse of dimensionality and increased model complexity. Therefore, this study proposes a feature selection algorithm based on HSI to sift through extracted physiological and cognitive features. Analogous to musical notes, each feature represents a note that may or may not be selected into a subset. Musicians repeatedly adjust the notes to achieve the best harmony effect until reaching a satisfactory harmony. Similarly, the feature selection algorithm based on HSI continuously tunes parameters and modifies the generated feature subset to ensure diversity and avoid convergence to local optima. In particular, we integrate Hamming distance into the HSI algorithm to gauge the disparity between the newly generated harmony vector and the optimal vector in the harmony memory. The Hamming distance is used to assess the similarity between these vectors to fine-tune the search probability. A high Hamming distance leads to a moderate reduction in the search probability to promote exploratory efforts, while a low Hamming distance results in a moderate increase in leveraging known information. Finally, to evaluate the quality of the harmony effect, we minimize the average classification error rate of all base learners and the feature selection rate as optimization objectives. The detailed algorithm is provided in Multimedia Appendix 2.

Dynamic Adaptive Stacking Classification Based on Improved Harmony Search

An essential goal of this study is to distinguish between healthy individuals and patients with MCI effectively. As mentioned, we opt for a subset of features demonstrating balanced performance across all base learners during the feature selection phase. Nevertheless, certain learners continue to demonstrate suboptimal performance, and merely stacking multiple base learners increases algorithmic complexity and computational demands. In essence, the selection of learners, akin to feature selection, constitutes a combinatorial optimization problem focused on enhancing classification performance. Thus, this study proposes using HSI to optimize the stacking of base learners. Unlike feature selection algorithms that use HSI, it leverages the accuracy of the current base learners and their quantity to guide hyperparameter adjustments. The strategy aims to mitigate the adverse effects of underperforming learners on the overall model while simultaneously enhancing model efficiency and minimizing computational costs. Furthermore, we selected the KNN, decision tree (DT), random forest (RF), Gaussian naive Bayes, SVM, multilayer perceptron, LR, gradient boosting DT, and XGBoost as base learners, with LR serving as the meta-learner. The detailed algorithm is provided in Multimedia Appendix 2.

Statistical Analysis and Machine Learning Model

This study analyzed demographic characteristics, cognitive parameters, and physiological features using the Statistical Package for the Social Sciences (SPSS, version 22.0 for Windows, IBM). Initially, the Kolmogorov-Smirnov test was used to assess whether continuous variables such as age, years of education, hours of sleep, years of smart device usage, and cognitive data conformed to a normal distribution. Descriptive statistics were described using means (SD) for normally distributed variables. Subsequently, the *t* test was used for between-group comparisons to determine if there were significant differences between the HC group and the MCI group. In contrast, we used the nonparametric Mann-Whitney U test for nonnormally distributed variables to assess intergroup differences. For categorical variables such as gender and hand preference, data were described in terms of counts (percentages), and the chi-square test was used for group comparisons. The significance level for all statistical analyses was set at $P<.05$. Furthermore, to validate the performance of the proposed detection framework, experiments were conducted using a 5-fold cross-validation approach, using 4 evaluation metrics (accuracy, precision, recall, and F_1-score) to assess the classification outcomes. All learners used the HSI for feature selection, and the average values were used as the final classification results.



Results

Statistical Comparison of EDA, HRV, and Cognitive Features Between Groups

We conducted statistical analyses on features extracted from EDA, HRV, and cognitive tasks to identify the key features distinguishing between healthy individuals and patients with MCI. As shown in Figure 3, red squares indicate significant differences ($P<.05$) between the 2 groups on specific features during certain cognitive tasks, and the depth of the color reflects the degree of significance of these differences.

XSL•FO
RenderX

Figure 3. Results of the t tests performed on features extracted from electrodermal activity, heart rate variability, and cognitive tasks between groups. HRV: heart rate variability; SCL: skin conductance level; SCR: skin conductance response.

Based on observations from Figure 3A, relatively few SCL features distinguish between patients with MCI and healthy individuals, including the SD, median, root mean square, and SD of spectral power. Conversely, Figure 3B reveals more significant differences in SCR features, including mean, energy, amplitude, rise time, delay time, and width in the time domain and mean in the frequency domain. These findings highlight several key points: (1) the SD and root mean square of SCL indicate variability and instability in physiological responses, with differences between patients with MCI and healthy individuals reflecting disparate levels of physiological variability; (2) statistical differences in the SD of SCL spectral power between the groups indicate that patients with MCI exhibit significantly different physiological responses within specific frequency ranges, possibly related to impaired cognition associated with MCI; (3) statistical differences in SCR time domain features between groups indicate that patients with MCI exhibit variations in the intensity and timing of physiological responses, suggesting impaired regulatory capabilities of their nervous systems; and (4) variations in the mean values in the SCR frequency domain indicate that patients with MCI have different physiological response frequency distributions when processing stimuli compared with healthy individuals.

Figure 3C depicts the statistical analysis results applied to features extracted from HRV between patients with MCI and healthy controls. The analysis indicates statistically significant distinctions in HRV indices such as SDNN (SD of N-N intervals), RMSSD (root mean square of successive differences), PNN50 (percentage of successive R-R intervals > 50 ms), LF/HF (low-frequency to high-frequency ratio) ratio, SD2/SD1 (ratio of the SD2 and SD1 of Poincaré plot), and SampEn (sample entropy). These results highlight several key aspects which are (1) SDNN, RMSSD, and PNN50, which quantify overall and short-term heart rate variations, reveal disparities in autonomic nervous system functioning between the groups; (2) the LF/HF ratio reflects imbalances between sympathetic and parasympathetic nervous activities, indicating autonomic dysregulation in patients with MCI relative to controls; and (3) SD2/SD1 and SampEn focus on balance between long-term and short-term variability, as well as the complexity and irregularity

XSL•FO
RenderX

of HRV, illustrating differences in autonomic nervous system adaptability and complexity between groups. Finally, observations from Figure 3D reveal that (1) multiple cognitive tests using time and scores as indicators can significantly distinguish between healthy individuals and patients with MCI, and (2) features such as handwriting, frequency, and curvature show varying degrees of significant differences across different drawing tasks.

Performance of the DAELF-HSI in Mild Cognitive Impairment Detection

Table 2 lists the classification outcomes of the DAELF-HSI compared with 6 machine learning models and the application of HSI for feature selection in these models. Following a thorough assessment involving 100 iterations of 5-fold cross-validation, the DAELF-HSI demonstrated an average accuracy of 88.5%, surpassing the performance of other algorithms significantly. Moreover, it exhibited superior precision, recall, and F_1-score metrics, achieving 89.1%, 88.7%, and 88.9%, respectively, all at notably high levels. When HSI-based feature selection was not employed, the SVM model outperformed other machine learning algorithms with an accuracy of 79.6%. However, after integrating HSI feature selection, models like KNN-HSI and multilayer perceptron-HSI displayed improved performance, surpassing that of SVM-HSI. Noteworthy is the consistent enhancement in performance observed across all machine learning models upon the introduction of HSI feature selection, with accuracy improvements ranging from 3% to 5%, resulting in all models achieving accuracy levels exceeding 81%. It highlights the efficacy of the feature selection algorithm based on HSI in identifying crucial features that enhance the predictive capabilities of the machine learning models under investigation.

Table 2. Performance comparison of Dynamic Adaptive Ensemble Learning Framework based on an Improved Harmony Search with 6 machine learning models and applying Improved Harmony Search to model feature selection.

Methods	Accuracy, mean (SD)	Precision, mean (SD)	Recall, mean (SD)	F_1-score, mean (SD)

[h]DAELF-HSI: Dynamic Adaptive Ensemble Learning Framework based on an Improved Harmony Search.

Similarly, Table 3 presents the effectiveness of DAELF-HSI in classification compared with 5 ensemble learning models, augmented by HSI feature selection. In line with the findings in Table 2, DAELF-HSI maintains its superior performance. Noteworthy is that the ensemble learning techniques outperform the individual machine learning models discussed earlier, with XGBoost achieving a commendable average accuracy of 81.9%. The Bagging model, which uses KNN as a base learner, demonstrates improved performance compared with the stand-alone KNN model. However, the bagging model using ensemble SVM as a base learner falls short of expectations, slightly underperforming compared with the stand-alone SVM model, possibly due to the inherent instability advantages associated with SVM.

Figure 4 illustrates the box plots of 12 algorithms after 100 independent experiments across 4 evaluation metrics. The quartiles within each box plot depict algorithmic performance, while the red numbers above each box plot represent the mean values for the respective metrics. DAELF-HSI outstrips competing models across all metrics, demonstrating superior stability and an absence of significant outliers. Conversely, SVM-HSI and GNB-HSI exhibit more outliers, indicating challenges in achieving precise model fits for specific data distributions, leading to notable performance fluctuations. Although LR-HSI and Bag (KNN)-HSI do not display outliers, their wide IQR suggests instability across diverse feature distributions. Notably, RF-HSI demonstrates significant outliers in the F_1-score, highlighting the model's vulnerability to certain data distributions or feature sets.

Analysis of the Optimization Module of the DAELF-HSI

Figure 5 presents the frequency analysis of physiological features (including SCL, SCR, and HRV) and digital cognitive parameters during 100 iterations of the DAELF-HSI model. Notably, SCR decay time (SCR feature set), PNN50, LF/HF (HRV feature set), and time (cognitive feature set) are highlighted for their importance in distinguishing between the 2 groups, appearing in over 80% of the selections. However, certain SCR features (eg, SCR amplitude, SCR width, and mean band) and HRV features (eg, SDNN, RMSSD, and mean HR), despite showing statistically significant differences (P<.05; Figure 3) in group differentiation, were infrequently chosen. This infrequency suggests that these parameters are highly correlated with features previously selected, leading the HSI feature selection algorithm to deem them redundant. Overall, the proposed HSI feature selection optimization algorithm can identify critical features, address redundancy, and accurately detect patients with MCI with limited features.

XSL•FO
RenderX

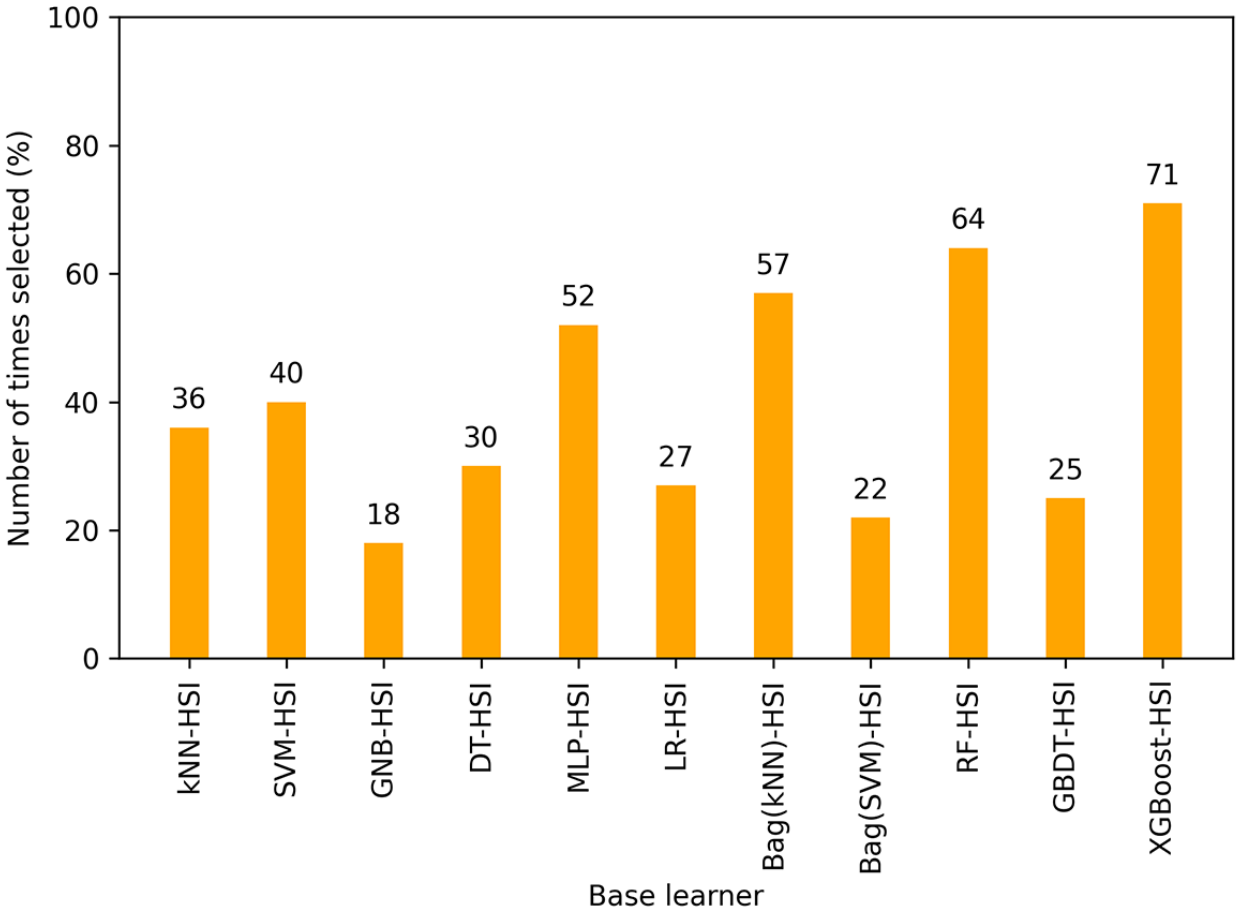

Figure 5. The number of times each skin conductance level, skin conductance response, heart rate variability, and cognitive feature was selected for mild cognitive impairment detection.

In addition, Figure 6 illustrates the frequency distribution of various base learners across 100 iterations within the DAELF-HSI model. Specifically, RF-HSI and XGBoost-HSI are the predominant selections, highlighting their substantial contributions to model efficacy and demonstrating the model's proficiency in selecting optimal learners. Conversely, GNB-HSI, Bag (SVM)-HSI, and GBDT-HSI are chosen less frequently. This bias in selection can be primarily attributed to 2 factors: first, these base learners inherently exhibit lower accuracy, leading the adaptive hyperparameter strategy of the DAELF-HSI to assign them reduced weights; second, a high level of correlation exists between these learners and other high-performing ensemble members, making their inclusion less impactful due to redundant error distributions and similarities in learner characteristics with more effective alternatives.

XSL•FO
RenderX

Figure 6. The number of times each base learner was selected for mild cognitive impairment detection. DT: decision tree; GBDT-HSI: gradient boosting decision tree-harmony search improved; GNB: Gaussian naïve Bayes; LR: logistic regression; KNN: k-nearest neighbors; RF-HSI: random forest-harmony search improved; SVM: support vector machines.

Finally, we substantiate the importance of feature selection and stacking optimization stages within the DAELF-HSI through ablation experiments. As delineated in Table 4, a total of 3 experimental models were structured to assess the impact of omitting 1 or both optimization stages, where "✓" denotes the inclusion of that stage. The models are configured as follows:

1. Model A uses 11 machine learning models as base learners and LR as the meta-learner, incorporating all features.
2. Model B uses 11 machine learning models as base learners with LR as the meta-learner, but only includes features selected through the HSI algorithm.
3. Model C integrates the HSI for stacking with 11 machine learning models, incorporating all features.

Table 4. Performance comparison of different ablation modules applied to the DAELF-HSI[a].

Methods	HSI[b] features selection	HSI learners stacking	Accuracy, mean (SD)	Precision, mean (SD)	Recall, mean (SD)	F_1-score, mean (SD)
Model A			0.826 (0.023)	0.819 (0.026)	0.831 (0.024)	0.825 (0.029)
Model B	✓		0.837 (0.027)	0.831 (0.028)	0.839 (0.030)	0.835 (0.035)
Model C		✓	0.854 (0.025)	0.858 (0.019)	0.849 (0.022)	0.853 (0.025)
DAELF-HSI	✓	✓	0.885 (0.020)	0.891 (0.021)	0.887 (0.024)	0.889 (0.025)

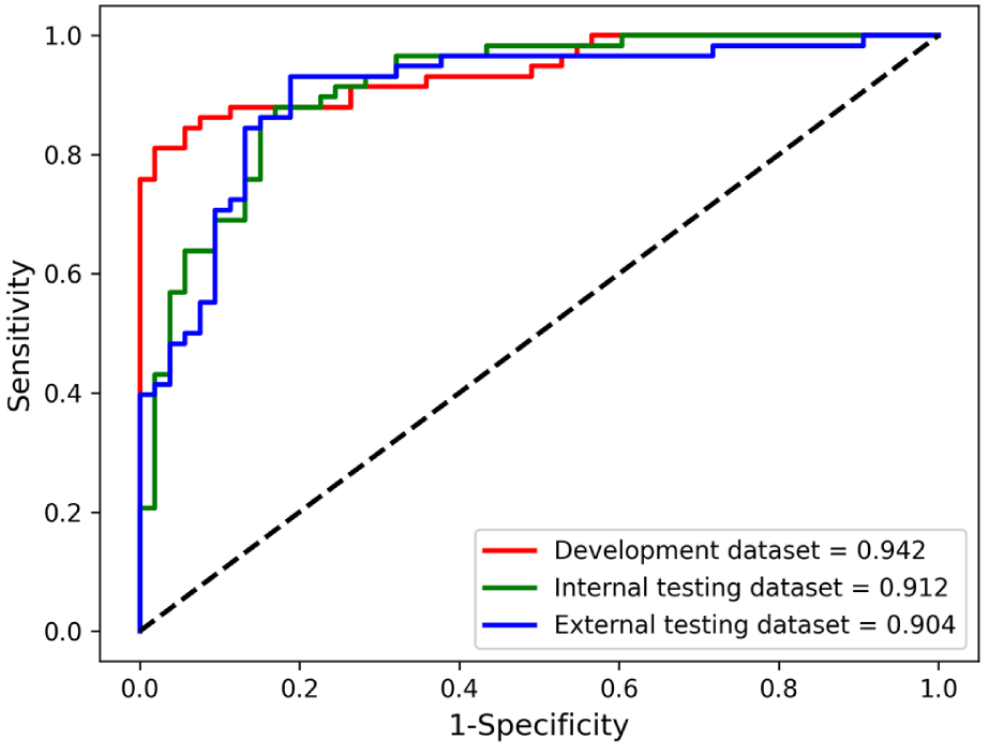
[a]DAELF-HSI: Dynamic Adaptive Ensemble Learning Framework based on an Improved Harmony Search.

[b]HSI: Improved Harmony Search.

According to the results in Table 4, model A shows lackluster classification performance in the absence of the 2 optimization stages, primarily due to the poor performance of certain base learners and the inclusion of numerous redundant features during training. Model B, which incorporates HSI-selected features, demonstrates a slight performance improvement of around 1%, suggesting that merely reducing feature redundancy is insufficient to enhance the output of underperforming base learners significantly. Furthermore, Model C, which solely incorporates the base learner stacking optimization stage, improves performance by nearly 3%, underscoring the importance of high-quality base learners in stacking algorithms.

XSL•FO
RenderX

Notably, the simultaneous implementation of both optimization stages substantially enhances the model's performance, highlighting the essential contribution of each stage to the overall efficacy of the algorithm.



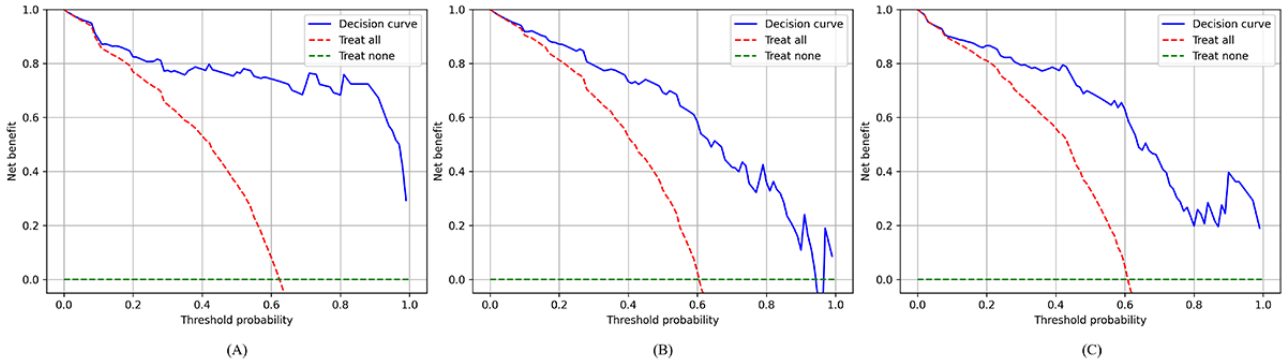
Performance Evaluation of DAELF-HSI Across Different Datasets

As shown in Table 5, we also used 4 metrics (including accuracy, sensitivity, specificity, and area under the curve [AUC]) to evaluate the binary classification performance of the classification model for patients with MCI versus healthy individuals in internal and external test datasets. Specifically, the model demonstrated excellent performance in the development dataset, with accuracy, sensitivity, and specificity at 88.4%, 86.1%, and 90.9%, respectively. In the internal test dataset, the model's accuracy slightly decreased to 85.5%, while sensitivity remained unchanged at 86.1%, and specificity dropped to 84.9%, suggesting that a small number of healthy individuals were misclassified as patients with MCI, but overall performance remained satisfactory. However, in the external test dataset, the model's accuracy, sensitivity, and specificity decreased by 3.9%, 0.4%, and 8.1%, respectively. Nevertheless, these results demonstrate the model's effectiveness, especially when evaluated on new and diverse samples. Furthermore, the AUC, which serves as an indicator of the model's validity, was recorded at 0.945 (95% CI 0.903-0.986), 0.912 (95% CI 0.859-0.965), and 0.904 (95% CI 0.846-0.962) across the 3 datasets, as illustrated in Figure 7. The AUC value reflects the classification performance of the model on different datasets. The DAELF-HSI model has an AUC value above the threshold of 0.9 on these datasets, demonstrating excellent sensitivity and specificity in detecting patients with MCI. In other words, the model cannot only effectively identify patients with MCI but also reduce the probability of misjudgment, enhancing reliability in clinical applications.

Table 5. The diagnostic value of the classification model in differentiating between healthy older adults and patients with mild cognitive impairment was assessed using internal and external testing datasets.

Dataset	Accuracy	Sensitivity	Specificity	Area under the curve (95% CI)	*P* value
Development dataset	0.884	0.861	0.909	0.945 (0.903-0.986)	<.001
Internal testing dataset	0.855	0.861	0.848	0.912 (0.859-0.965)	<.001
External testing dataset	0.845	0.857	0.828	0.904 (0.846-0.962)	<.001

Figure 7. The receiver operating characteristic curve of our model across different datasets.



Clinical Utility Analysis

To assess the practical clinical value of the proposed model, we performed decision curve analysis (DCA) on the development, internal testing, and external testing sets, presenting the model's decision curve along with the "Treat all" and "Treat none" strategies, as shown in Figure 8. Specifically, the model's decision curve demonstrated clear clinical benefits in the development set, with its net benefit consistently exceeding that of the "Treat all" and "Treat none" strategies. Notably, in the 0 to 0.85 threshold range, the model's net benefit declined from 1 to 0.75 and further decreased to 0.3 in the higher threshold

XSL•FO
RenderX

range, indicating that the model effectively avoids overtreatment in low-risk patient groups. In the internal testing set, the decision curve remained stable, with a gradual decline in net benefit that aligned with expectations, suggesting that as the threshold increased, the model opted for fewer treatment decisions, and validated the model's effectiveness in high-risk patient populations and its alignment with the clinical need to reduce unnecessary treatments. However, the model's decision curve showed slight variations in the external testing set compared with the other sets. The net benefit decreased from 1 to 0.2 in the 0-0.8 threshold range, indicating reduced efficacy in this range. However, in the 0.8-0.9 range, the net benefit rose from 0 to 0.4, suggesting that adjusting the threshold appropriately enhanced the model's predictive accuracy. In the 0.9-1 threshold range, the net benefit dropped again to 0.2, which may indicate cautious predictions in the high-risk zone, thus limiting its clinical utility. In conclusion, the model demonstrated a net benefit consistently higher than both the "Treat all" and "Treat none" strategies across the 3 sets, particularly in the mid-to-low threshold ranges, highlighting that the model can effectively guide clinical decision-making, reduce unnecessary treatments, and improve early disease detection and intervention efficiency.

Figure 8. Decision curve analysis on different datasets, showing the model's decision curves for the binary classification task, along with the "Treat all" and "Treat none" strategies. (A) Development set, (B) internal testing set, and (C) external testing set.

Discussion

Interpretability of Physiological Features

Previous studies demonstrate that HRV is an essential physiological assessment indicator that could differentiate physiological responses between patients with MCI and HCs under diverse stressors and conditions [46,47]. In this study, compared with healthy counterparts, patients with MCI exhibited decreased HR, prolonged N-N intervals, and an increased ratio of low to high-frequency components, consistent with trends observed in past research [10,48]. Moreover, higher levels of HRV have been associated with improved cognitive function, whereas lower HRV correlates with cognitive impairment [49]. During cognitive tasks, abnormal responses in the autonomic nervous system of patients with MCI were observed through monitoring HRV, highlighting the efficacy of HRV as a sensitive physiological indicator during cognitive engagement.

On the other hand, this research assessed the applicability of EDA features for identifying MCI, advancing upon sparse existing research in this field. Specifically, the EDA signal was segregated into tonic and phasic components, from which 39 features encompassing time, frequency, and SCR time domains were derived. Comparative statistical analysis revealed that, during cognitive tasks, patients with MCI exhibited significantly enhanced SCR amplitudes, elongated SCR widths, and protracted SCR decay time relative to healthy counterparts, indicating a more intense or unexpectedly elevated physiological response to stimuli. These pronounced variations in SCR parameters effectively discriminate between patients with MCI and healthy individuals, highlighting the sensitivity of EDA features in detecting autonomic nervous system dysfunctions, a common correlate of cognitive impairments [50].

Predictive Accuracy of the Proposed Model

A challenge in enhancing the classification accuracy for discriminating patients with MCI involves identifying the most discriminative feature set. Thus, we proposed a feature selection algorithm based on HSI to mitigate the presence of redundant features and alleviate the adverse effects of high-dimensional data on classification learning, as high dimensionality can impede effective target classification [11]. Furthermore, we explored how to balance the diversity of base learners and classification quality in stacking for a specific dataset, treating the selection of appropriate base learners as a combinatorial optimization problem and solving it using heuristic algorithms. The superior performance of the DAELF-HSI model has been validated on development, internal testing, and external testing datasets, achieving accuracy of 88.4%, 85.5%, and 84.5%. Furthermore, the model demonstrated excellent sensitivity and specificity in detecting patients with MCI, with corresponding AUC of 0.945 (95% CI 0.903-0.986), 0.912 (95% CI 0.859-0.965), and 0.904 (95% CI 0.846-0.962) for these datasets.

Clinical Implications

The proposed framework offers significant clinical potential for the early detection of MCI through a noninvasive and cost-effective approach, providing a viable solution for widespread screening, particularly in home settings. Heart rate variability, a sensitive marker of autonomic nervous system dysfunction, can serve as a reliable indicator of cognitive impairment, helping clinicians identify at-risk individuals early in the progression of MCI. Similarly, electrodermal activity features, such as skin conductance responses, effectively differentiate patients with MCI from healthy individuals, further highlighting the potential of autonomic measures in cognitive health assessments. Furthermore, the framework enables more

XSL•FO
RenderX

convenient and personalized MCI screening, especially in remote or underserved areas with limited access to specialized medical expertise. Its adaptability allows seamless integration into various health care environments without significant infrastructural changes, reducing the cost and logistical barriers typically associated with traditional diagnostic methods. Moreover, the model's high sensitivity and specificity, as demonstrated by its AUC performance, indicate its reliability in identifying patients with MCI, which is critical for timely intervention and monitoring the progression of dementia to more severe stages. In conclusion, it provides clinicians with a powerful tool for early detection, improving patient outcomes and ultimately alleviating the burden of cognitive disorders on health care systems.

Limitations and Future Work

For our study, it is important to acknowledge several potential limitations and proposed solutions. First, the developed detection model relies on data from electrodermal activity, photoplethysmography, and cognitive parameters and untested generalizability across different datasets, such as electroencephalogram and eye-tracking data. Future research plans to expand the dataset under laboratory conditions through electroencephalogram and eye-tracking tests to enhance the algorithm's adaptability to various data modalities. In addition, the clinical applicability of the Empatica 4 wristband is limited by its high cost, which may impede its widespread adoption for household use. Subsequent studies will explore the potential and accuracy of more cost-effective commercial wearables (such as Xiaomi Mi Bands, Huawei Bands, and Garmin Smart 5) in screening for MCI.

Conclusion

In this study, we proposed a Dynamic Adaptive Ensemble Learning Framework based on Improved Harmony Search, designed to consolidate data collected from wearable wristbands and tablet devices to establish a comprehensive and reliable method for auxiliary diagnosis of MCI. The framework uses the Empatica 4 wristband to collect EDA and photoplethysmography from participants, optimizing these physiological signals through a designed multistage automatic artifact removal algorithm. In addition, based on Improved Harmony Search, a dynamic adaptive feature selection algorithm deepens the analysis of the time, frequency, and nonlinear domain features, enhancing the model's predictive performance. An experimental study involving 1069 participants aged 60 and above demonstrated that DAELF-HSI achieved classification accuracies of 88.4%, 85.5%, and 84.5% on development, internal testing, and external testing datasets, respectively, proving its effectiveness in identifying discriminative information related to MCI. In summary, this study combines an iPad-based cognitive assessment tool with wearable devices, providing an innovative solution for developing a portable, home-friendly early detection and screening system for MCI, offering vital support to clinicians in early detection, improving patient outcomes, and alleviating the burden of cognitive impairments on health care systems.

Abstract

Background: Electronic medical records (EMRs) have undergone significant changes due to advancements in technology, including artificial intelligence, the Internet of Things, and cloud services. The increasing complexity within health care systems necessitates enhanced process reengineering and system monitoring approaches. Robotic process automation (RPA) provides a user-centric approach to monitoring system complexity by mimicking end user interactions, thus presenting potential improvements in system performance and monitoring.

Objective: This study aimed to explore the application of RPA in monitoring the complexities of EMR systems within a hospital environment, focusing on RPA's ability to perform end-to-end performance monitoring that closely reflects real-time user experiences.

Methods: The research was conducted at Seoul National University Bundang Hospital using a mixed methods approach. It included the iterative development and integration of RPA bots programmed to simulate and monitor typical user interactions with the hospital's EMR system. Quantitative data from RPA process outputs and qualitative insights from interviews with system engineers and managers were used to evaluate the effectiveness of RPA in system monitoring.

Results: RPA bots effectively identified and reported system inefficiencies and failures, providing a bridge between end user experiences and engineering assessments. The bots were particularly useful in detecting delays and errors immediately following system updates or interactions with external services. Over 3 years, RPA monitoring highlighted discrepancies between user-reported experiences and traditional engineering metrics, with the bots frequently identifying critical system issues that were not evident from standard component-level monitoring.

Conclusions: RPA enhances system monitoring by providing insights that reflect true end user experiences, which are often overlooked by traditional monitoring methods. The study confirms the potential of RPA to act as a comprehensive monitoring tool within complex health care systems, suggesting that RPA can significantly contribute to the maintenance and improvement of EMR systems by providing a more accurate and timely reflection of system performance and user satisfaction.

Introduction

The cutting-edge technologies in health care demand intense transformations in electronic medical records (EMRs) by adopting new services, including artificial intelligence (AI)–driven predictions, Internet of Things (IoT) supports, telemedicine interfaces, and cloud-based open services [1-5]. These transformations imply a rapid growth in complexity and necessitate process re-engineering in EMR systems. Complexity management in dynamic health care environments has been studied by researchers who perceived the uncertainty and unpredictability inherent to electronic health record (EHR) systems [6-8].

One significant limitation is that the actual end user experience is gradually neglected as the performance metric "improves." The focus is predominantly on component-level analyses, allowing engineers to divide labor and concentrate efforts. This approach can create gaps between the perceptions of end users and engineers in measuring system performance.

The crux of the problem lies in revealing the "interrelatedness of components" in EHRs, meaning that the mutual influences among services, modules, and business processes should be measured and tracked [9]. No single standardized model has yet emerged, leaving various complex approaches for identifying interacting components [10]. One contribution to identifying the degree of interrelatedness is end-to-end performance monitoring, which suggests measuring system complexity from an external, comprehensive, and user-centric perspective. Application performance monitoring (APM), for example, measures transaction latency from user applications, hence complementing the efforts of engineers focused on small, manageable, and self-contained components [11]. However, such approaches, sensitive to data interoperability and dynamically changing environments [12], have been too costly to be widely adopted in health care where the focus is on business re-engineering rather than system maintenance and monitoring [13].

Robotic process automation (RPA) shows potential competitiveness in external monitoring with functions focusing on human-mimicking features. A robot, in this sense, is an automated assistant residing in a computing environment, performing tasks that imitate those of people controlling other applications, usually upon an operating system [14]. The robotic metaphor thus includes 3 internal features corresponding to the human abilities of perceiving, deciding, and inputting, which have all been revolutionized by AI-based cognitive computing [15] and the three internal features are (1) an RPA bot interprets symbols on the graphical user interface (GUI); (2) an RPA bot determines actions to comply with predefined business rules; and (3) an RPA bot inputs signals into applications, mimicking those from peripheral devices used by end users.

These abilities allow the automated agents to perform manual and labor-intensive tasks, automating administrative tasks in back offices [16], including dashboard monitoring, low-judgment auditing tasks, and accounting process automation in finance, banking, and IT services [14,17-19]. Therefore, the implication of RPA in complexity management is end-to-end performance monitoring that reflects the experiences of end users by simulating their activities and freeing engineers from excessive feedback [20]. A "robot" can fulfill external monitoring with an outside-in approach that witnesses the same glitches end users perceive [21].

RPA, with its "build above system" features, has the potential to combine with business process management (BPM) and overcome the intrinsic limitation that systems should be re-engineered. BPM has succeeded in establishing patterns for business process integrations in health care but has not been effective at guiding process monitoring for risk management [22,23]. Continuous reforms in health care organizations have been mandated for their operational success and patient-focused process improvements [24,25]. Thus, the expected synergy between the 2 methodologies is that RPA enhances costly process automation, while BPM provides the holistic perspective of detecting, auditing, and optimizing business processes [26].

This study explored the potential of RPA in complex EMR systems with its role as "a canary in a coal mine" [11], presenting generalizable findings from a 3-year project at Seoul National University Bundang Hospital (SNUBH).

The paper posits RPA as a means to bridge the gap between the limitations of both component-level system monitoring and application-level monitoring. The former, with its engineering-centric approach, often fails to align with the end users' experiences, as system monitoring reports may not accurately reflect what end users actually encounter. The latter, while focused on the application level, cannot offer a universal solution due to its lack of scalability and the high costs associated with performance analyses. RPA, in contrast, facilitates a user-centric perspective by designing bots that act as representative users within the hospital, performing the most essential and shared activities. Consequently, any failures or performance degradations observed by the RPA bots are indicative of significant issues within the system, potentially leading to a systemic collapse in the worst case.

The analysis revealed significantly enhanced capabilities of RPA bots beyond initial expectations. Much like a meticulous human tester, RPA bots frequently identified errors immediately following software deployments and detected failures in external services outside the expertise of in-house developers. However, certain challenges hindered RPA from becoming a universal solution for monitoring services. This conclusion is supported by both quantitative data from RPA process outputs and qualitative insights obtained from interviews with hospital practitioners.

Methods

Ethical Considerations

Human Subject Ethics Review Approvals or Exemptions

This study was conducted in accordance with the ethical guidelines of the institutional review board (IRB) of SNUBH (approval number SNUBH-IRB-2021-004). The research involved secondary analysis of anonymized patient data extracted from hospital information systems. In addition, our

XSL•FO
RenderX

study included user interviews, for which individual approvals were obtained in accordance with the IRB guidelines. Due to the anonymization of patient data, the IRB granted an exemption from requiring individual informed consent for the secondary data analysis, as per institutional policies and national regulations.

Informed Consent

As the study used pre-existing anonymized data, informed consent was waived by the IRB. The original data collection process ensured that all participants consented to the use of their data for research purposes, which was documented in the hospital's consent forms. For the user interviews conducted as part of the study, individual informed consent was obtained from all participants, aligning with the guidance provided by the IRB. The scope of the consent for both the secondary data and interviews included future secondary analyses, adhering to institutional policies.

Privacy and Confidentiality

All patient data were anonymized before analysis, with direct identifiers removed and indirect identifiers encrypted. Access to the data was restricted to authorized personnel only, and secure servers were used to store and process the information. Data-sharing protocols adhered to the guidelines stipulated by the Health Insurance Portability and Accountability Act (HIPAA).

Compensation Details

No compensation was provided to participants, as this study exclusively involved the analysis of pre-existing, anonymized data and user interviews. The nature of the research did not require any direct monetary engagement with participants.

Project Background

SNUBH management expressed strong interest in integrating monitoring services to identify continuous performance degradations from the end user's perspective. The Healthcare Information and Management Systems Society in the United States has mandated health care organizations, especially those that have achieved Stage 7 certification, to detect and prepare for unexpected system downtime [21,27]. Furthermore, internal reports from users regarding performance degradations were often overlooked by engineers due to the absence of appropriate analysis tools. Application-level monitoring frameworks, such as APM [28], were not favored by the management mainly, primarily due to high reengineering costs associated with re-engineering [12].

In the meantime, hospital managers found themselves redundantly checking the performance of business processes in unsystematic ways. The requirement to manually perform these tasks led to intermittent execution and a lack of precision. Consequently, hospital management anticipated that RPA's mechanism could supplant the labor wasted on manual testing to monitor performance regression [29].

Robotic Process Automation Integration

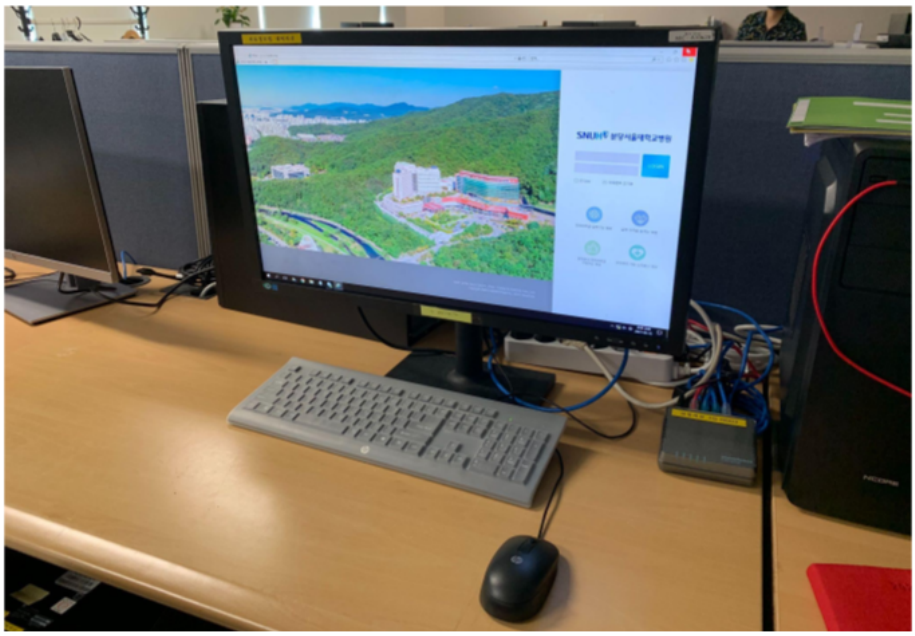
Iterative Development Process

A task force team engaged in an iterative process to implement system-monitoring RPA bots. The objectives were to reliably simulate business workflows on the hospital's production systems and to establish an organizational protocol for responding to detected performance anomalies.

The proof of Concept process, spanning from January to July 2020, involved repeating cycles from developing requirements to implementing prototypes. This approach was adopted because of the belief that establishing business requirements for a novel methodology should be carried out with meticulous attention to detail. To broaden their understanding of the field, the administration contracted with different RPA third-party vendors at each iteration. Alongside the software prototype development, managers also put in place organizational protocols to react to alerts, with responses tailored to the severity level of the incident.

The development of RPA bots followed an iterative process to address challenges specific to monitoring EMR systems. Frequent user interface (UI) updates initially made it difficult for bots to recognize dynamic elements, but this was resolved by implementing advanced pattern recognition algorithms and adaptive learning techniques to enable automatic adjustments to UI changes. Early versions of the bots also relied on timer-based execution, which caused inefficiencies when dealing with variable system latencies. To address this, event-driven configurations were introduced, allowing the bots to respond dynamically to system triggers.

Ensuring stable performance across diverse environments was another challenge. Extensive pilot testing and iterative adjustments refined the bots' logic, enabling them to operate reliably in varied setups. Incorporating feedback from multiple departments presented additional complexity, but this was streamlined by centralizing feedback and conducting regular cross-functional meetings to align bot functionality with operational needs.



This iterative approach significantly improved bot performance and adaptability for broader health care applications.

Technical Environment

The RPA bot environment is set up to mirror that of a worker performing the target tasks. This setup includes a dedicated personal computer in an IT office, equipped with the RPA program, one virtual private network program, and 3 hospital system applications. To enable manual oversight, a monitor, keyboard, and mouse are also provided, allowing a manager to take control of the machine if necessary. A notable feature in security configuration is that RPA bots can use the same virtual private network program that workers use to access external networks. This capability distinguishes RPA from other automation technologies and thus necessitates additional security channels. Figure 1 shows the personal computer dedicated to RPA usage in the hospital office.

XSL•FO
RenderX

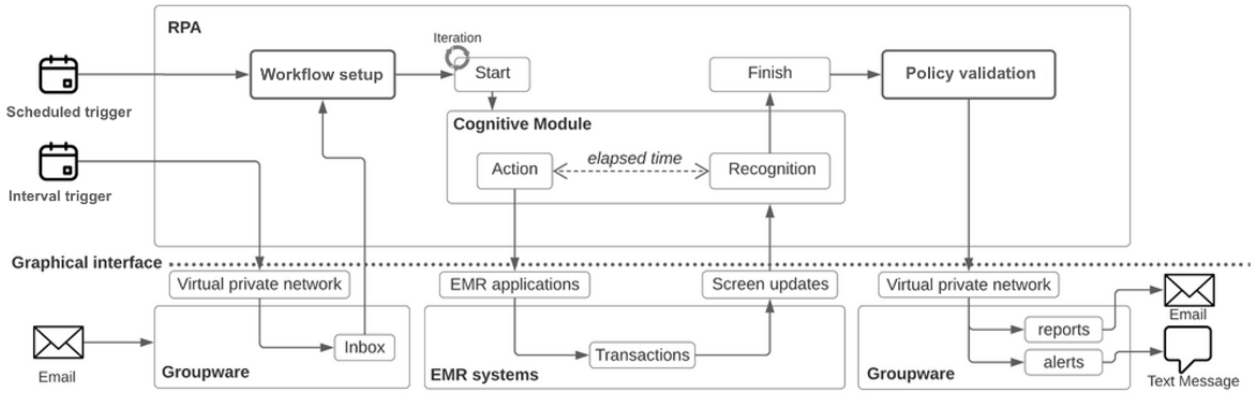


Figure 1. Monitoring unit with robotic process automation in Seoul National University Bundang Hospital. EMR: electronic medical record.

Robotic Process Automation Reports and Governance

RPA reporting processes and reactive governance were refined over several iterations. RPA bots could be activated either through a periodic scheduling system or upon receiving an email order from a supervisor. A single bot was responsible for executing dozens of business processes, estimating and reporting application performance while interacting with 18 modules within the systems. Each RPA business process was designed to mirror a critical business process within the hospital, affecting numerous other processes or significant clinical practices. The methodology for performance measurement was aligned with use perception. For instance, a request initiated by clicking a button on the interface was considered complete once a change was detected on a specific part of the screen. The performance metrics captured during this process were then recorded and documented in an Excel file. Based on the severity and abnormality of the data found, the RPA bot was also programmed to decide the recipients of email and SMS text message notifications, ensuring timely communication of potential issues. Figure 2 illustrates the process of system monitoring fulfilled by RPA agents.

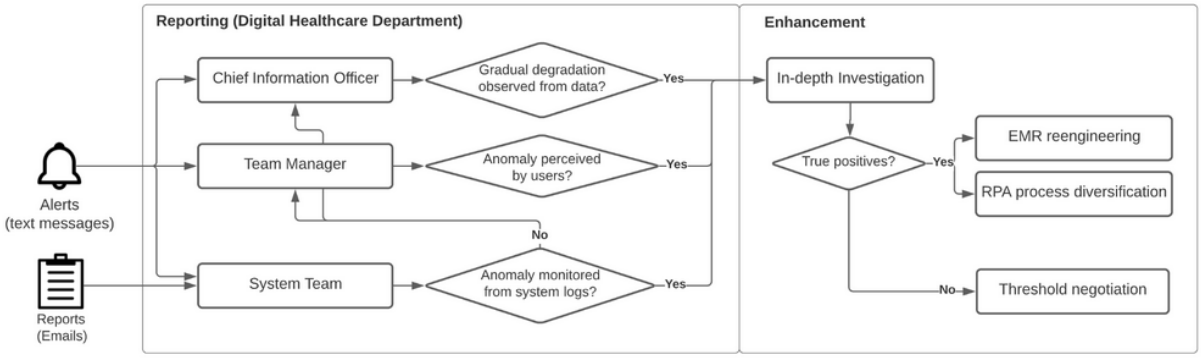

Figure 2. Process monitoring with robotic process automation.

There was a strong consensus within the organization that the governance should capitalize on the RPA alerts by establishing a feedback loop to prevent the IT department from disregarding the findings due to excess false positives. This governance mechanism was designed to align with the hospital's reporting structure. Mobile text messages were used to alert stakeholders about serious anomalies detected, while email served as the primary channel for routine reporting. To ensure oversight and prompt action, all alerts, if overlooked by middle managers and engineers, were escalated to the hospital's Chief Information Officer. Figure 3 depicts the governance structure for reporting anomalies detected by RPA agents.

Robotic Process Automation Monitoring Analysis

Overview

The goal of this study was to investigate the functionalities and advantages derived from implementing RPA in end-to-end monitoring within the health care sector. Given the innovative nature of this methodology in health care and the absence of quantitative benchmarks, a mixed methods approach was adopted. This approach aimed to assess the multifaceted value of RPA attributes, facilitating an understanding of how findings from quantitative and qualitative data converge [30].

Task-Oriented Robotic Process Automation Process Selection

The selection of RPA processes was deemed a critical aspect of the project to optimize the benefits of automation. Initially, 10 standardized processes at SNUBH, frequently used by clinicians, were identified. These encompassed 3 types of patient visits (inpatient, outpatient, emergency), as well as subsequent processes such as physician orders, common laboratory examinations, pharmacy visits, etc. These processes, while central to clinical practice, were noted for their significant latencies. RPA managers adopted a task-oriented approach in selecting the processes, aiming to ensure that the improvements or any degradations in performance would have a substantial effect on user experiences. As a result, functionalities across 56 pages in the main hospital application, which represent core interactions between the hospital's main system application and its end users, were selected for automation.

Monitoring Data

The monitoring data comprised request-response duration data, alert records, and resolutions provided by the engineering team. For the selected functionalities, RPA agents performed the defined processes by navigating through 17 large service modules of the hospital information systems. During each interaction, primarily initiated by mouse clicks, the RPA agent awaited a detectable change on the screen and verified whether the expected execution had taken place. A screen change was deemed "adequate" if the image match rate exceeded 90% upon comparison with the standard screen where fetched data were expected to appear. After each execution, thresholds were consulted to decide if an alert should be issued.

RPA agents were scheduled 4 times daily from January 2021 to December 2024. A report was generated and sent to managers whenever the response time exceeded the set threshold. Over 3 years, more than 700 such events were reported to the management. Engineers worked alongside managers to pinpoint root causes and resolve the cases whenever feasible.

The data produced by RPA bots effectively highlighted the long-standing discrepancies between end users' and engineers' perceptions. Many recorded latencies showed unexpectedly large variances, underscoring the challenge of replicating the slowdowns experienced by end users. To quantify this issue, the gradual increase in latencies over several years was calculated, with processes showing significantly high variations subject to in-depth analysis. Indeed, most services were showing meaningful high fluctuations. In some complex cases, it was discovered that a module required a fundamental overhaul of its information structure, indicating that extensive refactoring was unavoidable.

Robotic Process Automation Manager Interview

The qualitative study targeted managers and system engineers within the IT department of SNUBH who had experience in developing or managing the RPA program. The objective was to uncover the core experiences to shed light on the role and effectiveness of RPA in the organization [31].

The sample size was directed by the research question [32], consisting of 8 managers and 7 engineers, each with at least 3 years of experience at the hospital. Purposeful samples were collected using snowball sampling until data redundancy or saturation was achieved, this point was identified when no new information emerged and was added to the findings extracted from previous interviews [33].

The analysis of participants' experiences was primarily reductive as responses were broken down into smaller categories and later assembled to evaluate the measurement metrics. Initially, researchers thoroughly read the transcripts to immerse themselves in the texts. Subsequently, they coded the transcripts by identifying passages and meaning units that highlighted participants' fundamental experiences of RPA. Of the 15 transcripts, a total of 392 significant meaning units were extracted. Finally, researchers revisited the transcripts alongside

XSL•FO
RenderX

the measurement metrics to identify themes emerging from the meaning units.

Results

Overview

The results presented herein were derived from a dual approach that incorporates both quantitative and qualitative methods, combining the data generated by RPA robots with interviews conducted with RPA managers. The RPA bots, which have operated on predefined processes for over 3 years as introduced in the Methods section, have accumulated reports revealing significant insights. These insights, combined with the engineering team's reactions to the reports, particularly highlight gaps in the user-perspective analysis that engineers have struggled to bridge. Multimedia Appendix 1 outlines the business processes monitored by RPA, including the domain, category, specific process steps, screen names, and threshold values (in seconds) for triggering alerts. Sample monitoring results are provided in Tables S1 and S2 in Multimedia Appendix 2.

The quantitative analyses in the sections mentioned below, "Uncovering User-Level Performance Fluctuations: RPA Bridges the Analysis Gap Between Users and Engineers," "Holistic Incident Reporting: RPA Broadly Captures Diverse Causes of Issues," and "RPA Manager Interviews: Best Practices are Calibrated Through Iterative Discussions," focus on a comprehensive analysis akin to traditional end-to-end system monitoring. That is, the modern trend in software system monitoring emphasizes identifying core components and concentrating expertise in individual areas. However, the complexity of hospital information systems precludes a universally applicable strategy of compartmentalizing the structure. Unseen dimensions gradually undermine user experiences. The role of RPA agents has proven extremely effective in supplementing the existing monitoring governance, by performing important clinical processes "by hand." The most unexpected result is the extensive coverage of RPA processes, which ensured system stability by identifying hidden errors after regular system deployments. This indicates a broader variety of reasons for the RPA agent to report incidents, offering a more accurate reflection of realistic user experiences.

These insights uncover long-standing challenges that users have implicitly faced for years. Sections mentioned below, "Quantifying 'Real' User Experience: RPA Detects Gradual Degradation in End-to-End Service Latencies" and "Uncovering User-Level Performance Fluctuations: RPA Bridges the Analysis Gap Between Users and Engineers," detail how gradual performance degradation and inconsistencies have historically created disparities between user experiences and engineers' performance metrics. Furthermore, the section "Holistic Incident Reporting: RPA Broadly Captures Diverse Causes of Issues" extends the discussion beyond mere performance tracking to include external influences and errors invoked by a deployment. While these issues should not happen theoretically, they become apparent only when combined with substantial real-world data, which sometimes contradicts the consistency assumed by engineers.

Finally, interviews with 20 managers, as discussed in the section "RPA Manager Interviews: Best Practices are Calibrated Through Iterative Discussions," have further clarified the desired direction for RPA-driven monitoring systems. These interviews aimed to gather insights on both the perspective and progress of managers regarding RPA agents. The ability of RPA tools to provide a high-level system overview has quickly grown confidence in managerial support for RPA technology leading to more precise calibration of RPA tool usage. However, initial reservations about trust and data sensitivity persisted, highlighting areas where RPA agents are not effectively adaptable. This reveals practical limits that may vary depending on culturally diverse work ethics.

Quantifying End-to-End Level User Experience: Robotic Process Automation Detects Gradual Degradation in End-to-End Service Latencies

Table 1 summarizes the latency of service calls, sampled from the interaction reports of RPA processes, which exhibited performance degradation accumulated over 3 years. The sampled service calls belong to 3 categories: infrastructure check, outpatient process, and inpatient process. This summary presents the first comprehensive evidence of end user experience, concretely demonstrating the long-term latency increase.

XSL•FO
RenderX

Table 1. Service latency analysis over years.

Robotic process automation process	Mean of latencies (seconds)			
Theme and service call	Year 2021	Year 2022	Year 2023	Increase
Infrastructure				
Run the main client	4.9	5.1	6.5	1.6
Login to the main client	4.8	5.2	5.9	1.1
Run picture archiving and communication system	2	2	2.2	0.2
Login to picture archiving and communication system	9.2	9.5	12.2	3.0
Run groupware	3.5	3.6	3.8	0.3
Run virtual desktop infrastructure	12.9	13.4	13.2	0.3
Outpatient				
Outpatient listing	17.8	23.9	25	7.2
Outpatient selection	15	20.4	20.2	+5.2
Outpatient navigation	3.6	4.4	5	+1.4
Inpatient				
Inpatient listing	1.5	1.6	1.6	+0.1
Inpatient selection	2.3	2.8	3.2	+0.9
Inpatient navigation	2.5	2.3	2.5	+0
Nursing list	2.8	2.8	3	+0.2
Nursing list2	4	4.1	4.7	+0.7

The table above lists three representative cases of processes and their selected functions executed by the RPA agent on various time frames on a daily basis. The changes in end-to-end latencies are recorded over 3 years. Among the most distinct cases, the outpatient process emerges as the most challenging to manage, displaying a clearly increasing trend in latency.

This straightforward result serves as critical evidence for the user experiences of many end users of the hospital systems who frequently complain about the system “feeling like” it is slowing them down. Engineering teams typically focus their monitoring efforts on the system’s principal components, such as database queries, server API calls, and network latencies. These measures are particularly effective in the early stages of the health care organization because improvements in these components typically lead to noticeable enhancements in user experiences. However, as the complexity of the hospital information system increases and services mature, hidden factors increasingly contribute to its performance degradation.

Uncovering User-Level Performance Fluctuations: Robotic Process Automation Bridges the Analysis Gap Between Users and Engineers

Table 2 samples service calls that were highly ranked for showing significant variations. “Event Count” refers to the number of incidents reported by RPA agents over 3 years (2021-2023) due to exceeding their corresponding thresholds.

Table 2. Latency fluctuations.

Service call	Mean (SD)	Event count	Threshold
Nurse inpatient list	3.03 (0.55)	4	5
Nurse injection reservation	15.9 (1.6)	11	18
Health screening reservation	3.05 (0.52)	4	5
Examination results	6.94 (0.98)	19	8
Nutrition manage registration	2.66 (0.55)	7	5
Patient record viewer	4.24 (0.58)	112	5

One of the most significant contributions made by the RPA agent is the quantification of fluctuations in user experience. A significant number of the latencies recorded by the RPA agent demonstrated high SD, indicating that multiple incidents were detected and finally reported to hospital managers. For instance, the examination results function, which involves retrieving examination results for daily outpatients, exhibited notable instability, with an SD of almost 1 second against its usual

XSL•FO
RenderX

latencies of 7 seconds. This function encompasses multiple sub-fetching calls, updated weekly, making it difficult for individual performance testing to ensure stability from a holistic perspective, despite latencies generally falling within acceptable thresholds according to engineers' environments.

This evidence of a broad spectrum of latencies is particularly valuable in debates between users and engineers struggling with the lack of reproducibility of the delayed system response users experience. Even small bugs are difficult to pinpoint from a user's perspective, which is not their primary role in the organization. Expanding the scope to performance, many diagnoses suggested by users were considered insufficient as engineering reports were consistently indicating component-level monitoring within 0.01-second intervals. However, such evidence collected by engineers has failed to capture the true user experience.

Indeed, the complex nature of these systems, with their interdependencies and the frequent updates of components, can obscure the root causes of performance fluctuations. As systems evolve and expand over decades, new features introduced outside the existing framework often inadvertently introduce inefficiencies. Moreover, even if all individual factors are efficiently manageable, the dynamic nature of hospital operations, including variable patient loads and the unpredictable demand for different functions, exacerbates these challenges.

Holistic Incident Reporting: Robotic Process Automation Broadly Captures Diverse Causes of Issues

Table 3 groups events reported by RPA agents based on the cause of the occurrence and the response to each event. Initially, the focus was solely on detecting query degradation events. However, as monitoring progressed, the scope of categories expanded. Identifying erroneous deployment events proved particularly effective in preventing significant operational disruptions in the hospital. Query degradation is focused on specific query inefficiencies, while performance inconsistency encompasses broader, variable performance fluctuations across the system. Erroneous deployment: errors detected immediately after deployment due to misconfigurations or incomplete processes. Bad deployment: performance degradation observed postdeployment caused by insufficient planning or testing.

Table 3. Incident cases.

Event type	Cases	Reasons	Resolutions
Erroneous deployment	9	An error was detected immediately following a software deployment.	Resolve the identified error.
External program issues	5	External programs caused issues (network, authority, error, etc)	Resolve the identified issue.
Bad deployment	3	Performance deteriorated noticeably right after software deployment.	Optimize performance post-deployment.
Query degradation	3	Inefficiencies in query execution became evident with increasing data volume.	Enhance query efficiency and performance.
Performance inconsistency	660	Query response times fluctuate with daily data volume changes.	Develop a strategy for structural improvements.

One of the unexpected yet invaluable contributions of the RPA agent has been its holistic approach to testing. Originally aimed at measuring system performance from the users' perspective and quantifying their experiences, the scope of the RPA agent's coverage extended far beyond these initial objectives. For example, in the case of erroneous deployment, the RPA agent identified errors immediately following regular software deployments, with all 9 reported cases attributable to the intricate complexities of the hospital information systems. Often, modifications in one module inadvertently trigger errors in another, through the information flow of real data. These are the types of issues typically addressed by application-level testing, yet designing a comprehensive experiment often eludes the grasp of individual engineers.

Furthermore, the RPA's goal cannot solely be the exhaustive identification of errors, which is extremely difficult to achieve. Instead, the true value of the automated agent's reports lies in ensuring that common processes (daily tasks performed by thousands of employees for tens of thousands of patients) remain unaffected. This precaution helps prevent incidents from escalating into broader performance issues that could impact the entirety of hospital operations.

Second, the second row in the table illustrates that, while the RPA processes operate in the same environment as users, they are susceptible to the influence of external, peripheral, and temporary system components. Notably, one incident was reported due to a memory leak from an embedded external program. The integration of third-party applications or web-based services is sometimes overlooked due to their perceived minimal impact on the overall system. However, the trend toward incorporating a diverse array of software products has transformed the system into a complex assembly of heterogeneous components that interact with one another, potentially affecting major processes through their services.

Finally, as detailed in this section, the identification of 660 cases of performance inconsistencies has prompted the engineering team to strategize toward stabilizing the end-to-end latencies of major practices, including the outpatient management process. This initiative underscores the RPA agent's crucial role in addressing diverse issues; it not only detects immediate issues following regular deployments but also facilitates long-term improvements to enhance system reliability and user satisfaction.

Robotic Process Automation Manager Interviews: Best Practices Are Calibrated Through Iterative Discussions

The qualitative data collected through interviews illuminated how the adoption of RPA impacted the system and the organization. A central point of discussion was "Which processes should be monitored?" leading to a more explicit understanding of the pros and cons of adopting RPA bots.

Key phrases extracted from the interviews were then categorized into 5 clusters aligned with core themes: understanding of RPA, prediction capability, trust in robots, downsides of cognitive agents, governance facilitator, and the RPA epiphany. These encodings provide concrete descriptions of the abstract themes, underpinned by sampled phrases.

Table 4 categorizes the primary advantages of implementing RPA as identified by managers, with specific themes and corresponding coding. Sample phrases from interviews illustrate the practical impact of these benefits on process efficiency, cross-departmental cooperation, and governance within the organization.

Table 4. Summary of robotic process automation benefits based on managerial feedback.

Themes (pros) and coding	Sample phrases
Ease of understanding	
• Simplicity of processes • Repetition of processes • Well-defined processes	"The simplicity is that the task does not require human judgment and is defined by a clear business rule"
Cooperation invoking	
• Cross-departmental collaboration • Joint software update tests	"...Moreover, we can impose an RPA[a] bot on all tasks that were covered by 16 managers from different departments"
• Responsive governance	"...However, the bot now delivers an SMS or email to each manager responsible for each process. Speed has always been an issue, and now it is working...."
Governance facilitation	
• Evolving thresholds • Engineer-user negotiation	"...I argued that the right way is to focus more on whether it hampers the process for the user. Thresholds were set in such a conservative manner. "
• Enhancing business interoperability	"...And then another email can re-trigger RPA bots to confirm the resolution of the issue."

[a]RPA: robotic process automation.

A majority of managers highlighted the benefits of adopting this new technology as a reliable system monitoring and comprehensive testing service. First, the ease of understanding RPA was seen as a significant advantage, offering managers user-friendly methods to interpret processes focused primarily on clinical practices. Managers appreciated the intuitive and understandable process definitions, clearly outlined on the system's GUI.

Second, RPA to foster departmental cooperation was seen as ideal for addressing the challenges posed by hospital information systems, which are often divided into disjointed components. From the UI perspective, with which the RPA agent interacts to simulate human behaviors without assuming any engineering team affiliation, one RPA process can interact with up to a dozen components, identifying cross-departmental issues arising from information inconsistencies. Addressing one issue typically requires collaboration among engineers from multiple departments to determine its root cause.

Third, the RPA agent acts as a governance facilitator, enabling more realistic and evidence-based negotiations between engineers and users. The previously dominant engineer-driven metrics proved inadequate for sustaining effective discussions on system performance management. However, as indicated in the sections above, the focus could be shifted toward quantifying user experiences, thereby identifying how efforts should be allocated for process improvements.

Table 5 summarizes managerial feedback on the drawbacks of RPA, including trust issues, cognitive limitations, and insightful epiphanies from its application.

XSL•FO
RenderX

Table 5. Managerial insights on robotic process automation challenges.

Themes (cons) and coding	Sample phrases
Trust issues with the robots	
• Recognition accuracy • Handling of sensitive clinical tasks	"...The system suddenly alerts me of OCR failures which was the case until yesterday. We cannot allow its applications to patient-related tasks if it isn'*t* 100% consistently guaranteed."
Downsides of cognitive agents	
• Ambiguous state definition	"...The current configuration checks whether the hospital logo is floating to decide if the website has loaded. However, the image server often fails while the other functions are completely working."
• Unexpected maintenance costs	"...Yes, robotic process automation recognizes a shape as people do, but that depends on the context. The bot can find a red button after being relocated but it won't find the button when color or text changes."
Deriving robotic process automation epiphanies	
• Persuasive demonstration • Generation of personalized ideas	"...and I felt 'Oh, that's what this is doing'. After that, the application seemed to be limitless..."

However, the accumulated experiences have not repositioned RPA bots as a universal solution applicable to all clinical processes. First, the most sensitive issue relates to the scope of information that RPA agents handle. Many major processes involving complex and critical clinical information require RPA agents to manipulate information states. Although all state-modifying operations are designed to work with dummy data generated exclusively for the RPA agent, unpredictable incidents can arise from misinterpreting commands, affecting data on the production server. Ironically, as AI-based decisions become more complex and human-like, the likelihood of errors increases, mirroring those made by inexperienced workers. This risk has deterred managers from extending the monitoring scopes to clinically sensitive services, which are deemed crucial areas for robotic coverage.

Second, contrary to expectations, RPA agents, as cognitive agents, lack flexibility in varying situations. OCR-based recognitions depend on hints from managers, which may become outdated due to system maintenance. Since RPA processes involve complex commands based on OCR recognition logic (eg, detecting some pop-ups) there is a greater chance of encountering unadaptable modifications. For example, an unrelated pop-up appearing during a process, easily dismissed by a human tester, poses a challenge for an RPA agent interpreting it as an incorrect message response. These scenarios have led to unexpected maintenance costs and increased frustration due to inconsistencies, making the unambiguous definition of UI interactions a significant challenge for managing the vast number of RPA agents.

Third, the "RPA epiphany" has not been universally shared. Developing a productive RPA process requires the cooperation of clinicians and other hospital staff, yet reactions to the same approach can vary. Some employees fear job loss to highly efficient robots, while others see it as creating a burdensome new task, compelling them to manage the tedious robot postinitialization. Both perspectives hold some validity, necessitating extensive discussions to expand use cases.

Discussion

Study Summary

The effectiveness of RPA in monitoring EMR systems was measured through latency data and interviews. In response to the demand of end users who have sought a new indicator reflecting the quantification of their experiences, RPA processes were carefully chosen to monitor the essential clinical processes containing information-heavy user tasks. The latency data collected through the monitoring process proved that indeed the comprehensive perspective of RPA bots serves as the bridge valuing the cross-disciplinary efforts of users and engineers. Finally, the qualitative interview revealed notable characteristics of RPA that affected the EMR management organization to reform the governance, and highlighted RPA bots, as a new cognitive agent resembling humans, having pros and cons.

Which process should be selected for the monitoring tasks? This simple question has been an important topic ever since the first emergence of BPM [34] because most automation project lifecycles started from process identifications. With a prevalent top-down approach, the start of a project was focused on business goals [35] and then spread to subordinate departments and users. However, such an approach was often attributed to the failure of recent RPA implementations, motivating studies to standardize and quantify process selections in RPA projects [36,37]. The strategy used by managers in the SNUBH project involved iteratively identifying the most common components impacting real-world practices, with a focus on using RPA agents to simulate the tedious testing tasks performed by end users. This approach, though simple, proved to be exceptionally effective. The collected reports provided insights into end user experiences that were among the closest to any similar efforts done to gather data for the same purpose.

Previous studies in APM have been challenged by significant fluctuations due to user-level performance measurements, requiring extensive expert analysis [11,12]. However, the integration of RPA bots, aimed at mirroring the "real" user experience as closely as possible, transforms the apparent downside of APM into an advantage. The delays observed in

XSL•FO
RenderX

Table 1, although mostly under 5 seconds, may not significantly impact end user experience on an individual basis. However, the cumulative effect of these small delays over extended working hours could influence overall productivity. Furthermore, understanding the root cause of such delays is crucial. Delays resulting from natural database growth might be considered acceptable, while those stemming from other factors should prompt further investigation. RPA plays a pivotal role in identifying and quantifying these delays, enabling management to assess whether they fall within acceptable performance thresholds and take corrective actions when necessary. The RPA project team prioritized ensuring the usability of the most critical hospital processes to enhance end user experiences. This approach is entirely user-centric, lacking any scientific purpose or methodology, stemming from the recognition that the system's complexity prevents engineers from maintaining a comprehensive view of the services. User-driven process monitoring accurately reflects true priorities, preventing engineers from becoming overly fixated on component-level details.

The observed increase in task completion times, as shown in Table 1, aligns with the natural growth of the database over time, which can contribute to delays in end-to-end service. In addition, the system management (SM) team at the study hospital develops and implements approximately 700 new programs annually to enhance EMR operational efficiency. These frequent updates can also impact service performance. The integration of RPA proved beneficial in detecting such delays, enabling targeted analyses of their root causes. This facilitated database tuning by database administrators and prompted the SM team to review and optimize newly implemented program code, ultimately improving system performance and ensuring operational continuity.

Moreover, the monitoring process can still be initiated by engineers, serving as a starting point for identifying key areas for improvement. Performance degradation data collected by RPA agents involve multiple factors, necessitating cross-departmental collaboration, which can lead to inefficient practices in identifying root causes. Indeed, most cases required several hours to days to identify potential engineering factors. However, there is a consensus that these factors are of the highest priority for affecting the real-time practices of end users, and the performance standards to be maintained can be relatively easily negotiated. On the other hand, the consistent increase in system complexity has made component-centric analysis and improvements less impactful, as they no longer directly enhance user experiences. RPA agents act as proxy users, emphasizing the most critical information flows that the system must maintain smoothly. The low standard deviation observed in Table 2 indicates minimal fluctuation in delay times, suggesting stability. However, this stability also reveals that delays are consistently recurring rather than sporadic. Such persistent delays, even if small, can accumulate over time and impact overall system efficiency. This underscores the importance of addressing not just large fluctuations but also ongoing, minor delays. RPA's capability to monitor and report these patterns enables targeted optimization efforts, helping to mitigate their long-term effects on system performance and user experience.

Interview themes unveiled the complex ways in which the organization leverages new technology. RPA, acting as a cognitive agent, introduced a novel approach to automation integration. RPA bots remained "lightweight," effortlessly accessing functions by overlaying the interface of target EHR applications [38]. These features made technical barriers minimal, allowing RPA managers to implement RPA logic with their extensive knowledge of application-level practices without frequently consulting EHR engineers during the project. The speed of integration was accelerated by the straightforward development process and the flexible recognition capabilities supported by RPA.

However, as mentioned in the Method section, unforeseen drawbacks of RPA emerged due to its reliance on UI-based interactions. These included a vast number of screen change recognitions, and although RPA was adaptable enough to approximate detections, such as locating a button with a specific phrase, modifications to the UI itself exceeded the scope of its flexibility. Consequently, UI elements, being primarily graphical and perceived as less critical to service logic, now require a shift in perception and further study for extended and reliable RPA use.

An incident where an engineer identified the hospital logo as a weak point of the configuration, which defined the loaded groupware web page, illustrates this challenge. The logo's reliance on a content delivery network service, which frequently failed, underscored a common misunderstanding of UI behaviors. In previous studies, this issue has been explored in ontology-oriented UIs, which advocate for the declaration of high-level models and their translation into program UIs [39]. An ontology, in this context, is defined as "a logical theory comprising a formal vocabulary" [40] that supports UIs, ensuring precise and consistent conceptual organization of the UI [41]. Therefore, developing an intermediate ontological model of the UI to support RPA projects could be a crucial preliminary step.

Observation of the RPA adoption led to an evaluation of the organizational-level contribution of RPA to the complexity management of EHR systems. Meaningful subjects included threshold evolution, responsive governance, and business interoperability facilitation. Threshold evolution was the unanticipated practice where engineers and supervisors negotiated thresholds of alerting performances to cut off false positives while preserving enough predictive qualities.

Beyond performance monitoring, SNUBH supervisors emphasized that the RPA project significantly enhanced responsive governance. RPA acted as a conduit between users and machines, transforming subjective empirical experiences into objective, meaningful data. From this perspective, RPA emerged as an ideal evidence collector, silently tracking fluctuations in system performance without the burden of its repetitive, tedious tasks.

In terms of business interoperability, organizational responsiveness was notably improved through the use of RPA bots, which served as digital messengers at the application level. Users could send requests to and receive reports from RPA bots via email, mirroring the function of chatbots—computer

XSL•FO
RenderX

programs designed to simulate human conversation. Gradually, RPA bots became part of the workforce team, communicating through standard messaging channels and enhancing end user satisfaction [42].

Core Implications

This study's outcomes will enlighten decision-makers about the capabilities of RPA in evaluating business process performance, with a specific focus on simulating user activities on complex EHR systems. Initially, the adoption of RPA for monitoring EHR systems was anticipated to surge rapidly due to its direct and intuitive development procedures. However, the revealed end user experience was remarkably poor: the study uncovered significant variations in the latencies of crucial common service calls. Such monitoring data can be regarded as the definitive "ground truth" of end user experiences, fostering constructive discussions between users and engineers.

Nonetheless, challenges like UI-driven maintenance issues and the complexity of interpreting results complicate ongoing quality control efforts. To mitigate these issues, there should be the establishment of standardized, iterative practices aimed at judiciously identifying areas deserving daily attention from RPA agents. Furthermore, psychological resistance could decelerate RPA adoption in health care settings. This reluctance stems from the cognitive capabilities of RPA bots, which closely mimic tasks traditionally performed by human employees, raising concerns about their potential impact on the job market in the industry.

Future Directions

RPA naturally overcame the shortcomings by providing event-driven configurations based on cognitive analysis of the screen changes. However, some questions recognized in this study should be answered to aid in the success of future RPA projects.

Could RPA bots entirely replace traditional GUI-based testing frameworks? After stabilizing RPA bots to detect process performance degradations, the EMR management team found that RPA bots are eventually fulfilling an advanced GUI-based testing role by resolving the following challenges. Most GUI tests showed target application-dependent performance measurements [43] and object recognition techniques [44] that limited their usage across a large system. Also, GUI testing automation suffered a "temporal synchronization problem" arising from timer-based process execution, limiting flexibility for any latencies [45,46]. Recent studies seem to recognize the potential benefits of RPA in the field [47,48].

How can system complexity be managed after RPA adoptions? This question is directly connected to the practice in the project but, as a goal of this study, also applies to future RPA implementation projects. Since RPA sits upon the other systems, it creates another layer of complexity in the automation. It is anticipated that most RPA projects will devise a monitoring protocol as part of the automation to maintain performance. Furthermore, RPA is considered slow by certain companies because its front-end level execution is inferior to that of back-end systems [49], and performance measurement is difficult, so overall system complexity after integration has to be considered in the decision to adopt RPA.

How can RPA build trust among users of EHR systems? A common misunderstanding about RPA is that the automation is accurate simply because the implementation is easy and intuitive for users. However, as revealed in this study, users were skeptical in at least 2 cases. First, the mismatch between GUI and user intent remained unresolved. Ontological models were suggested to match the domain behind GUI. The growing importance of such models is due to their practical usage, which allows workers and automation engineers to seamlessly accept the domain that supports the GUI. Second, contrary to this pragmatic view, user trust in cognitive recognition was not sufficient even though failure rates were low. User trust issues in automation are not new and require time because EHR users tend to be more conservative about this.

How can RPA harmonize with organizations and their governance? It has been acknowledged that a common mistake in treating RPA is to limit its role as a simple piece of software rather than as a foundation for leading digital transformations [50]. Therefore, RPA governance should be an integral aspect of the implementation of RPA so that scalable cross-departmental use is realized. The components of RPA governance may include process identification and prioritization, distribution of RPA bot responsibility, RPA knowledge management, and reward systems [51].

Study Limitations

The limitations of this study lie in the practical constraints of the SNUBH project. First, this study only applied RPA to a single testbed. Significant considerations were required to make the business process performance monitoring model generalizable. However, the project results and other references imply that expanding and transferring RPA implementation is relatively straightforward once demonstrated to work for one scenario, unlike frameworks relying on specific technology stacks. This low degree of system dependency allows RPA modules to be adapted to similar systems.

A second limitation is that RPA was not configured to cover the diverse infrastructural environments and actual end user experiences. End users working in SNUBH have divergent computer environments and application usage patterns. This has raised criticism as to whether RPA bots properly contribute to complexity management when they operate in such a controlled environment. A compromise had to be made by setting the computer running RPA bots to mirror the computers used by general end users as closely as possible. This decision was also influenced by the fact that the initial goal of this project was not to measure the user experience comprehensively but to identify performance outliers where there was a noticeable change in business processes.

Third, the level of understanding of RPA among the interview participants was inconsistent, which was eventually accepted as part of their characteristics. The study intended to measure the differences from existing methodologies, but the perception of RPA was more varied than expected. For example, some engineers focused on RPA's effects as an automation tool rather

XSL•FO
RenderX

than understanding it as a source of modifying the governance structure of the organization. Furthermore, some supervisors lacked a clear understanding of the technical definition of RPA.

Fourth, implementing RPA in diverse health care settings presents additional challenges not addressed in this study. Variations in organizational structures, technological systems, and regulatory environments can significantly influence the success of RPA adoption. For instance, RPA integration may face difficulties in environments with legacy systems or fragmented workflows. In addition, scaling RPA across larger institutions often requires substantial resource allocation and staff training, which may limit its applicability. Compliance with data protection and privacy regulations adds another layer of complexity, demanding meticulous planning to ensure alignment with legal standards. Future research should investigate these challenges to provide a more comprehensive understanding of RPA's role in diverse health care contexts.

Abstract

Background: Research on chronic multimorbidity has increasingly become a focal point with the aging of the population. Many studies in this area require detailed patient characteristic information. However, the current methods for extracting such information are complex, time-consuming, and prone to errors. The challenge of quickly and accurately extracting patient characteristics has become a common issue in the study of chronic disease comorbidities.

Objective: Our objective was to establish a comprehensive framework for extracting demographic and disease characteristics of patients with multimorbidity. This framework leverages large language models (LLMs) to extract feature information from unstructured and semistructured electronic health records pertaining to these patients. We investigated the model's proficiency in extracting feature information across 7 dimensions: basic information, disease details, lifestyle habits, family medical history, symptom history, medication recommendations, and dietary advice. In addition, we demonstrated the strengths and limitations of this framework.

Methods: We used data sourced from a grassroots community health service center in China. We developed a multifaceted feature extraction framework tailored for patients with multimorbidity, which consists of several integral components: feasibility testing, preprocessing, the determination of feature extraction, prompt modeling based on LLMs, postprocessing, and midterm evaluation. Within this framework, 7 types of feature information were extracted as straightforward features, and three types of features were identified as intricate features. On the basis of the straightforward features, we calculated patients' age, BMI, and 12 disease risk factors. Rigorous manual verification experiments were conducted 100 times for straightforward features and 200 times for intricate features, followed by comprehensive quantitative and qualitative assessments of the experimental outcomes.

Results: The framework achieved an overall F_1-score of 99.6% for the 7 straightforward feature extractions, with the highest F_1-score of 100% for basic information. In addition, the framework demonstrated an overall F_1-score of 94.4% for the 3 intricate feature extractions. Our analysis of the results revealed that accurate information content extraction is a substantially advantage of this framework, whereas ensuring consistency in the format of extracted information remains one of its challenges.

Conclusions: The framework incorporates electronic health record information from 1225 patients with multimorbidity, covering a diverse range of 41 chronic diseases, and can seamlessly accommodate the inclusion of additional diseases. This underscores its scalability and adaptability as a method for extracting patient-specific characteristics, effectively addressing the challenges associated with information extraction in the context of multidisease research. Research and medical policy personnel can extract feature information by setting corresponding goals based on the research objectives and directly using the LLM for zero-sample target feature extraction. This approach greatly improves research efficiency and reduces labor requirements; moreover, due to the framework's high accuracy, it can increase study reliability.

KEYWORDS

large language model; zero-shot prompting; information extraction; chronic disease; multimorbidity; natural language processing

Introduction

Overview

Research on chronic multimorbidity has increasingly become a focal point with the aging of the population [1]. Major research directions include exploring multimorbidity patterns [2,3], investigating multimorbidity development and prediction [4,5], and examining the mutual interplay between multimorbidity and patient characteristics [6]. Amid ongoing research on frequently occurring diseases, extracting patient characteristics holds paramount importance. However, traditional machine learning–based feature extraction methods often rely heavily on extensive sample sizes for model training, and in some cases, even necessitate manual annotation. This renders the task of extracting patient features, albeit just 1 aspect of the research, not only laborious and time-consuming but also susceptible to errors [7]. To address this, we developed a framework specifically tailored for extracting features related to patients with multimorbidity. Leveraging the powerful capabilities of natural language understanding and the automation features of large language models (LLMs), this framework aims to expedite the feature extraction process, minimize extraction errors, and efficiently handle vast amounts of electronic health records (EHRs). Consequently, it significantly reduces the time and human resources required for subsequent research on comorbidities, enabling more efficient and accurate insights into this complex field.

In the task of feature extraction for patients with multimorbidity, natural language processing (NLP) technologies hold significant advantages, effectively addressing challenges such as participant scarcity and the intricacies of information extraction. Recently, LLMs have garnered significant attention across various domains, including NLP, biomedical sciences [8], and clinical practice, particularly after the emergence of ChatGPT with GPT-4. Through fine-tuning LLMs [9] and designing prompt modeling [10,11], researchers have successfully tackled diverse NLP tasks; for instance, Hu et al [10] developed prompt modeling specifically for radiology reports, enabling the extraction of pertinent disease information from these reports. In addition, Datta et al [11] designed a system based on LLMs using prompt modeling to automatically identify medical eligibility criteria. Inspired by these advancements, we propose using LLMs that have undergone medical information training and fine-tuning to extract features of patients with multimorbidity from EHRs.

We developed a comprehensive framework designed to extract pertinent feature information from patients with multimorbidity. This framework is rooted in ZuoyiGPT, a powerful architecture that builds upon the transformer model and has undergone extensive training and fine-tuning using extensive medical literature, clinical records, both online and offline patient visit data, and expert annotations. Compared to ChatGPT with GPT-4, ZuoyiGPT boasts more specialized medical information and clinical experience. Furthermore, unlike the Taiyi LLM [12], ZuoyiGPT has undergone more extensive training on clinical information and incorporates a user interaction platform, which enhances its utility and accessibility. The framework established in this study is highly adaptable and knowledge driven, ensuring its flexibility and relevance in various scenarios. Feasibility tests have confirmed the viability of ZuoyiGPT in extracting patient characteristics from EHRs. Moreover, the postprocessing module has enhanced the consistency and accuracy of the extracted feature information. To assess the framework's performance in a zero-shot scenario, we evaluated the results of extracting both straightforward and intricate features from 300 EHRs. In a zero-shot setting, LLMs evaluated are able to extract patient characteristics solely based on the content and format requirements specified in the prompts, without relying on any additional demonstrations or training.

The study conducted patient characteristic extraction on a vast array of EHRs to ensure consistency, scalability, and interoperability. The capability to facilely extract multidimensional patient characteristics through prompt content holds significant value for analyzing a wide range of comorbidities. This framework allows for the aggregation of diverse combinations of multimorbidity, symptoms, and semistructured and unstructured mixed treatment recommendations from EHRs as objects for feature information extraction. We have delved into the strengths and weaknesses of the framework presented in the evaluation framework, identified potential future optimization suggestions, conducted a concise analysis, and provided research recommendations tailored to the demands of multidisease research. The main contributions of this study are outlined as follows:

1. A comprehensive framework based on zero-shot LLMs has been established for extracting demographic and disease-related characteristics of patients with multimorbidity, without the need for manual annotation. This framework categorizes the extraction of feature information from semistructured and unstructured EHRs into straightforward and intricate tasks.
2. The prompt modeling of the framework is adaptable to various tasks aimed at extracting different characteristics, offering flexibility and the ability to span across different disease domains. It can seamlessly be extended to accommodate extraction tasks pertaining to patient EHRs with diverse formats and structures.

Background and Significance

An EHR contains a diverse array of patient information, including demographic statistics, disease profiles, and examination details. This comprehensive dataset serves as a cornerstone for numerous disease studies, facilitating clinical decision support and translational research endeavors; for example, Naimark et al [13] leveraged an EHR patient portal to help patients formulate their health care goals. Given the

XSL•FO
RenderX

widespread embrace of EHRs [14], extracting pertinent information from these records has emerged as a pivotal focus of research [15]. Most information extraction efforts have primarily focused on 3 key subtasks: entity recognition, relation extraction, and event extraction [16-18]. By contrast, our study directly addresses the exigencies of chronic disease and multimorbidity research by concentrating on the extraction of multiple patient characteristics.

Numerous studies on multimorbidity [19-21] require the necessity of incorporating patient-specific and disease-specific features as inputs for predictive modeling, serving as the foundation for disease prediction modeling. Specifically, in the research on predicting cardiovascular disease risk in patients with type 2 diabetes [19], the initial step involves extracting patient age, gender, and disease codes as crucial inputs for the prediction model. Furthermore, when anticipating the future disease progression of patients with 0, 1, or 2 major chronic diseases [20], it becomes imperative to screen patients with 1 or 2 major chronic diseases, as well as those without any major chronic diseases, as inputs for the prediction. In addition, Lu and Uddin [21] highlight the importance of considering factors such as patient age, gender, disease codes, and smoking history in predicting chronic diseases. Consequently, the use of scientific and efficient methods for extracting disease and personal information features holds paramount importance in the study of multimorbidity.

A substantial amount of work [22-24] involves methods for extracting feature information. Kumar et al [22] used classical machine learning and deep learning approaches, using word embeddings and bag-of-words representations combined with feature selection techniques to extract features from clinical records and identify incidence rates. Kamp et al [23] adopted manual annotation to extract data from a large corpus of literature regarding the definitions, measurement methods, included conditions, and characteristics of patients investigated in studies on multiple diseases. Hu et al [24] achieved entity recognition and relationship extraction of symptoms and details within EHRs through an end-to-end overlapping joint extraction approach.

LLMs exhibit emergent behavior due to their transformer-based architecture [25]. Since the release of ChatGPT, LLMs have garnered significant attention and are currently being applied across various fields, including NLP, data analysis, medicine, and artificial intelligence. In clinical practice, LLMs can generate diagnostic lists and aid in clinical decision-making by leveraging their intelligent question-answering capabilities [26]. In the field of medical research, LLMs are able to abstract complex social determinants of health from original and unidentified medical notes [27], which can also assess the likelihood of epidemics based on the content of tweets [28]. In addition, in the realm of medical texts, these models are capable of generating patient clinical information and medical records [29]. It is anticipated that LLMs may one day facilitate real-time monitoring and predictive analysis [30].

In the medical field, numerous studies have explored the use of LLMs for NLP. A significant proportion of these studies have emphasized the fine-tuning of these models to simulate physician-patient communication, ultimately aiming to provide patients with electronic physician services [12,31,32]. Specifically, Yang et al [31] introduced the first Chinese-based medical LLaMA–based LLM, which progressed through a comprehensive process ranging from continuous pretraining (supervised fine-tuning) to human feedback reinforcement learning. Luo et al [12] focused on bilingual fine-tuning of LLMs for various biomedical NLP tasks. Furthermore, Chen et al [32] are concentrated on psychological counseling, enhancing the empathy capabilities of LLMs through immersive multiturn dialogue contexts.

In the realm of information extraction, LLMs are primarily used to extract radiology reports [10] and meta-information from scientific literature [33]. In recent research, an LLM was used to develop an eligibility criteria extraction system [11], successfully extracting eligibility criteria from clinical trial data; however, this system is designed for 9 specific diseases and extracts information from a limited number of dimensions. Current research on chronic diseases and multimorbidity is patient oriented, requiring a broader range of dimensions. Notably, there is a dearth of studies exploring the use of LLMs for extracting patient characteristic information, which constitutes the focal point of our investigation.

Although both Hu et al [10] and Datta et al [11] alluded to suboptimal extraction results arising from the use of generic LLMs, few studies have capitalized on LLMs specifically fine-tuned with medical and clinical insights, apart from those exclusively dedicated to fine-tuning or creating such models. Consequently, drawing on previous research and anticipating future prospects, this study embraced ZuoyiGPT, an LLM that has undergone extensive training and fine-tuning, incorporating literature, clinical data, and expert physician insights. ZuoyiGPT offers an interactive, web-based platform tailored for patient feature extraction. Through a feasibility testing system, we assessed ZuoyiGPT's proficiency in extracting patient features and subsequently used it to successfully extract a comprehensive set of 84 patient features. Notably, our feature extraction framework holds the potential to significantly reduce or even eliminate the reliance on manual annotation, thereby expanding its applicability to a broader range of feature extraction tasks.

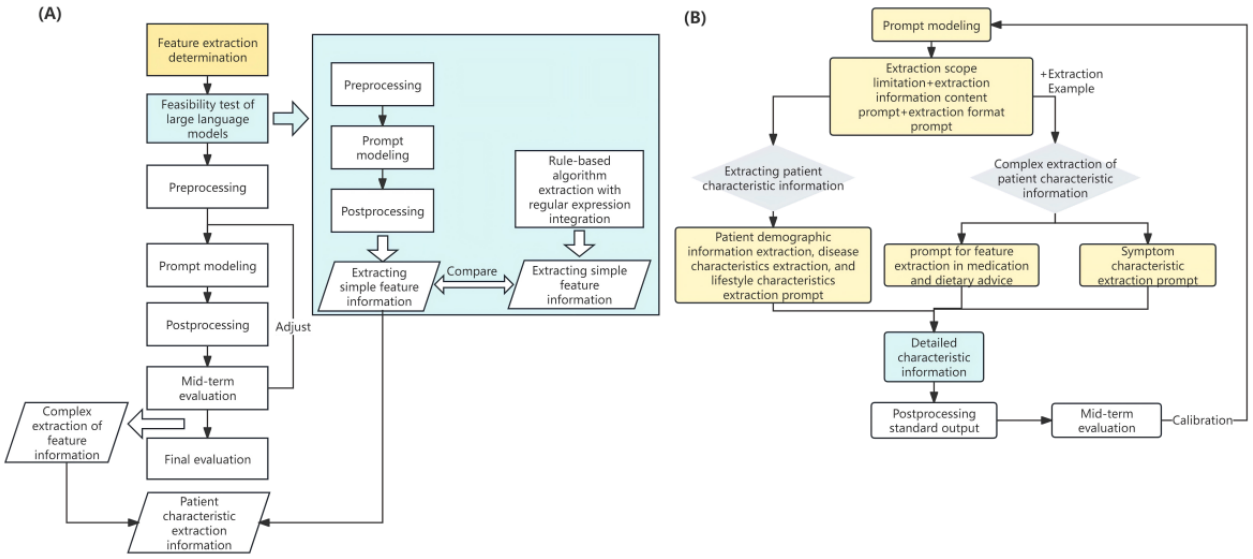
Methods

Data

We conducted a systematic random sampling from the EHRs of 19,000 patients with chronic diseases at the Wanping Community Health Service Center in Beijing, China, and manually extracted desensitized EHRs for 1225 (6.45%) patients. All participants were aged >40 years and had multiple chronic diseases. These EHRs included details of 41 chronic diseases, 235 symptoms, and 312 drug recommendations. Notably, 986 (80.49%) of these 1225 EHRs contained preliminary consultation information, including personal details, medical histories, family backgrounds, lifestyle habits, self-reported symptoms, drug recommendations, and nonmedication advice. Conversely, the remaining EHRs (239/1225, 19.51%) lacked initial consultation data and solely contained personal information, medical histories, family

XSL•FO
RenderX

backgrounds, and lifestyle habits. We selected a combination of longitudinal and cross-sectional EHR information for our experiments. The EHRs include both semistructured and unstructured information. The semistructured information mainly comprises basic personal details of patients, such as gender and date of birth, as well as medical history; family history; and lifestyle information related to smoking, drinking, and physical activity. The unstructured information consists of 2 parts: the patient's presenting complaints, which contain symptom information, and the physician's diagnostic results, which include dietary and medication recommendations. Consequently, we categorized the extraction of semistructured information as straightforward feature extraction and the extraction of unstructured data as complex feature extraction.



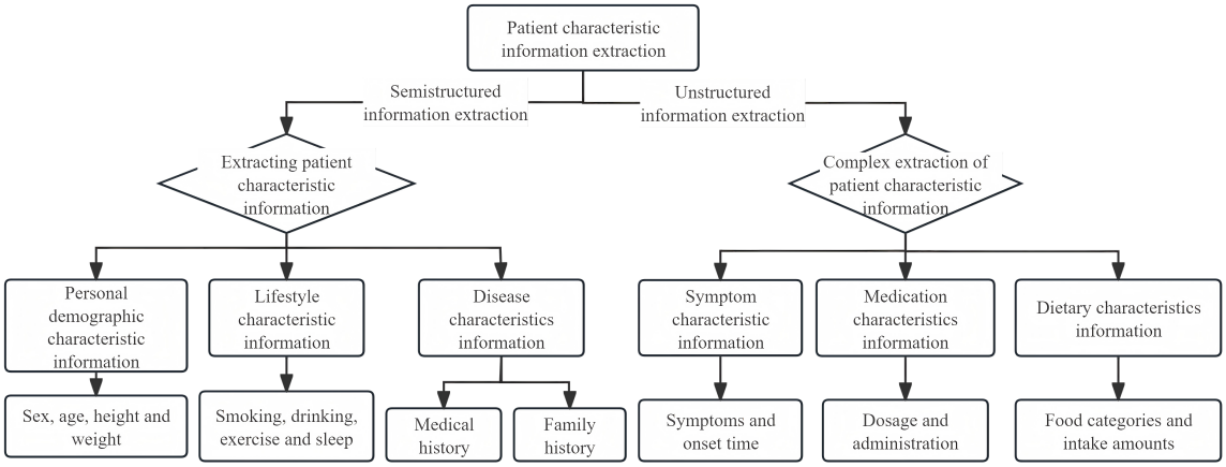
We used two methodologies to extract straightforward features from the 1225 EHRs: (1) a rule-based algorithm integrated with symbolic NLP and (2) ZuoyiGPT. Specifically, 10 features were used for prompt design, while 5 were designated for rapid prompt calibration. Furthermore, we manually annotated straightforward extraction information from 50 (4.08%) of the 1225 EHRs—those with preliminary diagnosis records as well as those without—to evaluate the capability of the LLM to extract simple features, thereby validating the feasibility of the ZuoyiGPT. Subsequently, ZuoyiGPT was used to extract intricate features from 986 (80.49%) of the 1225 EHRs, using 10 features for prompt design and 5 for rapid prompt calibration. Of these 986 EHRs, 200 (20.3%) were manually annotated to evaluate the LLM framework's performance in extracting patient features. Our manual annotations were completed by medical experts, and the prompt design was also guided by their expertise.

Framework for Extracting Characteristics of Patients With Multimorbidity

Overview

We developed a framework for extracting multifaceted characteristics of patients with multimorbidity. Leveraging the extensive language capabilities of ZuoyiGPT, this framework automatically retrieves demographic and disease-related information from EHRs. The following subsections introduce the various components of this framework, as illustrated in Figure 1.

Figure 1. System overview.



Feature Extraction Determination

Drawing upon insights from clinical experts and medical experts and extensive research literature on comorbidities associated with chronic and frequently occurring diseases, we arrived at a comprehensive set of extracted patient characteristic information. As outlined in the study by Cezard et al [4], research on chronic diseases typically falls into 2 categories: cross-sectional studies and longitudinal studies. Cross-sectional studies primarily focus on exploring symptoms and states as well as common risk factors, including age, unhealthy behaviors, and socioeconomic status. Conversely, longitudinal studies delve deeper into the exploration of diseases and their sequelae, tracing the trajectory of the illness over time. Dong et al [5] predicted multimorbidity through a graph convolutional network that integrated population phenotypes (including diet, physical activity, sleep, and smoking) and disease networks. Feng et al [6] investigated the effects of age and gender differences on multimorbidity. Ultimately, we opted to adopt a combined longitudinal and cross-sectional approach to studying chronic diseases. This holistic method integrates information extracted from electronic medical records, encompassing demographic characteristics, disease characteristics, lifestyle habits, symptomatic manifestations, medication profiles, and dietary patterns. This comprehensive approach aims to cater to the evolving needs of extracting patient characteristic information in future research endeavors on chronic diseases, as illustrated in Figure 2.

XSL•FO
RenderX

Figure 2. Extraction of patient characteristics.

Demographic information comprises patient ID, gender, date of birth, age, height, weight, and BMI. Among these, patient ID, gender, date of birth, height, and weight can be directly extracted from EHRs. Nevertheless, to facilitate subsequent research endeavors, we calculated the patients' age and BMI based on the extracted birth date, height, and weight.

Disease-related information consists of medical history and family history. The medical history includes 41 prevalent chronic diseases such as hypertension, type 2 diabetes, coronary heart disease, and stroke, along with the duration of each disease. The family history delves into 12 aspects, including whether the father or mother has coronary heart disease, diabetes, hypertension, hyperlipidemia, cerebrovascular disease, or stroke.

Lifestyle characteristic information includes smoking status, smoking duration, alcohol consumption, exercise patterns, sleep quality, and sleep disorders. Smoking status is categorized as follows: 1 signifies current smoking, 0 indicates nonsmoking, and –1 represents smoking cessation. For individuals who do not smoke or have quit smoking, smoking duration is recorded as 0. Similarly, alcohol consumption is classified as 1 for current drinking, 0 for nondrinking, and –1 for abstinence. Exercise status is differentiated into 5 categories: 3 represents daily exercise, 2 signifies exercising >3 times weekly, 1 indicates exercising 1 to 2 times weekly, 0 stands for no exercise, and –1 denotes irregular exercise. Sleep states are categorized into 3 levels: 3 for sleeping >10 hours daily, 2 for sleeping between 6 and 10 hours daily, and 1 for sleeping ≤6 hours daily. Finally, sleep disorders are dichotomized into 0 for the absence of sleep disorders and 1 for the presence of sleep disorders.

Symptom characteristic information includes a diverse range of manifestations, including dizziness, nausea, elevated blood pressure, dry mouth, headache, and 230 other symptoms. Our framework meticulously extracts the specific symptoms experienced by each patient, along with the corresponding time of symptom occurrence.

The drug characteristic information is equally extensive, encompassing enteric-coated aspirin tablets, acarbose tablets, controlled-release nifedipine tablets, atorvastatin calcium tablets, and a further 308 medications. Our framework accurately captures the medication information and dosage recommendations provided by physicians during the initial consultation for each patient. Dietary characteristic information covers 74 distinct types of food. Our framework diligently extracts the dietary categories and corresponding intake recommendations tailored by physicians during the initial consultation for each patient.

Furthermore, our framework demonstrates remarkable scalability and generalization ability by leveraging LLMs to expand its repertoire of diseases, symptoms, drug recommendations, and dietary suggestions. This enables it to continuously adapt and enhance its coverage, reflecting its sophisticated capabilities.

Feasibility Testing of LLMs

We used a rule-based algorithm integrated with symbolic NLP regular expressions to extract patient characteristics. These extracted results served as a benchmark for assessing the feasibility of leveraging LLMs for feature information extraction. Specifically, we used regular expressions such as "\d+\\.\d*" to identify patients' height characteristics and "\d+\.\d*|\d{2}|\d{3}" to identify and recognize their weight characteristics, enabling us to extract pertinent demographic and disease-related information. Our algorithm initially scanned through all EHRs of patients, pinpointing and cataloging all disease descriptions mentioned. Subsequently, based on the recommendations of medical experts, we consolidated various disease descriptions; for instance, "rheumatoid arthritis" was merged with "arthropathy" and "arthritis" into "rheumatoid arthritis," while "delusion" was merged with "mental illness" into "mental illness." Ultimately, we identified 41 chronic diseases, some of which encompass multiple disease characteristics, as detailed in Textbox 1.

XSL•FO
RenderX

Textbox 1. Characteristics of chronic diseases and comorbid conditions.

Disease categories and descriptions of the included diseases

- Cancer: cancer and malignant tumor
- Cerebrovascular diseases: cerebral infarction, cerebral ischemia, brain infarction, transient ischemic attack, cerebral thrombosis, cerebral arteriosclerosis, and atherosclerosis
- Mental illness: delusions and other psychiatric disorders
- Rheumatoid arthritis: osteoarthritis, arthritis, osteomyelitis
- Cardiovascular diseases (excluding coronary heart disease): heart failure, myocardial ischemia, valvular heart disease, and premature cardiac contractions
- Chronic ophthalmic diseases: bilateral retinitis pigmentosa and fundus atrophy

Subsequently, we selected 41 diseases as our benchmark and developed algorithms leveraging regular expressions to extract patient demographic characteristics, lifestyle information, disease details, and family histories from the semistructured text format.

We categorized EHRs into semistructured and unstructured information and implemented patient feature extraction and applied LLM-based extraction methods tailored to each type. Semistructured information incorporates explicit format identifiers, such as colons, carriage returns, and labels such as “personal information,” whereas unstructured information consists of patient-reported symptoms, physician-provided guidance based on patient descriptions and medical histories, as well as nonpharmacological guidance. We used the extraction of semistructured information as a feasibility test for assessing the information extraction capabilities of ZuoyiGPT. To facilitate processing by the LLM, we eliminated redundant spaces and carriage returns, simplifying the information extraction process.

On the basis of the specific information content required for extraction, we iteratively developed, tested, and calibrated a comprehensive prompt tailored as the input for ZuoyiGPT’s interactive platform. For the extraction of semistructured information, our prompt comprised 4 integral components: scope definition, extraction content prompt, extraction format prompt, and prompt query for the original text. The scope definition instructs the LLM to focus solely on extracting information from the provided text. The extraction content specification outlines the precise details that the model needs to capture. The extraction format guidance mandates the model to present the extracted information in a predefined format. The prompt query referencing the original text pertains to the segment of the EHR serving as the source material. Given the immense volume of original text involved in this information extraction task, we opted not to include an extraction example prompt. The actual prompt text and its output are illustrated in Textbox 2.

XSL•FO
RenderX

Textbox 2. Characteristics of chronic diseases and comorbid conditions.

Prompt composition

1. Please extract the following information based on the provided content:

2. height, weight, medical history, family history, smoking status, smoking duration, alcohol consumption, exercise habits, sleep duration, and sleep disorders.

3. Output the extracted results in the following format:

Height: XXX cm;

Weight: XX kg;

Medical History:

① Diagnosed with XXX disease in XXXX;

② ...;

Family History (1 if the parent has the respective disease, otherwise 0):

Father with coronary heart disease: 1/0

Father with diabetes: 1/0

Father with hypertension: 1/0

Father with hyperlipidemia: 1/0

Father with cerebrovascular disease: 1/0

Father with stroke: 1/0

Mother with coronary heart disease: 1/0

Mother with diabetes: 1/0

Mother with hypertension: 1/0

Mother with hyperlipidemia: 1/0

Mother with cerebrovascular disease: 1/0

Mother with stroke: 1/0

Smoking Status: Smoker/Non-smoker/Ex-smoker;

Smoking Duration (current year is 2024): XX years (0 if non-smoker);

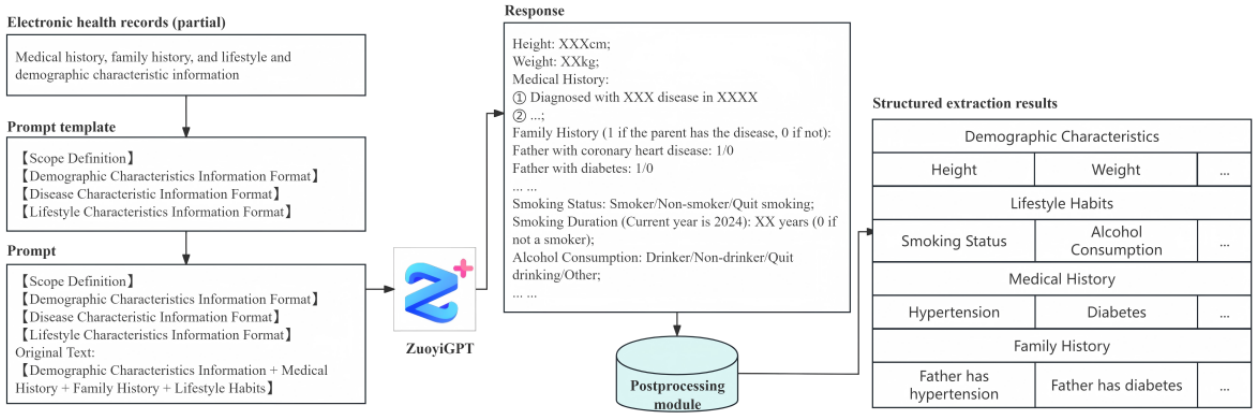
Alcohol Consumption: Drinker/Non-drinker/Ex-drinker/Other;

Exercise Habits: Sedentary/Irregular exercise/Exercise 1-2 times per week/Exercise 3 times per week/Exercise more than 3 times per week;

Sleep Duration: XX hours;

Sleep Disorders: Present/Absent.

4. Original Text: 【Demographic Characteristics Information + Medical History + Family History + Lifestyle Habits



Sample output

- Height: 168.0 cm; Weight: 65.0 kg; Medical History: ① Diagnosed with coronary heart disease in August 2013; ② Diagnosed with hyperlipidemia in May 2013; Family History: Father - Coronary heart disease: Yes; Father - Diabetes: No; Father - Hypertension: No; Father - Hyperlipidemia: Yes; Father - Cerebrovascular disease: No; Father - Stroke: No; Mother - Coronary heart disease: No; Mother - Diabetes: No; Mother - Hypertension: No; Mother - Hyperlipidemia: No; Mother - Cerebrovascular disease: No; Mother - Stroke: No; Smoking Status: Non-smoker; Smoking Duration (current year is 2024): 0 years; Alcohol Consumption: Drinks alcohol; Exercise Frequency: 1-2 times per week; Sleep Duration: 6 hours; Sleep Disturbances: Present.

After using ZuoyiGPT for batch information extraction from semistructured data, we resolved formatting issues in the actual extracted results using a straightforward rule-based algorithm; for instance, we corrected instances where the LLM merged 2 lines of output into a single line by adding line breaks and eliminating redundant line breaks. Subsequently, we used a rule-based algorithm to extract keywords and numerical values from the LLM's output, along with performing numerical substitutions. As an example, we extracted "coronary heart disease" and "2013" from "coronary heart disease in 2013," and converted "Smoking Status: Smoking" to "Smoking Status: 1." These extracted keywords and numerical values were then assigned to their corresponding labels, effectively transforming them into a structured tabular format. Figure 3 illustrates the entire process of extracting simple patient feature information from an EHR.

XSL•FO
RenderX

Figure 3. Overview of the process of simple extraction of feature information using a large language model (ZuoyiGPT).

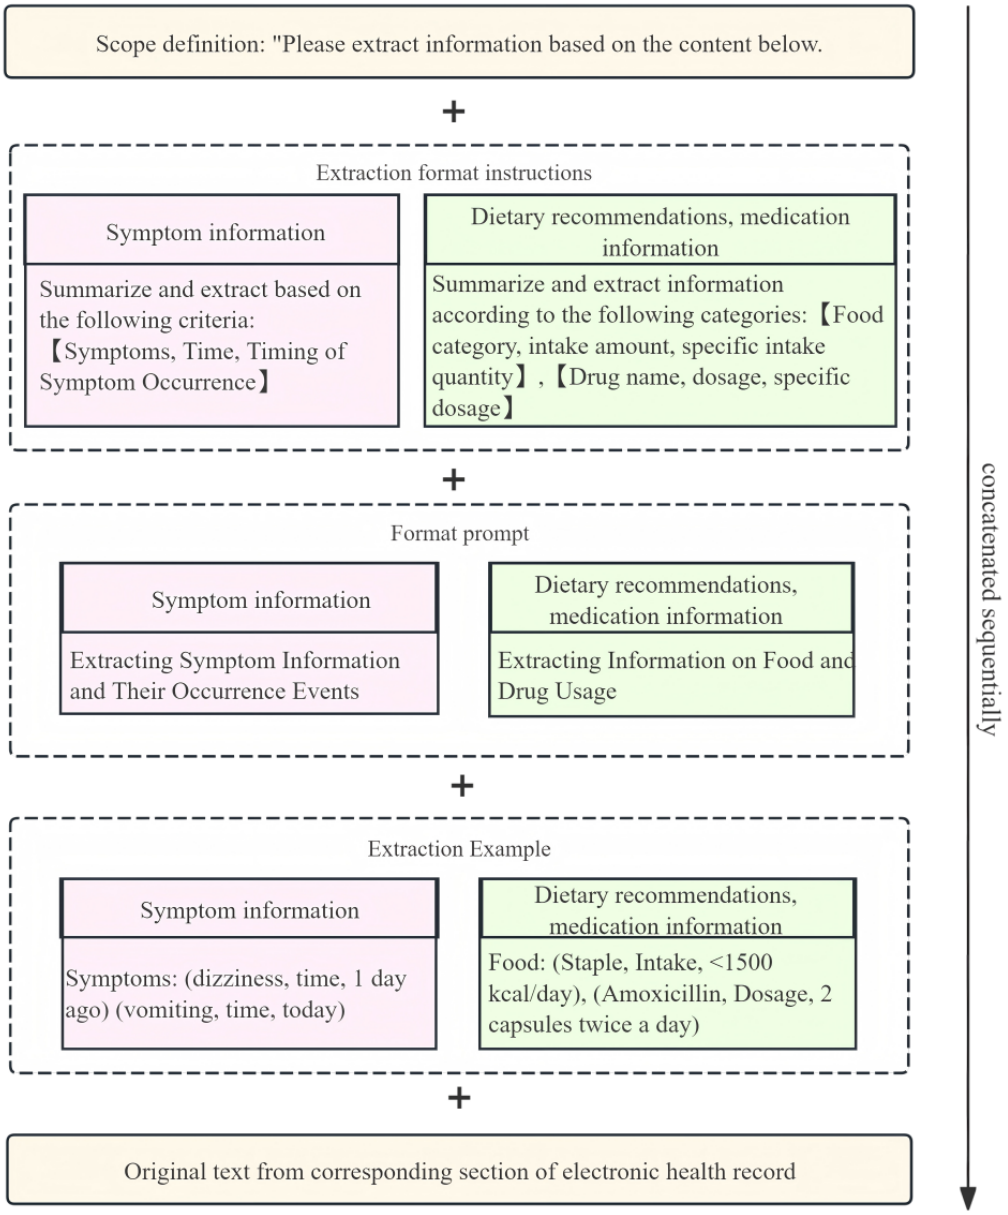
Finally, from the 1225 EHRS, we randomly selected 100 (8.16%) and manually annotated their semistructured data sections, including past medical history, family history, lifestyle, and specific objective examinations. Subsequently, we conducted a comparative analysis of the extraction results obtained through a rule-based algorithm and those achieved by using the LLM on these 100 EHRs. The comprehensive final results, showing the F_1-score values for both the rule-based algorithm and LLM extraction methods, are presented in Table 1.

Table 1. F_1-score values for simple extraction of feature information using a rule-based algorithm and a large language model (LLM).

Extraction method	Basic information (%)	Lifestyle (%)	Medical history (%)	Family history (%)	Overall (%)	SD value (%)
Rule-based algorithm	98	95	99.66	99.67	98.08	1.9049
LLM	100	99	99.7	99.67	99.59	0.3656

Clearly, the results extracted by the LLM outperformed those extracted by the rule-based algorithm, with F_1-score values consistently exceeding 95%, thus confirming the feasibility of using an LLM for patient feature information extraction.

Preprocessing



We began by considering the composition of unstructured text in EHRs and dividing each EHR into 2 sections: current illness history and medication guidance. The current illness history includes the patient's initial self-reported information, while the medication guidance consists of 4 parts: Western medicine prescription guidance, traditional Chinese medicine prescription guidance, nondrug guidance, and physician advice. Using prompt modeling, we guided the LLM to extract pertinent symptom information from the current illness history, including symptom names and their respective occurrence times. We also extracted medication guidance and dietary advice from the medication section, including drug names, dosages, food categories, and recommended intake quantities. We used the rule-based algorithm to extract the text related to the patients' chief complaints, as well as the sections on medication and nonmedication guidance, from the patients' EHRs. Unnecessary formatting elements, such as extraneous whitespace and line breaks, were removed.

Prompt Modeling

Compared to complex feature extraction, the original text content for simple feature extraction is considerably more limited in scope. To guarantee accurate information extraction by an LLM, we crafted a more comprehensive prompt and fed it into the ZuoyiGPT, which excels in identifying all facets of complex feature extraction. This model underwent rigorous iterative experiments, testing, and prompt calibration. Ultimately, we developed 2 stand-alone comprehensive prompts: one dedicated to extracting symptom information and the other to extracting drug recommendations and dietary advice. Each prompt consisted of five integral components: (1) scope definition, (2) extraction format prompt, (3) extraction content prompt, (4) extraction example, and (5) prompt query text. Figure 4 illustrates the formation of the comprehensive prompt; Textbox 3 showcases example prompt templates for symptom information, along with the corresponding output; and Textbox 4 presents medication recommendation and dietary advice information, along with the corresponding output.

XSL•FO
RenderX

Figure 4. Components of complex extraction feature information prompt modeling.

Textbox 3. Example of symptom information prompt, along with the corresponding output.

Prompt composition

1. Please translate the following content.
2. Summarize and extract the food and drug information from the text in the format of: 【Food Category, Intake Amount, Specific Intake Quantity】, 【Drug Name, Dosage, Specific Dosage】
3. Example: (Main Food, Intake Amount, <1500 kcal/day), (Metformin Hydrochloride Tablets, Dosage, 0.5mg / 4 times/day)

Original Text

【Drug Guidance + Non-Drug Guidance】

Sample output

【Diet】

Triples: (Low-sodium, low-fat diabetes diet, intake, no specific amount); (Sodium salt, intake, less than 6g/day); (Cooking oil, intake, less than 25g/day); (vegetables, intake, no specific amount); (Foods rich in vitamin C, intake, no specific amount)

【Medication】

Triples: (L-type amlodipine besylate tablets, dosage, 5mg once daily); (Simvastatin dispersible tablets, dosage, 20mg once daily)

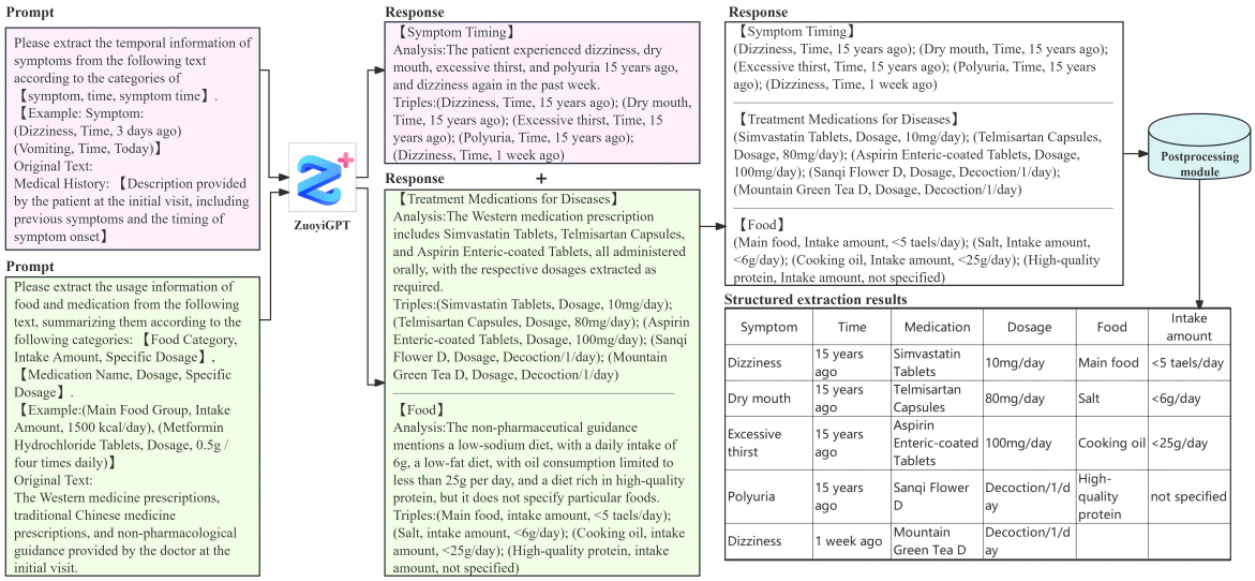
XSL•FO
RenderX

Textbox 4. Examples of drug suggestion information and dietary advice prompts, along with the corresponding output.

Prompt composition

1. Please summarize and extract the temporal information of symptoms based on the following content.
2. Organize the information in the format of 【Symptom Name, Time, Symptom Occurrence Time】.
3. For example:【Symptom: (Dizziness, Time, 2022), (Vomiting, Time, 1990)】
4. The original text includes 【Present Illness History, Chief Complaint】

Sample output



- Symptoms Triplet: (Dizziness, Time, 1985) (Weakness in Lower Extremities, Time, 1990) (Palpitations, Time, 1990)
- (Sweating, Time, 1990)

Using a prompt template, we developed a web automation program that leverages an LLM to efficiently extract information from EHRs in batches and obtain their corresponding responses. For each EHR, we initiated a new conversation to prevent the extraction results from being influenced by previous dialogues. Given the potential challenge of the LLM not recognizing the output format, we opted for the ZuoyiGPT, which is trained to generate triples. Although the training format of the Left-Hand Doctor model does not exactly match our required format, it includes the format and content we need. Therefore, we decided to save the output of each EHR into separate documents and subsequently process the extraction results in a sequential manner.

Postprocessing

Although we provided structured output requirements, the primary purpose of LLMs is to simulate human communication. The LLMs we used have been trained in formats different from our requirements. Therefore, the results extracted by the LLM are not always in line with our expectations. To address this issue, we developed a rule-based postprocessing module with regular expressions to convert the chaotic semistructured answers into structured answers that are conducive to generating tables. Specifically, we identified the positions of all triples related to symptoms, medication characteristics, and dietary recommendations and used regular expressions to recognize the 3 parts of the triples, outputting a unified format. Each EHR involves 3 parts of triples, which are separated by specific formats and subsequently exported to individual documents for each record. Ultimately, we converted all triples into electronic medical record formats into a tabular format, ensuring consistency in the output content throughout this process; for example, terms such as “oil type,” “oil,” and “cooking oil” were unified as “cooking oil,” while “heart and brain unblocking” and “heart and brain unblocking tablets” were unified as “heart and brain unblocking tablets.” In addition, when the LLM expressed the meaning of “not mentioned,” the results could appear as “not mentioned,” “not found,” or “not mentioned.” We unified these expressions as “not mentioned” in this module and removed any “not mentioned” entries from food categories, symptom names, and medication names. Figure 5 provides a comprehensive overview of the process of extracting complex feature information from a patient’s EHRs.

Figure 5. Overview of the process of extracting complex patient feature information using a large language model. The pink areas represent the extraction of symptom information, while the green areas represent the extraction of medication and dietary recommendations.

XSL•FO
RenderX

Evaluation

As part of the midterm evaluation of the patient feature extraction framework, we manually assessed the prompts and iteratively refined them based on feedback provided by medical experts. For the final framework evaluation, we conducted both quantitative and qualitative assessments. In terms of quantitative evaluation, we used 200 trial documents, manually annotated by medical experts. We reported the framework's precision, recall, and F_1-score values in identifying symptoms, symptom timing, medications, medication dosages, foods, and intake amounts. Furthermore, we calculated the framework's accuracy in extracting complex information across 3 categories. Specifically, we reported accuracy metrics for 3 combinations: symptom+symptom duration, medication+dosage, and food category+food intake, where each label had to match precisely with manually annotated information. In addition, we initiated a new dialogue for extracting EHRs for each patient to generate more accurate responses from LLMs. The data is split into 2 sets of 100, with each set being manually annotated by a different group, and the groups then cross-validate each other's annotations. For qualitative evaluation, we conducted a thematic analysis of missing and incorrect standard entities in 200 trials to explain the strengths and weaknesses of the patient feature extraction framework specifically tailored for patients with chronic disease.

Ethical Considerations

This study was approved by the Ethics Committee of Tongji Medical College, Huazhong University of Science and Technology (approval number:2024 IEC (A177), as part of the project "Research on Risk Situation Awareness and Response Strategies for Chronic Disease Comorbidity Based on Knowledge Association". This study used a desensitized dataset obtained from community health service centers in Beijing, China. The collection of this dataset complied with the "ethical review measures for biomedical research involving humans".

Results

Framework Performance

The framework's performance in terms of precision, recall, and F_1-score performance across symptoms, symptom duration, medications, medication dosage, food, and intake quantity is shown in Table 2.

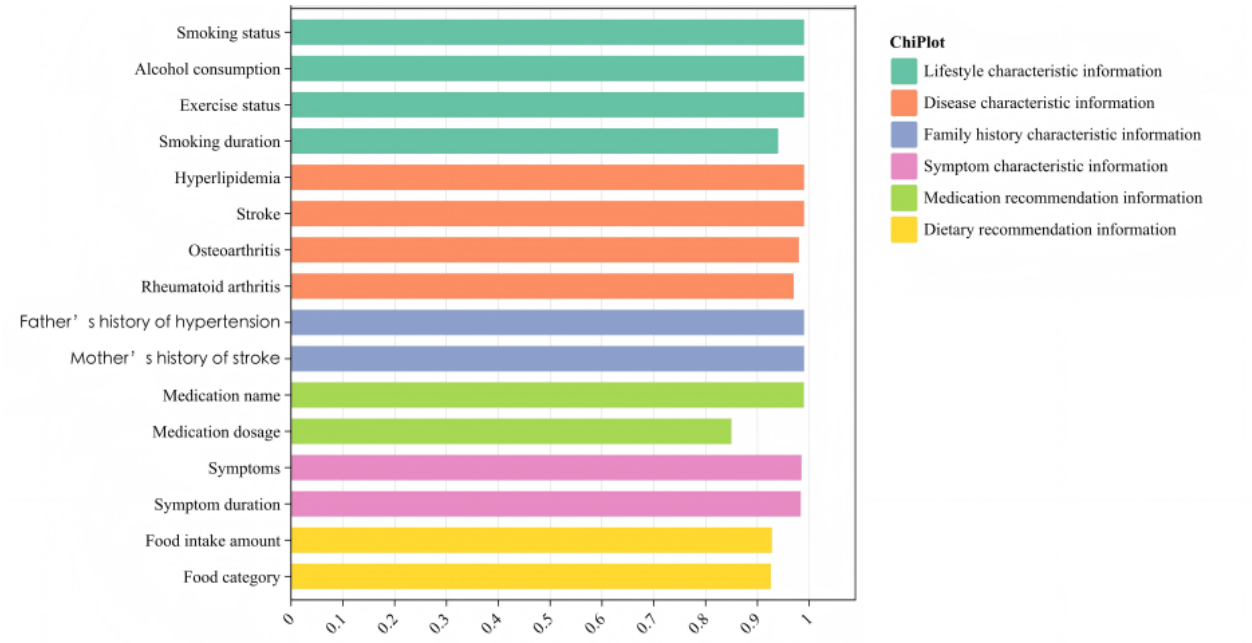
Table 2. Performance measurements of 6 complex extraction features.

Features	Precision (%)	Recall (%)	F_1-score (%)
Symptoms	100	97.05	98.5
Symptom duration	99.85	96.89	98.35
Medication	99.86	98.07	98.96
Dosage	77.2	94.6	84.98
Food	87.83	97.91	92.6
Intake	89.36	96.49	92.79
Overall	92.35	96.84	94.36
SD value	8.466	1.144	4.963

Table 3 demonstrates the framework's performance in extracting intricate patient information features, particularly from unstructured textual data. Notably, the framework performed well in identifying these 6 complex feature types, with the highest accuracy for medication extraction (98.96%) and the lowest for medication dosage extraction (84.98%). The framework achieved a high overall F_1-score of 94.36% across all labels. Table 3 presents the accuracy measurements for 3 combinations, revealing overall F_1-score values of 98.42%, 92.64%, and 88.05%, respectively.

Table 3. Accuracy measurements of 3 combinations.

Feature combination	Precision (%)	Recall (%)	F_1-score (%)
Symptom+symptom duration	99.92	96.97	98.42
Medication+dosage	88.99	96.6	92.64
Food category+food intake	80.38	97.35	88.05



Extraction Accuracy

By integrating the results of both simple and complex feature extraction, we visualized the F_1-score values of all features with extraction accuracy not reaching 100%, as shown in Figure 6. Of the 67 feature labels, 61 (91%) pertained to simple extraction, while the remaining 6 (9%) concerned complex extraction. Notably, the extraction results of simple features significantly outperformed those of complex features. Of the 61 simple extraction features, 10 (16%) exhibited errors during the extraction process. These errors were observed in lifestyle-related features, including "smoking status," "smoking duration," "drinking status," and "exercise status," with F_1-score values of 99%, 94%, 99%, and 99%, respectively. In the disease feature information, errors occurred in the extraction of "hyperlipidemia," "rheumatoid arthritis," "stroke," and

XSL•FO
RenderX

"osteoarthritis," with F_1-score values of 99%, 97%, 99%, and 98%, respectively. In addition, errors were encountered in the extraction of family history features, specifically "father with hypertension" and "mother with stroke," both achieving an F_1-score of 99%. Notably, all 6 complex features exhibited errors in their extraction.

Figure 6. Overview of F_1-score values for feature extraction.

Discussion

Feature Extraction Error Analysis

We developed a framework based on LLMs for extracting features of patients with multimorbidity. After completing performance measurements, we conducted an error analysis to elucidate the system's shortcomings in each category. The F_1-score values for all extracted features are visualized in Figure 6. Notably, the extraction of simple features involving unstructured text, such as "smoking status," "drinking status," and "exercise status," resulted in extraction errors. Our investigation revealed that the LLM incorrectly characterized smoking status as "Smoking status: Frequent (≥5 cigarettes/day)," whereas accurate descriptions typically followed the format "Smoking status: Started in 1982, Frequent (≥5 cigarettes/day)." The absence of smoking commencement years in patient health records hindered the model's ability to accurately infer smoking status based solely on the "smoking status: frequent" descriptor. Similarly, errors in "drinking status" stemmed from the omission of the prefix "drinking status:" in the text description, leading to misclassification and extraction by the model. The challenge with "exercise status" mirrored that of "drinking status" because it lacked the explicit textual segmentation "exercise status:"—this compromised the model's ability to accurately extract data from partially structured texts lacking proper segmentation. When errors occurred in the semantic segmentation of the text and the semantic understanding of general knowledge, we enhanced semantic segmentation by inserting line breaks before the "smoking status," "drinking status," and "exercise status" during the preprocessing of medical records. A better extraction method is to use general-purpose LLMs, such as Kimi and DeepSeek, for feature extraction tasks that do not heavily involve medical background knowledge. These models are superior in their training and understanding of everyday common knowledge compared to general-purpose LLMs that are trained extensively on medical terminology at a later stage.

In disease condition recognition, LLMs exhibit a lower probability of making errors in associating disease occurrence practices with disease names; for example, in the electronic medical record of a patient where the disease is described as "2013-06, hyperlipidemia; 2008-06, stroke," the LLM might incorrectly interpret it as indicating that the patient had hyperlipidemia in 2008 and stroke in 2013. The triggering factor for such recognition errors is unrelated to the names or categories of the diseases. Such errors can often be addressed by enhancing text preprocessing, for example, by inserting formatting separators such as a newline character or other delimiters after each disease.

In the recognition of family history, LLMs may erroneously attribute the disease status of siblings to that of the father or mother. Therefore, if a sibling has a certain disease, and this situation is described in the family history, it could lead to incorrect identification and extraction by the LLM. This issue can be addressed by incorporating the prompt "Please note the distinction between sibling illness and parental illness" into the prompt modeling or by using rule-based methods to eliminate cases of sibling illness during text preprocessing. Experiments show that adding the clarification prompt yields better results than deleting portions of the text during preprocessing.

The error rate of complex feature extraction is relatively higher than that of simple feature extraction. We categorized these errors into 6 distinct types: *incorrect extraction*, *nonrecordable*, *formatting error*, *incomplete extraction task*, *recognition error*, and *missed extraction*. *Incorrect extraction* refers to the situation

XSL•FO
RenderX

where the LLM includes information that does not belong to the intended label, such as extracting “exercise regularly” into the “symptoms” label. *Nonrecordable* occurs when the LLM includes information that, while fitting the category of the label, exceeds the required range, such as extracting “clear mind” into the “symptoms” label. A *formatting error* happens when the LLM fails to output the extraction results according to the specified format, leading to missing or incorrect information in the structured table, for example, extracting “dizziness a year ago” as “(dizziness; a year ago).” An *incomplete extraction task* refers to instances where the model fails to fully extract the required content for a given label, resulting in blank entries for this label in the corresponding medical records. A *recognition error* occurs when the extraction result fits both the label category and range but does not match the actual description in the medical record, such as extracting “dizziness a year ago” as (dizziness, symptom time, a week ago). *Missed extraction* happens when the LLM completes the extraction task for the corresponding label but fails to capture all relevant information described in the medical record, for instance, only extracting (dizziness, symptom time, a year ago) from a record that also mentions “dry mouth.” The distribution of the 6 types of errors is shown in Table 4. A total of 430 (11.03%) errors were identified among the 3898 valid information entries from 200 patients, resulting in an accuracy rate of 88.97% for valid information extraction. Among the 6 types of errors, formatting errors, incomplete extraction task, and incorrect extraction were the most prevalent.

Table 4. Incidence of 6 types of errors in complex feature extraction.

Error types	Incorrect extraction	Nonrecordable	Formatting error	Incomplete extraction task	Recognition error	Missed extraction
Symptoms	12	10	0	0	0	0
Symptom onset	2	19	0	0	1	0
Drug	14	0	5	0	6	13
Drug dosage	18	0	119	0	4	50
Food category	9	0	23	4	10	35
Food intake	9	0	27	4	6	33

Formatting errors and incomplete extraction task are most likely to occur in drug dosages. Our error analysis revealed that the causes of these errors often related to the LLM’s poor understanding of formatting, which aligned with our previous error analysis on simple feature extraction. When outputting drug triplet information, the LLM may produce results such as (Aspirin Enteric-Coated Tablets, drug, Aspirin Enteric-Coated Tablets), as well as expressions such as (Aspirin Enteric-Coated Tablets, dosage, 100mg once daily) or (Aspirin Enteric-Coated Tablets, dosage, 100mg daily). During postprocessing, it is challenging to uniformly handle such random and varied results using rule-based algorithms. If the LLM only provides extraction results such as (Aspirin Enteric-Coated Tablets, drug, Aspirin Enteric-Coated Tablets), it becomes even more difficult during postprocessing to obtain information on drug dosages without reviewing the original electronic medical record, increasing the risk of missing or inaccurate dosage entries in the structured output table. Format output errors can be resolved using a second feature extraction method with a general-purpose language model. Specifically, after the medical LLM performs the first feature extraction, we can concatenate the formatting requirements with the first extraction results and input them into a general-purpose language model (such as Kimi, DeepSeek, ERNIE Bot, etc) to obtain feature extraction results that meet our requirements through secondary extraction from these LLMs; for example, we inputted the information presented in Textbox 5 into ZuoyiGPT.

The extraction results obtained are presented in Textbox 6.

XSL•FO
RenderX

Textbox 5. Example of prompt content for simple extraction of patient characteristic information, along with the corresponding output.

- Please summarize and extract the symptom time information in the format of 【symptom name, time, symptom occurrence time】 【Example: Symptom: (dizziness, time, 2022) (vomiting, time, 1990)】. At the same time, summarize and extract food and drug information in the non-drug guidance according to the format of 【food category, intake amount, specific intake amount】, 【drug name, dosage, specific dosage】. Example: (staple food, intake amount, <1500 kcal/day), (metformin hydrochloride tablets, dosage, 0.5mg/4/day)】. Original text: Medical history: The patient experienced paroxysmal dizziness with nausea 15 years ago without obvious inducements, no vomiting, no significant activity impairment, no speech difficulties, no facial drooping, and no consciousness impairment. Blood pressure was recorded at a maximum of 160/100 mmHg, and the patient was subsequently referred to another hospital, where they were diagnosed with grade 2 hypertension. After treatment with 'amlodipine besylate tablets, orally / 1/day, 10.0000mg each', the blood pressure was controlled around 130-140 / 80-90 mmHg, and the dizziness symptoms significantly alleviated. Since the onset of the disease, the patient has been clear-minded, mentally stable, with normal diet and sleep, and normal bowel and bladder function.

Medication treatment

- Western Medicine Prescription: Clopidogrel Bisulfate Tablets, orally once daily, 1.0000 tablet per dose; Amlodipine Besylate Tablets, orally once daily, 10.0000 mg per dose; Simvastatin Tablets, orally once daily, 1.0000 tablet per dose.
- Traditional Chinese Medicine Prescription: None.
- Non-Drug Guidance: 1. Follow a low-salt, low-fat diet, controlling daily salt intake to less than 6 grams. 2. For abdominal obesity and overweight, maintain a reasonable diet, engage in moderate exercise, increase muscle mass, and enhance physical fitness. 3. Ensure a balanced diet with adequate nutrition, consume more vegetables and fruits, eat foods rich in vitamin C, reduce oil consumption to less than 25 grams per day, and limit staple food intake to less than half a kilogram per day. 4. Maintain a positive mood and reduce stress from work and life. 5. Reduce waist circumference and weight; prevent osteoporosis, falls, and accidental injuries; provide self-rescue guidance; regulate emotions, maintain psychological balance, avoid extreme emotions, maintain a balanced lifestyle, and cultivate a tranquil mind.
- Doctor's Advice: 1. Consistently adhere to prescribed antihypertensive medication and monitor blood pressure (self-monitor weekly and keep a record; measure clinic blood pressure at least once a month), and seek medical attention for any changes in condition. 2. Regularly conduct blood tests, urine tests, stool tests, chest X-rays (anteroposterior view), electrocardiograms, liver and kidney function tests, and fundus examinations. 3. Engage in appropriate gentle outdoor activities in sunny environments, and avoid exercising in windy, cold, or snowy conditions.

Textbox 6. Extraction results.

Symptoms

- (dizziness, time, 15 years ago)
- (nausea, time, 15 years ago)

Food

- (salt, intake, <6 grams/day)
- (cooking oil, intake, <25 grams/day)
- (staple food, intake, <250 grams/day)

Medication

- (Clopidogrel hydrogen sulfate tablets, dosage, 1/day, specific dosage, 1.0000 tablet)
- (Amlodipine besylate tablets, dosage, 1/day, specific dosage, 10.0000 mg)
- (Simvastatin tablets, dosage, 1/day, specific dosage, 1.0000 tablet)

We summarized the time information for the symptoms extracted according to the format "[symptom name, time, symptom occurrence time]". 【Example: Symptoms: (dizziness, time, 2022) (vomiting, time, 1990)】. At the same time, we summarized the nonmedication guidance for food and medication information according to the format "[food category, intake, specific intake amount], [medication name, dosage, specific dosage]". 【Example: (staple food, intake, <1500 kcal/day), (Metformin hydrochloride tablets, dosage, 0.5 mg/4/day)】. By concatenating the results extracted by ZuoyiGPT with the input to Kimi, a more standardized result that is conducive to postprocessing can be obtained (Textbox 7).

Textbox 7. Example of standardized extraction results after concatenating ZuoyiGPT outputs with Kimi input.

- Symptom Timeline Information
- (Dizziness, time, 15 years ago)
- (Nausea, time, 15 years ago)
- Food Information
- (Salt, intake, <6 grams/day)
- (Oil, intake, <25 grams/day)
- (Staple food, intake, <250 grams/day)
- Medication Information
- (Clopidogrel bisulfate tablets, dosage, 1 tablet/day)
- (Amlodipine besylate tablets, dosage, 10 mg/day)
- (Simvastatin tablets, dosage, 1 tablet/day)

The experimental results showed that Kimi exhibited the best sensitivity to formatting.

First, the error rates and quantities for various food categories and food intake amounts exhibited remarkable similarity. Second, there were significant instances of erroneous extractions without labels; yet, these errors were distributed almost uniformly across all complex feature extractions, excluding symptom timing. We conducted separate analyses for these 2 phenomena.

Incorrect extraction of food categories can lead to erroneous extraction of food intake. Our observations revealed that, among the 4 types of feature information pertaining to drug and food information, errors in time and dosage features were as frequent as—or more frequent than—those in content features. This is because, within the same feature type, errors in content often indicate that the corresponding descriptive information is also incorrect. Therefore, if an incorrect food category is extracted, such as misidentifying smoking and drinking as food, the subsequent extraction of food intake amounts often results in extracting information about quitting smoking and drinking. Similarly, the failure to extract food categories also leads to the failure to extract food intake amounts, and the omission of food categories results in the omission of food intake amounts. LLMs have relatively chaotic definitions of "food categories" and sometimes interpret the task of extracting food recommendations as tasks unrelated to drug guidance. This has led to incorrect extraction, omission, and even incomplete extraction. However, based on input from medical experts and observations of the extraction results, we identified a consistent pattern in physicians' dietary recommendations for patients with chronic and multiple diseases. These recommendations are typically focused on categories such as salt, cooking oil, vegetables, foods rich in vitamin C, staple foods, and foods high in dietary fiber. Moreover, the corresponding intake amounts remain almost unchanged. In other words, the description of food recommendation information is fixed, with fewer categories. Therefore, it is possible to first perform a rough extraction using an LLM and then summarize the results to provide a combination of food recommendations as a reference during prompt modeling, allowing the LLM to complete the secondary feature information extraction of food recommendations.

The issue of erroneous extraction remains consistently prevalent across 3 feature extraction categories: symptoms, medication characteristic information, and food recommendations. LLMs occasionally misclassify information into incorrect labels during the output process. Common errors include misclassifying diseases as symptoms, dietary recommendations as medication characteristic information, and lifestyle recommendations as dietary recommendations. This problem can be somewhat mitigated by incorporating error examples in the prompts.

Comparative Experimental Study of Multiple LLMs

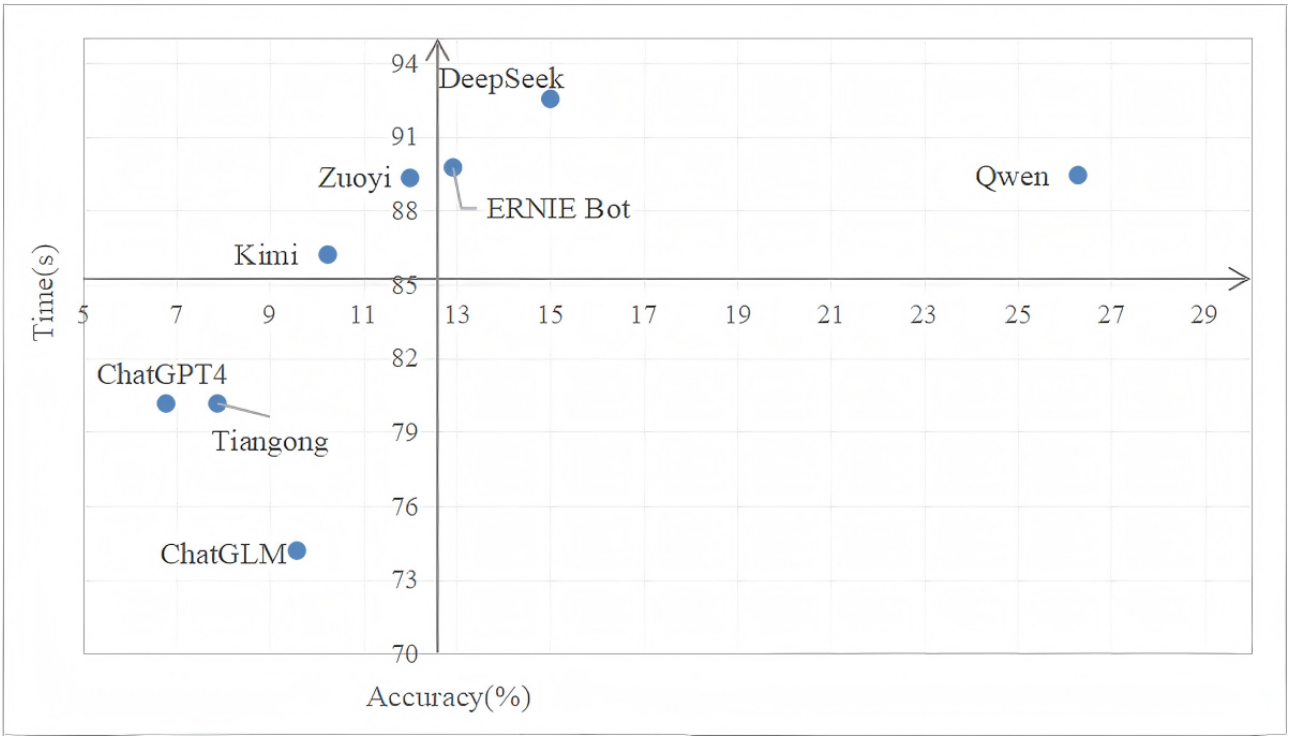
To further validate the ability of LLMs to extract patient features, we performed complex feature extraction experiments on data from 100 patients using 8 general-purpose or domain-specific LLMs—Kimi, DeepSeek, Tiangong, ERNIE Bot, Qwen, ChatGPT with GPT-4, ChatGLM, and Taiyi—and 1 biomedical domain model, BioBERT. For consistency and fair comparison, we applied the same prompt framework used with the ZuoyiGPT model. As shown in Table 5, the F_1-score values of 8 LLMs on complex feature extraction tasks indicated that each model had its own advantage in different feature extraction scenarios. Due to extensive training on medical clinical data, ZuoyiGPT performed well and consistently in symptom and drug extraction tasks. Kimi specializes in providing extraction results that better meet user formatting requirements; however, due to inadequate training in medical data, it occasionally misdiagnosed diseases as symptoms and even produced hallucinations in drug and food extraction tasks, adding features that were not present in the text. DeepSeek showed the best overall performance, but it showed misidentification problems in the symptom recognition task and unstable performance. Tiangong and ChatGPT with GPT-4 were prone to combining multiple symptoms and tended to misclassify "aerobic exercise" as food during the food extraction task. This problem also occurred with ChatGLM when extracting food but to a greater extent: in addition to misidentifying "aerobic exercise," ChatGLM extracted "fall prevention," "multiple diabetes diet," and other items as food categories. This resulted in the poor performance of ChatGLM on the food

XSL•FO
RenderX

extraction task. In addition to the 8 LLMs discussed, we tested Taiyi and BioBERT. However, these 2 models lack training on targeted feature extraction and extraction format, and the extraction performance is relatively poor. Therefore, we excluded them from the results table as the performance reference for evaluating large model performance on the feature extraction task.

Table 5. F_1-score values for complex extraction features using 8 large language models (LLMs).

LLMs	Symptoms (%)	Symptom duration (%)	Medication (%)	Dosage (%)	Food (%)	Intake (%)	Overall (%)	SD value (%)
Kimi	100	100	88.89	88.89	88.89	88.89	90.93	5.5
DeepSeek	93.61	93.61	100	100	94.74	94.74	96.12	2.58
ZuoyiGPT	98.5	98.35	98.96	84.98	92.6	92.79	94.36	4.96
Tiangong	80.6	80.6	97.44	97.44	88.89	88.89	88.98	6.88
ERNIE Bot	91.89	91.89	91.89	91.89	100	100	94.59	3.82
Qwen	90.41	90.41	100	100	92.86	92.86	94.42	4.09
ChatGPT with GPT-4	80.6	80.6	97.44	97.44	88.89	88.89	88.98	6.88
ChatGLM	96.1	96.1	100	100	46.15	46.15	97.43	29.66



Finally, we compiled the average time and accuracy of all complex feature extractions from the EHRs of individual patients for extracting features from 8 LLMs, as shown in Table 6. To understand their respective advantages, we integrated these tables into a chart, as illustrated in Figure 7. The performances of ZuoyiGPT and ERNIE Bot were more comprehensive, ChatGPT with GPT-4 required the least amount of time, and DeepSeek achieved the highest accuracy.

Table 6. The extraction time and overall accuracy of 8 large language models (LLMs).

LLMs	Time (s)	Accuracy (%)	SD value (%)
Kimi	10.24	86.2	4.32
DeepSeek	15.00	92.53	3.55
ZuoyiGPT	12.00	89.32	7.72
Tiangong	7.88	80.15	5.83
ERNIE Bot	12.92	89.74	4.23
Qwen	26.29	89.43	3.96
ChatGPT with GPT-4	6.78	80.15	7.23
ChatGLM	9.58	74.17	30.22

Figure 7. The extraction time and overall accuracy of 7 large language models.

A Practical Survey of Clinical and Research Applications

To validate the practicality of LLMs in extracting patient features for clinical practice, health policy, and medical research, we designed a survey and invited 2 clinical medicine experts, 2 health care policy managers, and 2 medical researchers to respond. All participants had >5 years of experience in health care–related work. The survey included questions about the application of LLMs in EHRs, the advantages and challenges of extracting patient features using these models, and the practicality of these methods in clinical practice, medical research, and the implementation and formulation of health care policies. It also solicited opinions on the accuracy of extracting patient features using LLMs and requested suggestions for method improvement. Statistical analysis indicated that, although the older medical experts and health care policy managers were not very familiar with the use of LLMs and the methods for extracting patient features, all 6 participants recognized the high practicality of these methods in clinical medicine, health care policy formulation, and medical research after using them. At the same time, all participants indicated that they would use and promote the use of LLMs to extract patient characteristic information in future work. The average κ statistic for this method was 83.41, with an average Cohen κ coefficient of 0.98 for the 2 clinical medicine experts, 0.95 for the 2 medical researchers, and 0.89 for the 2 health care policy managers. The Kendall W coefficient for the survey was 0.87, and the Cronbach α coefficient was 0.97. In summary, this method of extracting patient characteristics using LLMs is clinically valuable, and the survey demonstrated high reliability.

Conclusions

We developed a scalable framework for extracting the characteristics of patients with multimorbidity based on LLMs capable of extracting patient characteristic information from unstructured and semistructured EHRs. This framework has the potential to be extended to new disease domains and patient populations without the need for manual data labeling, thereby facilitating large-scale analysis. In medical research, researchers can quickly extract the necessary patient characteristic information using this method without extensive training or manual involvement, streamlining the research process for multimorbidity and other disease areas, significantly enhancing research efficiency and reliability, and aiding in the construction of knowledge bases and knowledge graphs. In clinical practice, clinicians can rapidly access information about patients through this method, greatly assisting their work and treatment decisions. In addition, health care policy makers can similarly use this approach to quickly understand the characteristics of patient clusters, providing a strong foundation for the formulation and implementation of health care policies.

Abstract

Background: Primary liver cancer, particularly hepatocellular carcinoma (HCC), poses significant clinical challenges due to late-stage diagnosis, tumor heterogeneity, and rapidly evolving therapeutic strategies. While systematic reviews and meta-analyses are essential for updating clinical guidelines, their labor-intensive nature limits timely evidence synthesis.

Objective: This study proposes an automated literature screening workflow powered by large language models (LLMs) to accelerate evidence synthesis for HCC treatment guidelines.

Methods: We developed a tripartite LLM framework integrating Doubao-1.5-pro-32k, Deepseek-v3, and DeepSeek-R1-Distill-Qwen-7B to simulate collaborative decision-making for study inclusion and exclusion. The system was evaluated across 9 reconstructed datasets derived from published HCC meta-analyses, with performance assessed using accuracy, agreement metrics (κ and prevalence-adjusted bias-adjusted κ), recall, precision, F_1-scores, and computational efficiency parameters (processing time and cost).

Results: The framework demonstrated good performance, with a weighted accuracy of 0.96 and substantial agreement (prevalence-adjusted bias-adjusted κ=0.91), achieving high weighted recall (0.90) but modest weighted precision (0.15) and F_1-scores (0.22). Computational efficiency varied across datasets (processing time: 248-5850 s; cost: US $0.14-$3.68 per dataset).

Conclusions: This LLM-driven approach shows promise for accelerating evidence synthesis in HCC care by reducing screening time while maintaining methodological rigor. Key limitations related to clinical context sensitivity and error propagation highlight the need for reinforcement learning integration and domain-specific fine-tuning. LLM agent architectures with reinforcement learning offer a practical path for streamlining guideline updates, though further optimization is needed to improve specialization and reliability in complex clinical settings.

Introduction

Background

Primary liver cancer (PLC) is the sixth most commonly diagnosed cancer and the third leading cause of cancer-related deaths worldwide [1]. Among PLCs, hepatocellular carcinoma (HCC) is the most common, accounting for approximately 80% to 90% of liver cancer cases worldwide [2,3]. HCC has a poor prognosis. In general, the overall 5-year survival rate for patients diagnosed with HCC is typically <20%, which is similar to that for lung cancer but notably lower than for colon cancer [4-6]. In addition, the treatment of HCC is highly individualized and

XSL•FO
RenderX

complex [7]. In general, for patients with early-stage HCC, surgical intervention is a viable option, and they often have a relatively good prognosis [8]. However, patients with HCC frequently present at an intermediate or advanced stage, and surgery alone may not be beneficial. Conversion therapies, guided by systemic and local therapy approaches, have demonstrated efficacy in downstaging and potentially resecting intermediate and advanced HCC, as well as enhancing outcomes [9,10]. It is evident that HCC is notably more complex to treat than many other medical conditions, requiring a nuanced decision-making process guided by evidence-based research and clinical guidelines.

However, there is often a delay between research publication and its incorporation into academic discourse, especially with guidelines based on systematic reviews and meta-analyses. An example of this lag can be observed in the 2021 guidelines disseminated by the Society for Immunotherapy of Cancer, which did not incorporate the outcomes of the HIMALAYA trial that same year [11,12]. This randomized controlled trial (RCT) demonstrated that the single tremelimumab regular interval durvalumab regimen, a combination of a single high dose of tremelimumab given as a first-line treatment followed by maintenance treatment with durvalumab, significantly improved overall survival and constitutes a new treatment option [12]. As such, the timely updating of information is of paramount importance, as it facilitates the refinement of guidelines and the evolution of treatment plans. Systematic reviews and meta-analyses represent the highest levels of evidence in the hierarchy of evidence [13]. They play an important role in updating the guidelines. However, meta-analysis and systematic reviews are time-consuming processes, especially the process of collecting and screening literature records [14]. To keep guidelines up to date, faster methods for conducting meta-analyses are essential. Given the standardized PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) framework, integrating artificial intelligence (AI) can help automate and improve this process.

AI is a discipline that allows computers to simulate intelligent human behavior, enabling machines to emulate human intelligence and problem-solving abilities [15]. Large language models (LLMs), built on transformer architectures, have become a central focus in AI research. By predicting the next word in a sequence, LLMs learn statistical patterns in text. Leveraging the transformer's self-attention mechanism, they effectively capture long-range dependencies and contextual meaning [16]. Therefore, LLM can be used to extract structured data from unstructured texts [17,18]. Previous studies have explored the automation of the literature screening process in systematic reviews and meta-analyses using a single LLM with good results [19,20]. However, previous studies often used a single LLM without simulating collaboration among models in different roles [19,20]. Meanwhile, newer models with more parameters or reinforcement learning have shown better performance than earlier approaches.

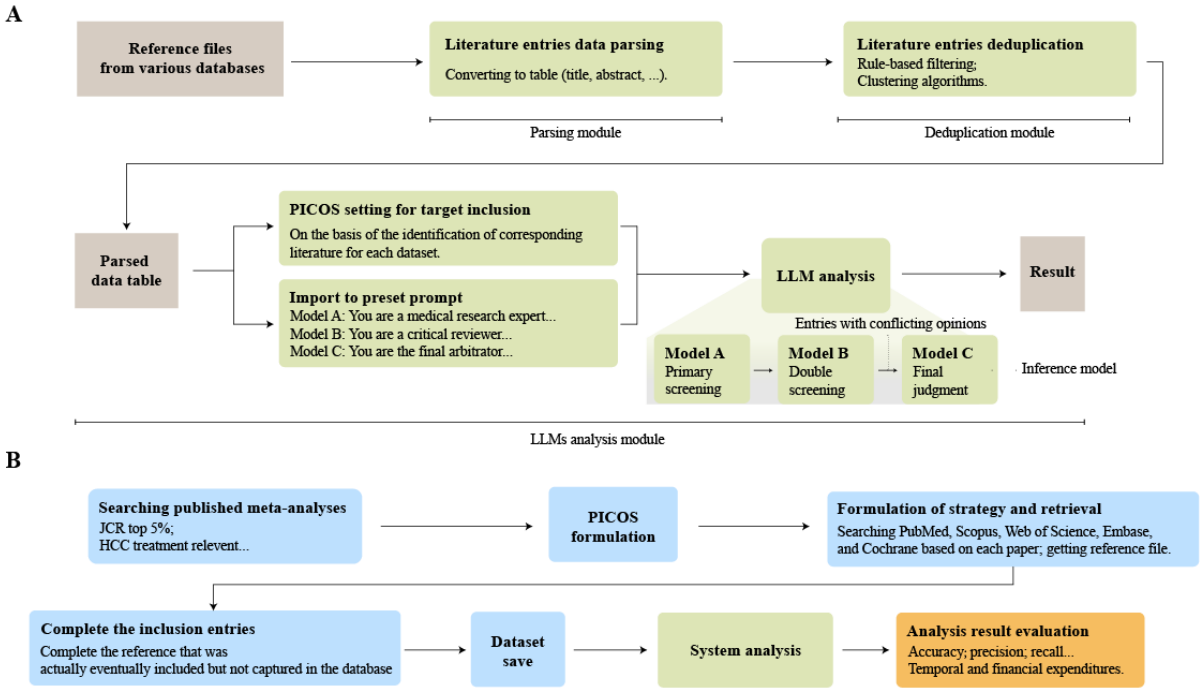
Objectives

In this study, we propose a literature screening workflow that leverages 3 distinct language models to automatically analyze titles and abstracts from multiple databases, aiming to support systematic reviews and meta-analyses. We evaluate its effectiveness in simulating real-world screening procedures and conflict resolution, using datasets from published studies. Furthermore, we investigate the types and causes of model errors across different datasets and explore the integration of reinforcement learning to enhance decision-making.

Methods

Overview

The overall process of this study is divided into 3 stages: application design, validation, and statistical analysis. In the application design section, a multimodule system was developed to parse literature entries, interface with the LLM service provided by the cloud computing platform, and perform literature entry analysis. Verification involved conducting simulations and constructing datasets based on meta-analyses published in high-impact journals, followed by comprehensive validation through analytic procedures implemented in our previously developed system. The final phase involved a comparative and analytic examination of the results generated by the system and the definitive inclusion outcomes of the aforementioned meta-analyses. All programmatic flows were implemented in Python (version 3.12.3; Python Software Foundation) and R (version 4.4.1; R Foundation for Statistical Computing).



Application Design

This study constructed a multimodule system consisting of 3 major parts: literature entry data parsing, duplicate item removal, and LLMs analysis. The workflow of the developed system is shown in Figure 1A. In the literature record parsing part, automated programs were used to process search results saved in RIS and NBIB formats, extracting key fields such as titles, author information, and abstracts into structured data tables. The deduplication part deployed a process based on certain fields of the literature entries to remove highly duplicated entries, as detailed in Multimedia Appendix 1. In the analysis of LLMs part, the program preset roles and inserted the population, intervention, comparison, outcome, and study design (PICOS) guidelines for 3 different large models and embedded the literature entries that needed to be analyzed into prompts in batches. Any analysis task performed by the system must contain at least 1 nonempty element from PICOS. Tasks lacking specific PICOS elements were flagged by the program as unspecified and triggered an expanded search scope. Specifically, this process was divided into 3 parts. The program first assigned model A as the initial reviewer, which made preliminary inclusion or exclusion judgments on the inputted literature entries based on the predefined PICOS criteria, along with the corresponding reasoning. Subsequently, model B was designated as the critic, reviewing the same literature entries and evaluating model A's decisions based on the same PICOS criteria, providing its own judgments and reasoning. Finally, model C was assigned the role of arbitrator, reanalyzing those entries for which models A and B had provided conflicting decisions and making the final determination along with the supporting reasoning. The role prompts and the hyperparameters used for

XSL•FO
RenderX

these 3 models are provided in Multimedia Appendix 1. In addition, a detailed explanation of this system is provided in Multimedia Appendix 1.

Figure 1. Schematic workflow of the study. (A) Workflow of the developed system. The system first parsed the fields in the referenced documents, then used the deduplication function to remove duplicates and parsed a data table. Subsequently, after setting the PICOS objectives of the studies to be included, it was sequentially submitted to three large language models for processing in combination with the prompts. (B) Workflow of the validation process performed for the system. The verification step first relied on existing meta-analyses in highly cited journals, manually identified their PICOS, and reproduced them according to the methods described in the articles to construct a dataset. Subsequently, the analysis process was carried out using the system we had developed. HCC: hepatocellular carcinoma; JCR: Journal Citation Reports; LLM: large language model; PICOS: Population, Intervention, Comparison, Outcome and Study Design.

Validation

The validation section includes the preparation of the verification datasets, system analysis, and data statistics, as shown in Figure 1B. To construct multiple validation datasets, we searched for meta-analyses related to the treatment strategies for PLC. The following inclusion criteria were used: (1) studies published within the past 5 years, (2) meta-analyses of treatment strategies for PLC, (3) studies that reported the search platforms used and described the basic search strategy in the text, and (4) studies published in the top 5% of journals indexed in the Science Citation Index Expanded and compliant with the PRISMA guidelines. The exclusion criteria included studies with search strategies that could not be replicated based on the description in the text, non-English studies, studies without accessible full texts, and studies that overlapped with or duplicated other publications.

After determining the meta-analyses to be included, each meta-analysis was manually reviewed, and the following tasks were undertaken: (1) identifying the PICOS elements by human (leave blank if PICOS components cannot be identified), (2) implementing search strategy to retrieve records according to the method part of each meta-analysis, (3) downloading NBIB or RIS files from various databases, and (4) deduplicating and converting NBIB or RIS files into data tables using the analysis system to construct the datasets. The initial number of candidate records in the data tables was aligned as closely as possible with the corresponding numbers in the PRISMA flow diagrams of the respective meta-analyses. To ensure minimal human intervention in the simulation, any studies that were ultimately included in the original meta-analyses but were missing from the search results were not added back to the datasets.

After constructing all the datasets, 3 major language models were selected based on considerations of research cost and model performance. These models were Doubao-1.5-pro-32k from ByteDance (model A), DeepSeek-v3 (model B), and DeepSeek-R1-Distill-Qwen-7B (model C), with model C distinguished as a reasoning-optimized LLM. The technical specifications for these models are outlined in Table 1. All datasets were analyzed using the previously described analytic workflow of our system, using default hyperparameters as detailed in Multimedia Appendix 1, and the results were exported in tabular format.

XSL•FO

Table 1. Large language models used in the validation process of the review screening workflow.

Model designation	Model name	Model type	Strengths	Limitations
Model A	Doubao-1.5-pro-32k	Closed; general purpose; MoE[a]	High performance and multimodal capability	Closed source model with low transparency
Model B	DeepSeek-V3	Open; general purpose; MoE	Open source, efficient training model	Signs of distillation may lead to identity inconsistency or output bias
Model C	DeepSeek-R1-Distill-Qwen-7B	Open; reasoning optimized	Open source, reasoning, small and efficient for local deployment	Relatively weak in long-context or multimodal tasks

[a]MoE: mixture of experts.

Statistical Analysis

The result tables from each validation set analyzed by the system were compared with the actual final results (excluding entries with missing or empty abstracts from the simulated search) included in their corresponding papers. The accuracy, precision, recall, F_1-score, κ, and prevalence-adjusted bias-adjusted κ (PABAK) of the analysis results for all datasets were calculated, where precision and recall were calculated separately based on exclusion and inclusion as the final goal. To improve comparability in imbalanced scenarios, F-β (a weight harmonic mean of precision and recall), balanced accuracy, and Matthews correlation coefficient (MCC) were also evaluated. The statistical indicators of the average were reported using the mean and, where applicable, the standard deviation (SD). The calculation formulas for the statistical metrics are presented in Multimedia Appendix 1. To further evaluate the effect of class imbalance on agreement measures, paired statistical significance tests were conducted to compare κ and PABAK to determine whether κ was systematically depressed under imbalanced class distributions. Depending on the distribution of the paired differences, either a paired 2-tailed *t* test or a Wilcoxon signed rank test was used at a significance level of $P<.05$. In addition, we evaluated the time and economic costs for the analysis of each dataset. The time cost was determined by recording the start and end time stamps from the analysis logs for each dataset. Due to billing latency in cloud computing platforms, the economic cost was estimated through a simulation program based on platform pricing and then validated against actual billing statements. The detailed design of the simulation program is described in Multimedia Appendix 1.

Results

Overview of Datasets

On the basis of the simulation process in the validation, 9 meta-analyses were ultimately included and used to construct the simulated datasets [21-29]. These studies were published in various prestigious journals, including the *British Journal of Surgery*, *Liver Cancer*, *Journal of Hepatology*, *JAMA Oncology*, and *Annals of Surgery*. Published between 2020 and 2025, these meta-analyses formed the foundation of the dataset and addressed a diverse range of topics related to PLC treatments, such as systemic therapies, radiation-based approaches, and posttransplant outcomes. These studies, conducted across multiple regions, including the United States, Europe, and Asia, involved single-center and multicenter collaborations. In addition, they used diverse data sources (RCTs, observational cohorts, and individual patient-level data) and applied meta-analytic methods, including pairwise comparisons, network meta-analyses, single-arm analyses, and individual patient data assessments.

In each of the meta-analyses included, 9 datasets were created to represent the initial records identified during their search process, as shown in Table 2. The number of initially identified records in these simulated datasets ranged from 309 to 8733. These datasets encompassed multiple perspectives on the treatment of PLC, including a diverse range of candidate study types, such as RCTs; observational studies (eg, cohort and case-control designs); systematic reviews; meta-analyses; and other evidence-based reports sourced from databases such as PubMed, Cochrane Library, and clinical trial registries. These datasets also featured various types of meta-analyses and varying numbers of initially identified records, reflective of real-world meta-analysis scenarios where data availability and completeness can differ widely. Information on these datasets, including the PICOS criteria corresponding to each meta-analysis and the search strategies used to construct the respective datasets, is provided in Multimedia Appendix 1.

Table 2. Characteristics of meta-analysis studies included in the validation stage.

Dataset name	Study title	Included records (n/N, %)[a]	Published journal	Study type
LORC-CH[b]	Laparoscopic versus open resection of hepatocellular carcinoma in patients with cirrhosis: meta-analysis [21]	11/770 (1.4%)	*British Journal of Surgery*	Meta-analysis of 2 interventions based on RCTs[c] and PSM[d] studies
FLSTN-AH[e]	First-line systemic therapies for advanced hepatocellular carcinoma: a systematic review and patient-level network meta-analysis [22]	11/5417 (0.20%)	*Liver Cancer*	Network meta-analysis based on RCTs
TLP-AH[f]	Efficacy and safety of transarterial chemoembolization combined with lenvatinib and PD-1 inhibitor in the treatment of advanced hepatocellular carcinoma: a meta-analysis [23]	12/309 (3.9%)	*Pharmacology & Therapeutics*	Single-intervention, multiple-control meta-analysis based on cohort studies
NCN-UH[g]	Comparative efficacy of novel combination strategies for unresectable hepatocellular carcinoma: a network metanalysis of phase III trials [24]	9/1698 (0.54%)	*European Journal of Cancer*	Network meta-analysis based on RCTs
FSTN-AH[h]	Efficacy and safety of frontline systemic therapy for advanced HCC: a network meta-analysis of landmark phase III trials [25]	15/8733 (0.17%)	*JHEP Reports*	Network meta-analysis based on RCTs
PTICI-PTHO[i]	Impact of pre-transplant immune checkpoint inhibitor use on post-transplant outcomes in HCC: a systematic review and individual patient data meta-analysis [26]	21/558 (3.8%)	*Journal of Hepatology*	Individual patient data meta-analysis
SBRT-HMG[j]	Stereotactic body radiation therapy for hepatocellular carcinoma: meta-analysis and international stereotactic radiosurgery society practice guidelines [27]	13/897 (1.4%)	*International Journal of Radiation Oncology - Biology - Physics*	Single-arm meta-analysis based on observational studies
STSN-AH[k]	Systemic therapy and sequencing options in advanced hepatocellular carcinoma: a systematic review and network meta-analysis [28]	13/3522 (0.37%)	*JAMA Oncology*	Network meta-analysis based on RCTs
LRAMC[l]	Liver resection versus local ablation therapies for hepatocellular carcinoma within the Milan criteria: a systematic review and meta-analysis [29]	24/6078 (0.39%)	*Annals of Surgery*	Meta-analysis of 2 interventions based on RCTs and NRTs[m]

[a]N represents the sample size of the corresponding dataset by simulating the retrieval strategy from the corresponding study, followed by system parsing, deduplication, and removal of entries with blank abstracts in our research; n indicates the actual number of final included literature records after excluding those not retrieved by our simulated search strategy and entries with missing abstracts, based on the final inclusion results from the corresponding study.

[b]LORC-CH: laparoscopic versus open resection in cirrhotic hepatocellular carcinoma

[c]RCT: randomized controlled trial.

[d]PSM: propensity score matching.

[e]FLSTN-AH: first-line systemic therapy network meta-analysis for advanced hepatocellular carcinoma.

[f]TLP-AH: transarterial chemoembolization plus lenvatinib plus programmed death receptor 1 inhibitor in advanced hepatocellular carcinoma.

[g]NCN-UH: novel combination network meta-analysis for unresectable hepatocellular carcinoma.

[h]FSTN-AH: frontline systemic therapy network meta-analysis for advanced hepatocellular carcinoma.

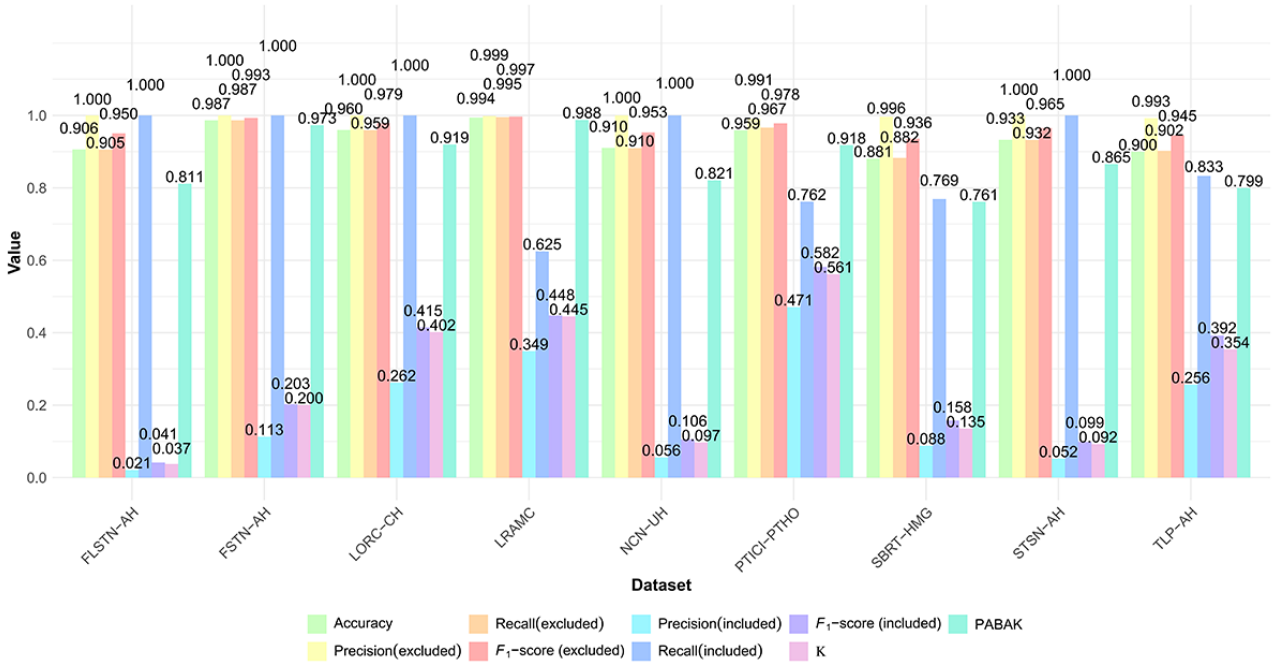
[i]PTICI-PTHO: pre-transplant immune checkpoint inhibitors impact on post-transplant hepatocellular carcinoma outcomes.

[j]SBRT-HMG: stereotactic body radiation therapy in hepatocellular carcinoma meta-analysis and guidelines.

[k]STSN-AH: systemic treatment sequencing network meta-analysis for advanced hepatocellular carcinoma.

[l]LRAMC: liver resection versus ablation within Milan criteria.

[m]NRT: nonrandomized trial.



Performance

The system performed well in both inclusion and exclusion tasks, as shown in Figure 2. Overall, the system correctly classified 26,735 (95.54%) of 27,982 records across the 9 datasets. When targeting exclusion, the weighted average precision and recall reached approximately 1.00 (SD < 0.01; range 0.99-1.00) and 0.96 (SD 0.04; range 0.90-1.00), respectively. In contrast, when targeting inclusion, the weighted average precision was 0.15 (SD 0.13; range 0.05-0.47), while the weighted recall was 0.90 (SD 0.16; range 0.62-1.00). F_1-scores for included articles were modest, with a weighted average of 0.22 (SD 0.16; range 0.04-0.58). Detailed inclusion and exclusion status and more detailed performance metrics are presented in Tables S1 and S2 in Multimedia Appendix 1. Furthermore, the paired *t* test comparing the mean κ (0.258) and the mean PABAK (0.873) revealed a statistically significant

XSL•FO
RenderX

difference (t_8=−11.740; P<.001), confirming that class imbalance biased κ downward and justifying the use of PABAK for a more accurate assessment of consistency. The weighted mean PABAK value across all datasets was high at 0.91 (range 0.76-0.99), indicating excellent overall consistency of the model predictions. The calculation results of the significance test of the difference between κ and PABAK are provided in Multimedia Appendix 1. In addition, the 3 metrics for imbalanced datasets, F-β, balanced accuracy, and MCC, demonstrated moderate performance levels. When β was set to 2, the weighted average of F-β was 0.45 (range 0.09-0.68). The weighted average of balanced accuracy was 0.93 (range 0.81-0.99). The weighted average of MCC was 0.27 (range 0.14-0.58). More detailed information about imbalance metrics is provided in Table S3 in Multimedia Appendix 1.

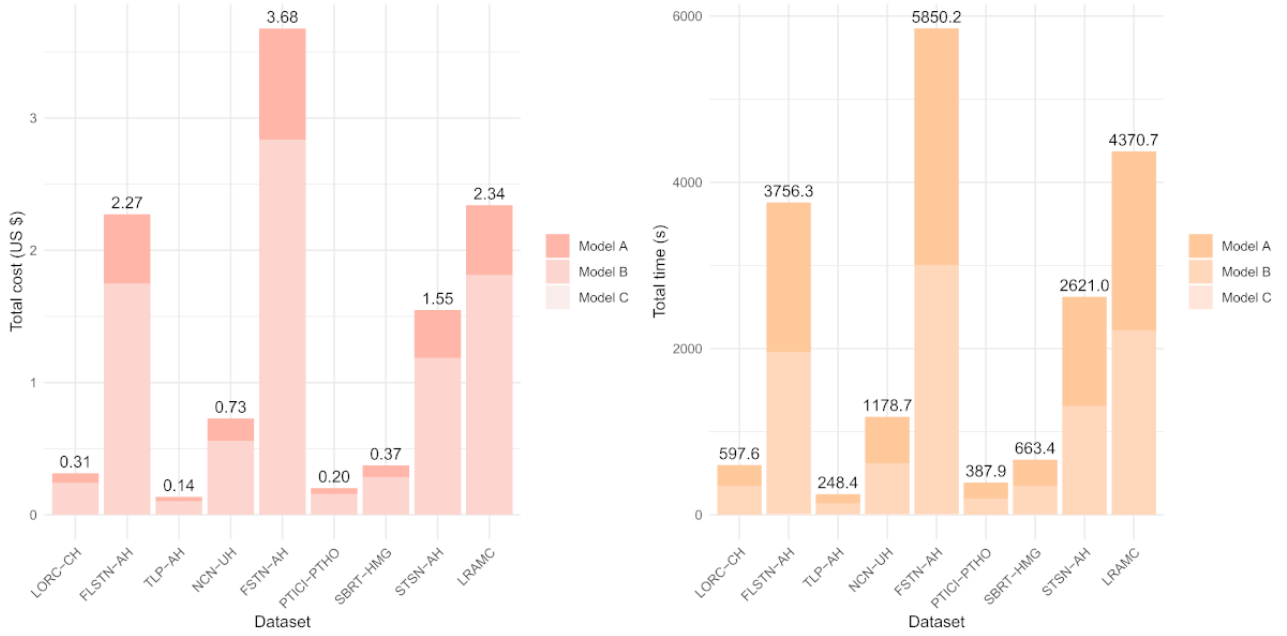


Figure 2. Comparative performance of 3 large language model–based analytic systems across 9 benchmark datasets. The metrics include accuracy, precision, recall, F1-score, κ, and prevalence-adjusted bias-adjusted kappa (PABAK). Precision, recall, and F1-score were calculated twice, once with "included" as the positive class (targeting the correct identification of articles to include) and once with "excluded" as the positive class (targeting the correct identification of articles to exclude). The system achieved high accuracy across all datasets, with recall and PABAK consistently displaying relatively high values, especially when focusing on inclusion. FLSTN-AH: first-line systemic therapy network meta-analysis for advanced hepatocellular carcinoma; FSTN-AH: frontline systemic therapy network meta-analysis for advanced hepatocellular carcinoma; LORC-CH: laparoscopic versus open resection in cirrhotic hepatocellular carcinoma; LRAMC: liver resection versus ablation within Milan criteria; NCN-UH: novel combination network meta-analysis for unresectable hepatocellular carcinoma; PTICI-PTHO: pre-transplant immune checkpoint inhibitors impact on post-transplant hepatocellular carcinoma outcomes; SBRT-HMG: stereotactic body radiation therapy in hepatocellular carcinoma meta-analysis and guidelines; STSN-AH: systemic treatment sequencing network meta-analysis for advanced hepatocellular carcinoma; TLP-AH: transarterial chemoembolization plus lenvatinib plus programmed death receptor 1 inhibitor in advanced hepatocellular carcinoma.

In terms of time and economic costs, as this system used cloud-based LLM calls and processing, most of the time and monetary costs depended on the processing time and pricing of the cloud computing platform. On the basis of the processing capacity and quotation of Volcano Engine (a cloud computing platform in mainland China), under the default hyperparameter settings, the system's expenditure could be considered low, as shown in Figure 3. Regarding time costs, 19,674.2 seconds (approximately 5 h and 28 min) were spent analyzing the 9 datasets, with an average of 2186.0 seconds (approximately 36 min; SD 2052.4 seconds) per dataset. In addition, the time required to analyze each 1000 entries was approximately 703.1 seconds (approximately 12 min). Among these datasets, the processing time ranged from 248.4 seconds (approximately 4 min [the shortest] observed for transarterial chemoembolization plus lenvatinib plus programmed death receptor 1 inhibitor in advanced hepatocellular carcinoma [TLP-AH];12/309, 3.9%) to 5850.2 seconds (approximately 1 h and 37 min [the longest] observed for the frontline systemic therapy network meta-analysis for advanced hepatocellular carcinoma [FSTN-AH]; 15/8733, 0.17%). Furthermore, the economic costs were modest, with the analysis of all datasets totaling US $11.59, an average of US $1.29 (SD US $1.25) per dataset, and approximately US $0.41 per 1000 entries. Among the individual datasets, the smallest (TLP-AH) incurred a cost of US $0.14, whereas the largest (FSTN-AH) incurred a cost of US $3.68. These fluctuations in time and economic costs underscore the computational resource implications associated with disparate dataset characteristics, as further elucidated in Tables S4 and S5 in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 3. Comparative analysis of financial and time costs for the system across 9 datasets. (A) Financial costs (in US $) associated with analyzing each validation dataset using 3 large language models (LLMs): model A (Doubao-1.5-pro-32k), model B (DeepSeek-v3), and model C (DeepSeek-R1-Distill-Qwen-7B). Each stacked bar represents the total cost per dataset, with segments corresponding to the expenditure for each individual model. (B) Time costs (in seconds) required by the same 3 LLMs to process each dataset. Stacked segments similarly represent the time consumed by each model. This figure provides a direct visual comparison of the distribution and overall scale of economic and temporal resources consumed by each model during the literature screening process across different validation datasets. FLSTN-AH: first-line systemic therapy network meta-analysis for advanced hepatocellular carcinoma; FSTN-AH: frontline systemic therapy network meta-analysis for advanced hepatocellular carcinoma; LORC-CH: laparoscopic versus open resection in cirrhotic hepatocellular carcinoma; LRAMC: liver resection versus ablation within Milan criteria; NCN-UH: novel combination network meta-analysis for unresectable hepatocellular carcinoma; PTICI-PTHO: pre-transplant immune checkpoint inhibitors impact on post-transplant hepatocellular carcinoma outcomes; SBRT-HMG: stereotactic body radiation therapy in hepatocellular carcinoma meta-analysis and guidelines; STSN-AH: systemic treatment sequencing network meta-analysis for advanced hepatocellular carcinoma; TLP-AH: transarterial chemoembolization plus lenvatinib plus programmed death receptor 1 inhibitor in advanced hepatocellular carcinoma.

Discussion

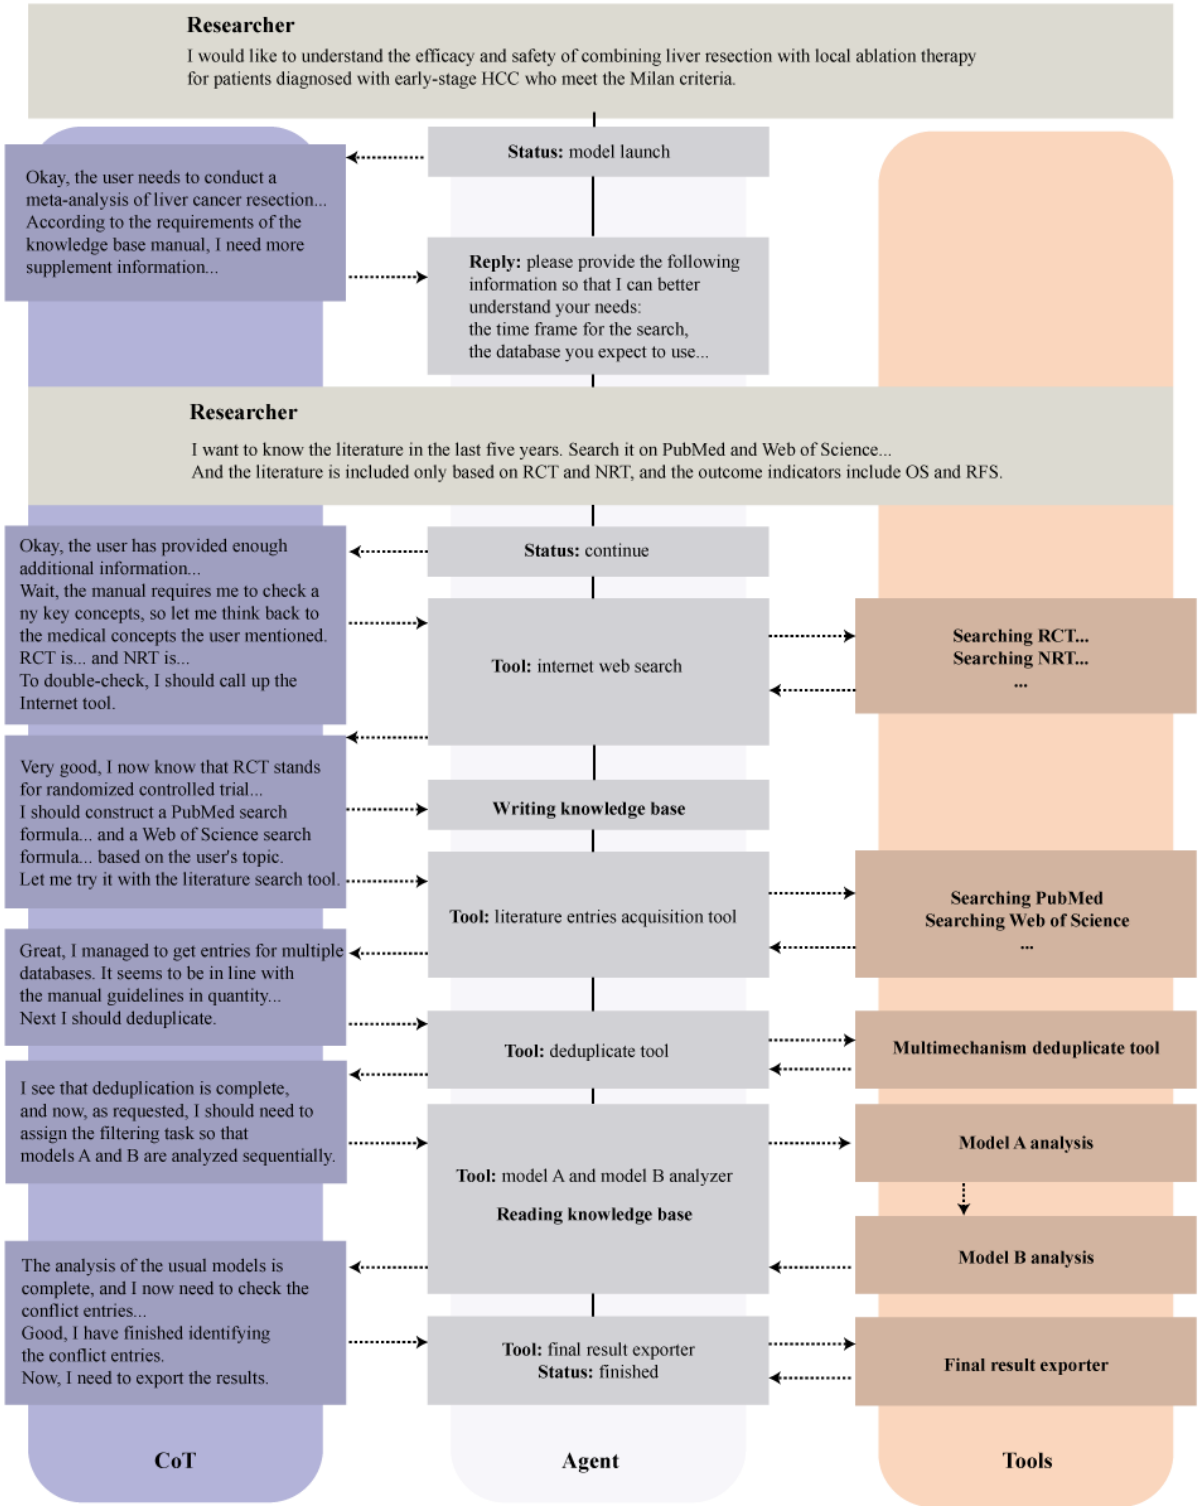
Principal Findings

Automation in the literature screening process during meta-analysis can save scholars significant time and effort. Targeting inclusion, our system achieved a weighted average accuracy of 0.96 and a weighted average PABAK value of 0.91. In addition, the system achieved a weighted average recall of 0.90, with evaluations across multiple datasets showing a recall value of 1.00. This suggests that our system and approach may have potential practical use. Furthermore, our system leverages a program that sends local requests to the LLM's cloud computing service, resulting in minimal requirements for user-side devices. It does not necessitate high-performance GPUs, and only terminal devices capable of multithreading are required, which greatly facilitates user deployment. Through the multithreaded design combined with certain cloud computing services, the processing duration ranged from approximately 4.1 minutes for the quickest run to approximately 1.6 hours for the most extensive one, thereby saving users' time. Simultaneously, owing to our selection of LLMs that are not mainstream top-tier ones, the costs remain low. On specific platforms, the analysis of our most complex dataset incurred <US $4, substantially expanding practical accessibility for researchers with limited budgets. Regarding scalability considerations, the system's multithreaded architecture can be enhanced by increasing the number of threads to achieve greater parallelism, thereby reducing processing times for larger datasets. In addition, expanding batch processing sizes would optimize LLM invocations, allowing more efficient handling of high-volume data. Finally, adopting more optimized models with faster inference could further improve performance and adaptability, ensuring viability for extensive real-world meta-analyses while maintaining modest resource demands.

A cornerstone of our system is the collaborative integration of multiple LLMs, drawing inspiration from the tripartite collaborative framework in cognitive science [30]. This design enables decision sharing among language models through the transmission of information, allowing subsequent models to optimize their judgments based on the results of preceding models. Such an iterative approach not only improves analytic accuracy but also enhances interpretability, partially mirroring the collaborative nature of manual meta-analysis. A previous study [19] has used a single GPT-4o model for similar classification tasks, achieving an accuracy of 0.91, whereas our system achieved a weighted average accuracy of 0.96, outperforming this prior work. Unlike prior studies reliant on a single model, such as ChatGPT, our system uses 3 distinct LLMs, which offer performance comparable to GPT-4o at reduced costs, and an advanced open-source reasoning model that further lowers deployment expenses [19,20,31].

Presently, there are already several tools that use AI in a comparable manner. These include Scispace, Elicit, Consensus, and Scite, which use literature titles and abstract information

XSL•FO
RenderX



to leverage LLMs to extract key insights from literature and integrate them. However, most of these platforms are primarily designed for conducting literature reviews, and these supporting systematic review analyses often come with high economic costs and lack transparency. In addition, platforms such as DistillerSR and RobotAnalyst have automated the systematic review process [32,33]. However, these tools are not currently strongly integrated with LLMs. In contrast, our system combines the strengths of LLMs and programmatic pipelines within its workflow to support the updating of systematic reviews and meta-analyses.

Our system has certain limitations. Although our datasets encompass multiple topics with substantial numbers of records initially identified, the Sankey diagram, as shown in Table S6 and Figure S1 in Multimedia Appendix 1, revealed that data flow across datasets exhibits remarkable consistency, indicating limited divergent perspectives generated by the secondary model. Refinements to model temperature and prompt engineering may prove beneficial in addressing this limitation [34,35]. Crucially, it should not be ignored that our overall precision and F_1-scores are relatively low, as shown in Figure 2. We conducted an in-depth analysis of the cases where misidentification occurred. First, nonspecialized models and potentially insufficient training corpora may be responsible for the initial misclassification of literature entries, as they fail to accurately grasp the key conceptual features within the texts, leading to incorrect categorization. For example, we found that cost-effectiveness analyses derived from RCTs published by other researchers were incorrectly identified as RCTs themselves. Providing a detailed description of key concepts in the prompt or collaboratively using a chain of knowledge approach may be a potential solution to improve this aspect [36]. In addition, the degradation in contextual understanding under long prompt contexts may limit model performance, which could be attributed to attention dilution [37]. Reducing batch size may mitigate this issue. Our selected model, DeepSeek-V3, being a distilled version, exhibits limitations in conceptual transformation and performance [38]. This phenomenon can be ascribed, at least in part, to the model collapse problem inherent to LLM [39,40]. Model collapse is a systematic degradation phenomenon that occurs in generative models during recursive training, which manifests itself as loss of output diversity, reduced semantic coherence, and even logical confusion [40]. This problem can be optimized in subsequent training of LLMs, such as through the use of data specific to the treatment of liver cancer to train or fine-tune, thereby reducing the risk of overgeneralization or improvements at the architectural level [41,42]. Moreover, our dataset is currently focused on HCC treatment. Although we selected HCC treatment as a complex test case to rigorously evaluate our system, and the workflow is theoretically generalizable, its performance on broader oncology topics or other disease domains remains to be validated.

Architecture construction based on LLM agents and reinforcement learning (RL) may be a more practical approach to address potential issues, such as the low recall observed in this study. Despite the lack of a unified definition, the LLM agent is driven by a core LLM that acts as the brain, completing the logical chain through collaboration [43-46]. As illustrated in Figure 4, our proposed system uses a reasoning model as the core foundation, leveraging its complete chain of thought capabilities. For ambiguous tasks, such as analyzing the “liver resection versus ablation within Milan criteria” dataset’s objectives (comparing efficacy and safety of liver resection combined with local ablation in early-stage HCC meeting Milan criteria), the model accepts the request, references the knowledge base for guidelines, and queries the researcher on parameters such as publication time range and search platforms. Upon receiving sufficient input, the core model initiates planning: it invokes internet tools to iteratively search key concepts (eg, Milan criteria metrics and local ablation therapies) until a reward threshold is met, storing results in the knowledge base. It then constructs platform-specific search queries, directing a literature acquisition tool to retrieve entries (including titles and abstracts) until the threshold is reached. Subsequently, a deduplication tool processes multiplatform entries to yield unique results. The core model then assigns 2 distinct regular models for primary and secondary screening, referencing the knowledge base, and resolves conflicts to finalize outcomes. This integration of RL and model specialization creates an advanced system, akin to OpenAI’s deep research feature, which eases the step of reviews. Nevertheless, it is important to note that hallucinations in LLMs are difficult to avoid, and appropriate human intervention remains crucial [47]. Key challenges include automating document retrieval across platforms and embedding RL throughout, warranting further empirical validation.

XSL•FO
RenderX

Figure 4. Integrated framework for systematic literature screening using a large language model (LLM) agent and reinforcement learning (RL) optimization. This diagram illustrates the workflow of a systematic literature screening process driven by an integrated LLM agent. The central agent uses a chain of thought (CoT) approach as its core reasoning mechanism, supported by automated tools and optimized throughout by RL. The process starts when the researcher initiates a request, prompting the agent to clarify the analysis scope, including publication timeframe, selected databases, and key outcome indicators. Following this, the central agent uses internet-based searches to verify essential medical concepts. Subsequently, automated tools conduct structured literature searches across databases, retrieving and deduplicating entries for a refined set. The central agent directs models for sequential initial and secondary screenings, then synthesizes results, resolves conflicts, and generates an optimized final output. HCC: hepatocellular carcinoma; RCT: randomized controlled trial; NRT: nonrandomized trial.

Conclusions

The results of this study showed that an automated screening process for systematic reviews and meta-analyses based on LLM was feasible in the context of treatment interventions for HCC. Our findings demonstrated the feasibility and effectiveness of an automated literature screening approach leveraging LLMs for systematic reviews and meta-analyses

XSL•FO
RenderX

related to treatment interventions in HCC. The proposed methodology exhibited high recall rates and promising accuracy metrics, highlighting its capability to reliably identify relevant literature while reducing both the time and financial resources required for manual screening. The tripartite collaborative integration of general-purpose LLMs with a reasoning-optimized model further enhanced transparency and interpretability throughout the analysis process. We propose refining the current framework by integrating an agent-based workflow augmented with RL, which could further enhance analytic precision and clinical relevance. Subsequent studies are warranted to empirically validate the effectiveness and feasibility of these proposed enhancements.

Acknowledgments

This study was supported by the research project fund of Chengdu Medical College (grant CYYZZ24-07). The authors gratefully acknowledge the technical support and service assistance provided by the Volcano Engine Computing Platform of ByteDance for the large language model used in this study.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request. A free demo is hosted on Hugging Face [48]. The source code is openly available on GitHub [49].

Authors' Contributions

CP contributed to the application development, testing, validation, statistical analysis, and manuscript drafting of this project. WL checked the original papers and corresponding datasets used for validation. BC ensured data integrity by verifying the accuracy of statistical results. GZ and ZY provided professional guidance on the medical academic practical use and core medical concepts of the application. JH played a key role in project management, provided medical expertise guidance, conducted code reviews, and participated in manuscript revision.

Abstract

Background: The primary health care service in Indonesia consists of 10,260 public health centers (Puskesmas), which play a major role in providing health care in the community, recording and reporting health data using digital health information systems (HIS) or manual reports. The utilization of HIS across Puskesmas is crucial to capture the dynamic evolution of health problems and monitor interventions, thus providing effective primary health care services for the community.

Objective: This paper provides a national-level baseline mapping of HIS utilization in Indonesian Puskesmas. It evaluates the number of HIS used, associated challenges, and contextual factors influencing system adoption.

Methods: A cross-sectional survey was carried out covering all Puskesmas across 34 Indonesian provinces between January and February 2022. The questionnaire covered a list of HIS used by Puskesmas, which developed the HIS, and the utilization and challenges during HIS implementation. Descriptive statistical analysis and bivariate analysis were applied.

Results: A total of 2606 (25.5%) public health centers across 34 provinces participated in this study. On average, Puskesmas reported using 30 different HIS platforms, with notable variation across provinces and islands. Most systems (n=62,060, 72.94%) were developed by national ministries, though local governments and third parties also contributed. Despite 91.5% of respondents reporting that HIS aligned with their needs and 90% claiming data use for decision-making, many centers faced operational barriers: 49% (n=132,300) of systems required excessive data entry, 33% (n=89,100) experienced frequent downtime, and 29% (n=78,300) lacked automated analysis features. In terms of the infrastructure supporting HIS implementation, 9.45% (n=138) of Puskesmas have no access to the internet, while only 28.9% (n=422) have access to robust and efficient internet connections. As for the human resources, the study reveals that each health personnel manages up to six different HIS for data reporting tasks, 74.30% (n=1133) of Puskesmas only received training at the initial system's implementation stage, and 80.51% (n=1225) of respondents report the existence of an informal knowledge transfer process among the staff. The bivariate analysis shows that Puskesmas with the characteristics of being located in Java island and urban areas possessed higher accreditation levels, had more training and knowledge transfer, and had a greater chance to use >30 HIS.

Conclusions: This descriptive study highlights substantial fragmentation in Indonesia's HIS environment and reveals critical disparities in system infrastructure, usability, and workforce capacity. Recommendations should be tailored to different contexts: offline-compatible systems and basic digital literacy training are needed in rural areas, while urban Puskesmas may benefit from advanced integration and analytics tools. Future research should address HIS interoperability, impact assessment, cost-effectiveness, and qualitative user experience through longitudinal and mixed methods studies to guide Indonesia's digital health transformation.

Introduction

Health information systems (HIS) are defined as a set of structures—including data, information, indicators, procedures, devices, technology, and human resources—that are interrelated and managed in an integrated manner; they provide information support for the decision-making process, health program planning, implementation monitoring, and evaluation at every level of health administration [1,2]. Globally, HIS have been used in primary health care facilities to record, analyze, report, and transfer patients' data, in which the data will be highly important to improve the health system's management [3]. The World Health Organization (WHO) report in 2010 highlighted the importance of HIS as a contributing factor to overall health management improvement [4]. Studies from low- and middle-income countries show that HIS implementation has been carried out, despite challenges and barriers to successful implementation [5].

Indonesia is the world's fourth most populous country with over 270 million people residing across more than 17,000 islands [6,7]. The country has adopted a decentralized administrative system since 1999, which granted provincial governors and district leaders the authority to govern their own areas, including health care service governance [8,9]. At the national level, the Ministry of Health plays a vital role in formulating health policies, regulations, and strategies that guide the entire health care system, setting standards, coordinating resources, and implementing national health programs. This responsibility extends to the provincial level, where each of the provinces has its own health office (provincial health office) responsible for implementing region-specific health care policies and programs. Additionally, at the district level, the 514 district health offices (DHOs) play a crucial role in managing and monitoring the provision of health care services [8,9].

The smallest unit of public health care service at the subdistrict level is called Puskesmas (Pusat Kesehatan Masyarakat or public health center), which stands for the primary health care service for the local community. The number of Puskesmas increased by 9.3% over the past decade, from 9510 in 2012 to 10,260 in 2021 [10,11]. The Puskesmas are spread across all areas of Indonesia, with the ratio of Puskesmas per subdistrict currently at 1.04, which means that in each subdistrict, there is at least one Puskesmas [7]. Puskesmas serve as the first point of contact for individuals seeking health care, providing preventive, curative, and rehabilitative services in the area of general medicine, maternal and child health, family planning, immunization, and more [12,13]. At the same time, each Puskesmas has the obligation to record and report all health program activities or health data within its working area, using digital HIS or manual reports, and submit it regularly to the DHO [14].

It is crucial for Puskesmas to ensure that robust HIS can accommodate the dynamic monitoring of health problems and interventions, supporting the provision of effective primary health care services for the community. HIS facilitate the collection, storage, analysis, and retrieval of health-related data, empowering Puskesmas and the DHO in making informed decisions within their working area [15]. Thus, Puskesmas can better manage patient records, track disease outbreaks, plan resource allocation, and contribute to the overall improvement of health care services in Indonesia [16,17]. Maintaining a timely and accurate data collection infrastructure, policy makers can then better allocate resources, plan health care services, and implement targeted interventions that address the health care challenges faced by the growing population [18-20].

To date, the use of HIS continues to grow across Indonesia, including in Puskesmas. However, only limited publications are available that discuss the national-scale HIS implementation in Indonesia. A study reported on the implementation of 12 selected HIS in Puskesmas at the national level [21]. Most studies discussed the HIS utilization only for specific programs, such as tuberculosis [22], immunization [23], malaria [24], and electronic medical record system [25,26]. Many studies only focus on HIS implementation in specific areas such as provinces [27,28]. A literature review highlights the utility of HIS but is limited to the Puskesmas scale and only focuses on Puskesmas' management information systems [27,29]. A narrative study in 2015 reveals the barriers and challenges of HIS implementation in a low- and middle-income country (LMIC) on a general basis [3].

This paper aims to provide, for the first time, a comprehensive national overview of the utilization of HIS across Puskesmas in Indonesia. It presents a descriptive mapping of the types and number of HIS in use, the institutional and infrastructural conditions that may be associated with their implementation, and the common challenges encountered at the facility level. The analysis includes aspects such as internet availability, accreditation status of Puskesmas, system usability, and the availability of training. Additionally, the study explores key workforce characteristics, including staff education background and reported HIS-related workloads. While the study does not assess system interoperability, causality, or performance impact, it offers a foundational evidence base to inform future digital health strategies and more targeted research.

Methods

Data Collection

A cross-sectional approach was chosen, using a survey carried out between January 28 and February 28, 2022. The population study covered 10,260 Puskesmas across 34 provinces in Indonesia. Slovin calculator [30] was used to count the sample size based on 5% margin of error. The Slovin formula was used in this study as it is widely used in public health and social science research, where the total population size is known but the population's variance or SD information is limited. The Slovin formula offers a practical and transparent means of estimating a representative sample size. Although it does not explicitly account for CI or statistical power, this limitation was addressed by selecting a conservative margin of error of 5%, in line with the accepted research standard. Accordingly, an expected sample was 385 participants out of 10,260 Puskesmas. To account for potential data incompleteness, an additional 10% was added, resulting in a final minimum sample size of 424 Puskesmas.

XSL•FO
RenderX

A questionnaire was used to obtain the data from the participants. The questionnaire was developed referring to the PRISM (Performance of Routine Information Systems Management) framework [31] to assess routine HIS in LMICs. We used and adopted the routine health information tools overview tool to list the information systems that exist in the country and the type of data they collect. A pilot survey test was conducted to ensure questionnaire validity and reliability with a total of 20 participants, resulting in a satisfactory Cronbach α value (0·76). The questionnaire consisted of two sections: (1) a list of HIS used by Puskesmas, which developed the HIS, and the utilization and challenges during HIS implementation; and (2) an exploration of factors that influence the utilization of HIS in Puskesmas, including human resources, supporting facilities, and infrastructure. The identities of participants were also captured as representatives from Puskesmas. As the survey relied on self-reporting from designated Puskesmas personnel, responses may reflect individual perceptions or institutional biases rather than objective system evaluations. To reduce response bias, the questionnaire was anonymized, and standardized definitions were provided throughout.

Data Analysis

Univariate analysis was conducted using SPSS (IBM Corp) software to examine the HIS utilization in Puskesmas across Indonesia. The major islands in Indonesia were divided into six categories: (1) Java Island, covering provinces such as Banten, DKI Jakarta (special capital region of Jakarta), West Java, Central Java, Yogyakarta Special Region, and East Java; (2) Bali and Nusa Tenggara, including Bali, East Nusa Tenggara, and West Nusa Tenggara provinces; (3) Sumatera, covering Aceh, North Sumatra, West Sumatra, Riau, Riau Islands, Jambi, South Sumatra, Bengkulu, Bangka Belitung, and Lampung provinces; (4) Kalimantan, including West Kalimantan, Central Kalimantan, South Kalimantan, East Kalimantan, and North Kalimantan provinces; (5) Sulawesi, including South Sulawesi, North Sulawesi, Central Sulawesi, Gorontalo, Southeast Sulawesi, and West Sulawesi; and (6) Maluku and Papua, consisting of Maluku, North Maluku, Papua, and West Papua provinces.

Puskesmas are systematically distributed across various regions, ensuring accessible health care services are available to all communities. Based on Article 21 of the Ministry of Health Decree Number 75 Year 2014 [12], Puskesmas are divided into three characteristic regions, which are urban, rural, and remote areas. To explore factors associated with HIS implementation in Indonesia, we used the average number of HIS [30] to calculate the degree of association of some risk factors. As the study uses a cross-sectional design, it captures association at a single point in time and cannot establish causality between factors such as training frequency, accreditation, or geographic location and HIS use.

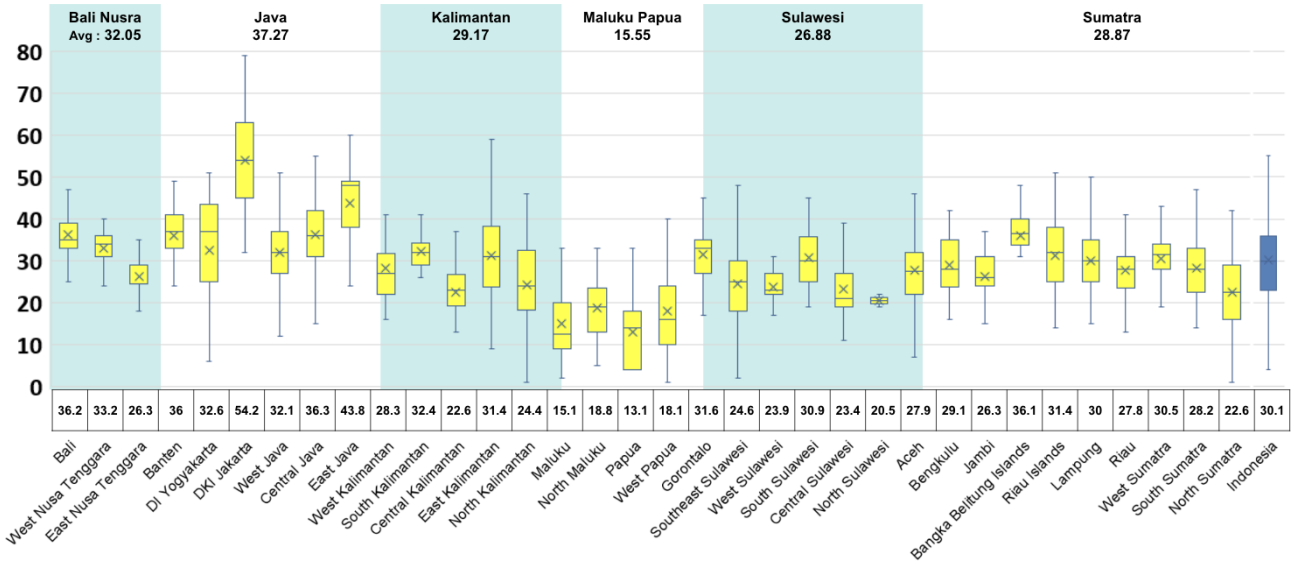
Box plots were used as data visualization tools to depict the average number of HIS used in Puskesmas, along with the minimum and maximum numbers across 34 provinces. Cross-tab analysis was used to examine the frequency of HIS utilization based on the type of Puskesmas' geographic characteristics (urban, rural, and remote) and accreditation level. Puskesmas accreditation level in Indonesia is categorized as follows: (1) not accredited, (2) basic accreditation (dasar), (3) medium accreditation (madya), (4) major accreditation (utama), and (5) comprehensive accreditation (paripurna).

Ethical Considerations

We declare that the data collected for this paper do not require ethical approval as no individual data are presented and informed consents were collected during the survey implementation. As such, this research qualifies for exemption from full ethical review in accordance with the provisions outlined in the 2021 Pedoman dan Standar Etik Penelitian dan Pengembangan Kesehatan Nasional (2021 National Health Research and Development Ethical Guidelines and Standards), issued by the Komite Etik Penelitian dan Pengembangan Kesehatan Nasional (KEPPKN)—National Health Research and Development Ethics Committee—under the Indonesian Ministry of Health [32]. Specifically, the exemption applies to studies that involve no personal identifiers, pose minimal to no risk, and focus on evaluating or monitoring public programs, as outlined in the guideline's section on research exemption criteria. These provisions are consistent with the earlier 2017 guideline and remain the current ethical standard [33]. In accordance with these criteria, all survey responses were anonymized upon collection, and no individual or facility-level identifiers were retained in the analytical dataset. Informed consent was embedded at the beginning of the survey, which provided thorough information about the study and what to expect from the participants. It also states that participation was entirely voluntary and no compensation was given in any form. Data were securely stored on encrypted servers with restricted access, ensuring the confidentiality and integrity of the dataset. The exemption status of this study was reviewed and confirmed by the Digital Transformation Office of the Indonesian Ministry of Health.

Results

Number of HIS Used in Puskesmas



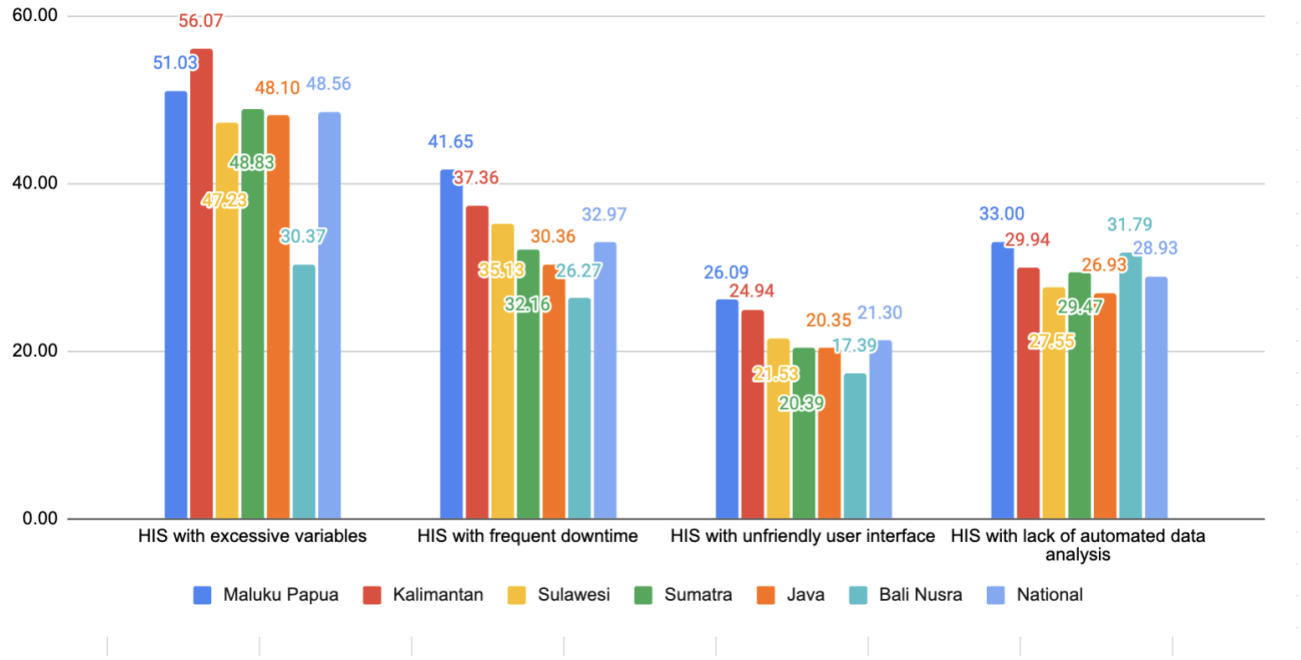
A total of 2616 public health centers (25.5% of the total 10,260 public health centers in Indonesia) spread across 320 districts or cities from 34 provinces participated in the survey. Provinces with the highest number of participating health centers were Central Java (326), Lampung (227), and Aceh (214). Among the health centers, 779 of 2700 (28.85%) were located in urban areas; 1143 of 2700 (42.33%) in rural areas; and 475 of 2700 (17.59%) in remote areas.

Based on the study results, the average number of HIS used in public health centers nationwide was 30 (SD 11.2). However, this number varied across provinces. The province with the highest average number of HIS was DKI Jakarta, with 54 (SD 12.6) systems deployed and used for recording and reporting various health services, followed by East Java (43, SD 8.0), Central Java (SD 9.7), Bali (SD 8.7), Bangka Belitung Islands (SD 6.5), and Banten (SD 7.6), which were all around 36 systems in average, while Papua had the lowest average of 13 (SD 9.1) systems. The variation of the number of HIS used by Puskesmas can also be observed based on the distribution of

XSL•FO
RenderX

major islands, with Java having the highest average of 37 (SD 11.3) systems, followed by Bali Nusra (32, SD 7.8), Kalimantan (29, SD 10.3), Sumatra (28, SD 8.8), Sulawesi (26, SD 8.5), and the lowest being 15 (SD 9.5) in Maluku Papua (Figure 1).

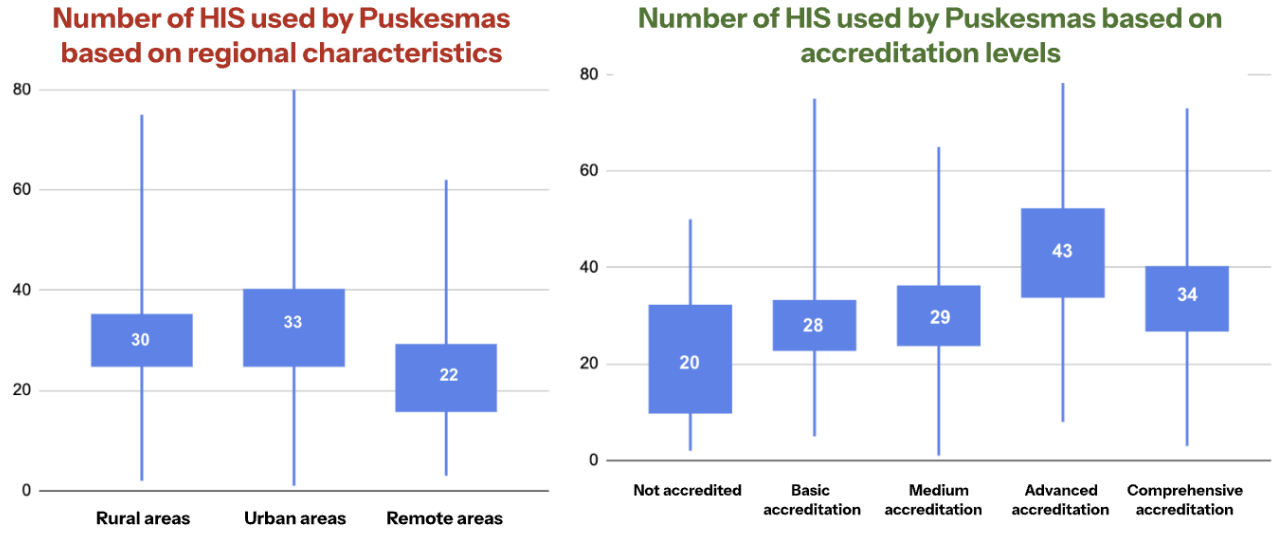
Figure 1. Average number of health information systems used by public health centers based on provinces and major islands.



On average, 72.94% (n=62,060) of the HIS used were provided or developed by the Indonesian Ministries (National Government), making the central government the primary contributor to the abundant number of different HIS available. City or district governments also play a significant role, contributing to 17.45% (n=14,844) of the HIS development, while the provincial government accounts for 5.27% (n=4485). Moreover, third-party organizations and other stakeholders contributed 4.33% (n=3685) and Puskesmas 0.01% (n=12) to the overall HIS deployment. A total of 75.07% (n=63,872) of the HIS were from health-related government offices, while 24.93% (n=21,214) were from non–health-related (eg, the Ministry of Internal Affairs, Ministry of Communication and Informatics, Ministry of Finance, Local and Provincial Governments).

Based on the study, the HIS used by public health centers was 91.54%, which aligned with their needs, and 90% of the data collected has been used as a reference for decision-making, health policy formulation, or program development. However, there exist challenges in using the existing HIS as depicted in the following graph.

The findings depicted in Figure 2 revealed major challenges of the existing HIS used by Puskesmas across Indonesia. Approximately, 49% (n=132,300) of all HIS in the country had excessive data input variables, leading to prolonged form-filling, extended patient registration queue times, and increased screen time for health care personnel. In addition, 33% (n=89,100) of the systems experience frequent downtime, posing challenges in health care service delivery and data management, 21% (n=56,700) of HIS were not user-friendly, and 29% (n=78,300) of HIS did not have the ability to generate automated data analysis.



XSL•FO
RenderX

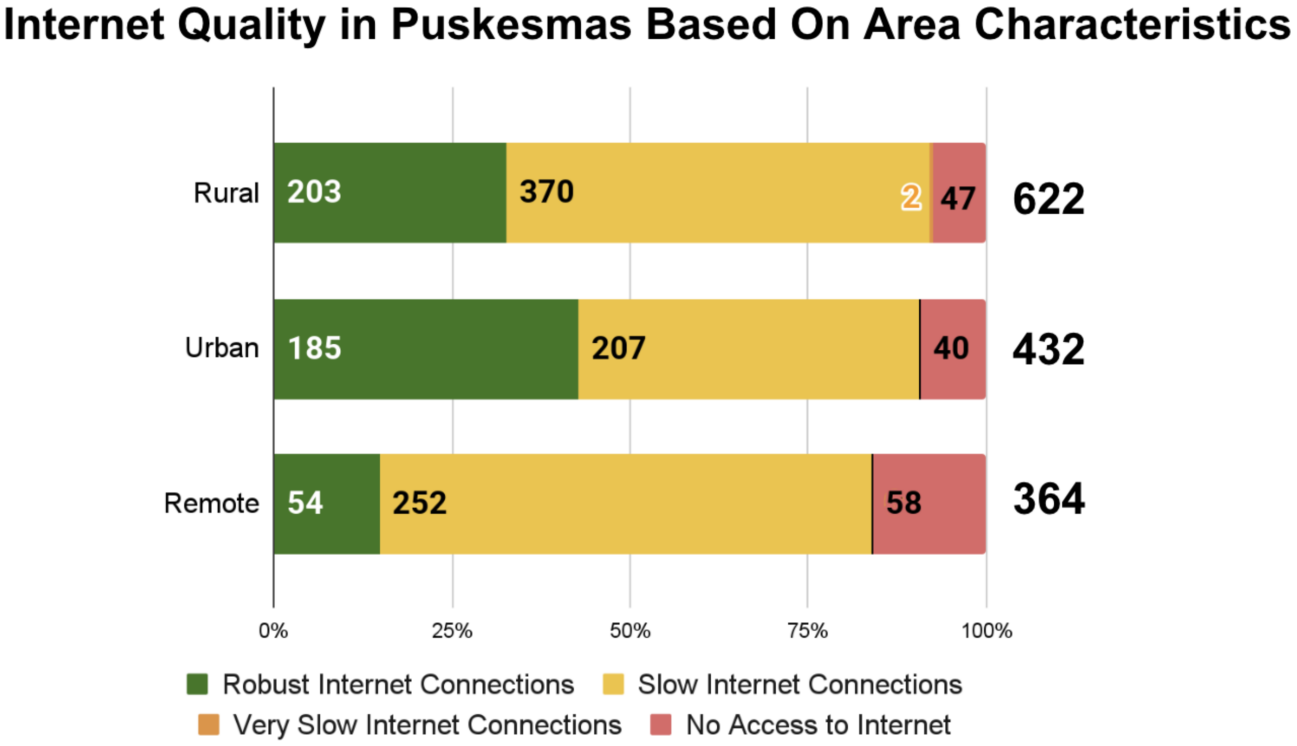
Figure 2. Several limitations of existing HIS based on major islands. HIS: health information systems.

Public health centers in rural areas used an average of 30 different HIS, while urban areas used 33 systems, and remote areas used 22 systems (Figure 3). Furthermore, based on the accreditation level, public health centers with no accreditation used an average of 20 different HIS, while Puskesmas with basic (*dasar*), medium (*madya*), accreditation (*utama*), and comprehensive accreditation (*paripurna*) levels used 28, 29, 43, and 34 systems, respectively.

Figure 3. Number of HIS used by Puskesmas based on geographic characteristics and accreditation levels. HIS: health information systems.

Factors Influencing HIS Utilization Across Public Health Centers

Internet Availability



A separate analysis was carried out to explore factors influencing HIS utilization. Based on the survey, 9.45% (138/1460) of Puskesmas had no access to the internet. Specifically, the majority of Puskesmas have internet access, but only 28.9% (422/1460) have access to robust and efficient internet connections; meanwhile, 51.1% (746/1460) reported slow internet connections, and 10.55% (154/1460) reported very slow internet connections (Figure 4A).

Figure 4B shows the types of internet facilities mostly used by health care personnel to access HIS in Puskesmas. Among the surveyed Puskesmas (n=1309), 417 (31.88%) relied solely on Puskesmas Wi-Fi for their internet access to input the health data reports; 280 (21.40%) used Puskesmas Wi-Fi and private home internet; and a large portion reported using a combination of Wi-Fi, private home internet, and internet credit fund paid by Puskesmas (422/1309, 32.27%). Figure 4C depicts that in urban areas, 42.8% (185/432) of Puskesmas have robust internet connections, while 47.9% (207/432) experience slow internet, and only 9.3% (40/432) have no access to the internet. In contrast, in remote areas, only 14.84% (54/364) of Puskesmas

XSL•FO
RenderX

have robust connections, whereas 69.2% (252/364) experience slow internet, and 15.93% (58/364) have no access.

Figure 4. (A) Internet quality in public health centers and (B) types of internet facilities used by health care personnel to access HIS in Puskesmas. (C) Internet quality in public health centers based on area characteristics. HIS: health information systems.

Human Resources

Human resources are pivotal in affecting the utilization and adoption of HIS. Table 1 depicts the background education of HIS managers in Puskesmas. Out of the total surveyed individuals (n=1330), 344 (25.86%) of HIS managers were from other health care professions such as nutritionists and pharmacists, followed by nurses (327/1330, 24.59%), public health staff (255/1330, 19.17%), non–health care professionals such as informaticians and computer technicians (241/1330, 18.10%), and midwives (147/1330, 11.05%).

Table . Educational background of HIS[a] managers in public health centers (n=1330).

Educational background of HIS managers	HIS personnel, n (%)
Other health care personnel	344 (28.86)
Nurse	327 (24.59)
Public health personnel	255 (19.17)
Nonhealth care personnel	241 (18.12)
Midwife	147 (11.05)
Doctor	14 (1.05)
Pharmacist	2 (0.15)

[a]HIS: health information systems.

Table 2 provides insights into the number of HIS or programs input by Puskesmas personnel. Among the surveyed Puskesmas (n= 850), the data showed that 22.71% (193/850) of Puskesmas required each health personnel to input data into one to two different HIS. Additionally, 188 (22.12%) of the Puskesmas personnel managed and input data into more than six different HIS or programs, while 159 (18.71%) of them handled one to three programs.

XSL•FO

Table . Number of HIS[a] programs input by public health centers personnel (n=850).

HIS programs input by public health center personnel	Puskesmas, n (%)
More than 6 programs	188 (22.1)
1 - 6 programs	79 (9.3)
1 - 5 programs	91 (10.7)
1 - 4 programs	87 (10.2)
1 - 3 programs	159 (18.7)
1 - 2 programs	193 (22.7)
1 program	53 (6.2)

[a]HIS: health information systems.

Further analysis shows that 74.30% (1133/1525) of personnel in Puskesmas only received training at the initial system's installation, 13.64% (157/1525) indicate that the training only occurs once a year, and 10.30% (157/1525) report that there was no training available for data input and management. Furthermore, 80.51% (1225/1521) of respondents report the existence of a knowledge transfer process, highlighting the significance of sharing expertise and information among the staff.

Table 3 presents a bivariate analysis of various characteristics influencing the adoption of information systems in public health centers. We categorized the below and above average number of HIS (30 HIS as a cutoff) and conducted binary logistic regression analysis on SPSS. Key variables include geographic factors (main islands and geographic characteristics), accreditation levels, training frequency, knowledge transfer, number of HIS programs input by personnel, and internet quality. Among geographic factors, health centers in Java show the highest likelihood of having >30 information systems (odds ratio [OR] 32.85, 95% CI 14.9-72·41) compared to Maluku Papua. Urban areas have a greater likelihood of higher system adoption compared to rural and remote areas (OR 4.73, 95% CI 3.43-6·50). Accreditation levels are strongly associated with system adoption, with comprehensively accredited centers being the most likely to use >30 systems (OR 10.20, 95% CI 3.41-30.51). Training frequency also plays a role, where biannual training is significantly associated with higher adoption (OR 1.77, 95% CI 1.01-3.08). Knowledge transfer presence slightly increases the likelihood of greater system use (OR 1.33, 95% CI 0.97-1.81). The number of HIS programs input by personnel does not show a strong pattern. Internet quality does not exhibit a substantial impact, as OR values remain close to 1.

[b]OR: odds ratio.

Discussion

Principal Findings

HIS are foundational to modern health care delivery and serve as critical tools for supporting evidence-based decision-making and policy development [34]. Well-functioning HIS should not only collect health data but also enable the analysis, synthesis, and timely dissemination of information across all components of the health system [35]. Previous studies have demonstrated that effective HIS use can contribute to improved care coordination, more efficient facility management, and enhanced patient safety outcomes [34-36]. While most existing research has focused on hospital-level or disease-specific HIS implementations, this study offers the first national-level descriptive mapping of HIS utilization across Indonesia's public primary health care centers (Puskesmas). It identifies the number and types of systems in use and highlights contextual factors that may influence HIS adoption and implementation at the facility level.

Various innovations in resource-limited areas are also making significant investments in national HIS. These initiatives are anticipated to enhance access to quality health care and contribute to the reduction of overall costs in the health care sector) [37-41]. This study reveals that there was a massive, recent development of multiple HIS or digital apps within Indonesia, driven by government initiatives (at all levels of government, from central, provincial, to district). In particular, massive development of HIS in Indonesia is caused by different needs of a key performance indicator for each division or directorate of the central government in Indonesia. Thus, there have been increased numbers of projects to develop different digital apps and HIS that focus on specific diseases, such as SITB (Sistem Informasi Tuberkulosis), for tuberculosis information system; SIHA (Sistem Informasi HIV-AIDS), for HIV-AIDS information system; SIHEPI (Sistem Informasi Hepatitis), or Hepatitis Information System; SIPTM (Sistem Informasi Penyakit Tidak Menular), or NonCommunicable Disease Information SysteM; SIPD3I (Sistem Informasi Penyakit yang Dapat Dicegah dan Diobati dengan Imunisasi), or Vaccine Preventable Diseases Information System; ESISMAL (Electronic System of Malaria), or Malaria Information System.

Digital app development initiatives were also increased due to a new specific program introduced by the central government to monitor specific programs, such as PISPK (Program Indonesia Sehat Pendekatan Keluarga), or the Healthy Family Program; SISTBM (Sistem Informasi Sanitasi Total Berbasis Masyarakat), or Health Sanitation Population-Based; e-PPGBM (Electronic Pencatatan dan Pelaporan Gizi Berbasis Masyarakat), or Nutrition Information System; SKDR (Sistem Kewaspadaan Dini dan Respon), or Early Warning of Epidemic Diseases; ASPAK (Aplikasi Sarana Prasarana dan Alat Kesehatan), or Health Facilities and Supplies Application; P-Care (Primary care), a medical record for health insurance; HFIS (Health Financing Information System), for financing of health insurance, and many more introduced by each provincial or district level due to decentralization health system regulation [21,37]. This greatly magnifies the fragmentation, disparities, burden for health care workers, fragmented data, lack of data integration and interoperability, and low level of system standardization [37-40]. Another common HIS in Puskesmas is also called SIMPUS (Sistem Informasi Manajemen Puskesmas), or Puskesmas Management Information System, which manages both patient electronic medical record management and administrative matters ranging from human resources, finance and planning, pharmaceuticals and medical devices, and reporting [42].

Based on Articles 3 and 6 of the Ministry of Health Decree Number 31 Year 2019 [15], SIMPUS is part of the district information system. In order to simplify all the different existing apps or information systems used by health care facilities, including Puskesmas, a national HIS (Sistem Informasi Kesehatan Nasional) is currently being developed by the Ministry of Health of Indonesia [43]. The systemic goal is to allow the deployment of Fast Healthcare Interoperability Resources-based standardization to be used by health care facilities' HIS developers to connect all health care institutions' services at all levels in the whole country [43]. In the context of primary health care, each Puskesmas and DHO has the opportunity to customize and enhance its SIMPUS framework as long as it complies with the Sistem Informasi Kesehatan Nasional standard, to better address its unique priorities, ensuring that the system effectively meets the diverse needs of its community. This initiative enables each district to confidently engage a diverse array of information technology developers.

The large number of HIS used is a major challenge. At the simplest level, the amount of different HIS affects the responsibility burden of each health worker, from data recording to reporting [44]. The reporting obligation of Puskesmas is centrally mandated; however, using different numbers of HIS adds to the medical staff workload. The study shows an average number of 30 different HIS used for various health data reporting functions, indicating a high burden for health care personnel to input data into different systems that are not integrated. Inevitably, this landscape of multiple siloed systems leads to duplication in data entry. It impacts the allocation of adequate time for health workers to deliver health care services due to data recording and reporting tasks [45].

In addition, the results suggest different numbers of HIS used for data reporting across provinces and major islands in Indonesia. This would create a technical challenge to future data integration attempts at a central government level. Java and Sumatra Island tend to use more HIS compared to Bali, Nusra, and other islands. This reflects the relative population distribution (much higher population density in Java and Sumatra in the western region of Indonesia) and is thus influenced by several factors such as the availability of human resources, infrastructure, organizational support, aid funding, and program priorities [45-47].

XSL•FO
RenderX

Considering the experiences of other countries, it seems that one of the root causes of the failure of HIS is the absence of adequate information and communication technology infrastructure [48]. A previous study shows that adequate access to the internet, computer availability, and availability of electricity play roles in the success rate of HIS utilization [49]. Findings in Haiti also show that the important factor for long-term implementation success of complex information systems is balancing investments in hardware and software infrastructure upkeep [50], and many other studies suggested that HIS utilization will be optimal, effective, and efficient when they are supported by adequate facilities and infrastructure [46-49]. In spite of the potential and opportunities that lie in HIS to transform the health care sector, including helping to foster the development of evidence-based policy, many challenges are evident and imminent. These challenges range from issues related to the technology infrastructure, human resources, system users, and financial constraints [49,51].

Based on the study results, health care workers felt that the variables of data that need to be recorded and reported in the HIS are too many, with complicated user interfaces. Data input with long required variables for reporting caused data duplication and poor usability of HIS [45,52]. Poor usability has been linked to a reduced acceptance of digital systems in the long term, increased errors, and reduced user efficiency and can even adversely affect patient safety [52,53]. The International Standard Organization has defined the usability of systems with three features of effectiveness, efficiency, and satisfaction, and user interface problems can be associated with all of these features [54]. Previous studies have shown that usability problems, such as overcrowded pages and many steps to perform a task, entail reduced user productivity [55,56]. Another study in Iran showed that HIS “flexibility and efficiency of use” and “consistency and standard” are problematic [3,5]. Furthermore, diversity in the presentation and visualization of data variables can result in ineffective communication and data reporting. For Indonesia, where universal health care coverage was introduced only recently in 2014, it is critical to use common standards and observe the consistency of data variables across the whole system [57]. Moreover, presented information in any format should be self-explanatory, so that the users can initiate actions at any time without recalling their experience from the previous use of the system [58].

Health care organizations are expected to increasingly depend on business intelligence tools, including “dashboards,” to capture, analyze, and present data on performance metrics [59]. For example, dashboards allow users to quickly visualize actionable data to inform and optimize clinical and organizational performance [60]. However, the multiplicity of HIS, and as such, the multiplicity of produced dashboards, is likely to impede the utilization of collected data. Thus, the data management problem is one of the important findings in this study, especially the lack of automated data analysis generation through the dashboard of the existing HIS. In reality, dashboards are typically embedded in complex health care organizations with massive data streams, servicing end users with distinct needs. Thus, designing effective dashboards is a challenging task, and the theoretical underpinnings of health care dashboards are poorly characterized; even the concept of the dashboard remains ill-defined [55]. Several LMICs face the same problem of insufficient quality of data produced by the systems that limit their usefulness with regard to decision-making [61-63].

The continuity of using HIS during routine operations depends on the information technology infrastructure. The discrepancies in communication technology infrastructure availability across the 34 provinces in Indonesia remain one of the obstacles when it comes to the need for a stable internet connection, even in urban areas that already have communication infrastructure with 5G networks [64]. The limitations of the internet coverage and limited network capacity impact HIS operability, since it may limit the network coverage area to only the registration counter [49]. Frequent downtime of HIS was found in this study, showing the need for further improvements in infrastructure and facilities. This lack of and instability of information technology infrastructure, such as the limitation of internet access, electricity supply, and availability of computers, was similar to that found previously in Brazil, Sub-Saharan Africa, and Tanzania [65-67].

Finally, human resources play a pivotal role in implementing the HIS in Puskesmas. However, the IT personnel remain one of the challenges to date, as the procurement of IT personnel in a primary health care center is not a mandatory requirement yet in Indonesia. This absence of highly trained IT personnel could be mitigated by well-trained health care staff; however, this is not the case, as most staff have reported inadequate amounts of training. According to this study, the amount of HIS managed by each staff ranges from one to six, combining the possibility of suboptimal handling of HIS with existing high workloads [49]. This is similar to studies in Saudi Arabia, Malaysia, and other LMICs [68,69].

Further analysis identified factors associated with the utilization of HIS. However, due to its cross-sectional nature, the study does not allow us to determine the direction or causality of observed relationships between institutional characteristics and HIS adoption. For example, while higher accreditation levels or urban status are associated with higher HIS use, these findings should be interpreted as correlational, not causal. Table 3 indicates that Java Island has a significantly higher number of HIS utilization (>30 information systems) compared to Sumatera, Kalimantan, Sulawesi (central part), and Maluku and Papua (eastern part). This pattern is common in LMICs where the numbers of HIS utilization are strongly influenced by several factors such as human resources, institutional funding, foreign aid, transparency, and prioritization issues [49]. Table 3 also shows the disparities in the numbers and percentages of HIS utilization based on geographical characteristics. In general, urban and rural areas had more HIS utilization than remote areas. The existence of information technology infrastructure remains the main challenge in LMICs, especially in rural and remote areas. These areas often have limited or no internet access, computer availability, and electricity supply [49]. The lack of stable and affordable internet connectivity can be an obstacle in using the HIS for sending and receiving health data effectively [33]. The findings indicate that Puskesmas with slower internet connectivity are making considerable efforts to effectively use the existing HIS. Interestingly, their performance

XSL•FO
RenderX

appears slightly better than that of Puskesmas with more robust internet connectivity. However, it should be noted that the majority of data input in areas with limited internet access is primarily conducted by the DHO.

This study has also evaluated the effectiveness of health care organization accreditation [38]. A previous study shows that accreditation leads to improved quality of care, better strategic planning, enhanced human resource management, stronger leadership, improved archiving, and increased patient satisfaction [38]. Based on our findings, the top level of accreditation status uses more numbers of HIS than the other levels of accreditation (medium and basic).

The human resource and capacity factor plays a vital role in the effectiveness of information systems implementation. This study demonstrates that when Puskesmas provides regular training and facilitates knowledge transfer among staff regarding the HIS, there is a marked increase in the system's utilization. This emphasizes the significance of ongoing education and support in optimizing the advantages of information systems. Like other studies conducted in Ethiopia [38,39], the study findings indicate that the odds of using HIS were significantly higher among primary health care that engaged in regular training and knowledge transfer. This might be due to the fact that health professionals who were trained on HIS had the potential to compile, analyze, and use information generated in the routine day-to-day activities.

Out of the variables that showed no significant difference between the numbers of HIS program input by the Puskesmas staff (1 - 5 staff and ≥6 staff) and the numbers of HIS utilization. This might be due to several factors, such as staff awareness, commitment, and motivation [50]. A study conducted in India underlined that, although the utilization of HIS is contingent upon data analysis skills, organizational factors play a crucial role in the effective application of these skills [40]. Reports also showed that strengthening HIS, focusing not only on technical but also behavioral and organizational structures, is one essential component for improving the quality and use of data for decision-making at all levels of the health system [68].

Strengths and Limitations

The research exhibits several strengths that contribute to its significance in the field. First, it represents the first-ever study of its kind, involving public health centers on a national scale to portray the utilization of HIS. This wide-scale view provides a comprehensive understanding of the current state of HIS implementation in Puskesmas throughout Indonesia. Additionally, beyond the mapping of HIS use, the research highlighted the key challenges faced by field personnel in effectively using HIS, offering insights into potential areas for improvement.

However, certain limitations should be acknowledged. First, while the overall sample size exceeded the national threshold, some provinces (eg, South Sulawesi, East Nusa Tenggara, and Jambi) were significantly underrepresented, limiting generalizability at the provincial level. Second, the cross-sectional nature of the study restricts causal interpretation; relationships observed between institutional characteristics and HIS use should be treated as associative rather than explanatory. Third, as the study relied on self-reported data, it is subject to recall and reporting bias, even though measures were taken to ensure anonymity and standardization. Fourth, the study did not capture qualitative insights from HIS users, which could have provided valuable context around user behavior, system workarounds, and local adaptations. Fifth, while fragmentation of systems was reported, no technical assessment of interoperability, data exchange mechanisms, or governance structures was conducted. Sixth, while basic human resource data were collected (eg, education, training, and HIS load), we were unable to assess the impact of digital workload on staff well-being, task performance, or gender-specific roles. Seventh, although 90% of respondents reported that HIS data supported decision-making, we did not explore how the data were used, by whom, or with what outcomes. Finally, we did not assess the cost-effectiveness or financial sustainability of managing multiple HIS platforms—an area that is especially important for integration planning and national budgeting.

To address these gaps, we recommend that future studies adopt stratified or purposive sampling strategies to ensure adequate representation of undersampled provinces. Longitudinal and mixed method research will be critical to explore causal mechanisms and contextual dynamics of HIS adoption and adaptation. System audits and process evaluations can help validate reported use and assess HIS quality, reliability, and integration performance. Additionally, qualitative interviews with HIS users and implementers—particularly in remote and low-resource settings—can shed light on the lived realities of system implementation and usability. Research on human resource burden, digital competency gaps, and gendered work distribution is also needed to inform equitable capacity building. Finally, economic evaluations and costing studies should be embedded into HIS consolidation efforts to assess long-term sustainability and ensure efficient resource allocation.

Despite these limitations, this baseline study provides critical insights into the HIS landscape in Indonesia and serves as a foundation for evidence-informed policy-making and more effective digital health planning.

Conclusions

HIS play a significant role in supporting policy-making at public health centers, districts or cities, provinces, and the national level. This study, the first of its kind to assess HIS utilization across more than 2600 Puskesmas nationwide, reveals a highly fragmented digital environment, with health centers operating an average of 30 different HIS platforms—many of which are redundant, nonintegrated, and burdensome to manage. The findings highlight challenges in internet connectivity, system usability, workforce digital readiness, and alignment with service delivery needs. Further analysis in this study suggests that geographic location, accreditation level, and training frequency are among the most influential factors in the adoption of information systems.

Policy interventions must consider the diverse operating environments of Puskesmas to avoid one-size-fits-all approaches. Urban Puskesmas, often with stronger infrastructure and digital capacity, are well-positioned to adopt interoperable

XSL•FO
RenderX

dashboards, advanced analytics tools, and integrated HIS platforms aligned with national systems like SATUSEHAT. These centers may also benefit from certification-based training in data analytics and the recruitment of dedicated digital health personnel to enhance system management and interoperability. In contrast, rural and remote Puskesmas operate with limited internet access, power supply, and IT support. For these settings, policy makers should prioritize offline-compatible, simplified HIS that minimizes data entry burdens and operates on low-resource devices, such as mobile phones. Training efforts should focus on basic digital literacy, with peer-to-peer cascading models to enhance local knowledge transfer and sustainability. Infrastructure support, such as solar-powered equipment or network boosters, may also be critical enablers in these areas.

Governance reforms should promote regional coordination, enabling DHOs to provide HIS oversight and technical support, particularly for underserved areas. National initiatives to consolidate and standardize HIS should be complemented with financial and operational feasibility studies to ensure sustainability, especially where overfragmentation currently burdens frontline services.

This baseline study provides a foundational understanding of HIS use and challenges in Indonesia and calls for differentiated, evidence-informed strategies tailored to each health center's digital maturity and contextual needs. Future research should explore HIS interoperability, real-world data use, user experience, and economic impact to guide Indonesia's journey toward a more integrated and equitable digital health ecosystem.

Acknowledgments

The authors would like to thank the Digital Transformation Office Ministry of Health Republic of Indonesia for supporting the study implementation; the Public Health Centers, Districts, and Provincial Health Offices across Indonesia who have participated in the study; and MoH Data and Information Center (Pusdatin), Directorate General of Public Health, Directorate General of Health Care Services who have supported the study implementation.

Data Availability

The datasets generated during or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

DNA led the study design, built the paper concept, main structure, and methodology. AHS, CAM, and AFL carried out the study and accessed and analyzed the data. DNA, AHS, CAM, and AFL wrote the first draft of the paper. ZK and LM validated the study and critically revised the manuscript content. DNA and AHS had primary responsibility for the final content. All authors read and contributed to reviewing the study data, the manuscript design, and the approval of the final manuscript.

Conflicts of Interest

The authors declare no potential conflicts of interest with respect to the research, authorship, and publication of this paper. While the author is affiliated with Aceso Global Health Consultants Pte Limited, which is a private company, we declare that this research project does not receive funding from Aceso Global Health Consultants. The company does not have a role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript. LM is the director of the company and contributed to this paper on a pro-bono basis. Where authors are identified as personnel of the International Agency for Research on Cancer/WHO, the authors alone are responsible for the views expressed in this article, and they do not necessarily represent the decisions, policy, or views of the International Agency for Research on Cancer/WHO.

Abstract

Background: The novel medical model of "Internet Plus continuous nursing" has received much attention under the dual background of aging and digitalization in China. However, there is a scarcity of studies that report on the potential barriers and challenges associated with the implementation of this practice.

Objective: This study aimed to investigate and understand nurses' experience regarding barriers to providing Internet Plus continuous nursing.

Methods: A sequential mixed methods design was adopted. In the first phase, a self-made questionnaire was used to quantify the barriers and challenges into 3 domains: management, relational, and information continuity. In the second phase, nurses who participated in the Internet Plus continuous nursing program were invited to attend semistructured interviews to further explore, explain, and understand the complexities behind these data, obtaining more detailed information on participants' experiences, perspectives, and meanings.

Results: A total of 4638 participants from 312 hospitals were selected for the final analysis; the adjusted mean score of the survey was 3.49 (SD 0.83). Among the 3 domains, management continuity had the lowest score (mean 3.32, SD 0.97), followed by relational continuity (mean 3.44, SD 0.9) and information continuity (mean 3.62, SD 0.92). The results of the multivariable analysis showed that age, education level, and a greater number of working years were predictors of continuity for Internet Plus continuous nursing (P<.001). Following the qualitive study, 8 subthemes emerged from 72 initial codes and were grouped into 3 themes: organizational changes, practice changes, and future directions.

Conclusions: This mixed methods study revealed that Chinese nurses may have differential challenges when providing Internet Plus continuous nursing, particularly in management continuity. To better benefit patients and improve health care delivery, health care organizations and policymakers should implement strategies to improve interdisciplinary relationships, establish and perfect organizational management, and enhance communication.

Introduction

Continuous nursing refers to a comprehensive approach to providing uninterrupted care and attention to patients in health care settings [1], combining the continuation of nursing services and time and health services [2]. As a part of overall care and as a core element of high-quality primary care, continuous nursing has been shown to reduce mortality rates and health costs, improve patient satisfaction, and enhance overall health care outcomes [3-5]. However, the traditional continuous nursing model still suffers from some drawbacks and does not comprehensively satisfy the complicated care needs of patients.

With the rapid development of mobile technology and the widespread use of mobile phones and the internet, the traditional continuous nursing model has slowly shifted to what is termed "Internet Plus continuous nursing," which has gained significant attention. Particularly, the outbreak of the COVID-19 pandemic has reminded the health care system of the importance of

XSL•FO
RenderX

creating new strategies, using traditional approaches alongside information technologies [6]. Internet Plus continuous nursing represents a paradigm shift in health care delivery [7], referring to the integration of internet technology with continuous nursing care or monitoring [8]. This approach aims to build a connection between health care providers and patients by leveraging the power of the internet to facilitate real-time monitoring, communication, and data sharing. Health care professionals can thus remotely monitor patients' vital signs, provide guidance, offer medication reminders, and deliver personalized care plans [9,10]. In addition, the novel model could also streamline clinical workflows [11], enhance patient engagement [12], and facilitate knowledge sharing [13]. The Chinese government and industry attach great importance to the development of this work and have introduced multiple policies to provide further guidance, such as the National Nursing Development Plan (2021 - 2025) [14] and the Action Plan for Further Improvement of Care Services (2023 - 2025) [15]. Driven by strong policy support, the initiative has garnered widespread attention from health care institutions and the public.

However, Internet Plus continuous nursing is still in the pilot stage in China and primarily targets key populations such as discharged patients, maternal and infant groups, and patients with chronic diseases [15]. For example, data from one Chinese province revealed that 85.45% of hospitals have yet to adopt "Internet Plus nursing services," despite 97.87% of nurses expressing a willingness to participate [16]. Only 14.55% of nurses are currently engaged in such services within their hospitals. Even among hospitals that have implemented these programs, gaps persist between service offerings (eg, scope, scheduling, continuity) and actual market demand [17].

Although prior research has examined the factors influencing nursing care continuity [18,19], few have specifically examined Internet Plus continuous nursing. Existing research has investigated nurse willingness and program effectiveness [20,21], yet there is a critical gap in understanding the implementation barriers and challenges, particularly in primary hospitals, where logistical and resource constraints may amplify these issues. Identifying these barriers from the perspective of participating nurses is essential not only for preparedness but also for improving service quality.

Therefore, the aim of this mixed methods study is to investigate the factors influencing the implementation of Internet Plus continuous nursing across primary, secondary, and tertiary hospitals, with a specific focus on barriers. The findings of this study will provide valuable insights for policymakers, health care administrators, and nursing practitioners, enabling them to develop strategies and interventions that can strengthen the continuity of care in the digital era.

Methods

Ethical Considerations

Ethics approval was obtained from the First Affiliated Hospital of Chongqing Medical University's research ethics committee (2023-34). All procedures complied with the Declaration of Helsinki.

Written informed consent was obtained from all participants prior to their involvement in the study. For online interviewees, verbal consent was obtained and documented. Participants were explicitly informed of their right to withdraw from the study at any time without penalty. No secondary data analysis was conducted in this study.

All collected data were deidentified prior to analysis. Personal identifiers were removed and replaced with coded numbers to protect participant confidentiality. Electronic data were stored on password-protected servers with access restricted to the research team.

Participants did not receive financial compensation for their involvement in this study. However, they were provided with the study results upon request and had access to any potential benefits emerging from the research findings.

Quantitative Study

Participants

Participants were convenience sampled from January 2021 to March 2021 in Chongqing, China. The inclusion criteria were: (1) nurses directly involved in Internet Plus continuous nursing services, (2) who had over 1 year of experience and (3) provided informed consent and were willing to participate. The exclusion criteria were: (1) visiting nurses who were not affiliated to the hospital and (2) nurses who were on vacation during data collection.

Measurement Tools

A 14-item questionnaire specifically tailored to health care professionals was developed based on the Continuity of Care model [22], with reference to patient-reported measures [23,24]. The questionnaire was constructed using the Delphi method (Multimedia Appendix 1), demonstrating strong expert consensus with authoritative coefficients (Cr) of 0.85 and 0.91 for the 2 rounds, respectively. The instrument comprises 3 domains, namely relational (5 items; Cronbach coefficient=0.832), information (3 items; Cronbach coefficient=0.865), and management (6 items; Cronbach coefficient=0.840) continuity, with a good content validity index (0.96) and an overall Cronbach coefficient of 0.871. Each item was scored from 1 ("Rarely") to 5 ("Always") on a 5-point Likert scale; higher scores reflect higher quality and efficiency of implementation of Internet Plus continuous nursing.

Data Collection

The questionnaire was distributed to hospitals through an online survey tool, Wenjuanxing [25], by the Chongqing Hospital Association. The hospital manager then sent the link to Internet Plus continuous nursing–related health care providers. On the first page of the questionnaire, the objective, process, and anonymization of data were introduced in detail. Individuals who received the link were also requested to provide informed consent. In addition, only those who clicked "accept" had access to the full questionnaire.

Statistical Analysis

The software SPSS version 26.0 (IBM Corporation) was used for analysis, the measurement of normal distribution data were

XSL•FO
RenderX

described by means and SDs, and 2-tailed independent sample *t* tests were used for comparison between groups. The count data were represented by the use case (%), and a chi-square test was used for the comparison between groups. The test level was bilateral (α=.05).

Qualitative Study

Participants

Participants (referred to as as P1, P2, and so on, up to P15) were selected using purposive and snowball sampling methods. The inclusion and exclusion criteria were the same as those for the quantitative study. To meet the maximum variation, the level, setting, and Internet Plus continuous nursing experience of the hospital were taken into account. Recruitment ceased once theoretical saturation was reached (ie, when no new codes and themes emerged from the data) [26]. Finally, a total of 15 participants were recruited (Table 1).

Table . Demographic information of participants in the qualitative study.

	Level of hospital	Age (years), n	Professional title	Working years, n
P1	Tertiary	49	Vice-senior	27
P2	Tertiary	32	Senior	31
P3	Tertiary	46	Vice-senior	27
P4	Secondary	48	Vice-senior	30
P5	Secondary	55	Vice-senior	32
P6	Secondary	47	Vice-senior	29
P7	Secondary	52	Middle	29
P8	Secondary	49	Middle	27
P9	Secondary	48	Middle	26
P10	Primary	47	Vice-senior	27
P11	Primary	50	Middle	29
P12	Primary	53	Middle	31
P13	Primary	48	Primary	28
P14	Primary	56	Vice-senior	36
P15	Primary	52	Middle	32

Interview Outline

The intention of holding interviews was to further explore, explain, and understand the complexities behind these data, obtaining more detailed information on participants' experiences, perspectives, and meanings. An interview outline containing 4 questions was used to structure the interview (Table 2). The outline was formed through literature review [27,28] and the quantitative study results, and pilot-tested with 4 participants to ensure the quality and feasibility.

Table . Interview outline.

Interview guideline	Detailed inquiry
Please provide a brief introduction to the current development of Internet Plus continuous nursing services at your esteemed institution.	1. What was the driving force behind the initiation of this endeavor? 2. Why was it not implemented? What challenges were faced?
As an implementer, what obstacles do you think have been encountered during the process?	1. Could you share your views on "information continuity"? 2. Could you share your views on "organizational continuity"? 3. Could you share your views on "management continuity"?
As an implementer, what factors do you think have facilitated the process?	1. In your opinion, how should these facilitating factors be implemented?
What advice would you give to organizations that have not yet implemented Internet Plus continuous nursing services?	—[a]

[a]Not applicable.

Data Collection

Descriptive qualitative research methods were applied and data were collected through semistructured interviews. Each interview was conducted by the first and second authors, who have both received qualitative research training and have experience interviewing. Due to the impact of the pandemic, interviews were conducted using a combination of online (n=5)

XSL•FO
RenderX

and offline (n=10) approaches. Prior to the interviews, the purpose, content, and methods of the study were communicated to the participants. For all interviewees, informed consent was obtained from before the interviews commenced. A quiet and independent space was chosen and sufficient time was provided for the interviews. Similarly, online interviews were scheduled based on a mutually agreed upon time, and participants were advised to select a quiet environment in an independent space and were provided with ample time. The online interviews were conducted via WeChat video calls, and video recordings were taken after obtaining informed consent from the interviewees. Throughout the interviews, a neutral stance was maintained by the interviewers, encouraging the participants to express themselves fully. When necessary, their viewpoints were clarified and confirmed. Note-taking and audio recording were performed during all interviews.

Statistical Analysis

A qualitative content analysis was used [29], comprising several rigorous steps:

1. Data processing: 2 researchers independently transcribed the raw data and generated initial codes. A third researcher verified the coding consistency and accuracy. The team discussed discrepancies until a full consensus was reached.
2. Thematic development: a researcher conducted higher-level analysis by synthesizing codes into meaningful categories and identifying emerging themes through iterative comparison [30]. Data collection continued until theoretical saturation was achieved (ie, no new codes emerged after 3 consecutive interviews and established themes demonstrated sufficient depth and variation) [26].
3. Validation procedures: all research team members participated in regular peer debriefings to compare interpretations of themes and subthemes and resolve any analytical disagreements through discussion. Member checking was implemented by sharing interview summaries with participants and incorporating their feedback to ensure the accurate representation of experiences [31].

Results

Quantitative Study

Overall, a total of 4911 health care providers from 312 institutions received the questionnaire, while only 4638 were selected for the final analysis (response rate=94.44%); 98 were excluded according to the inclusion and exclusion criteria, 135 were excluded for incomplete answers, and, to control quality, 40 were excluded for response times outside the 5th-95th percentile range.

As shown in Table 3, respondents were predominantly from tertiary hospitals (n=2630, 56.71%) or secondary hospitals (n=1883, 40.60%), and most were female (n=4505, 97.13%). The largest age group was 26 - 35 years (n=2750, 59.29%). Notably, older participants (≥46 years) accounted for 6.81% (n=316) but had the highest continuity scores (mean 91.0, SD 10.9). Most held an undergraduate degree (n=3386, 73.01%), while only 0.52% (n=24) had received graduate-level education. Job titles were primarily primary-level (n=2768, 59.68%), and the majority had 5 - 9 years of work experience (n=2679, 57.76%). Those with ≥10 years of experience (n=1039, 22.40%) reported significantly higher continuity scores (mean 84.1, SD 11.5).

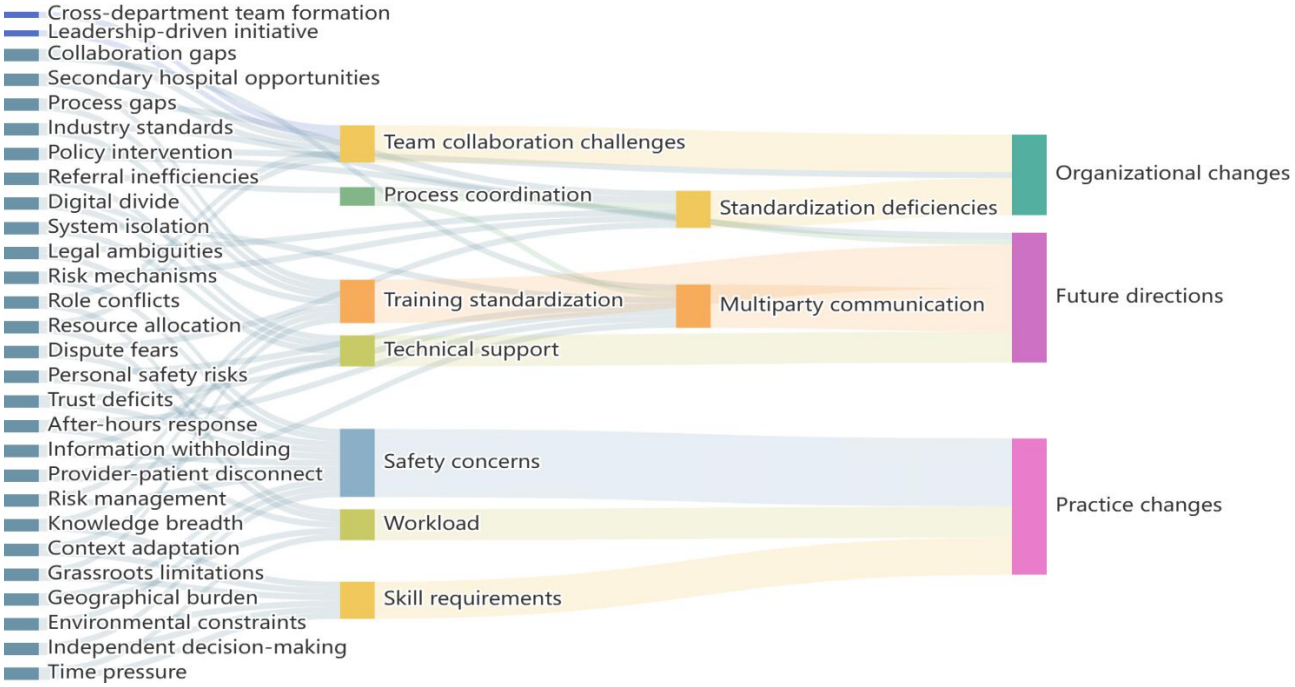
Advanced	373 (8.04)	86.0 (11.6)	–1.64 (–3.32 to 0.05)	.05
Working years				
≤2	365 (7.87)	72.6 (10.7)	Reference	—
2~4	555 (11.97)	72.8 (11.3)	–0.15 (–1.65 to 1.35)	.85
5~9	2679 (57.76)	75.6 (11.1)	1.94 (0.30 to 3.59)	.02
≥10	1039 (22.40)	84.1 (11.5)	3.94 (1.88 to 6.00)	<.001

[a]Not applicable.



Among the continuity domains, the information domain scored highest (mean 3.62, SD 0.92), followed by the relational domain (mean 3.44, SD 0.90) and management domain (mean 3.32, SD 0.97). The overall mean continuity score was 3.49 (SD 0.83), indicating moderate-to-high levels of perceived continuity. The results of multivariable analysis showed that age, education level, and a greater number of working years were predictors of continuity for Internet Plus continuous nursing (P<.05).

Qualitative Study

The initial open coding identified 72 initial codes (eg, “Process gaps,” “Legal ambiguities”), which were then clustered into 8 subthemes (eg, “Team collaboration challenges,” “Safety concerns”). After verification by team members, these were consolidated into 3 final themes, as illustrated in Figure 1.

XSL•FO
RenderX

Figure 1. Three-level coding framework for Internet Plus continuity care. Data were derived from the qualitative analysis of 15 health care providers.

Theme 1: Organizational Changes

Team Collaboration Challenges

Participants reported significant difficulties in establishing and sustaining interdisciplinary teams for Internet Plus continuity care, citing role ambiguity, resource disparities, and institutional resistance. P11 described the lack of structured team development: “We assembled staff from different departments overnight without clear role assignments. This meant starting everything from scratch.” The absence of transitional frameworks exacerbated role confusion, particularly in lower-resource settings. P13 emphasized disparities in institutional capacity: “How can we match tertiary hospitals? Our IT team consists of only 1.5 full-time staff maintaining basic systems.” Functional teamwork remained elusive even when teams were formally established. P4 noted systemic neglect: “The IT department never attends our meetings. When systems fail, we are told, ‘This is not a priority.’”

Standardization Deficiencies

Participants across all hospital tiers identified critical gaps in clinical protocols, legal safeguards, and financial sustainability, which collectively hindered Internet Plus continuity care implementation. Tertiary hospitals developed internal protocols, but these were rarely adopted by primary or secondary institutions. P3 stated, “We created our own post-discharge monitoring checklist, but it is ineffective if community clinics do not use it.” P2 raised critical questions about accountability: “If a patient deteriorates after a virtual consultation, who is responsible—the platform, the nurse, or the hospital? Without clear liability frameworks, many nurses as well as patients hesitate to engage fully.” Variability in care quality was another challenge, particularly in resource-limited settings. P12 noted, “Our rural patients expect hospital-level care at home, but with no training protocols, outcomes vary wildly.” Financial sustainability emerged as a major barrier too. Over 80% (12/15) of participants reported providing Internet Plus continuity care as an uncompensated service due to unclear reimbursement policies. P15 contrasted this with privatized models: “Affluent urban hospitals charge fees through third-party apps, but our rural patients cannot afford to pay. Shouldn’t the government subsidize this essential service?”

Theme 2: Practice Changes

Workload

The expansion of Internet Plus continuous nursing extends the reach of nursing services, enhancing patient care accessibility. However, in settings with existing nursing shortages, clinical staff face increased workloads due to additional responsibilities, training demands, and after-hours patient interactions. Nurses must balance traditional duties with Internet Plus continuous nursing tasks, leading to role overload. Most institutions lack specialized roles for this project, forcing existing nurses to absorb extra tasks. P1 stated, “After joining the team, I not only need to deal with the previous affairs, but also need to spend extra personal time to study and attend training, which increases the workload virtually.” Patients often seek support outside standard working hours, contributing to burnout. “The frequency of overtime work is higher, because some patients may contact you after work hours” (P15). Home visits for remote patients also add physical and logistical strain. “Some patients live in a faraway address, travel a long way, one after another cause people are also very tired” (P4).

Safety Concerns

In interviews, participants reported a wide range of worries and insecurities. First and foremost was the safety of medical staff. P7 stated, “At the beginning, I was very worried about going to a strange family to provide services, afraid of accidents,” and P9 added, “I prefer to interact with discharged patients who I manage, and we know each other better. For strange orders, I will have some concerns, so before the service is carried out, I

XSL•FO
RenderX

will generally communicate well in advance." Secondly, some respondents reported their own practice safety: "Some family environments have restrictions, lack of necessary space, equipment or drugs, and sometimes I even have no suitable place to carry out operations" (P10) and "I am very worried that some patients and their families do not take the initiative to report the history of allergy and infection because of their own reasons, which is very dangerous for patients and myself" (P14). Finally, some respondents cited concerns about medical disputes: "Although it hasn't happened yet, I hope it never will... What should I do in the event of a patient's death or medical malpractice?" (P6).

Skill Requirements

Implementing Internet Plus continuity services requires a higher level of competence from health care professionals, but in practice, most providers still report having their own challenges. Nurses often face questions or requests outside their specialization, requiring ad hoc problem-solving without immediate support. "This is not an individual case, when you provide a specialized service, the patient or family may 'politely' ask you some other questions, which may be beyond your expertise," stated P3. Unlike hospital settings, Internet Plus continuous nursing sometimes requires solo decision-making with a few colleagues or specialists for consultation. "This is very different from the hospital scene, you know that your teammates are around you, but at this time, you may be alone" (P11). Older or rural patients struggle with technology, forcing nurses to double as tech support. P13 noted, "Half my visit time is spent teaching older patients how to use the app. They forget by the next week, and we start over."

Theme 3: Future Directions

Multiparty Communication

Participants observed in their clinical practice that Internet Plus continuous nursing involves multiple stakeholders, and that there is a need to strengthen communication to ensure the smooth implementation of services. Patients often distrust community hospitals' capabilities, viewing them as limited to basic services (eg, health education), while overestimating tertiary hospitals' roles in continuous care. P3 suggested that "If community clinics adopt our monitoring tools, patients would see them as equal partners in care." Nurses reported inefficiencies when transferring patients between tertiary, secondary, and primary care due to unfamiliarity with the community teams. P8 stated, "Let patients meet 'their' community nurse before discharge—it humanizes the transition." Additionally, participants also admitted that while the model expands care accessibility, it also depersonalizes care, eroding rapport and leading to miscommunication. P5 provided the following insight: "We need to learn how to make 'digital warmth'—emojis aren't enough."

Technical Support

Although the current level of informatization varies significantly across health care institutions in China, interviewees expressed optimism about the potential for technical support to enhance the implementation of Internet Plus continuous care in the future. Participants emphasized that addressing existing disparities and investing in robust digital infrastructure could pave the way for the seamless integration of services. Several participants highlighted the need for a centralized patient record system as a cornerstone of future technical advancements. P13 suggested that "A centralized patient record system would eliminate duplicate tests and lost information." This sentiment was echoed by P4, who added, "In the future, we should aim for region-level interoperability so that patient data flows seamlessly across different levels of care." Additionally, participants expressed excitement about the potential of emerging technologies, such as artificial intelligence, big data analytics, and wearable devices, to transform continuous care. P7 offered a forward-looking view: "These innovations will require substantial investment and collaboration, but they hold immense promise for improving outcomes and reducing costs."

Training Standardization

Skill gaps, particularly in primary and secondary care settings, were a major concern. P3 noted, "Personnel are unprepared for new challenges, including risk prediction and process adaptation." P7 suggested targeted training in areas like data literacy and digital tools to bridge these gaps. Managing risks such as data breaches and miscommunication was seen as critical. P14 recommended training in risk prediction and mitigation. P9 added, "Predictive analytics tools can help nurses identify high-risk patients and intervene proactively." To ensure practical application, experiential learning and peer networks were suggested. P4 advocated for simulations, while P15 highlighted the value of collaborative platforms for sharing best practices.

Discussion

Principal Findings

In the context of aging populations and rapid digitalization, Internet Plus continuity care has garnered significant attention in China from both scholars and clinicians. To our knowledge, this is the first mixed methods study exploring nurses' experiences with Internet Plus continuity care services in China. Our research not only identified the most challenging aspects of implementation through objective measurements but also delved into the underlying reasons via semistructured interviews.

Consistent with prior studies [32], our results show that information continuity scored highest among the 3 dimensions of the Continuity of Care model. This aligns with the consensus that seamless information flow is critical for care continuity, with technology platforms serving as its backbone [33]. However, our qualitative data reveal persistent gaps: participants highlighted poor interoperability between institutional systems and emphasized the need for remote assistance. These findings are further supported by evaluations of 17 Internet Plus nursing service applications in China, where most platforms were rated "average" or "poor" in credibility (82%) and demand fulfillment (94%) [34]. To address these issues, future platform development should adopt a co-design approach, ensuring that the needs of both health care providers and recipients are prioritized [35].

XSL•FO
RenderX

Furthermore, our research demonstrates that relational continuity scores exhibit average performance. While continuity of care relies on stable, trusting relationships between patients and providers [36], it also depends on effective interdisciplinary collaboration [37]. Nurses play a pivotal role in sustaining continuity, even in physician-driven services [38], yet hierarchical nursing teams often struggle with complex supervision and authorization processes. This leads to diminished confidence among nurses [39,40], as reflected in our interviews. To mitigate this, preservice training, ongoing education, and structured support are essential to empower nurses in multidisciplinary teamwork and task delegation.

The most significant barrier identified was management continuity, mirroring the findings of Roy et al [41], who cited administrative burdens as a primary obstacle. In the Internet Plus context, these challenges appear amplified. Nurses in our study prioritized safety, income security, and collaboration with patients and their family—concerns echoed in prior research [8,42]. Safety risks, in particular, stem from perceived inadequacies in personal competency, lack of prescription authority, insufficient emergency equipment, and limited team support [43,44]. Notably, while shared nurses demonstrated moderate emergency response capabilities, their recovery capacity scored lowest [45]. Cross-sectional studies suggest that successful implementation hinges on insurance coverage, hospital-affiliated licensing, clear contractual terms, real-time location tracking, and emergency alert systems [46].

Our work clearly has some limitations. First, the questionnaire was self-developed and lacks external validation, though qualitative insights help counterbalance this concern. Future research should employ validated tools, such as the scale by Tian et al [47], for comparative analysis. Second, while all interviewees had experience with Internet Plus continuity care, the perspectives of nonparticipating nurses remain unexplored and warrant investigation. Despite these limitations, our findings provide actionable insights for improving the quality and scalability of Internet Plus continuous nursing services in China.

Conclusion

This study addresses a significant gap in the literature by investigating the barriers and challenges faced by nurses in providing Internet Plus continuous nursing, a novel medical model that has gained considerable attention under the dual background of aging and digitalization in China. Our findings revealed that Chinese nurses may have differential challenges when providing Internet Plus continuous nursing, particularly in management continuity. We recommend that, to better benefit patients and improve health care delivery, health care organizations and policymakers implement strategies to improve interdisciplinary relationships, establish and perfect organizational management, and enhance communication.

Abstract

Background: The digitalization of health care has advanced significantly in recent years. Consequently, physicians have needed to increasingly adopt new digital health technologies such as electronic health record systems and other health information systems. Digitalization has changed physicians' clinical work, work environment, management work, and use of tools for leadership. Many physician leaders have been critical of the capabilities of health information systems (HISs) to support leadership, management, and knowledge management.

Objective: We aimed to examine the association between leadership position and perceived changes in clinical work due to digitalization among a nationally representative sample of Finnish physicians and physician leaders. In addition, we examined physician leaders' perceptions of HISs as a support for management and whether their opinions differed based on their perceptions on changes in clinical work due to digitalization.

Methods: Altogether 4630 Finnish physicians (2960/4586, 64% women) responded to a cross-sectional nation-wide web-based survey conducted in spring 2021. Perceptions of improved preventive work, facilitated access to patient information, progressed interprofessional collaboration, and accelerated clinical encounters were used as measures of changes due to digitalization. First, we examined with multivariable logistic regression analyses whether being in a leadership position was associated with perceived changes in work due to digitalization (improved preventive work, facilitated access to patient information, progressed interprofessional collaboration, and accelerated clinical encounters in separate analyses) in the total sample. Second, we examined with analyses of covariance whether the variables related to perceived changes in work due to digitalization were associated with perceived management support from HISs among those who had administrative or management responsibilities (n=817). All analyses were adjusted for gender, age, and sector.

Results: Physician leaders had greater odds of agreeing that digitalization had improved preventive work (odds ratio [OR] 1.62, 95% CI 1.33 - 1.98), facilitated access to patient information (OR 1.28, 95% CI 1.09 - 1.51), progressed interprofessional collaboration (OR 1.81, 95% CI 1.53 - 2.14), and accelerated clinical encounters (OR 1.31, 95% CI 1.01 - 1.70) than those in nonleadership positions. Furthermore, leaders who perceived these changes in work due to digitalization positively also considered that health information systems supported their management work.

Conclusions: Physician leaders appeared to view the changes in work due to digitalization more positively than other physicians. In addition, those leaders who perceived these changes positively also perceived that HISs supported their management work. Thus, leaders should thoroughly evaluate and address physicians' perceptions of their routine clinical work and its evolving nature. Doing so ensures access to up-to-date and accurate insights, enabling more effective planning of staffing, training programs, and future implementations. Furthermore, our results show that to guarantee positive views about digitalization among physician leaders, information systems should also support managerial work. This highlights the need to focus on the quality, utility, and usability of information systems.

Introduction

Digitalization of health care has progressed during the past 20 years. Consequently, physicians have needed to increasingly adopt new digital health technologies (DHTs), such as electronic health record systems (EHRs) and other health information systems (HISs), remote monitoring, artificial intelligence, and robotics [1,2]. The clinical goals of healthcare digitalization include, for example, enhancing the possibilities for preventive work, facilitating access to patient data, progressing with interprofessional collaboration, and improving the efficiency of clinical encounters [3,4].

Digitalization has changed physicians' clinical work and work environment [5,6], and use of tools for leadership [7]. For example, clinical decision support systems may help physicians by acting as diagnostic support, assisting in administrative functions, helping clinical management, and improving patient safety [8]. Furthermore, physicians have described that the digitalization may support collaboration, decision making, continuous learning, and staying informed [6]. Indeed, health care professionals have stated that increased digitalization has accelerated their work and strengthened multidisciplinary collaboration, due to lower threshold for contacting colleagues of different professional groups [5]. Common data archives and databases facilitate the transfer of information between different units and service providers, and digitization of referrals has expedited the handling of patient matters [5]. Furthermore, previous studies show that HISs can facilitate in filtering, integrating, and interpreting information from diverse sources through better information sharing, improved communication, and timely access to data [9,10].

Despite the identified benefits, digitalization may also lead to pitfalls such as fragmented workflow, alert fatigue, and interoperability [8]. In addition, increasing number of studies report HISs-related stress among physicians [11,12]. Consequently, only a few physicians have perceived that the changes in clinical work due to digitalization were in line with the strategic goals [13], instead, they feel burdened by the undesired changes [14]. A qualitative study suggested that frontline health and social care professionals may perceive more adverse changes associated with digitalization in their work than their leaders [5]. These negative ramifications of digitalization present a challenge, as the reactions of employees play a pivotal role in determining the likelihood of the success or failure of such changes [15,16].

Many physician leaders have yet been critical of the capabilities of HIS support for leadership, management, and knowledge management [17]. They experience a need to put a lot of effort to gathering and updating necessary information from many different sources, and the information may be unreliable [17-19]. Physician leaders working in hospitals have reported that HISs supported decision-making and improved the ease of access to information, but did not improve the speed of access to information [20]. Furthermore, they had to use several systems to support their decision-making and wished for one HIS offering all the necessary information to support their decision-making [20]. Middle management has expressed difficulties in collection, mining, and systematic use of information due to different ways of producing and reporting information of the HISs [19]. Nevertheless, data collection for these findings occurred before the COVID-19 pandemic, during which information assets for knowledge management in healthcare may have evolved.

This study focused on examining the association between leadership position and perceived changes in clinical work due to digitalization (improved preventive work, facilitated access to patient information, progressed interprofessional collaboration, and accelerated clinical encounters) among a nationally representative sample of Finnish physicians and physician leaders. In addition, we examined physician leaders' perceptions of HISs as a support for management and whether their opinions differed based on their perceptions on changes in clinical work due to digitalization.

Methods

Sample

The data were collected with a web-based survey between January and March 2021 as a part of the "EHR systems as a tool for physicians 2021" study [21]. An invitation to participate was sent by email to all working-age (aged 65 y and younger) physicians from the Finnish Medical Association's register. A detailed description of the data collection, measures used in the questionnaire and the evolution of the questionnaire can be found elsewhere [21]. Altogether 4683 physicians (estimated response rate 24.5%) responded to the survey. We excluded 53 respondents who indicated that they did not use EHRs at all. Thus, the final sample included 4630 physicians. The sample was representative of the target population, with a slightly more older physicians, specialists, and hospital physicians compared to the eligible population [22].

Ethical Considerations

The study was conducted according to national laws, regulations, and the Declaration of Helsinki. The survey did not require a statement from the ethics committee, given that the Finnish National Board on Research Integrity [23] has defined that the administration of surveys to gather respondents' opinions, which are not anticipated to result in harm, does not necessitate a statement from the ethics committee. All respondents provided informed consent to participate, participated voluntarily, and received written information about the study. All responses were anonymous and the research data did not include any personally identifiable information. No compensation was provided to participants.

Measures

The variables used in this study can be found in Multimedia Appendix 1.

Perceived changes in clinical work due to digitalization were measured by respondents' opinions on the following statements on how the digitalization of health care had changed their work in the past 3 years:

1. Possibilities for preventive work have improved (improved possibilities for preventive work).

XSL•FO
RenderX

2. It has become easier to obtain information on patients (facilitated access to patient information).
3. Interprofessional collaboration has progressed (progressed interprofessional collaboration).
4. Consultations with patients have become faster (accelerated clinical encounters).

The statements were rated: 1=fully agree, 2=somewhat agree, 3=neither agree nor disagree, 4=somewhat disagree, and 5=fully disagree, which were then recoded as 0=disagree or neutral (response options 3 - 5) and 1=agree (1-2). These statements were developed by clinicians and healthcare digitalization experts according to the strategic goals of digitalization of health care [4] and pilot tested with physicians. The statements have been associated, for example, with work-related time pressure and stress related to information systems [14].

Perceived management support from HISs was assessed with 3 items (Cronbach α=0.81) measuring the supportiveness of information systems for knowledge management. The respondents were directed to this section if their professional title indicated that they might have a leading or managerial position. Furthermore, the respondents were advised that if they do not have administrative or management responsibilities, they should not grade these statements (817 responded to these statements). They were asked how, in all, do the information systems used in their organization work as tools for leadership and management The items were: “I use information systems daily for activity monitoring,” “information systems facilitate monitoring the quality of activities,” and “information systems help me to monitor the targets set by my unit (eg, numbers of patients, periods of treatment, and types of operations).” The response options with 5-point Likert scale ranged from 1=fully disagree to 5=fully agree. A mean of these three items was calculated, higher scores indicating better support for management. Respondents were advised not to answer this question if they do not have administrative or management responsibilities; thus, those who answered this question were considered as being in leadership position.

Furthermore, the survey asked respondents’ age (which was categorized as under 35, 35 - 44, 45 - 54, and 55 - 64 years) and employment sector (hospitals, primary care, private, and other such as universities). Respondents’ gender was received from registers.

Statistical Analyses

First, we examined whether being in a leadership position was associated with perceived changes in work due to digitalization in the total sample. Multivariable logistic regression analyses were conducted with the perceived changes in clinical work due to digitalization (improved preventive work, facilitated access to patient information, progressed interprofessional collaboration, and accelerated clinical encounters in separate analyses) as dependent variables and leadership position (yes or no), gender, age, and sector as independent variables.

Second, we examined whether the variables related to perceived changes in work due to digitalization were associated with perceived management support from HISs among those who had administrative or management responsibilities (n=817). Analyses of covariance were conducted, with perceived management support from HIS as the dependent variable and the four statements regarding perceived changes in clinical work due to digitalization as independent variables (in the same analysis), adjusted for gender, age, and sector. All analyses were conducted using IBM SPSS Statistics software (version 28).

Results

Characteristics of the study sample can be seen in Table 1. Almost 2 in 3 of the respondents were women. More than half of the respondents worked in specialized care. Approximately 1 in 6 worked in a leadership position. In addition, 1 in 5 agreed that digitalization had improved preventive work and more than 2 in 5 agreed that it had facilitated access to patient information. In total, 30% agreed that digitalization had progressed interprofessional collaboration, whereas only 1 in 10 agreed that it had accelerated clinical encounters. Among physician leaders, the mean score for perceiving HISs as supporting management was 2.70 (SD 0.99).

Table . Characteristics of the study sample.

Characteristics	Value, n (%)
Gender	
Man	1626 (35.5)
Woman	2960 (64.5)
Age (years)	
<35	948 (20.6)
35 - 44	1211 (26.4)
45 - 54	1148 (25.0)
55 - 64	1284 (28.0)
Sector	
Hospital	2759 (59.6)
Primary care	1037 (22.4)
Private	610 (13.2)
Other	221 (4.8)
Leadership position	
No	3813 (82.4)
Yes	817 (17.6)
Improved preventive work	
Disagree or neutral	3622 (80.4)
Agree	884 (19.6)
Facilitated access to patient information	
Disagree or neutral	2565 (56.4)
Agree	1986 (43.6)
Progressed interprofessional collaboration	
Disagree or neutral	2948 (65.0)
Agree	1586 (35.0)
Accelerated clinical encounters	
Disagree or neutral	4084 (90.2)
Agree	445 (9.8)
Information systems as support for management (range 1 - 5), mean (SD)	2.70 (0.99)

Table 2 shows the results of the logistic regression analysis for changes in clinical work due to digitalization in the total sample. Women had lower odds of agreeing that digitalization had accelerated clinical encounters than men. Older respondents had lower odds of agreeing that digitalization had improved preventive work and greater odds of agreeing that digitalization had facilitated access to information than younger respondents. Compared to respondents working in public specialized care, those working in public primary care and private care had greater odds of agreeing that digitalization had improved preventive work and facilitated access to information. Furthermore, respondents working in public primary care had greater odds of agreeing that digitalization had progressed interprofessional collaboration, and respondents working in private sector had greater odds of agreeing that digitalization had accelerated clinical encounters than those working in public specialized care. Respondents in leadership positions had greater odds of agreeing with all the statements concerning clinical work change due to digitalization than others. The clearest difference was observed regarding progressed interprofessional collaboration and improved preventive work.

[b]Reference category.

Table 3 shows the results of the analyses of variance for perceived management support from HISs among those who were in leadership positions. HISs were least experienced as supporting management in public primary care. Multimedia Appendix 2 shows that those who agreed that digitalization had improved preventive work, facilitated access to patient information, progressed interprofessional collaboration, or accelerated clinical encounters perceived HISs as more supportive compared to those who disagreed or were neutral about these statements.

Discussion

Principal Findings and Comparison With Previous Work

This study found that physician leaders agreed more often that digitalization had improved preventive work, facilitated access to patient information, progressed interprofessional collaboration, and accelerated clinical encounters compared to those without leadership positions. This suggests that leaders have a more positive view related to ramifications of digitalization than physicians without leadership positions. However, physician leaders did not experience that HISs support their management work, given that their average rating for support was 2.7 on a scale of 1 to 5. Nevertheless, although physician leaders considered HISs support for leadership and management insufficient, those who agreed with these statements also gave more positive responses about the impacts of digitalization.

Our finding that physician leaders had a more positive view related to digitalization than other physicians is congruent with a previous study [5]. A qualitative study among health and social care professionals suggests that leaders may overlook the new digital skills needs and problems caused by combining continuous learning with busy work schedules [5]. A possible reason why health care leaders may have a more positive attitude toward digitalization is that they play an active role in leading these initiatives by striving to demonstrate a visible commitment towards new DHTs [24]; they also try to convince reluctant users to envision digitalization in a more favorable manner [25]. It has been suggested that the successful implementation of DHTs among health care professionals is contingent upon managers being convinced of its positive effects [26].

Our study found that those leaders who agreed with the positive statements related to the changes in clinical work due to digitalization also perceived more often that HISs supported management work compared to those who disagreed or were

XSL•FO
RenderX

neutral. Due to the cross-sectional nature of our study, we cannot identify the causality of this association; that is, we cannot definitely identify whether effective support from HISs leads to improved efficiency in management work for leaders and contributes to a positive view toward digitalization. Alternatively, it could be that those who have noticed that digitalization has improved preventive work, facilitated access to patient information, promoted collaboration, and accelerated clinical encounters are therefore also more inclined to rate that HISs support their management work. It is possible that the general satisfaction with the benefits of digitalization for leaders in health care is reflected in their responses. Thus, it seems important to ensure that leaders keep themselves well-informed about the realities of clinical work and thereby avoid having excessively positive view related to digitalization [26]. Many physician leaders participate also to clinical work which makes it easier to stay up to date about the situation in clinical care. However, physicians working in nonleadership positions need to communicate work-related issues and digital challenges to management, providing nuanced insights for decision-making [26].

Our results suggest sector-specific variations, with physicians working in specialized care perceiving less improvement in preventive work and facilitated access to information compared to physicians working elsewhere. Whereas primary care focuses on preventive measures and health promotion, specialized care physicians mainly treat the diseases in their own specialty [27]. A previous study among specialized care physicians showed that day-to-day operations management HISs supported decision-making to some extent but did not improve access to information [18]. Hospital physicians have also reported that they need to use a number of information systems to support decision making instead of one HIS which they would prefer [18]. Hospital physicians have also reported that they were more able to monitor the use of personnel, equipment, or room resources through HISs compared to primary care physicians [17]. Furthermore, physicians in specialized care settings have previously stated fragmentation of information and data overload resulting from difficult-to-use EHRs [28]. In addition, the implementation of HISs has led to changes in professionals' workflow, potentially causing cognitive burden [29]. Notably, high levels of stress related to HISs have been reported, particularly among physicians working in specialized care [12]. These challenges may contribute to the perception of less improvement in access to information among physicians in specialized care. Furthermore, contextual factors such as workload, resource allocation and availability, and on-call work may have affected these sector-specific differences.

Physician leaders in primary care perceived that HISs supported less their management work than leaders from other sectors. This is congruent with previous results in Finland which showed that, of different working sectors, leaders from primary care were most dissatisfied with HISs in guiding daily activity, facilitating measurement of functional quality, and monitoring the achieving of the set targets [17]. Primary care leaders have been found to use less managerial HISs compared to physicians in specialized care and private sector [17]. Compared to other sectors, primary care differs in aspects such as care processes, outcome goals, and the validity of summative quality scorecards [30]; thus, needs for managerial HISs also vary. For example, patient-centered reporting and outcomes (eg, reduction in days of avoidable disability) have been suggested as priorities for quality management in primary care [30].

In our study, older physicians were less likely to perceive that digitalization has improved preventive work or facilitated access to information than younger physicians. This corresponds with previous findings that, compared to younger physicians, older physicians are less likely to perceive that HISs will improve data and care coordination [31]. Older physicians have also been found to perceive less affinity toward digitalization, as well as use and trust mobile apps less in their professional lives than younger physicians [32]. Our finding that older physicians did not consider digitalization as having facilitated preventive work, may influence their likelihood to recommend preventive DHTs to patients. Consequently, this may impact the extent of digital preventive work, as patients' unawareness of the potential DHTs or their benefits has been mentioned amongst the barriers of digital prevention [33].

Our study did not find many gender differences. However, we found that women were less likely to perceive that digitalization had accelerated clinical encounters compared to men. A previous study among physician students did not find gender differences related to fear of digital challenges, but women rated their knowledge in different fields of digital medicine as worse than men, whereas men frequently reported keeping themselves informed about digital medicine outside of their studies [34]. It has been found that women physicians tend to perceive digitalization-related differences in working conditions as more stress-reducing than men physicians [35].

Limitations

There are some limitations to this study. A major limitation of our study is the use of cross-sectional survey data, thus we cannot draw any causal inferences. Therefore, according to our data it is not possible to say whether efficient support from HISs to management work leads to more positive views toward digitalization or vice versa. Thus, future studies with longitudinal design should examine more thoroughly the causal associations between HISs support for management and perceptions of digitalization. Furthermore, a question related to problems associated with an inflation of the strengths of relationships and with common method variance always arise when using self-rated measures. Self-reported data are subject to many biases such as recall, desirability, and response biases along with problems in accuracy and generalizability [36]. The reliability of the variable measuring how HISs support management was .81; thus, it can be considered reliable.

In addition, even though we adjusted our analyses for age, gender, and employment sector, we cannot put aside the possibility of residual confounding. Some variables that were not adjusted for, such as competence in knowledge management, may have influenced the associations we examined and, thus, cause bias to our results. Furthermore, usability of HISs and experience as an HIS users are among factors that might have affected our findings, for example, by influencing the overall attitude toward HISs. We excluded 53 respondents who did not

XSL•FO
RenderX

use EHRs at all; thus, their opinion was not considered here. This was done because we reasoned that their work did not involve such tasks that they could accurately answer our questions related to digitalization and the supportiveness of information systems for knowledge management.

Our results can be considered generalizable to other countries with universal access to health care and long history of HISs [37]. Furthermore, generalizability of our findings is compromised by rather low response rate of our study, which indicates likelihood of nonresponse bias. However, our sample was rather large and it has been shown to be representative of the target population [22]. The response rates have been found similarly low also in other physician studies [38]. Unfortunately, it seems that response rates among health and social care professionals especially in Finland seem to have decreased. A potential factor contributing to the declining response rates may be survey fatigue, given the high volume of various surveys conducted in this sector in Finland. Another reason for low response rate in our survey may be that the survey was conducted via email, which may have caused problems in message deliveries and email addresses might have changed.

Conclusions

This study found that physician leaders were more optimistic related to the changes in clinical work due to digitalization compared to other physicians. Furthermore, those leaders who perceived these changes positively also perceived that HISs supported their management work. Leaders should comprehensively assess and address the perceptions of physicians in routine clinical work concerning work and its changes. This approach ensures that leaders possess current and accurate information to optimize planning for personnel resources, training initiatives, and future DHT implementations.

Furthermore, to ensure that leaders have a positive view related to digitalization, it is important that HISs support their management work. Thus, it is important to focus on the quality and usability of information systems. For example, it has been suggested that HISs designed for leaders should be flexible and consider the needs of different users to support a shared situational awareness and operational intelligence in the management [39]. It is important that the success of HIS development would be regularly monitored and that future studies would address HISs' effect to clinical and management work. Especially, because our study was cross-sectional, future studies with longitudinal study design are needed.

Acknowledgments

We would like to thank the Finnish Medical Association for collection of this data. We are also deeply grateful to all the physicians who took the time to respond to this survey. The study was funded by the Strategic Research Council at the Academy of Finland (grant 352501 for the DigiIN Project) and Finnish Work Environment Fund (grant 240074). The authors attest that there was no use of generative artificial intelligence (AI) in the generation of text, figures, or other informational content of this manuscript.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request

Authors' Contributions

All authors have made contributions to the conception of the work, such as the formulation and evolution of overarching research goals and aims. TH, LV, JR, and TL contributed to the design of the study. TH drafted the original manuscript. TH, LV, EK, and PS contributed to the development and design of methodology, statistical analyses, tables, and visualization. JR and TL contributed to the supervision of the study. All the writers participated in the writing of the study, including critical review, commentary, and revision. All authors reviewed and approved the final version of the manuscript.

Conflicts of Interest

TL has previously been employed by a publicly owned health information system (HIS) software provider, but the employer did not provide any support, financial or otherwise, to the study. The employer also was not involved in the design of the study or the collection, analysis, and interpretation of the data.

Abstract

Background: Traditional management methods can no longer meet the demand for efficient and accurate neonatal care. There is a need for an information-based and intelligent management system.

Objective: This study aimed to construct an information closed-loop management system to improve the accuracy of identification in mother-infant rooming-in care units and enhance the efficiency of infant admission and discharge management.

Methods: Mothers who delivered between January 2023 and June 2023 were assigned to the control group (n=200), while those who delivered between July 2023 and May 2024 were assigned to the research group (n=200). The control group adopted traditional management methods, whereas the research group implemented closed-loop management. Barcode technology, a wireless network, mobile terminals, and other information technology equipments were used to complete the closed loop of newborn exit and entry management. Data on the satisfaction of mothers and their families, the monthly average qualification rate of infant identity verification, and the qualification rate of infant consultation time were collected and statistically analyzed before and after the closed-loop process was implemented.

Results: After the closed-loop process was implemented, the monthly average qualification rate of infant identity verification increased to 99.45 (SD 1.34), significantly higher than the control group before implementation 83.58 (SD 1.92) (*P*=.02). The satisfaction of mothers and their families was 96.45 (SD 3.32), higher than that of the control group before the closed-loop process was implemented 92.82 (SD 4.73) (*P*=.01). Additionally, the separation time between infants and mothers was restricted to under 1 hour.

Conclusion: The construction and application of the information closed-loop management system significantly improved the accuracy and efficiency of maternal and infant identity verification, enhancing the safety of newborns.

KEYWORDS

mother-infant same-room management; information-based identity verification; closed-loop management system; newborn safety management

Introduction

In the modern medical environment, ensuring the safe movement of newborns and mothers and effectively managing room exits and entry is an important part of obstetric care and newborn health management. In the 2022 Safety Goals for Patients and the Action Plan to Improve Maternal and Infant Safety, the China Hospital Association clearly emphasized the importance of strengthening maternal and newborn safety. Strategies include improving neonatal access management systems, implementing continuous quality improvement measures, and enhancing safety protocols [1-3]. However, studies have shown that patient identification error rates in medical settings remain as high as 20% despite strict reconciliation procedures [4]. Intelligent systems play an important role in the treatment and care of diseases [5,6]. As the scale of the hospital and the number of beds increases, the traditional manual records and management methods can no longer meet the demands for efficient and accurate management; an information-based and intelligent management system is urgently needed to optimize this process [7]. Although information technology has been widely used in patient identity verification, there are limited reports on its

XSL•FO
RenderX

application in identity verification and door access time monitoring in the neonatal ward. The infant room entry and exit information management system for mother-infant co-care uses modern information technology and 'Internet of things' devices to achieve full process monitoring and management of an infant's movement from the rooms [8]. It uses radio-frequency identification tags, two-dimensional code scanning, and biometric identification technologies to automatically record and track an infant's entry and exit information and achieve closed-loop management. Implementing a full-process closed-loop management system is a core strategy of modern nursing quality management that can improve the intelligent neonatal care. Starting from July 2023, our hospital implemented identity verification and door access–time monitoring for the infant entry and exit rooms based on the mobile nursing platform and implemented closed-loop information management. This study expanded the application of information technology in the field of newborn identity verification and explored the effectiveness of closed-loop management in newborn care, which was an important supplement to the field of intelligent neonatal care. This study aimed to construct an information closed-loop management system to improve the accuracy of identification in mother-infant rooming-in care units and enhance the efficiency of infant admission and discharge management.

Methods

Study Setting

In July 2023, the information closed-loop management system for barrier-free neonatal wards was officially launched in the Obstetrics and Gynecology ward of the hospital. The study included 400 mothers (n=200 per group) admitted to the hospital between January 2023 and May 2024. The exclusion criteria were as follows: the mothers needed to be transferred to another hospital after admission, the medical records were incomplete, or the newborns needed to be isolated from the mother due to illness. The parturients admitted to the hospital between January 2023 and June 2023 were assigned to the control group, while those admitted between July 2023 and May 2024 were assigned to the research group. Data on metrics such as the workload and work efficiency of nurses, the satisfaction of mothers and their families, the standard rate of newborn identity verification, and newborn visit time qualification rate were collected and statistically analyzed.

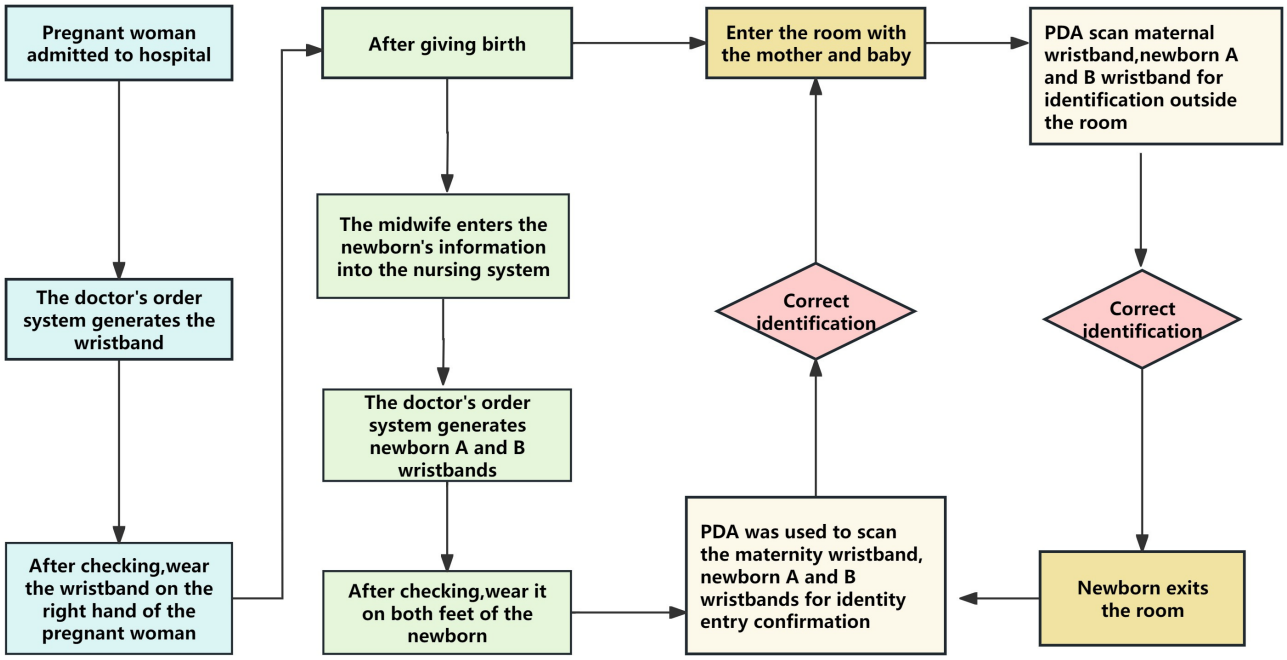
Information Closed-Loop Management System for Mother and Infant Newborns

Manual inspection methods are used in the traditional newborn admission and discharge management process. These methods rely on nursing staff to visually compare the wristband and foot information of the mother and the newborn and to conduct oral checks on the following main content: (1) room information verification, (2) oral confirmation, and (3) postadmission information verification. This method mainly relies on nursing staff or inquiries from the mother and her family, where the human factor has a large impact. Reports show that 40 - 60% of mothers experience postpartum fatigue, which manifests as decreased attention during medical examinations and communication, thereby increasing the risk of verification errors and medical accidents [9-11].

Design of a Closed-Loop Management System for the Neonatal Access Room

The closed-loop management system includes three functional modules: (1) the medical order module, which includes the medical order system and the electronic nursing system; (2) the label barcode printing module, which prints maternal wristbands and newborn 'A and B' wristbands; and (3) the statistical function module, which manages the statistical room time pass rates.

The management system includes a database management system (DBMS), handheld personal digital assistant (PDA) devices, and QR barcode recognition technology. PDAs equipped with a barcode scanner can print and scan the QR codes, which serve as identifiers, to read and transmit data to the central database server through a wireless network. The DBMS is responsible for processing data requests from the PDA device. During the management of newborn entry and exit, the PDA device is used to verify whether the QR code matches the DBMS records. If the match is successful, the server sends the confirmation information back to the PDA device and displays the correct identification details along with a voice prompt on the PDA device, indicating successful authentication. Simultaneously, the interface records the job number of the nursing staff and the time of entering and leaving the room for process management. It is worth noting that only authorized caregivers can use the PDA device for identification, ensuring the security of the system and avoiding mistrust. This management system provides a fast, accurate, and safe method for confirming the identity of the mother and child, thereby improving the efficiency of hospital work and ensuring the safety of the newborn.



Management Plan for Building a Closed-Loop Information System for Newborn Admission and Discharge

The management team comprised five members, including one leader, with the deputy director of the nursing department responsible for leading the entire closed-loop management work. The team members organized the neonatal exit and entry operation through multiple surveys and consulted relevant literature [12-17]. In conjunction with the Information Department, they designed the closed-loop management system for neonatal exit and entry with the objective of monitoring and controlling the entire process, to ensure the safety of children. The process uses barcode technology, a wireless network, mobile terminals, and other information technology equipment to facilitate closed-loop management of newborn exit and entry. Furthermore, the team secured a computer software copyright (certificate number: 11934939). The specific operational process is shown in Figure 1. This flowchart describes the closed-loop information management process from the time the newborn is separated from the mother to the time of returned to the mother, covering admission, through delivery, and the mother's discharge. The process is divided into the following steps:

XSL•FO
RenderX

1. Pregnant women complete admission registration in the outpatient system, generating accurate personal information based on their identity card or medical insurance card, including name, age, and unique hospitalization number.
2. Pregnant women enter the ward and use the ward system to generate wristbands, which are verified by two staff members before being worn on the right hand, include details such as name, hospitalization number, age and a QR code.
3. After the baby is delivered, the system imports delivery information and generates neonatal A and B wristbands with QR codes, which are verified by two staff members, and worn on the wrists and feet of the newborn.
4. When the mother and newborn leave the delivery room, a PDA device is used to scan the QR code on the wristbands of the mother and newborn for identification.
5. When the mother and infant enter the room, a ward nurse uses a PDA device to scan the QR code on the wristband of the mother and newborn again for identification to form a closed loop of admission and exit.
6. When the newborn leaves the mother for examination, vaccination, or treatment, a PDA device is used to scan the QR code on the mother and the newborn's wristband for identification in the exit room.
7. When returning to the mother, a PDA device is used to scan the wristbands of the mother and newborn again to check the QR codes at the admission identification site to form a closed loop of access. The entire process emphasizes closed-loop management, ensuring the safety and correct identification of mothers and infants during hospitalization and improving the quality and efficiency of medical services.

Figure 1. Identification process for neonatal admission and discharge. PDA: personal digital assistant.

Identity Verification of Pregnant Women's Admission Information

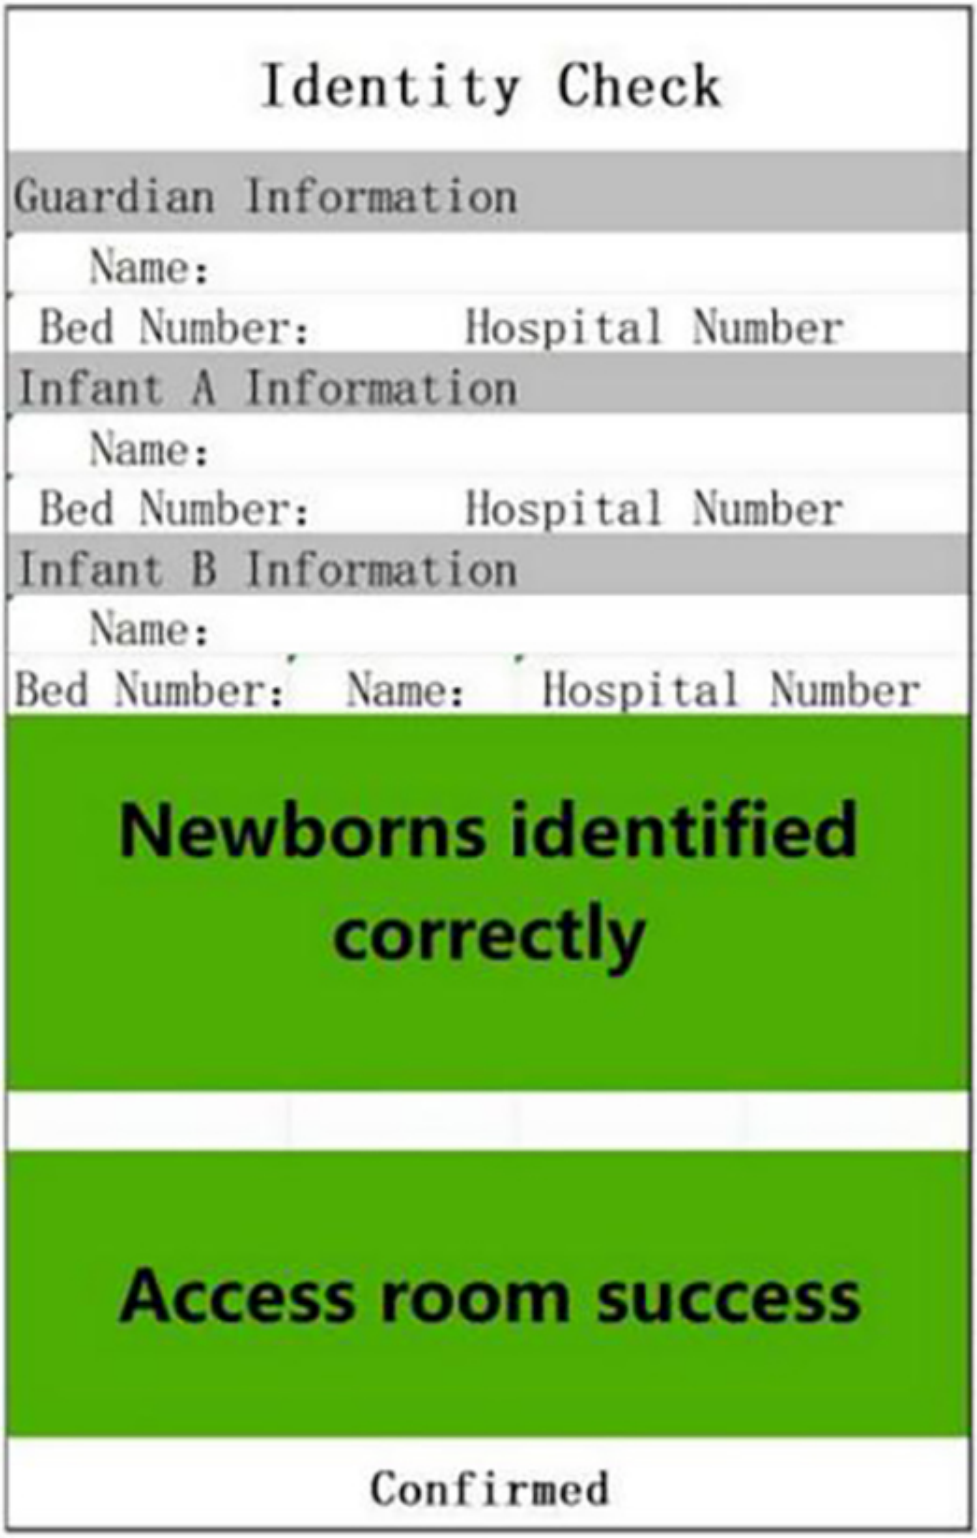
After the pregnant woman is admitted to the hospital, the identity verification process follows three steps: (1) completion of hospitalization registration: the system automatically assigns a unique hospitalization number as the pregnant woman's identifier within the hospital; (2) wristband printing: after the pregnant woman is transferred to the ward, the nursing staff initiates the wristband printing function through the medical order system. The wristband is printed with the name, gender, time of admission, age, the hospital number of the pregnant woman, and a unique information QR code; (3) review: before wearing the wristband, the nursing staff strictly review the printed information and the actual details of the pregnant women to ensure the consistency of information.

Newborn Identity Verification After Delivery

After delivery, the newborn identity verification process is as follows: (1) information entry: the midwife records the basic information of the newborn on the mobile nursing platform in the delivery room or operating room, including birth time, gender, and weight; (2) newborn wristband generation: the maternal personal medical consultation system generates the corresponding newborn A and B wristbands comprising the newborn's information. The wristband is printed by a barcode printer with information including the name of the pregnant woman, sex of the newborn, weight, hospital number, and QR code; (3) information check: the midwife performs a double-check to ensure that the wristband details match those of the newborn and the mother; (4) wristband wearing: after examination, the midwife attaches A and B wristbands to the newborn's ankles and informs the mother and family of their significance, emphasizing that they should not be removed to ensure the safety of the newborn; (5) identity matching: before the mother is transferred to the mother-baby room, the midwife scans the mother's and the newborn's A and B wristbands. If the PDA device shows a match, the identification is confirmed, and both are safely transferred to the room.

XSL•FO
RenderX

Verification of Maternal Identity in the Mother-and-Baby



To ensure the safety of the mother and child within the same room, the following strict identity verification process is implemented: (1) handover and information check: the midwife and nursing staff conduct a detailed handover according to the protocol, verifying the basic information of the mother and newborn and record them; (2) PDA scan to verify identity: the mother and child use the PDA device in the same room to scan the mother's wristband and the two-dimensional QR codes of the A and B newborn wristbands, ensuring identity consistency; (3) authentication completion: if the PDA indicates a successful match, the authentication process is considered complete.

Identity Verification During Newborn Entry and Exit from the Mother-and-Baby Room

Newborns often need to be temporarily separated from their mothers for routine nursing activities such as morning baths, examinations, and vaccinations. In this context, the safety risks are increased as multiple newborns may be under the custody of the nursing staff at the same time [18]. Accurate identity verification plays a vital role in ensuring the safety of newborns and avoiding identity confusion. The following identity verification process is executed: (1) identification before leaving the room: nursing staff use PDA equipment to scan the A and B wristbands of mothers and newborns to confirm the identity information. The PDA device confirms the identity-matching with the green module and voice prompt, and displays the job number of the executor and the time of the newborn's exit (Figure 2); the nurse confirms the information with the mother and family members to ensure accuracy; (2) post-entry verification: when the newborn is returned to the ward after completing the relevant project activities, the nursing staff scan the QR code of the mother and newborn again. Similarly, the PDA device verifies the identity and records the job number and the entry time of the executor to complete the entry verification.

XSL•FO
RenderX

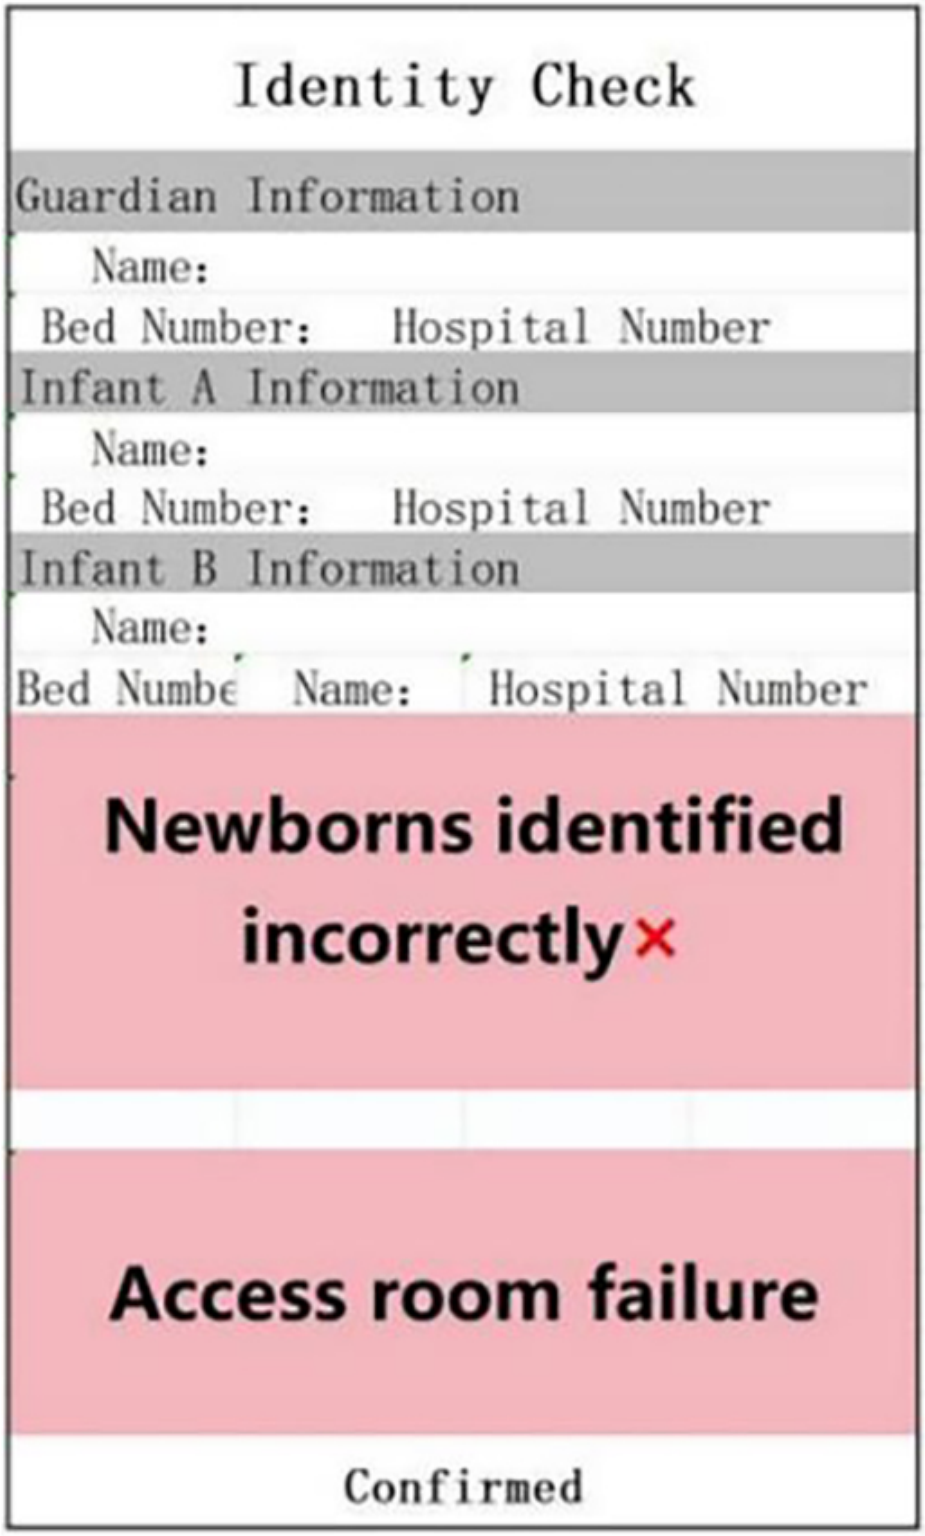


Figure 2. The system successfully identifies and confirms the mother-infant identity match.

Throughout the process, any error or unsuccessful verification is immediately indicated by the red module and the voice prompt "recognition error" (Figure 3), allowing for timely correction. The PDA green module and voice prompt confirm the accuracy of identity verification. This process not only improves the efficiency of identity verification but also enhances caregivers' alertness through color coding and voice prompts [19]. Additionally, new mothers and their families can actively participate in nursing safety management, increasing the sense of trust in the operation of nursing staff and ensuring the safety of both mother and child.

XSL•FO
RenderX

Figure 3. Identification failures due to identity mismatch or other issues.

Time Management of Newborns During Mother-Baby Separation

The evaluation criteria of baby-friendly hospitals require that—except for the separation of mother and child with medical indications—the mother and newborn should remain together for 24 hours, with separation not exceeding 1 hour per day. Therefore, to support this requirement, time statistics and alarm functions relating to the newborn access room were added to the closed-loop management system (Figure 4). When the separation time exceeds the set threshold (ie, 45 min), the PDA immediately issues an alarm, to remind the nursing staff to send the newborn back to the room promptly.

XSL•FO
RenderX

Figure 4. Key information on the management of neonatal admission and exit rooms.

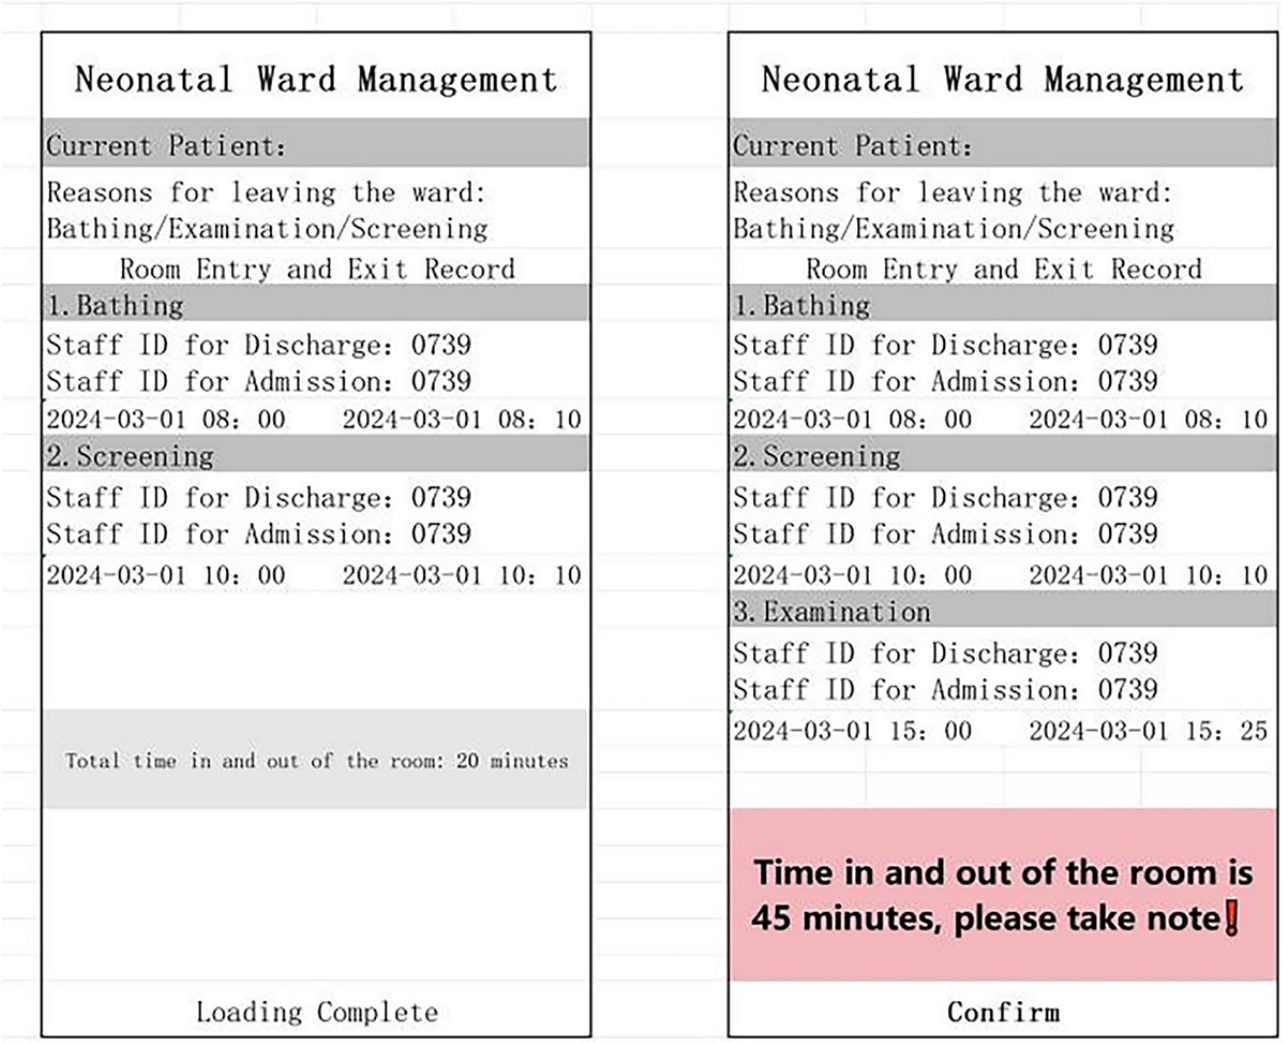

Figure 4 provides key information on the management of neonatal admission and exit rooms, specifically including the following aspects:

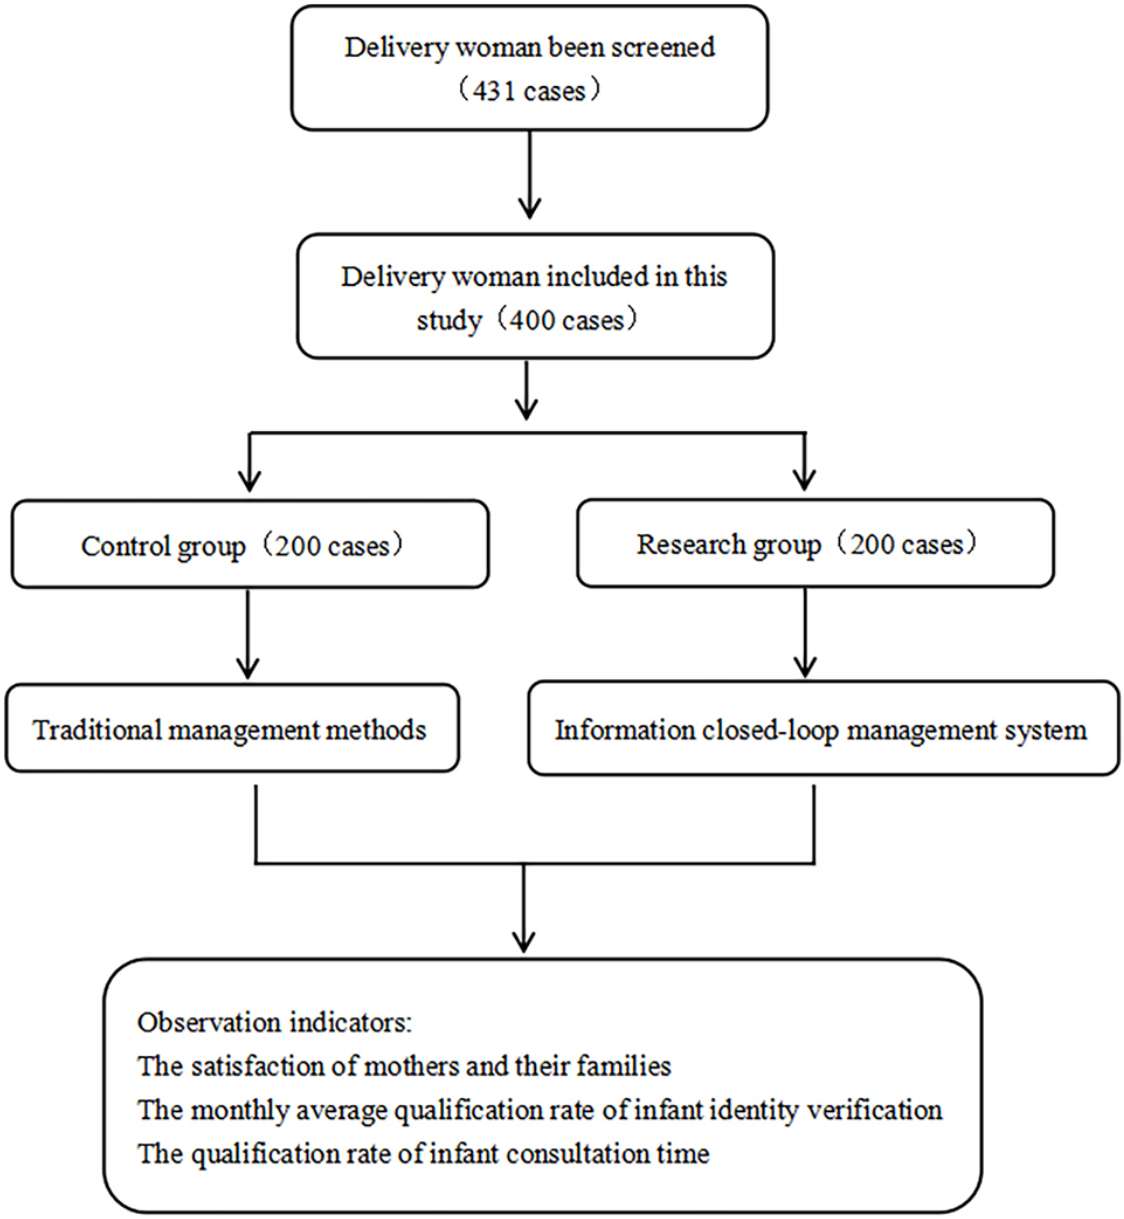
1. Patient information display: the interface displays information about the current neonatal patient.
2. Reasons for leaving the ward: the system lists reasons for the newborn leaving the ward, including bathing, examination, or disease screening.
3. Time record: the exact time at which the newborn leaves and returns to the mother is recorded.
4. Staff identification: the identification number of the responsible staff member for the admission and exit of the newborn is recorded to facilitate tracking of the person.
5. Entry and exit time limit prompt: the interface particularly emphasizes that the time limit for newborns to enter and exit the room is 45 minutes and reminds the staff to pay attention to the time, so as not to exceed the specified time (ie, 1 h).
6. Warning tone function: if the mother-infant separation time exceeds 45 minutes, the system issues a warning tone, which helps the staff track the newborns and ensures the safety and standardization of the process.

Statistical Analysis

The SPSS software (version 26.0; IBM Corp) was used for statistical processing. A paired design *t* test (two-tailed) was used for the comparison between the two groups. Categorical data were expressed as frequency (n) or percentage (%), and a *P* value of <.05 was considered statistically significant.

Ethical Considerations



This study was conducted in accordance with the Declaration of Helsinki. This study was conducted with approval from the Ethics Committee of The Affiliated Suzhou Hospital of Nanjing Medical University (ID: KL901515). All family members of newborns gave their informed consent to this study. All data collected during this study were anonymized to protect the privacy and confidentiality of the participants. No personally identifiable information was retained in the dataset. The data were stored securely, with access restricted to the research team members who had undergone appropriate training in data handling and confidentiality. No financial compensation was provided to the participants for their involvement in this study. Participation was voluntary, and no incentives were offered. No images or supplementary materials containing identifiable features of the participants were included in the manuscript.

XSL•FO
RenderX

Results

The participant screening process is shown in (Figure 5).

Figure 5. The participant screening process.

Effect Evaluation

There were no significant differences in age, time of delivery, mode of delivery, economic status, educational level, or general characteristics between the study groups (*P*=.14).

Identity Verification Pass Rate

Identity verification was performed at each entry, with the first verification result used as the assessment index for the identity verification pass rate. After implementation of the closed-loop process between July 2023 and May 2024, the average monthly pass rate of neonatal identity verification was 99.45 (SD 1.34), which was higher than that of the control group, 83.58 (SD 1.92) before the operation process (*P*=.02) (Table 1).

Table . Comparison of identity verification pass rate and satisfaction level between groups.

Variables	Control group (n=200), mean (SD)	Research group (n=200), mean (SD)	*P* value
Average monthly pass rate of neonatal identity verification	83.58 (1.92)	99.45 (1.34)	.02
Satisfaction level	92.82 (4.73)	96.45 (3.32)	.01

XSL•FO
RenderX

Satisfaction Level

After the closed-loop process, the satisfaction among the pregnant women and their families was 96.45 (SD 3.32), which is higher than that of the control group, 92.82 (SD 4.73) before the closed-loop process (P=.01) (Table 1).

Efficiency of the Entry and Exit Process

The efficiency of the traditional neonatal entry and exit process is low; for 80 newborns, a nurse must verify 240 labels daily, requiring approximately 80 minutes for copying and checking the labels. Compared to the traditional process, the closed-loop management system significantly reduced the execution time, decreasing the total verification time for 80 identity verifications to 15 minutes, with daily quality control verification requiring only 2 minutes. This improvement enhances the efficiency of neonatal nursing work and significantly improves the accuracy and efficiency of the verification work; thus, the process not only reduces the workload of nurses but also improves the quality of nursing services and ensures the safety of newborns. Before the implementation of the system, the exit and entry process could not effectively monitor the separation time between newborns and their mothers. After the implementation, the statistics of the background system showed that the real-time tracking and management of the newborn access times were achieved, with all newborns separations remaining below the 1-hour limit. These findings show that the newborn entry and exit times were effectively controlled to ensure their safety and timely nursing.

Discussion

Principal Findings

In this study, the monthly average qualification rate of infant identity verification after the implementation of the closed-loop process was higher than that of the control group. After the closed-loop process was implemented, the satisfaction of mothers and their families was higher than before the closed-loop process was implemented, and the separation time between infants and mothers was controlled within 1 hour.

Innovation and Implementation Effect

The primary aim of closed-loop management is to ensure the safety of mother and child and improve the quality of care. In the existing literature, research on information closed-loop management systems for neonatal access rooms is relatively rare, particularly regarding changes in the implementation rate of identity verification standards before and after the implementation of the system, as well as statistical analyses of time monitoring within the access room. The closed-loop information management system developed in this study demonstrates significant innovation. Through the close collaboration between the interdisciplinary team, this system not only simplifies the traditional manual verification process but also ensures the accuracy and real-time performance of information.

Research has shown that intelligent systems can help practitioners make decisions, reduce their workload, and increase their efficiency and accuracy by incorporating artificial intelligence systems into their daily practice [20,21]. Regarding implementation effectiveness, a comparative analysis of the data before and after implementation, we found that the implementation rate of the newborn identity verification standards was significantly improved. The average monthly pass rate of neonatal identity verification in the study group was higher than that in the control group before the operational process, with a statistically significant difference. With precise time management, we ensured that newborns received timely and continuous care and improved the efficiency and response speed of care work. After the implementation of the system, 24-hour neonatal access room time supervision was achieved, and the qualification rate reached 100%, demonstrating high efficiency and systematic improvement in time management. Detailed statistical analyses of different ventricular event durations provided valuable data support. These data provided the basis for both the evaluation and improvement of current care processes and a scientific temporal database for future process optimization and the development of time management strategies. By analyzing these data, potential bottlenecks can be identified, the allocation of resources can be optimized, and the overall quality and efficiency of nursing services can be improved.

Closed-loop management methods have been explored in blood transfusion, breastfeeding, and care of premature newborns, yielding promising results [22-25]. Compared to traditional neonatal access management approaches, the closed-loop management system can not only reduce human interference factors but also trace the source of the whole process, strengthen supervision, further reduce risks, enhance doctor-patient relationships, and enhance trust, facilitate postpartum recovery, and reduce the risk of postpartum anxiety [26-28]. This closed-loop management system can also be extended to continuous blood glucose monitoring in critically ill newborns and pharmaceutical management for newborns, further enhancing full-process management and advancing precision medical digitalization [29,30].

Improvements in Maternal and Infant Safety and Nursing Quality

The implementation of closed-loop management not only improves the safety of mothers and neonates but also significantly improves the quality of care. Through the data analyzed in this study, we found that after the implementation of closed-loop information management, the integrity of newborn access room records was significantly improved, and the traceability of nursing quality was enhanced. The completeness and traceability of data increased the safety of the mother and baby. Additionally, the intelligent system reduced the time burden on the nursing staff and provided convenient management of mother and baby information, which improved the quality of nursing and patient satisfaction. After the implementation of the system, caregivers' time spent on identity verification decreased by 84.55%, which enabled them to devote more time and energy to direct nursing work, thus improving the overall quality of nursing services. Specifically, in the patient satisfaction survey, maternal and family satisfaction was significantly higher after the implementation of the closed-loop process than before, with a statistically significant difference.

XSL•FO
RenderX

System Optimization and Prospects

Despite the system's positive outcomes, there are still areas for improvement. For example, real-time monitoring, security alerts, and authentication need to be enhanced. In the future, we will continue to optimize information use to further refine nursing processes and improve the humanization and intelligence level of the system, to achieve more accurate and efficient nursing services. Additionally, we will also focus on how to achieve better closed-loop management and security measures through upgrading technology.

Conclusion

The construction and application of an information-based closed-loop management system have enabled both real-time monitoring of newborns and comprehensive management of the entire nursing process. This system has significantly improved the safety of newborn care.

Abstract

Background: Diagnosis-related group (DRG) payment has become the main form of medical expense settlements, and its application is becoming increasingly extensive.

Objective: This study aimed to explore the correlation between DRG weights and nursing time and to develop a predictive model for nursing time in the cardiology department based on DRG weights and other factors.

Methods: A convenience sampling method was used to select patients who were hospitalized in the cardiology ward of Beijing Chest Hospital between April 2023 and April 2024. Nursing time was measured by direct and indirect nursing time. To determine the distributions of nursing time based on different demographics, a Pearson correlation was used to analyze the relationship between DRG weight and nursing time, and a multiple linear regression was used to determine the influencing factors of total nursing time.

Results: A total of 103 subjects were included in this study. The DRG weights were positively correlated with direct nursing time (r=0.480; P<.001), indirect nursing time (r=0.394; P<.001), and total nursing time (r=0.448; P<.001). Moreover, age was positively correlated with the 3 nursing times (direct: r=0.235; indirect: r=0.192; total: r=0.235; all P<.001). The activities of daily living (ADL) score on admission was negatively correlated with the 3 nursing times (direct: r=−0.316; indirect: r=−0.252; total: r=−0.301; all P<.001). In addition, the nursing level on the first day of admission was positively correlated with the 3 nursing times (direct: r=0.333; indirect: r=0.332; total: r=0.352; all P<.001). Furthermore, the multivariate analysis found that the nursing level on the first day of admission, complications or comorbidities, DRG weight, and ADL score on admission were the influencing factors of nursing time (R^2=0.328; $F_{5,97}$=69.58; P<.001).

Conclusions: DRG weight showed a strong correlation with nursing time and could be used to predict nursing time, which may assist in nursing resource allocation in cardiology departments.

Introduction

Measuring nursing time is beneficial to effectively avoid excess nursing labor costs from unreasonable time allocations. Nursing time is closely associated with the disease severity of patients [1], which is currently assessed through quantitative scoring systems, such as the Acute Physiology and Chronic Health Evaluation II scores and the Nursing Activity Scale [2]. However, these assessment methods are only suitable for assessing critically ill patients and have limitations [3]. The Patient Classification System (PCS) involves activities such as categorizing and quantifying the nursing level required by a

XSL•FO
RenderX

patient at a given time, assigning work using scales, and calculating personnel requirements [4]. The PCS-based scientific management of nursing personnel is of great significance [5]. The diagnosis-related group (DRG) system is a diagnosis and treatment classification system that can effectively evaluate the severity of a disease classification and can combine cases based on the discharge diagnosis and careful consideration of complex disease-related factors, such as patient complications, different treatment methods, and other patient-specific differences [6]. The basic principles of DRGs are as follows: they are patient-centered; grouping is performed according to factors such as disease diagnosis, treatment methods and individual characteristics; prepaid systems are used to control costs; they encourage hospitals to improve service efficiency and quality; and they ensure reasonable costs through supervision. At the same time, grouping and payment standards are continuously optimized with the development of medical technologies to improve the quality of medical services and patient satisfaction.

DRG classification is globally recognized as an effective tool for hospital management and health care quality evaluation, and there has been research on the application of DRG systems in China since the 1980s. The DRG system divides patients into different diagnostic groups for management according to factors such as disease diagnosis, treatment methods, age, comorbidities, complications, disease severity, and disease progression [7]. In 1983, Medicare (a US federal health care insurance program) used DRG systems for the first time as a health care payment method amid health care reform. The DRG system's prepaid model has highlighted certain advantages for controlling unreasonable medical expenses, standardizing diagnosis and treatment behaviors, enhancing patients' experience with medical treatment, and incentivizing hospitals to strengthen their internal management. Subsequently, it has been rapidly popularized, applied worldwide, and has become one of the most dominant medical payment methods for hospitals internationally [8]. Additionally, some research has been conducted internationally on the effects of the DRG payment model on nursing, mainly including the quality of nursing [9], career development of nurses [9], nursing costs [10], and nursing time. In the meantime, studies in China have also shown that DRG systems can be used as an evaluation index for the quality of medical services, work efficiency, operating costs, and performance [11]. In recent years, a meta-analysis showed that the DRG payment model can significantly reduce the length of hospital stays and medical costs for patients, help to comprehensively and effectively control medical costs, improve the quality of medical services, and help incentivize hospitals to improve their operation and management. Furthermore, it effectively reduces the management and medical expenditures of the medical insurance department, which facilitates the formation of a standardized model for medical resource expenditures [12]. Studying the relationship between DRG weight and nursing time is important for optimizing the allocation of nursing resources, improving the quality of nursing services, promoting the implementation of the DRG payment system, and promoting the development of the nursing discipline. As an advanced medical classification and payment system, DRGs have been used worldwide, but nursing management still needs to progress simultaneously. Through in-depth research, we can accurately predict the demand for nursing resources for different DRGs, avoid the wasting of resources, and improve nursing efficiency. At the same time, GRCs help nursing staff to better identify patient needs, provide personalized services, ensure patient safety, reduce adverse events, and provide a strong support for DRG payment system reform and nursing discipline innovation.

In August 2011, the General Office of the Ministry of Health of China issued the Notice on Promoting the Application of Diagnosis-Related Groups for Hospital Evaluation, which began using DRGs for related evaluations, such as hospital service performance [13]. In 2016, the National Health and Family Planning Commission stated that the DRG system is one of the critical tools for medical quality management [14]. In 2017, the Opinions of the General Office of the State Council on Further Deepening the Guidance Reform for the Payment of Basic Medical Insurance pointed out that it is necessary to carry out pilot programs for DRGs, actively explore the framework of DRG-based payment, and promote the reform of medical insurance payment mode in China. Since nursing is a part of medical treatment, the application and implementation of the DRG system not only promotes the reform of medical treatments but also exhibits a great impact on the profession of nursing. Therefore, this study explores the correlation between DRG weight and nursing time and establishes a nursing time prediction model based on DRG weight and other factors. The model can make up for DRG-related gaps in nursing time evaluation and provide a reference for the application of DRG weight and related indicators in nursing performance appraisal and staffing.

Methods

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee of Beijing Chest Hospital, Capital Medical University (LW-2024-032). This study obtained the informed consent of the patient or their family member and mainly carried out observational research and data analysis after obtaining patients' informed consent, which clearly indicated that this study will not have any negative impact on the rights and interests of the subjects and informed the patients that they do not need to give additional consent for secondary analysis of the existing data in the study. The research project adopts a method for data analysis that did not involve individual identification. For patients, this study only analyzed the costs incurred during the hospitalization of patients, without any additional time commitments of the patients. Thus, financial compensation was not given to patients.

General Data

This was a cross-sectional study on the relationship between DRG weight and nursing time. The convenience sampling method was used to select study participants who were hospitalized in the cardiology ward of Beijing Chest Hospital between April 2023 and April 2024. The inclusion criteria were as follows: (1) patients diagnosed with angina pectoris, hypertension, sudden death, arrhythmia, heart failure, premature beat, myocardial infarction, cardiomyopathy, myocarditis, or

XSL•FO
RenderX

other cardiovascular diseases and (2) patients who purchased employee medical insurance, urban and rural residents medical insurance, or commercial insurance. The exclusion criteria were as follows: (1) patients with aortic surgery, heart valve surgery, coronary artery surgery, acute myocardial infarction, major organ transplantation, haematopoietic stem cell transplantation, or severe primary pulmonary hypertension and (2) patients with multiple organ failure.

A total of 103 patients who were hospitalized aged 15 - 89 (mean 58.85, SD 15.17) years were included in this study, including 67 women with a mean age of 66.2 years and 36 men with a mean age of 58.1 years. The disease diagnoses were as follows: coronary atherosclerotic heart disease (n=28), paroxysmal supraventricular tachycardia (n=1), atrial fibrillation (n=5), unstable angina pectoris (n=44), and other cardiovascular diseases (n=25). These diseases were diagnosed by coronary angiography (n=74) or interventional cardiology procedures (n=29). Patients were assessed for clear consciousness (n=102) or somnolence (n=1). Furthermore, the activities of daily living (ADL) scores on admission were between 20-100 (mean 87.41, SD 18.61) points, including scores of 100 points (n=37), 41 - 99 points (n=51), and <40 points (n=15). Some patients had complications or comorbidities (n=77), including hypertension (n=47), diabetes (n=10), and others (n=30). The research was carried out in strict compliance with the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) cross-sectional checklist [15].

Workload Measurements

Identification of Nursing Items

The in-hospital nursing program for patients consisted of 2 parts: direct nursing and indirect nursing. Following the Technical Operating Procedures and Quality Management Standards for Nursing [16] and the Guidelines for Clinical Nursing Practice [17], nursing staff (1 nurse, 2 senior nurses, 4 supervisor nurses and 1 chief superintendent nurse) with different nursing experiences and professional titles in the cardiology department were organized by the research team to participate in the discussion of nursing items 3 times. Ultimately, 10 direct and 12 indirect nursing items were included for the calculation (Multimedia Appendix 1).

Preparation

First was the selection of observers. Nurses in the department with less than 3 years of service were selected as observers and received training over the course of 3 sessions in the following: use of timers, operation timing, precautions for frequency records of direct nursing operations, requirements for indirect nursing timing, and other techniques. Digital timers were purchased and calibrated by the logistics department. The Frequency Statistics Sheet for Cardiology Patients Receiving Direct Nursing was formulated, which included the date and direct nursing items and their frequency. The statistics sheet was distributed to the nursing group of the cardiology department, and nurses were informed of the requirements for completion.

Calculation of Nursing Hours

After training, the observers selected 6 members of the nursing staff (2 nurses, 2 senior nurses and 2 supervisor nurses) from the cardiology department by lottery to complete each direct nursing operation. The observers calculated the average duration for each direct nursing operation from the time the nurse prepared the supplies until the completion of the operation, rounding down to the nearest second with a timer. Each nursing operation was timed by the same observer. Finally, the average duration for each direct nursing operation was calculated. Meanwhile, the nurse responsible for the patient's nursing recorded the frequency of the direct nursing items during the hospitalization using the Frequency Statistics Sheet for Cardiology Patients Receiving Direct Nursing. Specifically, direct nursing time during hospitalization for each patient was calculated (direct nursing time = ∑average time consumption per direct nursing item × frequency of that item during hospitalization). Moreover, the indirect nursing time for patients during hospitalization was collected based on the observations from each nurse. The total nursing time per patient was equal to the sum of the direct nursing time and indirect nursing time during hospitalization.

Acquisition of Patients' DRG Weights

The DRG weight refers to the average cost or total cost of a DRG case divided by the average cost or total cost of all cases in the region, respectively [18], with other external influencing factors also taken into account according to regional differences [5]. In addition to the cost of the diagnosis and treatment of diseases, calculations for DRG weights also account for the proportion of first-level nursing, the average length of hospital stays, and mortality. To a certain extent, DRG weights reflect the consumption of nursing resources. In this study, case statisticians uploaded the data to the inpatient medical service performance evaluation platform after a quality audit of the data on the first page of the discharge paperwork. Then, they obtained the corresponding DRG weights through the DRG grouping device on the platform, which were then divided into DRG weights of ≤1, >1 to ≤2, and >2, in unit intervals. The number of patients with different DRG weights reflected the distribution of disease severity.

Activities of Daily Living Scale

The ADL scale included 10 items of examination, with each item having a total scoring criteria between 0 and 15 points, and the maximum total score was 100 points [19]. An ADL score of 0 points indicated that the patient was completely dependent on others for daily living, while a score of 100 indicated that the patient was completely self-sufficient in their daily living. Patients with a score of <40 points had a severe impairment in their ADL, while those with 41 - 60 points had a moderate impairment in their ADL, and those with >61 points had a mild impairment in their ADL. For each patient, the first assessment was performed 2 days after the stability of their vital signs or when they entered the study, and the second assessment was performed 6 months into the course of the disease.

XSL•FO
RenderX

Statistical Analysis

The SPSS version 26.0 software package (IBM Corp) was used for the statistical analysis, and the normality test was conducted using the Kolmogorov-Smirnov method. Measurement data that were normal were expressed as mean and SD, and a 2-tailed sample *t* test was used to compare the nursing times based on the patient's sex, complications, angiography, and surgery. The nursing time, nursing level, and DRG weight on the first day of admission were compared using a 1-way ANOVA. The Student-Newman-Keuls method was used for pairwise comparisons. Count data were expressed as frequency or rate, and the χ^2 test was used for intergroup comparisons. Pearson correlation analysis or Spearman rank correlation analysis was used for the correlation analyses, and the multivariate analysis was performed through multiple linear regression. A bilateral *P* value of <.05 was considered statistically significant.

Results

Nursing Time and DRG Weights for Included Patients

The screening process of the research is shown in Figure 1. A total of 103 subjects were included in this study. During hospitalization, the direct nursing time for patients was between 70.65 - 1228.71 minutes, with a median of 335.33 (IQR 277.44-452.09) minutes. The indirect nursing time was between 30.86 - 1024.30 minutes, with a median of 362.46 (IQR 229.97-584.15) minutes, and the total nursing time was between 116.48 - 2169.05 minutes, with a median of 702.76 (IQR 518.55-1019.64) minutes. The average daily nursing time per patient was 134.58 minutes, and the average daily direct and indirect nursing times were 70.34 minutes and 64.24 minutes, respectively. Additionally, the DRG weights for the included patients were between 0.52 - 2.57 (mean 1.51, SD 0.42; Table 1).

Figure 1. Research screening process. DRG: diagnosis-related group.

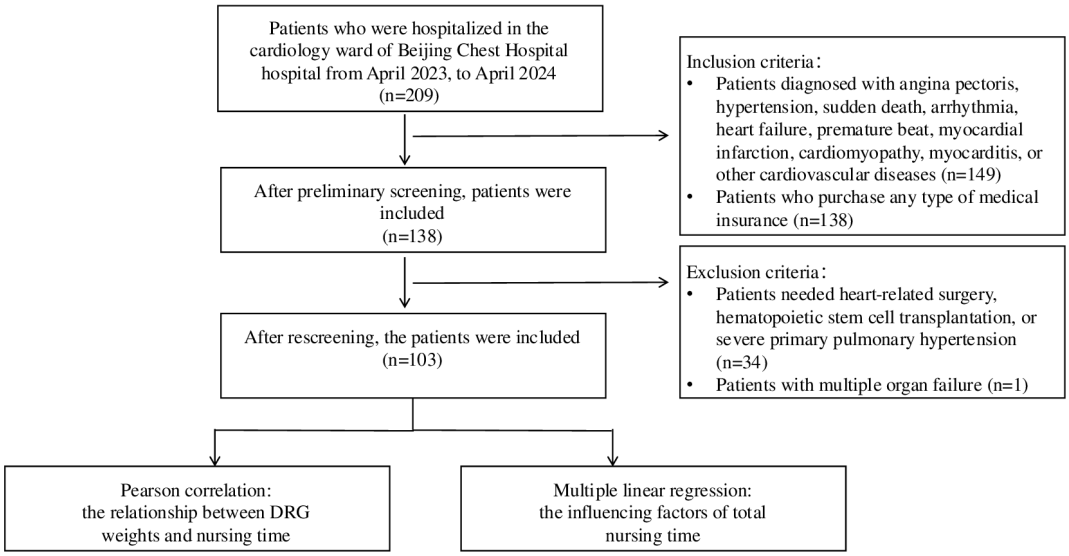

Table . Overall nursing time.

Variables	Values	Range
Direct nursing time (min), median (IQR)	335.33 (277.44 - 452.09)	70.65 - 1228.71
Indirect nursing time (min), median (IQR)	362.46 (229.97 - 584.15)	30.86 - 1024.30
Total nursing time (min), median (IQR)	702.76 (518.55 - 1019.64)	116.48 - 2169.05
DRG[a] weights, mean (SD)	1.51 (0.42)	0.52 - 2.57

[a]DRG: diagnosis-related group.

Correlation Analysis of Patient Nursing Time

The results suggested that DRG weights were positively correlated with direct nursing time, indirect nursing time, and total nursing time (direct: *r*=0.480; indirect: *r*=0.394; total: *r*=0.448; all *P*<.001). Furthermore, age was positively correlated with the 3 nursing times (direct: *r*=0.235; indirect: *r*=0.192; total: *r*=0.235; all *P*<.001). The ADL score on admission was negatively correlated with the 3 nursing times (direct: *r*=−0.316; indirect: *r*=−0.252; total *r*=−0.301; all *P*<.001), and nursing levels on the first day of admission were positively correlated

XSL•FO
RenderX

with the 3 nursing times (direct: r=0.333; indirect: r=0.332; total r=0.352; all P<.001), as shown in Table 2 .

Table . Correlation analysis of patient nursing time.

Item	Direct nursing time		Indirect nursing time		Total nursing time	
	Correlation coefficient	*P* value	Correlation coefficient	*P* value	Correlation coefficient	*P* value
DRG[a] weight	0.480	<.001	0.394	<.001	0.448	<.001
Age	0.235	<.001	0.192	<.001	0.235	<.001
ADL[b] score on admission	−0.316	<.001	−0.252	<.001	−0.301	<.001

[a]DRG: diagnosis-related group.

[b]ADL: activities of daily living.

Univariate Analysis of Patient Nursing Time

The results showed significant differences in the logarithmic values for direct nursing time (t_{101}=2.230; P=.03), indirect nursing time (t_{101}=2.449; P=.02), and total nursing time (t_{101}=2.445; P=.02) between patients with or without complications. There were also significant differences between patients with or without surgeries (direct: t_{101}=5.324; indirect: t_{101}=4.584; total: t_{101}=5.199; all P<.001), patients with different nursing levels on the first day of admission (direct: $F_{2,100}$=45.421; indirect: $F_{2,100}$=25.435; total: $F_{2,100}$=35.495; all P<.001), and patients with different DRG weights (direct: $F_{2,100}$=32.455, indirect: $F_{2,100}$=28.581, total: $F_{2,100}$=29.435, all P<.001). However, no significant differences were observed for the natural logarithmic values for direct nursing time, indirect nursing time, or total nursing time between patients with different sexes or for patients with or without an angiography, as shown in Table 3.

Multivariate Analysis of Patient Nursing Time

Stepwise regression analysis was performed with the participant's nursing time as the dependent variable and the collected information as independent variables. Categorical variables were grouped and coded, as shown in Table 4. The results showed that when 4 variables (nursing level on the first day of admission, complications or comorbidities, DRG weight, and ADL score on admission) were included and other variables were excluded, the model R^2 was 0.328, indicating that these 4 variables could explain 32.8% of the factors affecting the patients' nursing time. In addition, the $F_{5,97}$ test result of 69.58 (P<.001) indicated that the dependent variable fit well with these 4 variables. The Debin-Watson index was 1.842, suggesting no correlation between the independent variables of this model, and the significance test for all 4 independent variables indicated that they were statistically significant in the model and should be retained. Additionally, due to a variance inflation factor value of <10 for all 4 independent variables, there was no covariance between the respective variables, and the multiple linear regression equation was as follows:

$$Y=6.423+0.482X1+0.091X2-0.005X3+0.167X4$$

According to the standardized partial regression coefficients in the model, it can be concluded that the effect of the 4 independent variables on patient nursing time was ranked as

XSL•FO

follows (from strongest to weakest): DRG weight>nursing level on the first day of admission>ADL score on admission>complications or comorbidities (Table 5).

Table . Assigned values for variables.

Item and group	Assigned value
Nursing level on the first day of admission	
Level 1 nursing	1
Level 2 nursing	2
Premium-level nursing	3
Complications or comorbidities	
Yes	1
No	2
Surgery	
Yes	1
No	2
DRG[a] weight	Original value
ADL[b] score on admission	Original value
Age	Original value

[a]DRG: diagnosis-related group.

[b]ADL: activities of daily living.

Table . Multiple linear regression analysis of total nursing time. R=0.573, R^2=0.328, adjusted R^2=0.289; $F_{5,97}$=69.58.

Variable	Partial regression coefficient	Standardized partial regression coefficient (SE)	*t* test (*df*)	*P* value	VIF[a]
Constant	6.423	—[b]	8.395 (101)	<.001	—[b]
DRG[c] weight	0.482	0.446 (0.104)	8.352 (101)	<.001	2.194
Nursing level on the first day of admission	0.091	0.273 (0.110)	8.332 (101)	<.001	1.422
ADL[d] score on admission	−0.005	−0.191 (0.004)	9.535 (101)	<.001	1.310
Complications or comorbidities	0.167	0.161 (0.089)	6.582 (101)	<.001	2.140

[a]VIF: variance inflation factor.

[b]The standardized partial regression coefficient was not calculated for the constant value.

[c]DRG: diagnosis-related group.

[d]ADL: activities of daily living.

Discussion

By analyzing the correlation between DRG weight and nursing time, this study established a nursing time prediction model based on DRG weight and other factors. The results showed that DRG weight was positively correlated with direct nursing time, indirect nursing time, and total nursing time. The influencing factors affecting the patient's nursing time include DRG weight, the nursing level on the first day of admission, ADL score on admission, and complications or comorbidities.

Scholars in China have learned from more advanced nursing time measurement tools that are used globally, such as the Severity of Illness Index for Pediatric Patients, Comprehensive Nursing Intervention Score, and Patient Illness Severity Nursing Index, and they have conducted weighted evaluations of factors such as project difficulty and risk, without considering factors such as the complexity of disease and treatment methods for patients. Currently, the most commonly used metric for nursing time in China is the measurement of work hours [20]; however, this is time-consuming and labor-intensive with many influencing factors, making it difficult to implement in clinical practice. Kang et al [21] performed nursing time statistics based on the hospital information platform, and despite the slightly improved efficiency, the statistical workload was still a lot due to the extraction of data from multiple systems. Meanwhile,

XSL•FO
RenderX

Zhang et al [22] calculated nursing time using the load weighting method. The assignment of load weights mainly depended on the subjective assessment of experts, with a large influence from human factors. In contrast, DRG weights comprehensively considered factors such as the severity and complexity of the disease, different treatment methods, individual patient differences, and discharge outcomes [23]. These included many patient factors related to nursing time, such as the disease itself and individual characteristics, which could objectively reflect the nursing time, and the acquisition of parameters was relatively simple and easy to implement.

This study found that the average daily nursing time per patient during hospitalization in the cardiology department was 134.58 minutes. This was close to the average daily nursing time per patient (113.59 minutes) in a study by Yang et al [24] but less than the average daily total nursing time (171.02 minutes) calculated by Cai et al [25] for neurosurgery patients. This discrepancy was mainly due to the different types of diseases treated in the cardiology and neurosurgery departments, where the nursing times for neurosurgical operations were greater than that for internal medicine operations. In this study, the average daily direct nursing time per patient was 70.34 minutes, which was less than the average daily direct nursing time per patient (75 minutes) measured by Wang et al [26] for neurology patients. This was mainly due to the overall self-care ability of the cardiology patients included in this study, with 35.9% (37/103) having an ADL score of 100 on admission and 49.5% (51/103) having a score between 40 - 99, while neurology patients experienced more severe functional impairments and greater dependence on care, thus increasing the burden on nursing staff. Moreover, the average daily indirect nursing time per cardiology patient in this study was 64.24 minutes, which was longer than the average daily indirect nursing time per patient (45.34 minutes) measured by Zhang et al [27]. This was directly due to the different clinical support systems of the hospitals [28], in which a well-developed clinical support system helped to reduce indirect nursing time while increasing direct nursing time.

Specifically, DRG weights regard the treatment cost of the disease as the main factor while comprehensively considering factors such as primary nursing care, average length of the hospital stay, and mortality. This was followed by obtaining the DRG weight value through data modelling, with the corresponding DRG weight value for a disease type calculated through the DRG Grouper tool. In the univariate analysis, despite the correlation between complications or comorbidities, surgery, nursing level on the first day of admission, and age, the correlation between DRG weight and nursing time was more prominent and evident. This is because DRG weights have incorporated factors related to nursing labor costs, thereby making them more valuable for implementation in the management of nursing personnel. Furthermore, the results showed that DRG weights had the greatest impact on nursing time, and although evaluating nursing time with nursing levels alone is not desirable [29], nursing levels, to some extent, reflect the severity of the disease. Moreover, the time required for some direct nursing operations was different, such as bed-making and admission assessment, which corresponded to different ADL scores. The higher the ADL score was, the less the time was required for these items, indicating a negative correlation, thereby affecting the total nursing time [29]. Furthermore, the comorbidities of cardiovascular diseases were mainly hypertension and diabetes, with 45.6% (47/103) of the patients experiencing hypertension and 9.7% (10/103) experiencing diabetes, requiring an increased monitoring of blood pressure and blood glucose, respectively, which increased nursing time. Therefore, the above factors were all related to the nursing time in the multivariate regression analysis. At the same time, the prediction of workload using a multivariate regression equation with DRG weight as the main factor can be helpful for nursing managers to measure and adjust future staffing needs based on the current staffing situation in combination with other departmental needs.

DRGs have many contributions to nursing management. They promote the standardization of the nursing process, optimize the allocation of resources, improve the efficiency of nursing work, and make nursing services more efficient and stable [24]. At the same time, DRGs promote the transformation of hospital management from extensive to refined, provide data support for nursing management departments, and enable them to make more scientific, data-based decisions [21]. In addition, DRGs help to reduce nursing risks, improve patient satisfaction, and provide more personalized nursing services for patients. Through DRG systems, hospitals can more accurately meet the nursing needs of patients and ensure patient safety. Finally, the application of DRGs puts forward higher requirements for the professional skills of nursing staff, promotes the professional development of nursing staff, and promotes the innovation of nursing research. In short, the application of DRGs has brought many positive effects to nursing management, which helps improve the quality of nursing services and promotes the modernization and scientific process of the nursing speciality.

However, this study also has some limitations. First, due to the limitation of data accessibility, this study only used the data of one hospital, and the number of cases was small. This could lead to a deviation in data selection, and there may have been some bias in the extrapolation of results. Therefore, in future studies, multicenter longitudinal studies with a larger sample size can be used for further verification. In addition, due to an untimely update of hospital disease diagnosis and surgical coding, as well as operational errors by medical staff, the data quality of the first page of medical records was low, which affected the case registration rate. The training and practical operation of medical staff on DRG-related knowledge should be strengthened before future research.

In summary, DRG weight has a strong correlation with nursing time, which can be used to predict nursing time and contribute to the allocation of nursing resources in cardiology departments. This study can improve the satisfaction of patients and their families with hospital nursing work and reduce the pain of patients. In addition, this study can also make up for the DRG-related gap in the evaluation of nursing time in cardiology departments and provide a reference for the application of DRG weight and related indicators in nursing performance evaluations and staffing.

Abstract

Background: Artificial intelligence (AI) has been deemed revolutionary in medicine; however, no AI tools have been implemented or validated in Danish general practice. General practice in Denmark has an excellent digitization system for developing and using AI. Nevertheless, there is a lack of involvement of general practitioners (GPs) in developing AI. The perspectives of GPs as end users are essential for facilitating the next stage of AI development in general practice.

Objective: This study aimed to identify the essential prerequisites that GPs perceive as necessary to realize the potential of AI in Danish general practice.

Methods: This study used semistructured interviews and vignettes among GPs to gain perspectives on the potential of AI in general practice. A total of 12 GPs interested in the potential of AI in general practice were interviewed in 2019 and 2021. The interviews were transcribed verbatim and thematic analysis was conducted to identify the dominant themes throughout the data.

Results: In the data analysis, four main themes were identified as essential prerequisites for GPs when considering the potential of AI in general practice: (1) AI must begin with the low-hanging fruit, (2) AI must be meaningful in the GP's work, (3) the GP-patient relationship must be maintained despite AI, and (4) AI must be a free, active, and integrated option in the electronic health record (EHR). These 4 themes suggest that the development of AI should initially focus on low-complexity tasks that do not influence patient interactions but facilitate GPs' work in a meaningful manner as an integrated part of the EHR. Examples of this include routine and administrative tasks.

Conclusions: The research findings outline the participating GPs' perceptions of the essential prerequisites to consider when exploring the potential applications of AI in primary care settings. We believe that these perceptions of potential prerequisites can support the initial stages of future development and assess the suitability of existing AI tools for general practice.

Introduction

The research and development of artificial intelligence (AI) has progressed rapidly in recent years and has been deemed revolutionary in medicine. However, AI is still in its early phases of validation and implementation in all health care fields [1,2]. AI tools have predominantly been developed for hospital settings but are also believed to hold transformative potential in general practice, despite fewer AI tools being developed in this setting [3,4].

Denmark is a leading country in the digitization of health care systems [5]. Today, all Danish general practices use digital technology to handle electronic health records (EHRs), send prescriptions to pharmacies and referrals to hospitals, and receive laboratory analysis results and hospital discharge letters. Furthermore, emails and video consultations have become available [6,7]. Owing to this advanced digitization and the collection and management of data in Danish general practice, it is reasonable to believe that AI can be used at some level. In a review of 2023, identifying digital solutions for decision

XSL•FO
RenderX

support in Danish general practice, only 1 study dealt with AI [8]. This study described an AI tool for the identification of liver disease [9]. Since the publication of the abovementioned review, an additional study has reported an AI model that predicts cancer risk in patients referred from general practice based on routine blood tests [10]. None of the 2 AI tools reported in the identified studies are currently implemented in general practice. Thus, based on the identified evidence, research in this area is limited, with no validation, implementation, or application of AI tools currently available in Danish general practice.

When developing new technology, including potential end users and other stakeholders is essential [11]. This is defined as the exploration phase, an important step in the implementation process, creating awareness of the existing issues that need attention and potential improvement [12]. Contradictorily, the involvement of general practitioners (GPs) in developing concrete AI tools for general practice is limited [13,14]. In addition, limited research has been conducted to clarify the qualitative perspectives of GPs and other stakeholders regarding AI in general practice [15-20]. A closer examination of the same research reveals that only 3 studies have exclusively addressed the perspectives of GPs [18-20]. The research shows that GPs and other stakeholders generally have a positive attitude toward AI [15-18,20], but the practical and ethical implications of applying AI in general practice need clarification. This includes privacy, liability, and financial considerations [15]. Multiple uses of AI are envisioned in general practice, particularly within tasks of an administrative character [16,17]. This is due to concerns about replacing human competencies with AI [15,18,19]. Finally, it is essential to consider co-creation and collaboration with end users to ensure optimal adoption of AI in general practice [16,17,20].

Thus, when considering the development of AI in Danish general practice, it is necessary to understand the contexts and perspectives of the end users. Therefore, this study aimed to explore and define the prerequisites for applying AI in general practice from the GPs' perspective. GPs can provide insights into the essential conditions that must be met to realize the potential of AI in this setting. Establishing these foundational requirements will support the next steps toward advancing AI development in Danish general practice.

Methods

Qualitative Approach

This study applied an inductive approach using semistructured interviews and vignettes to iteratively explore and provide detailed insights into the GPs' perspectives on the prerequisites for AI in general practice. The vignette method was chosen to exemplify hypothetical scenarios of AI in general practice and create meaningful engagement with the participating GPs, as no AI tool has been implemented and validated in Danish general practice. Vignettes are typically used in qualitative research as sociological tools to study beliefs, attitudes, values, and perceptions [21-23]. The authors followed the Standards for Reporting Qualitative Research (SRQR) [24].

Researcher Characteristics and Reflexivity

The first author is a PhD student studying user perspectives on AI in general practice. The second author, an associate professor of anthropology, specializes in qualitative methods and perspectives of patients and GPs. The third author is a professor and a GP focused on integrating new technology as a support tool in general practice. The fourth author is a professor who specializes in responsible and value-driven AI. The fifth author, a professor of health economics, concentrates on health care innovations in medical technology. The final author is a professor and a GP studying the potential of new technology in general practice. All the authors believe that ethically applied and legally compliant AI can benefit general practice.

Context

Denmark is a welfare state with universal health care that ensures free and direct access to primary health care for all residents. The health care system is organized into 5 administrative regions, with general practice serving as a gatekeeper and the first point of contact [6]. The study was conducted in the North Denmark Region.

Sampling Strategy

Purposive sampling [25] was applied to recruit participants who were characterized as "first adopters" [26]. Therefore, the GP network was used to recruit GPs associated with the Center for General Practice at Aalborg University (CAM AAU) and consultants affiliated with the Quality Unit for General Practice in the North Denmark Region (Nord-KAP). We categorized GPs associated with these organizations as "first adopters" within their profession, as they typically demonstrate a distinctive interest in research in new medicine and technology. Thus, by sampling these specific GPs, we ensured satisfactory AI literacy for the interviews when discussing viewpoints on AI in general practice.

The study's first author, who also served as the only interviewer, had no personal or professional relationship with the participants, which might have influenced the results. Although the third and last authors were acquainted with several respondents, they did not know who provided specific statements. This ensured that any possible casual acquaintances had minimal influence on the analysis or conclusions of the study.

Ethical Considerations

Owing to the nature of the study, ethical approval was deemed unnecessary under Danish law (Section 14, Subsection 2 of of the Danish Act on Committees) [27]. This decision was based on legal provisions and confirmed through consultation with the institutional guidelines. According to Danish law, ethical approval is not required for qualitative interview studies that do not involve human biological materials or sensitive personal health data. However, written informed consent was obtained from all participants. To ensure privacy and confidentiality, all data were pseudonymized. Participants received no compensation for their participation in the interviews.

Data Collection Methods and Instruments

Interviews were conducted in Danish and face-to-face at the general practice clinics. The interviews lasted 35 to 95 minutes and were recorded using a dictaphone. Each interview began with introducing the respondents to the study and its purpose. The respondents were then presented with 5 individual vignettes, followed by questions from a semistructured interview guide. All vignettes depicted scenarios concerning a female patient presenting in general practice where different forms of AI are applied. The first vignette aimed to initiate a discussion on the understanding of data and AI to create a common frame of reference between the interviewer and the respondent. The following vignettes (numbers 2 - 5) aimed to clarify the GPs' point of view on AI in general practice, first on AI used in tasks concerning automation and then on AI applied to tasks related to decision support. The GPs were presented with a generic case and a more specific example for each type of AI task. The interview guide consisted of open-ended questions and prompted the exploration of GPs' perspectives on their experiences with new technology and AI in general practice, challenges and benefits, and their overall attitudes toward technology and AI in health care. The vignettes applied in this study are found in (Multimedia Appendix 1).

Units of Study

A total of 12 GPs participated in this study. In total, 9 semistructured interviews were conducted in 2019, and the remaining 3 were conducted in 2021. In addition, 6 men and 6 women participated in the study. At the time of the interviews, participants' ages ranged from 36 to 66 years, with a mean age of 47.7 years. Their professional experience as GPs varied from 2 to 30 years, with an average of 11 years. This diversity in age and experience closely reflects the general Danish GP population [28].

Data Processing and Analysis

For data processing, all collected interview data were stored safely on a file share server administered by Aalborg University in line with the obligations of the European Union's General Data Protection Regulation (GDPR). All the data were pseudonymized when uploaded to the secure file share with a key for safe reference storage.

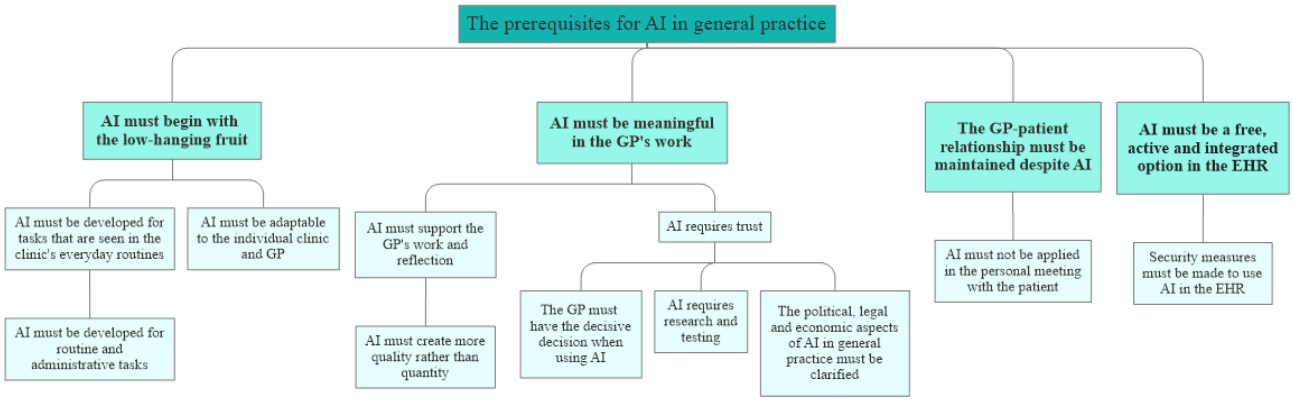
In addition, 2 student assistants were assigned to transcribe all interview data verbatim for subsequent analysis. The student assistants were verbally instructed and provided written guidelines for the assigned tasks.

NVivo 14 (QSR International) coding software was used for all data analysis. Thematic analysis guided by this study's research question was conducted on the collected interview data [29]. The analysis commenced with familiarization with the data by reading and rereading the transcripts and listening to the interview audio recordings. Initial insights and analytical ideas were noted while reading and listening to the data. Data coding was then initiated, which involved systematically coding the interview transcripts and identifying themes through an iterative process that prioritized transparency and rigor. All coded data were then re-read to collate the data relevant to each code. The initial themes were generated based on the developed codes. Each theme was then reviewed and refined to align with the study objective, resulting in a final set of themes. The authors have translated the quotes stated in this paper from Danish to English.

Techniques to Enhance Trustworthiness

A pilot test was conducted with 2 GPs before the primary data collection to enhance the validity and reliability of the vignettes and the interview guide. The pilot test evaluated the clarity, relevance, and comprehensibility of the vignettes and the appropriateness of the interview questions. Feedback provided by the GPs during this process was systematically incorporated to refine and improve the vignettes and interview guide, ensuring that they effectively addressed the study objectives and were suitable for target participants.

Although purposive sampling was used to ensure that participants were selected based on their relevance to the research objectives, efforts were made to achieve diversity among participants. This included considering variations in age, gender, and years of professional experience. Striving for diversity enhances the robustness of the findings by ensuring a broader range of perspectives.



The iterative process of dialogue and consensus building among all the authors validated the findings, strengthened the credibility of the results, and ensured that the final manuscript reflected the collective agreement of the authors.

Results

The analysis of data resulted in four themes: (1) AI must begin with the low-hanging fruit, (2) AI must be meaningful in the GP's work, (3) the GP-patient relationship must be maintained despite AI, and (4) AI must be a free, active, and integrated option in the EHR. All 4 themes contain codes that support the results of the analysis. Figure 1 shows the hierarchy of themes and codes.

XSL•FO
RenderX

Figure 1. Illustration of the four themes and connected codes defined in the analysis of the interview data. AI: artificial intelligence; GP: general practitioner; EHR: electronic health record.

AI Must Begin With the Low-Hanging Fruit

When GPs were asked to identify the most relevant tasks in general practice with the potential to develop AI, their response was to address "the low-hanging fruit," which was the first theme of the analysis. GPs defined "the low-hanging fruit" as low-complexity tasks with the necessary data available to develop AI that can facilitate GPs' work at a practical level, with minimal impact on the GP-patient relationship. The GPs highlighted the importance of developing AI for everyday clinical tasks rather than for rare or highly specialized diagnostic processes that might have limited use. They emphasized that AI should enhance tasks and tools that already perform well in general practice but have the potential for further optimization. A significant opportunity lies in applying AI to routine administrative tasks such as managing medications and processing test results, which are time-consuming but cognitively straightforward. In addition, the GPs suggested exploring the possibility of developing AI for tasks typically handled by practice staff, such as organizing test responses and scheduling annual check-ups, where systematic and repetitive processes dominate. Furthermore, the GPs emphasized that AI would be received constructively if initially introduced for tasks considered "low-hanging fruit," as this approach would allow them to build confidence in the technology through early practical successes.

The GPs also emphasized that AI must be grounded in tasks embodied in the practices and workflows of individual GPs and clinics. Owing to the individual general practice clinics varying in organization with different workflows and ways of approaching and handling tasks, it is necessary that AI can be adapted to a specific setting.

> *... but then again, I just think it is important that you get the opportunity to tailor it to the individual practice, that it does not just become a system that has to fit all clinics because we do it very differently. Some only do an annual check, some don't do annual checks at all, and some, as we do here, for example, have split it up and made an individual plan for people. It is not certain that you need to come for an annual check once a year; there may well be a large check every two years, but then you come to a smaller check. It has to be something where you can put your own prerequisites on it (AI), but it could be something like when the patient walks out the door, that you say send a message to the patient that they should contact us for the purpose of blood tests or something in six months.* [Participant No. 7]

AI Must Be Meaningful in GP's Work

The second theme is "AI must be meaningful in the GP's work." The GPs state that any AI with the potential for application in general practice must be relevant and sensible. Irrelevant information in the EHR becomes an annoyance rather than an aid in the GP's information-intensive work life.

> *There is a lack of reflection like this to say, well, when is this pop-up relevant, and when do we have to be confronted with it? Well, if you had set aside an hour to do a review of automated responses or what do I know, you could perhaps achieve a lot more health in that hour than on the four patients you see in an hour. So, it is a question of where you put your resources.* [Participant No. 4]

To be meaningful, the GPs emphasize that AI must function as a supportive tool in their work, leveraging its strengths, such as data analysis and processing, to enhance their practice. The GPs also proposed using AI as a sparring partner to support and challenge their professional judgment and create reflection in their practice. Furthermore, Participant No. 3 accentuated that AI should contribute to more quality than quantity in general practice to achieve "less useless work and more useful work." The GPs anticipate that introducing AI into general practice will likely lead to a redistribution of tasks. Consequently, more health-promoting activities will be prioritized, but the overall workload will remain high.

> *I think it's an illusion that we'll get to the point where robots and AI take over our work so that we don't have to work in the future - because it always brings other things along, but it's a good idea, as it can give me less useless work and more useful work. That's fine. But I think that the sum of work, it probably will for my part - and here in the clinic - it will probably be constant regardless of what you do. But it is also because we will probably just admit more patients and more tasks. That is what I imagine.* [Participant No. 3]

XSL•FO
RenderX

Trust is a critical prerequisite for GPs to find AI meaningful. The GPs emphasized that AI must not function independently but should assist the GP's work. It is also stated that authority should remain with the GP, as fear of AI taking control could lead to mistrust. Consequently, GPs suggest that the data generated by AI should be crosschecked with the GPs' observations and intuition to ensure that the tasks are performed correctly. In addition, AI must be flawless to benefit GP. The GPs prefer a challenging daily workload, valuing their ability to perform their tasks well rather than on AI for suboptimal results.

> …*What you can fear about AI is that it gets its own authority in a way—that the authority goes away—or that the decision goes from being the doctor's to being the system's. It is a slippery slope. It's not either or, it's on the way to something … Then, it has to be compared with the processes I go through when I sit across from a person who has all kinds of stories and compare them with the data I look at and perhaps all the ones I do not look at, which could be a weakness in my situation, but which can be the strength in the AI's situation. So this AI will have its strengths, but can also in some ways trump and perhaps blind us to some things we would otherwise have seen if we had sat and talked to the patient instead.* [Participant No. 4]

Several GPs stated the importance of making conclusive decisions and maintaining awareness of their responsibility rather than unquestioningly trusting AI. Consequently, questions were raised regarding the role of AI if GPs must always oversee and approve the decision-making process. Double-checking multiple outcomes is time-consuming if the GPs have to modify or override the AI-generated results.

Knowledge and familiarity with the AI algorithm were highlighted among the GPs as necessary. Thus, AI requires further research and testing to ensure the trust of GPs. Any AI tool developed for general practice is expected to undergo comprehensive evaluation in research studies to assess both the advantages and disadvantages of the technology. It is also essential to explore the impact of AI on external factors, such as work structures and the organization of general practice, as well as to consider patients' perspectives on AI tools.

In addition to the research-related and external outcomes of AI in general practice, the GPs emphasize the need to address political, legal, and economic aspects to build trust in the technology. Politically, the GPs stress that the use of AI should be initiated by the GPs themselves, ensuring that AI does not become a tool for political management. AI must be developed and used primarily for the benefit of general practice. and most importantly, for the benefit of patients. The legal implications of AI must be clarified, particularly regarding the distribution of liability in the event of errors. Finally, the GPs expect an investigation into the economic impact of AI in general practice at a societal level.

The GP-Patient Relationship Must Be Maintained Despite AI

Preserving the GP-patient relationship despite the integration of AI in general practice is the third essential prerequisite. The GPs consider a significant part of their work to occur at the human level, particularly during personal interactions with patients. While GPs see technological tools as beneficial for more standardized procedures such as administrative tasks, they view them as a distancing factor during patient consultations. Patients must not feel that they are interacting with a computer, as personal contact between the GP and the patient remains central to the practice. The GPs clarify that most health-promoting outcomes arise from the time spent with patients, and they would prefer to dedicate time to patient care rather than to computers and other technological aids.

> *So, what I am skeptical about is whether the patient feels they have a doctor or whether they feel they have a computer. So, the thing about whether you trust that the doctor knows that something has to be done and all that - I can fear that both I as a doctor will lose that, but also that patients will feel that they are losing it. Thus, the doctor-patient relationship could suffer slightly in such a scenario. However, it could also be that it does not suffer because they're just smart up there in that hospital, right ... So in that way, I am not so opposed to it, but I have some skepticism about whether you will achieve what you want with it.* [Participant No. 5]

To preserve the personal relationship between the GP and the patient, the GPs strongly prefer that AI is not present during consultations. Given that consultations typically last only 10 minutes, GPs must carefully manage their time to achieve all objectives, making it challenging to envision how AI can support personal connections with patients. Consequently, they did not foresee the use of AI during consultations. Instead, they suggested using AI to analyze historical data related to the reason for inquiry.

AI Must Be a Free, Active, and Integrated Option in the EHR

The fourth prerequisite highlighted by the GPs is the seamless integration of AI into existing clinical EHR systems. This integration should allow the AI to function as an optional tool that can be activated and accessed on demand. This ensures that GPs can use AI tools to seek assistance and support for specific tasks. The GPs express strong opposition to any interruptions in the EHR workflow, such as pop-ups, and emphasize the need for complete control over the AI functionality, including the ability to turn it on and off as needed, regardless of the tool's type or purpose.

A high level of security is another prerequisite for the GPs to adopt AI into EHR systems. The GPs emphasize that information must not be lost as it moves from human oversight to AI processes, nor should it accumulate unnecessarily within the EHR. Robust safety measures are essential to ensure that tasks handled by AI are appropriately followed by GPs or other practice staff, even if the information is not immediately

XSL•FO
RenderX

necessary. In addition, a "backstop" mechanism should be integrated into the EHR to collect and safeguard any AI-handled information that has not been acknowledged by a GP or other practice staff, ensuring no data is overlooked or mishandled.

> *No, then I wouldn't like it, because there are many of the test answers, we get here in the house, that are normal, but normal answers can also give rise to some form of action. So, if you imagine that you had a machine that sent normal responses to the patient, something would go wrong. Then we must have a stumbling block in relation to follow-up.* [Participant No. 6]

Discussion

Statement of Principal Findings

This study identified 4 main themes as prerequisites that GPs consider essential for realizing the perceived potential of AI in general practice: (1) AI must begin with the low-hanging fruit, (2) AI must be meaningful in the GP's work, (3) the GP-patient relationship must be maintained despite AI, and (4) AI must be a free, active, and integrated option in the EHR.

Strengths and Weaknesses of the Study

In this study, we applied vignettes as a stimulus for reflecting on hypothetical scenarios, given that AI has not yet been implemented or validated in Danish general practice. The vignettes served as a tool to facilitate discussions on topics in which the included GPs generally had limited experience. However, because vignettes are traditionally designed to simulate real-world scenarios, the absence of AI in current practice may reduce their perceived credibility [30].

A key reason for including first adopters associated with CAM AAU and Nord-KAP was to ensure satisfactory AI literacy among participants, addressing the low AI literacy observed in similar studies [15,20,31]. At the outset of the interviews, the participants were asked about their knowledge of AI, and we determined that their AI literacy was sufficient for the study. However, this study has limitations due to purposive sampling and recruitment from a limited geographical area (the North Denmark Region). This may have affected the transferability of the study to other contexts. Despite these limitations, the age and professional experience of the participating GPs provided a reasonable range of diversity, closely resembling that of the general Danish GP population [28]. Therefore, the results of this study should be interpreted in the specific context of data collection and as reflective of the participants' perceptions [29].

The interview data were collected in 2019 and 2021, and with the rapid technological advancements in AI in recent years, the evidence presented in this study may be outdated. However, because AI has not yet been widely implemented in general practice, the overall development of AI remains less directly relevant to the daily work of GPs. In addition, the core values of general practice have remained unchanged since the time of the interviews [32]. This argument is underlined in the paper by Nassehi and Ramvi [33], which states the continuous importance of care in general practice despite the prevalence of digital technologies. Thus, the insights from this study remain relevant in the context of the ongoing development of AI in general practice.

Comparison With Previous Work

Several views and attitudes similar to those identified in this study on the prerequisites for AI in general practice can, upon closer examination, be found in previous research [15-20]. Regarding what this study defined as "low-hanging fruit," referring to starting AI development for low-complexity tasks, other studies have shown comparable preferences, for example, introducing AI to reduce administrative burdens [17,19,20]. For instance, it has been suggested that the daily workload of GPs can be alleviated through preselection and patient prioritization [20].

In addition, the potential of AI to support administrative tasks such as clinical documentation, practice operations, and triage is seen to enhance efficiency. This allows GPs more time and cognitive freedom to focus on the medical and social complexities of patient care [17]. These findings highlight a discrepancy between the needs of GPs and the current dominant research trends in AI, such as diagnostic decision support tools [13]. This further emphasizes the importance of defining the prerequisites for AI, as outlined in this study, to ensure that the core values of general practice are preserved.

This study found that the included GPs are open to the potential of AI to alleviate specific routine tasks without diminishing their primary responsibilities. Other studies also support this view, emphasizing that AI will never fully replace GPs, especially in clinical decision-making [17]. It has been established that AI should act as a support tool, complementing the GP's clinical judgment while remaining sensitive to the patient's specific concerns and context [15,20]. Furthermore, 1 study demonstrated that technology could negatively influence GPs' decision-making, potentially impacting treatment outcomes [20]. Thus, our study findings reinforce that GPs should retain authority to make decisive decisions when working with AI.

Similarly, trust appears to be a crucial factor in AI acceptance of the included GPs. Our findings align with those of other studies that emphasize trust as a key driver of AI adoption and usage by GPs [34]. GPs must be open to AI and confident in the information it provides [15]. However, trust extends beyond GPs; patients' trust in AI depends on their GP's trust and acceptance [35]. Therefore, successful integration of AI into general practice depends on the trust of both GPs and patients, ensuring that a human-centric approach is at the core of AI adoption.

Furthermore, the GPs in our study underscored that AI should not detract time from patients. Comparably, previous research indicates that GPs fear that AI may compromise the quality of patient care and undermine the GP-patient relationship [15]. It has also been suggested by previous research that GPs believe that AI lacks the essential human competencies required for patient care [19]. AI is seen as unable to account for the social and economic factors that influence patient care, as the ability to maintain a holistic view of care develops through long-term relationships between individuals and communities [17,19,20]. Therefore, preserving the GP-patient relationship must be a key

XSL•FO
RenderX

consideration when developing AI for general practice, underscoring the importance of protecting this relationship in the AI integration process.

Finally, similar to our findings, previous studies have noted that the minimum requirements for AI in EHRs are essential for ensuring optimal use. For example, AI systems should be designed to preserve autonomy, health data privacy, and security within the EHR system [15,20]. GPs must be able to use AI intuitively and issues such as software interoperability, usability, and workflow integration must be addressed to ensure that AI has a meaningful impact on general practice [15,17]. This underscores the importance of minimizing the effort required by GPs to effectively use AI, making it a critical prerequisite for designing AI tools for general practice.

Possible Mechanisms and Implications of the Study

The GPs included in this study believe that meaningful use of AI in general practice begins with low-complexity tasks, aligning with the earlier definition of "low-hanging fruit." In this study, we understand "meaningful" as a quality in human-computer interaction [36]. Thus, by realizing AI for administrative and supporting tasks already embedded in everyday clinical routines, AI can support GPs' actual work and reflections at a practical level.

The results of this study further demonstrate that the GP-patient relationship can be preserved if AI is designed to handle routine and administrative tasks. The included GPs underline their central role in patient interactions, and their suggestion to assign AI to more peripheral tasks further underpins the narrative of GPs as family doctors [37]. However, today's general practice has evolved significantly from traditional family medicine, particularly regarding patient independence and symptom interpretation [38]. The time and space available to patients are becoming more restrained in modern general practice, yet patient involvement and autonomy are reaching unprecedented significance. Therefore, it is essential to clarify how AI can support the modernization of general practice while preserving the essence of GP-patient relationships.

It has previously been determined that patients trust the use of AI if their GPs trust it [35]. The trust of GPs in this study hinges on understanding the underlying algorithm and making conclusive decisions based on AI outputs. However, this raises the question of whether GPs can trust AI, particularly its current "black box" form. This challenge underscores the importance of exploring the possibility of explainable AI (XAI) [39]. XAI is an emerging research area that should be considered to realize the potential of transparent and trustworthy AI in general practice.

Furthermore, ensuring that AI is an optional and customizable feature within the EHR is critical. Allowing individual clinics to adjust AI tools according to their preferences and routines can improve their adaptability. This will enable GPs to determine the extent to which AI assists in health care work. Thus, modernizing the EHR system is essential for using the AI capacity. This ensures that the GP's use of AI remains an active and deliberate choice, reinforcing their autonomy and trust in the technology.

To further enhance trust and meaningful AI in general practice, it is essential to establish close collaboration among GPs, EHR suppliers, and other information technology stakeholders when developing and potentially implementing AI. This collaborative synergy would ensure that potential AI tools meet general practice needs while aligning with the upcoming regulatory framework introduced by the European Union, such as the GDPR and AI Act. These frameworks enhance transparency, accountability, and trust in AI systems, thereby supporting their integration into general practice [40,41].

Unanswered Questions and Future Research

When examining the study's defined prerequisites for AI in general practice, it becomes evident that the included GPs recognize the transformative potential of AI. Nevertheless, further research is imperative to identify relevant low-complexity tasks of a routine and administrative nature before commencing the development of suitable AI tools. Classifying suitable low-complexity tasks for AI in general practice will require comprehensive effort, but such classification is critical for aligning development with implementation. By identifying tasks suitable for AI in general practice, groundwork can be laid for a seamless transition from design to deployment.

While this study only addressed the exploration phase of implementation [12], it is essential to consider the remaining implementation phases before initiating development [42,43]. Furthermore, it could be favorable to incorporate the study's prerequisites into early implementation strategies, which could ensure the alignment of new AI tools with GPs' expectations and perceptions of how AI should function in general practice.

While the study results highlight the importance of addressing political, legal, and economic aspects to build trust in AI, it does not delve into concerns regarding privacy, liability, and financial considerations stated in previous research [15]. Future research exploring these areas within the context of AI in Danish general practice would be highly valuable.

As no AI tool has been implemented or validated in Danish general practice, we believe that the defined prerequisites of the study can guide the initial phases of the future development of AI. It will also be valuable to consider these prerequisites when evaluating new AI tools to determine whether they are suitable for general practice.

Acknowledgments

We extend our gratitude to the study participants for sharing their time, experiences, and insights.

Authors' Contributions

NLJ was the primary researcher in this study and was responsible for designing the study, conducting all interviews, analyzing the data, and serving as the primary author of this paper. CHM and JLT assisted in the study design, vignettes, and interview guide, and contributed to the data analysis. To enhance the trustworthiness of the findings, all authors participated in collaborative discussions to review and refine the themes. These discussions involved thoroughly examining the raw data, including excerpts from the transcripts to ensure that the themes accurately represented the participants' perspectives. MBJ, TBM, and KK provided feedback and assistance throughout the study. All authors have read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Fragmented sharing of health information is known to negatively impact patient care and outcomes. To support the sharing of health information between systems, Fast Healthcare Interoperability Resources (FHIR) has emerged as the global interoperability standard for health information exchange. To speed up the process of adoption, various FHIR accelerator groups have been formed. FHIR accelerators such as the Sparked program in Australia enable communities and collaborative groups to develop high-quality FHIR standards for health care information exchange and encourage widespread uptake. However, limited research exists on the development, delivery, and implementation of FHIR accelerator programs.

Objective: This study used qualitative methods to identify the key components of the Sparked FHIR accelerator, what factors influence implementation, and which strategies may help enhance its delivery.

Methods: Semistructured interviews were conducted with Sparked stakeholders in the early stage of the program. The Sparked FHIR accelerator intervention components were described using a standardized reporting checklist (Template for Intervention Description and Replication). The Consolidated Framework for Implementation Research (CFIR) 2.0 was used to analyze factors influencing implementation. On the basis of a cumulative majority analysis, the most mentioned factors influencing implementation were identified. These factors were then mapped to the Expert Recommendations for Implementing Change (ERIC) tool to identify strategies for enhancing the implementation of the Sparked program.

Results: A total of 17 participants were interviewed, including program leads, cochairs, representatives of software industry implementers, clinicians, and consumers. In total, 8 key CFIR influencing factors were identified: engaging, innovation design, assessing needs, local conditions, access to knowledge and information, partnerships and connections, capability, and work infrastructure. After mapping the top CFIR influencing factors to the ERIC tool, 5 strategy clusters were identified: adapt and tailor to context, develop stakeholder interrelations, support participants, train and educate stakeholders, and use evaluative and iterative strategies.

Conclusions: This study enabled the core components of the Sparked FHIR accelerator to be defined and identified the factors that have the strongest influence on program implementation. Using the CFIR-ERIC approach facilitated the generation of

XSL•FO
RenderX

expert-informed recommendations for improving the implementation of Sparked, but researcher recommendations were needed to supplement the tool. This research offers valuable insights for decision makers and implementers.

KEYWORDS

Fast Healthcare Interoperability Resources accelerator; FHIR accelerator; Sparked; Consolidated Framework for Implementation Research; Expert Recommendations for Implementing Change; implementation enhancement plan; digital health; interoperability standards

Introduction

Background

The adoption of digital health information systems and interventions is on the rise. However, the data informing these systems, such as requests for pathology tests and medical imaging, are often fragmented and represented using inconsistent terminologies and measurement units across various platforms. This phenomenon is known as the absence of interoperability. A lack of interoperability between digital health information systems and interventions can lead to adverse health outcomes and higher costs to the health system (eg, redundant laboratory testing, higher health care expenditure, and medication errors) [1-3]. To address fragmentation and promote interoperability, it is necessary to establish standardized measurements and terminologies that can be embedded into various health information systems. The Fast Healthcare Interoperability Resources (FHIR) [4] has rapidly emerged as one of the most favored standards for health information sharing and continues to show promise in developing an application-based approach to interoperability and health information exchange [5,6].

Health Level Seven (HL7) International, the global accredited standard development organization, has suggested 5 aspects of a rigorous standard development process that emphasizes consensus, fitness for purpose, implementability, community engagement, and ongoing maintenance [7]. During standard development, working groups adhere to a structured decision-making process to achieve consensus, openness, and fair representation of interests. In addition, all proposed standards undergo a formal balloting process to collect and reconcile feedback on specifications before they are published as normative standards. Despite the known benefits of implementing FHIR, work is needed to increase their uptake, adoption, and implementation [8,9].

Worldwide, numerous FHIR accelerators have been established to facilitate the development and adoption of agreed-upon core datasets, including Argonaut, CodeX, Gravity, and Da Vinci, as listed by HL7 [10]. These accelerators aim to develop local standards that expedite the adaptation and development of health information systems in an interoperable manner, enabling clinical information systems and health data applications to seamlessly and consistently share information regardless of the application source.

The Sparked accelerator program commenced in Australia in July 2023 [11]. This was part of the federal budget to implement new initiatives that improve digital health information sharing. It is facilitated by the Commonwealth Scientific and Industrial Research Organisation (CSIRO) Australian e-Health Research Centre and serves as a collaborative consortium to bring together government entities, technology vendors, health care organizations, peak bodies, practitioners, and domain experts to accelerate the creation, use, and adoption of national FHIR standards for health care information exchange [11,12]. By fostering community collaboration, Sparked aims to enable the community to develop robust, nationally agreed-upon, Australian context–specific HL7 FHIR standards, clinical information models, and terminology value sets. Technical and clinical design groups have been formed to bring a holistic perspective when defining requirements and specifications, as well as validating and implementing critical health care data and FHIR standards.

Although FHIR accelerators, including Sparked, have been carried out in various countries over the last few years, there is currently limited research available in peer-reviewed literature that reports on the development, delivery, implementation, and evaluation of accelerator programs. Furthermore, there is a lack of evidence concerning the key attributes and factors influencing the implementation of successful community practices in accelerator programs. A lack of formal intervention or program descriptions is not uncommon in the literature, and related work has focused on the technical development of FHIR implementation guides and pilot-testing of the FHIR standards to support a specialized domain, such as genomics, oncology, and health research [8,9,13-16]. Lessons learned from these smaller-scale individual developments have highlighted the importance of engagement from clinical work groups in addition to communication and coordination between the standard developers and the implementation team. These pilots have pointed out future directions in supporting community-driven HL7 FHIR accelerators, including the critical need for collaboration among the communities in developing consensus to accelerate interoperable data modeling and applications [9,13,14,16]. These lessons learned are often published on informal websites, and there is a lack of peer-reviewed evidence that operationalizes theory to help synthesize these learnings into generic recommendations. Standardized analysis and reporting of success can be achieved using implementation science.

Implementation science offers theories, models, and frameworks that help explain the conditions needed to optimize the uptake of evidence-based practice. In this context, there is evidence of the need to implement interoperable systems to promote health outcomes. In our study, the Consolidated Framework for Implementation Research (CFIR), a conceptual framework designed to systematically assess implementation using multiple

XSL•FO
RenderX

lenses (called domains), was used to identify factors influencing intervention implementation [17,18]. The CFIR, resulting from a systematic review of available implementation frameworks, integrates factors associated with effective implementation from various theoretical and empirical studies into a set of domains and constructs. The CFIR comprises 5 major domains: intervention characteristics, inner setting, outer setting, characteristics of the individuals involved, and implementation process. Among these domains are 48 constructs and 19 subconstructs. It has been widely cited since its publication in 2009 and recently updated as the CFIR 2.0 [17-20]. The study authors developed a virtual care *expansion pack* to the CFIR 2.0 that includes extended constructs related to the uptake of virtual care innovations, and it used in this study [21]. On its own, the CFIR is highly useful for gathering insights into implementation, but to truly maximize the output data, it should be used in conjunction with an implementation strategy selection tool.

The Expert Recommendations for Implementing Change (ERIC) tool was first developed to create a refined taxonomy of implementation strategies that can be used to improve the uptake of evidence [22]. In 2019, the strategies were mapped to the CFIR framework to identify which strategies are best suited to addressing factors influencing implementation [23]. The mapping process occurred through consensus among implementation experts and resulted in the development of the CFIR-ERIC Matching Tool [24]. Despite known heterogeneity in agreement among experts as to what strategies best address CFIR constructs, approaches using the combined CFIR-ERIC tool have been demonstrated to improve the uptake of interventions, including one study that showed a 10-fold improvement in compliance with clinical recommendations related to the optimization of patients' blood preoperatively [22,24-26]. The CFIR-ERIC approach can be flexibly applied and is particularly useful for guiding the evaluation of complex digital health care interventions, enabling the systematic identification of factors influencing the implementation of interventions across different contexts [27-30].

Implementation science promotes standardized reporting of interventions, and the Template for Intervention Description and Replication (TIDieR) checklist has been used to support clear articulation of intervention components [31]. Even when the optimal conditions for implementation are known, efforts to replicate these can be hampered by variations in the interventions for which the conditions are relevant. While we may understand the optimal conditions for implementing an FHIR accelerator, without knowing all the program elements that are necessary for success, key activities may be missed in future implementation attempts. For example, one FHIR accelerator may heavily rely on a mix of face-to-face and hybrid participation, and if this is not sufficiently articulated, other FHIR accelerators that instead rely on delivering the program entirely on the web may fail without realizing why despite having optimized the conditions for implementation. In this study, the TIDieR checklist was completed to enable replication of the Sparked program at the intervention level.

In this paper, we describe the core components of the Sparked FHIR accelerator and demonstrate how the CFIR-ERIC approach facilitated an understanding of factors influencing the implementation of the Sparked program. Our research provides actionable findings for decision makers and program implementers.

Objectives

This study had three key objectives: (1) to define the core components of the Sparked accelerator program and understand how those components interact with each other, (2) to identify factors influencing the implementation of the Sparked accelerator program as perceived by relevant stakeholders, and (3) to leverage implementation science theory to develop an implementation enhancement plan to improve the adoption of FHIR standards by optimizing the Sparked FHIR accelerator program.

Methods

Semistructured interviews were conducted with stakeholders of the Sparked program. Interview questions were developed based on CFIR constructs and focused on stakeholders' perspectives on the program's components, engagement experience, perceptions of the FHIR development process, and factors influencing its success.

Participants and Recruitment

Participants included those involved in the conceptualization, coordination, and delivery of the Sparked program and its target population, such as program leaders, cochairs, members of the clinical and technical work groups, and consumer representatives. We aimed to recruit a minimum of 2 to 3 individuals from all relevant stakeholder groups to ensure adequate representation.

A Sparked program manager sent invitation emails to potential participants. A purposive, snowball sampling approach was used for recruitment, where additional stakeholders may be revealed as the research progresses [32]. Participants were provided with an electronic invitation (a recruitment flyer) that contained a link to complete a digital information and consent form through a secure REDCap (Research Electronic Data Capture; Vanderbilt University) server hosted by the CSIRO.

Data Collection

Interview sessions were conducted over a 3-month period, with the first interview taking place 4 months after the program commenced. Each session was conducted via videoconferencing (Microsoft Teams; Microsoft Corp) and lasted 45 to 60 minutes. Audiovisual recordings of the interviews were professionally transcribed. In total, 4 authors conducted the interviews as available (JL, AD, EM, and RJ).

Data Analysis

The transcribed data were exported into Microsoft Excel (Microsoft Corp) for cleaning and preparation for coding. Once complete, 3 researchers (JL, AD, and EM) carried out the coding process using the CFIR. A directed content analysis approach was adopted, enabling results to be aligned with CFIR 2.0 constructs. Additional constructs relevant to virtual care generated from a previous systematic review and designed as

XSL•FO
RenderX

an extension to the CFIR, which are available as a preprint, were also used [21].

The initial coding was conducted independently by 2 researchers (JL and EM), and results were discussed and refined. Following this, a codebook was developed by 2 researchers (AD and JL) to define the CFIR constructs in the Sparked context (Multimedia Appendix 1). On the basis of the codebook, 2 researchers (AD and JL) independently evaluated and revised the initial results in a second-round coding and consistency-checking process. After finalizing the coding, a prioritization exercise was undertaken to identify the most mentioned influencing factors (barriers and enablers) based on the cumulative majority, similarly to other studies using the CFIR [27,28]. A list of brief statements for each of these factors was generated by the 2 researchers. Mapping of the barriers and enablers to the ERIC tool was conducted to select theory-informed strategies that could enhance the running of the Sparked program.

We reviewed information published on the Sparked website [9] and analyzed participants' descriptions of Sparked components using the TIDieR checklist. We focused on the statements from program leaders and cochairs as they had an overall understanding of the program. The TIDieR items were further validated through author consensus (KE, JS, MH, KL, DT-R, and GG). The checklist enabled standardized reporting of Sparked components from an intervention perspective. Understanding the processes and contextual factors surrounding the Sparked program supported the development of the codebook during the analysis of CFIR influencing factors.

Ethical Considerations

Ethics approval was obtained from the CSIRO Health and Medical Human Research Ethics Committee (project ID 2023_057_LR). All participants provided digital informed consent through the secure REDCap server hosted by the CSIRO before participation. Interview transcripts were deidentified before analysis, and the results were reported in an aggregated format to ensure participant anonymity. Participants did not receive compensation for taking part.

Results

Demographics of the Participants

A total of 17 participants were interviewed, including 5 (29%) program leads from the CSIRO, 4 (24%) cochairs, 3 (18%) technical design group members from software vendors, 4 (24%) clinical design group members, and 1 (6%) consumer representative. The demographics of the participants are summarized in Table 1. Participants' digital health experience ranged from 2 to >25 years. Regarding HL7 and FHIR standards, their individual experiences varied from 1 to >25 years.

Table 1. Demographics of the participants (N=17).

Characteristic	Participants, n (%)
Role

Sparked Components in the TIDieR Checklist

A detailed description of the Sparked intervention components is presented using the TIDieR checklist in Multimedia Appendix 2, including items and explanations related to the rationale, procedures, and materials; who was involved; and how the program is tailored, modified, and delivered. Figure 1 illustrates the components related to participation of design groups and their procedures and interactions with knowledge and artifacts.

Figure 1. Sparked participation (A) and process of interaction and feedback loop (B). AU: Australian; AUCDI: Australian Core Data for Interoperability; CDG: clinical design group; FHIR: Fast Healthcare Interoperability Resources; IG: implementation guide; TDG: technical design group.

A

B

Top CFIR Influencing Factors

Using a cumulative majority (frequency of mention on a per-participant basis), our results identified factors that positively or negatively influenced the participants' experience in the Sparked program and their perceptions of Sparked delivery.

A total of 65% (44/68) of the CFIR constructs were identified as factors influencing implementation. In addition, 44% (4/9)

XSL•FO
RenderX

of the newly proposed virtual care CFIR constructs [21] were identified as being relevant. We then identified the top 25% most mentioned barriers and enablers and combined them to create a final list of 8 influencing factors to be addressed, as summarized and highlighted in Table 2. These 8 constructs were considered as key influencing factors and were selected for prioritization and ERIC mapping. These constructs were engaging, innovation design, assessing needs, local conditions, access to knowledge and information, partnerships and connections, capability, and work infrastructure.

Table 2. Top Consolidated Framework for Implementation Research influencing factors (N=17).

Construct	Participants, n (%)
Engaging	17 (100)
Innovation design	17 (100)
Assessing needs	16 (94)
Local conditions	16 (94)
Access to knowledge and information	15 (88)
Partnerships and connections	15 (88)
Capability	13 (76)
Work infrastructure	11 (65)

Detailed Findings on the Top Factors Influencing Implementation

Overview

In the following sections, we present findings related to the 8 influencing factors organized by their CFIR domains. Their associated key (most mentioned) implementation condition statements in the Sparked context and exemplar quotes related to these statements are presented below. A full list of statements associated with each of these constructs is provided in Multimedia Appendix 3.

Innovation

Innovation design is related to how Sparked is designed and packaged, including how it is assembled, bundled, and presented. The key implementation condition statements for this influencing factor are presented in Textbox 1. Participants agreed that successful FHIR accelerators would require consensus-driven approaches, concurrent technical and clinical development, and effective coordination to ensure scalability and sustainability, supported by engagement that would encourage user interests and participation. Establishing a diverse community comprising the government, technology vendors, health care provider organizations, and experts was considered essential, and a centralized knowledge management system would be vital for information sharing among stakeholders.

Textbox 1. Innovation design—implementation condition statements.

A community comprising different stakeholders accelerates the creation and use of national Fast Healthcare Interoperability Resources standards

- "The aim for Sparked is actually to build community...and build a really active community that together will actually localize and profile the FHIR Foundation, SNOMED etc for use within Australia. So it's about coming together as a community together we go faster and actually fast tracking the adoption of these standards." [P5]

A facility to allow for concurrent technical and clinical development with opportunities to collaborate is needed

- "The trouble part is the connection between the clinical and the technical, we all come from different camps and we all have different...agendas or approaches, what we technically think we are capable of doing against what they clinically really want...so there can be a lot of tension between the two and I would highlight...we just sort of don't easily gravitate, integrate with each other." [P11]

A consensus-driven approach is a foundational component

- "I think keeping a genuine focus on community and consensus like genuine open consensus, so not sort of closing anyone out and focusing on an approach that does enable sort of an open market and really using this to sort of set foundations for Australia and I think key to success is...trying to see this as a bipartisan, multi-year initiative." [P15]

A centralized knowledge management system is integral for information sharing

- "They're the two elements, sort of the technical artifacts and the specifications and then the sort of the community process and making sure that that's inclusive, open and transparent and traceable...I think the biggest challenge...is making sure that people understand what they are, what the scope of them are, how they should be used, who should be governing them, how they should be maintained." [P4]

XSL•FO
RenderX

Outer Setting

Local conditions is related to the economic, environmental, political, and technological conditions that enable the outer setting to support the implementation and delivery of Sparked. The key implementation condition statements for this influencing factor are presented in Textbox 2. Australia has a mature digital ecosystem that recognizes interoperability as a key priority. However, participants also felt that some sectors of health care lagged in understanding the importance and implications of interoperability. The program's success may be influenced by uncertain political landscapes, and there was a perceived need for stronger support from educational and training institutions to enable a larger workforce to deliver program outputs.

Partnership and connections is related to how well the Sparked program and its members are networked with external entities. The key implementation condition statements for this influencing factor are presented in Textbox 3. Participants pointed out that Sparked had drawn individuals and organizations into participating, and the ongoing commitment of these stakeholders is vital for the program's sustainability. These partnerships not only strengthen the credibility and global recognition of the program but also facilitate the sharing of valuable lessons learned. However, there was a perceived gap between the technical and clinical realms, and this could pose a challenge to the program's output viability.

Textbox 2. Local conditions—implementation condition statements.

The digital ecosystem (at the macrolevel) in Australia has reached a requisite level of maturity

- "I think we're at a juncture in time in Australia where many in the industry, particularly the leaders that really are looking to see initiatives like FHIR really move forward, because of the efficiencies that it does bring the vendor, there's at least for the time being there's a window of opportunity for us to really bring them on board and use principles of good faith to work collaboratively together." [P14]

Some areas of health care (at the meso level) lack awareness of interoperability and its impact

- "There's different levels of maturity or organizations in terms of their understanding and awareness of what this is and what this means and specifically what this means for them. Like the aged care sector is quite a bit behind in terms of understanding how this works and how it can enable improved care delivery and information sharing." [P4]

The Sparked program's viability hinges on potentially turbulent political changes

- "I feel confident that the program can deliver, where it is today. It's probably other forces that are political of nature that are always probably the bigger risk points of budget changes and all that sort of stuff change...Hopefully that won't happen." [P15]

Greater engagement and support from educational and training institutions

- "The biggest pain point that we've got, I mean general lack of resources in the country...There's a finite set of FHIR experts, so how do we do this in the most efficient way possible...there's a longer term around how do we encourage across, like across universities...it's not shortage of people doing IT, it's shortage of people doing IT that want to go into healthcare." [P5]

Textbox 3. Partnership and connections—implementation condition statements.

The partnerships with important stakeholders support the sharing of lessons learned

- "There's many FHIR accelerators that are hosted by HL7 international...and a lot of those have been actually running a very long time...so we have been in communication with those folks for at least three years, sort of seeing what they're doing, learning how they've done things, what are their lessons learned." [P2]

The partnerships with important stakeholders strengthen the credibility and visibility of Sparked to be recognized as a world-class Fast Healthcare Interoperability Resources accelerator

- "Looking at the role of HL 7 International in supporting, particularly if you're wanting to use Sparked as an exemplar...the Sparked program could go international with the blessing and support and potentially additional resources from the international community." [P14]

There is a perceived disconnect between the technical and clinical worlds impeding the viability of the program outputs

- "You've got the clinicians providing the desirability and then you have the technologists or the TDG group providing the viability aspect, but it seems like there's a disconnect there, like they need to be working together more, those two teams need to be collaborating somehow and provide decision-making in tandem as opposed to like one to the other." [P10]

Inner Setting

Work infrastructure is related to the organization of tasks and responsibilities within and between individuals and teams and general staffing levels to support functional performance in Sparked. The key implementation condition statements for this influencing factor are presented in Textbox 4. Participants stated that balancing the need for progress with participants' time and energy constraints was challenging, especially in extensive consensus building and in an accelerated environment. To ensure smooth operations and effective event management, comprehensive administrative and logistical preparation was

XSL•FO
RenderX

required. Some participants pointed out that enhanced visibility of key participating organizations such as HL7 International would be essential for increasing community engagement, and the program would also require tools provided by software developers for delivering the test service and reference implementation.

Access to knowledge and information is related to how stakeholders in Sparked can access guidance and training to support their participation in the program. The key implementation condition statements for this influencing factor are presented in Textbox 5. Participants agreed that the Sparked program had ensured open access to program information and encouraged active use of its Confluence page. The program could benefit from a basic education package for individuals such as clinicians seeking to enhance their FHIR skills and from providing more detailed and user-friendly prereading materials.

Textbox 4. Work infrastructure—implementation condition statements.

Difficulty of balancing the need for progress with the demands on participants' time and energy

- "There's a lot of community good dialogue needed...There's not one way to solve the challenge...So consensus building takes time...and we're working in an accelerated environment...It's a lot of demand on their energy and time...I would say one of our challenges going forward will be sustaining the energy of our community to see it through." [P2]

Comprehensive administrative and logistical preparation is key for ensuring a smooth and productive event

- "Throwing more resources at the problem isn't necessarily going to solve the problem, but I do think in the case of the events coordination that would be something that would be beneficial and even a design team, a dedicated design team to help build much more digestible resources." [P4]

Enhanced visibility of each participating organization would enhance engagement

- "The role of HL 7...needs to be more visible. I know that they're a volunteer organization, so I think that's a change that could be very helpful and they should be more independent anyway. So they are the standards organization here, so I think their role needs to be a bit more, just a bit more forward in this...that as an optical suggestion is I think really important." [P15]

Need for software developers to provide tools to support delivering the test service and the reference implementation

- "Resourcing...for delivering the test service and the reference implementation and for our support of the standards we need tooling, software, tooling, so we need software developers to provide tools." [P1]

Textbox 5. Access to knowledge and information—implementation condition statements.

A basic education package or resources for consumers or people wanting upskilling would be helpful

- "There's been certainly attempts to explain the FHIR, but I do feel like we need to say go a little bit...it is a technical topic, so there's no avoiding it, but how do you make that a little bit more accessible for some of the, particularly some of the clinicians involved." [P15]

Anyone can access information about the Sparked program

- "We have a confluence page that CSIRO hosts that that information is available on—like our road map, our plans, the clinical group actually sets off that and for the technical groups they actually set off the HL7 pages. So all that is public, so anyone can make a judgment and share that communication." [P2]

Prereading materials could be more detailed or easier to understand

- "Just noting that...a good amount of the audience aren't technical FHIR experts. So a little bit more concise direction in this is what we're asking you to consider for this part of the workshop, these are the things that we'd like you to think about and discuss. I think just a little bit more clarity with those could've been helpful on the day." [P17]

Individuals

Capability is related to stakeholders' interpersonal competence, knowledge, and skills to fulfill their roles to participate in and deliver the Sparked program. The key implementation condition statements for this influencing factor are presented in Textbox 6. Enhancing training and education across various skill levels using practical examples was highlighted as a way to facilitate broader understanding and more meaningful engagement. There is a need to support technical and clinical knowledge development and address the challenge of enabling equal participation among stakeholders with varying backgrounds and knowledge levels. In addition to leveraging previous experience in FHIR activities to enhance capability, scaling existing formal academic training partnerships was identified as a potential solution.

XSL•FO
RenderX

Textbox 6. Capability—implementation condition statements.

Previous experience, knowledge, and involvement in other Fast Healthcare Interoperability Resources activities improve capability

- "I'm lucky in that I had some maybe it's tangential experience with FHIR...so I have some benefit of several years of that being developed and production...whereas most the people on those phone calls they are not from vendors who have had that US experience and so it's going to take them a longer time to understand what is going on?" [P6]

Formal academic training partnerships exist—they need to be scaled

- "In the short term, what we are trying to do is how do we build as much capacity as possible. So there's a training program which the digital health agency funds HL7, CSIRO and Uni of Melbourne to pull together to actually train as many people around FHIR. The shortest-term fix that we've got is actually to ramp up the training." [P5]

Implementation Process

Assessing needs is related to how well the Sparked program assesses the priorities, preferences, and needs of stakeholders participating to guide the delivery of the program. The key implementation condition statements for this influencing factor are presented in Textbox 7. Engaging diverse stakeholder perspectives was considered as important for understanding participant requirements, and tangible examples are necessary to assess community and clinician needs effectively. Participants pointed out that achieving consensus among stakeholders with diverse backgrounds can be challenging. Providing discussion options in documents before meetings could help facilitate decision-making, and active participation has been encouraged in Sparked consensus processes, such as contributing ideas on Confluence pages. Insufficient representation from specific stakeholder groups (eg, consumers and individuals from rural areas) could risk excluding their voices. Ensuring adequate representation of special interest groups could enhance efficiency and relevance of input.

Engaging is related to how Sparked attracts and encourages participation. The key implementation condition statements for this influencing factor are presented in Textbox 8. Engaging all relevant stakeholders to enable meaningful co-design and stakeholder integration was seen as crucial to the accelerator's success. Study participants believed that running events had played an important role in attracting participants and generating excitement and that the Sparked team had created an environment that supported and championed the engagement culture. Participants argued that ensuring an inclusive environment that accommodates diverse participant backgrounds and knowledge levels remained a significant challenge, whereas communicating the purpose and benefits of FHIR accelerators in accessible ways would be key to building interest. Creating a cohesive media and communication strategy was also considered as important despite challenges due to administrative and resource constraints.

Textbox 7. Assessing needs—implementation condition statements.

Community engagement that prioritizes listening to and recording of diverse stakeholder perspectives

- "There's been a real mix of like the people who've been in Digital Health for a long time but...a lot of new clinicians coming and joining...lots of people from different areas. So we've got a bunch of like immunologists who've joined, ED clinicians—all of these new digitally health young clinicians—I think that's really exciting to have new people to help carry that energy forward." [P3]

Achieving consensus among different stakeholders can be challenging at times

- "It's too hard, we can't do it or the technical people go and design this perfect solution and then the clinicians are like but that doesn't work for me. So for us it's really important that we remain in lockstep and make sure like yes we may be a little bit asynchronous, but we need to always be aware of where each other are going and not go too far ahead or in two different directions." [P3]

Ensuring adequate stakeholder representation and expertise of special interest groups ensures valuable input

- "As an example, we look at the Royal College of Australasian Pathologists. They are in the category of clinical and so we funnel them into the clinical design group for input and they are also very key to the E-requesting. So we make sure that there are also on the technical and functional input for the E-requesting FHIR engine, not necessarily the core though, because that one doesn't apply to them." [P1]

XSL•FO
RenderX

Textbox 8. Engaging—implementation condition statements.

Engaging all relevant stakeholders is seen as crucial

- "Overall the accelerator program has done a really good job of bringing communities together with a very diverse range of stakeholders and clinicians...so I think they're doing the best they can and really trying to be a very inclusive environment, very open...there's a genuine attempt by Sparked to gain consensus on decisions." [P7]

Communicating the purpose and benefits of Fast Healthcare Interoperability Resources accelerators in a way anyone can understand builds interest in participation

- "It needs to be technically based, that's what it's about, but to get clinician engagement you need them to understand what the potential benefits are and that's that marrying of the technical...you know this has been done I think very well by the CSIRO in the past and...to get clinicians involved." [P8]

Ensuring meaningful co-design and integration of stakeholder input

- "It's probably, it's the best I've seen, an approach, of having a community approach, where everyone's genuinely involved, rather than being told this is what we're doing, we'll have your feedback, but this is where we're going and I do think it's got a very good, so far, co-design culture about it and approach." [P15]

A dedicated effort to create cohesive media and communication strategies among partner organizations

- "I understand it can be a nightmare managing so many people and so many things at the same time, but it's just we're getting a lot of emails...So far it's been good...but sooner or later I'll reach a stage where I'll lag behind on all of these things...so how do we ensure we're not spamming everyone with comms...it has to be very relevant to the point and ensuring engagement." [P4]

ERIC Strategy Mapping

The top 8 influencing factors were mapped to the ERIC tool to guide implementation strategy selection. We used the updated CFIR-ERIC Matching Tool [33] for this purpose. Strategies were subsequently categorized into clusters to make application easier [25]. Strategies that had the highest percentage of agreement (eg, highest expert consensus regarding being effective to address barriers or amplify enablers) were selected and generated into high-level recommendations. However, not all CFIR 2.0 constructs currently have recommendations. Where recommendations were absent, the research team reviewed the strategy list in conjunction with evidence to recommend strategies for use.

These strategies were collated into an implementation enhancement plan for action. The recommended ERIC strategy clusters include adapt and tailor to context, develop stakeholder interrelations, support participants, train and educate stakeholders, and use evaluative and iterative strategies, as outlined in Multimedia Appendix 4.

Discussion

Principal Findings: Identification of Influencing Factors for the Implementation of the Sparked FHIR Accelerator and Strategies for Enhancement

Overview

This study enabled the identification of the core components of the Sparked FHIR accelerator and the factors that positively and negatively influence program implementation. The CFIR supported the identification of key factors influencing the implementation of the Sparked program. Subsequent mapping to the ERIC framework enabled the development of tailored strategies for enhancing the implementation of FHIR accelerator programs. However, researcher recommendations accounted for >50% of the strategies due to a lack of consensus in the ERIC tool, suggesting that future work is needed to improve the reliability and comprehensiveness of the tool.

In this section, we examine the top influencing factors and associated recommendations generated through ERIC and researcher recommendations in the context of the current body of evidence.

Innovation Design

Innovation design was identified as a key enabler for Sparked in this study. Our results highlighted the core components required for a successful FHIR accelerator, including a consensus-driven approach, concurrent technical and clinical development, effective coordination for scalability and sustainability, and engagement that encourages user interests and participation. The collaborative consortium aspect of the FHIR program can be conceptualized as a community of practice. Challenges faced by communities of practice have been reported in studies of health care programs that involve diverse groups working together toward a common goal to address specific problems [34-36]. Similarly to insights reported from FHIR standard developments [9,34], our participants noted that achieving consensus among stakeholders with diverse backgrounds and needs could be difficult at times during standard development. In the context of large-scale digital health initiatives such as the United Kingdom's delivery of digital health and well-being programs, tensions between communities of practice and the need for delivery at pace and scale were reported [37,38].

In digital health, co-design methods are used in the process of ideation, validation, and deployment involving both digital and health experts with different needs [39]. In the context of domain-specific FHIR standard development, community-driven connectathons, balloting, and centralized knowledge management systems for accessing program information have been pivotal in supporting the process [9,15]. Open dialogue

XSL•FO
RenderX

between the clinical and technical work groups helps in confirming comprehension, resolving discrepancies, and providing feedback on standard specifications [9]. The ERIC tool suggests adapting and tailoring approaches to context, such as identifying the ways in which Sparked can be tailored to meet local needs while retaining core elements of the program to preserve its integrity (eg, generating tailored educational materials to ensure wide engagement), creating a use case–focused group structure to help bring clarity.

Local Conditions

Studies on large-scale digital health implementation have shown various levels of factors influencing readiness, including macro (eg, market, infrastructure, and policy), meso (eg, organizational), and micro (eg, professional or public) levels [37,38,40]. In Australia, the digital ecosystem involving the government, vendors, professional organizations, and clinicians has attained a requisite level of maturity to support interoperability [11,12]. However, our study found that certain health care sectors at the meso level still lack a full understanding of the significance of interoperability. Concerns were also raised about the potential effects of an unpredictable political climate on the program and challenges associated with enhanced data sharing, such as liability and cost.

A longitudinal evaluation of a national digital health initiative highlighted the need for greater investment in infrastructure, guidelines for safe and transparent use, incentives for interoperability, and upskilling for professionals and the public [38]. These recommendations are consistent with the researcher-selected ERIC strategies, which include securing commitments from key partners (eg, governments, professional colleges, and vendors who provide support or incentive to participate), involving existing Sparked governance structures (eg, boards of directors, HL7, and medical boards) to address quality management needs, and enhancing support from educational and training institutions to build a larger workforce to deliver program outputs.

Partnership and Connections

Sparked has attracted a diverse range of individuals and organizations, with their continued involvement playing a key role in ensuring the program's long-term sustainability [11]. Partnerships with HL7 International will enhance the program's international visibility and foster the exchange of valuable lessons learned [10]. However, the perceived disconnect between the technical and clinical domains in Sparked was raised as one of the challenges.

Research on developing genomics data FHIR standards highlights the importance of involving potential adopters (eg, pathology testing laboratories) alongside technical developers during standard development and pilot-testing [9]. Evaluations of digital health innovations in the Australian context have also emphasized the need for ongoing partnerships between innovation implementers and a diverse range of innovation recipients (eg, health care professionals and consumers) [30,41]. In addition to these insights, the ERIC tool suggests strategies for building a coalition, such as continuing activities that attract stakeholders, as well as promoting network weaving, such as building on existing high-quality working relationships and networks to promote a shared vision.

Work Infrastructure

One of the most frequently reported barriers to collaboration in health care innovations is that community members such as clinicians often lack the time to participate and prioritize other commitments, such as service provision [34,35]. Our study found that this challenge was compounded by the difficulty of progressing while balancing the time and energy constraints of participants, especially in extensive consensus building among work group members. From an infrastructure and resource perspective, the program also required software developers for test service delivery and reference implementation, as well as a coordination team for comprehensive administration and logistical tasks.

Recent research on communities of practice in health care settings suggests that nonhierarchical collaborations between participating organizations, shared ownership of outputs, and a centralized leadership structure with rotating leaders can be effective [42,43]. Similarly, the need for an enhanced visibility of key participating organizations such as HL7 International to increase community engagement was identified in our study. These suggestions align with the researcher-selected ERIC strategies, which include developing partnerships with organizations that have the necessary resources to implement the program, shifting and revising roles among professionals managing the program, and redesigning job characteristics if needed.

Access to Knowledge and Information

Effective knowledge management and information sharing are crucial for innovations involving communities of practice [36,42,43]. The Sparked program uses knowledge management systems such as the online collaboration workspace Confluence as a central resource for program information and hosts community events to support ongoing knowledge development. Our study participants were positive about the open access to program information and the promotion of active engagement with Confluence and events. They also suggested that individuals such as clinicians seeking to enhance their FHIR skills would benefit from additional educational resources.

Research on communities of practice has reported similar effective methods for creating shared information spaces, such as learning hub platforms with website resources and asynchronous online discussion forums and periodic email updates with news and forum notifications [42,43]. Using live transcripts for groups with diverse skills and sharing meeting recordings to accommodate varying schedules also help members catch up [42]. The ERIC tool also suggests several strategies for training and educating stakeholders, including conducting educational meetings tailored to different groups; developing manuals and toolkits in ways that make it easier to learn about the program; providing supporting materials for clinicians to facilitate understanding of Sparked program products; and distributing educational materials through various channels, such as in-person sessions, mail, and email.

XSL•FO
RenderX

Capability

Stakeholders' requisite capabilities to participate in and deliver the Sparked program, such as health domain knowledge for technical work group members and FHIR knowledge for clinical work group members, were identified as an area for improvement in our study. Previous FHIR development efforts have also shown the need to support technical and clinical knowledge development and address the challenge of enabling equal participation among stakeholders with varying backgrounds and expertise levels [9].

While studies of digital health implementation have identified health care professionals' digital technology skills, abilities, and experience as one of the barriers [30,44,45], research on communities of practice has shown that community members can continuously advance their knowledge through ongoing learning and active engagement [36]. Enhancing cross-training and education for technical and clinical work groups and across various skill levels, along with practical real-world examples, will help facilitate broader understanding and more meaningful engagement, as suggested by the ERIC tool. In addition to leveraging previous experience in FHIR activities to enhance capability, scaling existing formal academic training partnerships was identified by the ERIC tool as a potential solution.

Assessing Needs

Community engagement that prioritizes listening to and recording diverse stakeholder perspectives (eg, clinical, consumer, and technical levels) emerged as an enabler in understanding stakeholder needs related to program operation and delivery. Encouraging active participation in consensus processes and collecting feedback during the ballot process has enabled stakeholders to voice their thoughts and raise issues freely. However, limited representation from certain groups, such as consumers or individuals from rural areas, might result in their perspectives being overlooked.

Studies on FHIR development have shown the importance of adequate representation and expertise within special interest groups to drive efficiency and ensure that stakeholders' needs are collected [9,13,14]. In addition to Sparked's current practices of ongoing monitoring of participation and engagement, researcher-selected ERIC strategies identified ways to enhance needs assessment activities. These include using evaluative and iterative methods (eg, surveys) to gather and analyze information on stakeholder needs for their participation in the program and developing an audit schedule to check that agreed-upon processes (eg, data sharing) are consistently followed.

Engaging

Engaging all relevant stakeholders to enable meaningful co-design and integration was considered as both an enabler and a barrier by our study participants. The Sparked program has engaged stakeholders through various activities with a focus on enhancing participation through both in-person and online events. However, the size and pace of some events make it difficult for participants with less experience in standards to contribute effectively. A stronger effort is needed to gather insights from clinicians and nonexperts.

Our study has shown that, to engage a wider range of organizations and clinicians in the program, the concept of standards needs to be communicated in a way that aligns with their interests. As observed in other community-based health care consortiums, effectively communicating the purpose and benefits of a program in accessible ways is one of the approaches to build interest [34,42]. Participants in our study suggested a dedicated effort to enhance the media and communication strategy, such as more targeted and coherent emails and media content. A study on a large-scale national digital health program also highlighted the importance of clear communication and branding in a multi-agent, heterogenous partnership model [37,38]. It also emphasized the need to engage smaller business partners, who often show less interest in co-design compared to large multinational companies. Echoing the recommendations from digital health implementations [30,37,38,46], the ERIC tool suggested strategies related to further development of stakeholder interrelations, such as identifying champions who dedicate themselves to supporting, marketing, and driving the implementation; involving consumers and other currently underrepresented sectors; and offering more flexibility and opportunities to facilitate their active engagement.

Implementation Science Approaches for Future Evaluations of FHIR Accelerators

Implementation science theory and approaches have been increasingly used in developing an improved understanding of how digital health services and innovations can be designed, developed, and delivered [27-30,47]. To our knowledge, no studies have reported the use of a systematic approach in evaluating FHIR accelerator implementation, thereby limiting the understanding of influencing factors and systematic investigation of the program implementation process. Our study illuminates the applicability and benefit of using the CFIR to identify factors influencing implementation and generate a structured, evidence-based plan to enhance it further. The findings of this study have informed an actionable implementation enhancement plan that has been developed by the Sparked team and will be evaluated later in the year.

We believe that the approach outlined in this study holds broad applicability and encourages others to adopt the CFIR with the ERIC tool to enhance the efficient delivery of accelerator programs. As FHIR and similar accelerator initiatives continue to expand [10], using research approaches and implementation evaluations guided by the CFIR and ERIC frameworks can facilitate more effective translation of the aims and objectives of FHIR accelerators and provide meaningful comparisons across them. These implementation science frameworks provide a common language and systematic approach for researchers to comprehensively study the implementation of multicomponent interventions. This approach enables synthesis of findings across different settings, interventions, and studies, contributing to an evidence base for understanding implementation processes and developing strategies to support successful collaborative FHIR standard development.

Limitations and Future Work

While this study identified factors influencing the FHIR accelerator program and theoretically informed enhancement

XSL•FO
RenderX

plan, several limitations should be acknowledged. First, this study was conducted within an accelerator program based in Australia; the results should be interpreted within the context, such as government support and Australian health care settings. Second, this study was conducted during the first quarter of the 2-year program, whereas ongoing efforts to improve the program by the Sparked management team have continued since then. Third, it is worth noting that the theoretically informed strategies will need to be discussed and co-designed with key stakeholders of the accelerator program for the Sparked team to develop actionable enhancement plans. Finally, this research forms part of a broader evaluation of the Sparked program, where we will incorporate a mixed methods design and additional evaluation data, such as surveys at multiple time points, to enrich the insights and contributions of the findings.

Conclusions

This paper demonstrated how we identified the factors influencing collaborative practices and engagement within a complex accelerator program tasked with developing FHIR standards. It outlines recommendations to address the factors influencing the implementation of the program. Our methodology involved using the TIDieR guidelines to understand the activities of the Sparked accelerator program, the CFIR to develop interpretive statements (assessing the key influencing factors), and the CFIR-ERIC Matching Tool in conjunction with researcher recommendations (informed by evidence) to derive an implementation enhancement plan relevant to activities within the Sparked program. These insights facilitated the identification of strategic improvements that program leaders can use to adapt and refine activities to better engage technical, clinical, and other stakeholders, thereby supporting the delivery and outcomes of the accelerator program.

Acknowledgments

The authors would like to thank the interview participants for their support of this study.

Abstract

Background: Patients are increasingly being offered online record access (ORA) through patient-accessible electronic health records (PAEHRs), but implementation is often met with resistance from health care professionals (HCPs). Experiences from previous implementations may provide important insights into potential barriers and facilitators.

Objective: This study aimed to investigate the factors influencing the implementation of the Swedish PAEHR system in primary care from the perspectives of HCPs.

Methods: We conducted 14 semistructured interviews with a diverse group of HCPs shortly after the implementation of the Swedish PAEHR system. The interviews were analyzed using the Consolidated Framework for Implementation Research (CFIR) and content analysis, identifying key themes related to PAEHR implementation.

Results: The analysis identified several potential factors influencing the implementation of the Swedish PAEHR system. According to the HCPs, the PAEHR system was *flawed* but also *flexible*. The HCPs described working in *a complex and imperfect organization*, which nonetheless had an *existing structure, support, and established communication* with patients. They also described *nondocumentation-related use of the electronic health record system*. Moreover, they reported dealing with a *complicated patient group* with varying needs and high expectations. The HCPs expressed that they worked in a patient-centered way and with *patient engagement*. The HCPs could see both the *advantages and disadvantages* of the PAEHR system and had some concerns. There were *mixed views of the extent of the change*, where some felt patient ORA would not affect their work at all and others expected a substantial impact. Some HCPs had experience using the PAEHR system themselves, while some *lacked knowledge and interest*. Furthermore, the implementation process was perceived as *long and uneventful*, with *fragmented communication*, where *existing communication activities were used*. The HCPs also reported receiving some information and education about PAEHRs outside the organization. The HCPs had limited awareness of how patients were introduced to the PAEHR system.

Conclusions: This study underscores the importance of having a usable electronic health record system and addressing organizational issues, such as issues with the work environment, for optimal implementation of eHealth services such as the PAEHR system. It also highlights the importance of HCPs' views and experiences with their patients, and their perceptions and attitudes toward the intervention. Additionally, this study stresses the importance of effective implementation processes and communication strategies for both HCPs and patients.

patient accessible electronic health record; implementation; consolidated framework for implementation research; primary care

Introduction

Background

In the present health care landscape, patient-accessible electronic health records (PAEHRs) have been implemented in several countries worldwide [1-4]. With the European Health Data Space proposal, this transformation is set to accelerate further [5]. Yet, despite the reported benefits of patient online record access (ORA), including improved patient-provider relationships, improved medication adherence, and reduced anxiety [6], implementation has proven challenging in many contexts, not the least due to concerns and resistance from health care professionals (HCPs) [7-10].

HCPs have expressed several concerns regarding patient ORA [11-15]. For example, although they acknowledge some potential benefits of PAEHRs, they also believe that the records might be incomprehensible or that patients might misunderstand them due to the presence of medical language and potentially complex content. Concerns are that patients may become unnecessarily worried or make decisions based on misunderstanding that could cause harm. HCPs have also reported changing documentation practices to reduce the risk of confusion by writing notes more comprehensively and by omitting hypotheses [12,16], which may make the documentation less clinically useful [17]. In addition, HCPs have been concerned about the potential increase in their workload due to the implementation of ORA [8]. After implementation, HCPs have reported some increase in their workload [12,16] related to, for example, helping patients access PAEHRs and understand their content. In contrast, for some professional groups, there have been reports of a decrease in workload related to administering paper copies of electronic health records (EHRs) to patients [16].

Furthermore, HCPs have expressed concerns that the record's content might worry patients [14,15]. After implementation, patients have reported experiencing distress from reading their records online [12,18]. In Sweden, according to a national survey study, 26% of participants worried about something they had read, and they usually searched for answers online, called the hospital, or raised their concerns at their next visit [18]. Another concern among HCPs is the safeguarding of vulnerable patient groups (eg, domestic abuse victims and at-risk children) [13,19]. Patients are, however, not as concerned about security and privacy and have not experienced many breaches [20-22].

While several studies have focused on attitudes and experiences of PAEHRs, few have investigated their implementation and how the implementation process could affect the concerns of HCPs. According to the Consolidated Framework for Implementation Research (CFIR), 5 domains are important to consider when studying the implementation of interventions: intervention characteristics, inner setting, outer setting, characteristics of the individuals involved, and the implementation process itself [23]. The framework can be used to both plan implementation projects and study successful and failed implementations. Considering the challenges and delays described in the implementation of patient ORA, it is important to deepen our understanding of the factors that may affect the introduction in different contexts, including HCP concerns. In this study, we used the CFIR to structure our analysis and help explain HCPs' concerns and attitudes toward patient ORA and their experiences of the implementation in a Swedish primary care context.

In Sweden, the first patient ORA trial took place in a primary care center (PCC) in 1997 and had promising results [24], but implementation soon faced legal roadblocks, which took years to resolve [25]. In 2008, the new Patient Data Act allowed health care providers to give patients ORA, and implementation could resume. Scale-up was step-wise, and eventually, all patients in Region Uppsala gained access to PAEHRs in 2012. The local PAEHR system was integrated with the National Health Information Exchange infrastructure in 2015, and in 2016, 17 of the 21 Swedish regions were providing patients with access to their EHRs [25]. By 2018, all Swedish regions were providing patients with ORA.

Aspects, such as what health record information is accessible to patients, who can access it, and when is it made available, can vary from region to region and between health care providers [1-4,26,27]. Sweden has a national regulatory framework for patient ORA, first established in 2012 with mandatory and elective paragraphs [28]. Due to the legal framework's flexibility, the 21 autonomous Swedish regions made different decisions on what information can be accessed, when it can be accessed, and who can access it. An updated national regulatory framework from 2016 promises more unification [29], but it is yet to be fully adopted. Individual HCPs have little control over the system and can, for example, not delay access to certain information. Health care providers can, however, opt to make specific keywords used in the EHR inaccessible to patients in PAEHRs to safeguard patients (eg, early hypotheses or concerns for domestic abuse) [30].

Swedish regions adopted different implementation strategies and faced various barriers [31]. In Uppsala, the first region to implement PAEHRs, HCPs were not involved, leading to resistance and negative impacts on implementation. Recognizing this, other regions engaged HCPs, influencing decisions such as restriction of patient access to EHR entries made after implementation [31]. Stakeholders globally emphasized that HCP and patient involvement and education, and institutional change strategies are key to successful implementation [7,32].

As HCPs play a critical role in the adoption of patient ORA, it is essential to further deepen our understanding of what factors, from their perspectives, influence successful implementation. This study, therefore, explores the implementation of the Swedish PAEHR system in primary care from the HCP perspective. Investigation of the factors influencing implementation might increase our understanding of important barriers and facilitators, offering valuable insights into the challenges and potential areas of improvement in PAEHR implementation.

XSL•FO
RenderX

To analyze the factors influencing the implementation of PAEHRs, we used the CFIR. The CFIR was chosen because it is a well-established and widely used framework in implementation science, providing a structured approach to identifying both barriers and facilitators across multiple levels of the health care system. Compared to other implementation frameworks, such as the Normalization Process Theory and the Theoretical Domains Framework, the CFIR offers a broader scope by incorporating individual, organizational, and contextual factors, making it particularly suitable for studying the adoption of digital health interventions in complex health care settings. The CFIR has previously been applied in research on eHealth implementation, including patient portals and EHRs, further supporting its relevance for this study [33].

Aim

We aimed to investigate the factors influencing the implementation of the Swedish PAEHR system in primary care from HCPs' perspectives.

Methods

Study Setting

The study was part of an investigation into the implementation of a PAEHR system in primary care and its usability and implications for HCPs. Swedish health care is mainly tax-funded, and most hospitals and PCCs are managed by regional councils [34]. Since the regions are autonomous, primary care can vary between regions. Both publicly and privately owned PCCs exist, and they are generally publicly funded. Most PCCs are team-based with a mix of different HCPs (eg, general practitioners [GPs], nurses, physiotherapists, and dietitians). The average national primary care visit count was 4.3 per person in 2009 [34]. Compared to the health care systems in other countries, the Swedish health care system struggles with waiting times, continuity of care, and support for chronically ill patients [35]. The PCC included in this study is located in the largest Swedish region, Region Stockholm, and has a mixed patient population with varying socioeconomic backgrounds. While it may not be representative of all PCCs in Sweden, it is an interesting center with a fairly large and diverse patient population and a common mix of health care and administrative staff.

The Swedish PAEHR system, also known as 1177 Journal, is accessible through the national patient portal [36]. Citizens in Region Stockholm had access to medical notes, lab results, diagnoses, and information about visits when the PAEHR system was launched (2016/2017). In 2023, they were provided access to maternity care, vaccination, and referral records, as well as log reports [37].

In Stockholm, over 73% of the population had good self-reported health, and the life expectancy was 82 years in 2014 [38].

Recruitment of Study Participants

Study participants were recruited from an academic PCC, which has a special focus on education and research. Information about the study was distributed via email through the PCC manager as well as orally during workplace meetings. HCPs were eligible to participate in the study if they were involved in the clinical documentation process by writing clinical notes themselves in the EHRs (eg, nurses), dictating clinical notes (eg, physicians), or being involved in the transcription of clinical notes (eg, medical secretaries). A convenience sampling approach was used, and it was voluntary to participate. Nonparticipation was not analyzed.

Data Collection

Data were collected through individual interviews. The interviews were conducted face-to-face at the PCC by the last author (MH) 6 months after the launch of the PAEHR system in Region Stockholm (2017). MH is a female researcher/lecturer with a PhD degree, who, at the time of the interviews, had extensive experience in qualitative research. The interviews were conducted using a semistructured interview guide developed by MH and the third author (IS). The interview guide was pilot-tested with 1 primary care physician, and minor changes were made to the order of questions and the terminology used. The interview guide is presented in Multimedia Appendix 1. The HCPs were interviewed about their experiences of the implementation process, which was the focus of this analysis, as well as the impact of the PAEHR system on the work environment [16] and what they would like to improve to increase the usability and usefulness of the PAEHR system [39]. The interviews were conducted in Swedish and lasted for 30 to 45 minutes. The interviews were audio recorded.

Data saturation was not fully achieved due to challenges in recruiting study participants.

Data Analysis Using the CFIR

The recorded interviews were transcribed and analyzed by the first author (IM) in discussion with the rest of the authors. The transcribed interviews were read and reread. The analysis was conducted in 2 steps using an abductive approach, that is, a combination of inductive and deductive analysis [40]. First, the analysis was conducted deductively using the CFIR, and the information was coded using the CFIR domains (intervention characteristics, inner setting, outer setting, characteristics of individuals, and implementation process) [23]. In this study, the CFIR was a fitting choice owing to its comprehensive nature and ability to capture the multifaceted implementation aspects in health care settings. By employing the CFIR, the analysis systematically examined various factors influencing the implementation of the PAEHR system, providing a holistic understanding of implementation. The information under the different domains was thereafter inductively analyzed using content analysis according to Graneheim and Lundman [41]. The information was coded, and the codes were grouped into categories under the theme of each CFIR domain. Feedback from participants was not collected. The analysis was conducted using NVivo 1.4 (Lumivero).

According to the CFIR, the following five domains are essential for the implementation of interventions in health care: (1) characteristics of the intervention (eg, adaptability and complexity), (2) inner setting (eg, structural characteristics and culture), (3) outer setting (eg, patient needs and resources;

XSL•FO
RenderX

cosmopolitanism), (4) characteristics of the individuals involved (eg, knowledge and beliefs), and (5) implementation process (eg, engagement, evaluation, and reflection).

The CFIR combines different theories and provides a comprehensive framework for implementation research. The different domains are further described below in the results section.

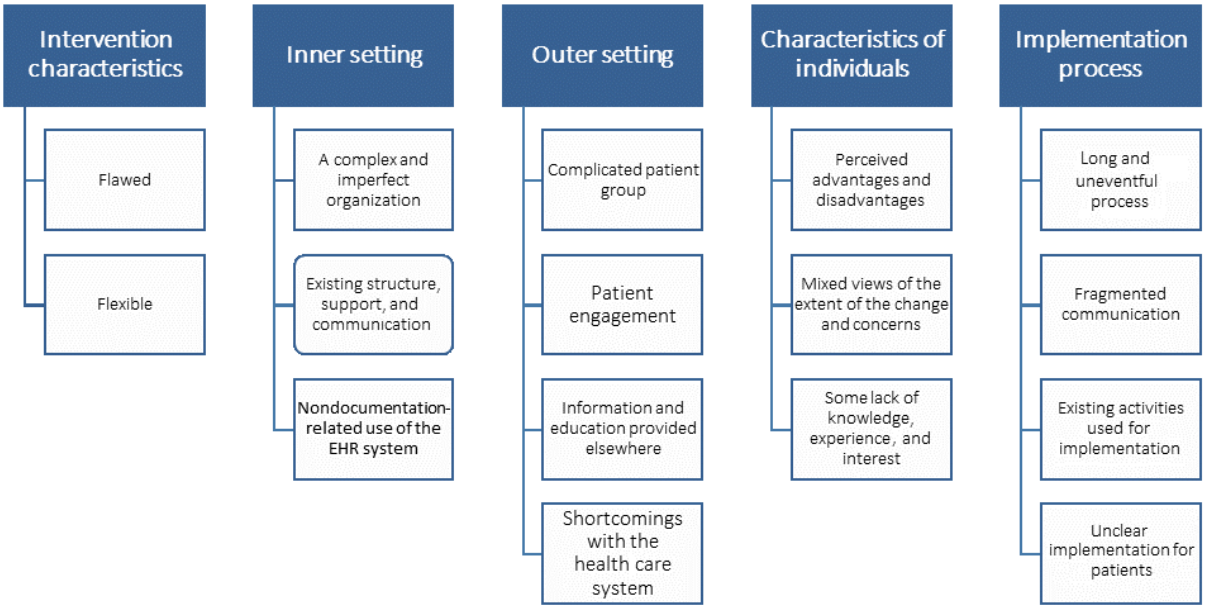
Consolidated Criteria for Reporting Qualitative Research (COREQ) guided the reporting of this study [42].

Ethical Considerations

The study received ethical approval from the Stockholm Ethical Review Board (2017/1028-31). All study participants provided written informed consent before participating in the study. In accordance with the requirements of the Swedish Ethical Review Authorities, participants were informed that their participation was voluntary and that they could choose to revoke their participation at any time. Transcribed interviews were deidentified to protect the participants' privacy, and confidentiality was preserved when reporting the results. No compensation was given for study participation.

Results

Fourteen interviews were conducted with a mix of HCPs, including a counsellor, dietitians, physicians, physiotherapists, medical secretaries, registered nurses, and an occupational therapist (Table 1). The ages of the participants ranged from 27 to 67 years, and their work experiences ranged from 5 to 36 years.



The analysis of the 14 interviews resulted in 15 categories under themes that were equivalent to the 5 CFIR domains (Figure 1). The categories have been further described below, with any subcategories italicized.

Table 1. Participant characteristics.

Characteristic	Value (N=14), n (%)
Profession	
Counsellor	1 (7)
Dietician	2 (14)
Medical secretary	3 (21)
Nurse	2 (14)
Occupational therapist	1 (7)
Physician	3 (21)
Physiotherapist	2 (14)
Age (years)	
<39	1 (7)
40-49	5 (36)
50-59	3 (21)
≥60	5 (36)
Experience (years)	
5-9	3 (21)
10-19	6 (43)
20-39	5 (36)

Figure 1. Themes that emerged under the Consolidated Framework for Implementation Research dimensions. EHR: electronic health record.

Intervention Characteristics

In the CFIR, intervention characteristics refer to the attributes of the intervention itself, including intervention source, features, complexity, and adaptability. In our case, the intervention was the PAEHR system that made EHRs accessible to patients. Our study uncovered two categories: (1) flawed and (2) flexible. These are mainly related to the concepts of complexity and adaptability in the CFIR domain.

Flawed

The HCPs voiced concerns regarding various shortcomings within the system, pointing to complexities in usage, challenges with terminology, and limitations in safeguarding sensitive patient information. The EHR system, from which information is shown to the patient through the PAEHR system, was perceived as complicated. Templates used to structure the documentation were perceived as challenging; hence, *writing the records was difficult*. Moreover, patient ORA caused uncertainties regarding medical terminology use.

> *It would have been good for patients if the record's templates looked the same, and for us too. I mean, the record's templates are difficult to follow sometimes. It's a lot to fill in and a lot to klick to fill in and sometimes it is forgotten.* [Dietician]

Additionally, the HCPs expressed that the PAEHR system *lacked flexibility* and *safeguarding features*, particularly for mental health patients. Some HCPs were worried that patients could still see if information was hidden, and 1 HCP felt reluctant to document suspicions or early hypotheses as a consequence.

In contrast, some HCPs would have liked more information from the EHRs to be accessible to patients and to be able to monitor patient activities in the PAEHR system.

Flexible

The HCPs highlighted features that would enable discreet communication between HCPs, options for some information blocking, and allowances for incomplete records not to be shown to patients for up to 14 days.

> *[…] we talked about the existence of the hidden part, where one could write where they [the patients] could not see.* [Dietician]

The HCPs also reported being aware of previous implementations of the PAEHR system, with favorable outcomes.

> *We were informed that Uppsala {another region} had also used it and that they were happy.* [Physician]

Moreover, the PAEHR system was perceived to be *more confidential* than paper copies. For example, for patients experiencing domestic violence, it reduced the risk of paper copies being accessible to others.

Inner Setting

According to the CFIR, inner setting refers to the organization's internal environment where implementation takes place. It encompasses the organization's structural, cultural, and political aspects [23]. In our case, it refers to the PCC where the HCPs worked. Three categories emerged under this domain: (1) a complex and imperfect organization, (2) existing structure, support, and communication, and (3) nondocumentation-related use of the EHR system.

A Complex and Imperfect Organization

The HCPs described a *challenging work environment*, with varying tasks and a high workload, where they constantly discuss priorities. They mentioned that reflection, education, and documentation are not prioritized.

> *We must increase the number of visits, we can't go to education since it takes time. There is a desire to be better and produce more simultaneously. There is no*

XSL•FO
RenderX

> *common sense and no regard for the staff, it should just move faster and faster and people can't keep up.* [Physician]

According to the HCPs, they cannot *adequately prepare* for visits, which can upset some patients. They deal with *unpredictable visits*, *unclear/unsolvable conditions*, and *complicated treatments*. Assessments can be complex, affecting the clarity of notes. Moreover, the visits are short, and there is a lot of knowledge and information transfer, requiring confirmation of the understanding of patients. In cases related to children, they may be required to rely on information from parents. Misunderstandings can thus occur.

In addition, *communication with patients was restricted*. Certain information (eg, test results) was supposed to be communicated by the responsible physician, which hindered other HCPs (eg, medical secretaries and nurses) from answering patient questions. Moreover, requests to make changes to the record must pass through the manager.

Further, some HCPs had *dealt with threatening, aggressive, and rude patients* and were fearful. Moreover, the HCPs were repeatedly questioned about the records by their manager and patients. Patients could question slightly irregular but otherwise typical test results, and explanations could be time-consuming. Additionally, the HCPs avoided documenting suspicion and were uncertain of how safeguarding functions, such as hidden keywords and hiding unsigned records, work.

> *Sometimes you get aggressive patients that yell and act badly […] we are exposed to a lot. If for example there is only 30 slots today but there is a lot of people calling.* [Registered nurse]

Furthermore, the HCPs *had encountered several issues* when caring for patients, and these were related to the systems they use in general. Serious diagnoses had mistakenly been revealed to patients, referrals and reports had disappeared, and lab orders had remained active despite completion. Their IT systems were described as ineffective, difficult to use, and annoying.

The HCPs also reported a *lack of unification in documentation practices*. Physicians dictate and others transcribe the notes, while other HCPs write their notes themselves. Some respondents wrote on notepads first. The length of the notes varied, often with more junior HCPs writing more comprehensive notes.

The HCPs also described issues with the *record's quality*. Errors and gaps could occur during transcription due to the transcriber's lack of experience. Substandard language could also be used. Moreover, patients have reported errors in their records, and the HCPs were uncertain if the errors were corrected. According to 1 respondent, corrections are seldom made.

Further, *documenting and transcribing on time were challenging*. Some HCPs reported documenting after every patient or on the next day, and some dictated their notes with patients in the room. Additionally, *unsigned records were problematic* for the management. Transcribed notes are not always reviewed due to time constraints, and unsigned notes may contain blanks and errors. According to 1 HCP, some HCPs simply refuse to sign.

> *That's something that is constantly being pointed out, that we have to sign the records. [Counsellor]*

Existing Structure, Support, and Communication

The HCPs reported *some documentation structure*. They have always been conscious of their writing but might be more restrictive now. The transcribing medical secretaries have always strived to write comprehensively, and this is something they learned during their education.

Moreover, some HCPs have always *strived to document and sign records promptly*. Some HCPs had received directives to document quickly to ensure nothing lingers. Further, according to 1 HCP, HCPs have time allocated for administration, which should enable them to complete the tasks. Certain registrations were also required for financial reasons.

> *I usually sign them immediately because I know they will linger on a list which will be difficult to sign afterwards.* [Registered nurse]

Additional structures include functionality for tracking the people accessing the records. Sometimes, HCPs must have the patient's consent to view the records. There are also routines for providing patients with paper copies and dealing with upset patients, as well as channels for communication between nurses and physicians related to patient requests.

Furthermore, in relation to the implementation of new services, there is an organizational desire to change and improve, and the HCPs had previously participated in pilot projects.

Moreover, *support for documenting is provided* in different stages. HCPs might point out significant errors to each other. Transcribers, who are often medical secretaries, point out or alert physicians to errors or missing information in the records. At times, they may correct the errors and inform the physician. Moreover, medical secretaries assist physicians with insurance-related documentation. Furthermore, unsigned records are tracked by managers, who remind HCPs to sign.

> *I try to reconstruct what the physicians have dictated, I try to reconstruct it into a more understandable language for patients.* [Medical secretary]

Further, a *structure for communication with patients about their health care exists*, but it varies among HCPs**.** Moreover, there is *established internal communication* among HCPs through regular discussions, seminars, and education about eHealth, which are led by HCPs at the PCC.

Nondocumentation-Related Use of the EHR System

Additionally, a few HCPs reported using the EHR system as an alternative communication channel among HCPs. HCPs could send internal letters to each other.

Outer Setting

In the CFIR, outer setting refers to the external context surrounding the organization where the implementation occurs. It includes patient needs and resources, external policies and regulations, and the broader sociocultural and economic environment. We have therefore included categories related to patients' needs and resources in this theme: (1) complicated

XSL•FO
RenderX

patient group, (2) patient engagement, (3) information and education are provided elsewhere, and (4) shortcomings with the health care system.

Complicated Patient Group

According to the HCPs, their *patients are heterogeneous* with varying levels of knowledge and engagement in their care. While some patients are *good at scheduling appointments and understanding*, are *curious*, and *show interest* in their health records, HCPs also encounter patients who do not cooperate and who misinterpret, overanalyze, and get stuck. Parents who come in without their children and patients who are worried, confused, or forgetful (losing papers and copies) can be unreachable. The HCPs reported having a mix of new patients and patients they meet often and know well. Many of their patients are old, and some are immigrants with difficulties with the Swedish language. These groups were perceived by our respondents to be less likely to read their records online. Moreover, 1 HCP believed that only a few people read their PAEHRs, with readers being those engaged in their care. The PAEHR system was described as inaccessible for some and thus was described as excluding. Moreover, the HCPs thought that patients would only be interested in reviewing their records in special cases. In addition, while there were many requests for printed copies, few were collected.

Further, according to the HCPs, the PCC's patient population has *substantial health care needs*, which the available care cannot meet. Patients were described as frustrated over the lack of accessibility. Some HCPs acknowledged the difficulty for patients, both in reaching the health care center and managing the information provided during the visit.

> *We have patients waiting for an appointment who haven't gotten to meet a physician. 'But you were here the day before yesterday…' and they say 'But now it is about this issue…* [Registered nurse]

Moreover, according to the HCPs, patients have *high expectations* and are often unsatisfied. The HCPs stated that there was an expectation to remember everything, have answers to all questions, and read the records before a meeting, or they may be perceived as unprofessional. Unpreparedness can upset patients. The HCPs also described unsatisfied patients who perceive HCPs as incompetent and may want to change or include notes in the record and request a second opinion, with some wanting to change health care centers. Some patients were described as being controlling.

Furthermore, according to the HCPs, some patients lack necessary technical equipment like a printer, a telephone, and personal electronic identification (eID), as well as knowledge about the use of the internet.

Patient Engagement

The HCPs reported working in a patient-centered way and *engaging patients in their care*. They aimed to engage patients in shared decision-making and encouraged patients to, for example, follow-up and prepare questions before their meetings. The HCPs also reported engaging patients during the meetings by showing them their records and encouraging them to use the PAEHR system when copies are requested. The HCPs also described how they engage patients in the documentation by confirming their notes with the patients and mentioned that they may read and explain part of the records to the patients. In addition, HCPs could meet with patients for a follow-up earlier if requested.

> *I have done it for many years, asked patients to write down things they are wondering about and they can also bring up things they have read.* [Counsellor]

Information and Education Provided Elsewhere

Some HCPs reported learning about documenting PAEHRs at their previous work or during their education. One HCP also recognized similarities to another implemented initiative called SVF (standardized care process), where HCPs must document findings quickly.

Shortcomings With the Health Care System

A few HCPs expressed *perceived shortcomings with the health care system*, including a lack of reimbursement, misprioritization, and unnecessary care processes.

Characteristics of Individuals

In the context of the CFIR, characteristics of individuals refer to the personal attributes, attitudes, and behaviors of individuals directly involved in the implementation. This domain considers their knowledge, skills, beliefs, and motivations related to the implemented intervention. In our case, the individuals are the HCPs, and we have included their more general opinions on patient ORA and the use of PAEHRs in health care. Three categories emerged under this theme: (1) perceived advantages and disadvantages, (2) mixed views of the extent of the change and concerns, and (3) some lack of experiences, knowledge, and interest.

Perceived Advantages and Disadvantages

The HCPs stated both the advantages and disadvantages of the PAEHR system. While some HCPs thought it was essential, others were ambivalent. Some had become more positive over time, while some remained negative. Some HCPs explicitly expressed that they were against ORA, while others were described as angry by their colleagues.

The HCPs perceived that the implementation of the PAEHR system was *patient-driven* and that it was at the request of patients. There was also the perception that the records are the patient's property and that the PAEHR system is the patient's right and beyond the control of HCPs. The HCPs also thought that it was part of a general trend toward more transparency in health care. One HCP reflected that the lack of understanding of the need for patients to read their records may be due to their old-fashioned views. Moreover, the PAEHR system was believed to increase access to records and participation and to engage patients. Further, the HCPs thought that patients accessed the records for many reasons: they were interested or curious, they wanted to follow-up, they wanted to remind themselves about the findings, they wanted to improve their understanding, and they desired to participate in decision-making. Some HCPs thought that some patients read their records because they were worried or because they were suspicious and wanted to see what was not said at the visit.

XSL•FO
RenderX

> *I think it is good for openness that it isn't a closed document, that they should be able to read {the record} without asking for it.* [Dietician]

In health care in general, the HCPs thought that the PAEHR system *increased health care quality*. It made them more reflective, clearer, more precise, and more direct with their assessments. The PAEHR system was also described as a reminder to write the notes on time, and patient understanding was thought to be more critical than using medical terms. Moreover, the PAEHR system was considered environmentally sustainable since it reduces the number of paper copies and letters sent. The HCPs perceived the PAEHR system to be beneficial for transparency. According to some HCPs, reading the records is important since it concerns the individual's health and is essential for patients to follow their care. They also perceived it as time-saving for patients and a way of making the information more accessible, especially for patients experiencing difficulties due to disability. Moreover, the PAEHR system was seen as a control function, where patients can see that the most important information is included and can make sure agreed-upon actions are being taken, such as sending referrals. The quality of documentation and the quality of care could potentially be improved if patients could point out errors. The HCPs also hypothesized that increased accessibility of the records would increase the likelihood of use among patients.

> *In terms of gains I don't know but the advantages in terms of me thinking a little extra of what I am doing in relation to patients. That I think about it so that it is clearer maybe in general.* [Counsellor]

For themselves, the HCPs saw a *potential to lighten the workload* of writing summaries and reduce calls from patients. The HCPs could refer to the PAEHR system if paper copies of the records were requested. Moreover, once patients read the reports online, they might not see the need to book a face-to-face visit, reducing unnecessary visits. They also saw the potential of using the PAEHR system as a treatment tool to clarify treatment plans and goals.

For patients, the HCPs saw the potential for the PAEHR system to *support participation and collaboration* through increased availability and accessibility. With the PAEHR system, patients could have information from a visit in writing, which could support understanding. This was especially important since the visits could be emotionally charged for some patients, making it hard to retain information and resulting in misunderstandings. According to 1 HCP, it is also a way for patients to see that something comes from the visit. The HCPs noted an opportunity for making treatment plans clearer for patients and potentially increasing compliance, and they wished that patients would read the reports in preparation for a visit. This could potentially reduce patients' worry and increase their confidence in health care.

> *I think a positive effect can be that patients may get a little control over their record and can look. We write what we have done and they follow the test results.* [Physician]

Additionally, the HCPs saw potential for increasing patients' involvement in their care by, for example, tracking medication changes and test results, and for facilitating patients' understanding of how their behaviors may influence their health. Further, the PAEHR system was perceived to be beneficial for families of older patients and patients with different health care providers as it gathers all information in one place. In addition, ORA was perceived to be time-saving and cost-saving, improving patients' response times when issues arise. According to some HCPs, the service was also easy to use. However, the PAEHR system was not purely positive according to some HCPs.

> *I think there are both pros and cons. If you are hypochondriac it can also be a risk. If you get more information than you need.* [Medical secretary]

According to the HCPs, *records have other sometimes contradictory purposes*. On the one hand, the HCPs perceived patients as the owners of their records, while on the other hand, the records were considered a professional tool and thus must be detailed. The records could include information that patients might not want on record and assessments that patients might disagree with.

Moreover, the HCPs argued that the records could contain confidential and sensitive information and that not all information is meant for the patient. Documentation is a way to reduce the cost of, for example, test duplication, and to be able to protect other patients from, for example, infections. Moreover, documentation is needed since patients may not be entirely honest about their previous health care contacts.

Further, some HCPs saw *limited benefit* with the PAEHR system or even considered it an *unnecessary* service. A few HCPs were uncertain of or did not see the importance of patient ORA. They thought that better solutions are present to engage patients in their care and argued that they keep the documentation in the best interest of patients, making it unnecessary for patients to access it. They could not see the benefits of the PAEHR system, as they believed that notes from the PCC might be basic, stressing that patients could already request copies of their records on paper if needed. They believed that health outcomes and personal contact between the HCP and patient were more important and that too much focus was being placed on EHRs. Moreover, they believed that the PAEHR system was unnecessary as their previously experienced issues with unsent referrals, which PAEHRs might have resolved, had already been addressed.

> *I don't think benefit from reading what the physician has written or what that test results show. If they are very interested they can ask.* [Physician]

Moreover, according to the HCPs, the PAEHR system was *not optimal*. They believed that the records contained little information, which might not be visually optimal. The information provided might also not be essential or summarized for patients. In addition, documentation was not standardized. Further, the HCPs thought that the service should be restricted to signed records and access should be delayed. Moreover, they thought that the platform was difficult to navigate.

Additionally, the HCPs believed that the PAEHR system was *unavailable or inaccessible to some patients*. They believed

XSL•FO
RenderX

that most users would be younger, while elderly people, people with dementia, and migrants with language difficulties would be excluded, creating a double system. They also believed that patients with low health or digital literacy would be excluded and that the use of the system would depend on the patient's illness.

> *I think the day I myself get dementia and sitting there struggling with all the passwords, It would be horrible and you cannot keep that organized.* [Physiotherapist]

Further, some HCPs believed that the PAEHR system would be a *disservice to patients.* It would give a false sense of control, increase worry, and be misinterpreted, increasing HCP workload with additional calls and questions. One HCP speculated that patients might read their records to find things to get sick over. Additionally, it might be unpleasant for patients to read serious diagnoses by themselves. According to 1 HCP, it might also be *difficult for patients to understand* the content without a medical education, and additional visits would be needed regardless. According to these HCPs, an oral explanation would be ideal, addressing additional uncertainties during a visit. One HCP did not think patients should read their records at all and stated that patients with severe mental health issues might be negatively affected. According to 1 HCP, the risk depends on the person.

Mixed Views of the Extent of the Change and Concerns

According to some HCPs, the implementation of the PAEHR system meant *little to no change*, potentially since the introduction was so recent that any impact was yet to be seen. Some HCPs were *unmoved* by the implementation. They did not believe the PAEHR system was meant to change care delivery or affect documentation due to, for example, fear of repercussions from patients. According to them, everyone knew it was coming long in advance and they were prepared.

Moreover, *few documentation requirements were new, and the HCPs therefore made little to no changes* to their practice. The HCPs reported that they have always been reflective when writing and tried to be careful and precise. They wrote in a way that the records would be readable for patients. Some HCPs reported that they always wrote and signed the records quickly. Moreover, the HCPs always discussed the notes with patients. The difference now was that the records were online.

> *What I have thought a little more about is writing the notes on time but that is something that should be done anyway so it is not really new. But it is a reminder to write more understandably which also is not something new, just a little extra.* [Occupational therapist]

In contrast, some HCPs thought that *the PAEHR system would require a change* for those HCPs who had not previously been educated about patient documentation. This could be especially true for more senior HCPs who often use medical terms and abbreviations. Some HCPs thought that it would take time to get accustomed to it and would be time-consuming since it was unfamiliar. One HCP reported that they now try to avoid Latin words, which requires effort.

Concerns

Many of the previously mentioned issues concerned HCPs, worrying them and making them skeptical. Some HCPs were skeptical as a patient as well. Although much had not turned out as they feared, there were still concerns that effects might come later. One HCP expressed that the novelty of the PAEHR system was scary.

The HCPs worried about *potential consequences*. They feared potential increases in criticism, questioning, and being reprimanded. They believed that their workload would increase, especially for physicians, due to patient calls and questions. Furthermore, they believed that the system could affect the health care center's reimbursement. In addition, the HCPs had *many thoughts and questions about implementation* and the related practicalities. The increased demands for clarity and timeliness of documentation were causes for stress due to the existing time pressures in their work. Furthermore, the HCPs were concerned that the documentation changes would make the notes less understandable. One HCP felt unprepared.

> *It was more of how it going to happen. What would happen if patients read, are they going to scold us …will they get mad over the information they have gotten.* [Registered nurse]

Further, the HCPs *worried that patients might be negatively affected.* They were worried that the records would upset their patients and that the patients would not like or agree with the contents and would shop around for care. This was particularly concerning in regard to children (eg, social service reports could potentially influence children's confidence in their providers). They were also worried that reading the records could affect patients' confidence or trust in their providers or the treatment. Moreover, the HCPs were concerned about patients who were unable to ask questions or get support from a provider. They believed that the system could cause unnecessary worry. They thought that the records might be especially difficult to understand or interpret for patients not working in health care, which might lead patients to search for information on Google. One HCP suspected that some patients had concealed an appointment upon reading the records, which was concerning. Patients also felt anxious because they did not know what was being written about them.

Moreover, the HCPs were *concerned about the security* and integrity of patients, the preservation of doctor-patient confidentiality, and unauthorized access to records.

However, the HCPs also expressed that things *did not turn out as they had thought or feared.* Patients were not reading their records before being contacted, calls to the PCC did not increase, and they were not reprimanded by the management. They had not made any of the changes that they thought they would need to make. According to 1 HCP, everything had solved itself.

Some Lack of Knowledge, Experience, and Interest

There was *little to no knowledge about the functions of the PAEHR system* among the HCPs. Some HCPs were unaware or unsure of what patients could view. One HCP wished that they had insights into implementation experiences from other regions.

XSL•FO
RenderX

> *I know they can see the notes, test results and referrals I think, but not for example biopsies and such, I don't think they can see that, and not Xrays.* [Physician]

Furthermore, the HCPs had *little to no knowledge about the service's benefits and effects on patients*. Patients' experiences and the number of patients accessing their records were unknown. A few HCPs had second-hand information about patients' experiences. According to some HCPs, patients appeared not to be reading their records and should be reading more. According to 1 HCP, few patients seemed to use online services in general, with 1 HCP speculating that patients in specialist care might be more interested.

Some HCPs did *have personal experiences* reading their own records or a family member's records online or on paper. Those with some ORA experience had just tried it once, and some of their records were empty. A few of them had read their records at the doctor's office out of interest, whereas some had requested paper copies of their hospital records. One HCP had experience with other services on the patient portal, and a few HCPs explicitly expressed disinterest in the service and in reading their records.

> *I have been in mine and apparently I have nothing there. But I have looked with my husband at his and then everything was actually correct.* [Registered nurse]

Implementation Process

According to the CFIR, implementation process refers to the methods, strategies, and activities used to facilitate the adoption and integration of an intervention into a particular setting or organization. This domain examines how the intervention is introduced, implemented, monitored, and evaluated over time. Four categories emerged under this theme: (1) long and uneventful process, (2) fragmented communication, (3) use of existing activities for implementation, and (4) unclear implementation for patients.

Long and Uneventful Process

According to the HCPs, information was provided, but the time until the service was available appeared *outdrawn* for some. It had been ongoing for years, and some HCPs had to be reminded that it was ongoing. According to 1 HCP, many had grown tired of nothing happening. Making the services available was, however, quick and smooth, and suddenly, it was there overnight. The long implementation process reportedly led to some loss of motivation to act.

> *The negative is that it had been talked about for so long but it never got started.* [Physiotherapist]

Fragmented Communication

HCPs were *partially informed*, discussions occurred, and some participated in educational activities. According to 1 HCP, they had a seminar about 1 year before the implementation of the PAEHR system. Some HCPs recollected an education day for some professions, where they learned about and looked at the service. They, however, received no information about when and how the PAEHR system would be launched. According to the HCPs, they did not discuss the technical aspects of the service. One HCP reflected that maybe they did not need more information, while another thought that a user video would have been beneficial.

> *I have no idea how it was done […] we just got information that it going to be online. Nothing more.* [Physician]

Additionally, the scope of information about different aspects of the implementation varied. According to the HCPs, there were discussions about work processes, safeguarding functionalities, how to write, and flexibility aspects, and the importance of completing the records on time was also emphasized. According to 1 HCP, they were told to "do as they do." Furthermore, the HCPs reported receiving information about experiences from other implementations and having some follow-ups at their usual meetings, according to individual accounts.

Existing Activities Used for Implementation

According to the HCPs, information related to the implementation of ORA was provided during their existing meetings related to eHealth. Information was also provided by the usual leader of these meetings, who was one of the HCPs at the center.

Unclear Implementation for Patients

The HCPs were uncertain about how patients were informed, and according to some HCPs, *patients were uninformed*. The HCPs had not noticed any major information campaign targeting patients. Some thought that HCPs were supposed to inform patients, and some occasionally did so. Those informing patients mainly did so with patients who showed an interest. One HCP reported now informing patients more frequently (6 months after implementation). Moreover, there were reports of some brochures in the waiting rooms. There were attempts to encourage physicians to inform patients.

> *[…] if they got something in their mailbox, I do not know but I don't think so.* [Medical secretary]

Discussion

Principal Findings

Although patients in Sweden have had ORA since 2018 (the first implementation began as early as 2012), few studies have focused specifically on implementation in primary care from the perspective of HCPs. To our knowledge, this is the first comprehensive study of the implementation of PAEHRs in Swedish primary care from the perspective of a diverse group of HCPs. Our study identified several potential barriers and facilitators related to PAEHRs, the primary care setting, and patients' and HCPs' characteristics, as well as barriers and facilitators related to the implementation process (Table 2). We will discuss the identified barriers and facilitators in relation to previous research.

XSL•FO
RenderX

Table 2. Potential barriers and facilitators related to patient-accessible electronic health record implementation.

Domain	Barriers	Facilitators
Intervention characteristics	• Shortcomings of PAEHRs[a]	• Flexibility of PAEHRs
Inner setting	• A complex and imperfect organization • Nondocumentation-related use of the EHR[b] system	• Existing structure, support, and communication
Outer setting	• Complicated patient group • Shortcomings with the health care system	• Patient engagement • Information and education provided elsewhere
Characteristics of individuals	• Perceived disadvantages of PAEHRs • Mixed views of the extent of the change and concerns • Some lack of experience, knowledge, and interest	• Perceived advantages of PAEHRs • Mixed views of the extent of the change
Implementation process	• Long and uneventful process • Fragmented communication • Unclear implementation for patients	• Use of existing activities for implementation

[a]PAEHRs: patient-accessible electronic health records.

[b]EHR: electronic health record.

Barriers for the Implementation of PAEHRs

The HCPs reported several shortcomings with the PAEHR system. Complexities in usage, challenges with terminology, and a lack of safeguarding features could be potential implementation barriers. Complexities in EHR system usage might explain the reported lack of unification in documentation practices, the poor quality, and the difficulties with accomplishing and signing the records, further explaining the related concerns. Challenges using EHR systems have previously been described [43,44], and documentation for patients is an additional challenge where support is needed. This reflects complexity, which is one of the intervention characteristics that influence implementation according to the CFIR [23]. Additionally, adaptability influences implementation according to the CFIR, and the PAEHR 1177 journal lacked flexibility regarding sensitive information according to the HCPs. However, the definition of sensitive information by the HCPs might need to be considered together with that by patients, as the limitation of information in the PAEHR system has previously been considered problematic by patients [45]. The improvement suggestions by HCPs have been related to these described issues [39]. Many related improvement suggestions have aligned with patients' experiences, but suggestions related to the restriction of information have not aligned, and patients want access to more information [46]. Enhancing the usability of the PAEHR system and providing support and education are potential solutions to these barriers.

The complexity of the health care organization and its imperfections are other potential barriers. The strained working environment has been raised as a cause for concern by HCPs in both specialized and primary care [14,47,48]. Further, the HCPs described several potential barriers related to documentation practices, that is, a lack of unification in documentation practices, poor quality, and difficulties documenting on time and signing the records. In a recent survey of GPs in the United Kingdom, the majority believed patients would find errors in their GP records [8]. Swedish patients have also reported finding errors in their records [49]. Addressing system-level issues within the primary care system by, for example, increasing resources and training HCPs might reduce these barriers.

HCPs' descriptions of their patient groups as challenging might explain their concerns about the negative impacts on patients. It has previously been reported that patients potentially do not understand their records [12-14], and patients have had similar concerns [50] and have reported difficulties understanding their records [51]. However, some research suggests that most patients understand most of the information available in their PAEHRs [20,52].

The potential exclusion of some patient groups has also previously been described [19,20] and needs to be addressed. Experts have recommended education or support for patients in using PAEHRs as a core part of the implementation of the PAEHR system [32].

According to the CFIR, beliefs and attitudes toward the intervention impact implementation [23]. Resistance among HCPs has been previously highlighted as the main barrier to PAEHR implementation [19]. According to the HCPs in this study, one of the perceived disadvantages was that the purpose of an EHR might not align with the purpose of a PAEHR, which has previously been highlighted [13,14]. As previously mentioned, the HCPs were unsure what needed to be changed. When ORA was first introduced in Sweden, the assumption was that this would not require substantial changes to HCPs' work processes [31], yet this is not the experience of all HCPs. Addressing this ambivalence with guidelines on how ORA will impact HCPs' documentation practices could overcome some of the experienced resistance.

Another disadvantage was that the HCPs perceived that there was little to no benefit of the PAEHR system. This could reflect a lack of existing research at the time of interviews or simply a lack of communication of existing evidence to HCPs. Current

XSL•FO
RenderX

research shows several benefits for patients [6], with minorities and elderly people reporting more significant benefits from ORA [20]. Whether the benefits are sufficient to motivate the introduction of ORA also seems to be questioned by HCPs.

The mixed views on the extent of the changes ORA entails highlight the previously mentioned ambiguity regarding the service. These mixed views might explain the perceived disadvantages expressed by some respondents, and as previously mentioned, the purpose of PAEHRs needs to be clarified. Regarding documentation, there have been several reports of it changing due to the implementation of ORA [12,16,17,53-55]. However, HCPs have also previously reported not experiencing all they feared [13,16,55].

Furthermore, HCPs and other stakeholders have previously expressed several of the concerns raised [13,31]. Studies have shown some negative impacts on HCPs' work environments in terms of increased demand and loss of control, as well as some positive impacts in terms of increased support [12,16]. Moreover, patients have expressed a fear of being worried [50]. According to a Swedish national patient survey, 26% of patients had been worried by information on their record, and they commonly called or raised their concerns at subsequent visits with their providers [18]. Furthermore, concerns regarding privacy and security have previously been raised [13]. Patients also have these security and privacy concerns, but to a smaller extent, and have not experienced many breaches [20,21,49]. Additionally, patients have mainly reported improvements in patient-provider relations due to ORA and have not reported worsening of the relations [21].

A lack of experience with the service among some HCPs could be another potential barrier, as previous research has found that HCPs with experience in using PAEHRs are more positive toward the service [56]. Exposing HCPs to the PAEHR system could thus potentially have a positive impact on its implementation.

The long and uneventful implementation process and the fragmented communication are potential barriers and might explain the lack of knowledge, experience, and interest among our respondents. In a study about PAEHR communication reach, HCPs (eg, nurses and physicians) received information from different sources, and despite several efforts, 7% of the HCPs had not received information at all [57,58]. A method for evaluating information reach might be a potential solution to this issue.

A more effective process for communication about delays could also have been beneficial. HCPs in other settings have requested more detailed information and more involvement in implementation [57]. More and timelier information about the service is thus a potential solution that could have mitigated some of the concerns.

Follow-up also seems to have been limited, which could have contributed to the concerns. According to the CFIR, reflection and evaluation are essential implementation activities [23]. More continuous discussions about the implementation of PAEHRs could have supported the implementation.

How the PAEHR system was introduced to patients was also unclear and could be related to the fragmented communication. There are reports of patient involvement in the development of the PAEHR system, but these efforts were minimal during regional implementation [7]. Better implementation activities for patients in terms of support and education in a more structured manner might mitigate HCPs' concerns about the potential negative effects on patients. There is also an indication that education might support patient use [59], and it has been recommended by experts [32]. The involvement of both HCPs and patients has been identified as an essential factor for successfully implementing PAEHRs [7]. A clearer and comprehensive implementation process for both HCPs and patients is a potential solution to these barriers.

Facilitators for the Implementation of PAEHRs

The HCPs acknowledged some system flexibility related to communication between HCPs, information blocking, and access to incomplete records, which could be potential facilitators. Flexibility is an influential intervention characteristic according to the CFIR, and further development of flexible software solutions enabling HCPs to closely monitor and control ORA could further facilitate acceptance and implementation.

The HCPs did report some existing structures and support for documentation, potentially facilitating implementation. The fact that there was some structure for communication with patients about their health care and some structure for documentation could have facilitated the implementation of ORA. By further strengthening these existing structures, perceived issues could potentially be mitigated and implementation could be facilitated. Outlining them could also be part of a readiness assessment of the inner setting.

Prior patient engagement could have fostered the perceived advantage of PAEHRs in supporting collaboration and patient engagement. The additional information channel provided by the PAEHR system might have been a facilitator since conventional channels have been proven inadequate [57].

The PAEHR system might also be a potential solution to some of the issues HCPs experience with patients. As highlighted by some HCPs, ORA can increase understanding and trust, and reduce workload. Moreover, HCPs have reported increased support in their working environment in patient interactions due to PAEHRs [16]. The HCPs did describe the PAEHR system as helpful for patients, and they mentioned that it could possibly improve health care quality, which is a potential facilitator. These views are supported by patient-reported benefits of PAEHRs, such as improved patient-doctor relationships, medication adherence, and reduced anxiety [6,12]. The reasons for reading, according to HCPs, also align with patient-reported reasons for reading [18]. These perceived advantages could be used to inform HCPs and change attitudes toward the service.

The use of existing activities might have been a potential facilitator. However, complementary activities are warranted as research demonstrates the lack of reach of existing communication channels [57,58].

We found substantial ambiguity and high variation in the opinions and experiences of HCPs regarding the implementation

XSL•FO
RenderX

of ORA. HCPs' views on the ability and readiness of patients to engage with ORA and their views on the purpose and usefulness of EHRs appear to affect their perceptions of the impact (positive or negative) ORA will have on their work. This can become a barrier or facilitator to implementation, depending on what narrative dominates a specific context. Understanding this relationship is essential to adapt implementation activities and communication strategies to HCPs' experiences.

Strengths and Limitations

The recruitment of HCPs from a single PCC, which can cause center-related bias, was a limitation. The inclusion of HCPs with different professions, which can provide multiple perspectives, was a strength that reduced the risk of profession-related bias. Medical secretaries might not have the same accountability as other HCPs regarding the records, which might have influenced their views. However, since they play an essential role in the documentation process, their inclusion was a strength. While data saturation was not fully achieved, the information provided by the HCPs was rich, providing many valuable insights.

Conducting the interviews at the center might have influenced the findings from the interviews. Yet, this influence appears to be minimal, as the interviews generated a diverse set of views and opinions. Based on the qualitative nature of the study, it was not possible to determine the prevalence of the identified barriers and facilitators for ORA implementation. Further research with a quantitative study design is therefore needed.

On one hand, the use of an interviewer without an HCP background can be considered a strength since it mitigates bias toward the views of HCPs. On the other hand, there might be a loss of information and understanding due to a lack of experience in the health care setting.

Since the analysis was conducted several years after the interviews, new experiences and information might have influenced the analysis and interpretation. The analyzing author attempted to keep the analysis close to the interviews and was mindful of alternative interpretations, all while discussing uncertainties and emerging themes with the other authors, which can be considered a strength. Additionally, using the CFIR in the analysis might have mitigated some risk of bias but might have influenced the generated themes.

Implications

Health care systems can better support HCPs adopting PAEHRs, particularly in settings with limited resources and high patient loads, by addressing the barriers highlighted in this study. They could enhance EHR systems, address the challenges with the primary care setting, support patients, address HCPs' concerns and knowledge gaps, and adopt clearer and comprehensive implementation strategies. Integrating patient experiences is also essential for improving PAEHR usability and its impact on care. Future research should examine systematic approaches, such as surveys, focus groups, and co-design methods, to ensure patient voices inform ongoing development and optimization. Exploring how PAEHRs can be integrated with emerging technologies to enhance coordination, personalization, and decision support presents another important avenue for future research and policy development.

While long-term engagement strategies were not the focus of our study, our findings suggest that ongoing support is crucial. Participants emphasized the need for open dialogue, shared experiences, and organizational backing to navigate the challenges of PAEHRs. These insights point to the potential value of sustained training, peer-support mechanisms, and clear communication from leadership as part of long-term implementation efforts.

While this study focused on Sweden, its findings may be relevant to other countries implementing PAEHRs. Many of the identified challenges, such as HCP engagement, documentation practices, and patient comprehension, are common across health care systems, regardless of national policies. However, variations in regulatory frameworks, EHR infrastructure, and patient access policies may influence how these findings translate to other settings. Future research could explore how similar challenges manifest in different health care models to further understand the global applicability of PAEHR implementation strategies.

Our study also revealed that some HCPs may alter or omit certain details in their documentation due to concerns about how patients might react, potentially affecting completeness. For example, the participants mentioned avoiding sensitive terms or adjusting wording to prevent misunderstandings. While we did not specifically evaluate the impact on clinical decision-making, these changes may have implications for the accuracy and utility of records. These issues have been explored in a recent scoping review [60], which also identified this as an area that warrants further investigation to understand the potential effects on care quality.

Conclusions

This study underscores the importance of having a usable EHR system to support developments such as the implementation of ORA. It also emphasizes the importance of addressing organizational issues, such as the work environment in primary care, for optimal implementation of eHealth services such as the PAEHR system. This study also highlights the importance of HCPs' views and experiences with their patients and their perceptions and attitudes toward the intervention in the implementation of services such as patient ORA. Additionally, this study stresses the importance of effective implementation processes and communication strategies for both HCPs and patients.

In summary, issues with the EHR system and organizational shortcomings need to be addressed for optimal implementation of ORA, where both patients and HCPs benefit and risks are mitigated. Furthermore, improved information and education for patients and HCPs are potential solutions to address many of the concerns and perceived disadvantages of implementing PAEHRs.

Abstract

Background: The European Union's General Data Protection Regulation (GDPR) has profoundly influenced health data management, with significant implications for clinical data warehouses (CDWs). In 2021, France pioneered a national framework for GDPR-compliant CDW implementation, established by its data protection authority (Commission Nationale de l'Informatique et des Libertés). This framework provides detailed guidelines for health care institutions, offering a unique opportunity to assess practical GDPR implementation in health data management.

Objective: This study evaluates the real-world applicability of France's CDW framework through its implementation at a major university hospital. It identifies practical challenges for its implementation by health institutions and proposes adaptations relevant to regulatory authorities in order to facilitate research in secondary use data domains.

Methods: A systematic assessment was conducted in May 2023 at the University Hospital of Rennes, which manages data for over 2 million patients through the eHOP CDW system. The evaluation examined 116 criteria across 13 categories using a dual-assessment approach validated by information security and data protection officers. Compliance was rated as met, unmet, or not applicable, with criteria classified as software-related (n=25) or institution-related (n=91).

Results: Software-related criteria showed 60% (n=15) compliance, with 28% (n=7) noncompliant or partially compliant and 12% (n=3) not applicable. Institution-related criteria achieved 72% (n=28) compliance for security requirements. Key challenges included managing genetic data, implementing automated archiving, and controlling data exports. The findings revealed effective privacy protection measures but also highlighted areas requiring regulatory adjustments to better support research.

Conclusions: This first empirical assessment of a national CDW compliance framework offers valuable insights for health care institutions implementing GDPR requirements. While the framework establishes robust privacy protections, certain provisions may overly constrain research activities. The study identifies opportunities for framework evolution, balancing data protection with research imperatives.

Introduction

Health data, once primarily recorded on paper, are now predominantly digital worldwide. The rise of artificial intelligence (AI) methods has amplified the value of these digital data across academic and industrial sectors globally. Countries around the world, including France, the United Kingdom, Germany, and the United States, are implementing strategies to structure, secure, and ethically process these data. For instance, the United Kingdom's NHS Digital and Germany's medical data initiatives are designed to centralize and facilitate data sharing, thereby stimulating research and innovation, particularly in AI algorithm development [1-3].

In the European Union, the European Health Data Space (EHDS) initiative aims to create a unified framework for health data access and exchange across member states. The EHDS will empower individuals by giving them greater control over their electronic personal health data and will support the reuse of

XSL•FO
RenderX

these data for research, innovation, and policy-making, fostering a genuine single market for electronic health record systems and AI-based health technologies [4,5].

Similarly, France's Health Data Hub centralizes health data to promote research and innovation, emphasizing the critical role played by clinical data warehouses (CDWs), particularly those within hospitals. These CDWs compile data generated during care for reuse, which is essential for achieving the ambitious goals set by these data strategies [6,7]. This approach is encouraged by public authorities, as evidenced by specific calls for projects in 2022 and 2023 [8]. The national ambition is to have large datasets to support extensive research projects. The University Hospital of Rennes, with its eHOP CDW [9], is a pioneer and has extended its use to other institutions [10].

However, these data, as personally identifiable information (PII), are subject to strict regulations, including the General Data Protection Regulation (GDPR) [11] and the French Data Protection Act (Loi Informatique et Libertés) [12]. Additionally, in 2021, the French data protection authority (Commission Nationale de l'Informatique et des Libertés; CNIL) published a specific framework for the processing of PII in the creation of CDWs [13], referred to as the CDW framework in this paper. While this regulatory framework ensures data security, it is also cumbersome to implement. Compliance with these stringent regulations is both a prerequisite and a necessity, but it poses significant challenges in practical application.

The aim of the GDPR is to protect citizens' privacy in the context of widespread digitization while facilitating the circulation of data. It emphasizes transparency in processing health data and enhances patients' control over their use, which are widely regarded as positive steps. However, the recent literature underscores several challenges in applying GDPR to the reuse of health data for research. It is often perceived as a barrier to data sharing due to burdensome administrative procedures [14-16] and strict requirements for preventing reidentification of individuals [15]. Moreover, discrepancies in interpretation among European Union member states lead to inconsistencies between national regulations, particularly in balancing privacy and solidarity [14,17]. Such disparities complicate the coordination of international research projects [14-18]. A survey conducted across 28 European countries found a slight preference among patients for direct control over their data rather than delegation to a scientific authority [18].

Proposals for implementing CDWs with privacy and security measures by design have been advanced in Ireland [19]. These include deidentification processes, stringent access controls, safeguards against cyberattacks, regulatory compliance, and governance structures defining authorized users and use parameters. However, these proposals remain theoretical and lack national-level recommendations. In France, the implementation of CDWs must align with the CNIL CDW framework, which sets rigorous standards to ensure GDPR compliance while enabling the seamless reuse of health data in a competitive environment.

To date, no other country has established comprehensive guidelines for CDW implementation, nor has any published an evaluation of the practical application of such measures. This paper addresses this gap by sharing insights from the deployment of the eHOP CDW in university hospitals (Centre Hospitalier Universitaire) across Western France.

The objective of this study is to assess the applicability of this pioneering framework. The evaluation criterion is the level of compliance of the eHOP CDW with the CNIL CDW framework. For requirements where compliance proves challenging, we propose adjustments for consideration by national authorities. This paper first outlines the defining features of CDWs and the regulatory requirements stemming from GDPR and the French Data Protection Act. It then introduces the CNIL CDW framework and the methodology for compliance assessment. Finally, we discuss the applicability of certain requirements in light of research challenges and propose alternative measures to facilitate the implementation of CDWs in health care institutions.

Methods

Ethical Considerations

The research reported in the paper was not a study on human participants, and no treatment of personal data was carried out during the research. The European GDPR does not apply to this research. The eHOP data warehouse was authorized by the French data protection authority (CNIL). Deliberation 2020-028 of February 27, 2020, authorized the University Hospital of Rennes to implement personal data processing for the purpose of a health data warehouse called "eHOP Rennes," ensuring respect of patients' information and rights.

Clinical Data Warehouses

A CDW is a repository of large health data already collected elsewhere, consolidated into a single database for reuse in various treatments whose purposes are not known in advance and differ from the initial purpose of collection. These data are stored for a long period.

The hospital CDW centralizes all health data from patients who visited the institution by extracting information from the hospital information system. The CDW is based on a robust technical architecture and an adapted data model, ensuring the reliability and relevance of the stored information. Before any use, the data undergo integration steps including pseudonymization, standardization, and validation.

To exploit the CDW, it is equipped with secure tools for targeting study populations, multicriteria queries, and data visualization. For each study, specific datasets called datamarts are generated.

Each CDW operates under a robust governance structure and strict access policies to ensure the security and ethical use of health data. In this study, we examine the eHOP CDW as a representative example. The development and implementation of eHOP CDW are the results of a collaborative effort between the University Hospital of Rennes, Institut National de la Santé et de la Recherche Médicale UMR 1099, and Enovacom, a subsidiary of the company Orange Healthcare, which specializes in digital health care solutions.

XSL•FO
RenderX

The deployment and maintenance of the eHOP CDW are managed by a dedicated team within each hospital. This multidisciplinary team comprises medical IT specialists, IT engineers, data scientists, and a data protection officer (DPO), ensuring compliance with data protection regulations and operational effectiveness. As of December 2024, the eHOP CDW at the University Hospital of Rennes holds health information on 2 million patients, represented across 167 million documents and including 1.3 billion data elements.

Current Regulations

The GDPR governs the processing of personal data belonging to European citizens. Adopted in 2016, it replaced European Directive 95/46/EC [20] to address the challenges posed by emerging digital technologies. While directly applicable in all European Union member states, the regulation allows some flexibility for the introduction of supplementary national provisions. Citizens' rights have been strengthened, particularly in terms of information and transparency regarding the processing of their personal data. New rights have also been introduced, such as the right to be forgotten (also referred to as the right to erasure).

The GDPR introduces key concepts such as "accountability" and "privacy by design," aimed at increasing the accountability of stakeholders and ensuring that privacy is considered from the earliest stages of data processing operations. It also requires data controllers to conduct a Data Protection Impact Assessment for high-risk processing operations. The regulation is built on 6 fundamental principles: lawfulness and transparency, explicit and legitimate purposes, data minimization (proportionality), storage period limitation, accuracy, and security—particularly confidentiality and integrity during data processing.

The French Data Protection Act (Loi Informatique et Libertés) has been amended to align with the GDPR and introduces specific provisions for processing health data, particularly in the context of research, study, or evaluation in the health field [21]. To simplify procedures, it includes reference methodologies such as MR004, which applies to studies not involving human participants [22]. It also provides reference frameworks for data controllers, offering them legal certainty in their operations. Additionally, the French National Commission for Data Protection and Liberties (CNIL) has issued guidelines for the creation and management of health data warehouses.

These guidelines define the legal and technical framework applicable to CDWs, establishing a trusted environment for the reuse of health data. They specify authorized purposes, governance principles, data categories to be processed, required security measures, and conditions for the use of CDW data in health-related research [23].

In 2022, the CNIL enhanced its recommendations by publishing a compliance checklist [24], which includes 116 criteria addressing 108 requirements. These criteria are grouped into 13 categories, with a particular focus on security and patient rights. Specifically, 56 (48.3%) criteria, representing nearly half, pertain to security measures, while 23 (19.8%) criteria focus on patient information and rights.

Evaluation Process

Once the CDW framework was published, an exchange was initiated between institutions and the CNIL to clarify the measures required for compliance with the framework's specifications. This process aimed to minimize the risk of misinterpretation.

In May 2023, we conducted an evaluation of the CDC's compliance at the University Hospital of Rennes with the CNIL framework. The framework's requirements were categorized into 2 groups: those related to the eHOP software and those pertaining to the health institution's implementation processes. Each criterion in the compliance checklist was assessed using 1 of 3 possible values: true, false, or not applicable. A criterion was deemed not applicable if the functionality addressed by the criterion was not present in the eHOP software (eg, manual CDW feeding). A criterion was marked true if appropriate measures were implemented to meet the requirement; otherwise, it was marked false.

The value assigned to each criterion was determined by consensus between 2 assessors. For criteria where consensus could not be reached, the information security officer (ISO) and the DPO of the University Hospital of Rennes reviewed the assessment. Their input provided the definitive evaluation for those criteria. Once all criteria were assessed, final validation was conducted by both the ISO and the DPO.

This approach enabled the identification of discrepancies with the CDW framework and the determination of the overall compliance level of the CDW. Results were presented by category and expressed as the number and percentage of criteria that were not applicable, met, or not met. The overall compliance level was calculated based on all applicable criteria.

Results

Evaluation of Criteria Relevant to the eHOP Software

Overview

Of the 116 criteria in the CDW framework, 25 were identified as relevant to the eHOP software (Tables 1 and 2), representing 22% (n=25) of the criteria. Compliance with the framework was 68% (n=15).

The results are presented in Table 2. In total, 3 of these 25 (12%) criteria were deemed not applicable to our implementation context. A total of 15 (60%) criteria were judged compliant, such as those concerning the storage of directly identifiable data in a separate space and those concerning user profiles, and 7 (28%) criteria were considered noncompliant or partially compliant and were subject to an action plan.

Table . Compliance of criteria relevant to eHOP software on May 5, 2023.

Number	Criterion	Compliance
5.2.1.1	Directly identifiable data mentioned in 5.2.1.1 are stored separately from other data	Yes
6.2	Access and use of identifiable data restricted to authorized persons for patient recontact and rights exercise	Yes
7.1 to 7.3	Data retention periods	No
7.4	Deletion or anonymization of data beyond the retention period	No
9.6	Rights of individuals: mechanism when there are no identifiable data or correspondence tables	N/A[a]
9.7	Exercise of the right to object possible permanently	Yes
10. Security		
SEC-LOG-5	Separation of profiles for access to identifiable and pseudonymized data	Yes
SEC-LOG-6.1	Separate encryption for genetic data and location data from other data	No
SEC-LOG-6.2	Encryption key for genetic data and location data accessible only by a data manager profile	No
SEC-ALI-2	Strong authentication for manual feeding of the clinical data warehouse from data entry software	N/A
SEC-PSE-1.1 to SEC-PSE-1.4	Pseudonymization of patients' personal data	Yes
SEC-PSE-2	New pseudonymization of already pseudonymized data	Yes
SEC-PSE-3	Pseudonymization of personal data collected from health care professionals	N/A
SEC-PSE-4	Deidentification of unstructured documents	Partially
SEC-HAB-1	Different authorization profiles are provided to manage access to data as needed and exclusively	Yes
SEC-HAB-2	Granularity of access (aggregated data, pseudonymized data, directly identifiable data)	Yes
SEC-ESP-2.1	Data minimization in study datamarts	Yes
SEC-ESP-2.2	Random generation of pseudonyms for each study	Yes
SEC-ESP-3	For cohort follow-up, the same unique pseudonym can be reused across multiple workspaces	Yes
SC-JOU-1	User action logging	Yes

[a]N/A: not applicable.

Nonapplicable Criteria

The nonapplicable criteria were as follows:

- Criterion 9.6: Linkage tables enabling patient reidentification eliminate the need for additional mechanisms to respect rights. In the absence of these tables, the warehouse could be queried based on information provided by a patient to respond to their rights requests.
- Criterion 10 SEC-ALI-2: The absence of a manual feeding modality for the CDW means that no specific authentication mechanism is implemented.
- Criterion SEC-PSE-3: No PII concerning health care professionals is collected in a structured form.

Compliant Criteria

The eHOP CDW database is divided into multiple segregated databases, ensuring that identifying data are stored separately from medical data, in compliance with requirement 5.2.1.1 of the framework

Access rights management is based on several predefined profiles, categorized as manager and user profiles, in alignment with SEC-HAB-1 and SEC-HAB-2 requirements. The data

XSL•FO
RenderX

manager profile is responsible for managing data flows from the hospital information system's source software to the CDW, integrating data, and ensuring database quality. The study manager profile allows for the creation of datamarts for specific studies without initially including any data and manages access rights. This profile has no direct access to the CDW data. The datamart manager profile enables querying the entire CDW, except for identifying data. This user populates the datamart with query results and ensures compliance with the SEC-ESP-2.1 minimization principle by selecting only the categories of documents and information strictly necessary for the study.

User profiles are divided into 3 levels with varying access permissions. They access only data of the study datamart. Level 1 users are limited to accessing aggregated statistics; they can query the database and retrieve aggregated results but cannot view individual patient information. Level 2 users inherit level 1 permissions and can access pseudonymized documents and individual data. Level 3 users are granted access to identifying data only under exceptional circumstances, such as for pharmacovigilance professionals performing regulatory tasks. A specialized recontact manager profile has been created to meet requirements 6.2 and SEC-LOG-5. This profile allows access to a datamart's patient list for recontact purposes. Authorized individuals with this profile cannot directly access identifying data but can activate the patient list generation function for specific studies.

The exercise of data participants' rights is governed by institutional procedures and facilitated by a dedicated module within the eHOP CDW for managing opposition. The Medical Information Department centrally collects opposition data, which is recorded in the patient-identifying database. Rather than maintaining a "blacklist," the system automatically excludes data from patients who have expressed opposition during the creation of datamarts, in compliance with paragraph 9.6 of the CDW framework.

Pseudonymization is performed during data integration into the CDW using a collision-free function that generates 20-byte random identifiers for patients, hospital stays, and documents. Correspondence with hospital information system identifiers is securely stored in a protected area. For each study, new pseudonyms are generated, and their correspondence with CDW identifiers is stored separately from the datamarts. All datamarts within a study share the same pseudonyms, ensuring compliance with SEC-PSE-1, SEC-PSE-2, SEC-ESP-2, and SEC-ESP-3 requirements.

Deidentification of unstructured documents is an area of ongoing improvement. Patient data deidentification has been effective since the warehouse's inception, while health care professionals' data are deidentified using external public databases. However, current processing times are incompatible with real-time integration of medical documents. As a result, health care professionals' data are deidentified only in datamarts. A new algorithm, developed using machine learning methods, shows promising performance, with *F* scores ranging from 0.96 to 0.99 in initial evaluations. Its integration into the CDW would enable full compliance with the SEC-PSE-4 requirement. Access traceability is ensured through a robust logging system, with all access logs securely maintained.

Partially Compliant Criterion

The partially compliant criterion was as follows:

- Criterion SEC-PSE-4: The pseudonymization of health care professionals' data in unstructured documents was not fully deployed due to incompatible processing times with real-time data integration into the CDW. However, this procedure is applied to study datamarts before making them available to users. A solution has been provided since May 2023.

Noncompliant Criteria

The noncompliant criteria were as follows:

- Criteria 7.1 to 7.3: Data retention periods are not yet managed in the eHOP software.
- Criteria SEC-LOG-6.1 and SEC-LOG-6.2: Implementing the functionality for encrypting and decrypting genetic data proves complex during analysis, as it requires a specific technical procedure and adapted organizational measures.

Evaluation of Criteria Relevant to Institutions

Overview

Among the 116 criteria outlined in the CDW framework, 91 (78%) are under the direct responsibility of health care institutions. These criteria encompass a range of domains, including governance, patient information, individuals' rights, and data security.

CDW Governance

Each institution is responsible for implementing the governance of its CDW. For instance, the University Hospital of Rennes has established governance structures such as the steering committee (comité de pilotage) and the scientific and ethical council (conseil scientifique et éthique [CSE]). The comité de pilotage determines scientific and ethical orientations and connects with other institutional bodies. The CSE provides opinions on projects requiring the use of CDW data.

Patient Information

The University Hospital of Rennes provides general, individual, and collective information regarding the reuse of care data for research and the implementation of the CDW through systematic notes given to patients upon their visit, posters, the welcome booklet, and the institution's website. Additionally, the University Hospital of Rennes has collectively informed the public through press releases and awareness campaigns.

For each study based on the CDW, a note complying with Article 14 of the GDPR is posted on the institution's website. For patients not informed about the reuse of their data and who have not revisited the institution since the CDW activation, a request for derogation from individual information was submitted to the CNIL. This derogation is required for studies involving large volumes of data where individual information is too complex and resource-intensive to implement.

XSL•FO
RenderX

Patient Rights

A procedure is in place to allow patients to exercise their rights. The health institution responsible for processing provides the patient with a contact point mentioned in the information note, usually the DPO. Existing procedures adopted by the institution to allow patients to exercise their rights of access and rectification of their health data are applied.

The exercise of the right to erasure (right to be forgotten) and the right to object is managed by a specific software module for managing oppositions. Once the opposition is registered, the data are flagged in the system, ensuring that they are not used in future studies. The right to erasure is treated similarly to the right to object. Patients can exercise these rights at any time.

For studies using the CDW, correspondence tables have been created to link patients' identity data with respective studies. Thus, any unexercised right to opposition can still be applied, provided it does not compromise the study's objectives under Article 21 of the GDPR. These guidelines regarding patient information and rights have been communicated to other institutions.

Security

Security requirements account for nearly half of the criteria outlined in the CDW framework. Of these, only 17 criteria are directly related to the eHOP software. For the remaining criteria, the responsibility for implementing the necessary measures to ensure compliance lies with the institution. As of May 5, 2023, 28 (72%) security criteria were deemed compliant, 3 (8%) were considered nonapplicable, and 8 (20%) were found to be noncompliant (Table 3). The overall compliance rate for security requirements stands at 77%.

Table . Criteria relevant to the institution's information system evaluated as nonapplicable or noncompliant on May 5, 2023.

Number	Criterion	Compliance
SEC-EXP-4	Anonymous reporting of management indicators according to G29 criteria; otherwise, a reidentification risk analysis.	N/A[a]
SEC-EXP-5	Monitoring of indicator exports.	N/A
SEC-SEN-3.2	Agreement established if workstations are not under the responsibility of the controller.	N/A
SEC-ESP-1	Warehouse data are handled by researchers only in internal workspaces dedicated to each research project, isolated from the warehouse database and each other.	Partially
SEC-AUT-1.1	Access to personal data requires strong multifactor authentication.	No
SEC-AUT-2	Strong authentication for internal and external access.	No
SEC-EXP-1	Data exports outside the CDW or workspaces only if anonymized according to G29 criteria. This conformity must be documented. Otherwise, a reidentification risk analysis must be conducted and documented.	No
SEC-EXP-3.1	Exports are monitored automatically or manually by a specialized operator to verify anonymity.	No
SEC-EXP-3.2	If monitoring is automatic, noncompliant exports are flagged, quarantined, and manually verified by a trained and authorized individual.	No
SEC-JOU-2	System and network administrator access requires strong authentication and detailed access traceability, for example, using an admin bastion.	No
SEC-JOU-3	Regular control of logs, at least bimonthly, and at the end of each authorization period by an automatic monitoring solution with alert processing by an authorized operator or semiautomatic control with a manual review of abnormal logs.	No

[a]N/A: not applicable.

Nonapplicable Criteria

The nonapplicable criteria were as follows:

- Criteria SEC-EXP-4 and SEC-EXP-5: As of now, there are no dashboards for monitoring accessible from the CDW implemented at the University Hospital of Rennes.

XSL•FO
RenderX

- Criterion SEC-SEN-3.2: Workstations allowing access to the CDW at the University Hospital of Rennes are under the institution's responsibility.

Partially Compliant Criterion

The partially compliant criterion was as follows:

- Criterion SEC-ESP-1: Considered partially compliant, this criterion is verified for data exploitation via the eHOP interface. Each datamart is isolated, and analyses are conducted on a secure server with controlled access. To fully comply, digital workspaces specific to each study with necessary processing and analysis tools need to be implemented for datamart exploitation.

Noncompliant Criteria

The noncompliant criteria were as follows:

- Criteria SEC-AUT-1.1 and SEC-AUT-2: Strong authentication was implemented in October 2023 after evaluation. This authentication concerns internal access within the institution. No external access is planned.
- Criterion SEC-EXP-1: Most studies result in publication; thus, users commit to publishing only anonymized data. They must verify the anonymity of exported results. The action plan includes revising the CDW use charter to specify this point and drafting a best practice guide for ensuring anonymity. The CSE will also verify that study protocols detail the content of the results.
- Criteria SEC-EXP-3.1 and SEC-EXP-3.2: Individual data exports are performed by CDW experts. Currently, only CDW experts conduct analyses within the CDW environment. Users commit to exporting only anonymized data.
- Criterion SEC-JOU-2: Compliance is planned.
- Criterion SEC-JOU-3: Specific alerts for the CDW have been configured since May 2023. Tools implemented by the institution, in accordance with its security policy, cover the CDW environment.

Discussion

Principal Findings

The framework, which is aligned with the GDPR, necessitates substantial technological and organizational adaptations to ensure compliance. Our findings highlight both the benefits and challenges associated with its implementation, offering a comprehensive perspective on its impact on CDWs.

In this discussion, we explore the study's contributions and limitations along with the areas for improvement identified within the CDW framework. Finally, we propose measures to facilitate research projects using CDW data. These recommendations could guide regulatory authorities in future framework developments.

Contributions and Limitations of the Study

This study is the first to evaluate the application of the CDW framework in a real-world setting within French university hospitals. The results were obtained through a rigorous evaluation process, involving dual assessments and consensus-building for all criteria. The findings were further validated by the ISO and the DPO of the University Hospital of Rennes. The proposed adjustments are grounded in practical and actionable solutions.

Our findings provide institutions with concrete insights into the challenges they face, the steps they can take to address these challenges, and potential regulatory adjustments. National authorities gain valuable field-based feedback and specific recommendations for refining the framework. Moreover, the compliance checklist proves to be an effective tool for monitoring privacy measures and could support future labeling or certification processes for CDWs.

However, the study has certain limitations. It focuses on a single institution in the French Great Western region and a single CDW technology. To generalize these findings, further studies involving diverse institutions and CDW solutions are necessary. Such studies would help uncover additional enablers and barriers to the application of the framework's criteria.

In terms of methodology, we initially considered using a validated evaluation grid to assess the applicability of the CNIL framework. However, this approach was not adopted due to its potential for introducing bias. The CNIL framework was published after the CDW's implementation, and a prior consultation phase with the CNIL had already defined the necessary compliance measures. Consequently, applying a retrospective evaluation grid would have been inconsistent with the timeline of the framework's release. Instead, we opted for a descriptive approach, which effectively highlights barriers to compliance and enables the proposal of tailored, practical alternatives.

Weaknesses of the Framework and Proposed Adjustments

Using CDW data for research requires balancing the advancement of scientific knowledge to improve patient care with the imperative to protect patient privacy. The framework imposes stringent data protection requirements, which, while essential, can hinder research efforts due to their complexity and associated costs. Our study has identified several key obstacles to the optimal use of CDW data for research purposes.

To address these challenges, regulatory adaptations could help streamline the implementation of research projects. We propose adjustments to the framework that aim to facilitate the efficient and compliant conduct of research studies and projects.

Regarding Data Categories

Vital Status and Date of Death

The framework permits the collection of this information solely from medical records, which limits the CDW to recording only hospital deaths. However, the French National Institute of Statistics and Economic Studies provides a comprehensive database of deceased individuals. Several matching algorithms have been developed to use these data effectively [25-28]. Integrating French National Institute of Statistics and Economic Studies data into the CDW could address this limitation, particularly as these data are publicly available and the matching algorithms have demonstrated satisfactory performance.

XSL•FO
RenderX

Genetic Data

According to the CNIL, variants and mutations are classified as genetic data. The CDW framework mandates their specific encryption, which complicates their reuse despite their critical importance for personalized medicine. These data often appear in diverse document types, such as genetic reports or hospitalization records, making them challenging to isolate. We recommend limiting this encryption requirement to sequencing data exclusively, as this would simplify their management and reuse while maintaining compliance with the framework.

Regarding Security Requirements

Some of the framework's security requirements are already part of hospitals' cybersecurity plans (eg, network flow segmentation, user awareness, alert setup, incident handling, and access review) [29,30]. Thus, the increasing investment of institutions in their cybersecurity should allow compliance, provided that substantial financial support is provided.

Pseudonymization is a major framework measure ensuring data confidentiality. However, this procedure does not ease regulatory steps, as pseudonymized data cannot be considered anonymous according to the European Data Protection Board [31]. Some authors argue that medical data anonymization is almost impossible [32,33], and the recommended anonymization methods are complex to implement [33]. Moreover, anonymity leads to information loss, potentially making an AI model less relevant. Greene et al [34] propose evaluating anonymity case-by-case, considering contextual factors, especially other data sources available to the user that may link back to the patient's identity. A reidentification risk analysis, as proposed by the Health Data Hub [35], could be conducted for CDW studies by the implementation manager. If the reidentification risk is deemed minimal for a study, individual patient information could be considered nonmandatory.

The framework stipulates that only anonymized data exports are permitted. However, in research using multisource data, pseudonymized individual data exports to secure data processing platforms should be possible. The crucial point is that this environment meets security requirements. We recommend explicitly stating this possibility in the framework.

Verifying study results exported from the CDW or its workspace in aggregate form by a specialized operator seems excessive for a health care institution. Researchers' commitment to ensuring anonymity should suffice for compliance. However, they should be supported with a best practice guide on result anonymization.

Trace control by institutions can be performed through automated control systems implemented as part of their cybersecurity plans. Integrating CDW traces into such systems is feasible, but exploiting these traces by a dedicated human operator capable of handling alerts requires additional resources that most institutions currently lack.

Architecture Schematics

Sample architecture diagrams of the "information system" for the CDW, including workspaces, should be included in the framework. These examples would help institutions build their CDWs in line with CNIL expectations.

Patient Information and Rights Exercise

MR004 refers to a French reference methodology for health data research that does not involve human participants. The MR004 facilitated research project implementation by waiving new individual information for each study when initial information on data reuse for research was provided to the patient, provided a transparency portal is implemented by the institution. However, initial information on CDW implementation can be challenging to deliver in practice within hospitals. One communication means to consider is the "Mon Espace Santé" platform [36], available to all citizens since February 2022. "Mon Espace Santé" is a French digital health platform where individuals can access their health data and manage their health information. Patient information could leverage this platform, similar to how organ donation opposition is integrated into the personal health record (dossier médical partagé) [37]. However, a survey by France Assos Santé, a French patient association, found that less than 50% of the population has activated their health space [38].

Public information campaigns at national, regional, and local levels would reach most of the population [39]. Collective information through a transparency portal could then replace individual study information [39].

Exercise of Rights in CDW Studies

Current procedures allow patients to exercise their rights over integrated CDW data. However, the right to opposition and erasure for CDW studies raises questions. Once data are being analyzed, removing them seems challenging without compromising the project.

Dynamic consent and meta-consent mechanisms should be considered. Dynamic consent [40], based on transparency, allows patients to consent to each study via a dedicated platform. However, this may lead to digital divide risk and frequent patient solicitations, which could harm system acceptance, leading to default responses (consent or refusal) unrelated to the study [41].

Meta-consent [41,42] could be a more interesting solution. It involves giving prior consent to study categories based on the data nature (medical records, genomic data, etc) and research context (public or private, commercial or noncommercial, and national or international). A study by Cumyn et al [42] on meta-consent acceptability shows that the public and national nature of the processing entity, nonidentifying data, and the absence of genetic data use are factors favoring patient acceptance.

Conclusions

This study represents the first effort to evaluate the application of the CNIL CDW framework within a real-world operational context, emphasizing its alignment with GDPR requirements. While the framework significantly enhances data security and compliance, its implementation poses practical challenges and requires substantial resources. Despite the study being limited to a single institution in France, the findings are broadly

XSL•FO
RenderX

relevant, given the GDPR's overarching influence in Europe and beyond.

The insights gained from this study are particularly pertinent, as they offer valuable lessons for other European countries and international bodies aiming to implement similar frameworks. The EHDS initiative, which seeks to create a unified framework for health data access and exchange across the European Union, can benefit from the findings of this study. The challenges and proposed adjustments highlighted here can inform the development of more efficient and scalable data governance frameworks that balance the need for rigorous data protection with the imperatives of research and innovation.

Future research should focus on expanding the scope to include multiple institutions and various CDW technologies to generalize the results and identify further facilitators or barriers to the framework's application. Additionally, international collaborations could provide a broader perspective on best practices and innovative solutions for managing health data securely and effectively.

The importance of harmonizing data protection standards and facilitating secure data sharing cannot be overstated, especially in the context of global health crises like the COVID-19 pandemic. Effective data governance frameworks, such as the CDW framework evaluated in this study, are crucial for enabling the rapid and secure exchange of health data, which is essential for timely public health responses and ongoing medical research.

In summary, while the CDW framework provides a robust foundation for data security and compliance, its practical implementation requires careful consideration of the challenges identified in this study. By addressing these issues and fostering international cooperation, we can enhance the utility of health data warehouses, thereby supporting advancements in health care research and ultimately improving patient outcomes across the globe.

Acknowledgments

The authors thank the jurists and the technical experts of the French Data Protection Authority (Commission Nationale de l'Informatique et des Libertés) for their advice. The authors remain solely responsible for the results of the conformity assessment to clinical data warehouse framework and the proposals for development. This research was funded by Agence Nationale de la Recherche (grant ANR-22PESN-0006). The funding body had no role in the design of the study, the collection, analysis, and interpretation of data, or in writing the manuscript. The sponsors were not involved in the study design, data collection, analysis, and interpretation, manuscript preparation, or the decision to submit the manuscript for publication.

Authors' Contributions

CR conceptualized the study, developed the methodology, and wrote the original draft of the manuscript. MEA contributed to the data collection, analysis, and interpretation. GC, AH, and EG provided critical revisions and approved the final version of the manuscript. MC supervised the project study. All authors reviewed and approved the manuscript for publication.

Abstract

Background: The diagnosis of sleep disorders presents a challenging landscape, characterized by the complex nature of their assessment and the often divergent views between objective clinical assessment and subjective patient experience. This study explores the interplay between these perspectives, focusing on the variability of individual perceptions of sleep quality and latency.

Objective: Our primary goal was to investigate the alignment, or lack thereof, between subjective experiences and objective measures in the assessment of sleep disorders.

Methods: To study this, we developed an aspect-based sentiment analysis method for clinical narratives: using large language models (Falcon 40B and Mixtral 8X7B), we are identifying entity groups of 3 aspects related to sleep behavior (day sleepiness, sleep quality, and fatigue). To phrases referring to these aspects, we are assigning sentiment values between 0 and 1 using a BERT-BiLSTM–based approach (accuracy 78%) and a fine-tuned GPT-2 sentiment classifier (accuracy 87%).

Results: In a cohort of 100 patients with complete subjective (Karolinska Sleepiness Scale [KSS]) and objective (Multiple Sleep Latency Test [MSLT]) assessments, approximately 15% exhibited notable discrepancies between perceived and measured levels of daytime sleepiness. A paired-sample *t* test comparing KSS scores to MSLT latencies approached statistical significance (t_{99}=2.456; *P*=.06), suggesting a potential misalignment between subjective reports and physiological markers. In contrast, the comparison using text-derived sentiment scores revealed a statistically significant divergence (t_{99}=2.324; *P*=.047), indicating that clinical narratives may more reliably capture discrepancies in sleepiness perception. These results underscore the importance of integrating multiple subjective sources, with an emphasis on narrative free text, in the assessment of domains such as fatigue and daytime sleepiness—where standardized measures may not fully reflect the patient's lived experience.

Conclusions: Our method has potential in uncovering critical insights into patient self-perception versus clinical evaluations, which enables clinicians to identify patients requiring objective verification of self-reported symptoms.

Introduction

Overview

The interplay between sleep quality, daytime fatigue, and daytime sleepiness is critical for understanding and diagnosing sleep disorders. Sleep quality—a multifaceted concept encompassing depth, continuity, and restorative nature of sleep [1]—is commonly assessed through polysomnography (PSG) or questionnaires [2]. Daytime fatigue significantly impacts quality of life [3], while daytime sleepiness reflects the propensity for unintended sleep episodes.

Past studies have shown inconsistencies between subjective experiences and objective measures. For example, Zavecz et al [4] linked self-reported sleep quality to cognitive performance, while O'Donnell et al [5] reported poor alignment between PSG outcomes and patient-reported sleep quality. Similarly, Aurora et al [6] analyzed how well Epworth Sleepiness Scale (ESS)

XSL•FO
RenderX

scores correspond to Multiple Sleep Latency Test (MSLT) values. In psychiatric populations, similar dissociations have been reported between perceived and physiologically measured fatigue, as demonstrated by Stanyte et al [7] who found that individuals with anxiety and mood disorders often exhibit mismatched subjective fatigue ratings and objective sleep parameters.

Critically, objective metrics such as sleep onset latency (SOL) and total sleep time (TST) require disorder-contextual interpretation. Valko et al [8] demonstrate that shortened SOL indicates pathological sleep-wake fragmentation in narcolepsy but signifies health in normal sleepers, while subjectively prolonged SOL in insomnia reflects hyperarousal despite normal PSG. Similarly, fatigue—though quantifiable via scales such as the Fatigue Severity Scale (FSS)—lacks consistent PSG correlates across disorders, complicating objectification[9].

Despite these assessments being routinely documented clinically, no study has leveraged real-world clinical records to analyze subjective-objective alignment across disorders.

To address this gap, we propose a novel natural language processing (NLP) framework for modeling subjective-objective alignment through aspect-based sentiment analysis. Our system extracts (1) patient-reported experiences, (2) objective test results (eg, MSLT and PSG), and (3) clinician commentary on alignment or mismatch between the two. This triadic analysis allows for identifying patterns of misperception—for instance, patients who perceive severe sleep onset problems despite normal PSG values.

Unlike prior work that focused on isolated biomarkers such as Apnea-Hypopnea Index (AHI) or ESS scores, our approach uses language models to extract detailed clinical reasoning from documentation. This allows identification of emerging “sleep-wake discrepancy” phenotypes, such as patients with objectively normal sleep but persistently poor subjective reports.

Sentiment Analysis in Clinical Text

Sentiment analysis in medical and clinical text has received increasing attention over the past decade [10,11]. Clinical documents often contain detailed descriptions of a patient’s health status, including observations, diagnostic findings, and treatment plans. Analyzing this information is important for determining whether patient outcomes are improving or deteriorating, and for assessing the overall impact of a condition on the patient’s well-being. In addition to objective clinical data, patients’ self-reported experiences may also offer useful indicators that complement medical assessments.

Recent developments in pretrained language models, such as those introduced by Devlin et al [12], have enabled the use of BERT-based architectures for sentiment analysis across multiple languages and granularities. In our work, we define sentiment across 5 discrete levels, which facilitates scaling into a normalized range between 0 and 1. Behera et al [13] presented a model combining Word2Vec embeddings with convolutional and recurrent layers (convolutional neural network and long short-term memory), achieving 91.2% accuracy. Their method also includes polarity normalization to improve classification performance. Other established techniques for sentiment and aspect identification in English-language texts include BiLSTM [12,14], TextCNN [15], TextRNN [16], TextRCNN [17,18], and DPCNN [19].

With the emergence of transformer-based models, research has increasingly focused on controlling language model behavior during fine-tuning, inference, and output postprocessing [20]. For example, Ziegler et al [21] applied reinforcement learning (RL) with human feedback to improve output coherence, while Schulman et al [22] proposed the Proximal Policy Optimization (PPO) algorithm for stable policy updates. Pascual et al [23] introduced Keyword2Text, a framework that guides text generation based on semantic similarity and topic constraints. These control strategies can enhance performance in tasks such as sequence labeling and sentiment classification.

Despite these advances, the use of large language models (LLMs) for aspect recognition in German clinical text remains limited. In addition, data privacy regulations restrict the use of commercial cloud-based models in health care environments. To address these challenges, our study investigates the deployment of open-source language models in secure, on-premises settings. We evaluate their performance in aspect recognition using manually annotated German clinical data. Subsequently, we apply sentiment analysis using a fine-tuned BERT model and compare its performance to a German GPT-2 model, which we adapt through supervised learning and reinforcement-based posttraining techniques.

As can be seen in Table 1, prior work has explored sentiment in clinical text [10,11], or compared ESS to MSLT [6], but none have jointly modeled aspect-level sentiment, LLM-based extraction, and alignment between subjective and objective sleep data. Our contributions include:

1. First application of aspect-based sentiment analysis to German clinical sleep data for sleep disorders.
2. Integration of LLM-based aspect extraction (Falcon 40B and Mixtral 8x7B).
3. Five-level sentiment scoring with normalization.
4. Quantified misalignment modeling between patient-reported and physiological sleep data.
5. Identification of misperception profiles at a large scale using real-world clinical records.

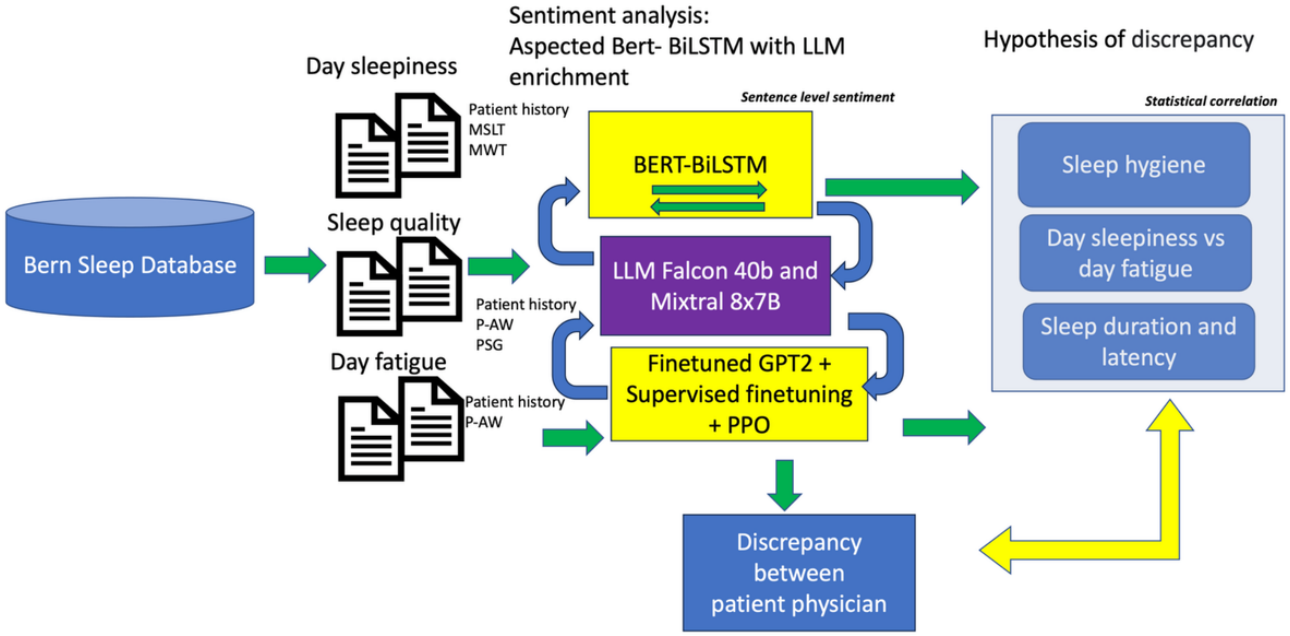
Methods

Overview



The developed pipeline for aspect-oriented sentiment analysis is shown in Figure 1. The single steps are described together with the dataset in the following. Our approach involves extracting subjective perceptions of sleep quality, daytime sleepiness, and daily fatigue from the clinical documentation. Specifically, we consider the documented patient history descriptions and the reports related to the PSG examination.

Concurrently, objective benchmarks will be gathered from numerical results in objective sources, including MSLT, MWT (Maintenance of Wakefulness Test), P-AW (Actigraphy Wrist), and parts of the PSG report.

In a first step, entities and phrases referring to our 3 aspects of interest (day sleepiness, sleep quality, and fatigue) are extracted. Once these aspects are identified, we classify them according to the sentiment expressed for each aspect separately. The next step involves calibrating the objective numerical assessments to match the subjective sentiment scores, allowing for a direct comparison between subjective and objective data. Finally, by evaluating these 2 sets of sentiment values, we statistically analyze the extent of discrepancies in the diagnosis of sleep disorders, providing insights into how patient perceptions align with clinical assessments.

Dataset

Our dataset originates from inpatient records created at the sleep laboratory of the University Hospital Bern, covering treatments between 2000 and 2021. This collection is part of the Bern Sleep Registry [25]. Its secondary use received approval from the Cantonal Ethics Committee (KEK-Nr. 2022 - 00415: "Bern Sleep Registry: the sleep disorder patient cohort of the Inselspital, University Hospital Bern").

The database comprises German-language coded clinical records of patients diagnosed with sleep disorders. Over 10,000 of these records have been retrospectively and meticulously categorized by physicians specialized in sleep disorders based on the *International Classification of Sleep Disorders, Third Edition* (*ICSD-III*). Table 2 shows the types of text documents that are considered from this database for this paper.

XSL•FO
RenderX

Table . The sentiment analysis mainly focuses on the subjective text (second column), while the objective value extractions are related to test results. Sample sizes reflect prevalence in clinical notes; fatigue records are rarer than sleep quality.

Aspect	Subjective data sources	Information sources and documents	Objective data sources	Statistics
Daytime sleepiness (129 records)	History: Daytime sleepiness, Epworth Sleepiness Scale, MSLT[a] /MWT[b] KSS[c]	History, Multiple Sleep Latency Test, Maintenance of Wakefulness Test	MSLT and MWT: eg, "In summary, a mild daytime sleepiness can be objectified," vigilance test results	• 36 (28%) of records show SOL-KSS[d] discrepancy • ESS[e] >10 correlates with MSLT latency <8 minutes (r=–0.72) • "Mild daytime sleepiness" documented in 58 (63%) of 92 cases with MSLT 5-8 min
Fatigue exhaustion depressive symptoms (450 records)	History: Fatigue, Fatigue Severity Scale, BDI-II[f]	Hist[g], P-AW[h]	Increased inactivity component	• FSS[i] >5 correlates with BDI-II >14 (r=0.68) • 189 (42%) show activity reduction • "Increased inactivity" noted in 112 (89%) of 126 severe fatigue cases
Sleep quality (3815 records)	Hist: Sleep quality, Insomnia PSG[j] Report: Estimated sleep onset Latency and sleep duration	Hist, PSG, P-AW	PSG Report: Objective sleep onset Latency and sleep duration, sleep efficiency (¡ 80%: reduced). Actigraphy Report: Actimetric sleep efficiency	• 2557 (67%) underestimate TST[k] (mean diff: –73 min) • SE <80% in 82%[l] of insomnia diagnosis • "Reduced efficiency" documented in 94%[m] of SE<75% cases

For various validations, we have prepared the following manually annotated datasets to validate and fine-tune the pretrained model:

1. Aspect extraction benchmark: 150 sentences manually labeled to validate entity and aspect extraction performance.
2. Sentiment analysis corpus: 2000 sentences annotated on a 5-point sentiment scale using on-premises LLMs (Falcon 40B [26,27] and Mixtral 8x7B [28]), with human-in-the-loop correction.

The 2000 sentences were sampled from clinical documents belonging to 100 unique patients, spanning multiple sleep disorder categories. These sentences were drawn proportionally from patient histories, diagnostic summaries, and follow-up reports to ensure a representative mix across conditions and report types. Stratified sampling was used to balance diagnoses, age groups, and sentiment distribution. To avoid patient-level bias, no more than 10 sentences per patient were included in the annotated set.

To ensure robust analysis of subjective-objective alignment in daytime sleepiness, we included only those patients who had complete paired data for the following instruments: Karolinska Sleepiness Scale (KSS)—subjective measure, MSLT—objective physiological measure, and MWT—behavioral sleepiness measure. This resulted in a final cohort of 100 patients with complete records across all 3 modalities, allowing for valid

XSL•FO
RenderX

computation of discrepancy and misperception scores. For other dimensions, such as fatigue and sleep quality, which currently lack standardized objective clinical benchmarks, we retained a broader set of records (eg, 3815 entries for sleep quality) to support exploratory sentiment-based analysis.

Aspect and Sentiment Distribution

To analyze sentiment by aspect, we annotated 50 representative sentences per aspect totaling 150 sentences. Table 3 summarizes the frequency of extracted entity groups by category, while Table 4 presents the sentiment annotations and related statistics.

Table . Aspect benchmark statistics regarding sleep quality, daytime sleepiness, fatigue, and the entire corpus.

Aspects	List of entity groups	Entity count
Sleep quality (50 sentences)	Sleep quality, Latency, Duration, Estimation	75
Daytime sleepiness (50 sentences)	Day sleepiness, Latency, PVT (Vigilance test), ESS[a]/KSS[b]	35
Fatigue (50 sentences)	Fatigue Severity Scale, Measurements BDI-II[c]	77
Entire benchmark (150 sentences)	Symptoms, Diseases, Complaints, Feedback, Measurements	119

Mathematical Description of Aspect-Based Sentiment Analysis for Sleep Disorder

In the following, we define the dataset and tasks considered in this paper.

Dataset Definition

Let the dataset be defined as:

$D=\{(x_i, A_i, y_i)|=1,...,N$

Where:

- x_i is the tokenized and embedded representation of sentence i, obtained via BERT or RoBERTa (shape: $T\times d$, where T=tokens, d=embedding dimension).
- A_i is the set of extracted aspect terms from x_i using LLMs (eg, Falcon 40B and Mixtral 8x7B).
- y_i is the discrete sentiment label $\in$ {0, 1, 2, 3, 4} representing 5-stage sentiment levels.
- The normalized score is:

XSL•FO
RenderX

si=yi4So $S_i \in [0,1]$

Aspect Extraction via LLMs

For each input sentence x_i and aspect category, for example, $c \in$ C_Categories, we define a prompt P_c and extract:

$a_i^{(c)=LLM\,(P_c,x_i)}$ for each aspect category c

The union of these yields the aspect set:

$A_i=U_c a_i^{(c)}$

To align with canonical medical terms, compute cosine similarity:

sim(e, c) = cosine(embedding(e), embedding(c))

Accept the match if sim≥threshold

Sentiment Classification (BiLSTM+Self-Attention)

1. Input embeddings
   Each x_iR is passed to a bidirectional LSTM:
   $h_i = BiLSTM\,(x_i) \in R^{T \times h}$
2. Sequential feature aggregation (concatenation or pooling):
   $f_i = Self - Attention\,(h_i) \in R^{h'}$
3. Classification layer (with softmax over 5 sentiment classes):
   Using a linear layer with parameters *W*, *b*:
   pi=softmax(W×fi+b) with y^i=argmax(pi)
   Where:

- $W \in R^{5 \times h'}$, $b \in R^5$are learnable parameters,
- $p_i \in R^5$ is the predicted class distribution.

Training Objective (Supervised Fine-Tuning: L1)

Use categorical cross-entropy for supervision:

LCE=−1N∑i=1N∑k=151yi=k·log(pi,k)

Sentiment Control via GPT-2 (L2: Reinforcement Learning)[29]

After initial fine-tuning, a GPT-2 model is trained to modify or generate text while controlling for sentiment class y_i

Logit Biasing /Reward Shaping: to

LRL=Exi^πθ[r(xi^,yi)]

Where r(xi^,yi) is a reward signal based on:

- Keyword inclusion (aspect control),
- Matching predicted sentiment from a fixed classifier with y_i

The full objective (SFT+RL) becomes:

$L_{total}=L_{CE}+\lambda \cdot L_{RL}$

where $\lambda \in [0,1]$ is a hyperparameter controlling the influence of reinforcement-based alignment.

Normalization of Subjective and Objective Measures

Min-max normalization for raw clinical scores *r* over scale [S_{min}, S_{max}]:

s=Smax−rSmax−Smin

Examples:

- Epworth Sleepiness Scale (0 - 24):
  s=24−r24
- Fatigue Severity Scale (1-7):s=7−r6
- Beck Depression Inventory II (0 - 63)
  s=63−r63
- Karolinska Sleepiness Scale (KSS) (1-9):
  s=9−KSS9−1

Aspect Extraction From Diagnostic Text

For aspect extraction, we define 4 distinct groups of clinical entities based on their frequency and contextual relevance, with the aim of analyzing discrepancies between subjective reports and objective clinical findings (see Table 2). While aggregating sentiment scores can offer a general view of polarity across different textual spans (eg, sentences or paragraphs), they are insufficient for capturing detailed sentiment variations related to specific medical aspects such as symptoms, complaints, diagnoses, or co-occurring conditions. To address this limitation, we implemented a fine-grained entity extraction approach that combines open-source LLMs with standard clinical entity recognition techniques.

Specifically, we use 2 self-hosted models: Falcon 40B [27] and Mixtral 8x7B [30]. Falcon 40B is a dense, decoder-only language model designed for a broad range of NLP tasks. Mixtral 8x7B, by contrast, follows a sparse mixture-of-experts architecture, activating 2 expert modules per token, thereby achieving a favorable balance between performance and computational efficiency. Despite having 46.7 billion parameters in total, only a subset is used at each step, making it suitable for resource-constrained environments. We evaluated Falcon 40B as a baseline but used Mixtral 8x7B for all final extractions reported here.

Aspect-level sentiment scoring is achieved by linking the extracted entities to their corresponding sentiment values within a given sentence. This allows us to compute sentiment scores that are specific to individual clinical aspects. The entity extraction process is carried out in 2 stages: (Stage 1) Aspect identification using prompt-based querying with the locally hosted Mixtral 8x7B model. Separate prompts are constructed for each category—symptoms, complaints, diagnoses, and patient feedback—to ensure focused and interpretable extraction.

To extract patient feedback entities, we design targeted natural language prompts structured to guide the model toward recognizing relevant subjective expressions. Below is a representative prompt used with the Falcon 40B model:

Prompt

You are a helpful clinical entity extractor. Given the following medical note, please extract any patient feedback or evaluative statements related to their condition, treatment experience, or overall well-being.

Text: “[Insert clinical sentence here]”

Output format: [feedback_1, feedback_2, ...]

The given prompt for entity extraction from clinical patient data can be efficiently reused by systematically substituting the target

XSL•FO
RenderX

category in the text. By iteratively inserting each category (eg, “symptoms,” “diseases,” “complaints,” and “feedback”) into the prompt, the same prompt structure can be applied multiple times to extract entities for one category at a time. This approach allows looping over the list of aspect categories and generating a valid JSON object for each without needing multiple distinct prompts. It ensures structured and repeatable extraction across all defined aspects.

To improve the identification of measurement-related entities in German clinical texts, which are often missed by LLMs due to domain-specific phrasing in German clinical texts, we apply a semantic similarity approach based on sentence embeddings. This method is more robust to morphological variation, word order, and paraphrasing than traditional string metrics such as Levenshtein distance.

We used German-specific sentence embeddings generated by the sentence-transformers library with the multilingual model distiluse-base-multilingual-cased-v1, which supports high-quality semantic representations of German phrases.

Matching Procedure

To identify and align relevant sleep-related entities from clinical narratives, we implemented a multistep matching procedure combining lexical, semantic, and synonym-based techniques, as detailed below:

1. Entity candidate generation: Candidate phrases were extracted from clinical documents using regex-based pattern matching and contextual heuristics (eg, token windows around sleep-related terms).
2. Embedding computation: Sentence embeddings were computed for each candidate phrase and compared to embeddings of canonical terms from our curated sleep measurement lexicon.
3. Similarity scoring: Cosine similarity was used to measure semantic closeness between candidate and canonical embeddings. A similarity threshold of 0.83 was used to determine a valid match based on manual validation (see Table 5).
4. Synonym expansion: A manually defined dictionary of common medical synonyms (eg, “Schlafqualität” ≈ “Qualität des Schlafes”) was integrated into the matching logic to further boost recall.

Table . Embedding-based semantic matching for German sleep disorder terms.

Canonical term	Variant detected in text	Cosine similarity	Matched?	English translation
Schlafqualität	Qualität des Schlafes	0.86	True	Sleep quality
Schlaflatenz	Zeit bis zum Einschlafen	0.85	True	Time to fall asleep
REM-Schlafanteil[a]	REM Schlafphasen Dauer	0.81	False	Duration of REM sleep phases

[a]REM: rapid eye movement.

Objective Measure Calibration

To enable comparability across heterogeneous clinical measurements and support sentiment interpretation, we apply min-max normalization to both objective and subjective metrics. This ensures all scores lie within the interval [0, 1], where 0 indicates maximal symptom burden and 1 indicates no impairment. This transformation provides a unified scale for downstream sentiment mapping.

For objective physiological measures such as PSG-recorded sleep latency, we applied the following normalization: Normalized Latency Score=1–(Raw Value/Max Latency) where the clinically derived maximum latency was set to 120 minutes, in accordance with standard clinical PSG protocols. This formulation ensures shorter latency (indicative of better sleep initiation) corresponds to higher normalized scores.

Subjective scale normalization

For subjective clinical questionnaires (see Table 6), we used min-max normalization based on each scale’s full range. The transformation ensures that higher symptom burden maps to lower normalized values:

Normalized Score=(Max Score – Raw Score) /(Max Score – Min Score)

Table . Normalization mappings between the objective score.

Instrument	Score range	Normalization formula
Karolinska Sleepiness Scale (KSS)	1 - 9	(9 – Raw Score) / (9 – 1)
Epworth Sleepiness Scale (ESS)	0 - 24	(24 – Raw Score) / (24 – 0)
Fatigue Severity Scale (FSS)	1 - 7	(7 – Raw Score) / (7 – 1)
Beck Depression Inventory II (BDI-II)	0 - 63	(63 – Raw Score) / (63 – 0)

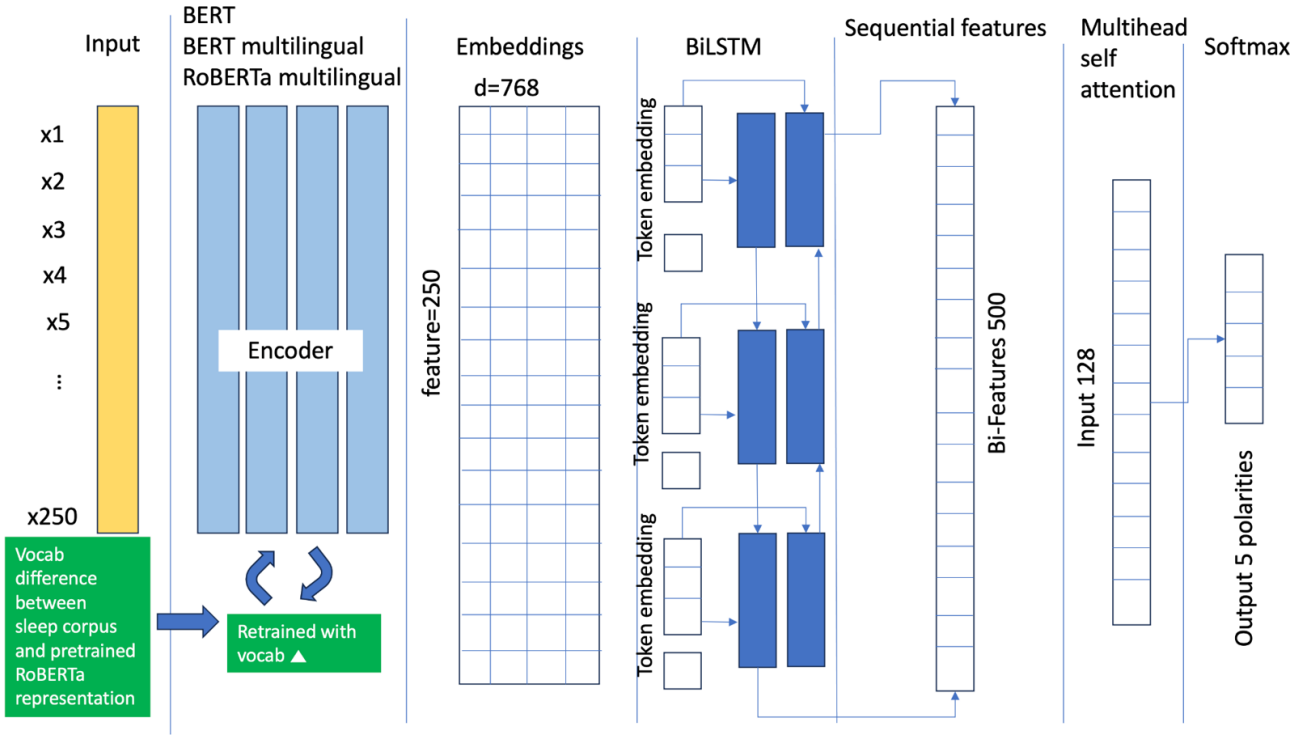
This ensures that 0 corresponds to the maximum raw score (most negative sentiment), and 1 corresponds to the minimum raw score (most positive sentiment).

Architecture for Clinical Sentiment Analysis

We deploy a BERT-based BiLSTM architecture to perform sentence-level sentiment classification across 5 polarity levels (see Figure 2). The model ingests token sequences up to 250

XSL•FO
RenderX

tokens, with BERT embeddings (768 dimensions) [31] providing context-aware representations.



We fine-tune both multilingual BERT and XLM-RoBERTa [32] on a corpus of 1200 German clinical sentences annotated with 5-stage sentiment labels, derived from Mixtral 8X7B prompting and manual correction (interannotator agreement >89%).

Negated expressions in German are normalized into unified tokens prior to BERT encoding to stabilize polarity signals. The resulting embeddings are processed by a BiLSTM layer followed by sequential feature aggregation. The output logits are mapped to 5 sentiment classes, which are rescaled to a [0, 1] range:

0 (very negative), 1 (negative), 2 (neutral), 3 (positive), 4 (very positive)

The model is trained using a 60/20/20 split across training (1200), validation (400), and test (400) sets.

Figure 2. BiLSTM based on BERT language modeling for clinical sentiment analysis.

Feature Fusion and Context Learning

The architecture incorporates multiple contextual sources:

F_{Mask}: local contextual features via dynamic masking

$F_{weighting}$: Dynamically weighted local embeddings

$F_{disorder}$: global BiLSTM features

The 5 stages of sentiment resulting from with or without BERT alignment and fine-tuning will be evaluated on these benchmarks.

Feature Ensemble and Context Learning for BERT BiLSTM

During the unified contextual feature assembling process for sleep disorder topics, both local and global contextual features derived from the contextual feature dynamic mask technique, the dynamic weighting mechanism, and the BiLSTM layers are integrated. In addition, features enriched by LLMs are incorporated. Specifically, the learned local and global contextual features are concatenated to produce a unified contextual feature output. This procedure is mathematically represented as follows:

Fensemble=Fmaskl Fweightingl Fdisorderaspectg

In this equation, FmaskL represents the set of local contextual embedding vectors computed by the dynamic mask technique, while FweightingL denotes the set of local contextual embedding vectors examined through the dynamic weighting mechanism. $F_{disorder}$ aspect refers to the set of global contextual embedding vectors captured via BiLSTM layers. The operator indicates the concatenation of these feature sets. These fused features are further processed through BiLSTM to capture sequential dependencies and then transmitted into Feedforward Network with Softmax to perform fine-grained aspect-based sentiment classification.

Network Configuration and Hyperparameters for BERT BiLSTM

The hyperparameter Table 7 outlines the configuration of the network, which operates in 2 main stages. In the first stage, aspect recognition is performed using the initial set of network parameters. The recognized aspects are then incorporated into the second stage through feature fusion, where they are linearly combined and pooled together with position features. This fused feature set is subsequently applied and jointly optimized within the fine-tuned RoBERTa model's loss function. The optimization is carried out using a 5-stage polarity classification,

XSL•FO
RenderX

ensuring that both aspect-level insights and positional information are effectively used for enhanced performance.

Finetuned German GPT-2 With Supervised Fine-Tuning and Logit Modification

In addition to our BERT-BiLSTM sentiment classification baseline, we fine-tune a German GPT-2 model [26,33,34] to generate text reflecting 5 clinically relevant stages of sentiment in sleep disorder narratives. As illustrated in Figure 3, our 2-stage fine-tuning approach involves both supervised learning (L1) and reinforcement learning (L2) to align the model's generations with targeted sentiment levels. In the first stage (L1), we perform supervised fine-tuning (SFT) using the Hugging Face Transformer Reinforcement Learning (TRL) framework [28] on a corpus of 1200 annotated German clinical texts (Table 8), each labeled with 1 of 5 sentiment classes: strong negative, minor negative, neutral, minor positive, and strong positive. The SFT phase runs for 3 epochs with a learning rate of 5e-5, a batch size of 16, and a maximum sequence length of 1024 tokens, using standard language modeling loss to adapt the pretrained GPT-2 model to the clinical sleep domain and sentiment-specific instruction format. Further details regarding the implementation are available in the GitHub repository [35].

Figure 3. Fine-tuned German GPT-2 followed by supervised fine-tuning, reinforcement learning, and logit modification. *RL indicates the steps of reinforcement learning RL1 and RL2. RL: reinforcement learning; SFT: supervised fine-tuning.

XSL•FO
RenderX

Table . Model hyperparameters for GPT-2 supervised fine-tuning.

Parameter	Value
GPT-2 sentiment classifier learning rate	2e-5
GPT-2 sentiment classifier batch size	16
SFT trainer learning rate	5e-5
SFT training epochs	3
SFT maximum sequence length	1024
RL[a] generation kwargs top-k	3
RL generation kwargs top-p	0.5
Maximum new tokens	100
RL PPO[b] mini-batch size	16
RL PPO configuration steps	41,000

[a]RL: reinforcement learning.

[b]PPO: Proximal Policy Optimization.

The second stage (L2) consists of RL via PPO [33], using the sentiment classifier as a reward model. Here, the model generates responses conditioned on prompts and randomly sampled target sentiment tokens. The classifier evaluates each generation and assigns a reward signal based on the logit of the target sentiment class, encouraging the model to reinforce sentiment-accurate responses. This process is iteratively optimized over 41,000 PPO steps, using a PPO mini-batch size of 16, and generation hyperparameters including top-k=3, top-p=0.5, and a maximum of 100 new tokens per sample.

We designate these PPO training phases as RL1 and RL2, which are now clearly labeled in Figures 1 and 3 *RL. Each RL phase refines the generator's ability to follow sentiment conditioning with increasing precision. This logit-based reward shaping strategy ensures granular control over sentiment realization in the output. Our evaluation metric during PPO optimization is the accuracy of generated sentiment, as classified by the same frozen classifier used for reward computation. The combination of supervised preadaptation and reward-driven fine-tuning allows our GPT-2 model to generate sentiment-aligned narratives that preserve clinical plausibility while reflecting emotional tone variations essential for downstream affective or patient-centered NLP tasks.

Derived Subjective Sleepiness Scoring and Comparison to Objective Measures

Subjective Sleepiness Approach

To robustly assess subjective sleepiness, we combined inputs from the KSS and clinician-documented descriptions to produce a harmonized subjective score. KSS ratings were first converted to a 5-stage ordinal scale (0‐4), with thresholds mapped as follows: 1‐2=4 (very severe sleepiness),

3‐4=3, 5‐6=2, 7‐8=1, 9=0 (no sleepiness).

This reverse scoring reflects the interpretation that lower KSS values indicate greater momentary sleepiness.

In parallel, clinical text segments were processed using a sentiment analysis pipeline based on a fine-tuned GPT-2 model trained with RL to optimize accuracy across 5 sentiment stages. This model provided a text-derived sleepiness score on the same 0‐4 scale, where 0 indicated no subjective complaints and 4 indicated severe functional impairment due to sleepiness.

Objective Sleepiness Derivation

The MSLT was used to obtain an objective index of daytime sleepiness. Since shorter latencies reflect greater sleepiness, raw MSLT values were inverted and scaled onto a 0‐4 range: objective score = ((20 – MSLT latency) / 20)×4. This allowed direct comparison of subjective and objective sleepiness on the same scale.

Paired Comparison and Findings

To evaluate the degree of alignment between subjective and objective sleepiness, we performed a paired-sample *t* test. For each patient, we computed the difference between the harmonized KSS sleepiness stage and GPT-2-RL–derived text score and the corresponding objective sleepiness score derived from MSLT latency.

The paired-sample *t* test evaluates whether the mean difference between the subjective and objective scores across all patients significantly differs from zero. The test statistic is calculated using:

$$t=\bar{d}Sd/n$$

where d is the mean of the differences between paired observations:

$$\bar{d}=1n\sum i=1n(xi-yi)$$

S_d is the standard deviation of the differences:

$$Sd=1n-1\sum i=1n(di-\bar{d})2$$

n is the number of paired samples, x_i is the subjective score for patient i, and y_i is the objective score for patient i.

Ethical Considerations

Ethical approval for this study was obtained from the Kantonale Ethik Kommission Bern (Cantonal Ethics Committee Bern) for multiple project components: Project part 1: SNS Project

XSL•FO
RenderX

(2000-2016), BASEC-ID 2016-00409 and Project part 2: Bern Sleep Registry ("The sleep disorder patient cohort of the Inselspital, University Hospital Bern"), KEK-Nr. 2022-00415.

The secondary use of data from the Bern Sleep Registry was also approved by the Cantonal Ethics Committee. All data were handled in accordance with institutional and Swiss data protection regulations. Informed consent was obtained as required for each project component, and all participants were informed of their ability to opt out of data use. All data were fully de-identified prior to analysis to protect participant privacy and ensure compliance with applicable data protection standards.

Results

Overview

This section presents the results of our aspect-based sentiment analysis pipeline, including [1] 5-stage sentiment classification using transformer-based models, and [2] LLM-based extraction of clinical entity aspects. The analyses were applied to a dataset of sleep-related medical texts and further supported by clinical insights into subjective-objective misperception.

Evaluation of the Aspect-Based Sentiment Analysis

Table 9 summarizes the performance of several models for 5-stage sentiment classification, evaluated using standard multiclass metrics. Initial models such as BERT and RoBERTa achieved moderate performance (accuracy 61% and 69%, respectively). Incorporating a BiLSTM layer improved performance to 78%. Further gains were achieved with a fine-tuned GPT-2 model. SFT alone yielded 81% accuracy, and RL with logit-space modulation increased it to 87%. These results demonstrate the effectiveness of multistage alignment in modeling sentiment nuances. Metrics reported in Table 9 are macro-averaged across 5 sentiment classes, based on an 80/20 stratified test split.

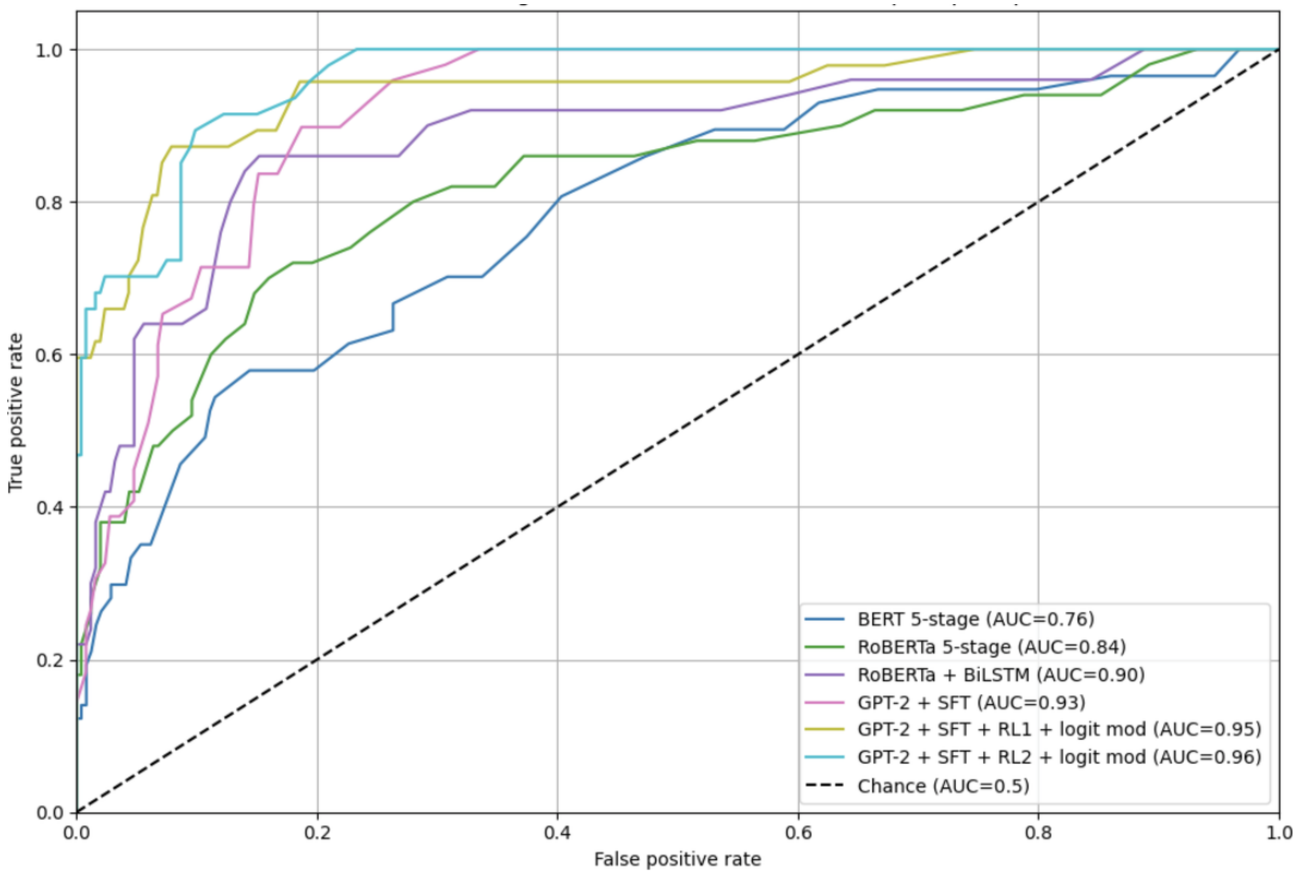
Table . Performance of sentiment classification of semiautomatically annotated 5-stage sentiment. Training: 1200 sentences (60%), Validation: 400 (20%), Test: 400 (20%) for hyperparameter optimization.

Sentiment task	Accuracy	AUC-ROC[a]	Precision (macro)	Recall (macro)	F_1-score (macro)
BERT 5-stage	0.61	0.76	0.62	0.60	0.61
RoBERTa 5-stage	0.69	0.84	0.70	0.68	0.69
RoBERTa+BiLSTM	0.78	0.90	0.79	0.77	0.78
GPT-2+SFT[b]	0.81	0.93	0.82	0.81	0.81
GPT-2+SFT+RL1[c]+ logit mod	0.85	0.95	0.86	0.85	0.85
GPT-2+SFT+RL2+logit mod	0.87	0.96	0.88	0.87	0.87

[a]AUC-ROC: area under the receiver operating characteristic curve.

[b]SFT: supervised fine-tuning.

[c]RL: reinforcement learning.



All metrics were computed using macro-averaging, giving equal weight to all sentiment classes. The AUC-ROC (area under the receiver operating characteristic curve) values were obtained using a one-vs-rest strategy, macro-averaged across 5 classes. These approaches ensure that both frequent and rare sentiment classes are equally represented in performance assessment.

Figure 4 visualizes the ROC curves of the models. GPT-2 variants with SFT+RL training consistently outperformed the baselines, reflecting enhanced class separability through reinforcement learning and logit regularization.

The ROC-AUC curves illustrate the one-vs-rest performance of 6 models on the 5-stage sentiment classification task using clinical text from sleep disorder records. All models perform substantially above the chance level (AUC=0.5), with performance steadily improving from BERT (AUC=0.76) to RoBERTa (AUC=0.84), and further to RoBERTa+BiLSTM (AUC=0.90). Fine-tuned GPT-2 (SFT) achieves strong performance (AUC=0.93), which is further enhanced by reinforcement learning (RL1 and RL2) and logit modification, reaching up to AUC=0.96. The stair-step shapes reflect the small test set (400 samples), but the consistent trend shows that reinforcement learning significantly boosts the model's ability to distinguish fine-grained sentiment levels, supporting its potential for clinical decision support in contexts such as misperception of sleepiness.

Aspect Extraction Through LLM Falcon 40B and Mixtral 8X7B

Clinical entity extraction was performed using prompting strategies applied to Falcon 40B and Mixtral 8X7B models. Table 10 compares their performance on 4 annotated categories: Symptoms, Diseases, Complaints, and Feedback. Mixtral 8X7B showed strong performance with macro F_1 of 0.8490, outperforming Falcon 40B (macro F_1 of 0.7265).

Table . Performance of the aspect extraction and benchmarks: 150 manually labeled sentiment aspects.

Performance of aspect extraction	Precision	Recall	Micro F_1	AUC-ROC[a]
Falcon 40B instruct entity extraction				
Symptoms	0.8157	0.7963	0.8054	0.903
Diseases	0.8321	0.8485	0.8397	0.920
Complaints	0.7829	0.7134	0.7466	0.873
Feedback	0.5416	0.4896	0.5142	0.757
Marco F_1	—[b]	—	0.7265	—
Mixtral 8X7B Instruct v0.1 entity extraction				
Symptoms	0.9175	0.9114	0.9054	0.953
Diseases	0.8812	0.8804	0.8797	0.940
Complaints	0.8411	0.8338	0.8266	0.913
Feedback	0.8616	0.8028	0.8312	0.903

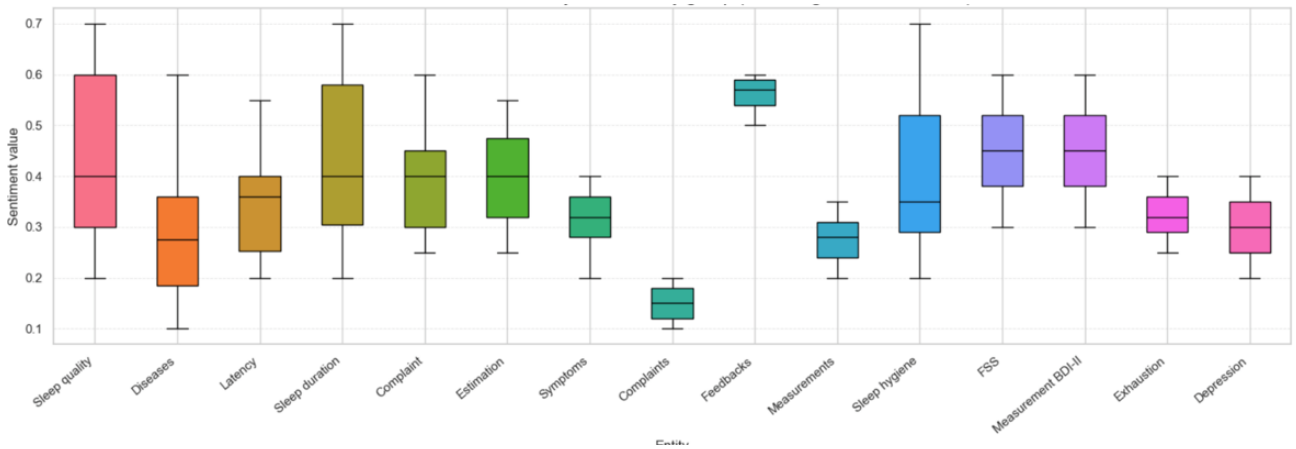
Since Mixtral 8X7B consistently outperformed Falcon 40B across all evaluated categories, we applied Mixtral 8X7B for all entity extraction tasks in our sentiment analysis pipeline. Beyond the benchmark evaluation, the model extracted a total of 873 unique symptom terms, along with 59 distinct diseases, 432 complaints, and 224 feedback-related entities across the full clinical corpus.

Sentiment Distribution Patterns



Currently, there are no established objective ground truth standards for evaluating misperception in insomnia, and for disorders such as hypersomnia or sleep-disordered breathing, further clinical validation is required. Thus, our focus was placed on daytime sleepiness, where both subjective (KSS) and objective (MSLT and MWT) data were consistently available.

The KSS and the ESS both assess subjective sleepiness but differ in temporal focus: KSS captures momentary state-level sleepiness, while ESS reflects trait-level sleepiness across habitual situations. Because KSS is time-specific, it aligns more directly with objective measures such as MSLT latency.

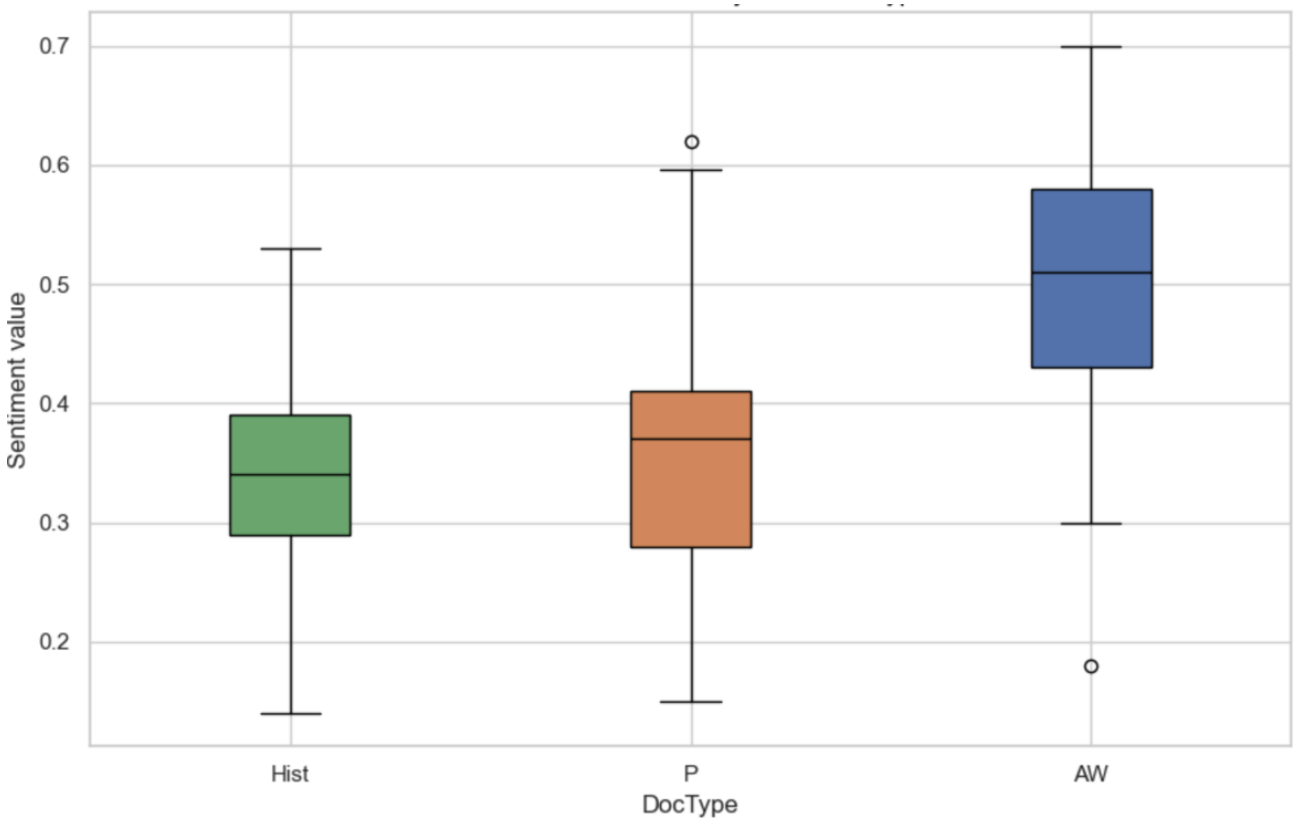
In this study, we focus exclusively on KSS—with or without clinical text—to assess momentary misperception in daytime sleepiness. This approach avoids confounding from chronic perception scales such as ESS and enables precise modeling of state-dependent discrepancies.

Figures 5-7 visualize the distribution of sentiment values across different clinical contexts. Figure 5 presents sentiment grouped by clinical entity (eg, Sleep quality, Symptoms, and Feedback). Positive sentiment distributions were observed for Feedback and Sleep Hygiene, while negative sentiment dominated in entities such as Complaints and Diseases. Figure 6 shows sentiment variation across document types: patient-generated narratives (P) and Actigraphy Wrist (P-AW) reports tended to be more emotionally expressive than historical records (Hist). Figure 7 aggregates sentiment by clinical aspect groupings, showing that Sleep quality included more variability in sentiment, whereas Fatigue and Day sleepiness showed predominantly negative sentiment patterns—suggesting a greater emotional burden associated with these complaints.

Figure 5. Sentiment distribution by clinical entity group. FSS: Fatigue Severity Scale; MSLT: Multiple Sleep Latency Test; MWT: Maintenance of Wakefulness Test.

XSL•FO
RenderX

Figure 6. Sentiment distribution by document type (Hist:History, P:Polysomnography, P-AW:Actigraphy Wrist), 5-stage sentiment score normalized into value between 0 and 1.



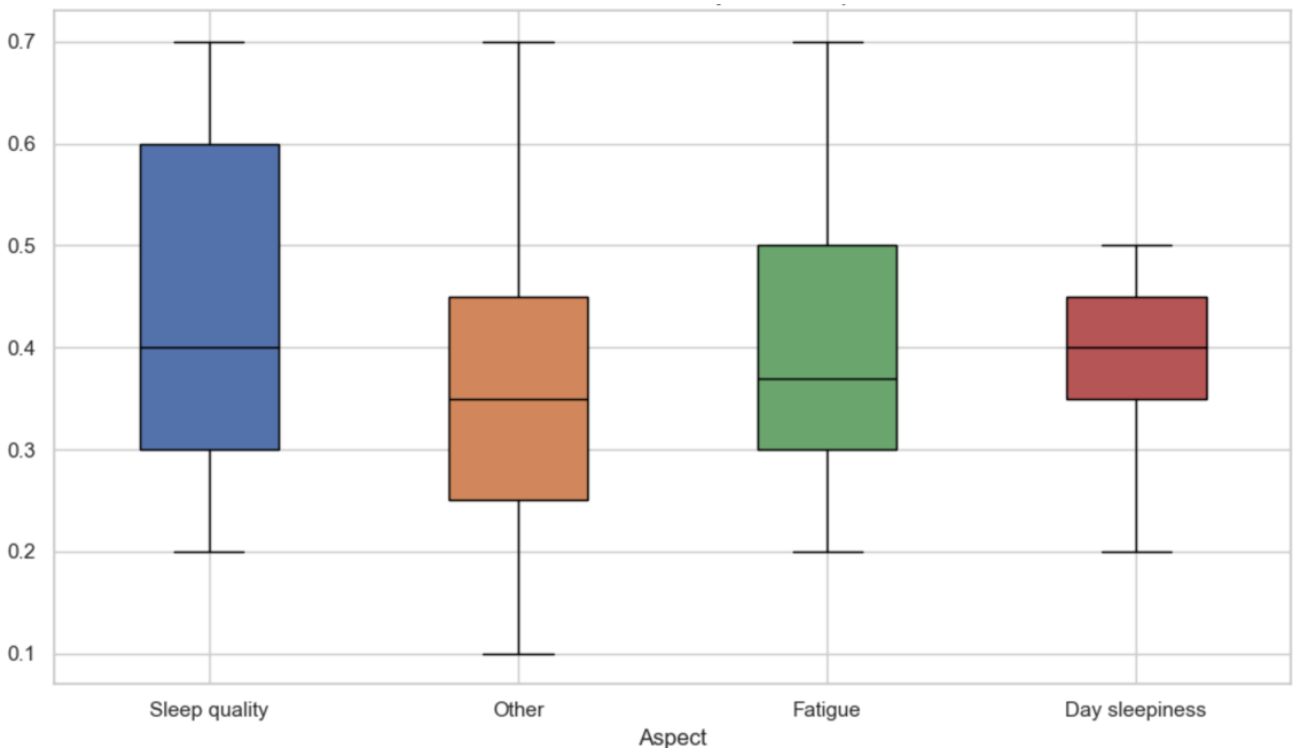


Figure 7. Sentiment distribution by sleep disorder aspect (quality, fatigue, and sleepiness).

Subjective-Objective Mismatch in Sleepiness Reporting

To examine potential misperceptions in day sleepiness, we compared subjective KSS reports with objective latency data from MSLT and MWT protocols. KSS values were normalized to a 0 - 1 range using the formula: KSS_normalized=(9–Raw Score)/(9–1) This transformation enables alignment with the inverse latency scale.

Figure 8 presents the misperception score distribution across 3 test conditions: 10 minutes pair: mslt_kssdur_10 versus latency_10, 12 minutes pair: mslt_kssdur_12 versus latency_12,

XSL•FO
RenderX

and mwt_kssdur versus latency. Misperception was defined as the deviation between normalized KSS and expected sleep latency levels. Across all pairings, positive misperception scores indicate that patients tend to report higher subjective sleepiness than measured objectively. The largest variability appeared in the mslt_kssdur_12 condition, while MWT tests showed narrower error bands.

Table 11 presents a representative subset of 10 patients illustrating questionnaire-expert-validated, text-predicted, and measured sleepiness scores. Although individual patterns vary, a general trend of overestimated sleepiness is observable.

Figure 8. Mismatch between subjective sleepiness (Karolinska Sleepiness Scale) and objective sleep latency (Multiple Sleep Latency Test and Maintenance of Wakefulness Test) in day sleepiness documents with a threshold of 10 and 12 minutes of latency. KSS: Karolinska Sleepiness Scale; MSLT: Multiple Sleep Latency Test; MWT: Maintenance of Wakefulness Test.

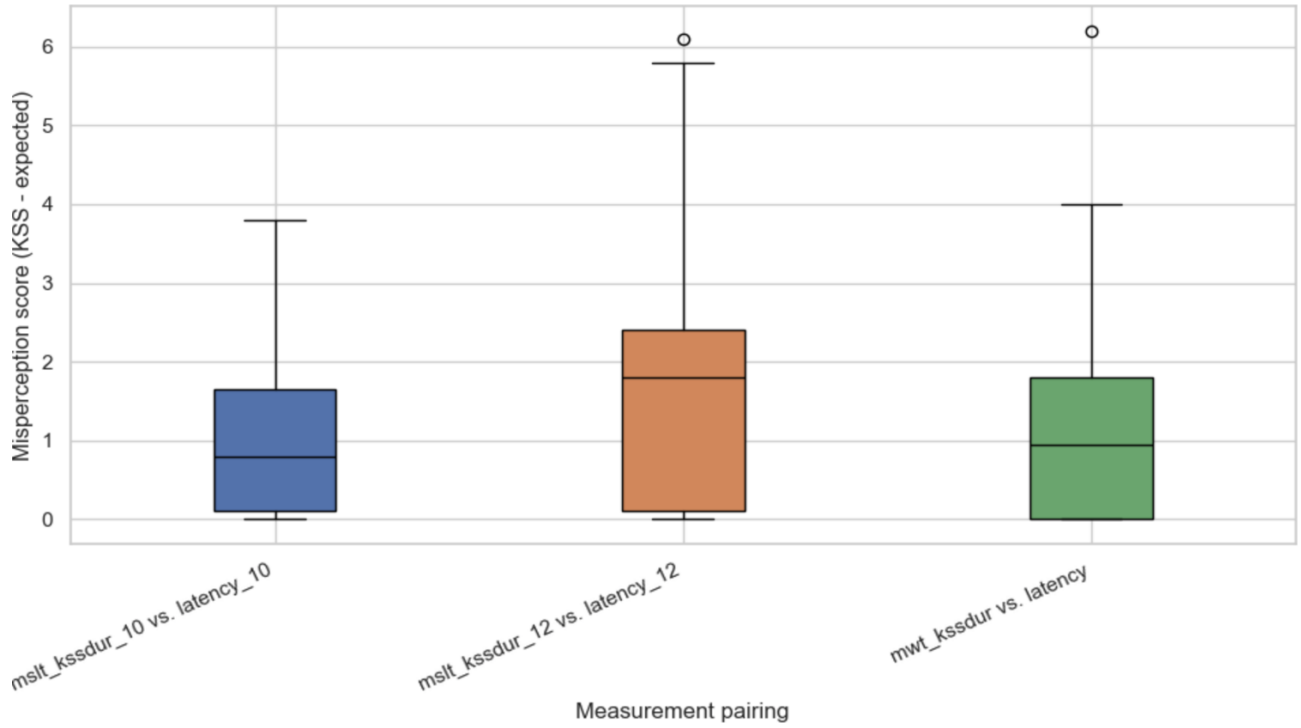

Table . A snapshot and working example with 10 patients from the selected cohort of 100 patients for day sleepiness, illustrating normalized Karolinska Sleepiness Scale (momentary) and text-derived score, expert-labeled and predicted subjective scores, along with corresponding Multiple Sleep Latency Test latencies and normalized objective scores.

Patient ID	KSS[a] stage	Text sentiment stage	MSLT[b] latency (min)	Objective score (0 - 4)	Differences KSS MSLT	Differences text MSLT
P001	2	2	5.04	2.992	−0.992	−0.992
P002	2	1	1.12	3.78	−1.78	−2.78
P003	3	2	7.76	2.45	0.55	−0.45
P004	0	1	1.13	3.77	−3.77	−2.77
P005	3	1	0.14	3.97	−0.97	−2.97
P006	2	1	15.99	0.80	1.20	0.20
P007	0	1	9.9	2.02	−2.02	−1.02
P008	3	1	10.54	1.89	1.11	−0.89
P009	3	3	8.83	2.23	0.77	0.77
P010	4	2	9.93	2.01	1.99	−0.01

[a]KSS: Karolinska Sleepiness Scale.

[b]MSLT: Multiple Sleep Latency Test.

A paired-sample *t* test conducted across the full cohort (n=100) revealed distinct patterns in the alignment between subjective and objective sleepiness assessments. While KSS scores showed a borderline nonsignificant divergence from MSLT-derived latencies (t_{99}=2.456, *P*=.06), text-derived sentiment scores demonstrated a statistically significant misalignment (t_{99}=2.324, *P*=.05). These findings suggest that free-text clinical narratives

XSL•FO
RenderX

more consistently diverge from physiological measures of sleepiness than structured scales such as the KSS. This may reflect the emotionally nuanced and context-rich nature of patient-reported symptoms embedded in narrative records. Importantly, although both subjective measures showed overestimation of sleepiness, only the text-derived sentiment reached statistical significance (P=.05), indicating a consistent, though not necessarily larger, misalignment with physiological data. More details can be found in Multimedia Appendix 1.

Discussion

Principal Findings

This study introduced a sentiment analysis framework for clinical sleep narratives, revealing key insights into both method performance and clinical relevance. The BERT-BiLSTM architecture improved sentiment accuracy by addressing negations and drift, while the Mixtral 8X7B model outperformed Falcon 40B in aspect extraction due to better handling of complex German syntax. A fine-tuned GPT-2 model with reinforcement learning achieved high sentiment classification accuracy (87%) and offered a resource-efficient alternative to LLMs. Clinically, sentiment-derived scores revealed consistent misperception patterns—such as underestimated sleep latency and overestimated duration—highlighting the importance of aligning subjective and objective measures. These findings support the integration of sentiment-informed misperception analysis into sleep medicine workflows to improve diagnosis, treatment selection, and patient safety.

Method Evaluation

In this study, we introduced and evaluated an aspect-based sentiment analysis approach tailored to clinical narratives in sleep medicine. Several key observations emerged from our findings. First, when mapping sentiment model outputs to scalar indicators of sleep disorders, it became necessary to adjust for negations and drifted sentiment—especially in baseline BERT models. Phrases that negated the presence of symptoms or diagnoses were frequently misinterpreted as negative sentiment. This issue was mitigated using a BERT-BiLSTM architecture, which improved performance through representation adaptation and fine-tuning.

For aspect (entity) extraction using prompted LLMs, recall was generally low, particularly for feedback-related content. In contrast, precision was high for identifying symptoms, diseases, and complaints. The poor recall is primarily attributed to the token limit and the generation style of Falcon 40B under one-shot prompting. Interestingly, few-shot prompting increased precision but further reduced recall and F_1-score. This reveals a trade-off that may be addressed either by increasing computational capacity (current setup: 128 GB Nvidia DGX server) or optimizing prompting strategies.

The Mixtral 8X7B model significantly outperformed Falcon 40B, delivering higher precision and recall for aspect recognition, even under single-shot settings. Its ability to handle longer input contexts and complex linguistic structures—such as German postnegation—proved particularly advantageous in the clinical domain. These results support the use of Mixtral 8x7B for German-language medical NLP tasks where nuanced comprehension is critical.

Compared to BERT-BiLSTM, a fine-tuned GPT-2 model trained on 1200 sleep-related clinical sentences achieved comparable performance (accuracy: 81%). Incorporating keyword-guided SFT and 2 RL epochs with logit modification raised accuracy to 87%. This dual-phase tuning strategy enhanced the model's flexibility and control. It also outperformed sequential prompting approaches commonly used with larger LLMs—offering higher precision with lower resource requirements, particularly important in privacy-sensitive clinical settings.

Clinical Outcomes

The interpretation of sentiment-derived misperception patterns must consider both the nature of subjective reporting and the inherent limitations of objective measurement in clinical sleep data. Misperception—defined as a mismatch between how patients feel and how their physiological state is measured—varies across dimensions of sleep disorders, with important diagnostic and therapeutic implications.

A key finding in our study was the divergence in sentiment-derived scores for similar clinical constructs. For instance, patients frequently underestimated their sleep latency (eg, reporting quick sleep onset) yet simultaneously overestimated their sleep duration, contrary to PSG and MSLT results. This subjective-objective mismatch—commonly referred to as sleep misperception—was particularly evident across latency, duration, and fatigue indicators. While traditional statistical tests may not fully capture the nuances of sentiment-informed scores, the consistent directionality and magnitude of these mismatches highlight their clinical importance.

However, the objectification of sleep quality and fatigue is inherently complex. Short sleep latency, often seen as a marker of healthy sleep, can paradoxically indicate pathological hypersomnolence in conditions such as narcolepsy. Similarly, fatigue—unlike sleepiness—lacks a gold-standard physiological test and is primarily self-reported, making its objectification more elusive. These nuances emphasize the need to interpret subjective scores considering disorder-specific clinical contexts.

In contrast, daytime sleepiness offers a more quantifiable target for misperception analysis. Here, subjective ratings such as the KSS and text-derived sentiment scores can be directly compared with objective markers such as MSLT latency. The KSS is particularly useful in this context, as it captures state-based, momentary sleepiness, allowing for meaningful trial-by-trial comparisons. For example, KSS values close to 0 (indicating "extremely sleepy") should theoretically align with MSLT latencies under 8 minutes. In our analysis framework, misperception magnitude increases when a patient reports low KSS (ie, "did not fall asleep") while objective data confirm they did—for example, falling asleep within 10 - 20 minutes in MSLT trials. This alignment enables fine-grained modeling of momentary misperception and supports targeted subanalysis of repeated MSLT and KSS pairs (eg, mslt_kssdur_10 vs mslt_sleeplatency_10).

XSL•FO
RenderX

From a clinical perspective, understanding the type and direction of misperception has actionable relevance.

For instance, in insomnia, patients often report exaggerated sleep difficulties (eg, longer sleep latency than measured). These cases may benefit more from cognitive behavioral therapy for insomnia rather than pharmacotherapy. Discussing the misperception with the patient is often therapeutic. However, because objective tests such as PSG are rarely used in routine insomnia management, wearable technologies (eg, smartwatches) could serve as surrogate tools to estimate sleep latency, duration, and fragmentation—offering scalable insight into real-world misperception.

In hypersomnia or sleep-disordered breathing, the opposite trend may occur—patients feel they slept well but exhibit abnormal sleep architecture or excessive daytime sleepiness in tests. In such cases, unrecognized sleepiness can elevate safety risks, such as motor vehicle or occupational accidents. Early identification of these cases using sentiment-objective comparison could trigger earlier clinical intervention or patient education.

Altogether, our sentiment analysis framework, enriched with structured objective metrics, offers a promising route for personalized assessment of sleep misperception. By comparing KSS, ESS, and text-derived sentiment scores against MSLT latency across multiple configurations, we can determine which input combination best captures the true subjective state. This multipronged analysis will inform future iterations of our clinical decision-support tools and help stratify patients for tailored treatment approaches.

Clinical Applications

Integrating sentiment analysis and misperception scoring into clinical workflows opens up new avenues for personalized, perception-aware sleep medicine:

1. Flag discrepancies in sleep latency and duration for targeted discussion or reassessment.
2. Stratify patients by degree of misperception to inform whether cognitive behavioral therapy for insomnia or pharmacotherapy is appropriate.
3. Highlight the underestimation of sleepiness in MSLT and MWT contexts for workplace or safety interventions.
4. Incorporate wearable data to validate or challenge patient self-reporting in follow-up care.

By aligning sentiment-derived patterns with objective sleep markers, clinicians can better understand not only what the patient reports but how they perceive their condition—a critical step toward improving diagnostic accuracy, treatment matching, and long-term outcomes.

Conclusion and Future Work

This study demonstrates that sentiment analysis applied to structured clinical narratives can uncover meaningful patterns in how patients perceive and report sleep disorders—especially in identifying discrepancies between subjective self-reports and objective assessments. Among the models evaluated, the BERT-BiLSTM architecture showed strong performance in domain-specific sentiment detection. However, the fine-tuned German GPT-2 model, enhanced with supervised and reinforcement learning (PPO), achieved the highest accuracy for 5-stage sentiment classification, offering an effective balance between adaptability and computational efficiency.

Our findings highlight the clinical value of sentiment-based misperception modeling. For example, patients with insomnia often overestimate wakefulness, while those with hypersomnia or sleep apnea tend to underreport daytime sleepiness. The use of reinforcement learning techniques proved especially effective for capturing emotionally nuanced language in clinical narratives while maintaining sensitivity to domain-specific clinical distinctions.

However, this study is not without limitations. All data were drawn from a single clinical registry, which may limit the generalizability of findings across institutions or populations. Furthermore, the annotated training set for sentiment and entity extraction was relatively small, potentially constraining model robustness and the diversity of learned patterns.

In future work, we aim to expand the dataset by incorporating records from additional clinical centers and to enrich the annotation set to enable more nuanced model training and validation. Sentiment modeling will be extended to cover additional clinical entities such as pain and cognitive symptoms, while correlations between sentiment-derived misperception scores and treatment outcomes or resistance will be further explored. We also plan to integrate physiological features—such as microarousals and sleep stage transitions—to improve subtype classification and to leverage wearable sensor data to validate and calibrate sentiment-based misperception metrics. Ultimately, our goal is to develop a precision sleep medicine framework that integrates objective physiological markers with patients' emotional and cognitive interpretations of their symptoms, captured through advanced sentiment and entity modeling of clinical narratives.

Acknowledgments

The secondary usage of Bern Sleep Data Base (BSDB) from Inselspital, University Hospital Bern, was approved by the local ethics committee (KEK-Nr. 2022 - 00415).

Data Availability

The datasets analyzed in this study are not publicly available due to data privacy considerations [31], but they may be obtained from the institutional review board of Inselspital upon reasonable application.

Abstract

Background: Manual review of electronic health records for clinical research is labor-intensive and prone to reviewer-dependent variations. Large language models (LLMs) offer potential for automated clinical data extraction; however, their feasibility in surgical oncology remains underexplored.

Objective: This study aimed to evaluate the feasibility and accuracy of LLM-based processing compared with manual physician review for extracting clinical data from breast cancer records.

Methods: We conducted a retrospective comparative study analyzing breast cancer records from 5 academic hospitals (January 2019-December 2019). Two data extraction pathways were compared: (1) manual physician review with direct electronic health record access (group 1: 1366/3100, 44.06%) and (2) LLM-based processing using Claude 3.5 Sonnet (Anthropic) on deidentified data automatically extracted through a clinical data warehouse platform (group 2: 1734/3100, 55.94%). The automated extraction system provided prestructured, deidentified data sheets organized by clinical domains, which were then processed by the LLM. The LLM prompt was developed through a 3-phase iterative process over 2 days. Primary outcomes included missing value rates, extraction accuracy, and concordance between groups. Secondary outcomes included comparison with the Korean Breast Cancer Society national registry data, processing time, and resource use. Validation involved 50 stratified random samples per group (900 data points each), assessed by 4 breast surgical oncologists. Statistical analysis included chi-square tests, 2-tailed *t* tests, Cohen κ, and intraclass correlation coefficients. The accuracy threshold was set at 90%.

Results: The LLM achieved 90.8% (817) accuracy in validation analysis. Missing data patterns differed between groups: group 2 showed better lymph node documentation (missing: 152/1734, 8.76% vs 294/1366, 21.52%) but higher missing rates for cancer staging (211/1734, 12.17% vs 43/1366, 3.15%). Both groups demonstrated similar breast-conserving surgery rates (1107/1734, 63.84% vs 868/1366, 63.54%). Processing efficiency differed substantially: LLM processing required 12 days with 2 physicians versus 7 months with 5 physicians for manual review, representing a 91% reduction in physician hours (96 h vs 1025 h). The LLM group captured significantly more survival events (41 vs 11; *P*=.002). Stage distribution in the LLM group aligned better with national registry data (Cramér V=0.03 vs 0.07). Application programming interface costs totaled US $260 for 1734 cases (US $0.15 per case).

Conclusions: LLM-based curation of automatically extracted, deidentified clinical data demonstrated comparable effectiveness to manual physician review while reducing processing time by 95% and physician hours by 91%. This 2-step approach—automated data extraction followed by LLM curation—addresses both privacy concerns and efficiency needs. Despite limitations in integrating multiple clinical events, this methodology offers a scalable solution for clinical data extraction in oncology research. The 90.8% accuracy rate and superior capture of survival events suggest that combining automated data extraction systems with LLM processing can accelerate retrospective clinical research while maintaining data quality and patient privacy.

KEYWORDS

natural language processing; breast neoplasms; data mining; clinical oncology; large language model; artificial intelligence

Introduction

Background

Recent advances in artificial intelligence, particularly in large language models (LLMs), have demonstrated remarkable capabilities of automated data extraction and organization from complex clinical documents [1-3]. These artificial intelligence–driven approaches can be used to process large volumes of clinical data with a consistent methodology, potentially reducing human bias and improving the collection efficiency of research data. Although LLMs show promise in health care applications, few studies on their practical efficacy compared with that of traditional, manual processing by physicians have been published, particularly in complex areas such as the extraction of surgical oncology data [4].

Clinical Challenges in Cancer Data Curation

In the field of breast cancer surgery, retrospective data analysis presents unique challenges owing to the complexity of unstructured clinical data. Electronic health records (EHRs) contain diverse information across clinical charts, operation records, and pathology reports, often in a free-text format. The complexity is compounded by breast cancer–specific characteristics, including the bilateral nature of the organs, concurrent malignant and benign lesions, and multiple radiological features. This complicates automated data curation and has traditionally necessitated manual review by physicians for accurate data interpretation and collection.

However, this manual approach has several limitations. As the volume of clinical data increases, consistency in physician reviews becomes increasingly difficult to maintain, potentially leading to discrepancies in data interpretation [5,6]. The time-intensive nature of manual review and the risk of errors in the processing of large volumes of clinical data present considerable challenges in retrospective research [7-10]. In addition, direct EHR access for manual data extraction raises privacy concerns when sensitive patient information is handled [11-13]. Although LLM-based automation of information extraction from anonymized EHR data may address these challenges, its effectiveness compared with that of traditional physician reviews remains to be evaluated.

Study Objectives

Although LLMs have been validated for the extraction of specific medical data, their potential for the curation of comprehensive data of patients with cancer remains largely unexplored [14]. In this study, we compared traditional physician reviews with LLM-based processing of anonymized clinical data in the field of breast cancer, focusing on the development of a practical approach for surgical oncologists. We hypothesized that LLM-based analysis would yield comparable results to manual review in handling large volumes of clinical data while reducing processing time and resource use.

Methods

Study Design and Data Collection

This retrospective comparative study included patients with breast cancer who underwent surgery at 5 academic hospitals from January 1, 2019, to December 31, 2019. This study was designed to compare 2 practical data curation pathways available in real-world clinical research settings. The manual review pathway represents the traditional method of direct EHR access. The LLM processing pathway uses preextracted, deidentified data. This study adheres to the Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis–Large Language Model (TRIPOD-LLM) reporting guidelines (Checklist 1).

We compared 2 data extraction methods: manual physician review (group 1) and LLM-based processing (group 2). In group 1, 1 dedicated breast-surgical oncologist from each hospital reviewed data spanning 2 years (2019 - 2020) over 7 months (May 2021–November 2021) using a standardized data collection form (Multimedia Appendix 1). The data encompassed 89 clinical variables across 3 domains: patient demographics (basic information, medical history, and family history), treatment information (surgical details, neoadjuvant or adjuvant therapy, complications, and follow-up treatment), and pathological information (tumor characteristics, tumor stage, biomarker status, and margin status). Follow-up observations regarding recurrence and mortality were updated until January 2024.

Patients in group 2 were initially identified using the clinical data warehouse (CDW) of Catholic Medical Center, an integrated data platform of 8 affiliated academic hospitals in Korea [15,16]. The CDW supports this research by providing anonymous clinical data to investigators following institutional review board approval [15]. The LLM structured 31 clinical factors from the raw data, including patient demographics (basic information, survival data, and diagnostic data), treatment information (surgery types and neoadjuvant or adjuvant therapy), pathological information (tumor characteristics, tumor stage, biomarker status, and nodal status), and imaging features. Data extraction and curation were performed from October 20, 2024, to November 1, 2024.

The CDW query identified 17,317 patients diagnosed with invasive breast cancer or ductal carcinoma in situ between July 2018 and July 2021. From this cohort, we selected patients diagnosed during the study period (January 2019-December 2019) who underwent breast cancer surgery. CDW extraction included unstructured EHR reports containing clinical information, operation records, and pathology reports (Multimedia Appendices 2-4). Follow-up data through October 31, 2023, were used.

XSL•FO
RenderX

Data Curation in LLM-Processing Group

Unstructured data extracted from the CDW were processed using Claude 3.5 Sonnet (Anthropic) to extract and structure the required factors into predefined categories.

LLM Implementation and Application Programming Interface (API) Access

We accessed Claude 3.5 Sonnet through the Anthropic web interface (claude.ai) using a professional subscription account. The implementation specifications are as follows:

1. Access method: web-based interface with manual copy-paste of clinical documents.
2. Processing approach: sequential processing of individual patient records.
3. Input size limitations: documents exceeding 100,000 characters were split into logical sections (diagnosis, surgery, and pathology) and processed sequentially.
4. Output format: structured CSV format directly generated by the LLM.
5. Session management: new conversation initiated for each batch of 50 patients to prevent context contamination.
6. Quality control: real-time review of outputs with immediate reprocessing for any parsing errors.

No API programming or authentication keys were required, as we used the standard web interface. This approach, while manual, ensured direct oversight of the extraction process and immediate error detection.

Prompt Development Process

Overview

The LLM prompt was developed through a 3-phase iterative process over 2 days (from October 20, 2024, to October 21, 2024). Rather than manually crafting the extraction rules, we used an interactive dialogue approach with the LLM itself to develop the prompt. We provided the LLM with sample data and target output requirements, and then iteratively refined the extraction protocol through conversational feedback.

The iterative refinement process consists of 3 phases.

Phase 1

This was the initial framework development phase and we included 10 cases. We presented the LLM with representative raw data and developed extraction rules through dialogue. The LLM proposed initial patterns for data extraction, which were tested using sample cases.

Phase 2

This was the rule refinement phase, and we included 20 cases. On the basis of the phase 1 outputs, we organized errors through manual review and engaged LLM to analyze the errors and modify them. Key refinements included diagnosis deduplication using International Classification of Diseases, 10th Revision code comparison, surgical procedure hierarchy establishment, pathology section prioritization, and biomarker interpretation standardization (particularly for human epidermal growth factor receptor 2 [HER2] status requiring in situ hybridization confirmation for 2+ cases).

Phase 3

This was the edge case handling phase, and we included 30 cases. The refined prompt was tested in diverse clinical scenarios. Additional instructions were added for handling bilateral cases (processing each breast separately), multiple surgical procedures (capturing all relevant operations), ambiguous staging information (requiring explicit notation rather than inference), and complex biomarker patterns (particularly HER2 equivocal cases).

The final prompt is available in the Multimedia Appendix 5. Due to its length, we provide a condensed version highlighting the key extraction rules, while the complete prompt with all edge cases and examples can be obtained from the corresponding author.

Prompt Structure and Components

The final prompt focused on accurate extraction from 4 distinct data categories: diagnostic information, clinical measurements, surgical procedures, and pathological findings.

Global Processing Rules Module

This module established standardized data formats and processing conventions. Key specifications included patient ID formatting (R[9-digit number]), laterality coding (right or left or bilateral), date standardization (YYYY-MM-DD), missing data coding (999,999), and CSV output structure. Each case was processed by laterality to handle bilateral breast cancers as separate entities, maintaining distinct Case_IDs formatted as “Patient_ID_Laterality” (eg, R000000001_RT).

Clinical Data Processing Module

This module handled diagnosis information, surgical procedures, and mortality data with specific extraction hierarchies. For diagnosis processing, the system prioritized primary diagnosis information, extracted English text only while removing Korean text, and implemented deduplication logic by comparing International Classification of Diseases, 10th Revision codes (first three characters) to identify identical diagnoses while preserving distinct diagnoses. For surgical information, we established clear precedence rules where therapeutic operations took priority over diagnostic procedures, with specific terminology mapping for breast procedures (eg, “wide excision,” “modified radical mastectomy,” and “lumpectomy”) and axillary procedures (sentinel lymph node biopsy [SLNB] and axillary lymph node dissection [ALND]).

Pathology Data Extraction Module

Given the variability in pathology report formats, we defined a section priority hierarchy: (1) microscopic description, (2) diagnosis, (3) immunohistochemistry, and (4) gross description. Specific extraction patterns were defined within each section. For tumor size determination, the search sequence was: “tumor size (size of largest invasive carcinoma)," “greatest dimension of largest invasive focus,” “size of largest invasive focus,” and “estimated size (extent) of DCIS.” For lymph node assessment, we standardized various reporting formats (eg, “X/Y [positive/total]," “metastatic carcinoma [n/total]," “lymph node metastasis; present or absent [n/total]") and classified metastasis

XSL•FO
RenderX

by size (macrometastasis >2 mm, micrometastasis 0.2 - 2 mm, and isolated tumor cell ≤0.2 mm).

Quality Control Module

this module implemented validation rules and error prevention strategies. The prompt excluded error-prone extractions, such as gross specimen sizes, surgical margin measurements, and lymph node sizes. It required explicit documentation of missing data rather than inference, implemented range validation for biomarkers (estrogen receptor or progesterone receptor or Allred score 0 - 8, Ki-67 0% - 100%), and cross-reference verification between different report sections.

Task Sequence and Processing Flow

Prompt execution of tasks in a specific sequence to ensure data integrity:

1. Initial parsing: identify patient ID and laterality from diagnostic records
2. Temporal alignment: establish diagnosis date as a reference point for all subsequent data
3. Hierarchical extraction: process data in order of clinical importance: diagnosis → surgery → pathology → imaging
4. Integration check: validate consistency across different data sources
5. Output generation: structure extracted data into a predefined .CSV format with quality flags

The prompt instructed the LLM to generate outputs directly in .CSV format with predefined column structures, automated date formatting (YYYY-MM-DD), and standardized missing data codes (999,999), eliminating the need for extensive after processing. The structured output was validated through the methodology described in the Data Quality Assessment and Validation section.

Objectives and Statistical Analysis

This study aimed to assess the feasibility of replacing manual physician reviews with LLM-based processing of breast cancer–related clinical data. We compared the demographic characteristics, clinical parameters, treatment patterns, disease characteristics, and survival outcomes between the 2 groups.

Categorical variables were compared using chi-square or Fisher exact tests, with agreement assessed using Cohen κ coefficient (κ<0.20=poor, 0.21 - 0.40=fair, 0.41 - 0.60=moderate, 0.61 - 0.80=good, >0.80=very good). Continuous variables were analyzed using the Student *t* test and the intraclass correlation coefficient. Effect sizes were calculated using Cohen *d* (continuous) and Cramér V (categorical).

Overall survival was analyzed using the Kaplan-Meier method and compared using the log-rank test. Both approaches were validated using the Korean Breast Cancer Society (KBCS) 2019 national registry data by comparing age, tumor stage, surgical procedures, molecular subtypes, and survival trends [17].

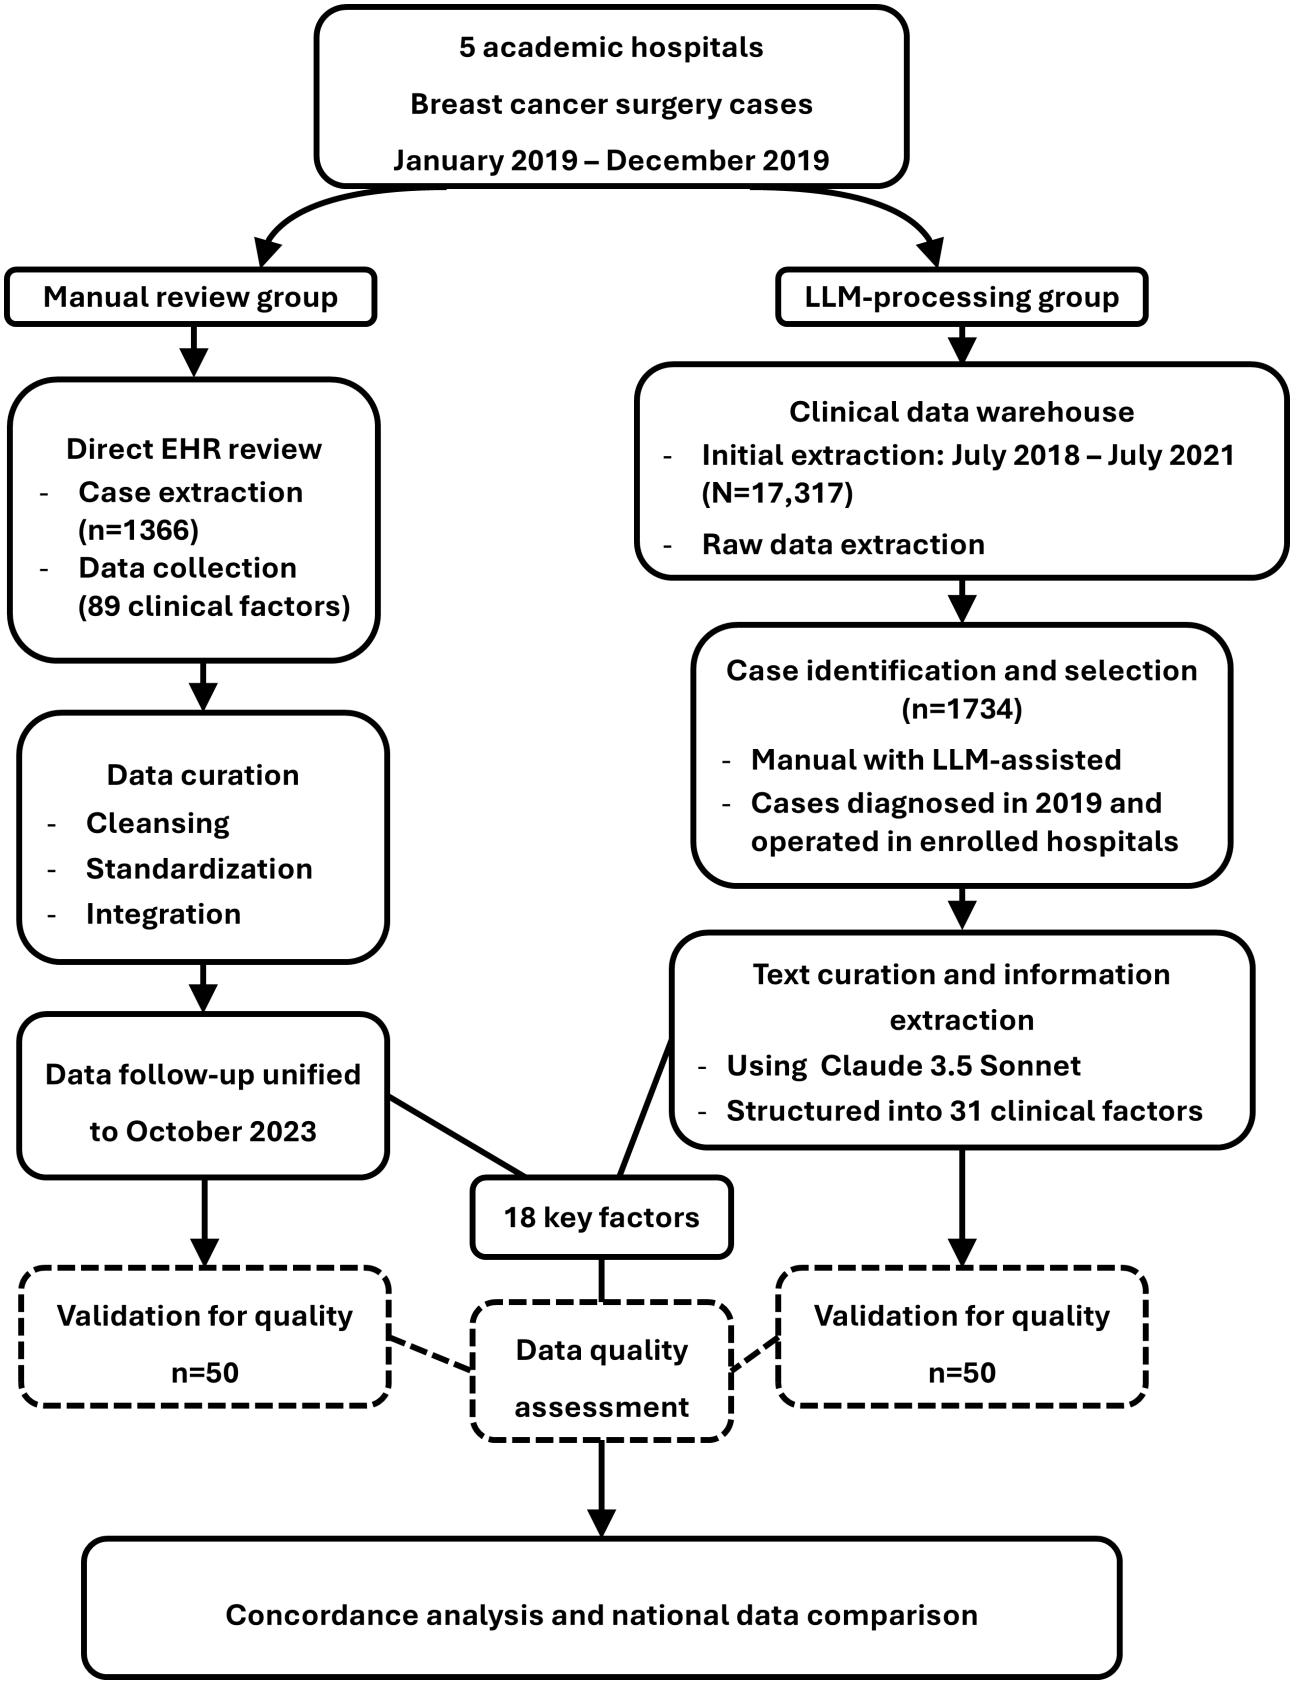
Data Quality Assessment and Validation

For validation, 50 cases from each group were selected using proportionate stratified random sampling. Stratification was based on the cancer stage (0-IV) and type of surgical intervention (breast-conserving surgery vs mastectomy) to ensure representative sampling across key clinical categories. Random selection was performed using Python (version 3.8; Python Software Foundation) with the *NumPy* (v.1.21.0) and *pandas* (v.1.3.0) libraries and a fixed random seed of 2,02,41,201 for reproducibility. Four breast-surgical oncologists (SJO, JPY, HK, and SL) independently evaluated 18 predefined clinical factors in each case (900 data points per group). Accuracy rates were calculated as the percentage of correctly extracted factors relative to the total number of factors. A dual-reference validation approach was implemented: group 1 was validated against the EHR, whereas group 2 was compared to the CDW raw data. The evaluation included both present and missing values. The accuracy threshold was set at 90% based on previous validation studies of clinical data extraction systems [18].

Ethical Considerations

This study was approved by the institutional review board of the Catholic Medical Center (approval: OC24WIDI0138). As this was a retrospective analysis of existing clinical data, the requirement for informed consent was waived by the institutional review board. All patient data were deidentified prior to analysis, with personal identifiers replaced by anonymized codes. The CDW platform ensures privacy protection through automated deidentification. No compensation was provided to participants, as this study involved retrospective data analysis only.

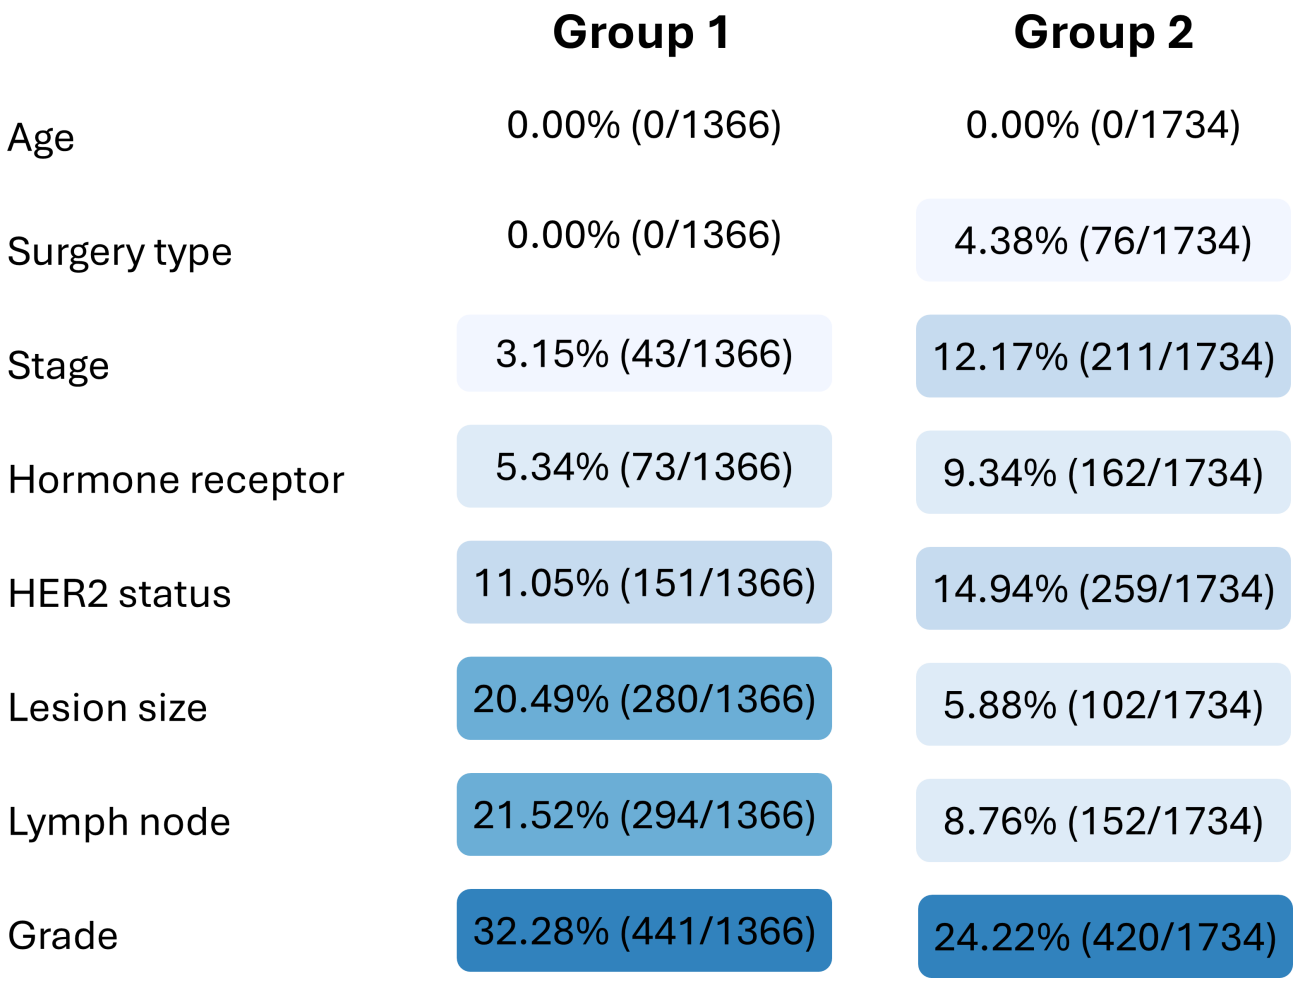
Results



Outcomes

For comparative analysis, 18 key clinical factors were selected from both groups (Figure 1). The manual review (group 1) and LLM processing (group 2) groups comprised 1366 and 1734 cases, respectively. Although both groups completely captured age data, they exhibited different patterns of missing data for the other parameters. Group 2 had higher missing rates in terms of cancer stage (12.2% vs 3.1%) and HER2 status (15.1% vs 11.0%), whereas group 1 had more missing data for lesion size (20.5% vs 5.9%) and lymph node assessment (21.5% vs 8.8%). Both groups maintained high documentation rates (>90%) for hormone receptor status (Figure 2).

The validation analysis encompassed 1800 data points (900 per group) across clinical factors. Group 1 demonstrated perfect accuracy with no discrepancies. Group 2 exhibited 83 discordant factors out of 900 data points with an accuracy rate of (817/900, 90.8%). Among 1734 patients in group 2, 260 (15%) underwent multiple surgical procedures. The LLM successfully integrated data from sequential operations in 53% (138/260) of these cases, while missing data integration in 47% (122/260).



XSL•FO
RenderX

Figure 2. Comparison of missing data rates (%) between manual review (group 1) and large language model (LLM) processing (group 2). Color intensity represents the magnitude of missing data, with darker shades indicating higher missing rates. HER2: human epidermal growth factor receptor 2.

Processing Time and Resource Use

LLM-based processing demonstrated efficiency gains compared to manual review (Table 1). Group 1 required 7 months (May 2021-November 2021) with 5 dedicated breast surgical oncologists. In contrast, group 2 processing was completed in 12 days (from October 20, 2024, to November 1, 2024) by 2 physicians, with data extraction taking 10 days and validation requiring 2 additional days.

Table . Comparison of processing efficiency.

Parameter	Manual review (group 1)	LLM[a] processing (group 2)	Difference
Total cases	1336	1734	+368
Processing period	7 months	12 days	−95%
Number of physicians	5	2	−60%
Total physician hours	Approximately 1025	Approximately 96	−91%
Direct EHR[b] access required	Yes	No	N/A[d]
API[c] cost	N/A[d]	Approximately $260	N/A

[a]LLM: large language model.

[b]EHR: electronic health record.

[c]API: application programming interface.

[d]N/A: not applicable.

Manual review required approximately 1025 physician hours total across 7 months. LLM processing required approximately 96 physician hours in total over 12 days, a 91% reduction in time investment.

Resource use differed substantially between the methods. The manual review required 5 breast surgical oncologists with a direct EHR access infrastructure and dedicated data entry personnel. LLM processing required 2 physicians using a

XSL•FO
RenderX

standard workstation without EHR access. The API cost for LLM processing was approximately $0.15 per case, totaling $260 for 1734 cases. Although direct personnel costs were not calculated due to institutional variations in physician compensation, the 91% reduction in physician hours represents substantial resource savings.

Demographics and Clinical Characteristics

The baseline characteristics of both groups are summarized in Table 2. The mean age differed slightly between groups 1 and 2 (55, SD 11.5 vs 53.5, SD 11.4 y; $P<.001$; Cohen $d=0.13$). For breast surgery, total mastectomy was performed in 19.2% of cases in group 1 and 26.5% in group 2, while nipple (skin)-sparing mastectomy rates were 15.7% and 9.6%, respectively ($\chi^{2}_{3}=164.3$; $P<.001$; Cramér V=0.29). When these procedures were combined, groups 1 and 2 exhibited similar proportions of breast-conserving surgery (63.5% vs 63.9%) and mastectomy (34.8% vs 36%), with a small effect size (Cramér V=0.10).

[b]LLM: large language model.

[c]N(S)SM: nipple or skin-sparing mastectomy.

[d]Combined mastectomy includes total mastectomy and N(S)SM.

[e]SLNB: sentinel lymph node biopsy.

[f]ALND: axillary lymph node dissection.

[g]ER: estrogen receptor.

[h]PR: progesterone receptor.

[i]HER2: human epidermal growth factor receptor 2.

In terms of axillary surgery, group 1 had a higher rate of SLNB than group 2 (68.4% vs 59.7%), whereas the rates of ALND were similar (χ^2_2=47.2; *P*<.001; Cramér V=0.13). The mean (SD) value of the harvested lymph nodes was similar between the groups (7.79, SD 7.03 vs 7.11, SD 7.20; *P*=.016).

The stage distribution differed between groups (χ^2_8=68.9; *P*<.001), but only slightly (Cramér V=0.16), with group 1 identifying more cancers as advanced. Hormone receptor status was similar between the groups (estrogen receptor: 78.3% vs 76.2%, *P*=.172; progesterone receptor: 68.7% vs 67.5%, *P*=.525). HER2 status differed negligibly, and Ki67 expression was similar between the groups (HER2: *P*=.003, Cramér V=0.003; Ki67: *P*=.391, Cramér V was approximately 0.00). Histological grade distributions were similar between the groups (*P*=.764).

Interrater Agreement Analysis

ICC analysis of continuous variables demonstrated a consistently low agreement: age (ICC 0.013, 95% CI –0.035 to 0.060), tumor size (ICC 0.029, 95% CI –0.021 to 0.078), number of metastatic lymph nodes (ICC 0.031, 95% CI –0.019 to 0.081), number of harvested lymph nodes (ICC 0.025, 95% CI –0.025 to 0.075), and Ki67 expression (ICC 0.027, 95% CI –0.023 to 0.077). All ICC values were negligible, and all CIs included zero.

Survival Outcomes

Survival analysis revealed significant differences between the groups (hazard ratio 2.917, 95% CI 1.496 to 5.688; *P*=.002). Group 2 captured more events (11 vs 41). The proportional hazards assumption was met (χ^2_1 =2.37; *P*=.120), and the log-rank test confirmed a difference in survival distributions (χ^2_1 =10.9; *P*=.001).

Comparison With National Registry Data

Comparison with the KBCS 2019 registry data (N=9447) revealed small differences in breast surgery patterns for both groups (Cramér V=0.03 - 0.04; *P*≤.018; Table 3). For axillary surgery, both groups had lower SLNB rates (group 1: 68.30% and group 2: 59.75% vs KBCS: 73.18%) and similar ALND rates (20.50% vs 20.88% vs 18.60%). Group 2 had a higher rate of no axillary surgery than group 1 (19.37% vs 11.20%).

Stage distribution analysis revealed significant but small differences from the national data (group 1: Cramér V=0.076, *P*<.001; group 2: Cramér V=0.038, *P*=.003). Regarding biomarker subtypes, both groups had slightly higher proportions of hormone receptor–positive with HER2-negative (group 1: 67.02% and group 2: 66.57% vs KBCS: 63.14%) and triple-negative cases (12.70% and 13.59% vs 11.98%) with minimal effect sizes (Cramér V=0.03 - 0.04).

ER[k] positive	1012 (78.28)	1198 (76.21)	7163 (75.82)		
PR[h] positive	886 (68.68)	1059 (67.50)	6254 (66.20)		
HER2[i] positive	249 (20.49)	298 (20.20)	1748 (18.50)		

[a]Percentages calculated based on cases with available data for each variable

[b]Statistical significance set at $P<.05$. Chi-square tests were used for categorical comparisons.

[c]KBCS: Korean Breast Cancer Society

[d]SLNB: sentinel lymph node biopsy.

[e]ALND: axillary lymph node dissection.

[f]Molecular subtypes were determined based on combined estrogen receptor (ER), progesterone receptor (PR), and HER2 status. HR+ defined as ER+ or PR+.

[g]ER: estrogen receptor.

[h]PR: progesterone receptor.

[i]HER2: human epidermal growth factor receptor 2.

Discussion

Principal Findings

This comparative study demonstrated that LLM-based processing achieved 90.8% accuracy in extracting clinical data from breast cancer records, with significant reductions in processing time (12 d vs 7 mo) and resource requirements (2 vs 5 physicians). The LLM approach captured substantially more survival events (41 vs 11; $P=.002$) and showed better documentation of lymph node assessment (91.2% vs 78.5%), although it had higher missing rates for integrated assessments such as cancer staging (12.2% vs 3.1%). Both methods yielded similar patterns in key clinical parameters, including breast-conserving surgery rates (63.5% vs 63.9%) and biomarker distributions.

A particular finding was the substantial difference in captured survival events between LLM processing (41 events) and manual review (11 events). This discrepancy may reflect fundamental differences in how humans and LLMs approach large-scale data extraction. Manual reviewers processing many charts may inadvertently adopt a mechanical approach, focusing on the most obvious data fields, while potentially overlooking mortality information scattered across multiple sections of the medical record. In contrast, LLM maintained consistent thoroughness throughout the extraction process, systematically examining all available data sources for each case without the cognitive fatigue that affects human reviewers during repetitive tasks.

XSL•FO
RenderX

This finding challenges the assumption that manual review is the gold standard for all types of clinical data extraction. While human expertise remains essential for complex clinical interpretation, our results suggest that LLM processing may provide a more complete capture of certain objective outcomes, particularly those requiring synthesis across multiple data fields. However, this interpretation requires further research to confirm whether the additional events captured by the LLM represent true positives or extraction errors.

Comparison With Prior Work

Although LLMs have shown favorable results in extracting specific medical data from radiology and pathology reports [19-22], our study represents the first comprehensive evaluation of surgical oncology data curation. Previous studies have focused on the extraction of single data points or specific types of reports. For instance, Park et al [20] demonstrated the effectiveness of LLM in extracting pulmonary disease information from radiology reports, whereas Cheng [22] reviewed its applications in pathology. Our study extends these findings by demonstrating that LLMs can handle the complex integration required for comprehensive oncological data including surgical procedures, pathological findings, and survival outcomes.

The observed statistical differences between groups, while significant, were mostly clinically negligible (Cramér V<0.30 for all comparisons), suggesting that LLM processing maintains clinical validity. The observed accuracy of 90.8% is comparable to recent studies, where LLMs achieved similar performance in extracting structured information from clinical notes, including the social determinants of health [23]. Although comprehensive systematic reviews of LLM applications in healthcare are still emerging [3], individual studies have consistently demonstrated their potential for automated clinical data extraction. However, unlike previous studies that focused on extracting discrete clinical variables or single-domain information [19-23], surgical oncology data require integration of multiple interconnected factors, presenting unique challenges in automated extraction.

Strengths and Limitations

Our study had several strengths. The large sample size provided robust statistical power. The use of real-world clinical data from multiple institutions enhanced the generalizability of the results. The head-to-head comparison with a manual physician review rather than against a reference standard alone provides practical insights for clinical research applications. Additionally, the demonstrated efficiency gains (12 d vs 7 mo) highlight the potential for scaling oncological research.

However, several limitations of this study must be acknowledged.

First, LLMs showed limitations in integrating multiple clinical events. Although the model performed well in extracting explicit data points, it struggled to synthesize information across sequential surgical procedures. This was evidenced by the higher rate of missing surgical data (12.2% vs 3.1%) in patients who underwent multiple operations. Manual reviewers could identify and integrate multiple surgical steps, such as lymph node assessment after initial diagnostic excision, while the LLM typically captured data from a single representative operation.

Second, the validation sample size of 50 cases per group represented only 2.9% and 2.6% of the respective cohorts. While this sample was stratified to ensure representation across cancer stages and surgical types and achieved adequate power for detecting clinically meaningful differences, a larger validation set would strengthen confidence in the accuracy estimates.

Third, differences in data sources between the groups may have affected direct comparability. The manual review group accessed complete EHRs directly, whereas the LLM group processed CDW-extracted data. This methodological design was unavoidable; manual reviewers needed direct EHR access for a comprehensive review, while the LLM required deidentified extracted data for processing. However, this means we cannot isolate whether performance differences stemmed from the extraction approach itself or from the inherent differences in available data. Future studies comparing both methods using identical raw data would overcome this limitation.

Fourth, generalizability to other LLM models requires evaluation. We used Claude 3.5 Sonnet, but the performance may vary across models, versions, and prompting strategies. The rapid evolution of LLM capabilities suggests that our findings represent a snapshot of current technology rather than definitive limits.

Future Directions

Future research should address several key issues. The first is the development of improved prompting strategies to handle complex clinical scenarios that require integrated assessment, particularly for sequential surgical procedures and temporal relationships. Second, LLM processing is compared with manual review using identical raw data sources to isolate the actual performance differences between the methods. Third, feasibility studies of integrated data curation across multiple clinical events are needed to overcome the current limitations in synthesizing longitudinal patient data. Fourth, a systematic examination of the performance characteristics of different LLM models is required to identify optimal models for specific clinical data types.

Conclusions

LLM-based processing demonstrated comparable effectiveness to manual review by physicians for breast cancer clinical data extraction, while significantly reducing processing time and resource utilization. Despite the limitations of integrated assessments requiring synthesis across multiple clinical events, this approach offers a solution for efficient clinical data extraction in oncology research. The ability to process large volumes of data consistently and rapidly while maintaining an accuracy above 90% suggests that LLM-based methods can accelerate retrospective clinical research.

Acknowledgments

This work was supported by the National Research Foundation of Korea grant funded by the Korea government (Ministry of Science and ICT; RS-2025-19643006). This study used the Claude 3.5 Sonnet (Anthropic) web interface (claude.ai) for large language model (LLM)-based data extraction, which did not require programming code. The extraction was performed through manual copy-paste operations with the structured prompt provided in Multimedia Appendix 5. Statistical analyses were performed using Python (version 3.8; Python Software Foundation) with NumPy (v.1.21.0) and pandas (v.1.3.0) libraries.

Abstract

Background: Diagnosis of venous thromboembolism (VTE) is often delayed, and facilitating earlier diagnosis may improve associated morbidity and mortality. Clinical notes contain information not found elsewhere in the medical record that could facilitate timely VTE diagnosis and accurate quality measurement. However, extracting relevant information from unstructured clinical notes is complex. Today, there are relatively few electronic clinical quality measures (eCQMs) in our national payment program and none that use natural language processing (NLP) techniques for data extraction. NLP holds great promise for making quality measurement more accurate and more efficient. Given the potential of NLP-based applications to facilitate more accurate VTE detection, primary care is one clinical setting in urgent need of this type of tool.

Objective: This study aimed to develop a tool that extracts VTE symptoms from clinical notes for use within an eCQM to quantify the rate of delayed diagnosis of VTE in primary care settings.

Methods: We iteratively developed an NLP-based data extraction tool, venous thromboembolism symptom extractor (VTExt), on an internal dataset using a rule-based approach to extract VTE symptoms from primary care clinical note text. The VTE symptoms lexicon was derived and optimized with physician guidance and externally validated using datasets from 2 independent health care organizations. We performed 26 rounds of performance evaluation of notes sampled from the case cohort (17,585 patient progress note sentences from 279 patient notes), and 5 rounds of evaluation of the control cohort (2838 patient progress note sentences from 50 patient notes). VTExt's performance was evaluated using evaluation metrics, including area under the curve, positive predictive value, negative predictive value, sensitivity, and specificity.

Results: VTExt achieved near-perfect performance in extracting VTE symptoms from primary care notes sampled from records of patients diagnosed with or without VTE. In external validation, VTExt achieved promising performance in 2 additional geographically distant organizations using different electronic health record systems. When compared against a deep learning model and 4 machine learning models, VTExt exhibited similar or even improved performance across all metrics.

Conclusions: This study demonstrates a data-driven NLP-based approach to clinical note information extraction that can be generalized to different electronic health record systems across different institutions. Due to the robust performance of this tool, VTExt is the first NLP application to be used in a nationally endorsed eCQM.

Introduction

Venous thromboembolism (VTE) is an often undetected condition that includes both deep vein thrombosis (clots in the deep veins of the body [1]), and pulmonary embolism (PE; clot breaking free and entering the pulmonary arteries [1,2]). VTE is associated with increased morbidity and mortality [3] with a 1-year VTE case-fatality rate estimated at 23% [4] and associated with increased health care costs [5].

The incidence of VTE in the United States is unknown as there is currently no national VTE surveillance system in place [1]. Cases are often missed since they are asymptomatic or associated with symptoms similar to those of other chronic conditions, leading to substantial undercounting. In a 2015 literature review, Heit [6] identified the incidence of VTE as ranging from 104 to 183 cases per 100,000 person-years. This rate is based largely on Caucasian populations [4,7-16] and differs by race where African American individuals face higher rates of VTE [17-19], and Asian [20], Asian American [21,22], and Native American individuals [23] see a lower VTE incidence. Higher levels of education, income, and employment status have also been shown to be associated with decreased risk of VTE [24]. Risk factors for VTE include a history of VTE [25] (rates of recurrent VTE range from 20% - 36% within 10 years of the initial VTE event [26,27]), older age [1], recent immobility or surgery, cancer, smoking, thrombophilia [28], and obesity [6].

Delayed diagnosis of VTE is common due to its nonspecific symptoms [29]. VTE can also be difficult to identify in the electronic health record (EHR) due to variability in how VTE is documented and coded [30]. Due to these challenges and the lack of national surveillance, the incidence of VTE is likely underestimated [31,32]. Tools to facilitate measurement and earlier diagnoses of VTE may help in better understanding VTE risk factors, reduce associated morbidity and mortality [33,34], and improve patient safety.

The widespread adoption of interoperable EHR systems after the 2009 Health Information Technology for Economic and Clinical Health Act [35,36] has led to a significant increase in unstructured text data, such as radiology reports, progress notes, and discharge summaries [37]. These unstructured data are estimated to constitute over 80% of health and biomedical information [37]. Free-text clinical notes in EHRs hold valuable insights for population-level quality improvement, but efficient strategies leveraging AI, machine learning, and natural language processing (NLP) are essential to harness this potential.

NLP is useful for analyzing unstructured EHR data in areas like radiology [38], oncology [39,40], endocrinology [41], substance misuse [42], PE identification [43], and postoperative VTE [44]. By extracting information from text, NLP creates structured data, reducing manual review and enabling large-scale automated processing [45]. High-throughput phenotyping algorithms using NLP-derived and structured data show promise for developing standardizing labeling [46] particularly for managing complex diseases in large-scale patient populations. NLP can also uncover critical information overlooked using structured variables [47,48]. While large language models (LLMs) are popular for NLP tasks, they are often more resource-intensive and costly than traditional machine learning or rule-based methods [49]. Though machine learning methods tend to have improved performance, a rule-based approach has advantages, such as traceability of results and speed of development [50].

NLP tools can detect VTE events, but more sensitive tools are needed to identify VTE events specifically in primary care EHR progress notes [44,51]. The objective of this study was to develop a simple, accessible NLP tool for identifying VTE symptoms in primary care EHRs, suitable for both high- and low-resource settings and aligned with the national quality payment program. The tool was tested on external datasets to evaluate its performance compared with deep learning and machine learning models. This main aim is to use narrative EHR data for clinical quality reporting to identify missed or delayed diagnoses of VTE after a primary care visit. A delayed diagnosis is defined as one that occurs >24 hours after the primary care visit when the VTE symptoms were documented.

Methods

Data Sources, Cohort Development, and Feature Selection Strategy

The study was conducted at Mass General Brigham (MGB), an integrated health care delivery system in Greater Boston, Massachusetts, using data from the MGB Enterprise Data Warehouse (EDW), an MGB central clinical data warehouse.

We used 2 internal datasets to develop and evaluate our NLP application for symptom extraction, and 2 independent external datasets to test how well it works in other settings. The first internal dataset, the case cohort, was used for development and evaluation. Inclusion criteria for this cohort are described below. The second internal dataset, the control cohort, included patients who did not meet case cohort inclusion criteria and was used for further evaluation. The external validation datasets came from 2 university health systems: the University of Kentucky and Penn State Health. These datasets were used to test if our symptom extractor works well with notes from different EHR vendors and health care systems.

We developed a multifactor phenotyping algorithm to identify VTE patients in the MGB cohort [52]. This included patients diagnosed with VTE from 2016 through 2021 who had a primary care visit in the 30 days before the date of diagnosis. We started by using *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) codes to identify an initial VTE patient cohort. Then we combined data from imaging records

XSL•FO
RenderX

(eg, current procedural terminology [CPT] codes) and anticoagulant orders (RxNorm codes) to further refine the initial cohort and develop the final VTE case cohort. The diagnosis date and time of VTE diagnosis was defined as when the radiologist signed off on the scan report [52,53].

We used a rule-based approach to identify terms from a lexicon derived from a set of VTE signs and symptoms. The lexicon was divided into 3 parts: one with relevant symptoms dependent on the part of the body (eg, swelling), another with the relevant symptom locations (eg, leg), and the last containing location-independent symptoms (eg, cough). Location-dependent symptoms required identification of both the symptom and a relevant location to be considered a symptom match. The lexicon was reviewed and revised over the course of the study in accordance with physician expert guidance.

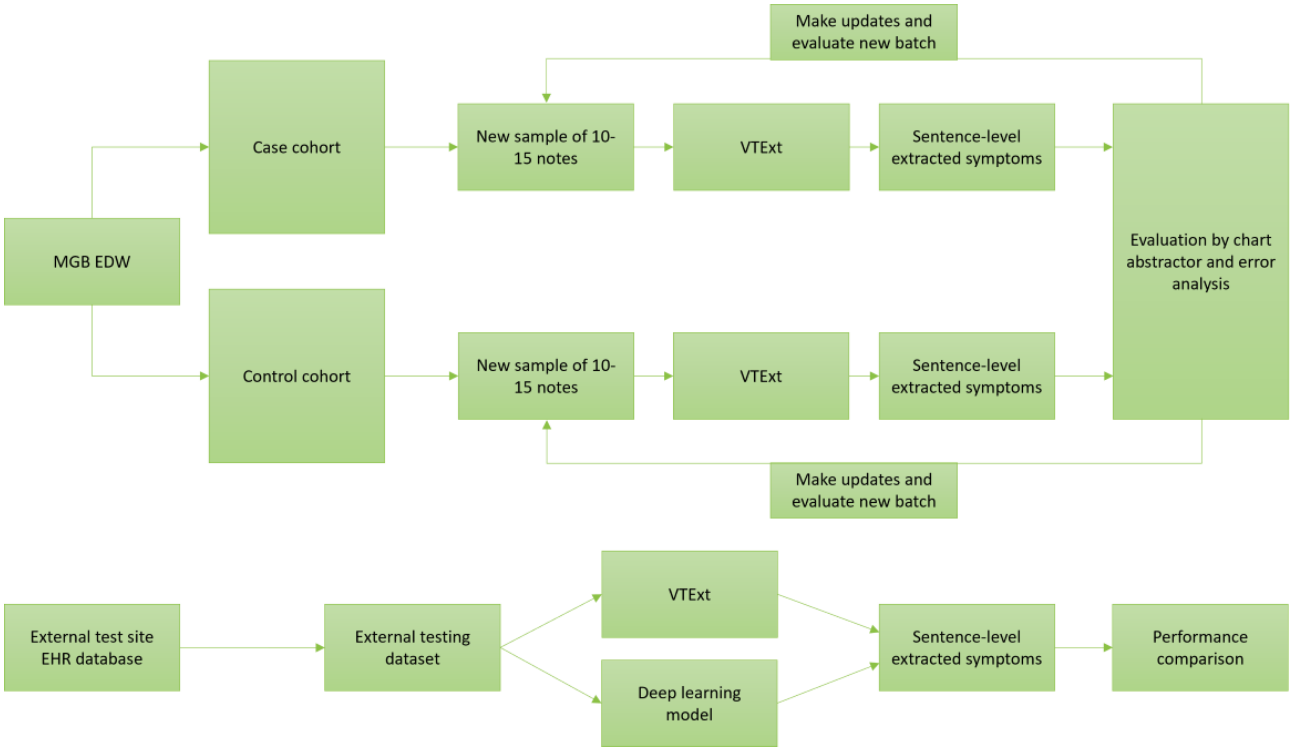
Clinician-Guided VTE Lexicon Development and Optimization

We identified VTE-related signs and symptoms by combining a literature review with interviews of physicians with experience in treating VTE patients. Multiple optimization steps were conducted: first, we conducted a comprehensive literature review to create an initial list of signs and symptoms. Then, we held 1-hour semistructured interviews with 5 experienced physicians to provide additional insight into signs and symptoms based on clinical experience. Signs and symptoms were also reviewed by a technical expert panel over the course of development, and their feedback was used to finalize the lexicon. In total, we included 29 distinct symptoms in the lexicon, consisting of 7 location-independent symptoms, 7 location-dependent symptoms, and 4 relevant locations. The final VTE symptom 3-part lexicon can be found in Multimedia Appendix 1. Inclusion criteria *ICD-10*, CPT, and RxNorm codes are provided in Multimedia Appendix 2. The prevalence of each symptom in each dataset is provided in Multimedia Appendix 3.

Extractor Development and Optimization

The Medical Text Extraction, Reasoning and Mapping System (MTERMS) [54] venous thromboembolism symptom extractor (VTExt) was developed using the Python programming language. We chose a rule-based approach to identify symptoms in order to facilitate transferability of the tool and to ensure transparency of its workings, which can be challenging when using more complex machine learning or LLM-based approaches [55]. Using a rule-based approach also suited the need for VTExt to identify VTE symptoms within specific contexts, for example, at specific body locations.

The development cycle used in the creation of VTExt entailed initial analysis of symptom extractor requirements, design and implementation of the extractor, iterative testing on samples of patient notes, and adjusting VTExt based on error analyses. The overall study design and development process is provided in Figure 1.



We first reviewed a small sample of cases from the dataset described above to understand how VTE symptoms appear in primary care progress notes, for example, how providers document VTE symptoms. The initial version of VTExt was then used to extract symptoms from a batch of sampled primary care progress notes. A trained chart abstractor reviewed each sentence analyzed by VTExt and determined whether the structured output was accurate, marking each case as a true positive, true negative, false positive, or false negative. Whenever an error occurred, the reason was identified, and adjustments were made to the extractor to avoid the error in the processing of future batches. We repeated this optimization process of running the extractor on a new sample of 10 - 15 notes, reviewing output, and refining the pattern-matching to iteratively improve the performance of the symptom extractor until we achieved a precision (positive predictive value [PPV]) of at least 0.95.

For each round, one progress note from each patient visit was extracted and combined into a single file. Patient notes were split into sentences using the MTERMS NLP system [54]. The symptom extractor then used regular expression-based rules to identify signs and symptoms of VTE in the curated lexicon and wrote output to a structured query language database to allow for integration of extractor output into other pipelines, including mapping symptoms to standardized terminologies. The NLP output table contains one column for each VTE symptom in the lexicon. Each row in the table corresponds to 1 patient note, and a binary output value for each symptom field indicates whether a given symptom was detected in the note by VTExt—if yes, presence was indicated with a value of “1,” and if not, a value of “0.”

To facilitate the clinical implementation of our tool, we developed a streamlined version of VTExt with simplified output for use with the electronic clinical quality measure (eCQM). Instead of producing output values for presence of individual signs and symptoms, this version produced a single “0” or “1” value for each patient note to indicate whether at least 1 VTE symptom was identified. This streamlined version of VTExt was used in the external evaluation of the tool. Pseudocode for the tool can be found on our project GitHub page [56].

Figure 1. Venous thromboembolism symptom extractor development and evaluation process. EDW; enterprise data warehouse; EHR; electronic health record; MGB; Mass General Brigham; VTExt: venous thromboembolism symptom extractor.

Note Processing and Evaluation

We evaluated the VTExt symptom extractor using both internal and external datasets. For internal evaluation, we used both a case cohort and a control cohort. The case cohort included patients who met our inclusion criteria for incident VTE based on the presence of 3 codes; *ICD-10* VTE codes, CPT imaging codes, and RxNorm anticoagulation codes [53]. The control cohort included patients who did not meet these criteria.

Internal evaluation of the VTExt symptom extractor was an iterative process, illustrated in Figure 1. From all patients who met the case cohort inclusion criteria, we randomly selected batches of 10 to 15 patient visits for each round of testing. We used a similar method to sample control notes to evaluate how well the symptom extractor generalized to patients that did not meet the case cohort inclusion criteria (eg, patients who did not have a VTE diagnosis).

External Evaluation

We worked with collaborators at both the University of Kentucky and Penn State Health (PSH) to test VTExt on patient notes. These sites used different EHR systems which also differed from MGB and had different textual data structures. In Epic (used at MGB), patient notes exist in tables, which include note-related information including metadata and the note content itself. Veradigm (formerly Allscripts; used by University of Kentucky) and Oracle Cerner (used by PSH) similarly store patient note data in document tables. For free text notes in Veradigm and Oracle Cerner, note contents of many documents are stored in “Character Large Objects” or “Binary Large Objects” fields. Notes in these areas of the database require special querying techniques to extract unstructured text, usually requiring certified analysts. Despite these differences, once note text data are available, the NLP tool functions properly irrespective of the EHR as it is not dependent on the EHR itself.

In addition, each system served a different population: MGB serving mostly urban and metro, University of Kentucky serving more rural, and PSH serving a mixed population of urban, metro, and rural. The diversity of sites included served as a good preliminary test for generalizability of VTExt.

During external evaluation, we compared the performance of the rule-based extractor against a pretrained sequence classification deep learning model derived from Bio+Clinical BERT (bidirectional encoder representations from transformers; using the HuggingFace transformers Python package), a contextualized word representation model based on BioBERT and trained further on Medical Information Mart for Intensive Care (MIMIC) data [57-60]. We also compared performance against 4 classical machine learning models: logistic regression, support vector machine (SVM), and random forest, implemented using the Python Scikit-learn module, and gradient boosting, implemented using the Python XGBoost module [61-63]. MGB data used during the development of VTExt were preprocessed using the Bio+Clinical BERT tokenizer for further training of the deep learning model. For training the four classical models, the MGB data were instead represented as unigrams transformed using term frequency—inverse document frequency (TF-IDF) [64]. For all models, data were divided into training and validation sets for training and tuning of model parameters, respectively. Final parameters for deep learning and machine learning models are provided in Multimedia Appendix 4. Each external site manually labeled a testing set of 500 note sentences for evaluation, 250 containing at least one VTE symptom and 250 with no VTE symptoms.

Ethical Considerations

This project was reviewed and approved by the Mass General Brigham institutional review board (protocol #2020P003979). In this protocol, a waiver of informed consent and a waiver of HIPAA (Health Insurance Portability and Accountability Act) authorization was requested because this quality improvement research involves no more than minimal risk to the participants and the research could not practicably be carried out without the waiver given the large number of patients who had a VTE diagnosis in a primary care setting. In addition, this research could not practicably be conducted without access to and use of the protected health information. The following procedures were followed to prevent breach in confidentiality: (1) data were accessed only behind MGB firewall using password-protected, secure devices by Collaborative Institutional Training Initiative–certified study staff, and (2) we will destroy all patient identifiers at the end of the study, once analysis and publications are finalized. In accordance with the approved institutional review board protocol, all electronic data were kept in password-protected files on a secure server behind the MGB firewall. Only study personnel were given a unique identifier—no participant identifiers are linked to the data. No compensation was provided for participation.

Results

We performed 26 rounds of evaluation of VTExt performance on notes sampled from the case cohort. This included 17,585 patient progress note sentences from 279 notes from distinct patients, 171 of which were found to contain 1 or more VTE symptoms. Evaluation of the control cohort included 2838 note sentences from 50 patient notes over the course of five rounds of evaluation, of which 21 notes contained at least 1 relevant symptom.

Performance was evaluated at the sentence level. We measured precision (PPV), recall (sensitivity), specificity, and negative predictive value (NPV; Table 1). Of these metrics, achieving a high precision score proved to be the greatest challenge. Many false positives initially arose due to 3 kinds of errors, shown in Table 2. Some errors were due to word misspellings in the notes (which we refer to as type A errors). For example, misspelling of the word “denies” caused VTExt to miss negation of subsequent VTE symptoms. In other cases, an error occurred because a symptom was identified but was attributed to the incorrect body part (a type B error). Many false positives arose in early stages of evaluation from failure to detect negation or context, as in the Type C error examples in Table 2.

Table . Venous thromboembolism symptom extractor validation performance on notes of case cohort (patients with venous thromboembolism diagnosis).

Validation round	Patients, n	Precision (positive predictive value)	Recall (sensitivity)	Specificity	Negative predictive value
Round 1	673	0.500	0.863	0.929	0.988
Round 9	692	0.851	0.966	0.984	0.997
Round 17	489	0.750	1.000	0.998	1.000
Round 26	938	1.000	1.000	1.000	1.000

Table . Examples of common sources of symptom extractor false positive errors.

Error type	Examples
Type A: misspelling	She “deneis” shortness of breath or pleuritic chest pain
Type B: symptom attributed to wrong body part	Worsening R hip “pain” as well as recent development of R “leg,” ankle, and foot erythema
Type C: negation or context	“Resolution” of hypoxia and chest pain. Nitroglycerin 0.4 MG SL tablet place 1 tablet (0.4 mg total) under the tongue every 5 (five) minutes “as needed” for chest pain

For the first example, VTExt captured the symptom hypoxia without identifying the negating phrase “resolution of.” In the second example, though chest pain is mentioned, it appears in the context of a medication to be taken as needed, which we deemed not to be strong enough evidence of the presence of a symptom. Repeated validation allowed us to learn what contexts and negating phrases appeared in clinical text, and this knowledge was used to improve VTExt’s ability to locate them.

Through this process, precision improved from 0.5 in the first round of testing to near-perfect in the final round. Near-perfect performance was also achieved for recall, specificity, and NPV in the final round of validation. In addition, we tested the extractor on several random samples of primary care clinical notes of patients in the cohort, that is, those not diagnosed with VTE (Table 3, in batches of 10 - 15 notes, with precision ultimately reaching 0.85).

XSL•FO
RenderX

Table . Venous thromboembolism symptom extractor validation performance on notes of the control cohort (patients with no venous thromboembolism diagnosis).

Validation round	N	Precision (positive predictive value)	Recall (sensitivity)	Specificity	Negative predictive value
Round 1	281	0.533	1.000	0.974	1.000
Round 2	471	0.556	1.000	0.991	1.000
Round 3	613	0.750	1.000	0.998	1.000
Round 4	559	0.806	1.000	0.989	1.000
Round 5	912	0.850	0.895	0.997	0.998

As seen in the external evaluation results in Table 4, performance metrics for the rule-based extractor were similar or better than those for the deep learning and machine learning models at both external testing sites. While VTExt's precision and specificity scored high, sensitivity showed room for improvement (0.61 and 0.66 at PSH and University of Kentucky, respectively).

Error analysis of external testing results showed many deep learning model false negatives falling into 2 categories. Some errors can be attributed to overrepresentation of negated instances of certain VTE symptoms in the training dataset. This then makes the model more inclined to mark note sentences containing said symptoms as negative, even when the symptom is not negated. For the second category, less common terms used to describe relevant symptoms appear in testing data, for example, "malleoli" used in describing swelling of ankle. If such terms are not present in the training data, the model has no way of knowing they are relevant.

The rule-based model also produced false negatives, many belonging to one of two types. First, some errors can be attributed to double negation, which VTExt is not currently able to handle. For example, "SOB not resolved"—here, we see a VTE symptom, shortness of breath (SOB), followed by negating term "resolved." However, "resolved" itself has been negated, and so this represents a positive instance. The second error type pertains to synonymous terms of phrases of VTE symptoms that are not currently included in the lexicon, for example, "black and blue area" as another way to phrase bruising. Since the phrase "black and blue area" is not part of the symptom lexicon, the rule-based model did not detect the symptom.

The results for the eCQM have been reported elsewhere [53]. The calculated rate of delayed VTE diagnosis was over 70% at both MGB and University of Kentucky, suggesting a clinically and practically meaningful measure for understanding delayed diagnosis rates across diverse health care sites.

Discussion

Principal Findings

Much of the data not captured in structured EHR fields, like patient symptoms, are found in clinical notes [48]. In this study, we developed and validated a simple and generalizable NLP tool to identify and extract signs and symptoms of VTE from primary care notes through an iterative optimization process. VTExt is novel as the first NLP application linked to a nationally endorsed eCQM [65], helping to quantify the rate of delayed diagnosis of VTE in primary care. Through multiple rounds of optimization, VTExt showed robust performance and speed. Testing at two external sites demonstrated its ability to work well with different datasets and system configurations and its potential for optimizing quality measurement. We suggest that analysts familiar with their EHR and its local configurations could readily apply this NLP tool to their patient notes.

We learned several important lessons during optimization. Reducing the prevalence of false positives was crucial for improving extractor performance. In early rounds of validation, type B and type C errors often arose in long sentences due to a lack of constraint on the allowed search distance between a VTE symptom and a body part, or between a negating or contextual phrase and a symptom. We experimented with search distances of various lengths and found a distance of 150 characters struck a good balance of incorporating context without introducing too much noise, improving precision while maintaining high sensitivity.

We focused on primary care progress notes for developing and testing VTExt. Our external evaluation indicated that differences in note styles and hospital policies can affect performance. However, consistent performance observed between the 2 external sites highlighted VTExt's strong generalizability. VTExt's rule-based approach offers advantages including easier implementation, faster processing, and easier interpretation of

XSL•FO
RenderX

results when compared with the tested machine learning and deep learning models. Error analysis also revealed further improvement opportunities for the symptom extractor. Working with collaborators at external sites to further refine VTExt to reduce false negatives would prove beneficial in improving sensitivity and NPV.

Comparison With Previous Work

Shi et al [44] developed an NLP tool to detect postoperative VTE from free-text EHR notes. Internal validation demonstrated a sensitivity of 0.71 and specificity of 0.99. In the 2 health care systems tested, this NLP approach demonstrated superior performance in DVT surveillance than existing tools, and similar performance in PE surveillance compared with existing tools. Chapman et al [51] developed an NLP-based application to classify pulmonary angiography reports for document-level identification of PE, with test set performance resulting in sensitivity of 0.98 and PPV of 0.83. Sabra et al [66] incorporated Unified Medical Language System concept mapping into an NLP tool to generate feature vectors. These were then used to train and test an SVM machine learning model that achieved a PPV and sensitivity of 0.55 and 0.86, respectively. Work done by Jin et al [67] to identify VTE in inpatient notes using rule-based NLP methods highlights an approach that achieved similar performance to VTExt (0.90 sensitivity, 1.0 specificity), splitting notes into sentences, and then aggregating sentence-level information to make VTE inference at the sentence, document, and patient level. Although many of their tools would not be sufficient for our study's goal of VTE symptom identification for quantifying delayed diagnosis, these studies show that NLP tools can effectively identify VTE events, and there is a need for more sensitive tools to identify VTE events using EHR progress notes in the primary care setting.

Limitations

Our study has a number of limitations. First, VTExt is currently unable to handle misspellings in note text. Revising VTExt to handle misspellings would result in improved performance. Second, MGB was unable to view clinical note data used by external sites in the testing of VTExt in order to maintain patient data privacy. This reduced our ability to improve the tool's generalizability, as MGB was unable to directly review output from the University of Kentucky and PSH other than performance metrics. Third, development and refinement of VTExt was based on 279 patient notes. While high performance was achieved, a wider dataset would provide additional context and understanding of the ways VTE symptoms are documented in clinical note text, allowing for further improvement of the tool.

Future Directions

While a rule-based approach was simpler to implement, future improvements in accessible, high-performance LLMs could make them useful and feasible for quality measurement. These tools have already shown good results in extracting information from radiology reports [68], and could also be used to extract signs and symptoms from other types of clinical notes. Since LLMs are trained on large volumes of data, such an approach may generalize better across different health care systems and differently formatted notes when compared with a rule-based method. An LLM approach may more easily generalize to extracting symptoms from types of notes other than primary care progress notes, a logical future direction for research in this area. An immediate LLM-based approach was not pursued because we began this project in 2020 before there was mass public access to LLMs. While LLMs prove a promising direction for future work, the cost, time, and knowledge required to test such an approach at the collaborating sites were real limiting factors. In addition to an LLM approach, future work to improve model performance could include expanding the lexicon of symptom synonyms, as well as more robust handling of context and negation.

In addition to an LLM approach, future work to improve model performance could include expanding the lexicon of symptom synonyms, as well as more robust handling of context and negation.

Conclusions

We developed a robust and efficient NLP-based tool, VTExt, to extract VTE-associated symptoms from primary care notes. VTExt achieved high sensitivity and specificity, performance that matches or exceeds that of deep learning models and demonstrates its reliability for clinical use. High sensitivity ensures that most patients with VTE symptoms are correctly identified, reducing the risk of missed or delayed diagnoses, which can have serious or fatal consequences. High specificity minimizes false positives, helping avoid unnecessary tests, anxiety, and resource use. Together, these metrics underscore VTExt's clinical value in supporting timely, accurate identification of potential VTE cases from unstructured data.

VTExt's generalizability across health care systems further supports its real-world applicability, enabling scalable deployment in diverse EHR environments. Its rule-based design facilitates transparency and ease of implementation, particularly for quality measurement initiatives such as tracking delayed diagnosis. Furthermore, the clinician-guided optimization process developed alongside VTExt provides a replicable framework for future NLP tool development and integration into clinical workflows, helping bridge the gap between EHR data and actionable insights for patient safety and care improvement.

Abstract

Background: Bleeding adverse drug events (ADEs), particularly among older inpatients receiving antithrombotic therapy, represent a major safety concern in hospitals. These events are often underdetected by conventional rule-based systems relying on structured electronic medical record data, such as the *ICD-10 (International Statistical Classification of Diseases and Related Health Problems 10th Revision*) codes, which lack the granularity to capture nuanced clinical narratives.

Objective: This study aimed to develop and evaluate a natural language processing (NLP) model to detect and categorize bleeding ADEs in discharge summaries of older adults. Specifically, the model was designed to distinguish between "clinically significant bleeding," "severe bleeding," "history of bleeding," and "no bleeding," and was compared with a rule-based algorithm using *ICD-10* codes.

Methods: Clinicians manually annotated 400 discharge summaries, comprising 65,706 sentences, into four categories: "no bleeding," "clinically significant bleeding," "severe bleeding," and "history of bleeding." The dataset was divided into a training set (70%, 47,100 sentences) and a test set (30%, 18,606 sentences). Two detection approaches were developed and evaluated: (1) an NLP model using binary logistic regression and support vector machine classifiers, and (2) a traditional rule-based algorithm relying exclusively on predefined *ICD-10* codes. To address class imbalance, with most sentences categorized as irrelevant ("no bleeding"), a class-weighting strategy was applied in the NLP model. Model performance was assessed using accuracy, precision, recall, F_1-score, and receiver operating characteristic (ROC) curve analyses, with manual annotations as the gold standard.

Results: The NLP model significantly outperformed the rule-based approach across all evaluation metrics. At the document level, the NLP model achieved macro-average scores of 0.81 for accuracy and 0.80 for F_1-score. Precision was particularly high for detecting severe (0.92) and clinically significant bleeding events (0.87), demonstrating strong classification capability despite class imbalance. ROC analyses confirmed the model's robust diagnostic performance, yielding an area under the curve (AUC) of 0.91 when distinguishing irrelevant sentences from potential bleeding events, 0.88 for identifying historical mentions of bleeding, and notably, 0.94 for differentiating clinically significant from severe bleeding. In contrast, the rule-based *ICD-10* model demonstrated high precision (0.94) for clinically significant bleeding but poor recall (0.03) for severe bleeding events, reflecting frequent missed detections. This limitation arose due to its reliance on commonly used *ICD-10* codes (eg, gastrointestinal hemorrhage) and inadequate capture of rare severe bleeding conditions such as shock due to hemorrhage.

Conclusions: This study highlights the considerable advantage of NLP over traditional *ICD-10*–based methods for detecting bleeding ADEs within electronic medical records. The NLP model effectively captured nuanced clinical narratives, including severity, negations, and historical bleeding events, demonstrating substantial promise for improving patient safety surveillance and clinical decision-making. Future research should extend validation across multiple institutions, diversify annotated datasets, and further refine temporal reasoning capabilities within NLP algorithms.

Introduction

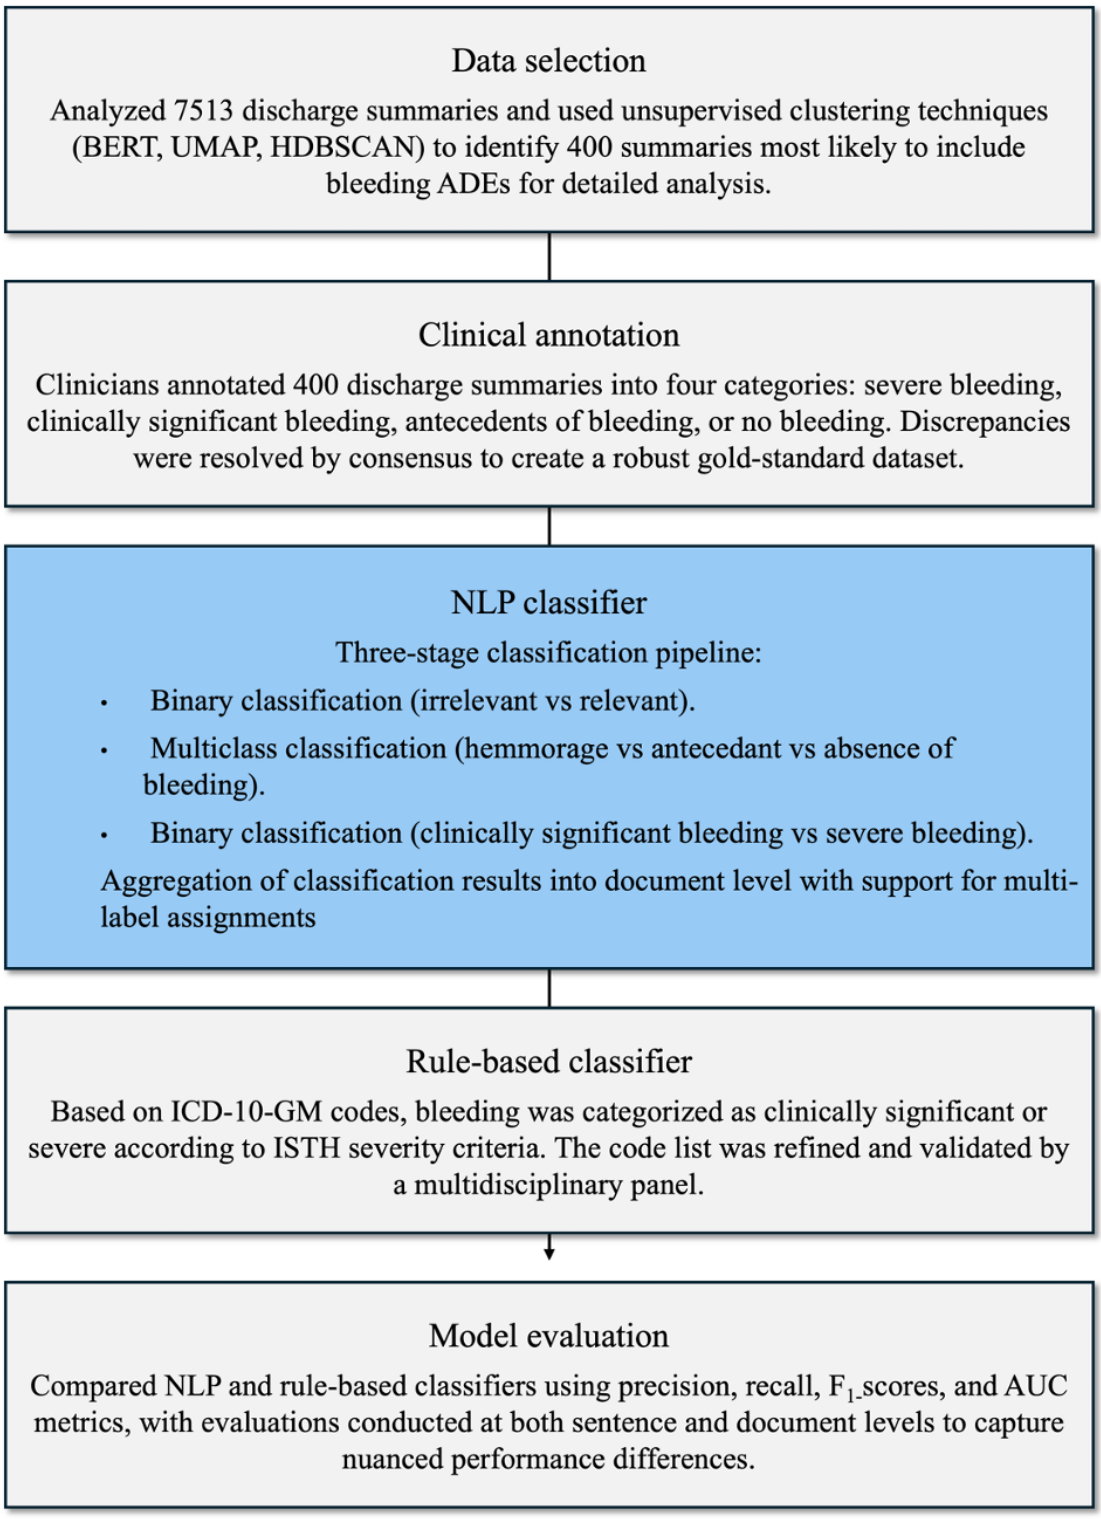
Adverse drug events (ADEs) are a significant patient safety issue, particularly among older adult inpatients. Globally, ADEs are estimated to affect 10%-40% of hospitalized patients, contributing to increased morbidity, mortality, and health care costs [1-3]. Among older adult patients, who are often treated using complex medication regimens, the risk of ADEs is even higher due to age-related physiological changes and a higher prevalence of polypharmacy [4,5]. Data on the incidence and impact of ADEs in Switzerland's hospitals are sparse, however, making it difficult to fully assess the scope of the problem [6].

Antithrombotic therapy, commonly prescribed to prevent thrombotic events, significantly increases the risk of bleeding by inhibiting normal clotting mechanisms. Studies have shown that approximately 36% of older adult inpatients on antithrombotic therapy experience bleeding complications, which can lead to extended hospital stays and increased morbidity and mortality [5]. The widespread use of polypharmacy in this population further compounds the risk of drug interactions, contributing to ADEs [7]. In Swiss hospitals, the timely and accurate detection of bleeding events is considered crucial to improve patient outcomes and ensure safer care [8].

Electronic medical records (EMRs) provide an opportunity to automate the detection of ADEs such as bleeding. Bleeding events are commonly identified through structured data, particularly via the diagnostic codes in the (*ICD*) *International Classification of Diseases*, which are frequently used for billing purposes. However, *ICD* codes often lack the specificity required to capture the complexity and nuances of bleeding ADEs [9-11]. Research has shown that *ICD* codes frequently underreport ADEs, with sensitivities below 50% in many cases, leading to an incomplete picture of patient safety [12]. In addition, coding algorithms for detecting ADEs usually exhibit low sensitivity and precision, and there is no universally accepted set of *ICD-10* (*International Classification of Diseases, 10th Revision*) codes or algorithms that ensures the consistent identification of bleeding ADEs in administrative data [13]. Although a manual review of medical records can be more accurate, it is labor-intensive and impractical for widespread use [10].

Natural language processing (NLP), a branch of artificial intelligence, provides a scalable solution to the automated extraction and classification of information on bleeding ADEs from unstructured text, such as inpatient discharge summaries and clinical notes [14,15]. These notes often contain detailed narrative descriptions of clinical events, such as "nonglomerular microhematuria" or "no visible bleeding at the anamnesis," which billing codes might miss [16]. NLP models can detect key clinical information buried within these narrative notes, providing more accurate insights into patients' conditions than frequently used methods such as *ICD* coding. Previous studies have demonstrated that NLP can detect ADEs from clinical notes with accuracies as high as 85%-90%, significantly outperforming standard methods [17-20]. By leveraging NLP and integrating it into hospital workflows, health care professionals can improve the surveillance of ADEs, make more timely interventions, and provide more responsive, personalized patient care [21].

In this study, conducted within the framework of the Swiss Monitoring of Adverse Drug Events (SwissMADE) project [8], we hypothesized that an NLP-based approach would be more effective than *ICD* code–based algorithms for detecting and categorizing bleeding ADEs among older adult inpatients receiving antithrombotic therapy at Lausanne University Hospital. The primary objective was to develop an NLP model capable of identifying bleeding ADEs from the discharge summaries of older adult inpatients hospitalized in 2015 and 2016 and to categorize these events based on their timing (ie, before admission or during the hospital stay) and severity (clinically significant bleeding or severe bleeding). The secondary objective was to compare the NLP model's performance against standard *ICD-10*–based algorithms and identify the most effective automated method for detecting bleeding ADEs in Switzerland's health care context.



Methods

Study Design

We conducted a secondary analysis of unstructured data in the EMRs investigated by the SwissMADE study, a multicenter, cross-sectional study that used retrospective medical data from 4 large Swiss hospitals [8]. Figure 1 provides an overview of the methodological framework used in this study.

XSL•FO
RenderX

Figure 1. Overview of the methodological framework used in this study. ADE: adverse drug event; AUC: area under the curve; BERT: Bidirectional Encoder Representations from Transformers; HDBSCAN: hierarchical density-based spatial clustering of applications with noise; *ICD-10-GM*: *German Modification of the International Statistical Classification of Diseases and Related Health Problems, 10th Revision*; ISTH: International Society on Thrombosis and Haemostasis; NLP: natural language processing; UMAP: uniform manifold approximation and projection.

Study Population and Dataset Selection

The dataset comprised the discharge summaries of patients aged 65 or older who were hospitalized for more than 24 hours in 2015 and 2016 and received at least one antithrombotic medication during their stay. These summaries also included administrative data, such as *ICD-10-GM* (*International Classification of Diseases, 10th Revision, German Modification*)

XSL•FO
RenderX

diagnostic codes. A detailed description of the SwissMADE study's methods has been published previously [8].

Of the 7513 discharge summaries examined, an unsupervised machine learning approach identified 400 as likely to contain bleeding ADEs (Figure S1 in Multimedia Appendix 1). This approach involved text scanning, thematic aggregation, and data extraction. The study generated unique sentence embeddings by integrating Bidirectional Encoder Representations from Transformers (BERT) into the Sentence Transformer library [22]. Techniques such as Uniform Manifold Approximation and Projection (UMAP) [23] and Hierarchical Density-Based Spatial Clustering of Applications with Noise (HDBSCAN) [24] were applied to organize these embeddings into "clusters" of bleeding ADEs. This methodology was instrumental in selecting the 400 discharge summaries most relevant to the study.

Annotation of Clinical Documents

The 400 discharge summaries were first annotated by clinicians and then divided into a training set (n=280) and a test set (n=120). The distribution of summaries was randomized to ensure the sample remained representative of the overall population of hospitalized patients.

Three clinicians independently annotated each discharge summary using four predefined labels:

1. Presence of severe bleeding: this label was used when a discharge summary explicitly identified severe bleeding, either by using the term "severe" or by describing conditions that meet the criteria for severe bleeding, such as fatal bleeding, bleeding at critical sites (eg, intracranial and intraspinal), a drop in hemoglobin of ≥20 g/L, or transfusion of ≥2 units of blood, as defined by the International Society on Thrombosis and Haemostasis (ISTH) [25].
2. Presence of clinically significant bleeding: this label was used when bleeding was mentioned in the clinical documentation but did not meet the criteria for severe bleeding.
3. History of bleeding: this label was applied when a discharge summary mentioned bleeding in the patient's medical history before their hospital admission.
4. Absence of bleeding: this label was used when a discharge summary did not mention bleeding.

A fourth clinician resolved any disagreements, and this classification was used as the gold standard for training the machine learning model. Fleiss kappa coefficient, calculated from 30 summaries, showed 96% agreement among clinicians, allowing a shift to a single-reviewer approach. Only discharge summaries signed by an attending physician were included to ensure data credibility.

Development of the NLP-Based Classifier

The development method comprised three phases: segmenting discharge summaries into sentences, classifying those sentences, and aggregating them at the document level.

Phase 1: Segmentation

Sentences were segmented from the discharge summaries using the pretrained French spaCy model (Explosion AI) [19], chosen for its efficiency, robustness, and widespread adoption in NLP pipelines [26]. Given that sentence segmentation is a standard preprocessing step with minimal differences among comparable models [27], no additional comparative analyses were performed. To reduce noise, sentences with fewer than three characters were excluded, a decision supported by pilot tests demonstrating minimal loss of meaningful content.

Phase 2: Classification Process

The classification process addressed the challenge of class imbalance, particularly at the sentence level, where the majority of sentences were labeled as "Irrelevant," indicating no bleeding-related information.

To mitigate this imbalance during training, a class-weighting strategy was applied in the logistic regression model used for the initial binary classification [28]. This approach adjusted the contribution of each class to the loss function by assigning higher weights to minority classes, such as "severe bleeding," and lower weights to the majority class, "Irrelevant." This adjustment improved the model's ability to identify rare but clinically critical cases. Additional details on the dataset preparation and the class-weighting strategy are provided in the supplementary materials.

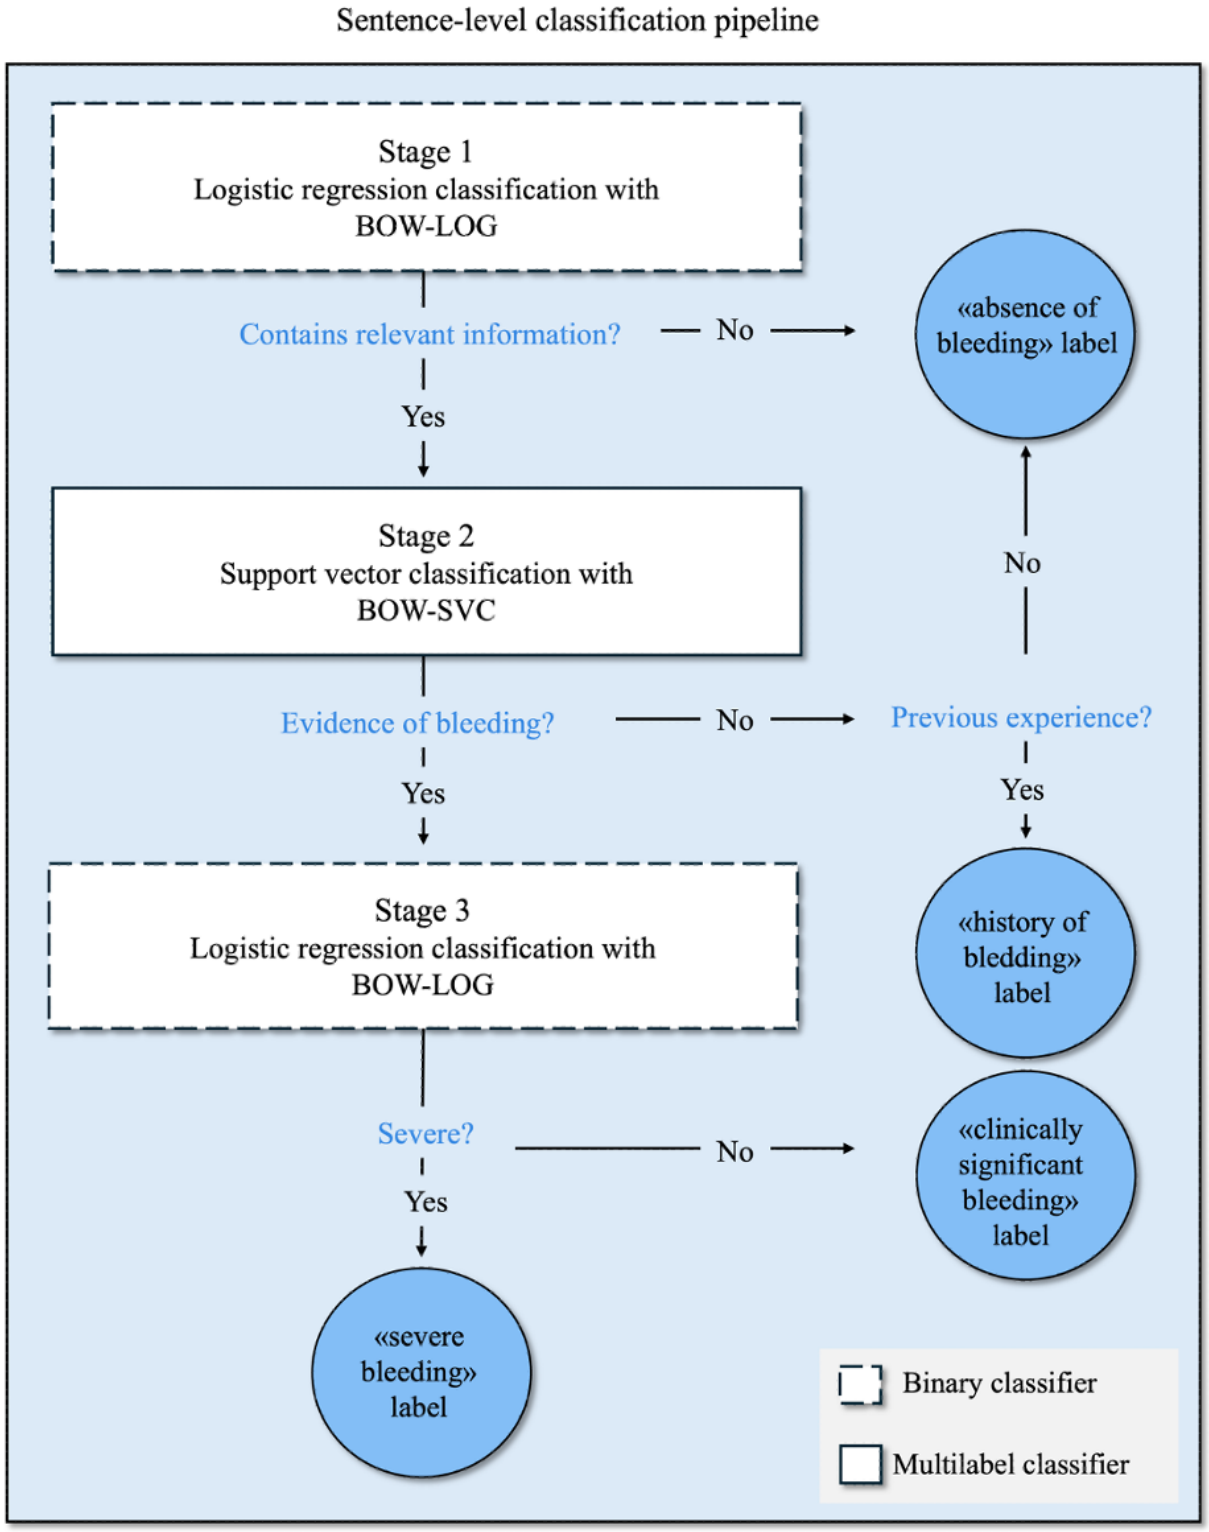


Figure 2 illustrates the multistage classification process for identifying bleeding ADEs in clinical narratives. Stage 1 used a binary logistic regression model to classify sentences as either containing bleeding-related information (labeled "relevant;" value=1) or not ("irrelevant;" value=0), reducing the number of nonrelevant sentences. Stage 2 used a support vector machine (SVM) classifier to further divide the relevant sentences into three categories: "irrelevant," "antecedent," or "bleeding-related." Stage 3 applied a second binary classification to "bleeding-related" sentences, categorizing them as either "clinically significant" (value=0) or "severe" (value= 1).

Logistic regression and a bag-of-words–based SVM were selected due to their simplicity, interpretability, and effectiveness on smaller datasets, minimizing the risk of overfitting compared to more complex deep learning methods. Preliminary experiments using deep learning models yielded poor performance, likely due to the limited size of the dataset; therefore, these methods were not pursued further in this study.

The entire process used bag-of-words encoding to convert the text into a format suitable for machine learning algorithms. Robustness was ensured through 5-fold cross-validation [29], regularization techniques (eg, L2 regularization for logistic regression and optimization of the penalty parameter [C] in SVM), and hyperparameter tuning via grid search [30,31]. These methodological choices optimized performance while preventing overfitting.

XSL•FO
RenderX

Figure 2. Sentence-level classification pipeline for detecting bleeding events. In this pipeline: BOW-LOG: logistic regression classification using a bag-of-words (BOW) model to determine whether the sentence contains bleeding-relevant information; BOW-SVM: support vector machine (SVM) classification using a BOW model to assess whether there is evidence of bleeding in the sentence; BOW-LOG: a second logistic regression classification using a BOW model to evaluate the severity of the bleeding event (ie, whether it is severe or clinically significant).

Phase 3: Document Aggregation

Sentence-level classification results were aggregated at the discharge summary level by grouping sentences under their corresponding document ID and combining the predictions using a union-like operation. If all sentences in a document were labeled “irrelevant,” the entire document was classified the same. Otherwise, the document was assigned one or more of the following labels: “antecedent,” “clinically significant

XSL•FO
RenderX

bleeding," or "severe bleeding." Unlike sentences, documents could receive multiple labels.

Rule-Based Classifier Development

In parallel with the NLP approach, we developed a rule-based classifier using *ICD-10-GM* codes to detect bleeding ADEs. This classifier enabled us to compare the analysis with the NLP methods. We began by compiling a comprehensive list of *ICD-10* diagnostic codes related to bleeding, drawing on subdivisions defined by the ISTH and codes identified in previous studies [32-34].

We thoroughly explored *ICD-10* ontologies to identify additional codes for terms such as "bleeding" and "hemorrhage." A multidisciplinary panel of physicians, pharmacologists, pharmacists, and statisticians reviewed and expanded this list, adding codes for conditions such as hemodynamic instability, drug-induced bleeding, and contusions. We then categorized these codes into two mutually exclusive groups based on the ISTH's severity criteria: "clinically significant bleeding" and "severe bleeding." The classification considered factors such as the site of bleeding.

The complete list of codes used appears in Tables S1 and S2 in Multimedia Appendix 1. However, unlike the NLP approach, the rule-based method was limited to just 2 labels due to the absence of specific *ICD-10* codes for identifying a patient's history of bleeding. Moreover, the rule-based approach did not account for timing, making it difficult to determine whether bleeding occurred before or during the hospital stay.

Model Evaluation and Comparison

We conducted a comparative analysis of the rule-based classifier and the NLP method to assess their effectiveness and accuracy in identifying hemorrhagic events from discharge summaries. Using the independent test dataset to ensure unbiased assessments, we applied standardized evaluation metrics, namely precision, recall, specificity, and F_1-score, focusing on each method's ability to detect clinically significant and severe bleeding. We used a receiver operating characteristic (ROC) curve to evaluate the NLP model's diagnostic capacity, measuring its overall performance through its area under the curve (AUC) [35]. We also calculated Cohen kappa to facilitate a comparative analysis of the methods' detection accuracies [36].

All statistical analyses were performed using Python software (version 3.9, Python Software Foundation), ensuring a robust computational environment. We calculated both micro- and macro-averages to provide a comprehensive evaluation of the classifiers' performances. Micro-averages were computed at the sentence level, measuring overall performance across all sentences, while macro-averages were calculated at the document level, giving equal weight to each document regardless of the number of sentences it contained.

Ethical Considerations

This study involved secondary analysis of pre-existing clinical data from discharge summaries collected within the SwissMADE project, a multicenter, retrospective, cross-sectional study approved by the Swiss Ethics Committees (CER-VD, No. 2016 - 02008). This analysis used retrospective data from EMRs collected within the SwissMADE study. The original study protocol, approved by the ethics committee, included a waiver of informed consent. Due to the narrative nature of the clinical data, complete anonymization was not feasible. Strict confidentiality measures were implemented, including restricted data access, secure data handling, and reporting of results in aggregate form only, in compliance with Swiss federal and institutional data protection standards. No patient compensation was provided, as the study involved secondary analysis of pre-existing clinical data. No identifiable images or other materials from individual patients were included in this paper or its supplementary materials. Consequently, there was no requirement for obtaining consent from individuals for use of identifiable images.

Results

Overview

A total of 400 discharge summaries were analyzed, comprising 65,706 annotated sentences. Of these, 47,100 sentences were allocated to the training set and 18,606 to the test set. Detailed demographic and clinical characteristics of the hospital stays associated with each dataset are presented in Table 1.

The distribution of sentence lengths in Figure 3 reveals a right-skewed pattern, with most sentences under 100 characters. To reduce noise, sentences shorter than 3 characters were excluded, accounting for 2.72% of the dataset, ensuring more meaningful content for robust model training and evaluation.

Sentence-level analysis revealed a predominance of "irrelevant" annotations, reflecting the large amount of information in discharge summaries unrelated to bleeding. However, class distribution was more balanced at the document level, demonstrating the complexity of clinical documentation, where multiple annotations often coexist within a single summary. Table 2 provides the detailed distribution of these categories.

The NLP model demonstrated strong classification capabilities, achieving over 85% accuracy across all categories at the document level. It also showed robust performance, with a precision exceeding 72% across categories and a recall of 98% for "irrelevant" instances. F_1-scores indicated balanced performance despite class imbalances, highlighting the model's ability to manage diverse data distributions. A detailed summary of the performance metrics for our multilabel classification model is provided in Table 3.

As shown in Figure 4, ROC curve analysis further highlighted the model's diagnostic accuracy. In stage one, the model achieved an AUC of 0.91 for classifying sentences as either "irrelevant" or "potentially bleeding-related," effectively filtering out irrelevant data. In stage 2, it refined these classifications into the "irrelevant" and "antecedent" categories, with AUCs of 0.88 and 0.83, respectively. Stage 3 focused on distinguishing "clinically significant bleeding" from "severe bleeding," achieving an AUC of 0.94. Overall, the ROC curves demonstrated the model's consistently high performance across all stages, with elevated AUC values reflecting its strong ability to distinguish between classes.

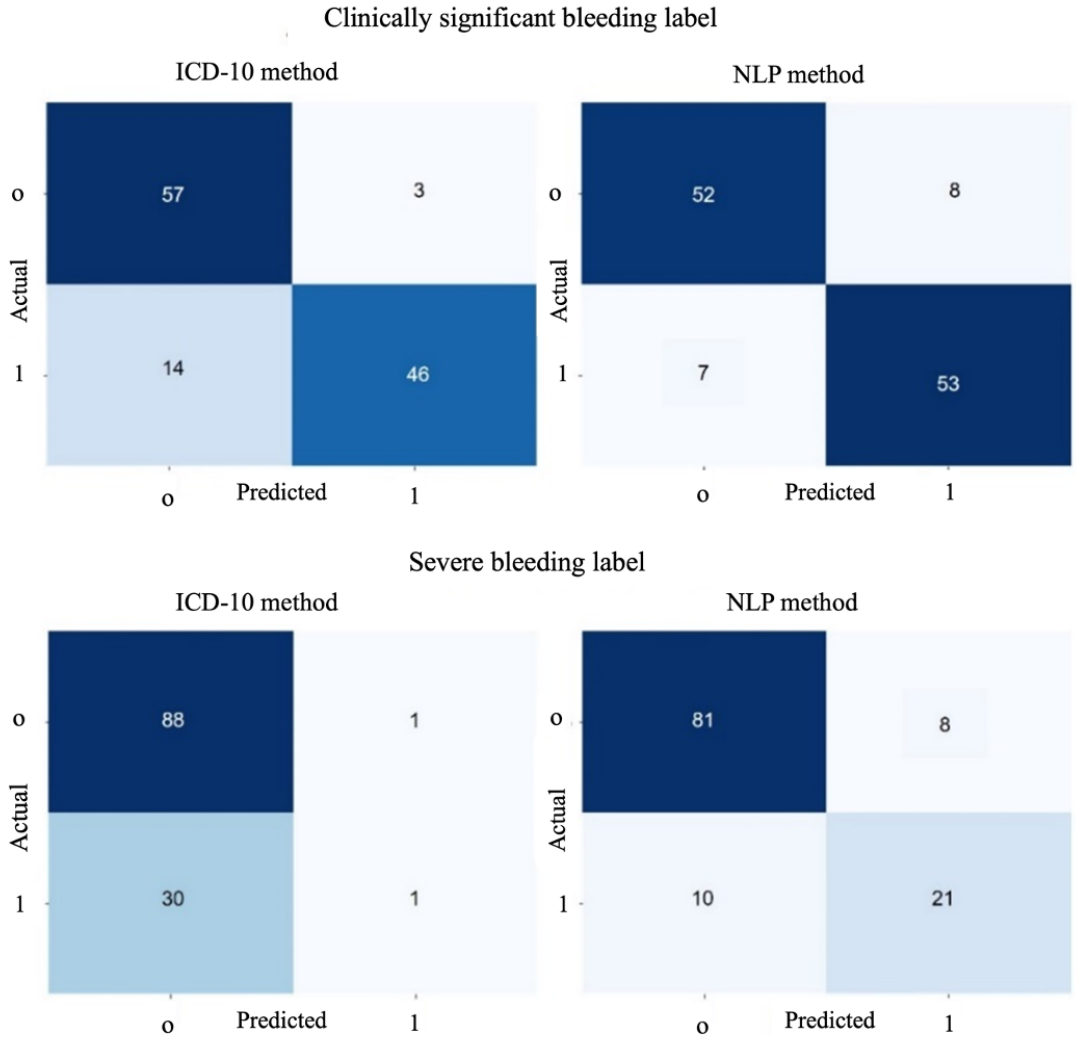
Table . Detailed performance metrics of the rule-based classification model.

Metric	Irrelevant	Antecedent[a]	Clinically significant bleeding	Severe bleeding	Macro-average	Micro-average[b]
Accuracy	0.81	—[c]	0.86	0.74	0.80	—
Precision	0.80	—	0.94	0.50	0.75	—
Recall	0.95	—	0.77	0.03	0.58	—
F_1-score	0.87	—	0.84	0.06	0.59	—

[a]Metrics for the "Antecedent" category are not provided due to the absence of corresponding *International Statistical Classification of Diseases and Related Health Problems, 10th Revision* codes.

[b]"Micro-average" was not calculated as the rule-based model uses *International Statistical Classification of Diseases and Related Health Problems, 10th Revision* codes linked to hospital stays.



[c]Not available.

The rule-based classifier achieved a precision score of 0.94 for "clinically significant bleeding," highlighting its accuracy in detecting these events. However, its performance in identifying "severe bleeding" was significantly weaker, with a recall of only 0.03. This low recall indicates that while the model could detect severe bleeding when present, it also frequently missed such events.

For "clinically significant bleeding," the classifier relied heavily on frequently used *ICD-10* codes, such as K92.2 (gastrointestinal hemorrhage, unspecified), R31 (hematuria, unspecified), and K26.4 (gastric ulcer, acute with hemorrhage), which contributed to its high precision. In contrast, codes associated with "severe bleeding," including R57.1 (shock due to hemorrhage) and I85.3 (esophageal varices with bleeding), were less common in the dataset, resulting in poorer performance for this category. The rule-based model achieved an F_1-score of 0.84 for "clinically significant bleeding" but only 0.06 for "severe bleeding," underscoring the disparity in its ability to handle these 2 categories. Figure 5 highlights the comparative performance of the NLP and rule-based models in detecting clinically significant and severe bleeding. The NLP model consistently demonstrated higher recall and balanced classification across both categories, effectively addressing limitations observed in the rule-based approach.

RenderX

Figure 5. Comparative analysis of confusion matrices for bleeding detection using natural language processing (NLP) and *ICD* (*International Classification of Diseases*) coding methods. This figure contrasts the performance of the NLP model and the *ICD* coding approach, displaying the counts of true positives, true negatives, false positives, and false negatives, thus providing a comparative evaluation of both methods. *ICD-10*: *International Statistical Classification of Diseases and Related Health Problems, 10th Revision*.

Discussion

Principal Findings

This study developed and validated an NLP-based model for detecting bleeding events from clinical narratives, achieving a high level of accuracy. The model demonstrated 91% sentence-level accuracy and 88% document-level accuracy. Compared to traditional *ICD-10* code–based methods, the NLP model provided more nuanced and precise detection of bleeding events, effectively capturing details that *ICD-10* codes often miss, particularly in cases involving secondary conditions or multiple types of bleeding ADEs. These findings underscored NLP's potential to improve the detection and management of adverse events.

One of the model's primary strengths lies in its high precision and recall, even in the presence of class imbalance, particularly when differentiating between "clinically significant" and "severe bleeding." It performed well in interpreting complex clinical data, including negations (eg, "no evidence of bleeding") and secondary conditions, which are typically challenging for rule-based *ICD-10* approaches [9]. By integrating these nuances, the NLP model provided a more comprehensive understanding of patients' clinical status. Its ability to analyze unstructured clinical narratives highlights its potential for real-time decision-making, enabling clinicians to identify bleeding events more accurately and promptly, ultimately improving patient outcomes in hospital settings [10,11,37].

Comparison With Prior Work

The model's accuracy, precision, recall, and F_1-scores compare favorably with those reported in the literature, including models based on deep learning architectures such as biLSTM-CRF or transformers such as BERT [38]. However, most of these studies use larger English-language datasets and cover a broader range of clinical events. Differences in language (French vs English),

XSL•FO
RenderX

dataset size, annotation schemes, and outcome definitions make direct comparisons difficult. While transformer-based models have shown excellent performance in clinical NLP [39,40], their computational demands and limited interpretability may hinder real-world implementation [41]. In this study, we prioritized interpretable and efficient models, such as logistic regression and SVM, offering a favorable trade-off between performance and usability. Future efforts may explore hybrid frameworks that combine advanced performance with interpretability [42].

A distinctive advantage of our approach is the use of multilabel classification, which allows the model to detect co-occurring conditions, such as clinically significant and severe bleeding, or current and historical bleeding, within a single document. This contrasts with most previous studies that rely on single-label classifiers and enhance adaptability to real-world clinical scenarios. However, the model still faced challenges with temporal reasoning, particularly in distinguishing recent events from past ones, underscoring the need for more advanced temporal analysis techniques [43-45].

The limitations of *ICD-10* coding, particularly its inability to reflect clinical nuances, are well documented in the literature. As previously observed by Johnson et al [46], reliance on a small number of broad codes, such as K92.2 (gastrointestinal bleeding, unspecified) and R57.1 (shock due to bleeding), likely contributed to low recall for severe bleeding. *ICD-10* lacks the granularity to differentiate historical versus active bleeding, mild versus severe presentations, or to correctly interpret negations. Furthermore, *ICD* codes are primarily designed for billing and administrative purposes, contributing to underreporting or misclassification of bleeding ADEs [9-11,17]. These limitations further support the relevance of NLP approaches, which offer greater flexibility and contextual understanding.

Negation handling was a particular strength of our model. Where many previous approaches have struggled, our model correctly interpreted expressions such as “no source of bleeding” [47], substantially reducing false positives and enhancing clinical utility [48]. In hospital settings, accurate interpretation of negation is essential to avoid unnecessary investigations or treatments [49].

Limitations

This study had several limitations that should be acknowledged. First, the dataset consisted solely of discharge summaries from Lausanne University Hospital, which may limit its generalizability. Data from a single large tertiary care institution might not represent the variety of clinical settings and regions in which the model could be deployed. In addition, the over-representation of certain *ICD-10* codes, such as K92.2, likely contributed to the model’s high precision for detecting clinically significant bleeding. Expanding the baseline dataset could help improve the model’s robustness and ability to generalize across different hospital environments [50]. Future work should therefore focus on expanding the dataset with discharge summaries from multiple hospitals, enabling broader validation and assessment of the model’s temporal robustness and applicability in diverse health care environments.

Second, class imbalance in the dataset, particularly the limited number of “severe bleeding” cases, posed a challenge. While the model performed well overall, its detection of rare events was enhanced by applying class weighting during training, adjusting the contribution of each class to the loss function. This strategy improved detection of underrepresented but clinically important categories without compromising overall performance. Further improvements could involve oversampling techniques, synthetic data generation, or advanced loss functions such as the segmented harmonic loss [51,52]. Domain-specific keyword-enhanced classification may also refine the model’s ability to identify severe bleeding [53]. Despite these possible improvements, the current class-weighting strategy and multistage framework offered a robust and interpretable solution suited for deployment in resource-constrained health care settings.

Third, despite satisfactory overall performance, the model’s accuracy for detecting severe bleeding dropped to around 70%. This decrease was largely due to the model’s tendency to overinterpret numerical data (eg, hemoglobin and hematocrit values) as indicative of severe bleeding, particularly when such values appeared near bleeding-related terms. These misclassifications led to false positives and suggest a need for improved contextual differentiation between clinically relevant data and incidental numeric values. The model also struggled to capture the timing of bleeding events, a critical limitation in clinical decision-making, where understanding whether a condition is active or historical can influence diagnosis and treatment [54]. Future research should aim to enhance contextual differentiation and temporal reasoning capacities within NLP models.

Finally, the study was restricted to data from 2015 to 2016 due to the reliance on high-quality, manually annotated data from the SwissMADE project, making our analysis primarily a proof-of-concept. Future studies should integrate more recent clinical discharge summaries to validate temporal robustness further and ensure the model remains applicable in evolving health care environments [55].

Future Directions

NLP models, particularly those using deep learning or transformer-based architectures, require significant computational resources for training and deployment. Although our model was relatively efficient, scalability remains challenging, particularly for real-time clinical applications requiring continuous updates and large datasets. Furthermore, although integrating large language models such as GPT-3 (OpenAI) or BERT holds the promise of improved performance, it also introduces concerns around computational cost and the secure handling of sensitive patient data [50,56-59]. These practical challenges will have to be addressed before the widespread adoption of NLP models in clinical settings [54,60].

Conclusions

Despite some limitations, this study adds to the growing evidence supporting the use of NLP for detecting ADEs such as bleeding. The model outperformed standard *ICD-10*–based approaches by capturing nuanced clinical information often

XSL•FO
RenderX

missed in structured data, including negations and secondary conditions. The use of multilabel classification improved its flexibility, allowing it to handle overlapping bleeding events in complex clinical scenarios. These features position NLP as a promising tool for enhancing real-time clinical decision-making and patient safety. Future work should focus on expanding the dataset to include records from multiple hospitals and care settings, improving generalizability. Integrating additional data sources, such as laboratory results, imaging, and progress notes, and exploring advanced NLP techniques such as BERT or GPT could further improve accuracy and temporal reasoning. Validating the model across diverse clinical environments and combining structured with unstructured data will be essential to build robust tools for bleeding ADE detection and support broader clinical implementation.

Acknowledgments

The authors would like to acknowledge all members of the SwissMADE study group for their contributions to the overall project. We particularly thank the IT team at Lausanne University Hospital, notably Nathalie Casati, for their invaluable support and efforts in extracting the clinical narratives used in this study. This study was supported by the Swiss National Science Foundation (grant no 407440_167381).

Data Availability

In compliance with patient confidentiality requirements and institutional agreements, the dataset used in this study is not publicly accessible. Researchers interested in collaborative projects may contact the corresponding author.

Authors' Contributions

FG, MZ, CCO, ZS, MB, EB, MALP, and CCS wrote the manuscript. FG, MZ, MALP, and CCS designed the research. FG, MZ, CCO, ZS, MB, EB, MALP, and CCS conducted the research. FG, MZ, CCO, ZS, MB, EB, MALP, and CCS analyzed the data. FG, MZ, CCO, EB, MALP, and CCS managed the project and acquired the necessary resources.

Abstract

Background: Identifying neuroinfectious disease (NID) cases using International Classification of Diseases billing codes is often imprecise, while manual chart reviews are labor-intensive. Machine learning models can leverage unstructured electronic health records to detect subtle NID indicators, process large data volumes efficiently, and reduce misclassification. While accurate NID classification is needed for research and clinical decision support, using unstructured notes for this purpose remains underexplored.

Objective: The objective of this study is to develop and validate a machine learning model to identify NIDs from unstructured patient notes.

Methods: Clinical notes from patients who had undergone lumbar puncture were obtained using the electronic health record of an academic hospital network (Mass General Brigham [MGB]), with half associated with NID-related diagnostic codes. Ground truth was established by chart review with 6 NID-expert physicians. NID keywords were generated with regular expressions, and extracted texts were converted into bag-of-words representations using n-grams (n=1, 2, 3). Notes were randomly split into training (80%), 2400 notes out of 3000, and hold-out testing (20%), 600 notes out of 3000, sets. Feature selection was performed using logistic regression with L1 regularization. An extreme gradient boosting (XGBoost) model classified NID cases, and performance was evaluated using the area under the receiver operating curve (AUROC) and the precision-recall curve (AUPRC). The performance of the natural language processing (NLP) model was contrasted with the Llama 3.2 auto-regressive model on the MGB test set. The NLP model was additionally validated on external data from an independent hospital (Beth Israel Deaconess Medical Center [BIDMC]).

Results: This study included 3000 patient notes from MGB from January 22, 2010, to September 21, 2023. Of 1284 initial n-gram features, 342 were selected, with the most significant features being "meningitis," "ventriculitis," and "meningoencephalitis." The XGBoost model achieved an AUROC of 0.98 (95% CI 0.96 - 0.99) and AUPRC of 0.89 (95% CI 0.83 - 0.94) on MGB test data. In comparison, NID identification using International Classification of Diseases billing codes showed high sensitivity (0.97) but poor specificity (0.59), overestimating NID cases. Llama 3.2 improved specificity (0.94) but had low sensitivity (0.64) and an AUROC of 0.80. In contrast, our NLP model balanced specificity (0.96) and sensitivity (0.84), outperforming both methods in accuracy and reliability on MGB data. When tested on external data from BIDMC, the NLP model maintained an AUROC of 0.98 (95% CI 0.96 - 0.99), with an AUPRC of 0.78 (95% CI 0.66 - 0.89).

Conclusions: The NLP model accurately identifies NID cases from clinical notes. Validated across 2 independent hospital datasets, the model demonstrates feasibility for large-scale NID research and cohort generation. With further external validation, our results could be more generalizable to other institutions.

Introduction

Meningitis and encephalitis pose serious threats to the health of an individual, potentially leading to severe neurological compromise or even death [1-7]. Many neuroinvasive pathogens, including viruses (eg, enterovirus, herpes simplex virus, West Nile virus, and HIV), bacteria (eg, *S. pneumoniae*, Mycobacterium tuberculosis), and fungi (eg, Cryptococcus), are linked to long-term cognitive sequelae [2,8]. Recent population-based studies suggest associations between pathogen exposures, especially neuroinvasive viruses causing encephalitis or meningitis, and the subsequent risk of developing dementia such as Alzheimer disease (AD) [9-12]. The risk of AD appears to increase with longer time since the first infection, peaking after 12 - 30 years [9]. Prior viral encephalitis and bacterial or viral meningitis were found to be associated with significantly increased hazard ratios for future AD, with rates of 30.72-fold and 2.81-fold, respectively, based on the Finnish Biobank, suggesting that exposure to neuroinvasive pathogens may contribute to lower cognitive reserve, likely in part due to brain inflammation [10].

These findings underscore the need for comprehensive, longitudinal studies to elucidate the mechanisms by which neuroinvasive pathogens might contribute to neurodegenerative diseases. However, such research is severely hampered by the scarcity of large, well-annotated hospital datasets. This data gap not only impedes rigorous epidemiological analyses but also hinders mechanistic investigations that could reveal how pathogens interact with neural tissues to potentially trigger or accelerate neurodegenerative processes. Therefore, to support evidence-based clinical decision-making and enable large-scale, high-powered research into the long-term consequences of neuroinfectious diseases (NIDs), accurately identifying these conditions in hospital patient records remains a significant challenge.

NIDs stem from a diverse array of pathogens and often present with clinically indistinguishable symptoms such as fever, headache, and confusion. Physicians often grapple with challenges in promptly identifying these pathogens, resorting to less precise shotgun testing methods, leading to delayed or unconfirmed diagnoses, unnecessary antimicrobial treatments, and preventable morbidity [13-18]. Most epidemiological studies linking infectious disease burden to subsequent dementia rely on health care databases that use International Classification of Diseases (ICD) codes 9th (ICD-9) and 10th (ICD-10) revisions (combined as ICD codes) and do not validate diagnoses with microbial assays [19]. The limited reliability of ICD codes in accurately identifying infectious diseases has been previously reported [20-23], more recently underscored by the 56% - 57% positive predictive value observed in the Danish National Patient Registry investigating herpes simplex virus encephalitis [19]. The combination of ICD miscoding and the potential misclassification of encephalitis etiology poses significant obstacles to generating actionable recommendations for preventing AD and other dementias. This challenge further hinders clinical guidance, particularly in cases of viral encephalitis with unknown origins—a subgroup identified in epidemiological studies as having the highest risk of future dementia [10,11].

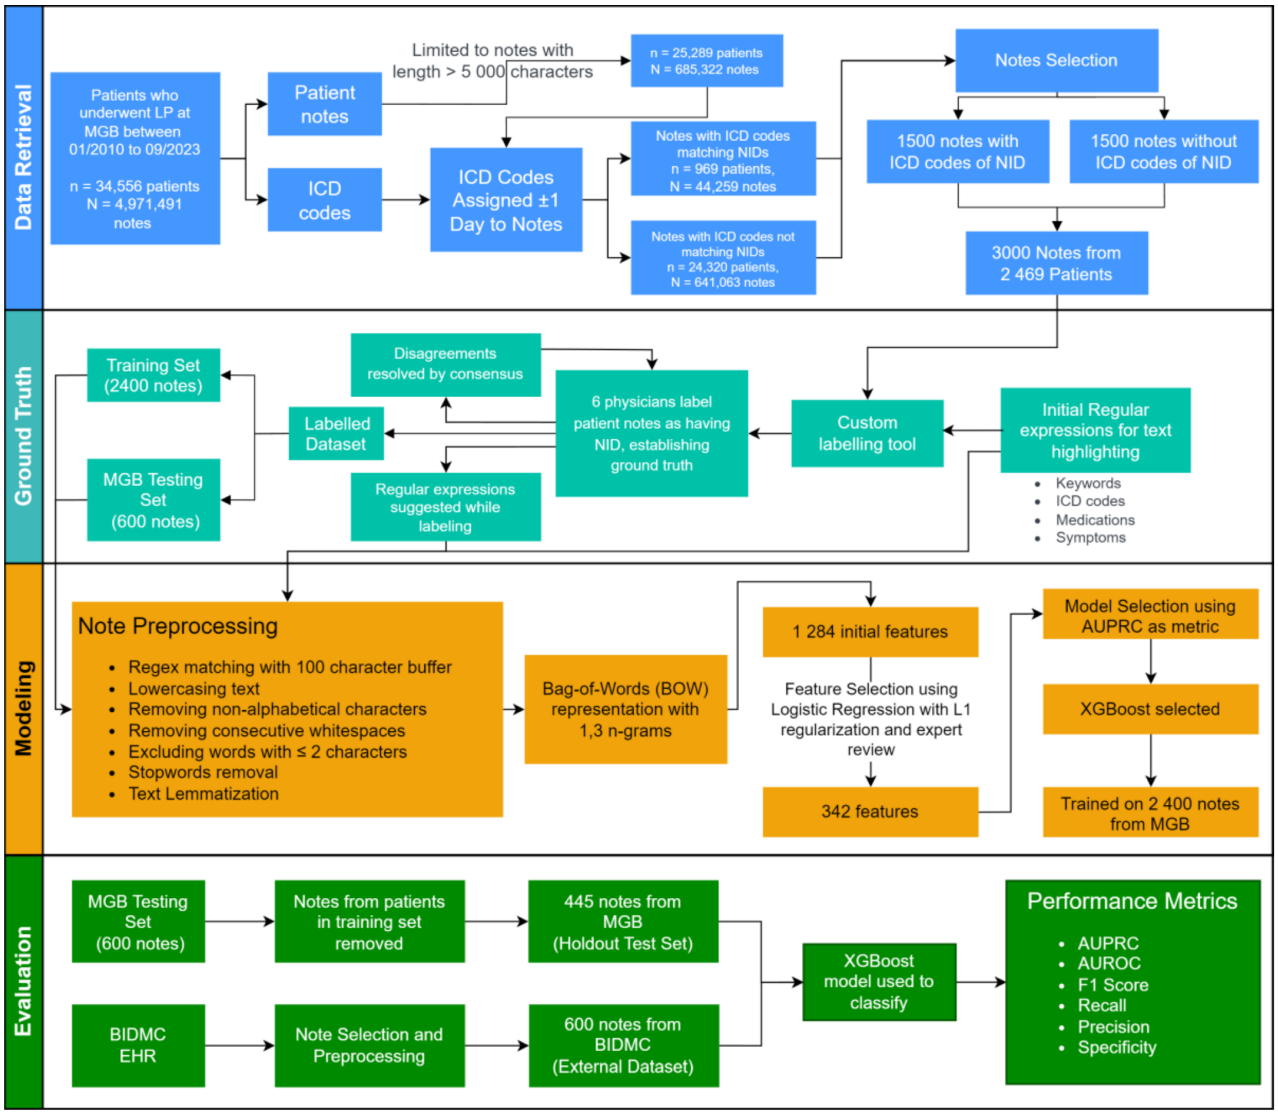
Recent efforts to move beyond ICD-based coding have aimed at improving the timely and accurate diagnosis of NID etiologies, particularly in differentiating between viral and bacterial meningitis. These efforts predominantly use approaches such as decision trees and ensemble methods. For example, a study using a Brazilian dataset of 12,774 patients described by 19 clinical attributes aimed at distinguishing bacterial from aseptic meningitis found that a hybrid bagging approach with Naive Bayes Trees outperformed 27 other tested models. This model achieved a sensitivity of 96% and a specificity of 82% [24]. While promising, most other classification studies on NIDs, using techniques like logistic regression [25-27] or hybrid models [24,27-32], are primarily in pediatric populations, lack external validation, or rely on small datasets with limited cross-validation [33]. To our knowledge, no study has used unstructured data such as clinical notes, which limits the insights that could be derived.

The 2015 global research priorities for infections that affect the nervous system underscored the need for accurate disease burden estimates and improved tools for neurological and cognitive impairment assessment [2]. Natural language processing (NLP) tools can leverage the rich information present in large-scale comprehensive electronic health records (EHRs), including unstructured clinical assessments and notes [34-36]. Therefore, NLP holds the potential to surpass the accuracy of traditional ICD-based phenotyping while reducing reliance on semi-structured data formats [30,35,37,38].

When structured lab data is unavailable, NLP techniques leveraging unstructured clinical notes can potentially generate more accurate NID cohorts than ICD codes alone. Many NLP algorithms are computationally lighter and require less computing infrastructure compared to more recent large language models (LLMs), making them more feasible for widespread research applications. Building on this advantage, our goal is to develop a more accurate and efficient method for classifying NID cases in EHRs. Previous studies have successfully used NLP to identify patients with epilepsy [38] or classify neurological outcomes from medical notes [39].

Here, we aim to tackle NID patients by building upon these studies and detailing our NLP algorithm leveraging discharge summaries and progress notes to identify NID patients and investigate the model's accuracy across 2 independent hospitals. Our NLP algorithm outperforms ICD codes in identifying NID patients and achieves competitive performance compared to the Llama 3.2 autoregressive model (an LLM with 3B parameters) in zero-shot learning tasks, making it a valuable tool for large-scale EHR-based research to investigate the relationship

XSL•FO
RenderX



between NID exposure and short- and long-term neurological outcomes.

Methods

Overview

Figure 1 provides a summary overview of the key steps involved in this study, including data extraction, note selection, regular expression development, ground-truth labeling, text preprocessing, feature extraction, model training, and evaluation.

Figure 1. Methods overview: data retrieval and machine learning pipeline for NID classification. AUPRC: area under the precision-recall curve; AUROC: area under the receiver operating characteristic curve; BIDMC: Beth Israel Deaconess Medical Center; BOW: bag-of-words; EHR: electronic health record; ICD: International Classification of Diseases; LP: lumbar puncture; n: number of unique patients; N: number of unique notes; MGB: Mass General Brigham; NID: neuroinfectious diseases.

Data Extraction and Note Selection

We included 34,556 patients who underwent lumbar punctures (LP), sourcing medical notes from the EHR database of the Mass General Brigham (MGB) network of hospitals. This approach enriched individuals likely to be evaluated for central nervous system (CNS) infections, with a total of 4,971,491 notes extracted between 01/22/2010 and 09/21/2023. ICD diagnostic codes billed one calendar day before and after the notes were extracted and labeled as likely to be associated with NID. Multimedia Appendix 1 lists the NIDX ICD 9 and 10 codes.

We excluded notes with fewer than 5000 characters, as they likely lacked the necessary detail for clinicians to accurately assess patient status or provide valid training for models. We categorized notes into two groups: (1) notes with NID-related ICD codes (969 unique patients, 44,259 notes) and (2) those without NID ICD codes (24,320 unique patients, 641,063 notes). From these 2 groups, we randomly selected 3000 notes from 2469 patients at MGB, of which 50%, 1500 out of 3000, were associated with NID-related ICD codes, and 50% were not. For external validation, we also extracted 600 inpatient notes from patients in the Beth Israel Deaconess Medical Center (BIDMC) EHR system located in the Brain Data Science Platform

XSL•FO
RenderX

(bdsp.io) maintaining a 50:50 split of cases with and without NID-related ICD codes to match the MGB test set size.

Ethical Considerations

All procedures involving human participants in this study were reviewed and approved by the Institutional Review Board (IRB) of MGB, under protocol #2013P001024. The research was conducted in accordance with the ethical standards of the MGB and the principles of the WMA Declaration of Helsinki.

This study involved analysis of EHR data. The IRB approved a waiver of informed consent due to the retrospective nature of the study and minimal risk to participants. In accordance with the IRB's requirements, no identifiable personal information is included in the manuscript or supplementary materials. While the data were not fully de-identified at the time of analysis, strict procedures for maintaining privacy and confidentiality were implemented. Access to identifiable information was restricted to certified study personnel who have completed training in ethics and responsible conduct of research. The research team was committed to upholding high standards of data privacy and confidentiality throughout the entire study process. No compensation was provided to participants, as only de-identified retrospective data were utilized.

Ground-Truth Labeling

In total, 39,245 regular expressions were formulated based on domain-specific knowledge, categorized as (1) positive NID (eg, "cerebrospinal fluid (CSF) positive for Epstein-Barr Virus via polymerase chain reaction," "ID felt encephalitis and seizures triggered by a viral illness," "Currently on empiric antibiotics and acyclovir for possible CNS infection"); (2) negative NID (eg, "LPs have been negative," "no signs of any infectious," "autoimmune epilepsy/encephalitis"); (3) NID drugs (eg, ceftriaxone, acyclovir, trimethoprim-sulfamethoxazole, etc); (4) NID-likely keywords (eg, "headache," "fever," "lumbar puncture," etc). Regular expressions were developed by listing relevant organisms based on source materials for infectious diagnoses, antimicrobial agents, and symptoms associated with meningitis and encephalitis. Many terms were combined to create comprehensive positive and negative expressions. In addition to domain expert input, source materials included national guidelines related to CNS diseases in adults and pathogen data from global burden of disease studies [4,40-43]. The positive, negative, and antimicrobial regular expressions are provided in Multimedia Appendices 2-4.

In total, 6 physicians (AS, CQ, KH, GH, ST, and SM), all domain experts in neuroimmunology or infectious diseases, independently classified 500 notes each from the MGB dataset (3000 notes in total) following a standardized operating procedure. This procedure provided detailed guidelines for reviewing notes, including assessing symptoms and evaluating laboratory tests when referenced in the notes. Ambiguous cases flagged by the physicians were reviewed by an independent physician who was not involved in the initial classification. A consensus approach was used to resolve discrepancies in classification. To facilitate labeling, a labeling software tool was created to show the notes while highlighting the keywords (eg, meningitis, encephalitis, ceftriaxone, etc) and phrases (eg, "meningitis, likely bacterial," "CSF pleocytosis noted"). Domain experts had the option to recommend additional regular expressions during the MGB ground-truth labeling phase. Regular expressions proposed by domain experts were incorporated if proposed on the training dataset only. External model validation on 600 BIDMC notes was classified by 2 experts (AS and SM) (300 notes each). While the MGB test set was reduced to 445 notes to address overlap with the training set, the BIDMC dataset was solely used for external validation and retained its full size of 600 notes.

Preparing Text Data for Feature Extraction

Preprocessing notes to identify model features required (1) limiting text to regions matching regular expressions with a 100-character buffer, (2) converting to lowercase letters, (3) removal of non-alphabetical characters, (4) replacing consecutive whitespaces with a single whitespace, (5) using words with more than 2 characters, and (6) removing stop words (see Multimedia Appendix 5). The remaining text was lemmatized using WordNetLemmatizer [44]. The text was transformed into a bag-of-words (BOW) representation, considering unigrams (1 gram), bigrams (2 grams), and trigrams (3 grams).

Model Features, Training, and Performance Evaluation

To reduce the number of features and enhance model interpretability, we used an iterative approach using logistic regression with L1 regularization, similar to our previous NLP-based methods on unstructured EHR text in studies on epilepsy or neurological status following COVID-19 hospitalizations [38,45]. The regularization strength (10) and maximum iterations (1000) were chosen to balance between model complexity and computational efficiency. We addressed class imbalances by incorporating class weights inversely proportional to the sample size. We used this process to identify the most common features, resulting in a set of 1284 features. A manual review by 3 experts (AS, SM, and MBW) eliminated the remaining irrelevant features, leading to a reduced set of 342 non-zero features. For example, terms like "Boston," "heart rate," and "primary care" were removed as they were irrelevant to NID classification and had no pathophysiological connection to the condition.

The MGB dataset (3000 notes) was randomly split 80:20 for training (2400 notes) and the hold-out (600 notes) test set, maintaining the 50/50 ICD code distribution. Since there were only 969 unique patients with ICD codes for NIDs, some notes originated from the same patients. To ensure no patient appeared in both the training and test sets, the initial hold-out test set of 600 notes was reduced to 445 notes by excluding notes from patients who were also present in the training set. To select the optimal model, we used 5-fold cross-validation on the MGB training dataset. Given the imbalanced nature of the dataset, with only 16%, 480 out of 3000, of the total observations positive for NID, we compared logistic regression, random forest, and XGBoost using the area under the precision-recall curve (AUPRC). AUPRC is more informative for imbalanced datasets, as it focuses on the performance of the model in predicting the positive class, unlike metrics such as accuracy

XSL•FO
RenderX

or the area under the receiver operating characteristic curve (AUROC) [46-49]. XGBoost was selected for its AUPRC performance.

We then trained an XGBoost model on the 2400 training notes and tested its performance on both the hold-out dataset (445 notes from MGB) and an external dataset consisting of 600 notes from patients at BIDMC. Model performance was based on the AUPRC and the AUROC. We performed bootstrapping with replacement and performed 1000 iterations to estimate the 95% CIs for these metrics.

Evaluation of Llama 3.2 for Zero-Shot NID Classification

We assessed the performance of the Llama 3.2 auto-regressive model (3B parameters) as a zero-shot learning approach for classifying NID from clinical reports in the MGB test set. Llama was neither fine-tuned nor trained on task-specific examples and classified the presence or absence of NID from clinical notes formatted in JavaScript Object Notation.

Results

Cohort Characteristics

The demographic characteristics of the 2469 patients comprising the 3000 MGB clinical notes are presented in Table 1 (the linkage between notes and demographic data for the BIDMC dataset was lost and is therefore not shown).

Table . Characteristics of the study cohorts.

MGB (N=2469)	
Age (years)	
Median (IQR)	61.0 (46-73)
Age group, n (%)	
<18	101 (4.1%)
18 - 34	254 (10.3%)
35 - 49	403 (16.3%)
50 - 64	718 (29.1%)
65+	993 (40.2%)
Sex, n (%)	
Male	1119 (45.3%)
Female	1350 (54.7%)
Race, n (%)	
White	1911 (77.4%)
Black	174 (7.0%)
Asian	86 (3.5%)
Other	298 (12.1%)
Ethnicity, n (%)	
Hispanic	252 (10.2%)
Not Hispanic	2041 (82.7%)
Missing	176 (7.1%)

The median age (IQR) was 61.0 (46 - 73 y) years, of which 55% (n=1350) were female sex at birth, 77% (n=1911) reported being of white race, and 83% (n=2041) reported being of non-Hispanic ethnicity. Out of the 3000 notes, 16% (479 notes) were labeled as NID based on expert review, and 97% of these 479 notes had an NID-related ICD code. Among the 1500 notes with an NID-related ICD code, 465 notes (31%) were confirmed as NID cases by expert review. Conversely, among the 1500 notes without an NID-related ICD code, 0.93% (14 notes) were identified as NID cases by expert review. The sensitivity of detecting NID patients using the presence of any NID-related ICD code was 97.1%, and the specificity was 59.1%, suggesting reliance on ICD codes alone for a patient's true clinical diagnosis may be more likely to overestimate, rather than underestimate, the number of cases with NID.

Performance of EHR NID Classifier

The training set consisted of 2400 notes from MGB, where 16.1% (387/2400) were classified as NID-positive by expert review. The hold-out testing set from MGB consisted of 445 notes, where 16% (71/445) were classified as NID-positive.

Performance characteristics using XGBoost on the MGB training set and hold-out test set are shown in Table 2.

XSL•FO
RenderX

Table . Average performance for the XGBoost[a] model on the training set and 2 independent testing sets.

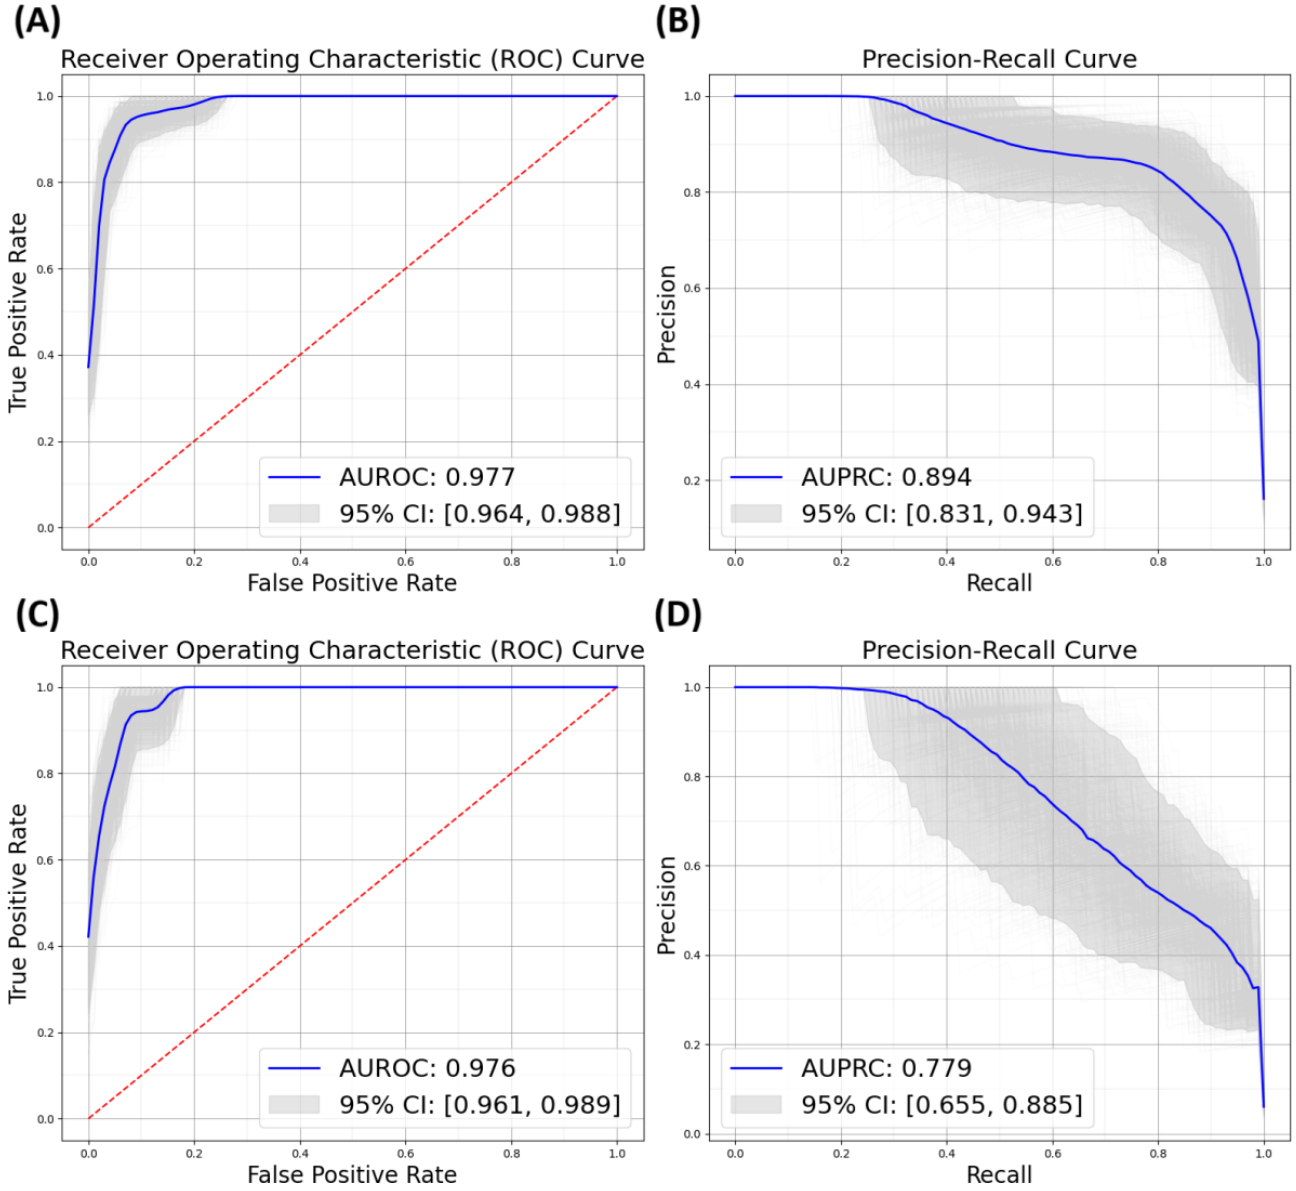
Metric	Training set (MGB) (2400 notes)	Testing set (MGB) (445 notes)	Testing set (BIDMC[b]) (600 notes)
AUROC[c], median (95% CI)	1.000 (1.000 - 1.000)	0.977 (0.964 - 0.988)	0.976 (0.961 - 0.989)
AUPRC[d], median (95% CI)	1.000 (0.999 - 1.000)	0.894 (0.831 - 0.943)	0.779 (0.655 - 0.885)
F1 score, median (95% CI)	0.987 (0.978 - 0.995)	0.822 (0.752 - 0.879)	0.658 (0.528 - 0.778)
Recall, median (95% CI)	0.974 (0.957 - 0.989)	0.846 (0.753 - 0.923)	0.687 (0.538 - 0.839)
Precision, median (95% CI)	1.000 (1.000 - 1.000)	0.802 (0.709 - 0.889)	0.637 (0.487 - 0.795)
Specificity, median (95% CI)	1.000 (1.000 - 1.000)	0.960 (0.939 - 0.978)	0.976 (0.963 - 0.988)

[a]XGBoost: extreme gradient boosting model.

[b]BIDMC: Beth Israel Deaconess Medical Center.

[c]AUROC: area under the receiver operating characteristic curve.

[d]AUPRC: area under the precision-recall curve.



The MGB hold-out test set showed good performance metrics (95% CI), including an AUROC of 0.977 (0.964 - 0.988), AUPRC of 0.894 (0.831 - 0.943), recall of 0.846 (0.753 - 0.923), and F1 score of 0.822 (0.752 - 0.879). The AUROC and AUPRC curves for the hold-out set are illustrated in Figure 2.

To assess performance metrics using patient notes extracted outside the MGB network, we ran the NLP-based model on 600 notes from BIDMC, of which 5.8% (35/600) were NID-positive by expert review. Although performance declined compared to the MGB test set, the model maintained a high AUROC of 0.976 (95% CI 0.961 - 0.989) and an AUPRC of 0.779 (95% CI 0.655 - 0.885). Precision was 0.637 (95% CI 0.487 - 0.795), and recall was 0.687 (95% CI 0.538 - 0.839), resulting in an F1 score of 0.658 (95% CI 0.528 - 0.778).

Additionally, we assessed the performance of Llama 3.2, a zero-shot learning model, for classifying NID as present or absent using clinical notes on the MGB test set. The model achieved an AUROC of 0.800 and a balanced F1 score of 0.799, demonstrating high specificity (0.940) but lower recall (0.640). These results highlight notable performance differences between the Llama model and the NLP-based approach, particularly in recall and overall F1 score.

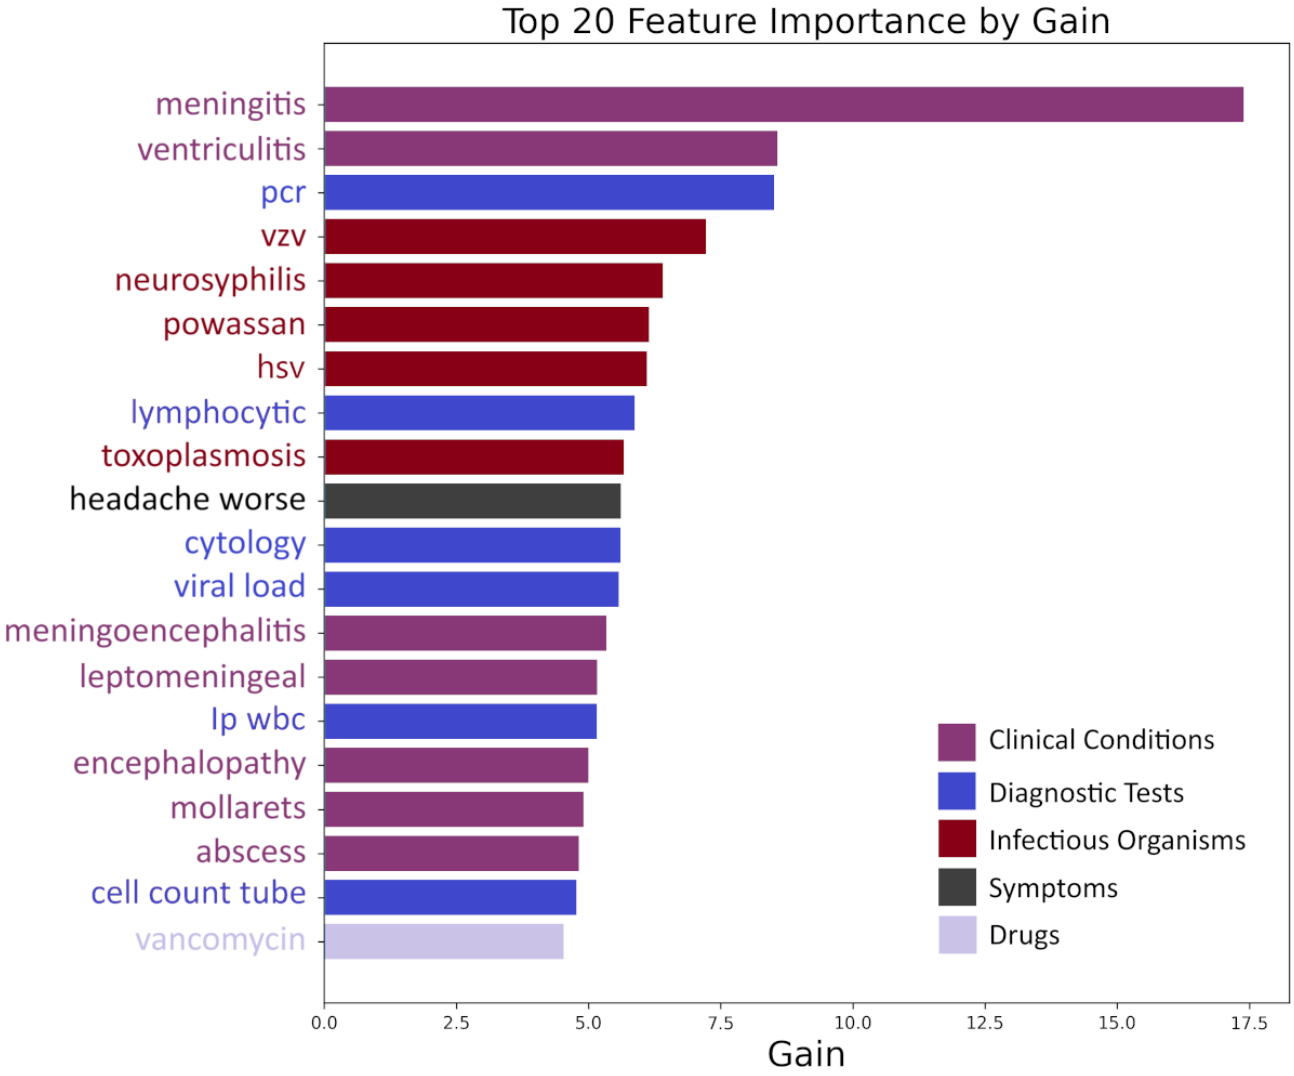
Figure 2. XGBoost model performance on 2 sets of unseen notes, as evaluated by AUROC and AUPRC. 95% CIs were estimated using 1000 bootstrapping iterations. (A) AUROC and (B) AUPRC on notes from MGB and (C) AUROC and (D) AUPRC on notes from BIDMC. AUROC: area under the receiver operating characteristic (ROC) curve; AUPRC: area under the precision recall curve; CI: confidence interval.



Significant Features for NID Prediction

The feature selection steps reduced the initial training feature sets by 73.36% (342/1284). The top 20 features selected by XGBoost to identify individuals with NIDs are plotted in Figure 3.

The importance of these features was assessed based on their average gain across all decision points within the model, providing a measure of their contribution to predictive accuracy. These features primarily consist of clinical indicators and diagnostic markers essential for identifying NIDs. Prominently featured are direct markers of CNS inflammation, such as "meningitis," "ventriculitis," and "meningoencephalitis." Other features included diagnostic tests such as "cytology," "viral load," and "polymerase chain reaction"; cell types ("lymphocytic"), specific pathogens, and medical conditions associated with NID were identified, suggesting identified NID-associated features used in the NLP classifier were clinically relevant and interpretable.

XSL•FO
RenderX

Figure 3. Top 20 features ranked by the feature importance (information gain measured by entropy), arranged in descending order (from top to bottom). The x-axis is the feature importance. It does not differentiate the association directions, ie, positive or negative association with the NID label.

Error Analysis

In our analysis of cases where the model's predictions differed from the manually assigned labels, we discovered a few common factors that led to incorrect positive and negative classifications across both the internal (MGB) and external (BIDMC) datasets.

A common reason for false positives was the presence of prior NID mentions in patient notes. Another frequent issue was cases where patients were awaiting LP results, leading to a manual negative label, but the notes suggested a possible positive. False positives were also caused by notes indicating symptoms suggestive of NID but lacking confirmatory LP results. Additionally, specific pathogens or conditions, like JC virus neurocysticercosis and neurosyphilis, mentioned in the notes but not confirmed as active NID, added to the error rate. False negatives were often due to notes that did not discuss NID in detail.

The type of clinical note played a significant role; physical therapy and psychiatric notes were less likely to contain detailed clinical information relevant to NID, leading to both false positives and false negatives.

Discussion

In this study, we developed and evaluated an automated NLP-based model in 2 independent datasets that classifies people with NID using unstructured notes to generate an NID cohort, with the intention that these cohorts could be used for predictions of susceptibility risk and short- and long-term medical outcomes. The NLP model demonstrated high specificity (0.96), outperforming the specificity observed using NID-specific ICD codes (0.59), suggesting that relying on ICD codes alone may overestimate cases of infectious meningitis or encephalitis. These findings align with recent literature reporting low precision (0.58, 95% CI 0.53 - 0.63) for the ICD-10 codes associated with herpesviral (herpes simplex) encephalitis, herpesviral (herpes simplex) meningoencephalitis, and herpesviral encephalitis, common causes of NID, in the well-established Danish National Patient Registry [19]. The lack of specificity underscores the risk of false positives when using ICD coding alone, posing challenges for accurately identifying clinical research cohorts, particularly for rare disorders like NID [50,51].

To contextualize our findings, prior studies in meningitis and encephalitis largely focused on structured data, including lab

XSL•FO
RenderX

results, imaging, and other EHR data, to classify meningitis etiology or distinguish subtypes [24,31,32,52-58]. In comparison, alternative machine learning models applied to a Brazilian dataset of 22,602 suspected meningitis cases, including J48, Alternating Decision Tree, and Support Vector Machine, demonstrated varying levels of performance. One model, based solely on observable symptoms, achieved an AUROC of 0.869 for differentiating meningitis from non-meningitis cases [31], while a combined ensemble and decision tree method integrating observable symptoms with rapid CSF analysis attained an AUROC of 0.95 in distinguishing bacterial from viral meningitis in a dataset of known infectious meningitis cases [34]. However, the best model for classifying NID cases (sensitivity 97.0% - 97.6%) was at the expense of specificity (24.0% - 43.0%), limiting utility in reducing false positives in clinical decision-making [59]. In the context of HIV and cognitive disorders, machine learning models leveraging clinical data reported AUROCs of 0.83 - 0.87, though most relied on structured cohort data, not data in the EHR, with limited validation in independent datasets [60-62]. These comparisons underscore the value of our NLP-based method as a more precise phenotyping tool, offering an improved balance between sensitivity and specificity for identifying NID cases.

We also evaluated LLMs, focusing on the Llama3.2 model applied in the MGB test set. This method yielded an AUROC of 0.800 and a balanced F1 score of 0.799, with high specificity (0.940) but lower recall (0.640). In contrast, the proposed BOW NLP approach achieved balanced results, with an AUROC of 0.977, an AUPRC of 0.894, and an F1 score of 0.822, with high recall (0.846). On the BIDMC validation set, the NLP model achieved an AUROC of 0.98, and while the performance declined (AUPRC reduced from 0.894 (0.831 - 0.943) to 0.779 (0.655 - 0.885)) likely due to variations in documentation styles, differences in clinical terminology, and institutional biases in diagnosing rare conditions, the model maintained good discriminative ability. These results demonstrate potential for broader application with further fine-tuning, with enhanced precision and interpretability offering significant advantages for NID phenotyping in clinical research.

In our clinical experience, we have observed that unstructured clinical notes serve as a rich source of information crucial for ensuring clinical accuracy and care for NID patients. Here, using only clinical notes, we achieved consistent AUROC exceeding 0.95 across 2 different EHR systems, with a modest decrease in AUPRC, underscoring the importance of developing classifiers that effectively leverage the information embedded within these notes. Compared to Llama, the BOW approach offers advantages such as reduced computational overhead, faster inference, and ease of deployment in settings with predictable patterns and resource limitations. These attributes make it particularly suitable for time-sensitive applications and adaptable to diverse health care settings. Most importantly, the proposed method's balanced performance, particularly in the context of NID classification, highlights its utility in both clinical research and practice. The model's reliance on unstructured notes reduces dependency on specific EHR system designs for structured data, broadening its applicability. By identifying clinically interpretable features such as specific markers of CNS inflammation and diagnostic tests, the model enhances both accuracy and clinical relevance, making it a valuable tool for improving care and outcomes for NID patients.

Our study had several limitations. First, the model was developed and validated using unstructured EHR notes from Massachusetts, impacting its relevance in other regions due to regional variations in medical terminology and disease incidence. For example, region-specific diseases like "Powassan," found predominantly in northeastern states and the Great Lakes region of the United States, were a feature selected in the XGBoost model and may not generalize to other regions. Second, while notes were enriched for NIDs by considering patients who had an LP procedure, the timing of the procedure in relation to the analyzed notes was not considered when developing the model. This approach aimed to enrich the dataset with relevant LP-related language and details from patient notes while avoiding overfitting the model narrowly to notes from a specific temporal context like the post-procedural period. While this approach prevents overfitting to unique details concentrated in the post-LP notes, it could limit broader applicability. Future work could explore incorporating the temporal relationship between the LP and the notes, which may provide additional context for classification performance. Third, lab results from CSF cell counts or microbial assays were not specifically considered in our analysis. The availability of lab data for each patient is inconsistent due to factors such as its assessment at another institution prior to transfer to a tertiary center, safety concerns regarding CSF retrieval, or delays due to logistical considerations. This NLP-based model, operating independently of lab results, resulted in high AUROC and AUPRC, suggesting that in settings where structured lab data is not available, the tool could potentially generate an NID cohort. Our study focused on broad NID classification and did not subtype into encephalitis or meningitis. We anticipate that future model development will involve training on unstructured EHR notes from diverse sources across the United States and may explore incorporating microbial data and antimicrobial therapy details as features.

Abstract

Background: Transportation insecurity is a known barrier to accessing eye care and is associated with poorer visual outcomes for patients. However, its mention is seldom captured in structured data fields in electronic health records, limiting efforts to identify and support affected patients. Free-text clinical documentation may more efficiently capture information on transportation-related challenges than structured data.

Objective: In this study, we aimed to identify mention of transportation insecurity in free-text ophthalmology clinic notes using natural language processing (NLP).

Methods: In this retrospective, cross-sectional study, we examined ophthalmology clinic notes of adult patients with an encounter at a tertiary academic eye center from 2016 to 2023. Demographic information and free text from clinical notes were extracted from electronic health records and deidentified for analysis. Free text was used to develop a rule-based NLP algorithm to identify transportation insecurity. The NLP algorithm was trained and validated using a gold-standard expert review, and precision, recall, and F_1-scores were used to evaluate the algorithm's performance. Logistic regression evaluated associations between demographics and transportation insecurity.

Results: A total of 1,801,572 clinical notes of 118,518 unique patients were examined, and the NLP algorithm identified 726 (0.6%) patients with transportation insecurity. The algorithm's precision, recall, and F_1-score were 0.860, 0.960, and 0.778, respectively, indicating high agreement with the gold-standard expert review. Patients with identified transportation insecurity were more likely to be older (OR 3.01, 95% CI 2.38 - 3.78 for those aged ≥80 vs 18 - 60 y) and less likely to identify as Asian (OR 0.04, 95% CI 0 - 0.18 for Asian patients vs White patients). There was no difference by sex (OR 1.13, 95% CI 0.97 - 1.31) or between the Black and White races (OR 0.98, 95% CI 0.79 - 1.22).

Conclusions: NLP has the potential to identify patients experiencing transportation insecurity from ophthalmology clinic notes, which may help to facilitate referrals to transportation resources.

social needs screening; electronic health record; social determinants of health; transportation needs; natural language processing

Introduction

Health-related social needs (HRSN) affect access to eye care [1], and transportation needs in particular are a commonly cited barrier to accessing care for chronic eye diseases, such as diabetic retinopathy and glaucoma [2,3]. For instance, among respondents to the National Health Interview Survey, lack of transportation was associated with delayed follow-up with an ophthalmologist or optometrist, and transportation-related barriers to care disproportionately affected respondents with glaucoma or vision loss [4]. Separately, telephone interviews with patients with glaucoma following appointment no-show revealed that transportation was commonly cited as the reason for a missed appointment [5].

Fortunately, transportation needs are addressable, and referral to social work or patient navigator services can connect patients in need with medical transportation through local resources and programs [6-8]. At our own institution, the need for transportation to eye appointments is the most common indication for referral to our patient navigator program, and

XSL•FO
RenderX

these transportation referrals are addressed successfully through engagement with local resources or by enrollment in patients' insurance-sponsored medical transportation programs [8].

A barrier to connecting vulnerable patients to transportation resources is identifying which patients have a transportation need. Clinic-administered questionnaires to assess for HRSN are important screening tools, but survey uptake in clinical settings is suboptimal [9,10]. Furthermore, social determinants of health (SDoH), which encompass HRSN, are rarely available in structured electronic health record (EHR) data, such as diagnosis codes, and are more commonly documented in unstructured, narrative clinical notes [11-13]. Fortunately, unstructured notes may be accessible for analysis using technology such as natural language processing (NLP), an artificial intelligence (AI) tool that extracts and classifies free-text language [14]. In preliminary studies, NLP has demonstrated capability to identify SDoH terms from EHR text with reasonable accuracy compared to expert review [15,16].

The aim of this study was to determine whether NLP can be used to identify patients' transportation needs from existing unstructured clinical notes in the EHRs of our academic ophthalmology practice.

Methods

Ethical Considerations

This retrospective, cross-sectional, observational study was approved by the University of Pittsburgh institutional review board (STUDY21040204), adhered to the tenets of the Declaration of Helsinki, and complied with the Health Insurance Portability and Accountability Act of 1996. Patient informed consent was waived by the institutional review board. Privacy and confidentiality protection was ensured by leveraging an honest broker to deidentify patient data before analysis, and all analyses were performed on secure university servers. No patient compensation was provided.

Data Source

EHR data were obtained from outpatient clinical encounters of adult patients with the University of Pittsburgh Medical Center Department of Ophthalmology from January 2016 through February 2023. These data included unstructured free text from clinical notes, demographic information (including age, race and ethnicity, and sex), and semistructured text. Semistructured text included questionnaires in the social history section of physician and clinic staff notes, which indicated whether transportation needs were available on file. All signed clinical notes from an ophthalmology encounter were included, including office visit notes from technicians, trainees, and attending physicians, as well as documentation from telephone and refill encounters. These data were extracted from our institution's EHR (Epic Systems) using a custom-made research data warehouse [17]. After extraction, the structured data were deidentified by an honest broker, who is an official certified by the health system and the university to remove identifying information from health records, including names, addresses, and phone numbers, before transferring the dataset to investigators. Free-text notes were deidentified by National Library of Medicine Scrubber [18]. For patients with multiple encounters over the study period, demographic information was included from the first visit.

Algorithm Development

Due to the sparse documentation of transportation in encounter notes, we used a list of keywords (eg, "transportation" and "ride") to sample a subset of notes that contain transportation-related information. We then randomly selected 300 notes to create a gold-standard dataset manually reviewed by 2 ophthalmologists (LMW and AMW) and a research assistant (JC). We used 70% as training data to develop the rule-based NLP algorithm, termed NLP4Eye, with the remaining 30% serving as validation data for evaluation. After removing duplicated notes, there were 188 notes in the training dataset and 106 notes in the testing dataset.

NLP4Eye was iteratively refined on the training dataset. Embedded text of standardized questionnaire items that included transportation language was filtered out, as were transportation-related terms that predominately referred to visual function rather than social need (eg, terms related to "driving" were frequently mentioned during cataract evaluation encounters and thus removed from the algorithm dictionary as indicators of a transportation need). Similarly, due to its frequent mention in the context of fluorescein angiography, "transit" was removed from the dictionary of transportation-related terms in the NLP algorithm.

The NLP algorithm uses these rules within detected sentences to identify transportation needs from notes. The rules are "\b(%reTransportation).(%reNeeds)\b" or "\b(%reNeeds).(%reTransportation)\b," where "reTransportation" represents regular expressions for transportation-related words and "reNeeds" represents needs-related information, as detailed in Textbox 1. The NLP algorithm was then evaluated on the held-out testing data.

After the NLP algorithm development was completed, its validation was assessed on the testing dataset. The F_1-score of the NLP algorithm was then calculated to determine its performance in relation to the gold-standard testing dataset. The F_1-score, reported between 0 and 1, is a common metric of NLP performance relative to a reference standard. F_1 is calculated as a harmonic mean of the algorithm's precision (analogous to positive predictive value) and recall (analogous to sensitivity). An F_1 value of 0.7 or greater was considered adequate.

Finally, we assessed the algorithm for potential false negatives by conducting an additional post-hoc evaluation. In this evaluation, we assessed 200 clinical notes prefiltered for the tokens "transport*" and "mobility restriction*." These broader tokens were selected to capture any transportation-related mentions that might have been missed by our NLP algorithm, allowing us to evaluate potential false negatives in our algorithm's performance. An ophthalmologist (AMW) then annotated these notes for transportation needs, and discrepancies between the algorithm and physician annotations were analyzed using the taxonomy for systematic error analysis in clinical concept extraction by Fu et al [19].

XSL•FO
RenderX

The NLP4Eye algorithm was developed using the Open Health Natural Language Processing Toolkit, an NLP tool based on the Apache Unstructured Information Management Architecture pipeline, to facilitate information extraction from clinical narratives [20]. We created rules for identifying transportation needs based on physicians' knowledge and experience, refining these rules through physician verification. The regular expressions used in our NLP algorithm are listed in Textbox 1.

Textbox 1. Expressions used by the NLP4Eye algorithm to identify transportation needs.

- Transportation terms: "transportation," "ride," "driv(e|ing)"
- Transportation need terms: "work on," "option(s)," "issue(s)," "due to," "assist(ance)?," "access," "adequate," "discuss(ed|es|ing)," "(un)?able," "accommodation," "support," "agree(s)?," "appl(y|ies)," "arrang(es|ed|e|ing)?," "need(s)," "blam(e|es|ing)," "find(s|ing)," "connect(ing|ed)?," "could(n't| not)," "did(n't|not)," "difficult(y|ies)?," "get(ting)?," "help," "does(n't| not)," "lack(s|ing)?," "easier," "EMS," "investigate," "us(es|e|ing)," "depend(s|ing)?," "organiz(es|e|ing)," "coordination," "possible," "resources," "limit(s|ations)?," "convenience," "trouble(s)?," "secur(es|e|ing)," "concern(s)?," "regarding," "reli(es|able|ant)," "time allowance," "problem(s)?," "challeng(es|e|ing)," "purpose(s)?," "offer(s|ed)," "provid(es|ed|e|ing)"

Statistical Analysis

Statistical analyses were performed using R software (version 4.4.1; R Core Team). Descriptive statistics were used to summarize continuous variables as mean (SD), and categorical variables were presented as percentages and compared using chi-square tests (Fisher exact tests when cell values were less than 5). Longitudinal descriptive statistics were summarized as median (IQR) due to a violation of the normality assumption. Binary logistic regression analysis was conducted to identify predictors of NLP-identified transportation needs. Odds ratios (ORs) were calculated with 95% CIs, and a *P* value <.05 was considered statistically significant.

Results

Study Population

A total of 1,801,572 clinical notes from 118,518 unique adult patients were extracted from ophthalmology encounters over the study period, averaging 15.2 (SD 25.19) encounters per patient. Half (59,299/118,518, 50.0%) of the patient population was aged 60 years or above, 57.8% identified as female (68,485/118,518), and the racial composition was mostly White (90,699/118,518, 76.5%), followed by Black (17,594/118,518, 14.8%; Table 1).

NLP Algorithm Validation

In the training stage of NLP algorithm development, 176 out of 188 (93.6%) notes were determined to be correctly labeled by the algorithm. The most common contexts for the 12 false hits were confirmed transportation support (6/188, 3.2%; eg, “agrees to be his transportation to and from and assist with care”), mention of transportation as the setting for an ocular injury (2/188, 1.1%), typographical error (2/188, 1.1%; both instances included “transportation” in place of “transplantation” in the context of corneal grafting), and transportation in the wrong context (2/188, 1.1%; eg, cellular transportation as a target for drug delivery). The algorithm was further refined based on these reference data and implemented across the dataset.

In the validation stage of NLP algorithm development, 95 of 100 (95%) notes were confirmed to represent a transportation need. Of the 5 false positives, 2 were typographical errors in the notes (both meant to refer to eye muscle “transposition”), 2 referred to the Pennsylvania Department of Transportation (one for a required vision screening examination and one to state that the patient retired from that organization), and 1 confirmed reliable transportation. The NLP algorithm’s precision, recall, and F_1-score were 0.860, 0.960, and 0.778, respectively, indicating high agreement with the gold standard expert review.

In addition to measuring our algorithm performance with the F_1-score, we also assessed for false negatives or transportation needs that could be detected using broad transportation terms but later missed during the iterative development of the algorithm. Our post-hoc evaluation on 200 notes containing the tokens “transport*” and “mobility restric*” revealed additional insights about algorithm performance. Within this broader sample, our algorithm correctly identified 101 notes without true transportation needs and 70 of 99 (70%) notes with true transportation issues (accuracy 85.5%, precision 1.00, recall 0.71, and F_1-score 0.83). Analysis of the 29 false negatives using the taxonomy by Fu et al [19] showed that approximately half represented contextual errors (primarily negation and possible or probable language) and half were linguistic errors (mainly synonym mismatches and implied inferences; additional details are available in Multimedia Appendix 1). These findings suggest that our reported prevalence of transportation needs likely represents a conservative estimate.

NLP Identification of Transportation Needs

We applied the NLP algorithm to the entire cohort of 118,518 unique patients. The NLP algorithm flagged 726 (0.6%) unique patients as having at least one mention of a transportation need

XSL•FO
RenderX

in their ophthalmic clinical notes. These 726 patients had a total of 1033 mentions of transportation needs, averaging 1.42 mentions per patient over the study period. As delineated in Table 2, the most common transportation-related terms identified by the NLP algorithm included the following phrases: "due to transportation," "transportation issues," and "transportation difficulties."

Textbox 2 illustrates representative examples of sentences from clinical notes that provide context for the NLP search hits.

Table . Top 10 transportation-related terms identified by the NLP4Eye algorithm.

Term	Encounter hits, n	Unique patient hits, n
Due to transportation	171	121
Transportation issues	154	109
Difficulty with transportation	48	24
Transportation difficulties	19	9
Arrange transportation	16	14
Issues with transportation	10	6
Access transportation	10	9
Transportation options	9	6
Unable to get transportation	8	6
Needs transportation	5	1

Textbox 2. Representative examples of sentences from clinical notes that were identified as expressing transportation needs by the NLP4Eye algorithm.

Example 1

- Identified sentence: "She is unable to stay for an injection due to ride issues today and wishes to observe."
- Regular expression: "due to ride issues"

Example 2

- Identified sentence: "He states that he never returned for any post-operative exams after the surgery in December due to transportation issues."
- Regular expression: "due to transportation issues"

Example 3

- Identified sentence: "It was decided by the Pt to use Ozurdex today for [PERSONALNAME] but no ozrudex in the office today and she has no transportation."
- Regular expression: "no transportation"

Example 4

- Identified sentence: "Huge change os, noticed 3 months ago, had appt in Aug. 2016, had to cx that appt., no ride."
- Regular expression: "no ride"

Demographic Characteristics Associated With NLP-Identified Transportation Needs

Compared to patients without an identified transportation need, patients who had at least one mention of a transportation need identified by the NLP algorithm were more likely to be aged above 80 years rather than below 60 years (adjusted OR 3.01, 95% CI 2.38 - 3.78), and they were less likely to identify as Asian (adjusted OR 0.04, 95% CI 0 - 0.18 for Asian patients vs White patients; Table 3). There was no difference between the female and male sexes (OR 1.13, 95% CI 0.97 - 1.31) or between the Black and White races (adjusted OR 0.98, 95% CI 0.79 - 1.22; Tables 1 and 3).

Longitudinal Analysis of Transportation Needs Over Time

Among patients with at least one documented transportation need, the average annual rate of transportation need mention per year from 2016 through 2022 ranged from 2.6% to 4.9%, with the lowest in 2017 and the highest in 2022 (Table 4). Regarding the number of documented transportation needs, most patients were identified only once (566/726, 78.0%), occurring for a median of 127 (IQR 21.3-595.3) days after their first encounter. Of the total, 20.0% (145/726) of patients had between 1 and 5 additional transportation needs, with a median time of 4, 69, 42, and 96 days between each respective event; 2.1% (15/726) of patients had more than 5 documented transportation needs, with the highest being 9 instances. Overall, the median time from the first visit to transportation-related events gradually increased over time, whereas the time between consecutive needs did not follow a consistent pattern (Table 5).

Table . Rates of transportation needs by calendar year among patients with at least one documented transportation need.

Calendar year	Total notes, N	Counts of transportation needs	Rates of transportation needs (%)
2016	2542	76	3.0
2017	2986	78	2.6
2018	3180	91	2.9
2019	3824	115	3.0
2020	4616	182	4.0
2021	5364	230	4.3
2022	5276	260	4.9

XSL•FO

Discussion

Principal Findings

In this study, we developed a rule-based NLP algorithm to identify transportation needs from the free text of outpatient ophthalmology clinic encounters. Our model was trained and validated using human-labeled gold-standard datasets, and the NLP algorithm demonstrated a satisfactory performance with an F_1-score of 0.860. Overall, we found that 0.6% (726/118,518) of patients had a transportation need that was identified from their ophthalmology clinic documentation.

The performance of our algorithm is comparable to the F_1-score of 0.60 reported by Guevara et al [12], who used large language models to identify mention of transportation issues in oncology clinical notes. Their study focused on a similar patient population but used different methodologies, using fine-tuned Flan-T5 models and ChatGPT family models. Interestingly, despite the differences in approach, this study and the study by Guevara et al [12] demonstrated the feasibility of using NLP to identify mention of transportation needs from clinical documentation. Guevara et al [12] also noted that text-extracted SDoH identified significantly more patients with needs than structured data that use diagnostic codes, which aligns with our findings about the value of mining unstructured clinical notes.

Our model demonstrated higher precision than recall, which indicated a tendency to produce more false negatives than false positives, suggesting that this result may represent the lower limit of identified transportation needs. Our post-hoc evaluation revealed important limitations in recall when applied to notes with more diverse expressions of transportation difficulties. Transportation needs may be expressed through complex linguistic constructions, including negations (“cannot drive”), hypothetical language (“may have difficulty with transportation”), synonyms not included in our keyword list (eg, “mobility issues”), and implied inferences that require contextual understanding (eg, “patient’s vehicle was under repair”). These linguistic challenges are consistent with those identified in other NLP applications for SDoH text extraction from clinical notes [19]. The error analysis of false negatives in our post-hoc evaluation highlighted specific areas for improvement: handling negation patterns, detecting hypothetical language, expanding synonym recognition, and developing more sophisticated contextual understanding. These findings align with previous research on the challenges of extracting social needs information from clinical text [12,16].

Comparison to Prior Work

Previous studies have explored using NLP to identify transportation needs within EHRs [12,16]. One group developed algorithms to detect housing, food, and transportation insecurity among patients in a large health care network. Their transportation algorithm demonstrated relatively low performance compared to the algorithms for housing and food insecurity, and its performance was also lower than that of our algorithm [16]. Another team created an algorithm to identify social needs among oncology patients, with lower performance for the transportation algorithm than other SDoH domains [12]. However, the transportation cases in their study are low, with only 41 in the training set and 6 in the testing set, which may limit the reliability of their algorithm.

Our unique focus on ophthalmology clinics presented distinct challenges in EHR data mining. Free text from ophthalmology clinic encounters often includes abbreviations and terminology that are highly specific to the field [21,22]. We found that refining our algorithm for identifying mention of social needs in ophthalmology was an important step in the process. It required collaboration between ophthalmologists and data scientists to ensure the algorithm did not mistakenly identify common ophthalmology terms, such as “difficulty driving” for cataract patients and the “transit” phase of fluorescein angiography—an ophthalmic dye-based imaging test—as transportation needs. The most common transportation terms identified from unstructured clinical notes were “due to transportation,” “transportation issues,” and “transportation difficulties.”

The 0.6% prevalence of transportation needs identified by our NLP algorithm is similar to the reported transportation needs hit rate of 1.3% reported from a social needs algorithm developed and tested on unstructured medical notes in another

XSL•FO
RenderX

large health system [16]. Interestingly, the use of NLP algorithms to detect mention of social needs in health care settings may result in a lower hit rate than the use of structured EHR-based social needs questionnaires. For example, an EHR-based social needs screening questionnaire for 1696 primary care patients in Boston identified that 7% of screened patients reported a transportation need, which is much higher than the approximately 1% rate in the NLP-based studies [23]. Another reported the presence of transportation insecurity in 2% (3062/147,150) of patients [24]. Different clinical settings will have a variable proportion of underserved patients and unique HRSN, and differences may be apparent between primary care settings and subspecialty offices. Nonetheless, there does seem to be a pattern of a higher proportion of detected needs in survey studies than in NLP algorithms. For example, in our own patient population—encompassing some of the same cohort that underwent NLP assessment—5.1% (68/1340) of patients who completed an EHR-based social needs questionnaire reported a transportation need [25]. While the proportion of patients identified in structured questionnaires is higher than that in NLP algorithms, surveys depend on participant uptake, which may be low and subject to nonresponse bias [24]. Furthermore, screening surveys may increase the documentation demands on health care providers [16]. The vast amount of data available in unstructured clinical notes makes it a promising resource for automated EHR mining. While the percentage of identified social needs may be lower for NLP algorithms than survey-based assessments, the absolute number of patients identified can be much greater [26]. As such, a robust NLP model capable of detecting mentions of social needs during clinical encounters, along with their frequency, offers a valuable alternative for understanding and tracking these needs over time cost-effectively.

Patients with a transportation need identified by the algorithm were more likely to be older and of a non-Asian race, with no difference between sexes or between Black and White patients. Our study's finding that older age is a risk factor for transportation insecurity is consistent with previous research [27]. While some studies have identified the female sex as a risk factor for transportation barriers to health care access [27], our findings align with other research indicating no significant difference between sexes [28]. Previous studies have demonstrated that racial and ethnic minority groups have higher rates of transportation insecurity [28]. Specifically, one study that used an NLP algorithm to extract SDoH text from the clinical notes of patients with cancer and opioid users found that transportation documentation was higher among Black patients [29]. Our study found no difference in transportation insecurity between Black and White patients. Possible explanations for this discrepancy could be a decreasing gap in travel burdens between Black and White Americans in recent years or a hesitance among minority patients to communicate with health care providers, which may result in the absence of this information in the unstructured clinical note in the EHR, but further study is warranted [30,31].

Knowledge about how a person's social needs, particularly transportation needs, change over time remains limited. One study surveyed 228 participants about transportation difficulties at baseline and then reassessed them at either 3 or 6 months [32]. It found that 9% of the population initially reported transportation difficulties, and these needs remained largely stable over time. Only 6% to 8% reported improvement, and 5% reported worsening. The authors suggested that a 3- to 6-month follow-up may be sufficient for identifying changes in social risk [32]. In contrast, our study found that just 0.1% (n=117) of individuals were identified as having transportation needs at their first encounter, which was substantially lower than the findings of the previous study. This discrepancy may reflect differences in population characteristics; for example, our cohort had less racial diversity, and race is a known factor associated with travel-related disparities [33].

Among individuals identified as having transportation needs, 78.0% (566/726) had only one documented need, with a median of 127 (IQR 21-595) days from their first encounter. For those with 2 documented needs, the median interval was 282 (IQR 15-776) days since the initial visit. While these results do not clarify whether the transportation needs identified by the NLP algorithm precisely reflect the timing of the actual need, it is possible that the observed delay stems from a growing sense of trust between patients and their physicians, which may lead patients to disclose their needs only after several visits [34]. Regardless of the cause, these findings suggest that a 3- to 6-month follow-up period may be insufficient to capture meaningful changes in transportation needs among patients facing such barriers.

Potential Interventions

Identification of transportation needs by NLP algorithms may facilitate the implementation of actionable interventions to address transportation barriers. Medical transportation resources are readily available through health insurance and county-based programs, but many patients are not aware that they are eligible for these benefits. For example, at our own institutions, 50 out of 52 ophthalmology patients with transportation needs who were referred to our patient navigator program for resources had their transportation issues resolved by enrolling in a transportation assistance program [8]. The biggest challenge in assisting patients with transportation resources is identifying the patients with transportation needs. By implementing a transportation-oriented NLP algorithm in clinical practice, institutions can identify patients who are at high risk of transportation insecurity and contact them in advance of an upcoming appointment to assess for transportation challenges and to offer resources. In fact, patients with missed appointments have expressed support for outreach with resources to maintain eye care [5], and the implementation of an NLP algorithm to flag patients with needs could greatly facilitate resource allocation to help vulnerable patients maintain access to care.

Limitations

To our knowledge, this study is the first to apply an NLP-based transportation analysis to a corpus of ophthalmology clinic notes from the EHR of a large health care system. Our algorithm identified 726 ophthalmology patients with a transportation need, demonstrating its potential to detect transportation insecurity without adding to health care providers' workloads. Our study does have several limitations. First, our algorithm

XSL•FO
RenderX

was validated and applied to a population local to western Pennsylvania, which may not be nationally representative [35]. In particular, the preponderance of White patients in our dataset may limit our ability to detect racial disparities in transportation needs for patients of the Black race or Hispanic ethnicity. Future work should examine the performance of our algorithm using ophthalmology clinic notes from other geographic settings, particularly those that represent greater racial and ethnic diversity.

Second, the true prevalence of transportation insecurity among our patient population is unknown, making it difficult to compare our findings to actual rates. To assess our findings in the context of an unknown true prevalence of transportation insecurity, we conducted a post-hoc analysis with broad transportation terms to examine for false negatives. While the precision (1.00) of the algorithm in this post-hoc analysis remained high, the recall (0.71) was less robust, indicating that some true transportation needs are missed by the algorithm in an attempt to mitigate false positives. The implications of our post-hoc analysis suggest that our results are probably underreporting the true prevalence of transportation needs in our population. Specifically, our model's higher precision than recall suggests that we likely present a conservative estimate of identified transportation needs in our patient population.

A third limitation of this study is the examination of transportation needs without the consideration of other concomitant, and likely interrelated, HRSN. For this study, we used "transportation needs" as an umbrella term to mine the EHRs, but transportation insecurity has many components and can overlap with other SDoH domains, such as financial insecurity [36]. Patients who express financial difficulties, for instance, may also have difficulty with transportation, but these patients would not be identified by our algorithm unless their needs are documented with transportation-specific language. Therefore, our detected prevalence of transportation needs may again be lower than the true burden faced by the patient cohort. Future work should develop algorithms to identify other SDoH domains in the context of eye care encounters. It is important to explore the different facets of transportation and how they interact with other social needs to identify specific transportation challenges and direct patients to the appropriate services to address these issues.

As a fourth limitation, relevant factors such as socioeconomic status, education level, and residence information were not included in the data source. Absence of these data limits our ability to gain further insights into baseline characteristics that may warrant attention. Future work should incorporate these sociodemographic components, which could facilitate predictive modeling of a patient's risk of transportation needs.

Future Directions

External validation of this model using data from other health care systems across the United States is necessary to test its generalizability. For implementation into clinical practice, further research is needed to assess how health care teams may engage with potential notifications in the EHR about transportation needs identified by the NLP algorithm.

Conclusions

Our NLP algorithm successfully identified previously unknown transportation needs from unstructured ophthalmology clinic notes in the EHRs. The algorithm demonstrated reliable identification of transportation insecurity; thus, it offers an additional method for leveraging large amounts of available data to screen for transportation needs among ophthalmology patients, without adding to the documentation burden on health care providers. Our findings indicate age disparities in transportation needs within our patient population, with older patients indicating a greater burden of transportation needs. In addition to survey-based social needs screening, NLP can identify mention of social needs from EHR text, thus potentially facilitating referrals to transportation resources for vulnerable ophthalmology patients.

Abstract

Background: Drug repositioning is a pivotal strategy in pharmaceutical research, offering accelerated and cost-effective therapeutic discovery. However, biomedical information relevant to drug repositioning is often complex, dispersed, and underutilized due to limitations in traditional extraction methods, such as reliance on annotated data and poor generalizability. Large language models (LLMs) show promise but face challenges such as hallucinations and interpretability issues.

Objective: This study proposed long chain-of-thought for drug repositioning knowledge extraction (LCoDR-KE), a lightweight and domain-specific framework to enhance LLMs' accuracy and adaptability in extracting structured biomedical knowledge for drug repositioning.

Methods: A domain-specific schema defined 11 entities (eg, drug, disease) and 18 relationships (eg, treats, is biomarker of). Following the established schema architecture, we constructed automatic annotation based on 10,000 PubMed abstracts via chain-of-thought prompt engineering. A total of 1000 expert-validated abstracts were curated into a drug repositioning corpus, a high-quality specialized corpus, while the remaining entries were allocated for model training purposes. Then, the proposed LCoDR-KE framework combined supervised fine-tuning of the Qwen2.5-7B-Instruct model with reinforcement learning and dual-reward mechanisms. Performance was evaluated against state-of-the-art models (eg, conditional random fields, Bidirectional Encoder Representations From Transformers, BioBERT, Qwen2.5, DeepSeek-R1, OpenBioLLM-70B, and model variants) using precision, recall, and F_1-score. In addition, the convergence of the training method was assessed by analyzing performance progression across iteration steps.

Results: LCoDR-KE achieved an entity F_1 of 81.46% (eg, drug 95.83%, disease 90.52%) and triplet F_1 of 69.04%, outperforming traditional models and rivaling larger LLMs (DeepSeek-R1: entity F_1=84.64%, triplet F_1=69.02%). Ablation studies confirmed the contributions of supervised fine-tuning (8.61% and 20.70% F_1 drop if removed) and reinforcement learning (6.09% and 14.09% F_1 drop if removed). The training process demonstrated stable convergence, validated through iterative performance monitoring. Qualitative analysis of the model's chain-of-thought outputs showed that LCoDR-KE performed structured and schema-aware reasoning by validating entity types, rejecting incompatible relations, enforcing constraints, and generating compliant JSON. Error analysis revealed 4 main types of mistakes and challenges for further improvement.

Conclusions: LCoDR-KE enhances LLMs' domain-specific adaptability for drug repositioning by offering an open-source drug repositioning corpus and a long chain-of-thought framework based on a lightweight LLM model. This framework supports drug discovery and knowledge reasoning while providing scalable, interpretable solutions applicable to broader biomedical knowledge extraction tasks.

Introduction

Drug repositioning, also known as drug repurposing, has emerged as a pivotal strategy in pharmaceutical research, enabling the discovery of novel therapies for existing drugs [1]. This approach significantly facilitates the drug development process, shortens the required time, and reduces the cost [2]. However, biomedical information relevant to drug repositioning is often complex and dispersed across various sources [3], such as literature, clinical trials, and databases. These valuable resources remain underutilized because of the challenges associated with knowledge extraction [4,5]. Extracting knowledge from biomedical literature, such as entities, relationships, and structured triplets, can facilitate drug repositioning research by uncovering hidden connections between drugs and diseases [6]. Recent studies have demonstrated the effectiveness of knowledge extraction in supporting knowledge discovery in drug repositioning. For example, Bang et al [7] developed a semantic multilayer guilt-by-association approach to extract drug-disease associations from large-scale biomedical corpora, while Huang et al [8] leveraged TxGNN, a graph foundation model for zero-shot drug repurposing, to identify therapeutic candidates even for diseases with limited treatment options or no existing drugs. These advancements underscore the importance of automated knowledge extraction in identifying potential drug candidates for the treatment of complex, multifactorial diseases.

Traditional knowledge extraction methods have evolved from manual annotation and rule-based techniques to machine learning and deep learning approaches. Early methodologies relied heavily on expert-curated databases and handcrafted rules, which lacked scalability while being precise [9,10]. Machine learning models, such as conditional random fields (CRF), introduced statistical learning to automate entity recognition and relationship extraction [11-13]. More recently, deep learning models, including BERT and transformer-based architecture, have achieved remarkable performance in biomedical natural language processing tasks. For example, domain-specific language models, such as BioBERT [14], PubMedBERT (trained on biomedical literature) [15], ClinicalBERT (trained on the MIMIC-III dataset) [16], and PharmBERT (trained on prescription drug labeling) [17], have been further developed. Despite their success, these methods still have several limitations. They often require extensive labeled datasets for training, which are costly and labor-intensive to obtain. Furthermore, deep learning models demonstrate limited generalizability across diverse biomedical domains [18] and often overlook implicit knowledge that extends beyond surface-level textual patterns [19]. As a result, refining extraction methodologies to achieve greater adaptability and performance continues to be an important focus in drug repositioning studies.

Large language models (LLMs) have emerged as a promising solution for biomedical knowledge extraction, demonstrating superior performance across various natural language processing tasks. Models such as ChatGPT (OpenAI) [20], LlaMA (Meta) [21], GLM (Tsinghua) [22], Qwen (AlibabaCloud) [23], and Deepseek [24] have been extensively used in biomedical text mining because of their advanced semantic comprehension and text generation capacities. By leveraging key methodologies, including pretraining [25], prompt engineering [26], and domain-specific fine-tuning [27], these models demonstrate improved accuracy and adaptability for specialized tasks [28], such as named entity recognition [29] and association prediction [30]. Xie et al [31] developed Me-LLaMA through continual pretraining and instruction tuning of LLaMA2 models and outperformed existing open medical LLMs on 6 text analysis tasks. Hao et al [26] developed and evaluated MedScaleNER, a task-oriented prompt framework, advancing the application of LLMs and prompt engineering for specialized named entity recognition tasks in Chinese medical literature. Recent advances such as BioGPT [32] and OpenBioLLM-70B [33] have demonstrated the potential of large-scale generative pretrained transformers in enhancing biomedical text generation and domain-specific knowledge mining. Focusing on a more specific biomedical task, Yuan et al [34] introduced BioFocal-DDI, a framework combining BioGPT for data augmentation, BioBERT, and BiLSTM for contextual and sequential feature extraction to optimize drug-drug interaction extraction.

Compared to traditional methods, LLMs demonstrate superior knowledge extraction capabilities, including better generalization, reduced reliance on annotated data, and stronger contextual comprehension. Nevertheless, persistent challenges [35,36], including model hallucination, output accuracy, interpretability, and high computational demands, must be addressed. For drug repositioning applications, these issues can be mitigated through gold-standard corpus validation, careful prompt engineering, and chain-of-thought (CoT) [37] methodologies. Chen et al [38] leveraged retrieval‐augmented generation combined with instruction prompting to build LLMs specialized for osteoarthritis diagnosis and treatment Q&A, providing reliable clinical decision support to health care professionals.

While LLMs demonstrate promise in biomedical knowledge extraction, challenges persist in domain-specific adaptability, particularly in drug repositioning, where sparse annotated data, semantic ambiguity, and cross-sentence dependencies hinder accurate knowledge inference [39,40]. To address these limitations, we proposed long chain-of-thought (LCoT) for drug repositioning knowledge extraction (LCoDR-KE), a lightweight framework that combined LCoT prompting, supervised fine-tuning (SFT), and reinforcement learning (RL). To enhance the performance of knowledge extraction, our approach also introduced a dual-level reward mechanism to guide knowledge extraction and a high-quality drug repositioning corpus (DrugReC), meticulously curated from biomedical publications in PubMed. Through comparative and ablation studies, we validated the framework's superiority over traditional models and its competitive performance against state-of-the-art LLMs, offering a scalable, interpretable solution for accelerating drug discovery and biomedical knowledge inference.

Methods

Overview

The workflow of the proposed *LCoDR-KE* is illustrated in Figure 1 and consisted of 4 main stages: drug repositioning schema design, data preparation and gold standard annotation, implementation of LCoT framework, and in-depth evaluation.

- *Drug repositioning schema design*: This stage established a structured schema for drug repositioning, defining 11 entity types (eg, drug, gene, disease, target) and 18 relationship types. The schema provided a standardized ontology that enabled accurate knowledge extraction while maintaining conceptual consistency across the domain.
- *Data preparation and annotation*: We first annotated a scale of 10,000 PubMed abstracts via CoT prompt engineering, incorporating role definitions and k-shot demonstrations. Among these, 1000 abstracts were subjected to meticulous manual annotations, resulting in a high-quality corpus specifically curated for the task of drug repurposing, DrugReC. The remaining 9000 abstracts were used as part of the training data in this study.
- *Implementation of the LCoT framework:* We first conducted SFT to establish a strong output with explicit reasoning chains for LLM. Following this, we applied Group Relative Policy Optimization (GRPO), an RL strategy guided by reward modeling. Tailored reward functions were specifically designed for drug repositioning entity and triple recognition, enabling more accurate and structured output aligned with domain-specific requirements.
- *Evaluation and performance analysis*: We evaluated the model's effectiveness through performance comparisons, ablation studies, k-shot performance, reward parameter optimization, CoT reasoning patterns, steps of training iterations, and error analysis.

Drug Repositioning Schema Design

We developed a multidimensional knowledge model by conducting in-depth analyses of drug mechanisms [41-43] while precisely defining core entity dimensions and their relationships. We conducted comprehensive analyses of drug labels, literature, and multiple biomedical databases (including DrugBank, CTD, PharmGKB, and DisGeNET) to establish foundational knowledge. In addition, this multidimensional knowledge framework was subsequently refined and validated through expert consultation, incorporating specialized domain knowledge from pharmacology, bioinformatics, clinical medicine, and computational biology.

Data Preparation

A total of 10,000 PubMed abstracts were extracted using a 4-step filtering strategy to ensure quality and domain relevance:

1. Initial search: Articles published between January 1, 2015, and January 1, 2025, were retrieved via PubMed using Medical Subject Headings (MeSH) terms and keywords related to drug repositioning, drug mechanisms, and pharmacology.
2. Journal filtering: We retained articles published in top-tier pharmacological journals ranked in Q1 of the Journal Citation Reports (Multimedia Appendix 1).
3. Relevance filtering: Abstracts were kept if the title or abstract mentioned at least one drug or disease entity from a standard drug repositioning dataset [44].
4. Length filtering: Abstracts under 50 characters were excluded to ensure basic content adequacy.

This rigorous selection process (detailed in a PRISMA [Preferred Reporting Items for Systematic Reviews and Meta-Analyses] flow diagram in Multimedia Appendix 1) ensured the inclusion of the latest high-quality research articles relevant to pharmacological mechanism and repurposing strategies.

Data Annotation With CoT-Prompt Engineering

Owing to the lack of annotated datasets for drug repositioning knowledge extraction, we constructed an annotated corpus from 1000 PubMed abstracts mentioned earlier. The prompt was evaluated on DeepSeek-R1 [45] via CoT [46], which required LLMs to generate coherent intermediate reasoning steps leading to a final answer [47].

We summarized the execution steps and proposed a task-specific prompt as follows and outlined them in Multimedia Appendix 2.

- Step 1: Role assignment and task description. Initialized the LLM as a biomedical annotation specialist, explicitly defining the drug repositioning schema and incorporating k-shot demonstrations to establish contextual understanding of target entities and semantic relationships.
- Step 2: Identification of entity and relationship types. Identified candidate entity types and contextual relationship types in text according to predefined schema.
- Step 3: Entity and relationship annotation. Based on the categories identified in step 2, this step extracted specific entities (eg, “Metformin” as *drug*, *“Diabetes” as disease*) and their contextual relationships (eg, *treats*) from text.
- Entity annotation principles. (1) Nonoverlapping: A single string cannot be assigned to multiple entity types. (2) Nonnesting: An entity should not contain another entity within its span. (3) Minimal punctuation and conjunction: Entities should exclude unnecessary punctuation or connecting words.
- Relationship annotation principles. (1) Intrasentence priority: Triplets within a single sentence are preferred; cross-sentence triplets are permitted only if no valid intrasentence relation exists. (2) Unidirectional relations: Only 1 directional relation is retained between any 2 related entities.
- Step 4: Triplets construction. Extracted drug repositioning entities and their contextual associations into semantically coherent triplets.
- Step 5: Output format standardization. Specified the output format and standards, setting clear expectations for the output as {Entity1; Type1; Relationship; Entity2; Type2} in JSON format.

To ensure the quality of the DrugReC, we manually reviewed the standard results from 1000 abstracts as well. A total of 3 annotators in pharmacology, clinical medicine, and bioinformatics were recruited, with 2 conducting cross-review and the third senior expert adjudicating conflicting or ambiguous cases. The corpus was subsequently partitioned into a training set (n=800) for RL algorithm development and a test set (n=200) to evaluate model generalizability. The remaining 9000 abstracts were used as training data for SFT.

Long Chain-of-Thought

LLM Deployment

The Qwen2.5-7B-Instruct model [48], developed by Alibaba Cloud, represented a significant advancement in the Qwen series of LLMs, specifically optimized for semantic comprehension and complex task processing. This 7-billion-parameter transformer-based architecture demonstrated exceptional performance in specialized applications, including knowledge extraction [49] and conversational interaction [50] scenarios. Meanwhile, an extended context window of 128,000 tokens facilitated precise capture of fine-grained semantic features within textual data.

For the Qwen2.5-7B-Instruct setup, we used temperature sampling with the parameter of 0.02. A lower temperature parameter can limit the model to make excessive creative jumps, thus ensuring accurate and consistent outputs. Meanwhile, we set the max_token parameter to 16,384 while leaving all other hyperparameters at their default values. The used hyperparameters during model training included a training batch size of 8, a learning rate of 1e−6, a cutoff length of 16,384, and a gradient accumulation step of 1. The model was trained on the Wuwen Xinqiong platform. Training the 7B model with 8× NVIDIA A100 40GB GPUs took approximately 40 hours, with a total cost of approximately 1000 RMB (US $140.47).

XSL•FO
RenderX

Cold-Start SFT

To address the output incoherence and unstable reasoning patterns caused by directly initializing RL [51] in foundation LLMs, we implemented cold-start SFT [52] with CoT data from 9000 PubMed literature as mentioned earlier. These domain-specific annotated triplets were used to optimize model parameters under a supervised learning framework, enabling the model to progressively acquire human-aligned reasoning patterns. This phase implemented multistep reasoning paths and strict output formats, significantly enhancing the model's complex problem decomposition capacity and intermediate step interpretability. In brief, the approach of cold-start SFT provided stable initialization for subsequent RL stages.

RL Algorithm

To reduce the training costs associated with RL, we used GRPO to further optimize reasoning paths through self-iteration in an unannotated environment [53]. Specifically, GRPO generated multiple candidate outputs {o1,o2,…oG} from the old policy πθold and then optimized the policy model πθ by maximizing the following objective:

(1)JGRPO(θ)=E[∑i=1G(min(πθ(oi|q)πθold(oi|q)Ai,clip(πθ(oi|q)πθold(oi|q),1−ε,1+ε)Ai)−βDKL(πθ||πref)]

(2)DKL(πθ||πref)=πθref(oi|q)πθ(oi|q)−logπθref(oi|q)πθ(oi|q)−1

and the advantage Ai was defined as follows:

(3)Ai=(ri−μgroup)/σgroup

where ri was the raw reward for the *i*th answer and μgroup and σgroup represented the mean and SD, respectively, of rewards within the candidate outputs. The group-wise contrastive mechanism mitigated absolute reward scale bias while encouraging high-quality reasoning.

For the task of drug repositioning knowledge extraction, this optimization process facilitated complex cognitive mechanisms based on a high-performance RL training framework, EasyR1 [54], leading to enhancement of task-specific reasoning performance.

Reward Modeling

Subsequently, we proposed a novel dual-reward mechanism specifically for drug repositioning knowledge extraction to guide model self-evolution. This mechanism integrates 2 complementary reward types: (1) an accuracy reward targeting factual correctness in entity and triplet extraction and (2) a structural format reward focusing on the integrity and interpretability of the model's reasoning process through structured tag compliance.

Accuracy Reward Mechanism

This mechanism established a multidimensional evaluation that compares model outputs with annotated references. Dynamic scoring rules for entity recognition and triplet extraction are presented in Table 1.

According to these scoring rules, the accuracy reward was as follows:

(4)Racc=αSentity+βStriplet+γSrare

where Sentity was accuracy reward of entity recognition, Stripletwas accuracy reward of triplet extraction, and Srare was reward of rare entity or relationship. This hierarchical award mechanism effectively balanced comprehensiveness and granularity in drug repositioning knowledge extraction.

Table . Scoring rules of accuracy reward.

Reward factor and detail	Reward mechanism
Entity recognition	
Exact match: boundary and type fully consistent	Score rewarded (+)
Partial overlap: correct type with boundary overlap	Partial rewarded (+)
False positive: misrecognition and false negative: omission	No score (0)
Triplet extraction	
Correct triplet	Score rewarded (+)
Dependency error: incorrect entity in relation	No score (0)
Others	
Rare entity/relationship	Score rewarded (+)

Structural Format Reward

To enhance the model's step-by-step reasoning, we also introduced an XML tag–guided mechanism (Table 2) that enforced structured output. It was required to encapsulate complete reasoning processes within "<think>……</think>" tags and nested <step> tags, enabling multilevel logical decomposition.

According to these scoring rules, the structural format reward was as follows:

(5)Rfmt=δStag+εSlength

where Stag was format reward of tag integrity and Slength was format reward of thinking length. This approach ensured machine-parsable outputs while enhancing the interpretability of inference pathways.

XSL•FO
RenderX

Table . Scoring rules of structural format reward.

Reward factor and detail	Reward mechanism
Tag integrity	
Missing/redundant tags	No score (0)
Tag closure disorder: closing tag appears before opening tag	No score (0)
Thinking length	
Underlength/overlength content	No score (0)

In-Depth Evaluation and Comparison

To comprehensively assess the performance of LCoDR-KE, we conducted an in-depth analysis.

First, comparative experiments were conducted to benchmark LCoDR-KE against traditional machine learning models (eg, CRF), general-purpose pretrained models (BERT), domain-specific biomedical models (BioBERT), and state-of-the-art LLMs, including ChatGPT-4, Llama3, QIANWEN, and variants with different parameter scales. These comparative analyses served to validate the effectiveness of our proposed model against established benchmarks, thereby highlighting its superior performance in addressing specialized biomedical knowledge extraction problems.

Second, ablative experiments were designed to evaluate the individual contributions of the key technological advancements, including high-quality data-driven prompt engineering and LCoT reasoning mechanism. By removing or substituting these modules, the study quantified their independent contributions and synergistic effects on task performance.

Finally, we conducted an error analysis by manually reviewing 100 randomly selected abstracts from the model outputs to identify common types of mistakes and areas for future algorithmic improvements.

Meanwhile, we used precision, recall, and F_1-score for model evaluations. Precision quantifies the proportion of correct identifications among all model predictions, reflecting the reliability of positive results. Recall evaluates the coverage for true positive instances, indicating the comprehensiveness of knowledge extraction. The F_1-score, as the harmonic mean of precision and recall, provides a balanced assessment that mitigates the impact of omissions and false extraction, thereby offering a comprehensive evaluation. For rigorous validation, we compared model outputs against manually annotated corpus using exact string matching, which ensured high quality of model performance.

Ethical Considerations

This study did not involve human participants or animal experiments. All data used in the research, including biomedical literature and structured databases, were publicly available and deidentified before analysis. Therefore, ethics approval was not required in accordance with institutional and international research ethics policies.

Results

Knowledge Representation for Drug Repositioning

Drug repositioning schema (summarized in Multimedia Appendix 3) encompassed 11 entity categories, including core entities (drug, disease, and target) along with extended dimensions, such as side effect, gene, biomarker, symptom, complication, anatomical structure, clinical examination, and treatment. Furthermore, 18 relationship categories were defined in detail to comprehensively characterize semantic features among multilevel entities, such as “treat...,” “is target of,” “is side_effect of,” “is biomarker of.” This framework substantially enhanced semantic representation capabilities and facilitated the discovery of latent associations in drug repositioning research.

Statistics of DrugReC

Via defined prompt engineering and manual review, we constructed a high-quality DrugReC, specially for drug repurposing text mining. This corpus, annotated from 1000 PubMed abstracts, contained 11 entity types and 18 relationship types closely related to drug repositioning. After the concordance test and revision, a total of 9329 entities and 4879 triplets consisted of this standard dataset (presented in Table 3). Among the entity types, *disease* (19.10%) and *drug* (15.80%) were the most frequently represented, followed by *anatomy* (13.62%), *test* (10.32%), and *biomarker* (10.26%). Less prevalent but critical categories included *complication*, *target*, *treatment*, *symptom*, *gene*, and *side effect*. Regarding knowledge triplets, *is_examination_for* (18.16%), *treat* (17.20%), and *is_biomarker_of* (17.16%) together accounted for more than half of all triplets, emphasizing the corpus’s focus on clinically relevant associations. This distribution reflected DrugReC’s design to support comprehensive text mining efforts in drug repositioning by capturing key therapeutic and diagnostic linkages. We have made this corpus publicly available on GitHub with Apache License version 2.0, providing a high-quality data foundation to advance biomedical informatics mining.

Then, this dataset was randomly divided at the document level into training (80%) and test (20%) subsets, with detailed statistical characteristics of both partitions provided in Tables 3 and 4.

Knowledge Extraction With Different Types

LCoDR-KE achieved an overall F_1 score of 81.46%. High performance was observed for the most frequent entity types, including drug (F_1=95.83%) and disease (F_1=90.52%), likely due to their distinct semantic boundaries and abundant contextual representations. Mid-range performance was observed for anatomy (82.38%) and test (82.11%), while categories such as gene (74.70%), complication (73.93%), and biomarker (72.03%) showed moderate degradation. The lowest entity F_1 scores occurred for target (64.05%) and treatment (67.21%), not solely due to lower frequency but likely due to greater semantic ambiguity and overlapping usage with other types. Performances are detailed in Table 5.

Triplet extraction yielded an overall F_1 score of 70.39% (Table 6). The model excelled on treat relations (F_1=84.47%) and is_target_of (74.73%), which may benefit from clearer syntactic patterns. In contrast, performance declined for is_biomarker_of (57.69%) and increases_expression_of (50.00%), reflecting both data sparsity and higher contextual variability.

Performance differences can largely be attributed to variations in data distribution, semantic complexity, and context dependency, rather than entity or relation frequency alone. These findings suggested that targeted data augmentation, finer-grained annotation, or context-aware modeling strategies may further improve performance across challenging categories.

Performance Comparisons

Performance Comparison With State-of-the-Art Models

To evaluate the performance, we compared our LCoDR-KE model with several state-of-the-art models, including CRF (machine learning model), BERT (general-purpose pretrained language model), BioBERT (domain-specific biomedical model), and LLMs, including DeepSeek-R1, QIANWEN, and variants with varying parameter scales. These LLMs were evaluated under a 5-shot setting, consistent with the configuration used for our LCoDR-KE model. This ensured a fair comparison under equivalent prompt-based conditions. Detailed hyperparameter settings for each model are provided in Multimedia Appendix 4.

The comparative evaluation against state‐of‐the‐art baselines (Table 7) demonstrated that LCoDR-KE delivered substantial advances in both entity and triplet extraction. Classical sequence learners, such as CRF, scored poorly (entity F_1=29.18%; triplet F_1=14.51%), while general‐purpose pretrained models (eg, BERT, BioBERT) achieved modest gains (entity F_1≈37%; triplet F_1≈30%). The Qwen2.5-7B variant improved entity extraction (F_1=53.16%) but remained weak on triplets (F_1=18.04%). In contrast, LCoDR-KE-0.5B reached 62.67% entity F_1 and 35.05% triplet F_1, and the 7B model further advanced to 81.46% and 69.04%.

Notably, at 7B parameters, LCoDR-KE approached DeepSeek-R1's entity F_1 (81.46% vs 84.64%) and marginally exceeded its triplet F_1 (69.04% vs 69.02%). Although LCoDR-KE did not surpass DeepSeek-R1, it reached a similar level of effectiveness under a smaller parameter scale (7B vs 671B).

We further evaluated the OpenBioLLM-70B, which achieved an entity F_1 of 59.66% (precision: 56.63%; recall: 63.04%) and a triplet F_1 of 16.52% (precision: 13.92%; recall: 20.31%). In contrast, our LCoDR-KE-7B model achieved notably higher performance with 81.46% (precision: 83.37%; recall: 79.64%) in entity extraction (21.8 percentage points increase) and 69.04% (precision: 72.43%; recall: 65.96%) in triplet extraction (52.5 percentage points increase).

Impact of Model Scale on Extraction Performance

Across the LCoDR-KE series (Figure 2), increasing model capacity from 0.5B to 1.5B, 3B, and 7B yielded consistent performance improvements, with entity F_1 rising from 62.67% to 72.91%, 74.57%, and 81.46%, triplet F_1 rising from 35.05% to 48.34%, 51.83%, and 69.04%, respectively. These gains suggested that larger models better capture the complex contextual dependencies required for accurate biomedical knowledge extraction.

Figure 2. Performance of LCoDR-KE across different model scales (0.5B, 1.5B, 3B, 7B) on biomedical entity and triplet extraction tasks. Larger models yielded better precision, recall, and F_1-scores. LCoDR-KE: long chain-of-thought for drug repositioning knowledge extraction.

Ablation Studies

To evaluate the contributions of different components within the LCoDR-KE model, we conducted ablation studies to examine the impact of strongly SFT and the LCoT model on knowledge extraction outcomes for drug repositioning. We removed the 2 components of the LCoDR-KE model to observe changes in performance.

As presented in Table 8, the ablation studies demonstrated significant performance degradation when removing either SFT or GRPO module. Removing GRPO reduced F_1-scores by 6.09% for entity extraction and 14.09% for triplet extraction, indicating that GRPO substantially enhances knowledge extraction. In comparison, removing SFT caused sharper declines in precision (8.61% for entities and 20.70% for triplets), underscoring the critical role of task - specific supervision in adapting pretrained representations. Together, these results demonstrated that both components contribute synergistically to the model's knowledge extraction capabilities, with GRPO enhancing reasoning and SFT improving supervised alignment. Meanwhile, the absence of SFT caused more pronounced degradation in both entity and triplet extraction, indicating its broader influence on model performance (Figure 3).

Table . Ablation study results: precision, recall, and F_1-scores for different components of LCoDR-KE[a].

Ablation models	Entity extraction			Triplet extraction		
	Precision (%)	Recall (%)	F1 (%)	Precision (%)	Recall (%)	F1 (%)
LCoDR-KE$_{\text{-w/o GRPO}}$[b]	76.53	74.25	75.37	54.58	55.33	54.95

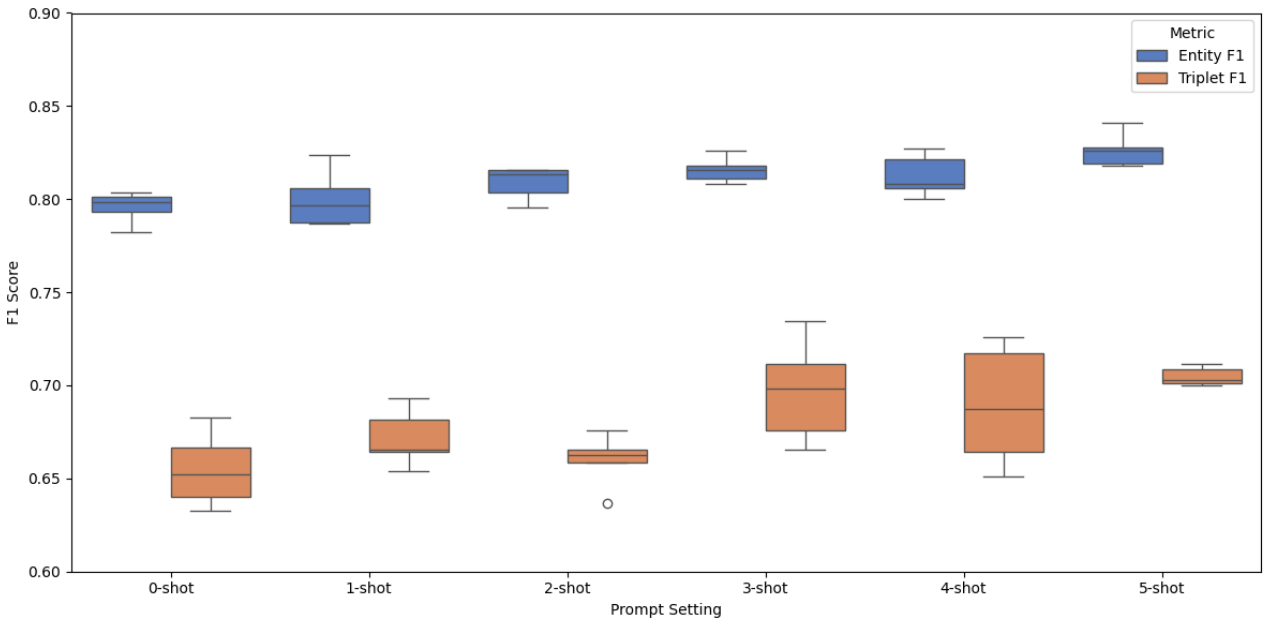
Figure 3. Radar chart comparing the full LCoDR-KE model with its ablation variants (without Group Relative Policy Optimization [GRPO] and without supervised fine-tuning [SFT]) across 6 evaluation metrics. Both the GRPO and SFT modules significantly enhanced performance, with SFT contributing more broadly across precision and F_1-scores, especially for triplet extraction. LCoDR-KE: long chain-of-thought for drug repositioning knowledge extraction.

External Benchmark Evaluation

To further assess generalizability beyond our in-domain DrugReC corpus, we evaluated LCoDR-KE directly on the widely used BC5CDR benchmark, which comprises 500 PubMed abstracts manually annotated for chemical (drug) and disease entities and their binary associations. OpenBioLLM-70B achieved entity F_1 of 47.39% and relation F_1 of 25.52%, while DeepSeek-R1 scored 60.93% and 38.33%, respectively. Without additional fine-tuning, LCoDR-KE obtained an entity F_1 of 59.17% (precision: 85.92%; recall: 45.12%) and a triplet F_1 of 35.16% (precision: 33.84%; recall: 36.59%), closely matching DeepSeek-R1 and substantially outperforming OpenBioLLM-70B. Thus, our method demonstrated generalizability beyond in-domain abstracts, achieving robust performance on external biomedical corpora such as BC5CDR.



Effect of K-Shot Examples on Model Performance

To evaluate the impact of prompt on corpus generating, we conducted a small-scale experiment comparing 0- to 5-shot

XSL•FO
RenderX

prompting settings. As shown in Figure 4, k-shot prompting consistently outperformed the 0-shot baseline in both entity and triplet extraction. Entity F_1 rose from 80.01 (0 shot) to 82.63 (5 shots), while triplet F_1 increased from 67.16 to 70.48. Performance steadily improved as the number of examples increased, particularly between 1 shot and 3 shots. Notably, the model achieved stable and high performance in the 3- to 5-shot range, suggesting that moderate prompt context enhances annotation quality.

Figure 4. Effect of k-shot prompting on entity and triplet extraction performance. F_1-scores for entity and triplet extraction across 0- to 5-shot settings. Performance improved with more shots and stabilizes between 3 shots and 5 shots.

Reward Parameter Optimization

To optimize the reward function for knowledge extraction and structured reasoning, we used a progressive tuning strategy through multiple rounds of controlled experiments. The reward formulation includes a hierarchical accuracy component where the coefficients for entity recognition (α), triplet extraction (β), and rare entity/relation enhancement (γ) satisfy the constraint $\alpha + \beta + \gamma = 1$. Given the high computational cost of jointly searching in a 3D space, we adopted a 2-stage approach. We first optimized α and β under the constraint $\alpha + \beta = 1$ to balance entity- and relation-level performance. Once optimal base weights were identified, we introduced γ by gradually adjusting the proportion of reward allocated to rare cases. Subsequently, we adjusted the weights associated with structured reasoning, namely tag integrity (δ) and reasoning length (ε), to ensure syntactic validity and controlled verbosity in the model's output. Finally, we calibrated the overall balance between accuracy-related rewards and format-related rewards by modifying the global weight of accuracy reward and format reward parameters.

In addition, we introduced 2 top-level coefficients (ie, accuracy reward weight and format reward weight) to control the relative contribution of accuracy-based and format-based rewards in the overall objective. These weights were jointly tuned to ensure a trade-off between extraction performance and output structure quality.

Throughout the process, evaluation was based on both entity and relation F_1-scores, as well as the structural completeness of generated outputs (Multimedia Appendix 5). The final parameter configuration, with α=.45, β=.45, γ=0.1, δ=0.7, ε=0.3, accuracy reward=0.5, and format reward=0.5, demonstrated optimal performance in terms of extraction accuracy, robustness, and output interpretability and was therefore adopted in subsequent experiments.

Interpretable CoT Reasoning Patterns

To evaluate whether the model engaged in structured reasoning, we examined its CoT outputs during knowledge extraction. We gave an example (Table 9) to demonstrate that the model performed structured, schema-aware reasoning beyond pattern matching. It explicitly validated entity types, rejected schema-incompatible relations, and enforced output constraints, ultimately generating a compliant JSON structure. The complete example of CoT is summarized in Multimedia Appendix 6.
