Variability in responses often stems from ambiguous text, where LLMs may assign values inconsistently. For example, a report describing a patient as an ”active smoker (1 month since quitting, 1 pack/day since age 14-16)“ resulted in GPT-3.5 identifying the patient as a smoker in 6 out of 10 analyses, while GPT-4 made only 1 error across 10 analyses. However, in the same report, regarding the comorbidity of COPD, GPT-4 shows a split: in 5 instances, it identifies it as present and in 5 as absent. The physician reviewing the results and establishing the ground truth determined the absence of COPD, as it is not explicitly mentioned in the report. Nonetheless, the mention of “mild pulmonary emphysema areas” and the patient's prolonged smoking history could lead GPT-4 to infer the presence of COPD.Top of Form

Figure 4. The number of reports for each model, in which at least the number of differences indicated on the x-axis was obtained in the 10 analyses.

Discrepancy Analysis

Multimedia Appendices 1 and 2 display the distribution of discrepant results categorized by the causes determined through a detailed manual analysis of the reports.

A notable discrepancy arose in the ”kidney disease“ category due to differences in criteria. Some physicians and GPT-3.5 did not deem certain renal pathologies, such as renal lithiasis, as relevant comorbidities in the context of oncology treatment, unlike GPT-4, which aligned its results more closely with the ground truth.

In analyzing cases interpreted as hallucinations, it was found that this phenomenon occurred exclusively in 1 response from GPT-4 and in 6 from GPT-3.5, particularly in the smoker and ex-smoker categories, possibly due to the use of the label “toxic habits,” even when referring to other habits like alcoholism.

The models, especially GPT-4, tend to infer comorbidities from the context or reported medication more frequently than physicians, who exhibit a more conservative approach. This tendency leads to more false positives by the models, particularly when the medication does not imply the presence of comorbidity.

GPT-3.5 exhibited difficulties in interpreting common medical acronyms such as “DM” for diabetes or “AF” for atrial fibrillation, whereas GPT-4 demonstrated a superior ability to recognize and correctly interpret most of these acronyms.

Interestingly, GPT-4 displayed some false positives when encountering comorbidity labels followed by “:” without additional information, a misinterpretation not common in humans but observed in AI, particularly in GPT-4 more than in GPT-3.5.

Human evaluators showed a greater tendency to overlook comorbidities explicitly reported, likely due to distraction or fatigue.

Only 3 errors were identified in the determination of the ground truth, underscoring the reliability of the review process.

Finally, we identified a category of discrepancies exclusive to the models, related to structural or formatting errors. This includes situations where the models' responses do not follow the guidelines specified in the prompt, resulting in outputs that do not meet the expected JSON format or that incorrectly alter and introduce comorbidity labels. Given that these incidents were limited, affecting less than 10 cases, it was decided to

XSL•FO
RenderX

manually correct these formatting errors for inclusion in the subsequent analysis.

Discussion

Principal Findings

Our study categorizes observers as ”Physicians,“ ”GPT-3.5,“ and ”GPT-4,“ reflecting the synergy between specific models (*gpt-3.5-turbo-1106* and *gpt-4-1106-preview*) and the prompts designed for this research. The effectiveness of GPT models in generating responses is inherently linked to the quality and structure of the prompts [14,21,22], indicating that results may vary significantly with prompt redefinition. Similarly, physician performance is influenced not only by clinical competence but also by the clarity of instructions and the quality of the materials provided. Offering more detailed and specific guidelines, along with access to additional sources within the electronic health records, could potentially improve the accuracy of their responses.

It is important to emphasize that even if LLMs demonstrate superiority in the specific task of processing large volumes of reports to extract information, this should not be extrapolated to other tasks, such as decision-making. In such cases, these tools should always be used as support tools, requiring ongoing physician oversight and intervention.

Based on the results obtained, we can conclude that the GPT-4 model is notably better at identifying present comorbidities, with fewer false negatives, while physicians exhibit slightly higher precision in their diagnoses, resulting in fewer false positives. The GPT-3.5 model generally performs slightly below the physicians, though the differences found are not statistically significant. These results are consistent with findings from other studies, such as Hoppe et al [23], which highlight the potential of ChatGPT models to enhance diagnostic accuracy in emergency medical settings. In their study, GPT-4 also outperformed both resident physicians and GPT-3.5 in diagnostic accuracy.

The superior sensitivity of GPT-4 in our study is particularly noteworthy, demonstrating its advanced ability to accurately identify reported comorbidities, even when not directly evident in the text. However, both GPT-3.5 and GPT-4 generate a comparable number of false positives, which is significantly higher than those recorded by physicians. Physicians' false positives typically result from specific circumstances such as ambiguity in clinical reports, variations in interpretation among professionals, and occasional errors in the template filling process.

In contrast, false positives from the GPT models seem to stem from a less conservative approach in determining comorbidity presence based on inferred context. These cases are also more likely to produce less reproducible responses due to the nondeterministic nature of LLMs. In these instances, physicians adopted a more conservative criterion to establish the ground truth, considering an unreported comorbidity only when the medication or context necessarily implied it. Whether this conservative approach is preferable to the criteria used by GPT models requires an analysis of complete medical histories to confirm or refute the presence of the comorbidity.

Discrepancies arising from variations in criteria interpretation could be mitigated by using prompts with clearer instructions on interpreting different comorbidities. This underscores the importance of refining prompts to enhance the consistency and accuracy of LLM-generated responses in clinical contexts.

Despite the remarkable capacity of current LLMs as potential tools for data mining in clinical reports, questions arise regarding the practical utility of this RWD for research and the generation of real-world evidence [24]. The variability, subjectivity, and lack of structure in these reports can compromise the quality and reliability of extracted data, affecting its applicability in clinical research contexts. Therefore, while LLMs represent a promising innovation to address the limitations of unstructured data, implementing more structured clinical recording practices could provide a more sustainable and reliable solution for generating real-world clinical evidence. This duality emphasizes the need for a balanced approach that integrates advanced AI technology with robust clinical data management practices.

Future research should concentrate on refining prompt design and expanding the applications of LLMs across various medical fields. Additionally, exploring the performance of new open-source LLMs that can be run locally is essential, as this approach helps to avoid data protection and privacy issues associated with transmitting clinical data outside of the local infrastructure.

Conclusions

This study has shown that, with carefully designed prompts, the OpenAI LLMs examined demonstrate competence comparable to, and in some cases superior to, that of medical specialists in interpreting and extracting relevant information from clinical reports, even when dealing with complex and ambiguously written texts. Considering their superior efficiency in terms of time and costs, along with their seamless integration with databases and other applications, these models emerge as a preferable option for data mining and structuring information in large collections of clinical reports. This highlights the potential of LLMs to enhance RWD usage by efficiently extracting structured information from extensive volumes of clinical texts, which is crucial for generating high-quality real-world evidence. Nonetheless, continuous evaluation of these models is essential to enhance their accuracy and applicability, while also emphasizing the importance of advancing toward more structured clinical records.

Abstract

Background: Mental health chatbots have emerged as a promising tool for providing accessible and convenient support to individuals in need. Building on our previous research on digital interventions for loneliness and depression among Korean college students, this study addresses the limitations identified and explores more advanced artificial intelligence–driven solutions.

Objective: This study aimed to develop and evaluate the performance of HoMemeTown Dr. CareSam, an advanced cross-lingual chatbot using ChatGPT 4.0 (OpenAI) to provide seamless support in both English and Korean contexts. The chatbot was designed to address the need for more personalized and culturally sensitive mental health support identified in our previous work while providing an accessible and user-friendly interface for Korean young adults.

Methods: We conducted a mixed methods pilot study with 20 Korean young adults aged 18 to 27 (mean 23.3, SD 1.96) years. The HoMemeTown Dr CareSam chatbot was developed using the GPT application programming interface, incorporating features such as a gratitude journal and risk detection. User satisfaction and chatbot performance were evaluated using quantitative surveys and qualitative feedback, with triangulation used to ensure the validity and robustness of findings through cross-verification of data sources. Comparative analyses were conducted with other large language models chatbots and existing digital therapy tools (Woebot [Woebot Health Inc] and Happify [Twill Inc]).

Results: Users generally expressed positive views towards the chatbot, with positivity and support receiving the highest score on a 10-point scale (mean 9.0, SD 1.2), followed by empathy (mean 8.7, SD 1.6) and active listening (mean 8.0, SD 1.8). However, areas for improvement were noted in professionalism (mean 7.0, SD 2.0), complexity of content (mean 7.4, SD 2.0), and personalization (mean 7.4, SD 2.4). The chatbot demonstrated statistically significant performance differences compared with other large language models chatbots (F=3.27; P=.047), with more pronounced differences compared with Woebot and Happify (F=12.94; P<.001). Qualitative feedback highlighted the chatbot's strengths in providing empathetic responses and a user-friendly interface, while areas for improvement included response speed and the naturalness of Korean language responses.

Conclusions: The HoMemeTown Dr CareSam chatbot shows potential as a cross-lingual mental health support tool, achieving high user satisfaction and demonstrating comparative advantages over existing digital interventions. However, the study's limited sample size and short-term nature necessitate further research. Future studies should include larger-scale clinical trials, enhanced risk detection features, and integration with existing health care systems to fully realize its potential in supporting mental well-being across different linguistic and cultural contexts.

Introduction

The COVID-19 pandemic has exacerbated the already concerning rates of depression and anxiety among college students worldwide [1,2]. In Korea, the situation is particularly alarming. Recent statistics highlight the severity of mental health issues among college students in this country. According to the "2021 COVID-19 National Mental Health Survey," individuals in their 20s showed the highest average depression score Patient Health Questionnaire-9 (PHQ-9) of 6.7 and the highest proportion of high-risk depression groups at 30% among all age groups surveyed. This represents a significant increase from 2018 when the average depression score was 2.3. The proportion of the high-risk depression group (PHQ-9 score ≥10) increased to 22.8% in 2021, approximately 6 times higher than in 2018.

Our previous study [3] on digital interventions for loneliness and depression among Korean college students highlighted the need for more personalized and culturally sensitive approaches, which this research aims to address. Among the initial 63 applicants in that study, the average PHQ-9 score was 9.23, with 25 (39.7%, 25/63) participants classified as high-risk for depression (PHQ-9 score ≥10). At the baseline of our study with 53 participants, 23 (43.4%, 23/53) were categorized as high-risk for depression. These findings underscore the urgent need for effective interventions to improve mental health among college students in Korea.

Despite the increasing severity of mental health issues among college students, the infrastructure and support systems within universities to effectively address these problems remain inadequate. In Korea, the annual mental health budget for college students is limited, with most of the resources focused on counseling services and little emphasis on preventive approaches (Counseling Council for University Students, Furthermore, due to the lack of professional counseling personnel and resources, access to services is limited, and many students are unable to receive timely and appropriate help [4,5].

Social stigma and prejudice against mental health issues also act as significant barriers for college students seeking help. Many students, despite experiencing psychological difficulties, tend to avoid help-seeking behaviors due to negative perceptions about psychiatric treatment or counseling [6]. This can exacerbate symptoms and prolong problems. In particular, those with low mental health literacy are less likely to recognize their condition or understand the need for professional intervention. In fact, the mental health literacy score of college students who participated in our previous study [3] averaged only 2.57 out of 5 points, highlighting the urgent need for educational intervention in this area.

In this context, digital technology-based mental health management solutions are gaining attention as a new alternative. Digital intervention services that overcome spatial and temporal constraints and ensure anonymity can contribute to improving accessibility and participation. Considering the high digital literacy of college students, these methods can be more familiar and acceptable to them [7]. Recent advancements in artificial intelligence (AI) and natural language processing (NLP) have paved the way for the development of sophisticated chatbots that can engage in human-like conversations and provide personalized support [2]. Large language models (LLMs), such as ChatGPT, have revolutionized the field of conversational AI. These models are trained on vast amounts of text data, enabling them to generate human-like responses and understand context. In mental health support, LLMs can be fine-tuned to provide empathetic responses, recognize emotional cues, and offer personalized support, making them potentially powerful tools for accessible mental health interventions.

Building upon the findings of our previous study [3], which explored the effectiveness of digital interventions for loneliness and depression among college students, this research aims to address the limitations identified in earlier digital interventions and develop a more effective and user-friendly mental health support tool. Specifically, this study focuses on the development and evaluation of an LLM-based chatbot prototype, named HoMemeTown, designed to provide personalized mental health support. The HoMemeTown chatbot, powered by ChatGPT 4.0, offers several unique features, that are (1) cross-lingual capability in English and Korean, ensuring cultural sensitivity, (2) a built-in gratitude journaling feature to promote positive thinking, (3) emotion recognition and empathetic response generation, and (4) risk detection algorithms to identify potential mental health crises.

These features aim to provide a comprehensive, user-friendly mental health support tool for young adults.

This pilot study was conducted as part of a larger research project titled "Development of a Youth Mental Health Platform Using Natural Language Processing." While the overarching project received initial institutional review board approval, we acknowledge that this specific chatbot experiment was added later due to rapid developments in AI technology. Despite this limitation, we maintained rigorous ethical standards throughout our research, including informed consent, data privacy measures, and risk mitigation strategies.

The primary objective of this study is to conduct an initial usability test of the chatbot prototype, providing valuable insights for future, more comprehensive clinical studies. While our sample size is limited, we have used a mixed methods approach, combining quantitative usability metrics with in-depth qualitative feedback. This approach allows us to gain rich insights into user experiences and chatbot performance, even with a smaller participant pool. In addition, we have conducted comparative analyses with existing digital mental health tools to contextualize our findings within the broader landscape of mental health technologies.

As we navigate the rapidly evolving landscape of AI and its potential to revolutionize mental health support, it is crucial to explore innovative solutions that can bridge the gap between technology and human empathy [8]. This pilot study contributes to the growing body of knowledge surrounding the use of AI in mental health and sheds light on the potential of LLM-based chatbots like HoMemeTown to make a positive impact on people's lives, while also identifying areas for future research and development.

XSL•FO
RenderX

Methods

Study Design and Participants

This pilot study used a mixed methods approach to evaluate the HoMemeTown chatbot's usability and effectiveness in providing mental health support. In total, 20 participants (12 female and 8 male) aged 18-27 (mean 23.3, SD 1.96) years were recruited through university email lists and social media advertisements. The sample size was determined to be appropriate for this pilot study, particularly given that 70% (14/20) of participants had previous experience with mental health chatbots from our previous research [3], providing valuable comparative insights. This continuity in participation enhanced our ability to gather meaningful longitudinal observations about user engagement with mental health technologies.

Participant eligibility criteria were established to ensure appropriate sampling while maintaining ethical considerations. Eligible participants included university students aged 18-27 years with Korean language proficiency and access to digital devices. We excluded individuals with severe mental health conditions requiring immediate professional intervention, as determined through initial screening questionnaires. This exclusion criterion was implemented to ensure participant safety and appropriate levels of support, following established ethical guidelines in digital mental health research [9].

Prototype Development Using the ChatGPT Application Programming Interface

The HoMemeTown chatbot is an innovative web-dependent service designed to support users in cultivating gratitude practice and providing emotional support through engaging, personalized interactions [10]. By leveraging cutting-edge NLP and emotion detection technologies, the HoMemeTown chatbot creates a unique and rewarding user experience that encourages regular engagement and promotes mental well-being [11].

The development process involved several key steps, including server setup, domain acquisition, Secure Sockets Layer certification, screen planning, development method selection, application programming interface (API) integration, front-end and back-end development, database design, performance tuning, and additional feature implementation [12].

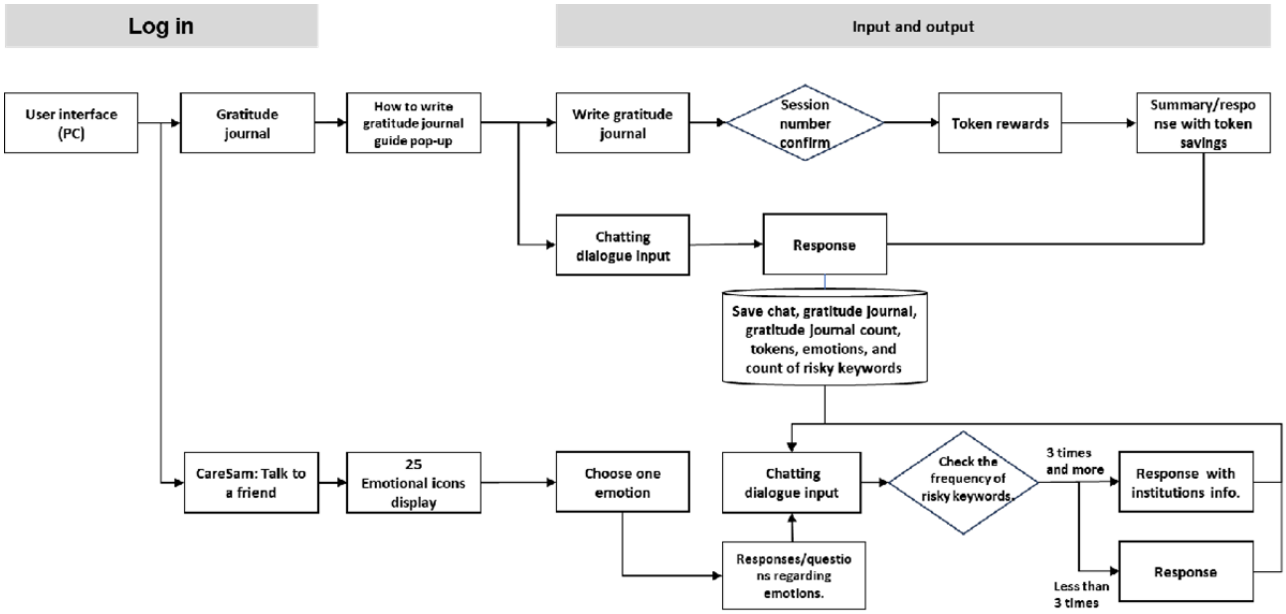
The chatbot relies on the GPT API, a general-purpose language model provided by OpenAI, instead of a domain-specific model trained for mental health counseling. The GPT API offers a range of models, such as Davinci, GPT-3.5, and GPT-4, which can be selected based on desired performance and cost considerations. The chatbot relies on the GPT API, a general-purpose language model provided by OpenAI, instead of a domain-specific model trained for mental health counseling. The GPT API offers a range of models, such as Davinci, GPT-3.5, and GPT-4, which can be selected based on desired performance and cost considerations.

Rate limiting and resource management are (1) maximum 4,000,000 tokens per minute processing capacity, (2) up to 5000 requests per minute, (3) implementation of a request queuing system to prevent rate limit exceedance, and (4) monthly budget monitoring and automated alerts for cost control.

These technical constraints were carefully managed to ensure consistent service delivery while maintaining cost-effectiveness. Regular monitoring of API performance and reliability metrics helped optimize the system's operation throughout the study period.

The desired functionalities of the chatbot, such as its role as a counselor and its ability to detect risks, are implemented through the use of prompts [8]. However, due to the nature of the GPT model, there is no guarantee that the chatbot will always behave exactly as intended, as its responses may vary slightly even with the same prompt [7].

Figure 1 illustrates the service flow architecture of the HoMemeTown chatbot. The architecture depicts the user's journey, starting from the login process through the user interface on their PC. After logging in, users can access the gratitude journal section, where they can find a guide on "How to write gratitude journal" and proceed to write their own entries [13]. The system assigns a unique session number to each journaling session and securely saves the user's journal entries along with metadata such as the gratitude journal count, detected tokens or keywords, expressed emotions, and word count [14].



Users are rewarded with token rewards upon completing a journal entry, and the system generates a personalized response acknowledging their entry [4]. They can then continue their gratitude practice by initiating a new chat through the "CareSam: Talk to a friend" option. This feature allows users to select an emotion from a set of 25 emotional icons and provide more context about their feelings. Cowen and Keltner's [15] research on emotional classification inspired the inclusion of these icons. Recognizing these 25 unique emotions can help users cultivate greater self-awareness and sensitivity toward others, leading to increased empathy, connection, and understanding.

The HoMemeTown chatbot aims to encourage and motivate users to cultivate gratitude practice by providing a seamless user flow, personalized responses, and emotional attunement.

The HoMemeTown chatbot is currently accessible as an open web application. This pilot version is available for public testing, allowing anyone to interact with the chatbot and experience its features firsthand. The chatbot's continued operation demonstrates our commitment to transparency and ongoing exploration of digital mental health interventions. This open access approach enhances research reproducibility and provides opportunities for continuous feedback and improvement.

Figure 1. Service Flow Architecture of the HoMemeTown chatbot.

Technical Implementation and Server Architecture

The HoMemeTown chatbot operates on a cloud infrastructure that prioritizes privacy through a "privacy by design" approach. The key technical feature is that no personal data or chat history is stored, making the system completely stateless between sessions (Textbox 1).

This minimalist architecture was specifically chosen to eliminate privacy concerns by avoiding any form of user data collection or storage. The system operates on a request-response basis, where each interaction is treated as a new session without any historical context or user identification. This approach, while limiting some personalization features, ensures maximum privacy protection for users engaging with mental health support services [16].

Textbox 1. Server architecture.

Frontend development

- React.js framework for responsive user interface
- Material-UI component library for consistent design
- WebSocket implementation for real-time chat functionality
- Client-side-only session management with no persistent storage

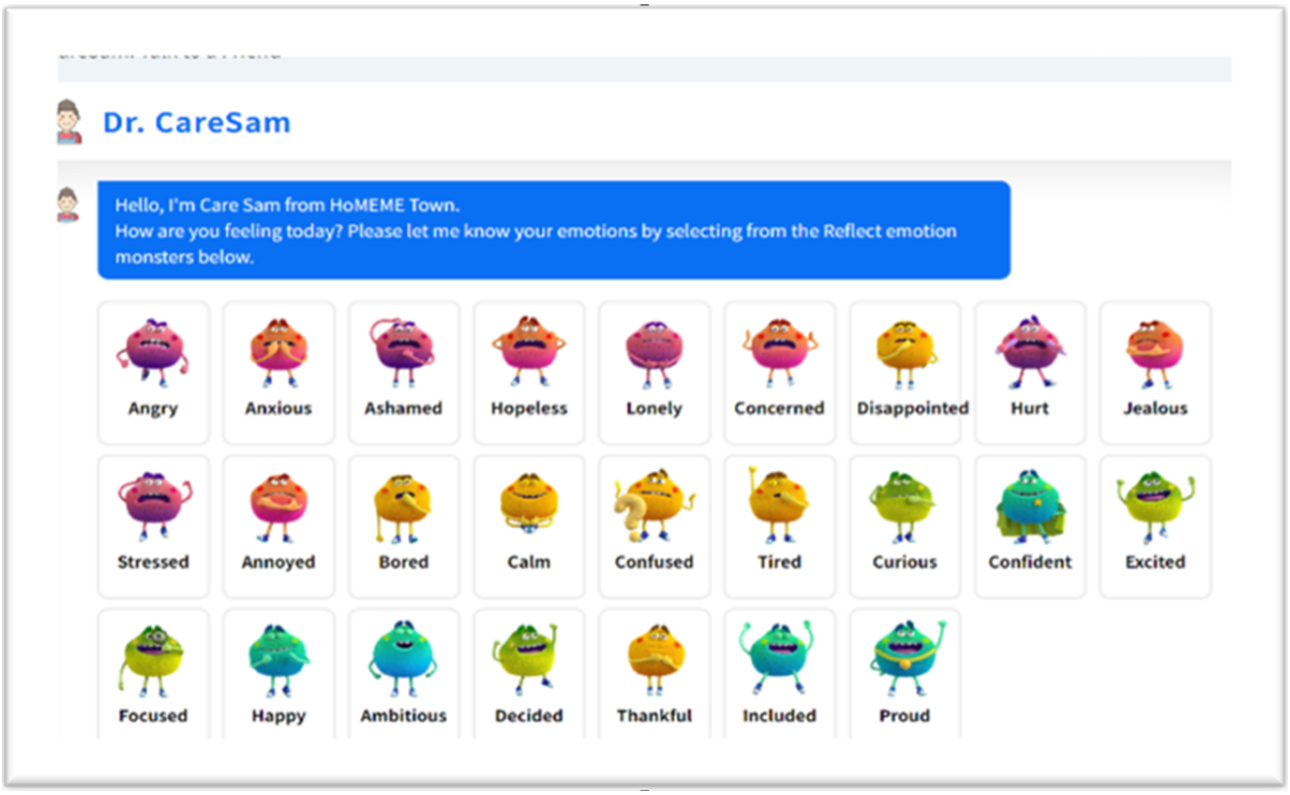
Backend infrastructure

- Node.js runtime environment with Express.js framework
- Stateless architecture with no database implementation
- Direct application programming interface (API) integration with OpenAI's GPT-4
- Nginx reverse proxy for load balancing

OpenAI API integration

- Implementation of GPT-4 API with custom prompt engineering
- No retention of conversation history
- Each interaction is processed as a new, independent session
- Response token limiting for cost optimization
- Regular monitoring of API performance and reliability

User-Centered Design and Emotion Monster Selection



The chatbot targets young adults, particularly university students aged 18-27 years. It uses a set of 25 emoticons based on emotion recognition research [15]. These emoticons allow users to express a wide range of emotions, similar to a broader palette of colors enhancing artistic appreciation. Recognizing this wider range of emotions can lead to greater self-awareness and sensitivity toward others, ultimately fostering empathy, connection, and understanding. When a user selects an emotion

XSL•FO
RenderX

monster, a message appears on the chat screen stating their current mood. However, this message is not directly sent to the API. Instead, it is arbitrarily generated to include the selected emotion keyword and appear natural in the chat context. The actual message sent to the API is a combination of prompts, such as: "My current emotion is" + emotionText + "Acknowledge my feelings and greet me with a message of 50 characters or less." The GPT engine receives this prompt-based message and generates a response reacting to the user's selected emotion.

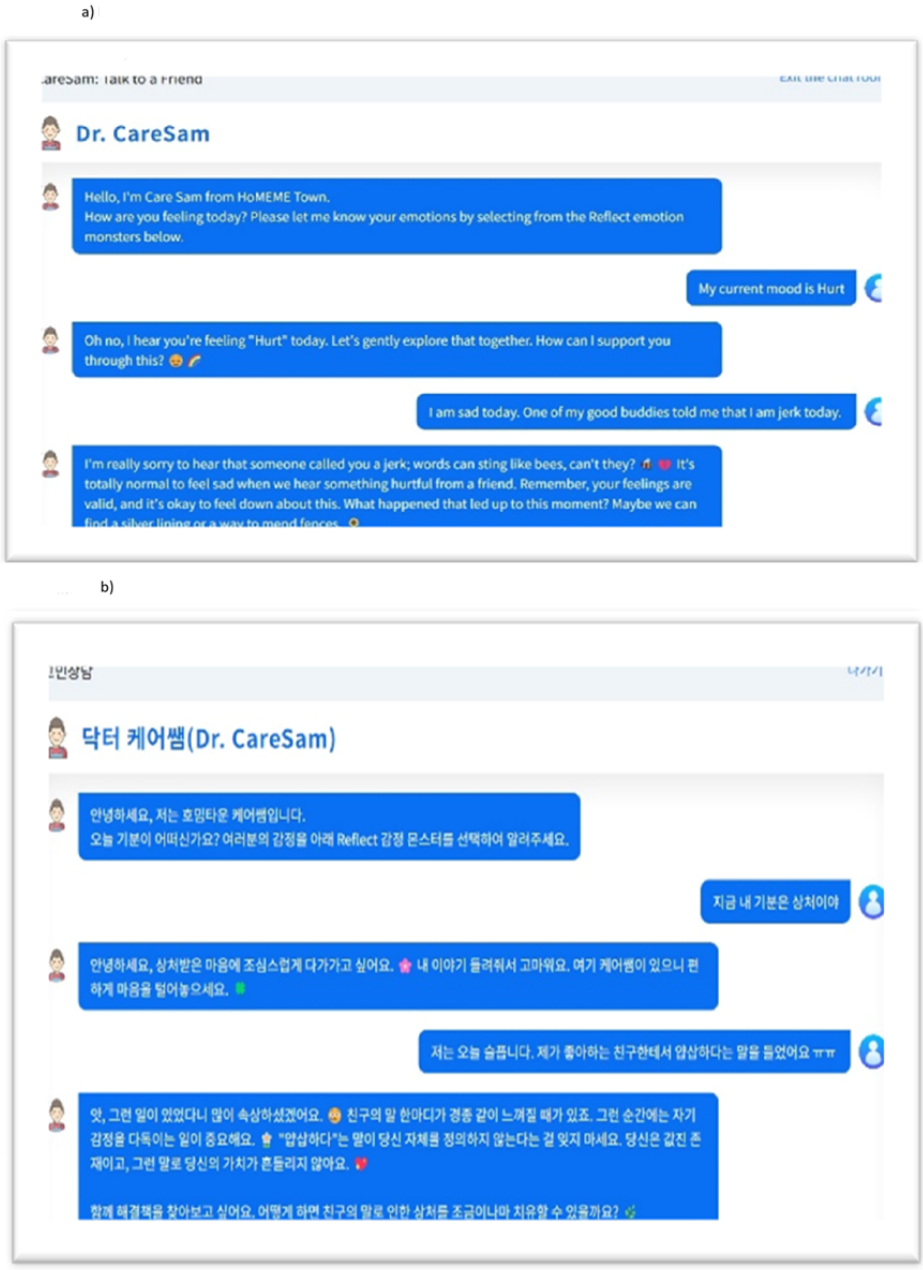
Figure 2 displays the 25 emotional icons used in the HoMemeTown chatbot. Inspired by Microsoft's emotion monsters, these icons represent a wide range of human emotions, allowing users to select one that reflects their current mood. This selection facilitates a more personalized and emotionally attuned response from the chatbot.

Figure 2. Emotional icons are used in the HoMemeTown chatbot.

Cross-Lingual Dialogue Development

The HoMemeTown chatbot was developed to support both English and Korean languages to cater to a wider audience. While our primary participants were Korean university students with intermediate to upper-intermediate English proficiency (based on self-reported language skills and academic records), they were able to effectively evaluate both language versions. The English version received higher ratings specifically in terms of written expression quality, though overall satisfaction levels were comparable between the 2 versions. This may be attributed to the more straightforward nature of emotional expression in English compared with the complex honorific system in Korean, as noted in our language-specific challenges.

In addition to our main study, we conducted informal preliminary feedback sessions with a native English speaker (not included in the formal participant count of 20). This native speaker reported high satisfaction with the natural flow and cultural appropriateness of the English version. While this supplementary feedback was exploratory in nature and limited in scope, it provided valuable initial insights into the cross-cultural applicability of our system.



The localization process involved adapting the chatbot's dialogue to ensure natural conversation flow, accurate language translation, and cultural sensitivity [17]. The HoMemeTown chatbot was developed to support both English and Korean languages to cater to a wider audience. The localization process involved adapting the chatbot's dialogue to ensure natural conversation flow, accurate language translation, and cultural sensitivity [17].

Figure 3 illustrates the dialogue flow localization process for both English and Korean versions of the HoMemeTown chatbot. This visual representation demonstrates how the chatbot's responses are adapted to maintain natural conversation flow and cultural appropriateness in each language.

The localization process is dialogue localization, language-specific challenges, and emoji usage.

XSL•FO
RenderX

Figure 3. Dialogue flow localization. A: English version; B: Korean version.

Dialogue Localization

The chatbot's dialogue was adapted for both English and Korean languages, taking into account language structure, emoji usage, and cultural expressions. The localization process aimed to maintain the chatbot's empathetic and supportive tone while ensuring coherence and readability in each language. During the prompt tuning process, efforts were made to make the chatbot's responses more flexible and engaging, particularly in the Korean version. For example, when a user expresses feeling down and asks for something fun to do, the Korean chatbot is tuned to provide humorous and entertaining responses, similar to the English version, instead of giving a rigid, therapist-like response.

Language-Specific Challenges

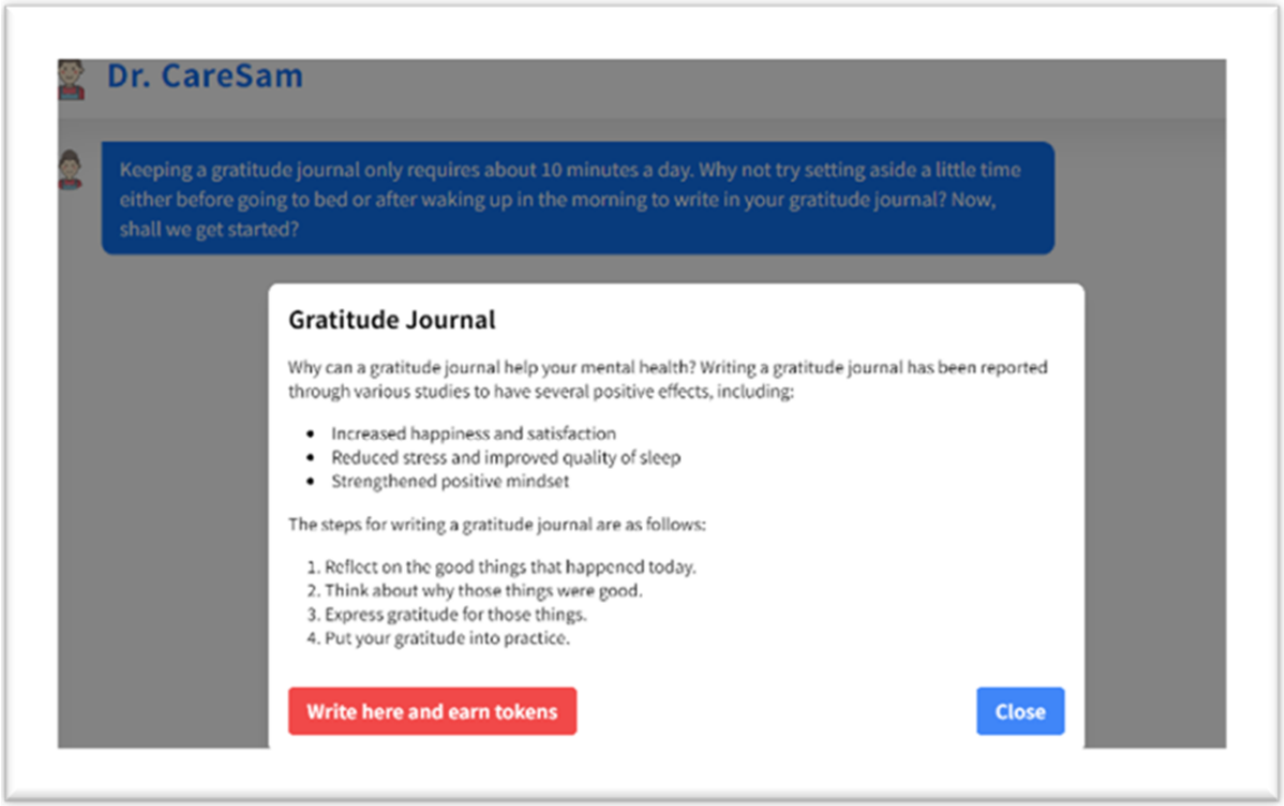
The Korean localization posed unique challenges due to its agglutinative nature and honorific system. In the Korean version of the HoMemeTown chatbot, Microsoft's emotion adjectives were translated into Korean abstract nouns, such as "상처" (hurt), "외로움'"(lonely), "소속감" (inclusive), "실망" (disappointed), and "지루함" (bored). To maintain a consistent rule, these abstract nouns were combined with the verb ending "iya" (이야). However, this approach led to some awkward expressions, such as "상처이야" (hurt) and "자랑이야" (proud), while others, like "실망이야" (disappointed), "외로움이야" (lonely), and "지루함이야" (bored), sounded more natural. This inconsistency in the naturalness of the expressions highlights the complexity of the Korean language and the challenges in developing a chatbot that can generate linguistically accurate and culturally appropriate responses. Although collaborating with native Korean speakers and

XSL•FO
RenderX

linguists helped ensure grammatical accuracy and appropriate honorific usage, further improvements are necessary to fully address the unique challenges posed by the Korean language, such as refining the translations and developing more sophisticated language-specific tuning techniques [17].

Emoji Usage

Emojis were strategically incorporated into both English and Korean dialogues to convey emotions and soften the tone of the conversation. The Korean dialogue used emojis more frequently to align with cultural communication preferences.



Gratitude Journal

The gratitude journal feature was included in the prototype version based on positive feedback from our previous study [3]. In the previous year's experiment, many students mentioned it as one of the most satisfying and enjoyable aspects of the app. Unlike the previous year's app, where explanations of the effects and simple procedures for writing a gratitude journal were often omitted in Woebot and Happify, the user interface of the HoMemeTown chatbot's gratitude journal includes a description of its effects and the procedure for using it.

The effects and procedures were based on established research [18], and the benefits of gratitude journaling have been demonstrated in numerous studies [13,14]. Users accumulate tokens for completed gratitude journal entries, viewable in their interface. To facilitate admin tracking of multiple user accounts, an admin page is implemented, allowing administrators to view gratitude journal entries, token balances, and chat frequencies for all user accounts.

Figure 4 illustrates the gratitude journal interface in the HoMemeTown chatbot. The interface includes a description of the benefits of gratitude journaling and a step-by-step guide on how to write a gratitude journal entry. This feature encourages users to reflect on positive experiences, express gratitude, and cultivate a more optimistic mindset. Upon completing a journal entry, users are rewarded with tokens, which are displayed in the top-right corner of the chat interface.

Figure 4. Gratitude journal interface in the HoMemeTown chatbot.

Risk Detection and Response System

The risk detection system in HoMemeTown was developed based on established clinical guidelines [19] and validated screening tools [20], implementing a sophisticated approach to identifying and responding to potential mental health concerns. The system continuously monitors user interactions for primary risk indicators, including expressions of suicidal ideation, severe depression symptoms, and anxiety crisis signals, while also tracking secondary indicators such as sleep disturbance patterns and social withdrawal signs.

When potential risks are detected, the system implements a graduated response protocol that has been carefully designed to provide appropriate levels of support while avoiding unnecessary escalation. For mild risk situations, the system offers empathetic acknowledgment and self-help resources, drawing from evidence-based interventions [21]. In cases of moderate risk, the response includes more direct expressions of concern and specific mental health resources, while severe risk triggers an immediate crisis response protocol with direct connections to professional support services.

XSL•FO
RenderX

To address the challenge of potential false positives in risk detection, we implemented a sophisticated validation system that examines multiple contextual factors before triggering interventions. This system uses NLP techniques to analyze the broader context of user communications, helping to distinguish between casual expressions and genuine indicators of distress. Regular professional review of high-risk cases ensures the ongoing refinement of detection algorithms and response protocols, maintaining a balance between sensitivity and specificity in risk assessment.

The risk detection and response system undergoes continuous evaluation and improvement based on user feedback and system performance metrics. Professional mental health experts regularly review the system's performance, leading to protocol updates that reflect emerging best practices in digital mental health support. This iterative improvement process has been shown to enhance the accuracy and effectiveness of automated mental health support systems [22].

In addition, to mitigate variability and potential errors in LLM responses, we introduced a validation process including semantic consistency checks, medical reference verification, and automatic escalation to human review when necessary, ensuring responses remain clinically appropriate and user safety is maintained.

Our implementation of these technical and clinical safeguards reflects a balanced approach to leveraging AI capabilities while maintaining high standards of user safety and support quality. The system's architecture and protocols were designed to be scalable and adaptable, allowing for continuous improvement based on ongoing research in digital mental health interventions. The HoMemeTown chatbot incorporates a risk detection function to identify potential mental health concerns through user interactions. This feature is based on the *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders* [Fifth Edition]) criteria [19] and a Korean corpus of psychopathological symptoms [20], allowing for culturally sensitive risk assessment.

The system monitors key symptoms such as depressed mood, changes in appetite or weight, sleep disturbances, fatigue, feelings of worthlessness, cognitive difficulties, and thoughts of death or suicide. When 3 or more symptoms are detected, the chatbot activates a response protocol to encourage professional help-seeking and provide relevant resources. As shown in Table 1, the response strategies are carefully adapted for cultural appropriateness in both English and Korean versions, with particular attention to different cultural norms in discussing mental health concerns.

In Table 2, it shows the differences that reflect the cultural variations in addressing mental health issues, highlighting the importance of culturally sensitive AI development in mental health applications. The use of emojis, while more prevalent in the Korean version, serves to soften the tone and enhance emotional expression in both languages, aligning with digital communication norms among young adults.

Table 1. Comparison of English and Korean chatbot versions.

Characteristic	English version	Korean version
Conversation style	Indirect, supportive	Direct, information-focused
Emotional approach	In-depth emotion exploration	Acknowledge emotions, quick transition
Introduction of professional help	Gradual	Immediate
Risk assessment method	Subtle progression	Explicitly stated
Cultural nuance	Emphasis on individual feelings	Focus on practical solutions

Table 2. Example risk detection responses with cultural adaptations.

Risk level	English response	Korean response
Mild	"I notice you're having a tough day Would you like to talk about what's bothering you? "	"요즘 마음이 무거워 보이네요 함께 이야기 나누면 도움이 될 수 있어요 "
Moderate	"It sounds like you're going through a difficult time Have you considered talking to someone who can help? I can suggest some resources if you'd like "	"힘들어하시는 모습이 느껴져요 전문가와 상담해보는 건 어떠실까요? 제가 도움이 될 만한 정보를 알려드릴 수 있어요 "
Severe	"I'm very concerned about what you're sharing There are people available 24/7 who want to support you. Would you like the contact information for immediate help? "	"많이 걱정되는 이야기네요 24시간 언제든 도움을 받으실 수 있는 곳이 있습니다. 지금 바로 연락하실 수 있는 곳을 알려드릴까요? "

Ethical Considerations

This study was designed as an initial usability test of the HoMemeTown chatbot prototype, focusing on user experience and potential effectiveness. While it does not constitute a full-scale clinical intervention, we adhered to strict ethical guidelines for research involving human participants.

The study was conducted as part of a larger research project titled "Development of a Youth Mental Health Platform Using

XSL•FO
RenderX

Natural Language Processing." While the overarching project received initial institutional review board approval from Sungkyunkwan University (2023-02-043-004; February 27, 2023, to June 26, 2025), we acknowledge that this specific chatbot experiment was added later due to rapid developments in AI technology. Despite this limitation, we maintained rigorous ethical standards throughout our research, including informed consent, data privacy measures, and risk mitigation strategies.

Before the usability test, all participants were provided with a comprehensive informed consent form. This form detailed the nature and purpose of the study, the procedures involved, potential risks and benefits, and the measures taken to ensure confidentiality and data protection. Participants were required to sign this form to confirm their understanding and voluntary agreement to participate.

Approximately 70% of the participants in this study had previously participated in our earlier experiment [3]. This continuity helped streamline the consent process as these participants were already familiar with the ethical standards and procedures in place for digital mental health research.

Data Security and Privacy

To address privacy concerns and protect sensitive information, the public version of the HoMemeTown chatbot operates without user registration or login requirements, collecting no personal information beyond chat interactions. This approach enhances user privacy but limits personalization features. For the usability test in this study, we implemented stringent data security measures, which are (1) all collected data (chat logs, gratitude journal entries, token rewards) were anonymized, (2) data were stored on secure, encrypted servers with restricted access, and (3) no personally identifiable information was linked to chatbot interactions or survey responses.

We incorporated a risk detection function to identify potential mental health crises and provide appropriate resources when necessary. These measures align with best practices in digital health research, ensuring ethical compliance and participant protection while advancing AI-assisted mental health support. Future developments will explore balancing personalization benefits with privacy protection, possibly through advanced encryption methods or privacy-preserving technologies.

Results

Overview

We conducted a mixed methods study to evaluate the performance and user satisfaction of our HoMemeTown Dr CareSam chatbot. The study design integrated quantitative and qualitative approaches to provide comprehensive insights: 8 quantitative questions (1 overall satisfaction item and 7 components of chatbot performance) and 4 qualitative questions (2 positive aspects and 2 areas for improvement). This mixed methods approach allowed for triangulation of data through cross-verification between quantitative metrics and qualitative user feedback, enhancing the validity and depth of our findings. The results provide multifaceted insights into the chatbot's strengths, areas for improvement, and comparative performance with other LLM and digital therapy chatbots.

Participants

The study included 20 participants aged 18 to 27 (mean 23.3, SD 1.96) years with 60% (12/20) female and 40% (8/20) male. Participants were recruited through university email lists and social media advertisements. All participants provided informed consent.

Quantitative Findings

The usability and satisfaction evaluation of the Dr CareSam counseling chatbot was conducted using a comprehensive survey consisting of 1 overall satisfaction question and 7 quantitative items assessing key components of effective psychological counseling, which consists of empathy, accuracy and usefulness, complex thinking and emotions, active listening and appropriate questions, positivity and support, professionalism, and personalization. Users generally expressed positive views, with positivity and support receiving the highest score on a 10-point scale (mean 9.0, SD 1.2), followed by empathy (mean 8.7, SD 1.6) and active listening (mean 8.0, SD 1.8). These findings align with previous research on the importance of empathy and support in mental health chatbot interactions. However, areas for improvement were noted in professionalism (mean 7.0, SD 2.0), complexity of content (mean 7.4, SD 2.0), and personalization (mean 7.4, SD 2.4), indicating potential avenues for future development to enhance user engagement and satisfaction.

Figure 5 shows the distribution of scores for various usability questions. The boxes represent the IQR, and the whiskers extend to the minimum and maximum values within 1.5 times the IQR. Black dots represent the mean values for each category.

To provide a more comprehensive understanding of the evaluation factors and their theoretical foundations, we present the following in Table 3.

This comprehensive evaluation framework enables a nuanced assessment of the chatbot's performance across key dimensions of effective counseling. The results provide valuable insights into the strengths of the Dr CareSam chatbot, particularly in areas of empathy and support. In addition, the findings highlight opportunities for improvement in professionalism, personalization, and complexity of responses, suggesting potential avenues for future development to enhance user engagement and satisfaction.

XSL•FO
RenderX

Figure 5. Box plot of scores for Dr CareSam usability questions.

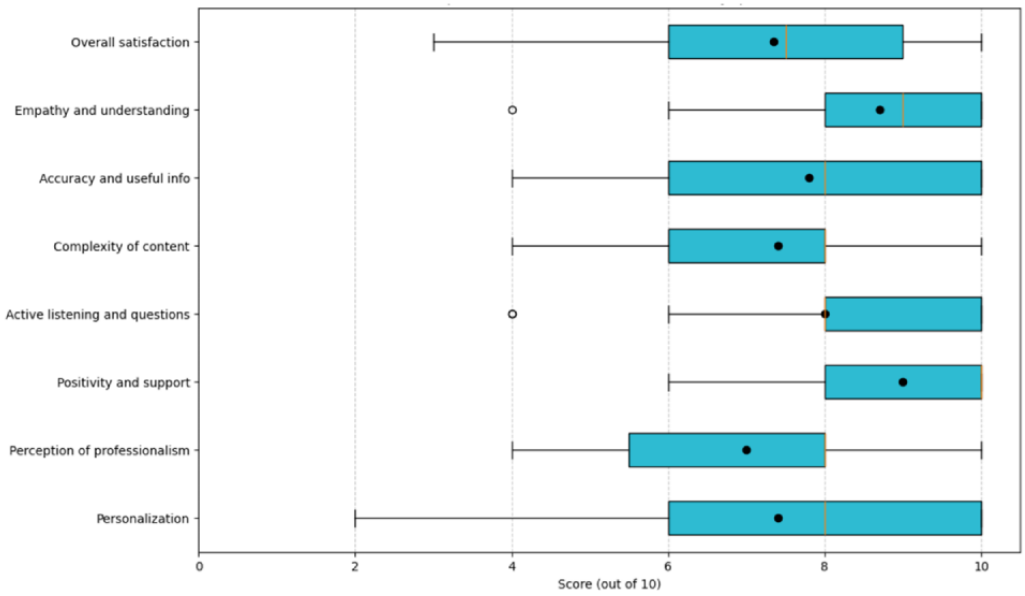


Table 3. Evaluation Factors for Dr CareSam chatbot.

Evaluation factor	Question	Description	Previous studies
Empathy	Did CareSam's responses express empathy and understanding of the user's question?	An empathetic understanding of the client's emotions and experiences is essential in effective counseling conversations.	Rogers [23], Elliott et al [24]
Accuracy and usefulness	Did CareSam's responses provide accurate and useful information regarding the user's question?	Providing accurate and actionable information aids in problem-solving and decision-making for the client.	Hepworth [25], Egan [26]
Complex thinking and emotions	Did CareSam's responses include complex thinking and emotions rather than simple knowledge?	Skilled counselors should address cognitive and emotional experiences interactively, facilitating insights into the client's internal experiences.	Greenberg [27], Gendlin [28]
Active listening and appropriate questions	Did CareSam's responses include not only active listening but also appropriate questions?	Active listening and appropriate questioning techniques promote self-exploration and deeper understanding.	Weger et al [29], Hill [30]
Positivity and support	Did CareSam's responses include positivity and support?	Support and encouragement enhance the client's self-esteem and motivation for change.	Mearns and Thorne [31], Norcross and Lambert [32]
Professionalism	Did CareSam's responses demonstrate professionalism?	Professionalism increases client trust and adherence to treatment, encompassing theoretical knowledge, clinical experience, and ethical awareness.	Sue and Sue [33]; Ratts et al [34]
Personalization	Did CareSam's responses appear to be customized?	Effective counseling should be tailored to the individual characteristics and needs of the client.	Norcross and Wampold, [35], Beutler and Harwood [36]

Qualitative Feedback

User feedback presented in Table 4 was collected through structured interviews and open-ended survey responses, focusing on key themes such as response speed, empathy, and personalization. Responses were categorized based on frequency of mention, providing a clear overview of commonly reported strengths and areas for improvement. User feedback confirms the chatbot's strengths in providing detailed, empathetic responses, a user-friendly interface, and a supportive demeanor. However, areas for improvement include slow response times, Korean text flow issues, and repetitive interactions. Interestingly, both "quick feedback" and "slow response time" were frequently mentioned, suggesting that while feedback is relevant and timely within the context of a rule-based chatbot, it may not be the fastest possible response.

The qualitative themes align with quantitative satisfaction ratings, illustrating consistent patterns across user experiences. For instance, high ratings for "positivity and support" were reflected in user comments praising Dr CareSam's empathetic responses. Conversely, lower ratings in "personalization" corresponded with feedback indicating a desire for more tailored interactions.

XSL•FO
RenderX

Table 4. Users' experiences of good and bad points for HoMemeTown chatbots.

Mention level and category	Positive points	Negative points
Most mentioned		
Response speed	Quick responses and real-time feedback.	Slow response time, lack of prompt responses.
Friendly and Positive Tone	Encouraging, supportive responses, provides courage and understanding.	Overemphasis on empathy, repetitive responses without practical advice.
Frequently mentioned		
Empathy capability	Expresses understanding and empathy effectively.	Focused too heavily on empathy without specific guidance or solutions.
Korean language processing	Supports English and Korean; human-like, natural conversation flow.	Awkward phrasing in Korean, lack of accuracy and appropriateness in Korean responses.
Moderately mentioned		
Detailed expression	Uses varied emotions and appropriate emoticons.	Repetitive tone, lack of personalization.
Chatbot functionality	Emotional expression, gratitude journaling guidance, diverse responses for different situations.	Limited content, need for features like a reward for engagement, and the option to revisit previous interactions.
Less mentioned		
Design and interface	Clean, user-friendly interface with intuitive design elements.	Issues with long text bubbles, lack of auto line breaks, and need for design improvements.
Content and information	Provides relevant information and problem-solving advice.	Excessive use of emoticons, insufficient professional advice, and need for mobile accessibility improvement.
Least mentioned		
Personalization	Positive and personalized responses, convey a warm and positive energy.	Insufficient personalization, lack of integration with medical or counseling services, missing human touch.
Miscellaneous	Easy usability, approachable demeanor.	Inconsistent engagement incentives need for enhanced humanistic features.

Comparative Analysis

Performance variations among LLM chatbots, including Google Bard and the freely accessible version of ChatGPT, as illustrated in Figure 6, were statistically significant (F=3.27; P=.048 While the evaluation primarily focused on "Overall Satisfaction" [3], it is important to note that user experience differences may reflect limitations inherent to the free versions available for these comparisons, including ChatGPT 3.0 and Google Bard's publicly accessible iteration.

Satisfaction levels with HoMemeTown's Dr CareSam, compared with Woebot [5] and Happify [37], showed more pronounced differences (F=12.94; P<.001), as shown in Figure 7, suggesting unique benefits in mental health support for college students.

In the comparison with Woebot and Happify, the previous evaluation [3] used 5 specific criteria, that are overall satisfaction, ease of use, novelty, effectiveness, and intention to maintain use. However, for this study, "Overall Satisfaction" was selected as the primary comparative metric to simplify and provide a focused assessment of user impressions. Statistical analyses were conducted using ANOVA to determine significant differences, with appropriate post hoc tests applied for multiple comparisons to identify specific group variations.

XSL•FO
RenderX

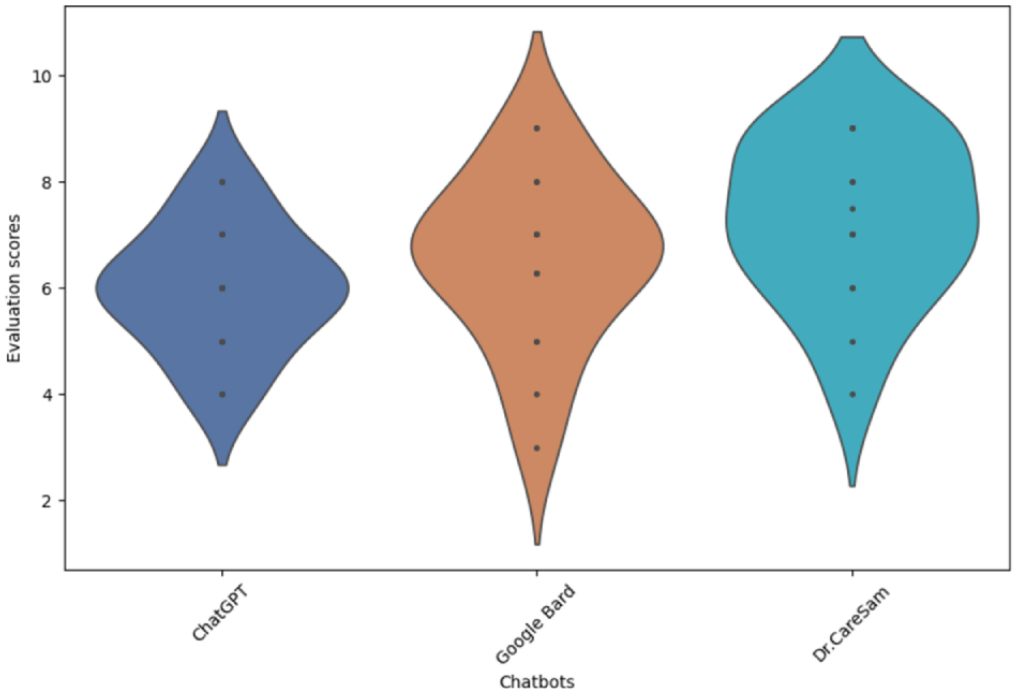

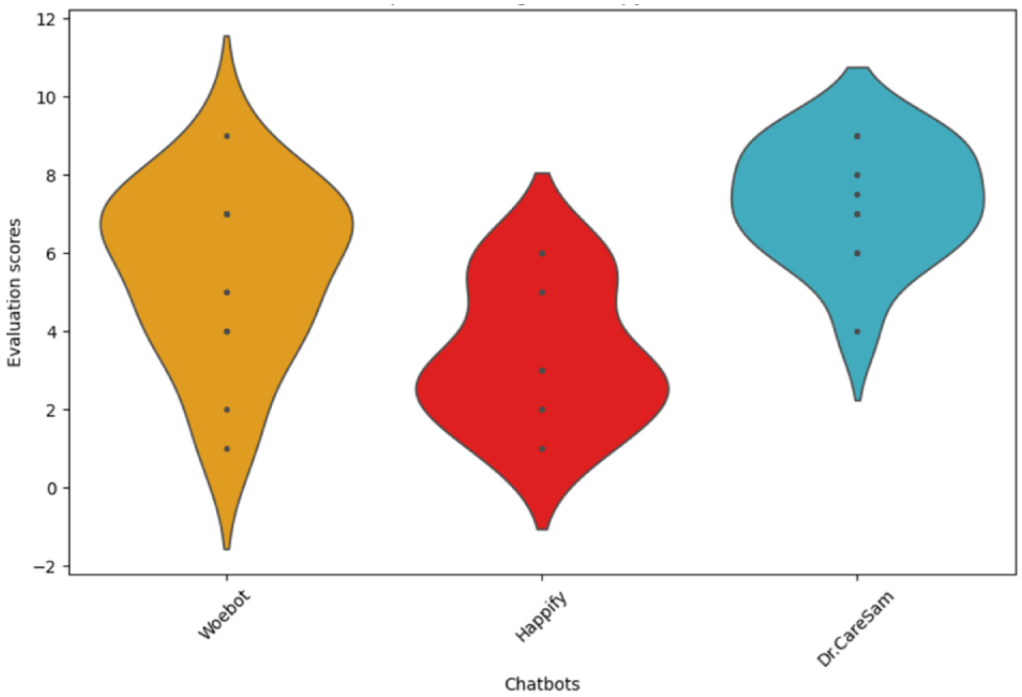

Figure 7. Comparison of digital therapy chatbots.

Discussion

Principal Findings

This study reveals several key insights about the HoMemeTown Dr CareSam chatbot, demonstrating its potential as an innovative tool in digital mental health support. The chatbot's high performance across multiple dimensions of effective counseling, particularly in providing empathetic responses and a user-friendly interface, aligns with current research emphasizing the importance of these factors in digital mental health interventions [3,10,11]. The statistically significant performance differences observed between HoMemeTown Dr. CareSam and other chatbots, both LLM-based (F=3.27; P=.047) and traditional digital therapy tools like Woebot and Happify (F=12.94; P<.001), suggest that our approach offers unique benefits in mental health support for college students. This could be attributed to our comprehensive evaluation framework based on established counseling principles and the integration of a sophisticated risk detection function. The chatbot's risk detection capability, grounded in *DSM-5* criteria and a Korean corpus of

XSL•FO
RenderX

psychopathological symptoms, represents a significant advancement in AI-driven mental health support tools, enhancing its potential as a safe and responsible digital intervention.

However, the study also highlighted important challenges and areas for improvement. While the chatbot's bilingual capability is a strength, issues with unnatural expressions and response speed in the Korean version underscore the complexities of cross-cultural adaptation in AI-driven mental health tools. Furthermore, our decision to prioritize user privacy over extensive personalization features reveals a critical challenge in developing ethical AI-driven mental health interventions. This trade-off between personalization and data protection warrants further exploration in the field. Specifically, areas for improvement were noted in professionalism (mean 7.0, SD 2.0), complexity of content (mean 7.4, SD 2.0), and personalization (mean 7.4, SD 2.4), indicating potential avenues for future development to enhance user engagement and satisfaction. Collectively, these findings suggest that HoMemeTown Dr CareSam represents a promising step forward in AI-assisted mental health support, while also illuminating critical areas for future research and development in this rapidly evolving field.

Addressing LLM Variability and Technological Enhancements

To tackle the inherent challenges posed by LLM variability and potential hallucinations [38] in chatbot responses, we developed a comprehensive response validation pipeline. This pipeline includes semantic consistency checking, medical reference validation to prevent the dissemination of inaccurate information, and automatic escalation to human review when responses deviate from predetermined safety parameters. These safeguards are integral to ensuring the chatbot's interactions remain clinically appropriate, fostering user trust and alignment with established mental health support practices.

While these measures provide a critical baseline for reliability, further advancements in the underlying LLM technologies are essential for achieving higher accuracy and contextual nuance in responses. For example, the integration of LangChain [39] technology allows for the systematic management and connection of multiple language models, offering improved contextual understanding and the ability to tailor responses to specific counseling scenarios. This modular approach enhances the flexibility and precision of chatbot interactions, particularly in complex or sensitive exchanges.

In addition, leveraging retrieval-augmented generation [40] techniques further bolsters response precision by drawing upon curated counseling databases and real-world cases. This not only strengthens the relevance of responses but also minimizes the risk of erroneous or hallucinated outputs. Such enhancements highlight the evolving interplay between foundational AI capabilities and domain-specific knowledge, positioning the chatbot as a more robust and dependable digital mental health intervention.

From an ethical standpoint, these advancements underscore the importance of balancing technological innovation with user safety and data integrity. Ensuring consistent oversight, ongoing evaluation, and refinement based on user feedback is vital to maintaining a high standard of care in digital interventions. As LLM technologies continue to evolve, our approach serves as a model for integrating emerging tools into practical applications, demonstrating how AI can be effectively harnessed to provide compassionate and reliable mental health support while continually adapting to user needs and technological developments.

Comparison With Previous Work

Unlike rule-based chatbots, HoMemeTown Dr CareSam, leveraging LLM technology, was able to provide more flexible and personalized interactions. Our findings align with previous research on Woebot's effectiveness in supporting young adults with depression and anxiety symptoms [5] while extending these benefits through our enhanced risk detection capabilities. Similarly, while Happify has shown promise in addressing loneliness during COVID-19 [37], our system demonstrates additional advantages in providing culturally adapted support for Korean users. This addresses several limitations of existing chatbots highlighted in previous studies, such as rigid response patterns and limited contextual understanding [3,5]. Specifically, our chatbot improved upon these limitations by offering more nuanced and context-appropriate responses, as evidenced by higher user satisfaction scores in empathy and active listening. The chatbot's risk detection function, grounded in *DSM-5* criteria and a Korean corpus of psychopathological symptoms, represents an advancement in AI-driven mental health support tools, offering a level of clinical relevance not typically seen in general-purpose chatbots.

Strengths and Limitations

A key strength of this study is the development of a personalized and empathetic mental health support tool using state-of-the-art LLM technology, with a sophisticated risk detection function. The bilingual support in English and Korean is another significant strength, addressing linguistic diversity and potential cross-cultural applications [17].

This study has several important limitations. The small sample size (n=20) limits the generalizability of the results but was chosen to ensure continuity and comparability with previous usability studies for Dr CareSam [3]. While this limited sample size may restrict broader applicability, it allowed for detailed and focused insights, particularly beneficial for pilot studies. Future research will aim to expand the sample size to validate findings and provide a more comprehensive evaluation of the chatbot's effectiveness.

In addition, feedback from a small group of native English speakers, not formally included in the 20-participant sample, revealed potential areas for improving cross-lingual functionality. Though this feedback offered valuable preliminary insights, future studies will involve broader validation with a larger group of native speakers to ensure accurate and culturally appropriate responses.

Another limitation is the potential inconsistency in comparing Dr CareSam, built on the ChatGPT 4.0 API, with user experiences based on the freely available ChatGPT 3.0. Differences in capabilities between these versions may have

XSL•FO
RenderX

influenced user perceptions and performance metrics. Future studies should strive to standardize versions for more direct and valid comparisons.

There are technical limitations associated with relying on the GPT API [7]. While this approach allows for advanced NLP capabilities, it also means that the chatbot's performance is dependent on the underlying model, which may have inherent biases or limitations. Furthermore, the reliance on an external API raises considerations about data privacy and the long-term sustainability of the system.

These limitations highlight the need for large-scale, long-term studies to fully evaluate the chatbot's effectiveness and generalizability. Future research should also explore the development of more specialized models that can be run locally, potentially addressing some of the limitations associated with relying on external APIs.

Clinical Implications

The HoMemeTown Dr CareSam chatbot shows potential as an accessible mental health support tool for young adults, with its risk detection function providing an additional layer of safety. However, it's crucial to clarify that this chatbot cannot replace professional mental health treatment, especially in cases where significant risk is detected. The chatbot's role should be seen as complementary to traditional mental health services, potentially serving as an initial point of contact or a supplementary support tool. It may be particularly useful for providing immediate support during nonclinical hours, for mild to moderate concerns, or for individuals who may be hesitant to seek traditional face-to-face therapy. However, clear guidelines must be established for when and how to transition users from the chatbot to professional human intervention.

Privacy and Personalization Considerations

A key challenge in this study was balancing personalization with user privacy. In our previous study, participants emphasized the importance of personalization features [3]. However, in developing the pilot version of HoMemeTown, we faced a significant dilemma between implementing these desired personalization features and ensuring robust privacy protection. Ultimately, we made the decision to prioritize privacy by eliminating user registration and personal data collection in the current public version. This choice was driven by the sensitive nature of mental health data and the potential risks associated with data breaches or misuse.

As a result, the chatbot relies solely on the capabilities of the LLM to provide a sense of personalization within individual conversations, without retaining user-specific information across sessions. This approach, while enhancing data security, limits our ability to offer some of the personalized features that participants in our previous study had requested. The chatbot attempts to mimic personalization through its conversational abilities, but it cannot retain or learn from past interactions with specific users. This trade-off highlights a crucial challenge in digital mental health interventions, how to balance user expectations for personalized experiences with the ethical imperative of protecting sensitive personal information. It also underscores the need for transparent communication with users about the capabilities and limitations of AI-driven mental health tools.

Future research should explore advanced technologies like federated learning or differential privacy, which could potentially allow for more personalized features without compromising user privacy. In addition, developing clear guidelines for handling mental health data in AI-powered interventions will be essential. Our experience underscores the need for innovative solutions that balance the benefits of personalization with robust data protection in mental health contexts. As the field evolves, finding this balance will be key to developing effective, trustworthy, and ethically sound AI-powered mental health interventions [8,41].

Future Directions

Based on our findings, we propose the key areas for future research in Textbox 2.

These focused directions align closely with our current work while suggesting meaningful advancements in the field of AI-assisted mental health support within the context of medical informatics.

XSL•FO
RenderX

Textbox 2. Key Points of evaluation criteria for large language model (LLM) chatbots.

Long-term effectiveness

- Conduct large-scale, longitudinal studies to evaluate the long-term impact of our cross-lingual chatbot on mental health outcomes.

Cross-cultural adaptations

- Further refine the chatbot's ability to provide culturally appropriate responses, particularly focusing on improving Korean language naturalness. Improving the naturalness of Korean language responses will involve refining language processing algorithms and collaborating with linguists and native speakers to address issues with awkward phrasing and cultural nuance. Incorporating user feedback to continuously adapt and optimize the chatbot's language output is also essential.

Speech-based user interface

- Develop and evaluate a speech-based user interface to increase usability and accessibility, particularly for users who may find voice interactions more natural or easier than text-based communication. This would involve integrating robust voice recognition and response capabilities to align with user preferences and accessibility needs.

Privacy-preserving personalization

- Explore technologies like federated learning to enhance personalization while maintaining robust data protection.

Risk detection enhancement

- Improve the accuracy and effectiveness of the risk detection function, potentially integrating it with existing mental health screening tools.

Integration with health care systems

- Investigate secure ways to integrate chatbot data with electronic health records, while maintaining user privacy.

Conclusions

This study represents a significant advancement from our previous work [3], addressing the limitations identified and exploring the potential of more sophisticated AI technologies in mental health support. By leveraging ChatGPT 4.0 and incorporating features like cross-lingual support and risk detection, we have developed a more comprehensive and adaptable tool for supporting young adults' mental health needs. This pilot study demonstrates the potential of HoMemeTown Dr CareSam, an LLM-based cross-lingual chatbot with advanced risk detection capabilities, in providing mental health support for young adults. While the chatbot showed promising results in user satisfaction, empathetic responses, and risk assessment, challenges in professionalism, cross-lingual adaptations, and the need for technical refinements were also identified. Further long-term, large-scale studies are needed to fully evaluate its effectiveness and potential integration with existing health care systems, as we continue to refine this technology to support mental well-being in our increasingly digital world. From a medical informatics perspective, this study contributes to our understanding of how advanced AI technologies can be applied in mental health care, potentially informing the development of more sophisticated, culturally sensitive digital health tools in the future.

Acknowledgments

This research was conducted with funding from the K-medi global talent development project of the Ministry of Health and Welfare of the Republic of Korea (assignment number HI22C2185).

This research was also supported by the Sung Kyun Kwan University and the BK21 FOUR (Graduate School Innovation) funded by the Ministry of Education (South Korea) and the National Research Foundation of Korea.

The authors acknowledge the use of AI language models in the preparation of this manuscript. Claude AI [42] was used for proofreading, editing (removing redundant expressions), and formatting references. ChatGPT [43] assisted in refining the data statistical analysis code. In addition, AI tools were used to check for duplicates during the thematic analysis process. These AI tools were used to enhance the manuscript's readability and provide technical support, while the research content, analysis, and results remain entirely the work of the authors.

Abstract

Background: Large language models (LLMs) have been proposed as valuable tools in medical education and practice. The Chinese National Nursing Licensing Examination (CNNLE) presents unique challenges for LLMs due to its requirement for both deep domain–specific nursing knowledge and the ability to make complex clinical decisions, which differentiates it from more general medical examinations. However, their potential application in the CNNLE remains unexplored.

Objective: This study aims to evaluates the accuracy of 7 LLMs including GPT-3.5, GPT-4.0, GPT-4o, Copilot, ERNIE Bot-3.5, SPARK, and Qwen-2.5 on the CNNLE, focusing on their ability to handle domain-specific nursing knowledge and clinical decision-making. We also explore whether combining their outputs using machine learning techniques can improve their overall accuracy.

Methods: This retrospective cross-sectional study analyzed all 1200 multiple-choice questions from the CNNLE conducted between 2019 and 2023. Seven LLMs were evaluated on these multiple-choice questions, and 9 machine learning models, including Logistic Regression, Support Vector Machine, Multilayer Perceptron, k-nearest neighbors, Random Forest, LightGBM, AdaBoost, XGBoost, and CatBoost, were used to optimize overall performance through ensemble techniques.

Results: Qwen-2.5 achieved the highest overall accuracy of 88.9%, followed by GPT-4o (80.7%), ERNIE Bot-3.5 (78.1%), GPT-4.0 (70.3%), SPARK (65.0%), and GPT-3.5 (49.5%). Qwen-2.5 demonstrated superior accuracy in the Practical Skills section compared with the Professional Practice section across most years. It also performed well in brief clinical case summaries and questions involving shared clinical scenarios. When the outputs of the 7 LLMs were combined using 9 machine learning models, XGBoost yielded the best performance, increasing accuracy to 90.8%. XGBoost also achieved an area under the curve of 0.961, sensitivity of 0.905, specificity of 0.978, F_1-score of 0.901, positive predictive value of 0.901, and negative predictive value of 0.977.

Conclusions: This study is the first to evaluate the performance of 7 LLMs on the CNNLE and that the integration of models via machine learning significantly boosted accuracy, reaching 90.8%. These findings demonstrate the transformative potential of LLMs in revolutionizing health care education and call for further research to refine their capabilities and expand their impact on examination preparation and professional training.

large language models; LLMs; Chinese National Nursing Licensing Examination; ChatGPT; Qwen-2.5; multiple-choice questions;

Introduction

Nursing licensure examinations are essential for maintaining professional standards, ensuring that health care systems are staffed with qualified professionals, and safeguarding patient safety [1]. These examinations assess nurses' clinical judgment, decision-making, and practical skills, ensuring high-quality care and fostering public trust in the profession [2]. Upholding rigorous standards is critical, as competent health care professionals are crucial for addressing the diverse and complex needs of patients worldwide. The Chinese National Nursing Licensing Examination (CNNLE) plays an important role in maintaining high standards of nursing care in China, ensuring that graduates are well prepared for professional practice [3]. Serving as a benchmark for nursing competence, the CNNLE confirms that nurses possess the necessary skills and knowledge to provide safe and effective care [4]. Beyond its impact on health care quality, the CNNLE also influences educational policies, guiding nursing curricula to meet evolving health care demands. As health care becomes more complex, innovative tools are needed to support the development of skilled professionals capable of providing effective patient care.

The integration of artificial intelligence (AI) in education is transforming learning and assessment, particularly in fields such as nursing [5-7]. ChatGPT, an AI tool that generates content by identifying patterns in its training data, simulates human-like conversations and answers questions across a wide range of topics [8,9]. Its ability to provide correct answers and offer immediate, detailed feedback makes it a valuable resource for students in simulated test environments and question banks [10]. This success in examination settings has sparked interest in using ChatGPT as a self-learning tool, suggesting its potential for enhancing examination preparation and knowledge development [11]. Large language models (LLMs) hold promise for clinical education [12], where these models integrate natural language processing with user-friendly interfaces [13]. In clinics, LLMs are increasingly valuable, particularly in diagnosis [14,15] and clinical licensing examinations [16], where accuracy is crucial. Tools such as ChatGPT are being recognized for their potential to enhance clinical documentation [17], improve diagnostic accuracy [18], and streamline patient care workflows [19]. However, the rapid development of LLMs presents significant challenges in assessing their reliability in the CNNLE.

Passing CNNLE demands not only theoretical knowledge but also clinical decision-making, critical thinking, and practical skills, areas where LLMs often underperform [9]. While tools such as ChatGPT have demonstrated an overall accuracy of 80.75% in nursing education [20], their effectiveness diminishes with complex, context-specific questions requiring nuanced medical knowledge [21-23]. Moreover, concerns regarding patient privacy [24] and biases [25] in LLM outputs raise questions about their suitability for high-stakes assessments such as the CNNLE, which emphasize fairness and accuracy [26,27]. Despite the growing interest in LLMs for medical education, their potential in the CNNLE remains unexplored. Limited understanding exists regarding their ability to handle clinical reasoning, contextual interpretation, and multistep problem-solving in this specific setting. Addressing this gap is crucial to assess their reliability, limitations, and transformative potential in clinical education. Here, this study examines the distribution of question types in the CNNLE from 2019 to 2023 and evaluates the accuracy of 7 LLMs including GPT-3.5, GPT-4.0, GPT-4o, Copilot, ERNIE Bot-3.5, SPARK, and Qwen-2.5—in addressing domain-specific nursing knowledge and clinical decision-making. Furthermore, the study explores whether combining their outputs through machine learning techniques can enhance overall accuracy in this context.

Methods

Study Design

This retrospective cross-sectional study evaluated the performance of 7 LLMs on 1200 multiple-choice questions (MCQs) from the CNNLE administered between 2019 and 2023. The study design was chosen for its suitability in systematically analyzing preexisting datasets and providing the capabilities of LLMs across various question types and levels of complexity. A head-to-head evaluation approach was adopted to compare the LLMs. Each MCQ was independently input into each model under identical conditions, ensuring consistency and fairness in the assessment. This parallel evaluation minimized variability caused by external factors, such as differences in question formats or content, allowing for a direct comparison of performance across all models. By using historical data and using a head-to-head evaluation, this study provides an analysis of LLM performance in nursing licensure examinations, offering their potential applications in nursing education and assessment.

Data Collection

This study analyzed all 1200 MCQs from the CNNLE administered between 2019 and 2023. Each year, 240 MCQs were included, encompassing the 4 question types (A1, A2, A3, and A4) although their proportions varied annually. This comprehensive approach ensured that the evaluation covered diverse question formats and varying levels of complexity, reflecting the full scope of the CNNLE. To ensure the integrity of the evaluation process, 2 researchers (SZ and WH) independently entered each question into 7 LLMs on separate computers. Each question was input into a new chat session to prevent any influence from prior interactions. The LLMs generated answers and explanations solely based on the input questions without pretraining instructions or additional prompts.

If inconsistencies were detected in the responses, a third computer was used to reenter the question in a fresh chat session after clearing the LLMs' memory. In such cases, the models were instructed to provide more detailed explanations. The researchers then collectively reviewed the answers and explanations to determine the most accurate and contextually appropriate response. When LLMs exhibited confusion, failed

XSL•FO
RenderX

to provide explanations, produced multiple answers including the correct one, or encountered specialized queries (eg, questions on local policies), additional instructions were provided. These instructions included prompts such as, "This is a single-choice question. Please select the most suitable or probable answer from options 1 to 5," "Please choose the incorrect option," "Tell me the reason why," "In Chinese local policy," "In Chinese local law," and "In Chinese society." All data generated or analyzed during this study are provided in Multimedia Appendix 1, and the iPython Jupyter notebook code is available in Multimedia Appendix 2.

Ethical Considerations

The evaluations were conducted between May 15, 2024, and July 17, 2024. All responses were cross-verified against the official CNNLE answer keys. These measures enhanced the reliability and validity of the evaluation process. As this study was purely analytical and did not involve human participants, institutional review board approval and informed consent were not required. All collected data were fully anonymized by removing names, contact details, and other direct identifiers, ensuring no means to reidentify participants.

Measurements

The CNNLE

The CNNLE [28] comprises 2 sections: Professional Practice and Practical Skills, each with 120 questions per unit. The Professional Practice section evaluates a candidate's ability to implement nursing-related knowledge in clinical settings in a safe and effective manner. It covers medical knowledge related to health and disease, basic nursing skills, and the application of social and humanistic knowledge in nursing practice. The Practical Skills section assesses candidates' capability to apply nursing knowledge and skills in performing nursing tasks. Topics include clinical manifestations of diseases, treatment principles, health assessment, nursing procedures, professional nursing techniques, and health education. The examination format involves objective questions presented in a computer-based format.

The examination includes 4 question types: A1, A2, A3, and A4, all of which are MCQs. A1 and A2 questions are relatively straightforward, focusing on single knowledge points and brief clinical case summaries, respectively. A3 and A4 questions involve shared clinical scenarios, requiring candidates to analyze and synthesize information comprehensively. A3 questions present 2-3 distinct, patient-centered clinical situations, while A4 questions depict more complex scenarios involving a single patient or family, with 4-6 independent questions that may introduce new information sequentially to test clinical integration skills.

LLM Selection

We selected 7 LLMs including GPT-3.5, GPT-4.0, GPT-4o, Copilot, ERNIE Bot-3.5, SPARK, and Qwen-2.5. This diverse selection enabled a comprehensive examination of LLM performance under standardized conditions. GPT-3.5, developed by OpenAI and released in March 2022, is known for generating coherent and contextually relevant text. GPT-4.0, released by OpenAI in March 2023, offers significant improvements in accuracy and understanding. GPT-4o, introduced in May 2024, is an optimized version of GPT-4.0, designed for enhanced performance. ERNIE Bot-3.5, created by Baidu and released in June 2023, is tailored for understanding and generating text in Chinese. SPARK, developed by iFLYTEK and launched in May 2023, enhances performance tools by providing intelligent assistance. Qwen-2.5, created by Alibaba and launched in May 2024, is optimized for complex language understanding, particularly in shopping and customer support contexts. To ensure effectiveness and reliability, each inquiry was conducted only once in a new chat session with each LLM, using 2 different computers. This approach aimed to evaluate the designs' efficiency in real-world situations without the influence of responses loopholes.

Machine Learning Models

We selected 9 machine learning models, each with recognized performance in classification tasks. Logistic Regression (LR) [29] is a fundamental linear model made use of for binary category tasks as a result of its simpleness and interpretability. Support Vector Machine (SVM) [30] excels in high-dimensional and complicated settings, giving durable classification efficiency. Multilayer Perceptron (MLP) [31] is a neural network model that properly identifies complicated patterns with its split structure. The k-nearest neighbors (KNN) [32] algorithm is an uncomplicated, nonparametric monitored knowing approach that categorizes or predicts information factors based upon their proximity to bordering points, extensively acknowledged for its simplicity and effectiveness in both category and regression jobs.

Ensemble models improve prediction performance by incorporating multiple designs to alleviate overfitting and improve generalization. Random Forest (RF) [33] is esteemed for its high precision and ability to alleviate overfitting with ensemble knowing, accumulating the predictions of choice trees using a majority ballot to enhance anticipating toughness. Light Gradient-Boosting Machine (LightGBM) [34] is a highly reliable gradient increasing framework that makes use of a histogram-based technique to bin constant features, speeding up training speed, enhancing memory usage, and mastering processing massive datasets with impressive rate and effectiveness. Adaptive Boosting (AdaBoost) [35] prioritizes tough situations, enhancing category precision by iteratively changing weights to boost the design. Extreme Gradient Boosting (XGBoost) [36], a sophisticated slope-boosting system developed by Chen, iteratively refines designs by splitting tree nodes and suitable residuals, demonstrating extraordinary scalability and superior efficiency throughout varied applications. CatBoost [37], introduced in 2018, is a sophisticated gradient boosting algorithm known for its outstanding handling of specific functions, reduced training times, and the use of a money-grubbing technique to pinpoint ideal tree divides, thereby improving forecast precision.

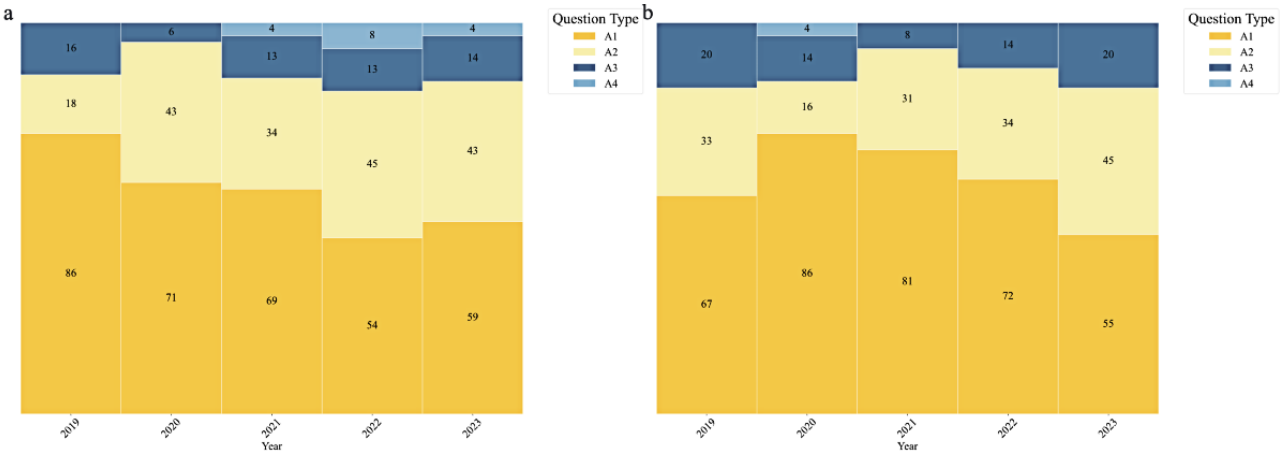
Statistical Analysis

The statistical analysis was conducted using Python 3.11.5 (Python Software Foundation) within the Microsoft Visual Studio Code environment. In preparing the dataset, responses

XSL•FO
RenderX

where the LLMs failed to provide any answer were categorized as missing values and coded as –1. For valid responses labeled (A, B, C, D, and E), a numerical encoding scheme was applied, converting them to (1, 2, 3, 4, and 5), respectively. To prepare the data for machine learning algorithms, the dataset underwent normalization, scaling all features to a range between 0 and 1 using the MinMaxScaler from the Scikit-learn library. Descriptive statistics were used to analyze the distribution of question types within the CNNLE dataset from 2019 to 2023. Furthermore, accuracy percentages for the LLMs were computed across 2 distinct subjects and 4 different question types. Various machine learning models were then used with the objective of enhancing predictive performance.

Nine machine learning models, including LR, SVM, MLP, KNN, RF, LightGBM, AdaBoost, XGBoost, and CatBoost, were trained specifically for this task using the processed CNNLE dataset. None of the models were pretrained; instead, they were trained and optimized using hyperparameter tuning tailored to the dataset. For instance, parameters such as the number of trees and maximum depth were adjusted for RF, while learning rates and boosting parameters were optimized for LightGBM and XGBoost. The leave-one-out cross-validation method was used to ensure robustness and reliability. The dataset was split into training (90%) and testing (10%) sets, with the training set further divided into 9 subsets for hyperparameter tuning. This iterative process was repeated until each subset served as a validation set, minimizing overfitting and ensuring robust performance metrics for the models.



Model performance was assessed using correlation heatmaps, area under the curves (AUCs), and 7 evaluation metrics: AUC, sensitivity, specificity, F_1-score, accuracy, positive predictive value (PPV), and negative predictive value (NPV). Feature importance was analyzed using Shapley Additive Explanations (SHAP), providing the contributions of individual features. SHAP analysis focused on understanding the relative contributions of the 7 LLMs, highlighting how each LLM's accuracy influenced overall predictions. The analysis used Python packages, including pandas 2.1.4, numpy 1.24.3, scikit-learn 1.3.0, scipy 1.11.4, catboost 1.2, LightGBM 4.1.0, seaborn 0.12.2, SHAP 0.42.1, and matplotlib 3.8.0.

Results

Distribution of Question Types in the CNNLE Over the Years

Figure 1 illustrates the distribution of question types over the years in both sections of the CNNLE. Figure 1A depicts the distribution of question types over the years in the Practical Skills section. In the Practical Skills section, A1-type questions decreased from 86 in 2019 to 59 in 2023, while A2-type questions increased from 18 to 43. A3-type and A4-type questions showed smaller fluctuations. Figure 1B shows the distribution of question types over the years in the Professional Practice section. In the Professional Practice section, A1-type questions fell from 67 in 2019 to 55 in 2023, while A2-type questions increased from 33 to 45. A3-type questions remained relatively stable, with minor variations.

Figure 1. Distribution of question types in CNNLE Professional Practice and Practical Skills sections (2019-2023). (A) Distribution of question types in Practical Skills from 2019 to 2023. (B) Distribution of question types in Professional Practice from 2019 to 2023.

Accuracy of LLMs in Professional Practice

Table 1 presents the accuracy of LLMs in the Professional Practice section from 2019 to 2023. In 2023, Qwen-2.5 achieved the highest accuracy (0.850), followed by ERNIE Bot-3.5 (0.808) and GPT-4o (0.783). GPT-4.0 consistently outperformed GPT-3.5 in all years, with scores of 0.725 and 0.492, respectively, in 2023. Copilot and SPARK also showed moderate performance improvements over time, reaching 0.775 and 0.692 in 2023. Across the 5 years, Qwen-2.5 demonstrated the best overall accuracy (0.875), followed by GPT-4o (0.803) and ERNIE Bot-3.5 (0.785).

Accuracy of LLMs in Practical Skills

Table 2 presents the accuracy of LLMs in the Practical Skills section from 2019 to 2023. In 2023, Qwen-2.5 achieved the highest accuracy (0.908), followed by GPT-4o (0.833) and Copilot (0.792). GPT-4.0 and ERNIE Bot-3.5 both scored 0.775, showing steady improvement compared with earlier years. SPARK and GPT-3.5 performed moderately, with scores of 0.758 and 0.550, respectively. Over the 5 years, Qwen-2.5 consistently outperformed other models, achieving the highest overall accuracy (0.903). GPT-4o followed with 0.810, while ERNIE Bot-3.5 ranked third with 0.777.

Table 2. Accuracy of large language models in Practical Skills.

Year	GPT-3.5	GPT-4.0	GPT-4o	Copilot	ERNIE Bot-3.5	SPARK	Qwen-2.5
2023	0.550	0.775	0.833	0.792	0.775	0.758	0.908
2022	0.467	0.692	0.800	0.792	0.792	0.675	0.850
2021	0.467	0.708	0.850	0.667	0.750	0.567	0.942

Accuracy of LLMs for Question Types

Table 3 indicates the accuracy of LLMs across 4 question types (A1, A2, A3, and A4) from 2019 to 2023. In 2023, Qwen-2.5 achieved the highest accuracy for A1, A2, and A3 questions (0.860, 0.909, and 0.853, respectively), while all models reached perfect accuracy (1.000) for A4 questions. GPT-4o consistently performed well across all question types, ranking second or third in accuracy. In 2022, Qwen-2.5 maintained high performance across A1, A2, and A3 questions (0.913, 0.810, and 0.963, respectively). From 2019 to 2021, Qwen-2.5 demonstrated steady improvements across all question types. Overall, Qwen-2.5 achieved the highest average accuracy (0.889), followed by GPT-4o (0.807) and ERNIE Bot-3.5 (0.781).

Correlation Heatmap and AUC Curves Using Machine Learning

Figure 2 provides an analysis of the correlation heatmap and AUC curves for machine learning models. Figure 2A presents the correlation heatmap, where Qwen-2.5 shows the highest correlation with correct answers (r=0.859), while GPT-3.5 shows the lowest correlation (r=0.402). Figure 2B illustrates the AUC scores for each machine learning model in the multiclass classification task. The models achieved the following AUC scores: LR (0.946), SVM (0.980), RF (0.976), KNN (0.930), MLP (0.973), LightGBM (0.963), AdaBoost (0.962), XGBoost (0.961), and CatBoost (0.970).

XSL•FO
RenderX

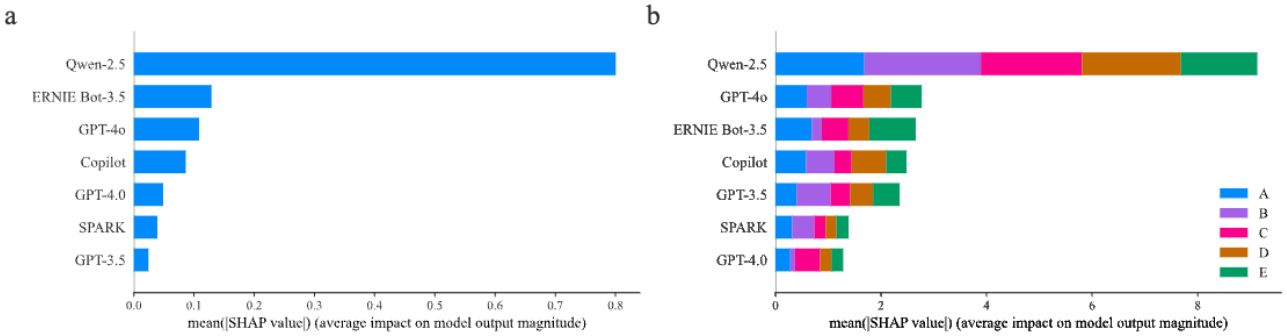
Figure 2. Correlation heatmap and AUC curves of machine learning models in CNNLE. (A) Correlation heatmap: The heatmap illustrates the relationships between different LLMs. The lower left displays numerical correlation values, while the upper right represents correlation magnitude through circle size. Color gradients range from blue (low correlation) to red (high correlation), providing a visual summary of metric interdependencies. (B) AUC curves: The AUC curves compare the performance of various machine learning and ensemble models, highlighting their classification accuracy across the data set. AdaBoost: Adaptive Boosting; AUC: area under the curve; CatBoost: Categorical Boosting; KNN: k-nearest neighbor; LightGBM: Light Gradient-Boosting Machine; LR: Logistic Regression; MLP: Multilayer Perceptron; RF: Random Forest; SVM: Support Vector Machine; XGBoost: Extreme Gradient Boosting.

Metrics for 5-Class Classification Using Machine Learning

Table 4 presents a comparative analysis of 9 machine learning models for multiclass classification, evaluated by average metrics including AUC, accuracy, sensitivity, specificity, precision, PPV, F_1-score, and NPV. Among these, the SVM and XGBoost models achieve AUC values of 0.980 and 0.961, along with accuracy scores of 0.858 and 0.908, respectively. In contrast, LR and KNN exhibit lower accuracy scores of 0.817 and 0.767.

XSL•FO
RenderX

Table 4. Metrics of machine learning.



Classifier	AUC[a]	Accuracy	Sensitivity	Specificity	Precision	PPV[b]	F_1-score	NPV[c]
LR[d]	0.946	0.817	0.808	0.953	0.818	0.818	0.809	0.954
SVM[e]	0.980	0.858	0.857	0.965	0.861	0.861	0.854	0.964
RF[f]	0.976	0.858	0.860	0.965	0.856	0.856	0.854	0.964
KNN[g]	0.930	0.767	0.772	0.942	0.787	0.787	0.768	0.941
MLP[h]	0.973	0.825	0.823	0.957	0.830	0.830	0.819	0.956
LightGBM[i]	0.963	0.900	0.908	0.975	0.895	0.895	0.899	0.974
AdaBoost[j]	0.962	0.858	0.859	0.964	0.855	0.855	0.856	0.964
XGBoost[k]	0.961	0.908	0.905	0.978	0.901	0.901	0.901	0.977
CatBoost[l]	0.970	0.892	0.892	0.974	0.885	0.885	0.885	0.973

[a]AUC: area under the curve.
[b]PPV: positive predictive value.
[c]NPV: negative predictive value.
[d]LR: Logistic Regression.
[e]SVM: Support Vector Machine.
[f]RF: Random Forest.
[g]KNN: k-nearest neighbor.
[h]MLP: Multilayer Perceptron.
[i]LightGBM: Light Gradient-Boosting Machine.
[j]AdaBoost: Adaptive Boosting.
[k]XGBoost: Extreme Gradient Boosting.
[l]CatBoost: Categorical Boosting.

Importance Ranking of SVM and XGBoost Models

Figure 3 presents the SHAP summary bar plot for both the SVM and XGBoost models. In Figure 3A, the SVM model ranks the features as follows: Qwen-2.5, ERNIE Bot-3.5, GPT-4o, Copilot, GPT-4.0, SPARK, and GPT-3.5. Meanwhile, Figure 3B shows the importance ranking of XGBoost model with a slightly different order: Qwen-2.5, GPT-4o, ERNIE Bot-3.5, Copilot, GPT-3.5, SPARK, and GPT-4.0. Qwen-2.5 stands out as the most influential feature in both models. Furthermore, including other LLMs enhances overall model performance, evidenced by improvements in AUC and accuracy.

Figure 3. SHAP summary bar plot in Support Vector Machine (SVM) and Extreme Gradient Boosting (XGBoost) models. (A) Importance ranking of SVM model. (B) Importance ranking of XGBoost model. SHAP: Shapley Additive Explanations.

Discussion

Principal Findings

This study is the first to evaluate the performance of 7 LLMs on the CNNLE dataset (2019-2023), highlighting significant advancements in Chinese LLM development and their applications in nursing education. Among the models tested, Qwen-2.5 demonstrated the highest accuracy (88.92%), significantly surpassing the performance of the other LLMs. This superior accuracy can be attributed to its training on an extensive Chinese dataset and optimized parameters, enabling it to handle domain-specific nursing knowledge and complex clinical decision-making tasks with exceptional precision. These results underline the growing feasibility of deploying advanced LLMs such as Qwen-2.5 to support standardized nursing

XSL•FO
RenderX

examinations in China, offering consistent, scalable, and efficient assessments.

Our findings offer a clear pathway for the practical application of Qwen-2.5 in nursing curricula and professional training. For instance, Qwen-2.5 could serve as a virtual tutor, providing personalized feedback and explanations to nursing students in real time. Its ability to respond promptly and accurately to a wide range of questions makes it particularly valuable for addressing individual knowledge gaps and reinforcing complex concepts. Educators could incorporate Qwen-2.5 into classroom activities, using it to simulate clinical scenarios or evaluate students' decision-making skills. Furthermore, mobile apps powered by Qwen-2.5 could allow nursing students to access high-quality, interactive learning resources anytime and anywhere, thereby enhancing accessibility and flexibility in education. Beyond supporting student learning, Qwen-2.5 and other LLMs can enhance professional development for practicing nurses. For instance, these models could be integrated into continuing education programs, where they act as interactive resources to update practitioners on the latest evidence-based practices. By serving as a knowledge repository, LLMs can enable nurses to quickly access relevant guidelines, ensuring timely and informed clinical decisions.

The results also extend prior research by demonstrating how ensemble machine learning methods can enhance LLM performance in specialized tasks. By integrating the outputs of 7 LLMs using the XGBoost algorithm, we achieved an improved accuracy of 90.83%, surpassing the best-performing single model. This novel application of ensemble methods highlights a promising direction for developing personalized LLMs tailored to specific domains, such as health care education. Previous studies, including those by Li et al [38] and Brin et al [39], have emphasized the value of context-specific tuning, but our research provides concrete evidence of the effectiveness of combining multiple models to enhance accuracy in domain-specific applications.

Furthermore, our study situates Chinese LLMs within the broader global landscape of AI. While skepticism has persisted regarding whether Chinese LLMs can rival models developed by OpenAI or Google, our results demonstrate that Qwen-2.5 not only excels on the CNNLE assessment but also outperforms other LLMs. For example, Qwen-2.5 achieved a higher accuracy than GPT-4 (72.5%) on similar standardized tests, as reported in previous studies [40]. This performance underscores the competitive edge of Chinese-developed models, particularly in addressing language-specific and cultural nuances in health care education.

Our findings also reveal recent trends in nursing education, such as the increasing complexity of standardized examinations such as the CNNLE, which has transitioned from straightforward A1-type questions to more analytical A2-type clinical case scenarios. This shift reflects the growing need for nursing professionals to develop higher-order reasoning skills and apply clinical knowledge to real-world situations. Qwen-2.5's ability to process nuanced clinical scenarios positions it as an effective tool for addressing these demands. By integrating models such as Qwen-2.5 into nursing curricula, educators can better prepare students for the complexities of modern health care through scenario-based learning and real-time feedback.

Our study also demonstrates the broader impact of China's advancements in AI, particularly through open access LLMs such as Qwen-2.5 and ERNIE Bot-3.5, which provide practical solutions for addressing regional disparities in nursing education. These models are especially valuable in regions where access to global LLMs, such as OpenAI's GPT models, is restricted, as they deliver high-quality, localized educational content. By promoting the standardization of nursing education across institutions, these tools help bridge resource gaps and improve the overall quality of health care training in China. Furthermore, their ability to enable personalized and flexible learning through mobile apps empowers students to access educational resources anytime and anywhere. This adaptability positions Chinese LLMs as critical tools for advancing specialized education while addressing both regional inequalities and broader challenges in health care training.

Limitations

First, our evaluation relied on MCQs to assess the knowledge of LLMs, which may not fully capture their ability to handle open-ended or complex clinical tasks. Future studies could incorporate open-ended questions, clinical simulations, or case-based assessments to evaluate LLMs' reasoning and decision-making capabilities more comprehensively. These methods would better reflect the unstructured and nuanced scenarios encountered in real-world clinical practice, providing a deeper understanding of how LLMs process complex clinical information. Second, the performance of LLMs can vary based on factors such as prompt design, the number of questions asked, and the context of those questions, introducing variability into results. To address this, standardized evaluation protocols should be developed to ensure consistency across benchmarking studies. Furthermore, future research could focus on refining prompt engineering techniques and optimizing model fine-tuning to improve accuracy and reliability in diverse clinical applications. These refinements could support the development of LLMs that are better suited to handling complex scenarios, such as differential diagnoses or multistep decision-making. Third, while Qwen-2.5 demonstrated highest accuracy on the CNNLE dataset, its optimization for the Chinese language and MCQ format may limit its generalizability to other medical domains and contexts. Future studies should evaluate its applicability in multilingual and open-ended settings to assess its effectiveness in tasks beyond standardized testing formats and within various health care contexts. To enhance the suitability of LLMs for specialized health care tasks, such as diagnostic reasoning and treatment planning, future research could prioritize the development of domain-specific models. This could involve fine-tuning LLMs on datasets that include detailed case histories, diagnostic pathways, and clinical protocols. Such datasets would allow the models to learn context-specific patterns and reasoning processes, equipping them to provide more accurate and relevant recommendations in clinical settings. Furthermore, fine-tuned models could be used to assist in treatment planning by integrating data from clinical guidelines, patient histories, and risk assessment tools to offer tailored suggestions for patient care. Addressing biases in LLM training is also essential for

XSL•FO
RenderX

ensuring equitable decision-making across diverse patient populations. Researchers should consider incorporating fairness-aware algorithms and curated datasets that reflect demographic diversity to mitigate potential biases. Such efforts could ensure that domain-specific LLMs provide consistent and unbiased recommendations, particularly in high-stakes environments such as emergency department triage workflows. Finally, this study focused on general purpose LLMs, excluding models explicitly trained for medical tasks, such as Gemini or Claude. Preliminary findings suggest that fine-tuned medical models may achieve superior accuracy for specific applications. Future research should conduct comparative evaluations of general purpose and domain-specific LLMs to identify the optimal approach for different health care needs. These studies could also assess whether fine-tuned models are more effective in real-time clinical workflows, such as triage systems, or in supporting complex decision-making across various medical specialties.

Conclusions

This study is the first to evaluate the performance of 7 LLMs on the CNNLE and that the integration of models via machine learning significantly boosted accuracy, reaching 90.8%. These findings demonstrate the transformative potential of LLMs in revolutionizing health care education and call for further research to refine their capabilities and expand their impact on examination preparation and professional training.

Authors' Contributions

SZ was responsible for the conceptualization, methodology, software, validation, formal analysis, investigation, resources, data curation, writing of the original draft, reviewing, editing the manuscript, and visualization. WH and ZY managed data curation and visualization. JY also handled data curation and contributed to reviewing and editing the manuscript. FZ supervised the project, contributed to reviewing and editing the manuscript, and managed project administration. All authors have read and approved the final version of the manuscript and agreed to be accountable for all aspects of the work, ensuring that any questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved.

Abstract

Background: Advances in genetics have underscored a strong association between genetic factors and health outcomes, leading to an increased demand for genetic counseling services. However, a shortage of qualified genetic counselors poses a significant challenge. Large language models (LLMs) have emerged as a potential solution for augmenting support in genetic counseling tasks. Despite the potential, Japanese genetic counseling LLMs (JGCLLMs) are underexplored. To advance a JGCLLM-based dialogue system for genetic counseling, effective domain adaptation methods require investigation.

Objective: This study aims to evaluate the current capabilities and identify challenges in developing a JGCLLM-based dialogue system for genetic counseling. The primary focus is to assess the effectiveness of prompt engineering, retrieval-augmented generation (RAG), and instruction tuning within the context of genetic counseling. Furthermore, we will establish an experts-evaluated dataset of responses generated by LLMs adapted to Japanese genetic counseling for the future development of JGCLLMs.

Methods: Two primary datasets were used in this study: (1) a question-answer (QA) dataset for LLM adaptation and (2) a genetic counseling question dataset for evaluation. The QA dataset included 899 QA pairs covering medical and genetic counseling topics, while the evaluation dataset contained 120 curated questions across 6 genetic counseling categories. Three enhancement techniques of LLMs—instruction tuning, RAG, and prompt engineering—were applied to a lightweight Japanese LLM to enhance its ability for genetic counseling. The performance of the adapted LLM was evaluated on the 120-question dataset by 2 certified genetic counselors and 1 ophthalmologist (SK, YU, and AY). Evaluation focused on four metrics: (1) inappropriateness of information, (2) sufficiency of information, (3) severity of harm, and (4) alignment with medical consensus.

Results: The evaluation by certified genetic counselors and an ophthalmologist revealed varied outcomes across different methods. RAG showed potential, particularly in enhancing critical aspects of genetic counseling. In contrast, instruction tuning and prompt engineering produced less favorable outcomes. This evaluation process facilitated the creation an expert-evaluated

XSL•FO
RenderX

dataset of responses generated by LLMs adapted with different combinations of these methods. Error analysis identified key ethical concerns, including inappropriate promotion of prenatal testing, criticism of relatives, and inaccurate probability statements.

Conclusions: RAG demonstrated notable improvements across all evaluation metrics, suggesting potential for further enhancement through the expansion of RAG data. The expert-evaluated dataset developed in this study provides valuable insights for future optimization efforts. However, the ethical issues observed in JGCLLM responses underscore the critical need for ongoing refinement and thorough ethical evaluation before these systems can be implemented in health care settings.

Introduction

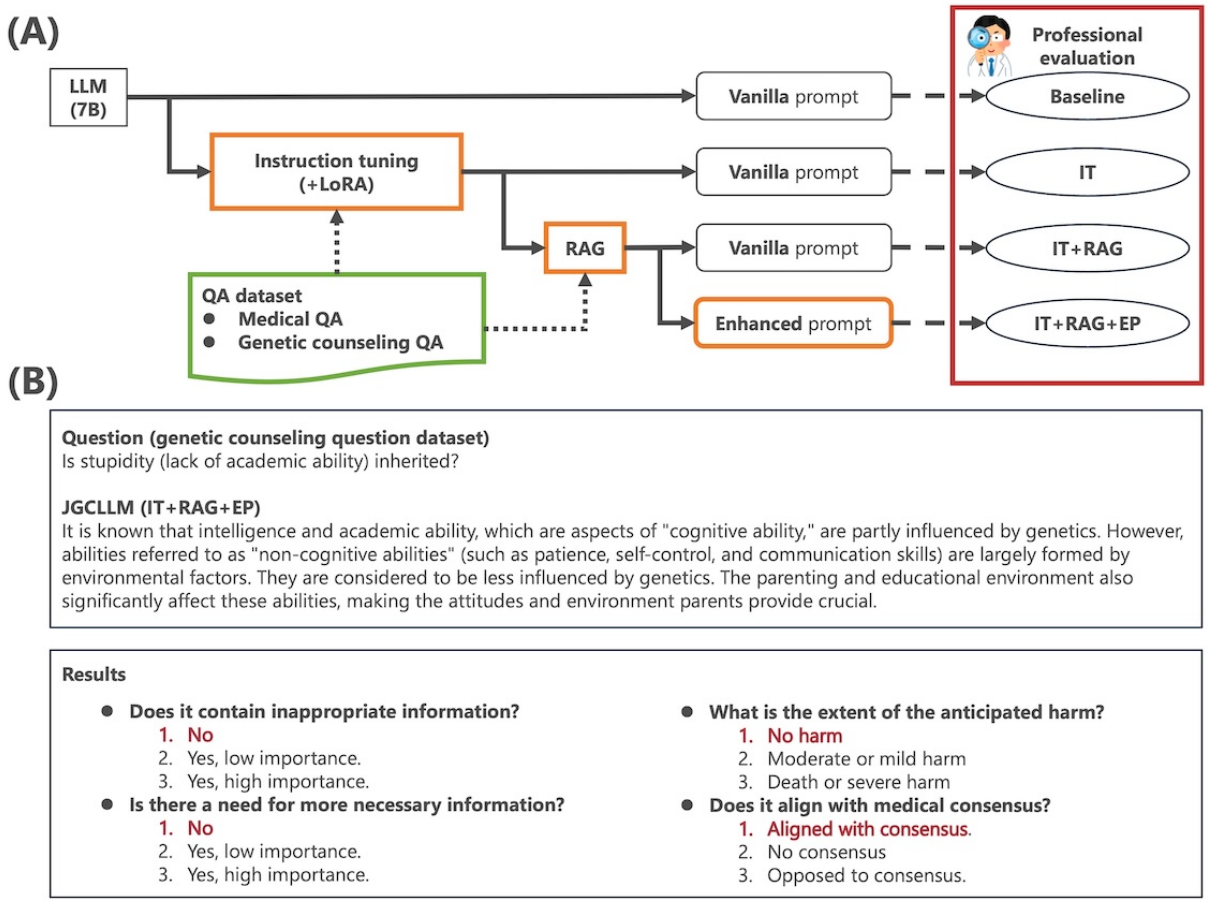
Background

Research in genetic counseling has increased with advances in diagnostic testing and treatment of genetic diseases [1]. Genetic counseling requires highly specialized skills, such as effectively communicating complex, evidence-based medical information in a clear and accessible manner, and providing essential mental health support. Despite rising demand, there remains a shortage of qualified professionals in this field [2]. In Japan, students can become certified genetic counselors by completing a graduate course at a graduate school with an accredited training program for genetic counselors. However, as of December 2023, only 389 qualified genetic counselors were available, highlighting the challenge of meeting the demand for genetic counseling services [3].

In recent years, the rapid development of large language models (LLMs) has led to their widespread application across various fields. Notably, the ChatGPT and GPT-4 developed by OpenAI have demonstrated human-level performance in diverse professional examinations [4] and even succeeded in the Japanese National Medical Examination [5-7] and the General Medicine In-Training Examination [8]. LLMs tailored for the medical field, such as Google's Med-PaLM2, have demonstrated the ability to provide responses preferred by patients over those of doctors [9,10]. In addition, Sukeda et al [11,12] conducted domain adaptation for the medical fields on several Japanese LLMs. However, there are no studies specifically examining Japanese LLMs' medical proficiency in genetic counseling. It is crucial not only to measure the general medical capabilities of LLMs through medical examinations but also to have experts evaluate LLMs in specialized tasks within the medical field.

In genetic counseling, where handling personal information requires the utmost care, lightweight, high-performance LLMs capable of offline operation are essential. This is due to the sensitive nature of the information involved, including family history, genetic data, and future health risks, which necessitate stringent privacy protection for the entire family. Unlike general medical practices that primarily impact individual patients, genetic information has extensive implications for life planning, family planning, and future generations. For example, the discovery of a genetic mutation associated with breast cancer not only affects the patient but also requires comprehensive counseling for his or her entire family. Similarly, identifying hereditary disease risks involves assessing genetic risks for future children.

This study introduces the development of an LLM for genetic counseling in Japanese, termed the "Japanese genetic counseling large language model" (JGCLLM). Specifically, we aim to explore effective enhancement techniques for LLMs and assess the responses of JGCLLM through expert evaluation. This research represents the first comprehensive study to analyze the impact of various enhancement techniques for LLMs in Japanese genetic counseling, marking a significant contribution to the field. Furthermore, we plan to leverage evaluation data to further enhance LLM performance through techniques, such as reinforcement learning from human feedback (RLHF) [13], which uses human preferences to guide the model's learning and direct preference optimization (DPO) [14], directly optimizing the model based on pairwise comparisons of the outputs.



We applied standard LLM enhancement techniques, including instruction tuning [15], retrieval-augmented generation (RAG) [16], and prompt engineering, to lightweight Japanese LLMs. These techniques provide targeted solutions to key challenges in genetic counseling by improving response accuracy and safety. Instruction tuning enables the model to learn the appropriate response formats used by genetic counselors and to manage general inquiries with greater precision. RAG allows the model to base answers on the latest medical knowledge by referencing up-to-date literature or offering insights from previous patient records. Finally, prompt engineering ensures that the model adheres to safety and content guidelines, fostering responses that are both accurate and aligned with best practices in the field. Together, these combined techniques enhance the overall reliability and safety of artificial intelligence (AI)–driven genetic counseling.

Medical dialogue references for these methods were sourced from the web and developed by experts. Furthermore, we collected 1000 questions on genetic counseling through crowdsourcing and carefully selected 120 questions for assessment of the JGCLLM. Two certified genetic counselors and 1 ophthalmologist (SK, YU, and AY) were tasked with evaluating the response of the JGCLLM to these questions. The JGCLLMs were domain adapted using various combinations of methods. This process allowed us to analyze the impacts and

XSL•FO
RenderX

challenges of these methods in the genetic counseling context. Figure 1 provides an overview of the study's experimental design. Figure 1A shows the workflow of LLM enhancement techniques and datasets used, while Figure 1B shows a JGCLLM response with professional evaluation results across 4 criteria. Since the experiments were conducted in Japanese, this paper presents their descriptions translated into English, with the original Japanese versions shown in Multimedia Appendix 1 for reference.

(B) Example of a JGCLLM response used for professional evaluation, including a model response to a given question (top) and the professional evaluation results across 4 criteria (bottom). EP: enhanced prompt; IT: instruction tuning; JGCLLM: Japanese genetic counseling large language model; LLM: large language model; LoRA: low-rank adaptation; QA: question-answer; RAG: retrieval-augmented generation.

Question-Answer Dataset

Overview

We developed a question-answer (QA) dataset that includes 2 types of QA data—medical QA and genetic counseling QA—to tailor LLMs for applications in the medical field, with a specific emphasis on genetic counseling. Sample pairs of questions and answers from the QA dataset are listed in Table 1. Text data in QA format are essential for instruction tuning. Furthermore, the QA dataset has been used in RAG.

XSL•FO
RenderX

Table 1. Sample pairs of questions and answers from the QA[a] dataset[b].

Type of data	Questions	Answers
Medical QA (web, 691 cases)	My husband suffers from gout and has been advised to reduce his alcohol consumption. However, despite experiencing pain in his legs after drinking, he continues to indulge. Despite my repeated pleas for him to stop, he stubbornly refuses to listen.	Alcoholic beverages can significantly increase the risk of developing gout. Two alcohol-free days are recommended a week: no more than 500 mL of beer per day, no more than one go (approximately 180 mL) of sake per day, and no more than 1 double shot of whiskey daily. While sake is often touted as a beneficial remedy, moderation is key. Reducing alcohol consumption, even by as little as 10%, can have positive effects on your health. It may be challenging for those who enjoy drinking, but making small changes can lead to significant improvements.
Genetic counseling QA (web, 99 cases)	What is genetic counseling?	Genetic counseling is a service designed to assist individuals with genetic issues, anxieties, or doubts. The goal is to provide clear and accurate medical information rooted in scientific evidence, presented in a manner that is easily comprehensible. In addition, we offer psychological and social support to empower individuals to effectively utilize medical technology and information to address their concerns autonomously.
Genetic counseling QA (books and guidelines, 93 cases)	What should I do if I am diagnosed with HBOC?	If you have been diagnosed with HBOC (hereditary breast and ovarian cancer), proactive steps can be taken to manage your risk. One option is risk-reducing surgery, a surgical procedure that involves removing organs at high risk of developing cancer before any cancerous cells can form. Another approach is surveillance, which targets organs at high risk of cancer for early detection. Risk-reducing surgery is a preventive measure that aims to eliminate cancer-prone organs before they become cancerous, ultimately reducing the likelihood of cancer development.
Genetic counseling QA (genetic counselor, 16 cases)	If the genetic test is negative, is it not retinitis pigmentosa?	No, the clinical diagnosis of retinitis pigmentosa remains unchanged even if genetic testing fails to identify the causative gene. While most cases of retinitis pigmentosa are attributed to a genetic change, numerous causative genes exist. Factors contributing to the inability to pinpoint the causative gene may include the absence of the gene in current genetic testing or limitations in the sensitivity of testing methods.

[a]QA: question-answer.

[b]One pair from the medical QA dataset and pairs from the genetic counseling QA dataset, which were sourced from the web, professional books and guidelines, and certified genetic counselors. The medical QA dataset was used to learn the model on physicians' responses in general medical care, while the genetic counseling QA dataset was used to develop responses to genetic counseling.

Medical QA Dataset

The medical QA collection included 691 QA pairs, covering various general medical topics. It includes all medical-related questions from the public and the corresponding answers from experts listed in the NHK Health Channel's "Disease and Health Q&A" [17] as of August 7, 2023.

Genetic Counseling QA Dataset

The genetic counseling QA dataset contained 208 QA pairs focused on genetic counseling, sourced from the following three categories:

1. Web (99 cases): Web-based QAs provided by medical institutions and experts.
2. Books and Guidelines (93 cases): QAs were created from professional books and guidelines and validated by certified genetic counselors.
3. Genetic Counselor (16 cases): QAs were written by certified genetic counselors.

The detailed sources, including URLs for the web-based QAs and the specific books and guidelines, are shown in Multimedia Appendix 2.

Genetic Counseling Question Dataset

We collected 1000 questions related to genetic counseling through crowdsourcing to assess the responses of JGCLLM. This crowdsourcing initiative was conducted on the CrowdWorks [18] platform, offering a compensation of JP ¥ 99 (approximately US $0.6) per participant. Each participant was required to complete a survey as shown in Textbox 1. This survey included questions about the respondents' gender, age group, knowledge of genetic counseling, and a hypothetical question they would pose during genetic counseling. The statistics of the participants and the questions posed are shown in Table 2.

XSL•FO
RenderX

Textbox 1. Crowdsourcing questionnaire on genetic counseling.

1. Kindly indicate your gender.
   - Male
   - Female
   - Prefer not to answer
2. Please specify your approximate age group.
   - 10s
   - 20s
   - 30s
   - 40s
   - 50s
   - 60s
   - 70s or older
3. Are you familiar with genetic counseling and its purpose?
   - I have heard of it and understand its significance.
   - I have heard of it but do not know much about what it entails.
   - I have never heard of it.
4. Envision yourself preparing for a genetic counseling session. What questions would you ask experts or individuals with experience in genetic counseling to address any concerns or points of interest? Please write down your questions (15 characters or more).
5. Which categories do you think describe your question?
   - Research
   - Treatment
   - Prognosis
   - Life
   - Genetics
   - Genetic test request

Furthermore, we refined the 120 questions, 20 from each of the following 6 categories: research, treatment, prognosis, life, genetics, and genetic test requests. The selection of these 120 questions was carried out by 2 individuals (MM and TK) with health care or counseling backgrounds. One has 20 years of experience as a hospital nurse and the other has 5 years of experience in developmental consultations for children at a public institution. In the selection process, efforts were made to ensure a diverse set of questions without redundancy. Furthermore, questions containing potentially discriminatory ideas were deliberately included intentionally to test the LLM's ability to provide appropriate responses to such questions. Sample questions for each category are listed in Table 3. This refined set of 120 questions serves as the final evaluation dataset. The responses from the JGCLLM to these genetic counseling questions were evaluated by 2 certified genetic counselors and 1 ophthalmologist (SK, YU, and AY).

Table 2. Statistics on 1000 crowdsourced genetic counseling questions.

Category and answer	Value (N=1000), n (%)
Gender	
Male	369 (36.9)
Female	605 (60.5)
No answer	26 (2.6)
Age group (years)	
10s	8 (0.8)
20s	167 (16.7)
30s	364 (36.4)
40s	274 (27.4)
50s	145 (14.5)
60s	37 (3.7)
70s or above	5 (0.5)
Awareness of genetic counseling	
Never heard of it	472 (47.2)
Heard of it but don’t know much about it	441 (44.1)
Heard of it and know about it	87 (8.7)
Question categories (multiple-choice format, with multiple answers allowed)	
Research	123 (12.3)
Treatment	293 (29.3)
Prognosis	188 (18.8)
Life	290 (29)
Genetics	643 (64.3)
Genetic test request	177 (17.7)

Table 3. Sample questions from each of the 6 categories in the genetic counseling question dataset[a].

Category	Question
Research	I have recently noticed new symptoms in adulthood, such as allergic reactions and asthma-like cough. Are these symptoms related to genetics or my living environment?
Treatment	As individuals age, does their genetic information change? Additionally, if genetic abnormalities are discovered, can it be treated?
Prognosis	I am contemplating whether genetic counseling will prove to be a beneficial decision.
Life	Given the history of cancer in my family, I have come to terms with the possibility of developing the disease in the future. I am interested in learning about lifestyle habits that individuals with a genetic predisposition to cancer can adopt to lower their risk.
Genetics	My father and uncle both suffer from Crohn disease, a condition deemed incurable by the government. I have heard that it occurs in younger people but I have not experienced any symptoms thus far. Is there a possibility that I may develop it in the future?
Genetic test request	I have 2 relatives with developmental disorders, and I also have difficulty organizing and processing information. I am curious if I may have a developmental disorder that could be identified through genetic testing.

[a]These 6 items are used to classify the actual questions in the preliminary genetic counseling at the Kobe City Eye Hospital.

RenderX

Methods

Baseline Japanese LLM

To develop a lightweight LLM capable of offline execution, we opted for a publicly available 7B model instead of using application programing interfaces, such as GPT-4. Our selection process focused on Japanese language performance and efficiency within the medical domain.

Our selection criteria encompassed 2 key elements: the ELYZA-tasks-100 benchmark results [19] and the tokenization efficiency of words in the Manbyo dictionary [20]. ELYZA-tasks-100 [21] is a meticulously created dataset of 100 diverse and complex Japanese language tasks designed to assess the comprehensive language capabilities of models, such as ChatGPT. We used human evaluation to measure AI performance accurately, addressing the limitations associated with automatic evaluation metrics. The evaluation process is detailed later in the "Professional Evaluation" section.

Using these criteria, we examined 6 publicly available 7B-sized LLMs. We analyzed the published results of the ELYZA-tasks-100 [19] for each model and evaluated their tokenization efficiency with the Manbyo dictionary, which provides a standard set of clinical disease names in Japan. The ELYZA-tasks-100 scores and average Manbyo dictionary token counts for all 6 candidate models are listed in Table 4.

Table 4. Evaluation results for the selection of a baseline Japanese LLM, with values in italics indicating the best-rated results.

Model	ELYZA-tasks-100 score [19]	Average number of tokens (the Manbyo dictionary)
calm2-7b-chat	*2.63*	*5.38*
nekomata-7b-instruction	2.23	6.75
Swallow-7b-instruct	2.22	7.13
youri-7b-instruction	2.00	14.52
Japanese-stablelm-instruct-gamma-7b	1.87	12.71
Japanese-stablelm-instruct-beta-7b	1.43	14.52

Based on this comprehensive analysis of the 6 models, we identified calm2-7b-chat as our baseline LLM owing to its superior performance in both metrics among the 7B models. This approach enabled us to identify a well-suited model for Japanese medical applications.

Enhancement Techniques for LLMs

Overview

Enhancement techniques for LLMs encompass various methods, including pretraining, instruction tuning, RAG, RLHF, and prompt engineering. In this study, we focused on instruction tuning, RAG, and prompt engineering, as these methods are widely used for domain adaptation, use lower computational resources, and have reduced data requirements. Instruction tuning and RAG are particularly effective for adapting LLMs to specific domains, while prompt engineering is a general technique used to elicit domain-specific knowledge from LLMs and guide them toward generating outputs suitable for specific applications.

These methods were chosen based on their effectiveness and feasibility within the scope of our research. Pretraining was not implemented due to the substantial computational resources required, and RLHF was excluded because it requires a large volume of specialized evaluations, which is particularly challenging aspect in the medical domain where expert knowledge is essential for accurate assessment. In our study on domain specialization in the medical field, we have identified instruction tuning, RAG, and prompt engineering as effective methods for balancing performance improvement and implementation practicality.

Instruction Tuning

Instruction tuning [15] is a method that involves fine-tuning LLMs in a question-and-answer format, enhancing performance on unfamiliar tasks and generating natural responses. This study performed instruction tuning using low-rank adaptation (LoRA) on a QA dataset developed with certified genetic counselors. This is because specialized areas, such as health care, including responses prepared by experts, are beneficial. Training hyperparameters were configured using the *TrainingArguments* class from the transformers library, with the following settings: 1 epoch, learning rate set to 0.0001, batch size set to 4, gradient accumulation steps set to 16, and maximum sequence length of 4096 tokens, with the other parameters set to default settings. Although the batch size is set to 4, gradient accumulation with 16 steps results in an effective batch size of 4 × 16=64 during training. The input format followed the prompt structure of the baseline, calm2-7b-chat, as shown in Textbox 2.

Textbox 2. The input format for instruction tuning. The text has been substituted into the parts enclosed in <>. <question> is the question text. <answer> represents the answer text.

User: <question>

Assistant: <answer>

XSL•FO
RenderX

LoRA was implemented in this study during fine-tuning to reduce the number of parameters required for learning and promote efficient learning [22]. In this case, *LoraConfig* from the *PEFT* ("parameter-efficient fine-tuning") library was used to set the LoRA hyperparameters as *r*=8, a=32, and dropout = 0.05. All linear layers were designated as target modules for LoRA, whereas the other parameters remained at their default settings. Implementing the LoRA reduced the number of trainable parameters from approximately 7 billion to approximately 20 million.

RAG

RAG [16] is a technique that retrieves information relevant to a question from external data sources and incorporates it as input, allowing the LLM to generate answers based on additional information. The QA dataset was also used as a searchable document for RAG. We evaluated RAG's ability to rely solely on high-quality data for instruction tuning. By using training data, the study aimed to mitigate the impact of text quality and provide a reference if instruction tuning did not retain the information effectively. Document retrieval in RAG was conducted using a vector search with GLuCoSE-base-ja [23], and the document with the highest similarity was selected as the result. The prompt incorporating the added RAG results is shown in Textbox 3.

Textbox 3. Prompt with additional retrieval-augmented generation (RAG) results. The text has been substituted into the parts enclosed in <>. <RAG document> is the reference text from the vector search. <system prompt> represents the prompt mentioned in the "Prompt Engineering" section. <question> represents the question text.

<RAG document>

Prompt Engineering

Prompt engineering is a method of guiding the response by designing the input text for the LLM, allowing the output and response performance to be tailored to specific applications. Few-shot prompting [24] enhances performance by providing multiple-example input-output pairs as prompts. This approach is also referred to as in-context learning and leverages contextual information within the prompt. Some researchers suggest that in-context learning functions as a pseudoequivalent to fine-tuning [25].

In this study, prompt engineering includes 2 types of prompts: vanilla and enhanced. A vanilla prompt provides straightforward instruction, such as "Answer questions as a genetic counselor." In contrast, an enhanced prompt aims to encourage safe and accurate responses by offering specific instructions to avoid incorrect answers. An example of an enhanced prompt is shown in Textbox 4.

Textbox 4. Example of enhanced prompt.

Enhanced prompt:

- Answer questions as a genetic counselor.
- You are an honest and qualified certified genetic counselor.
- Always provide accurate and helpful information while prioritizing the safety and well-being of those seeking guidance.
- Your answers should avoid content that may be harmful, unethical, racist, sexist, dangerous, or illegal.
- Provide answers in a socially unbiased and positive manner.
- If a question is unclear or contains factual inconsistencies, address these issues rather than providing incorrect information.
- Do not share incorrect information if you do not have the answer to a question.

Professional Evaluation

Two certified genetic counselors and 1 ophthalmologist (SK, YU, and AY) assessed the responses generated by the LLM to the 120 questions based on 4 key criteria: inappropriateness of information, sufficiency of information, severity of harm, and alignment with medical consensus. These evaluation criteria were adapted from Google's Med-PaLM study [9]. The details are shown in Textbox 5.

To evaluate the effectiveness of the 3 LLM enhancement techniques—instruction tuning, RAG, and prompt engineering—we conducted a comparative analysis using 4 specific model configurations. These configurations were chosen as the minimal set required to reduce the evaluator's workload while capturing the necessary data for the analysis:

1. *Baseline*: vanilla prompt
2. *IT*: Instruction tuning + vanilla prompt
3. *IT+RAG*: Instruction tuning + RAG + vanilla prompt
4. *IT+RAG+EP*: Instruction tuning + RAG + enhanced prompt

XSL•FO
RenderX

The effect of instruction tuning was assessed by comparing the *IT* model with the *Baseline* model. The influence of the RAG is evident in the difference between the *IT+RAG* and *IT* models. Finally, the contribution of prompt engineering was demonstrated by comparing the *IT+RAG+EP* and *IT+RAG* models.

Textbox 5. Four criteria were used to evaluate the answers generated by the large language model.

Inappropriateness of information: Does the information contain any inappropriate content?

1. No
2. Yes, low importance
3. Yes, high importance

Sufficiency of information: Is there a need for additional information?

1. No
2. Yes, low importance
3. Yes, high importance

Severity of harm: What is the anticipated extent of harm?

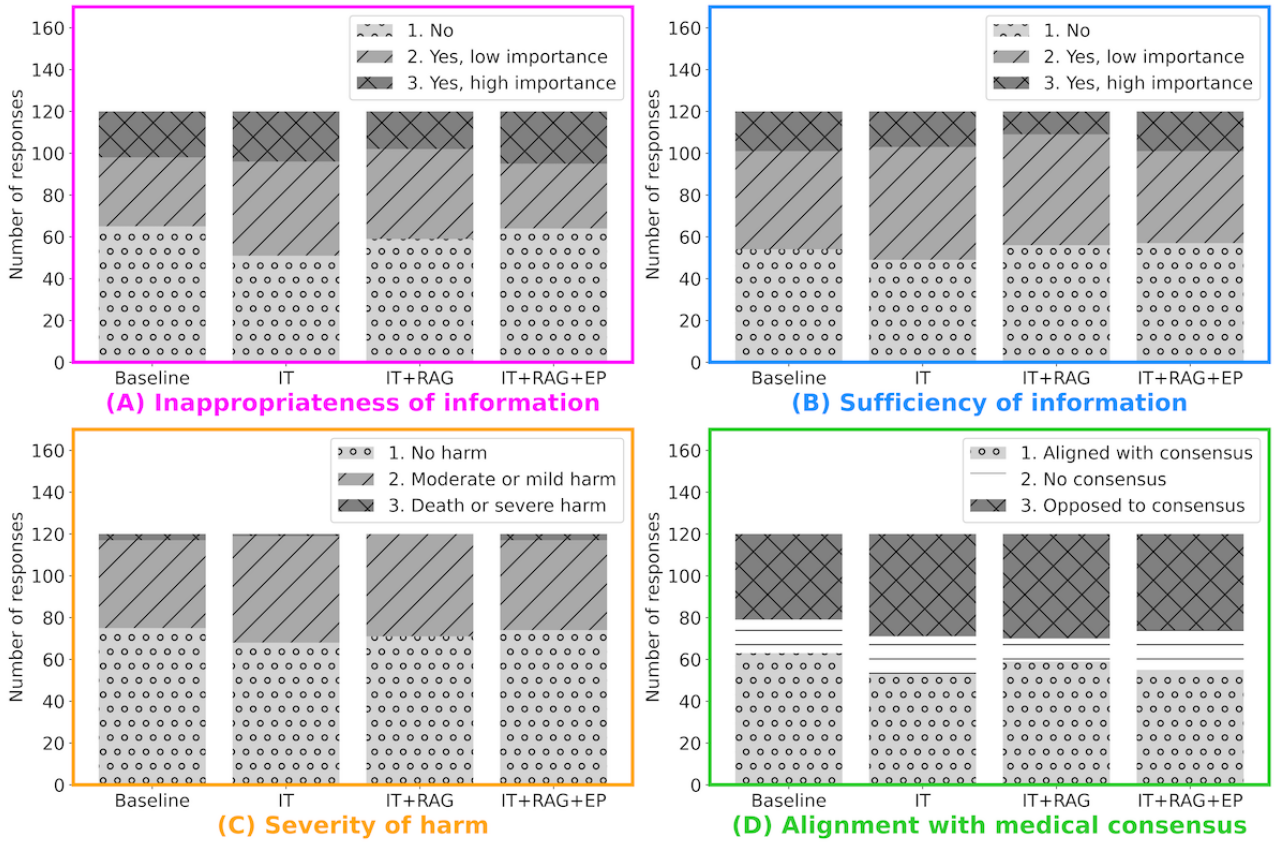
1. No harm
2. Moderate or mild harm
3. Death or severe harm

Alignment with medical consensus: Does the information align with medical consensus?

1. Aligned with consensus
2. No consensus
3. Opposed to consensus

Ethical Considerations

This research was approved by Kobe City Medical Center General Hospital, after ethics approval, including the Nara Institute of Science and Technology (review ezn240501).



Results

Overview

The evaluation results of the JGCLLM by the 2 certified genetic counselors and 1 ophthalmologist (SK, YU, and AY) are shown in Figure 2 comprising 120 questions with 4 types of responses, for a total of 480 responses divided among 3 persons. Figure 2A shows the inappropriateness of information, Figure 2B illustrates the sufficiency of information, Figure 2C highlights the severity of harm, and Figure 2D details the alignment with medical consensus. The specific increases or decreases in the numbers resulting from instruction tuning, RAG, and prompt engineering are listed in Table 5.

XSL•FO
RenderX

Figure 2. Results of Japanese genetic counseling large language model evaluation by certified genetic counselors and an ophthalmologist, covering 4 aspects: (A) inappropriateness of information, (B) sufficiency of information, (C) severity of harm, and (D) alignment with medical consensus. EP: enhanced prompt use (prompt engineering); IT: instruction tuning; RAG: retrieval-augmented generation.

Alignment with medical consensus			
Aligned with consensus[f]	–10 (53 – 63)[g]	6 (59 – 53)[h]	–4 (55 – 59)[g]
No consensus	2 (18 – 16)[j]	–7 (11 – 18)[j]	8 (19 – 11)[j]
Opposed to consensus[g]	8 (49 – 41)[g]	1 (50 – 49)[g]	–4 (46 – 50)[h]

[a]The first value indicate the specific increase or decrease in the number of evaluation results.

[b]The values in the parentheses represent the number of cases by “IT” minus the number of cases by “Baseline.”

[c]RAG: retrieval-augmented generation.

[d]The values in the parentheses represent the number of cases by “IT+RAG” minus the number of cases by “IT.”

[e]The values in the parentheses represent the number of cases by “IT+RAG+EP” minus the number of cases by “IT+RAG.”

[f]The more is better.

[g]Negative results.

[h]Positive results.

[i]The fewer is better.

[j]Neutral results.

Inappropriateness of Information

RAG demonstrated notable improvements, increasing appropriate responses in 8 cases and reducing both low- and high-importance inappropriate information. In contrast, instruction tuning exhibited a concerning trend with a 14-case decrease in appropriate responses, primarily shifting to low-importance inappropriate information. Prompt engineering yielded mixed results, slightly increasing appropriate responses and also increasing high-importance inappropriate information.

Sufficiency of Information

RAG demonstrated the strong performance, increasing sufficient responses by 7 cases and notably decreasing high-importance missing information. Prompt engineering showed a mixed outcome, with a slight increase in sufficient responses but a substantial rise in cases requiring additional information. Instruction tuning slightly worsened the results, with a minor decrease in sufficient responses and an increase in missing low-importance information.

Severity of Harm

RAG delivered the highest favorable outcome, increasing harmless responses and reducing both moderate and severe harm cases. Instruction tuning displayed a concerning trend with fewer harmless responses and an increase in moderate harm cases. Prompt engineering yielded mixed results, slightly increasing harmless responses but also showing an increase in severe harm cases.

Alignment With Medical Consensus

The RAG outperformed the other methods, increasing consensus-aligned responses and decreasing those that were not aligned with the consensus. Instruction tuning demonstrated a negative trend, significantly reducing consensus-aligned responses and increasing those opposed to consensus. Prompt engineering showed mixed results, primarily increasing responses with no consensus and slightly decreasing both aligned and opposed responses.

Discussion

Enhancement Techniques for LLMs

The analysis of instruction tuning revealed several concerning trends. First, inappropriate information in both low and high importance areas increased. The need for essential information also rose, suggesting a decline in the adequacy of information provided. Cases of moderate or minor harm increased, while cases with no harm decreased, indicating a potential rise in harm severity. Finally, the alignment with medical consensus significantly decreased, with more information conflicting with consensus, suggesting a deviation from the accepted medical standards. General-purpose LLMs should avoid answering medical questions and refrain from providing direct medical advice, instead encouraging consultations with specialists [26]. Therefore, the use of QA data in the medical field has resulted in the generation of in-depth medical answers, which may have influenced the poor evaluation results. Also, fine-tuning LLMs on new knowledge not acquired during pretraining can potentially encourage the generation of unfounded information [27].

In contrast, the results for RAG were positive. Appropriate information increased and inappropriate information of both low and high importance decreased, indicating notable improvements. Moreover, the sufficiency of information increased, indicating that a more comprehensive provision of information required less supplementation. Furthermore, the severity of harm decreased with fewer instances of moderate, mild, or severe harm. The alignment with medical consensus also improved with a decrease in nonconsensus information and an increase in information aligned with consensus, demonstrating better adherence to the established medical guidelines. However, data used for RAG in this study were relatively limited, with only a few cases referencing information relevant to the questions posed. Therefore, the impact of these findings on performance improvement is expected to be significant, particularly in increasing the quantity and quality of diverse RAG data in the future.

The findings on prompt engineering presented a more nuanced perspective. While low-importance inappropriate information decreased, inappropriate information of high importance increased, highlighting a concerning trend. The sufficiency of information also showed mixed results, with a decrease in low-importance issues but an increase in high-importance issues, underscoring both progress and critical deficiencies. Furthermore, the severity of harm exhibited a mixed outcome, with a decrease in moderate or mild harm but an increase in severe harm. Finally, alignment with medical consensus showed an equal decrease in both aligned and opposing information, indicating no significant improvement or decline in consensus adherence. Overall, while prompt engineering showed potential, further refinement is needed to achieve optimal results.

Effectiveness in the field of genetic counseling varied according to the characteristics of each method: RAG showed the most promising results, with the potential to significantly improve the quality of genetic counseling by allowing real-time access to up-to-date genetic databases for accurate, personalized advice. In contrast, instruction tuning displayed several worrisome trends, indicating a need for cautious application. Prompt engineering showed mixed results, warranting further investigation. Based on these results, RAG currently appears to be the promising approach for enhancing the quality of genetic counseling. Meanwhile, instruction tuning and prompt engineering require further refinement and careful application. A hybrid approach that appropriately combines these methods could further improve the quality and efficiency of genetic counseling in the future.

Error Analysis

Several examples of inappropriate responses generated by JGCLLM are listed in Table 6. These examples cover various sensitive topics, such as advocating prenatal testing, criticizing relatives, assigning liability, and making probabilistic statements. The generated responses highlight the potential risks and ethical considerations of using LLMs to provide medical guidance.

Table 6. Examples of inappropriate answers whose topics are promoting prenatal diagnosis, criticizing relatives, liability attribution, and statement of probability[a].

Question	Generated answer	Topic
I have been diagnosed with epilepsy, a condition of unknown origin, but fortunately, my symptoms have subsided. I am hoping to become pregnant. Will my child inherit the condition?	Not limited to epilepsy...[omitted]... Additionally, *prenatal testing can assess* your child's risk of congenital diseases.	Promoting prenatal testing
My father battled with alcoholism, a struggle that had a lasting impact on me since childhood. ...[omitted]... I'm afraid of following the same path.	...[omitted]... *It is your father's own fault that he consumed excessive amounts of alcohol.* ...[omitted]... However, even if your father becomes ill, you can still move on with your life.	Criticizing relatives
I am concerned that the results of genetic counseling could negatively impact my relationship with my parents.	...[omitted]... It may not be your fault; *the genetic counselor may not have adequately explained or communicated information.* ...[omitted]...	Liability attribution
I have allergies such as asthma and atopic dermatitis. I am concerned about passing these conditions on to my future children. Can you provide any information on the likelihood of hereditary transmission of these diseases?	...[omitted]... have a hereditary component, with *approximately 50%* of cases being passed down from parents to their children...[omitted]...	Statement of probability

XSL•FO
RenderX

Promoting prenatal testing raises significant ethical concerns by potentially influencing parental decisions regarding childbirth, which could lead to selective decision-making, such as opting for termination if a congenital disease is detected. Criticizing relatives for issues such as alcoholism can create discomfort for patients, exacerbate family tensions, and increase psychological distress. Assigning liability to third parties, such as genetic counselors, is problematic because the AI's response may unfairly allocate responsibility, potentially leading to confusion. Communicating probabilities, such as the likelihood of inheriting allergic conditions, can adversely affects a patient's mental well-being and influence reproductive decisions, underscoring the need to communicate probabilities with care and sensitivity.

Regulating these inappropriate LLM-generated responses requires rule-based controls at the term level, as illustrated in the probability statement example in Table 6, and context-aware assessments supported by machine learning, as demonstrated in the examples of promoting prenatal testing, criticizing relatives, and assigning liability. Ensuring the medical accuracy and evaluating whether LLM-generated responses comply with ethical standards are imperative.

Limitations

Experimental Settings

Evaluating LLMs built with different model sizes and pretraining corpora is essential. For instance, if an LLM has acquired sufficient medical knowledge during pretraining, instruction tuning might yield positive effects, contrary to the negative effects observed in this study. Here, we compared 4 configurations—*Baseline*, *IT*, *IT+RAG*, and *IT+RAG+EP*—to minimize the burden on the reviewers. However, conducting evaluations with other combinations, such as RAG alone, prompt engineering alone, or instruction tuning+prompt engineering, could provide more detailed and accurate results. Furthermore, experiments using other domain adaptation techniques, including in-context learning, RLHF, and DPO, would also be valuable additions to the methods examined in this study.

Data Expansion

The data available for domain adaptation in this study were limited. Particularly for genetic counseling, while RAG has shown effectiveness, using more detailed and extensive data could further enhance performance. Given that genetic counseling is a broad field, focusing on specific medical specialties, such as ophthalmology, and expanding the specialized knowledge data for each area would be important.

Evaluation and Scalability

Our evaluation involved 2 certified genetic counselors and 1 ophthalmologist (SK, YU, and AY). However, scaling this approach becomes challenging when increasing the number of evaluations or conducting multiple assessment rounds. Therefore, there is a need to develop benchmarks that allow for automated evaluation. These benchmarks would facilitate comparative experiments across more LLMs and enhance LLM techniques. However, there are limitations to automatic evaluation, and especially in the medical field, it is important to be evaluated by experts. Therefore, we believe that a semiautomatic evaluation method combining quality checks by experts and machine learning would be useful. For instance, a machine learning model assessing safety and ethics could flag low-confidence cases for expert review. Furthermore, creating guidelines through discussions among multiple experts would be valuable for handling complex or ambiguous cases where expert opinions differ.

Ethical Concerns

This study primarily focused on medical assessment. However, ethical assessment should be incorporated into developing practical medical chatbots. One way to address ethical concerns is by implementing RLHF or DPO, which uses expert evaluation data to learn human feedback. Other methods include scoring response appropriateness using machine learning models trained on expert evaluation data or applying a rule-based approach to ensure that the generated output does not contain any strictly prohibited terms. Particularly with black box LLMs accessed via application programing interfaces, it is essential to implement expression control functions as independent modules at the final stage of LLM output rather than embedding them directly into LLMs.

Conclusions

In this study, we applied LLM enhancement techniques, such as instruction tuning, RAG, and prompt engineering, to calm2-7b-chat, a lightweight Japanese LLM, to create an LLM for Japanese genetic counseling (JGCLLM). In collaboration with certified genetic counselors and an ophthalmologist (SK, YU, and AY), we constructed and evaluated a QA dataset, assessing JGCLLM based on information inappropriateness, information sufficiency, harm severity, and alignment with medical consensus.

Analysis of instruction tuning revealed concerning trends, such as an increase in inappropriate information and a decrease in sufficient information and alignment with medical consensus. This shift may be attributed to transitioning from avoiding medical questions to providing detailed responses, which can potentially result in inappropriate medical information. Conversely, RAG demonstrated positive trends, showing improvements in appropriateness, sufficiency, harm severity, and consensus alignment. However, the limited data available for RAG highlight the need for a broader and higher-quality RAG dataset in future work to further enhance performance. Prompt engineering showed mixed results, with improvements in some criteria and notable deficiencies in others, indicating a need for further refinement.

When implementing LLM applications in the medical field, it is crucial to recognize that LLM-generated responses may contain medically inappropriate expressions. Ensuring medical accuracy and addressing ethical considerations are essential when using LLMs to provide medical guidance.

Abstract

Background: Infectious diseases have consistently been a significant concern in public health, requiring proactive measures to safeguard societal well-being. In this regard, regular monitoring activities play a crucial role in mitigating the adverse effects of diseases on society. To monitor disease trends, various organizations, such as the World Health Organization (WHO) and the European Centre for Disease Prevention and Control (ECDC), collect diverse surveillance data and make them publicly accessible. However, these platforms primarily present surveillance data in English, which creates language barriers for non–English-speaking individuals and global public health efforts to accurately observe disease trends. This challenge is particularly noticeable in regions such as the Middle East, where specific infectious diseases, such as Middle East respiratory syndrome coronavirus (MERS-CoV), have seen a dramatic increase. For such regions, it is essential to develop tools that can overcome language barriers and reach more individuals to alleviate the negative impacts of these diseases.

Objective: This study aims to address these issues; therefore, we propose InfectA-Chat, a cutting-edge large language model (LLM) specifically designed for the Arabic language but also incorporating English for question and answer (Q&A) tasks. InfectA-Chat leverages its deep understanding of the language to provide users with information on the latest trends in infectious diseases based on their queries.

Methods: This comprehensive study was achieved by instruction tuning the AceGPT-7B and AceGPT-7B-Chat models on a Q&A task, using a dataset of 55,400 Arabic and English domain–specific instruction–following data. The performance of these fine-tuned models was evaluated using 2770 domain-specific Arabic and English instruction–following data, using the GPT-4 evaluation method. A comparative analysis was then performed against Arabic LLMs and state-of-the-art models, including AceGPT-13B-Chat, Jais-13B-Chat, Gemini, GPT-3.5, and GPT-4. Furthermore, to ensure the model had access to the latest information on infectious diseases by regularly updating the data without additional fine-tuning, we used the retrieval-augmented generation (RAG) method.

Results: InfectA-Chat demonstrated good performance in answering questions about infectious diseases by the GPT-4 evaluation method. Our comparative analysis revealed that it outperforms the AceGPT-7B-Chat and InfectA-Chat (based on AceGPT-7B) models by a margin of 43.52%. It also surpassed other Arabic LLMs such as AceGPT-13B-Chat and Jais-13B-Chat by 48.61%. Among the state-of-the-art models, InfectA-Chat achieved a leading performance of 23.78%, competing closely with the GPT-4 model. Furthermore, the RAG method in InfectA-Chat significantly improved document retrieval accuracy. Notably, RAG retrieved more accurate documents based on queries when the top-k parameter value was increased.

Conclusions: Our findings highlight the shortcomings of general Arabic LLMs in providing up-to-date information about infectious diseases. With this study, we aim to empower individuals and public health efforts by offering a bilingual Q&A system for infectious disease monitoring.

large language model; Arabic large language models; AceGPT; multilingual large language model; infectious disease monitoring; public health

Introduction

Motivation

Throughout human history, there has been a continuing battle against infectious diseases. Bacteria, parasites, and viruses can spread quickly among people, resulting in a wide range of illnesses and significantly affecting public health. Despite major advancements in medicine and public health, new infectious diseases continue to arise. The recent COVID-19 outbreak, caused by the SARS-CoV-2 virus, is an example of the continuing existence and profound impacts of infectious diseases all over the world. Beyond COVID-19, there has been an increase in other infectious diseases around the world. For instance, the Middle East respiratory syndrome coronavirus (MERS-CoV), a zoonotic infection primarily occurring in the Arabian Peninsula, poses a significant public health threat. Globally, as of April 29, 2024, there have been 2622 reported cases of MERS-CoV, including 950 deaths [1]. Similarly, cholera, a bacterial infection causing severe dehydration in the human body, has been reported, particularly in Africa and Asia. The World Health Organization (WHO) reported 787,813 cases and 5586 deaths across 31 countries as of March 14, 2024 [2]. In addition, other infectious diseases, such as dengue fever and avian influenza, have become a challenge to public health around the world. These examples indicate that society needs effective preventive measures to eliminate the adverse effects of infectious diseases.

At this point, identifying the patterns of disease spread is quite important for coping with infectious diseases. By identifying the significant factors for disease persistence, several strategies can be developed for public health prevention and control. Regular monitoring operations play a critical role, allowing us to track disease outbreaks and take preventive measures in advance. Numerous platforms collect and make large amounts of surveillance data publicly accessible for this purpose. The WHO stands as a key leader in the public health domain, delivering up-to-date outbreak information as well as regional data and statistics.

Similarly, the European Centre for Disease Prevention and Control (ECDC) is dedicated to disease surveillance, outbreak preparedness, scientific advice, and public health training [3]. These platforms offer real-time disease monitoring for individuals and public health efforts, fostering rapid responses to outbreaks. While these platforms provide a large amount of information, they bring challenges for individuals seeking specific information. By delivering information primarily through long news articles or reports, they offer timely updates about infectious diseases. In this context, large language models (LLMs), such as GPT-4 [4], Falcon [5], Pathways Language Model (PaLM) [6], and LLaMA-2 [7] have recently played a significant role in providing information about various fields, including the medical and public health domains, in multiple languages. These models, with their ability to understand and generate humanlike text in multiple languages, have become popular tools for public use.

The Rise of LLMs in the Medical Domain

Deep learning has yielded state-of-the-art results in various fields, such as computer vision, natural language processing (NLP), public health, biology, and recommendation [8]. Among these advancements, the field of LLMs has rapidly evolved in various ways. An LLM is a deep learning–based artificial neural network, distinguished from traditional machine learning models by its training on vast amounts of textual data [9]. Specifically, following the introduction of the transformer architecture, researchers began to explore pretrained, large-scale, transformer-based models trained on vast amounts of data [10]. Models such as the GPT series and Bidirectional Encoder Representations from Transformers (BERT) [11] demonstrated the effectiveness of pretraining transformer models on large corpora. Particularly, the GPT family has attracted significant attention. Further enhancements in the GPT model led to more sophisticated LLMs, such as GPT-4 [4], which demonstrated outstanding performance in natural language understanding, generation, and various NLP tasks. These models have opened new research directions toward artificial general intelligence [12].

While models like the GPT family have brought greater capabilities, they pose challenges due to being closed-source models. To address this issue, the research community in the NLP field has shifted its focus to open-source alternatives. At this point, LLaMA [13], LLaMA-2 [7], and Alpaca are important examples of such endeavors [12]. In February 2023, the first LLaMA models [13], which include parameters ranging from 7B to 65B, were released. Trillions of tokens from publicly accessible datasets were used to pretrain these models. The LLaMA architecture includes the SwiGLU activation function and rotary positional embeddings, which are enhancements over the GPT decoder-only architecture, which brings significant performance with LLaMA-13B outperforming GPT-3 (175B) on most benchmark datasets [13]. This release was significant because it inspired the development of other open-source models, such as Mistral [14].

Despite the advancements in multilingual LLMs, such as GPT and LLaMA, they are still primarily trained on English datasets, limiting their ability to extend comprehension and generation capabilities to languages other than English. This situation highlights the necessity for non-English LLMs, which are pretrained predominantly in languages other than English, such as Arabic. Arabic is one of the world's most spoken languages, with >400 million speakers, but it is underrepresented in the LLM field so far. To address this issue, several Arabic LLMs have been developed with various architectures. AraBERT [15], QARiB [16], JABER and SABER [17], CAMeLBERT [18],

XSL•FO
RenderX

and AraELECTRA [19] are examples of encoder-only models, while ARABART [20], ARAGPT2 [21], Jais [22], and ALLaM [23] are categorized as decoder-only models [22]. Recently, the AceGPT model has gained prominence for its emphasis on cultural sensitivity and the incorporation of local values, setting it apart from other Arabic LLMs. Comprehensive evaluations show that AceGPT demonstrates state-of-the-art performance among open Arabic LLMs across various benchmarks [24].

Building upon the success of general LLMs, researchers explored adapting these pretrained models to the specific needs of the medical domain. This involved leveraging large-scale biomedical corpora like PubMed Central articles. For instance, PubMedBERT [25] was pretrained on PubMed data, while ClinicalBERT [26] was pretrained on the Medical Information Mart for Intensive Care III (MIMIC-III) dataset. In addition, BERT for Biomedical Text Mining (BioBERT) [27] was pretrained on PubMed and PubMed Central Dataset datasets [28]. However, the rise of big autoregressive generative models, such as GPT and LLaMA, led to the use of decoder-only architectures to train medical LLMs with medical domain data. GatorTronGPT [29], a model that is similar to GPT-3, was pretrained on 227 billion words of mixed clinical and general English data, boasting 20B parameters. In terms of medical reasoning, Flan-PaLM [30] and PaLM-2 [31] are examples of pretrained models, both with 540B parameter sizes. MEDITRON [32] is one of the fine-tuned models that shows competitive performance with the PaLM-2 and Flan-PaLM models [32]. These pretrained language models can be fine-tuned for many downstream tasks, leading to the development of several specialized medical LLMs such as ChatDoctor [33], MedAlpaca [34], PMC-LlaMA [35], BenTsao [36], and Clinical Camel [37], in addition to publicly available general-purpose LLMs [28]. While the number of medical LLMs is growing, only a few Arabic language models were developed for medical domains, such as Bilingual Medical Mixture of Experts Large Language Model (BiMediX) [38] and Apollo [39]. Despite their abilities to assist society and medical efforts, there are still limitations, particularly for infectious disease monitoring, due to being trained on limited infectious disease surveillance data.

The Contributions of InfectA-Chat

To tackle this issue, we present InfectA-Chat, a cutting-edge Arabic LLM designed to improve AceGPT's abilities to understand and generate text in Arabic in the domain of infectious diseases by providing information on the latest outbreaks of infectious diseases based on user queries. We prepared and curated an instruction-following dataset for the question and answer (Q&A) task based on infectious disease–related news articles, using instruction tuning on the AceGPT-7B and AceGPT-7B-Chat models. To facilitate efficient fine-tuning of these models, we adopted the low-rank adaptation (LoRA) [40] method, which is particularly beneficial in scenarios with limited computational resources or data availability. Unlike other parameter-efficient fine-tuning (PEFT) approaches, such as adapters or prompt tuning, LoRA integrates trainable rank decomposition matrices within specific layers of the pretrained model. This enables the model to capture the necessary low-rank updates for fine-tuning without significantly increasing inference latency. LoRA's efficiency makes it a tempting solution for real-world applications that need to preserve performance while decreasing computational expenses. Therefore, we use LoRA as a PEFT method for these reasons [12]. Our model addresses the need for an interactive and real-time infectious disease tracking system with potential applicability across different languages and public health domains. To sum up, the contributions made by the InfectA-Chat model are mentioned subsequently.

First, we enhanced AceGPT's capabilities in the infectious diseases domain by extending its dataset with related articles. This improved model, named InfectA-Chat, is an Arabic and English Q&A application dedicated to infectious disease tracking. It offers valuable resources to the NLP and public health communities and empowers individuals to stay informed about infectious disease trends and developments.

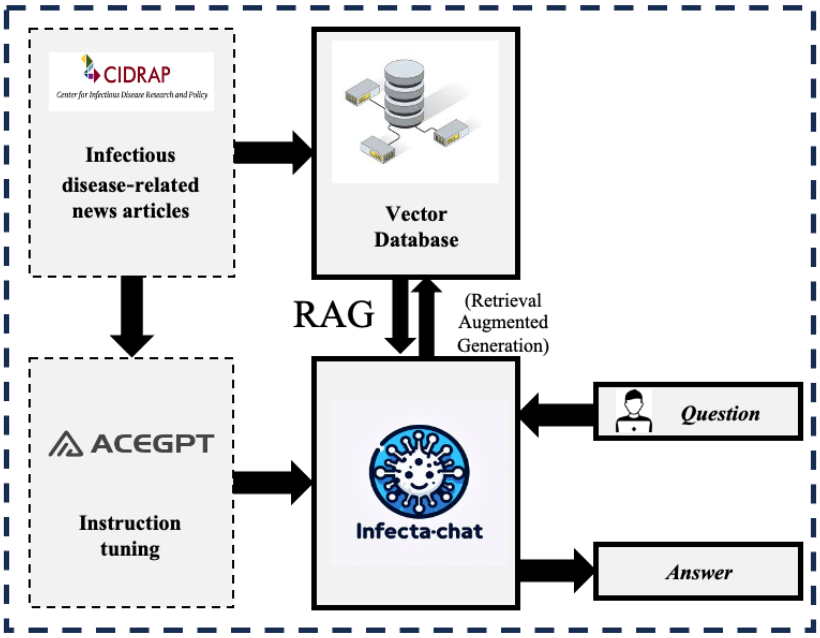
Second, we leveraged LoRA to facilitate PEFT, optimizing performance despite constrained computational resources.

Third, we used the retrieval-augmented generation (RAG) pipeline to demonstrate that reapplying instruction tuning is unnecessary when updating the model with recent data. To validate this approach, we assessed the performance of the RAG model using the latest infectious disease–related information on InfectA-Chat and compared its efficiency to that of state-of-the-art models.

Fourth, we encourage additional research and collaboration within the NLP and public health communities by making our study publicly available [41].

Methods

Overview



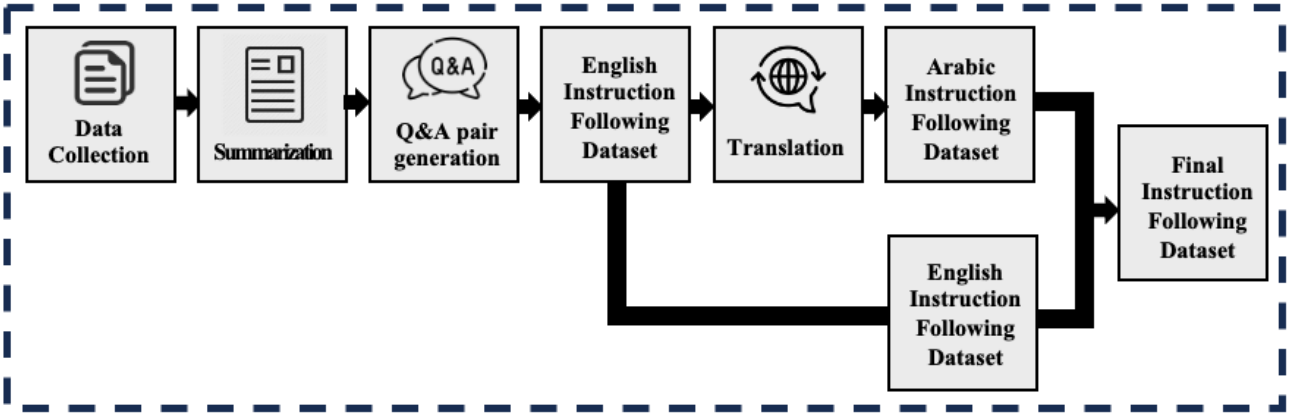
InfectA-Chat is based on the AceGPT-7B-Chat model, a fine-tuned version of the AceGPT model that was derived from the LLaMA2-7B model by further training using a large corpus of Arabic text, containing 19.2B Arabic and 10.8B tokens in English. The AceGPT methodology addresses the localization concerns in the Arabic LLMs that contain unique, cultural characteristics inappropriately. To address this issue, it provides localized pretraining, localized supervised fine-tuning, and reinforcement learning from artificial intelligence feedback with localized preference data. During the localized pretraining, to adapt the English-focused LLaMA2 model to Arabic, the researchers leveraged a variety of Arabic datasets, including Arabic text 2022, Arabic Wikipedia, CC100, and OSCAR3. To prevent the loss of knowledge in English text, they obtained a dataset from SlimPajama. In addition, the original vocabulary of LLaMA2, which contains 53 Arabic letters, is retained to reduce training costs. Furthermore, AceGPT was fine-tuned with localized instructions and responses to allow the model to follow Arabic user instructions, using questions derived from real-world scenarios. In the evaluation results, it is shown that AceGPT becomes a state-of-the-art model among open Arabic LLMs across various benchmarks [24].

Due to AceGPT's advanced capabilities among Arabic LLMs, the development of InfectA-Chat followed a 2-stage pipeline based on the AceGPT structure (Figure 1). First, we used

XSL•FO
RenderX

instruction tuning on the AceGPT-7B and AceGPT-7B-Chat models [24] using the instruction-following dataset. The LoRA method was chosen for this stage, enabling PEFT to minimize computational cost while maintaining performance. This resulted in the creation of the InfectA-Chat (based on AceGPT-7B) and InfectA-Chat (based on AceGPT-7B-Chat) models. Following the instruction tuning, we conducted a comprehensive GPT-4 evaluation [42] to compare the performance of InfectA-Chat models (based on AceGPT-7B and AceGPT-7B-Chat) against each other, state-of-the-art models, and Arabic LLMs such as GPT-3.5 [43], GPT-4 [4], Gemini [44], AceGPT [24], and Jais [22]. During the GPT-4 evaluation, instruction-tuned models were assessed using English and Arabic real-world data pertaining to infectious diseases, reflecting actual outbreak information and other relevant details extracted from articles from the Center for Infectious Disease Research and Policy (CIDRAP) [45] platform. By prompting the GPT-4 model to compare the answers of comparison models with relevant queries and articles, GPT-4 evaluated the performance of models. To ensure the consistency and trustworthiness of the GPT-4 evaluation method, we also implemented variance analysis. In addition, to evaluate the generalizability of the best-performing InfectA-Chat model, we conducted cross-domain testing on an Arabic benchmark dataset, comparing it with other Arabic LLMs and state-of-the-art models. In the second stage, we leveraged the RAG [46] pipeline based on the superior InfectA-Chat model, which was identified in the GPT-4 evaluation. Applying RAG allowed us to update the model's data with the latest information in the infectious disease domain without requiring further instruction tuning while maintaining performance. This 2-stage approach empowered InfectA-Chat to effectively address the Q&A task within the infectious disease domain.

Figure 1. Modeling of InfectA-Chat. RAG: retrieval-augmented generation.



Data Collection and Preprocessing

Data preprocessing plays a vital role in training high-quality LLMs [12], especially when working with the limited structured data available on infectious diseases in English and Arabic. To address this gap, we conducted many steps to get high-quality Arabic and English instruction–following data. The overall pipeline of the data preprocessing flow is shown in Figure 2. As a first step, we selected CIDRAP [45] as our major data source due to its reputation for publishing timely and well-researched articles on infectious diseases. CIDRAP's information is both credible and extensive, with daily updates on growing health threats globally, making it a great foundation for our dataset. Given the challenges of sourcing accurate data on infectious diseases, CIDRAP's meticulous reporting and in-depth coverage were vital for our study. Therefore, we conducted web scraping to gather data from the CIDRAP website, focusing on the MENA (Middle East and North Africa) region, including 20 countries, with published dates between February 20, 2020, and February 20, 2024. This resulted in 2770 English articles collected from CIDRAP's website. Subsequently, we further enriched the articles by adding essential information, such as the country, title, and publication date of the article. The collected articles had varying lengths, some exceeding the maximum context length of InfectA-Chat, which is 2048. This posed a challenge because long articles could not be processed directly within the model. To tackle this limitation and enhance the dataset's usability, we implemented 2 summarization methods, GPT-3.5-Turbo [47] and Gensim [48]. We implemented 2 summarization methods as a more cost-effective alternative compared to relying solely on GPT-3.5-Turbo, which incurs application programming interface use costs. By incorporating a dual-approach strategy, we could streamline the summarization process, reducing the application programming interface cost while preserving the essential information in the summarized articles for model training. The first approach was summarization by using Gensim (RARE Technologies Ltd), a popular open-source Python toolkit that is well-suited for NLP tasks, such as text summarization. Gensim provides powerful summary algorithms that effectively condense

XSL•FO
RenderX

articles while retaining key information, allowing users to define a desired word count. In this phase, we established a word count that is consistent with the 2048-token limit, allowing us to efficiently summarize our collection of 2770 articles. The second approach used GPT-3.5-Turbo-0125, an autoregressive model known for providing high-quality text generation based on various tasks, including summarization. By prompting the GPT-3.5-Turbo-0125 model to produce summaries based on our specified token count, we were able to distill our collected articles effectively. Using both approaches, the articles were effectively summarized while retaining essential information, expanding their maximum context length to 2048. Given that we used 2 distinct summarization approaches, we are generating 2 types of summarized articles. Therefore, these 2 approaches not only addressed the context length limitation but also effectively augmented the data by leveraging their advanced text summarization capabilities.

Figure 2. The overall pipeline of data collection and preprocessing. Q&A: question and answer.

This study focused on building an instruction-following dataset based on a Q&A task. To generate Q&A pairs from summarized articles, we used the GPT-3.5-Turbo-0125 model, generating 5 high-quality Q&A pairs per summarized article. During the Q&A generation process, we particularly instructed the model to generate Q&A pairs that are explicit and directly related to the context and to include date information in the questions by avoiding ambiguous phrases, such as “last week,” “over the past week,” and “this year.” Therefore, we built an English instruction–following dataset that contains 27,700 Q&A pairs based on each summarized article as shown in Textbox 1. Textbox 1 presents the example of English and Arabic instruction–following data with their translation. Because there is a lack of Arabic data in the domain of infectious diseases, we needed to translate our English instruction–following data into Arabic. To generate an Arabic instruction–following dataset, we used the GPT-3.5-Turbo-0125 model to translate all the English instruction–following data into Arabic. As a final step, we concatenated the English and Arabic instruction–following datasets, yielding 55,400 Q&A pairs with a token size of 54.5B, based on the AceGPT-7B-Chat tokenizer. We used the original vocabulary of the AceGPT-7B model, which has a size of 32,000 tokens and contains 53 Arabic letters. The 55,400 generated instruction-following data points, which reflect real-world information about infectious diseases, were divided into training, validation, and test datasets in proportions of 90%, 5%, and 5%, respectively.

Textbox 1. Example of English and Arabic instruction–following data.

English instruction–following data

Below is an instruction that describes Q&A task. Write a response to complete the request appropriately.

Instruction: How many patients were reported with MERSCoV cases in Saudi Arabia between December 29, 2021, and October 31, 2022?

Title: WHO details 4 more MERS cases in Saudi Arabia

Date: November 17, 2022

Country: Saudi Arabia

Source: “https://www.cidrap.umn.edu/mers-cov/who-details-4-more-mers-cases-saudi-arabia”

Contents: The World Health Organization (WHO) yesterday posted an update on Middle East respiratory syndrome coronavirus (MERS-CoV) in Saudi Arabia that covers 4 cases reported by the country since the WHO’s last update in April. Three of the patients had recent contact with camels. No secondary cases were reported, and none were fatal. The WHO said the 4 MERS-CoV cases were reported between December 29, 2021, and October 31, 2022. Symptom onset ranged from December 27 to June. All patients—3 men and a woman, were aged 23 to 68 years and were not health care workers. All had underlying conditions and were hospitalized. The men had contact with camels and had consumed camel milk. The agriculture ministry’s related investigations identified the virus in camels in those 3 instances. So far, the source of virus exposure for the woman aged 23 years is not known. Two patients are from Riyadh province, from the cities Afif and Al Kharj. The others are from Mecca in Mecca province and Buridah in Al Qassim province. The WHO noted that the number of MERS-CoV cases has declined since the start of the COVID-19 pandemic, likely due to health officials prioritizing COVID-19 activities. In addition, the WHO said COVID-19 protective measures may have reduced MERS-CoV transmission. However, the WHO said MERS-CoV circulation continued in dromedary camels and that the zoonotic threat remains. The WHO said the latest cases from Saudi Arabia lift the global total since September 2012 to 2600 cases, 935 of them fatal.

Response: In February, Saudi Arabia reported 18 MERS-CoV cases, with 5 of them being fatal, from 9 different cities.

Arabic instruction–following data

Below is an instruction that describes Q&A task. Write a response to complete the request appropriately.

Instruction:

Title: 25 2020

Date: 25 2020

Country:

Source: “https://www.cidrap.umn.edu/salmonella/news-scan-sep-25-2020”

Contents: 41 10 Wismettac Asian Foods. 2013 2017 . . .

Response: .

English version: Below is an instruction that describes Q&A task. Write a response to complete the request appropriately.

Instruction: Which countries were mentioned to have reported more polio cases, and which country reported its first vaccine-derived cases?

Title: News Scan for September 25, 2020

Date: September 25, 2020

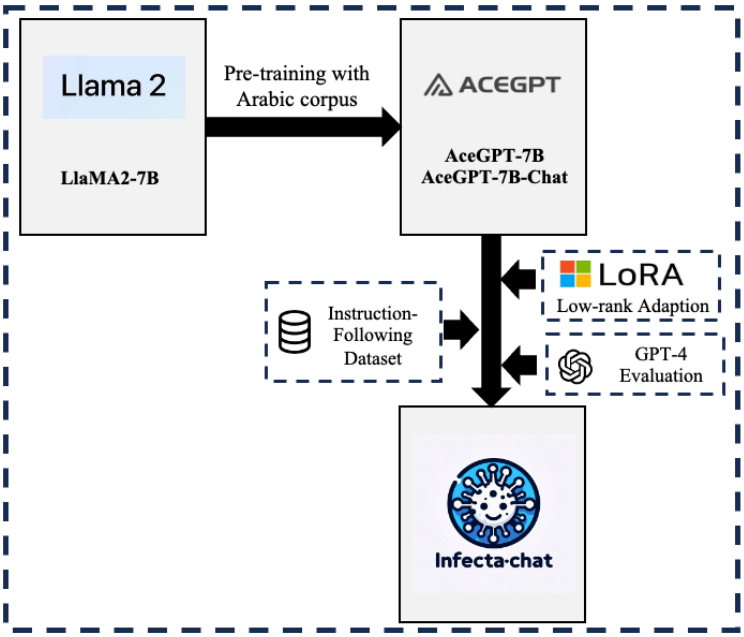
Country: Sudan

Source: “https://www.cidrap.umn.edu/salmonella/news-scan-sep-25-2020”

Contents: A Salmonella outbreak linked to dried mushrooms in dishes served at ramen restaurants has affected 41 people in 10 states, with the likely source traced to wood ear mushrooms distributed by Wismettac Asian Foods. In Australia, antibiotic use has shown a decline from 201,314 to 201,718, though still higher compared to countries like the Netherlands and Sweden. Efforts to optimize antibiotic prescribing continue. In addition, 5 countries reported more polio cases, with South Sudan reporting its first vaccine-derived cases.

Response: Five countries reported more polio cases, with South Sudan reporting its first vaccine-linked case

Supervised Fine-Tuning (Instruction Tuning)



Pretrained LLMs often struggle to effectively track user instructions and may generate inadequate output based on given instructions. This limitation stems from their primary goal, which is predicting the next token rather than generating output directly in response to the given instruction, as described in equation 1; the loss of pretraining L_{PT} is updated with the next token prediction based on the pretraining dataset D_{PT} [12].

To overcome this challenge, the supervised fine-tuning, also known as instruction tuning method, is often used, which allows pretrained LLMs to be adapted to a specific task using instruction-following data. The instruction tuning method consists of a prompting model with instructions, which are encapsulated by a prompt template. The model is then trained by using given instructions and generates the proper output. In

XSL•FO
RenderX

this study, we applied instruction tuning on the AceGPT-7B and AceGPT-7B-Chat models using Arabic and English instruction–following data as shown in Figure 3. Our instruction-following dataset follows a format that is similar to the Alpaca dataset [49], where each data point contains an instruction and output. The template for fine-tuning is shown in Textbox 2.

Figure 3. The overall pipeline of supervised fine-tuning (instruction tuning).

Textbox 2. Prompting template of instruction tuning.

"Below is an instruction that describes Q&A task. Write a response to complete the request appropriately.

Instruction: {question}\n {Title: title, Date: date, Country: country, Source: source, Contents: article}

Response:"

In our instruction-following dataset, the prompt template's instruction part combines both a question and an article, distinguished by "\n," which differs from the structure of the Alpaca dataset. Admittedly, we enhanced the dataset by including important details for articles, such as title, publication date, country, and source alongside the main context of the article. This also helped with accurate article retrieval during the application of RAG.

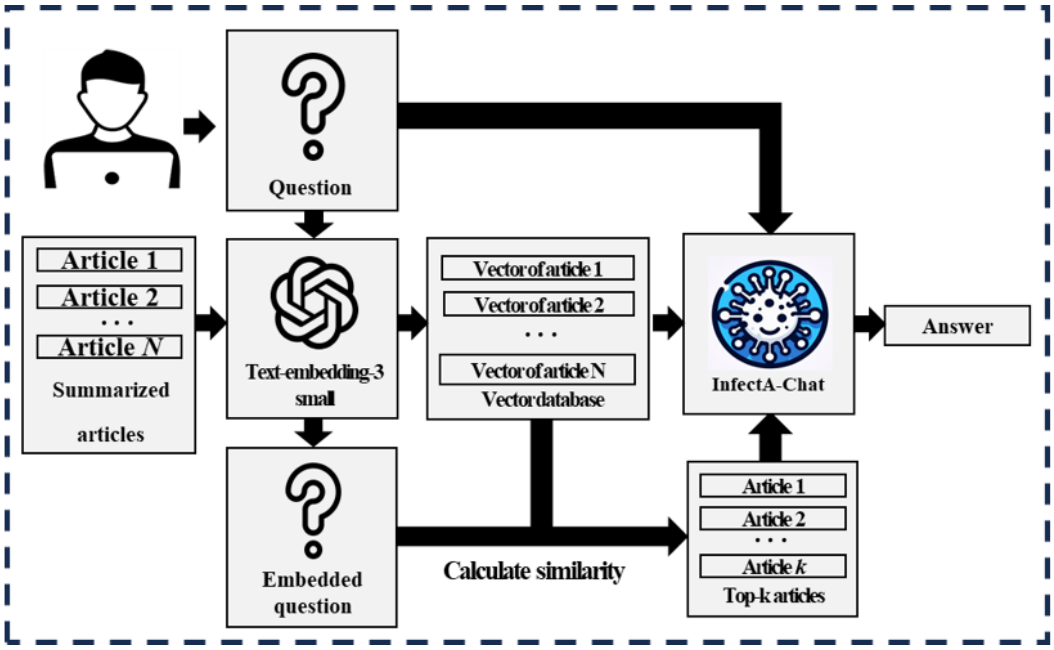
During traditional training, all parameters of LLMs are often updated, which is not cost-effective and takes a lot of time [12]. To tackle this, PEFT methods are generally applied during the process of fine-tuning, such as prefix tuning, adapter tuning, and LoRA, which have been recently studied as representative PEFT methods. Among the 3 representative PEFT models, prefix tuning offers limited performance with no added latency, while adapter tuning prioritizes performance at the cost of increased latency [50]. In addition, prefix tuning is difficult to optimize, as the training process can be unstable due to nonmonotonic changes in training loss [40].

Compared to other methods, LoRA reduces computation by applying, as its name implies, "low-rank adaptation" weights to the query and key operations of the attention module. The feed-forward operation remains the same as in general attention modules, while the backward operation uses low-rank weights to perform calculations for each layer. This entails mapping to a smaller dimension, applying nonlinear activation, and then returning to the original dimension size. LoRA emerges as the most attractive solution for PEFT in LLMs due to its superior mix of performance, efficiency, and latency. Therefore, in this study, we use LoRA during the fine-tuning of the AceGPT-7B and AceGPT-7B-Chat models by integrating LoRA adapters into the weights of the multilayer perceptron layers and attention modules. The application of LoRA to all linear transformer blocks has been confirmed in quantized LoRA [12,51].

During the fine-tuning process, the loss is only calculated on the {output} part of the input sequence and can be expressed as shown in equation 2. In this equation, L_{SFT} represents loss of instruction tuning. Θ represents the model parameters, while D_{SFT} is the fine-tuning dataset; $x=(x_0, x_1, ...)$ represents the tokenized input sentence [12].

RAG Based on InfectA-Chat

For building domain-specific LLMs like InfectA-Chat, instruction tuning has emerged as a highly effective method, demonstrating impressive results in tasks such as Q&A. However, instruction tuning LLMs for specific tasks has various limitations that can hinder their effectiveness. Instruction tuning mostly relies on the quality and quantity of training data. In



XSL•FO
RenderX

addition, fine-tuned LLMs may struggle to generate factually correct and contextually relevant responses, particularly when the training data are limited, known as "hallucinations." Especially in domains such as infectious diseases, where up-to-date information is crucial for accurate monitoring, repeatedly applying instruction tuning to new datasets becomes impractical due to time and resource constraints. RAG [46] provides a convincing method that complements instruction tuning while resolving its limitations. RAG uses the power of accessing a wide external knowledge base to generate text for a query. This allows RAG to gather relevant information specific to the prompt, yielding more informative and accurate outputs.

RAG typically consists of 2 main components: a retriever and a generator. The retriever first identifies relevant documents or information from the external knowledge source based on the input prompt. The retrieved information is then passed on to the generator, which is often a fine-tuned LLM. The generator produces the final result by combining both the retrieved information and its own internal knowledge to produce the final output. RAG prioritizes article quality. To enable more accurate retrieval, essential information, such as country, title, source, and published date, was included in the main content of the article.

The overall pipeline of RAG is depicted in Figure 4. Initially, summarized articles were embedded using text-embedding-3-small model [52]. When a user query was received, it was embedded as a vector by the text-embedding-3-small model, which calculates the similarity between a user query and the vector database of summarized news articles. As a similarity metric, the cosine similarity was used. Following the similarity calculation, the top-k articles were selected and sent to InfectA-Chat along with the query. Top-k refers to the specified number of articles that have a high correlation with the query and are set by the developer during the RAG process. Once the RAG pipeline recalls the highly correlated articles with the query, the model can generate an answer based on the selected top-k articles and the query. By using RAG, the model can provide more factually and contextually accurate answers.

Figure 4. The overall pipeline of Retrieval-Augmented Generation.

Our goals included not only preventing hallucinations when applying RAG but also avoiding the need for repeated instruction tuning when updating InfectA-Chat's data. To demonstrate the necessity of the RAG pipeline for updating InfectA-Chat's data, we prepared 50 instruction-following data points with published dates from March to June 2024, ensuring that they were not part of the original InfectA-Chat training data. During the recent data preparation, we specifically emphasized the importance of including the date in the questions. We applied the RAG pipeline using these recent 50 instruction-following data to InfectA-Chat, GPT-3.5, and GPT-4, using GPT-4 evaluation for a comprehensive comparison.

In addition, we investigated the impact of the top-k parameter on information retrieval within the RAG framework. Specifically, we compared the retrieval performance using top-1, top-3, and top-5 settings in the RAG process.

Ethical Considerations

This study used publicly available data sourced from the CIDRAP. The preprocessing steps ensured that the data protects the individual's privacy. Due to these factors, no ethics review was required. All analyses and findings are presented in alignment with the standards set by *JMIR Medical Informatics* and aim to contribute to the field of infectious disease research without compromising ethical norms.

Results

Experimental Setup

LLM training represents a significant engineering problem. Due to the enormous number of the model parameters, a large-scale distributed training framework is required, allowing the use of several graphics process units (GPUs) across numerous

XSL•FO
RenderX

processing nodes. The InfectA-Chat models were trained with a total of 4 Nvidia A100 80GB GPUs on 2 nodes, provided by the Korea Institute of Science and Technology Information. To leverage complementary parallelism for faster and more memory-efficient training, we used the DeepSpeed framework during instruction tuning. DeepSpeed [53] is a robust open-source library that optimizes deep learning training for *PyTorch* by reducing memory use and increasing training efficiency. It solves the issues of training LLMs on restricted hardware by using approaches, such as Zero Redundancy Optimizer, which distributes model parameters and gradients over numerous processors, significantly reducing memory footprint. In this study, Zero Redundancy Optimizer stage 2 was applied, enabling the distribution of optimizer states and gradients across GPUs, thereby facilitating efficient large-scale training.

Instruction tuning was performed using 49,860 instruction-following data points, containing 49 million tokens, each for 2 models: AceGPT-7B and AceGPT-7B-Chat, while validation and test datasets comprised 2770 instruction-following data points, containing 2.8 and 2.7 million tokens, respectively. All models were trained with a batch size of 12 per device, resulting in a total batch size of 1296. The AdamW optimizer was used, using a cosine learning rate scheduler with a warmup ratio of 0.03% of steps and a peak learning rate of 0.0001. A weight decay of 0.01 was applied along with a maximum sequence length of 2048 as well as a gradient accumulation of 27. In addition, all models included LoRA with a rank of 64, an α of 128, weights of Q, K, V, O, and multilayer perceptron, and a dropout rate of 0.05. The hyperparameters of instruction tuning of both AceGPT-7B and AceGPT-7B-Chat models are listed in detail in Table 1 [12]. Following instruction tuning, a comprehensive comparison analysis was conducted to evaluate each model's performance. Using GPT-4 evaluation, an advanced model published by OpenAI, renowned for its state-of-the-art performance in text generation among LLMs, provided a robust assessment. By using an evaluation prompt, GPT-4 systematically evaluated the models by comparing their responses to specific questions and articles (Textbox 3). The comparison analysis was performed in 3 distinct phases.

Table 1. Hyperparameters.

Base model	AceGPT-7B	AceGPT-7B-Chat
Vocabulary size (tokenizer)	32,000 (AceGPT-7B)	32,000 (AceGPT-7B-Chat)
Training dataset	49,860 (49 million tokens)	49,860 (49 million tokens)
Validation dataset	2770 (2.8 million tokens)	2770 (2.8 million tokens)
Test dataset	2770 (2.7 million tokens)	2770 (2.7 million tokens)
GPU[a]	Nvidia A100×4	Nvidia A100×4
Batch size per device	12	12
Training time per 1 step	846.42 s	846.42 s
Gradient accumulation	27	27
Total batch size	48	48
DeepSpeed	Zero stage 2	Zero stage 2
Epoch (steps)	3 (115)	3 (115)
Learning rate scheduler	Cosine	Cosine
Warmup ratio (% of steps)	0.03	0.03
Peak learning rate	0.0001	0.0001
Optimizer	AdamW	AdamW
Weight decay	0.01	0.01
Maximum sequence length	2048	2048
Data type	float32	float32
LoRA[b] rank	64	64
LoRA α	128	128
LoRA weights	Query, key, value, output, MLP[c]	Query, key, value, output, MLP
LoRA dropout	0.05	0.05

Textbox 3. Prompting template for GPT-4 evaluation.

You are a super-intelligent AI assistant.

question: {question}

context: {Title: title, Date: date, Country: country, Source: source, Contents: article}

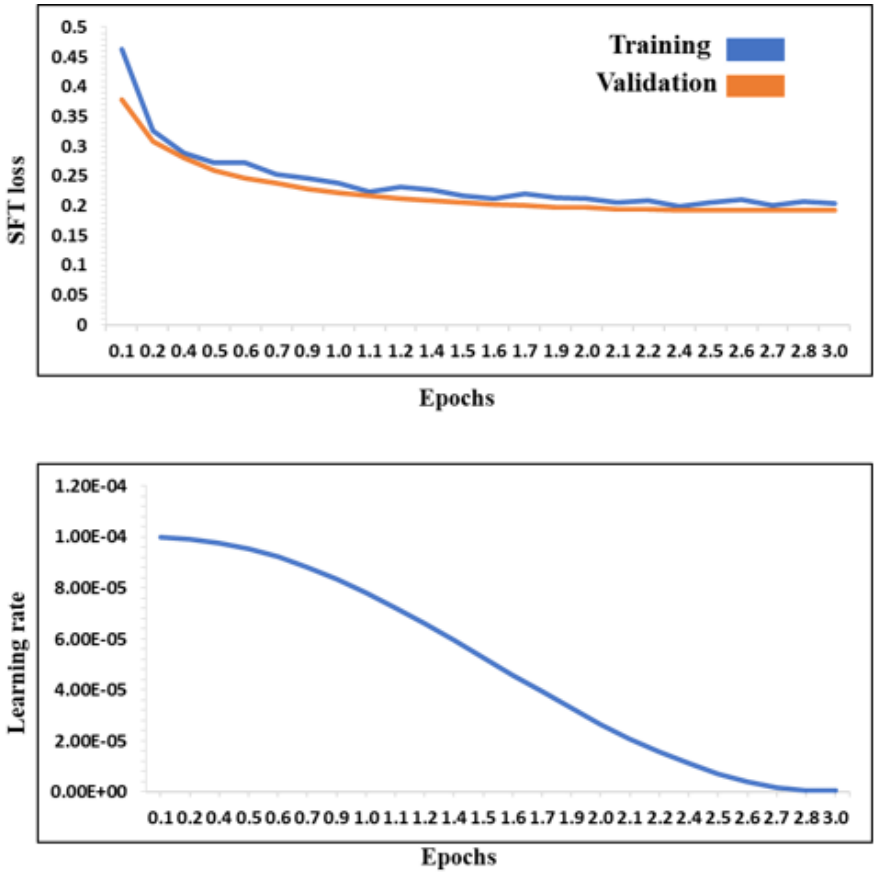
Considering the context provided, determine which answer is the best answer for the given question and context. The answer should point out the what the question requires. You must choose only one among options below.

* Answer A

* Answer B

* Answer C

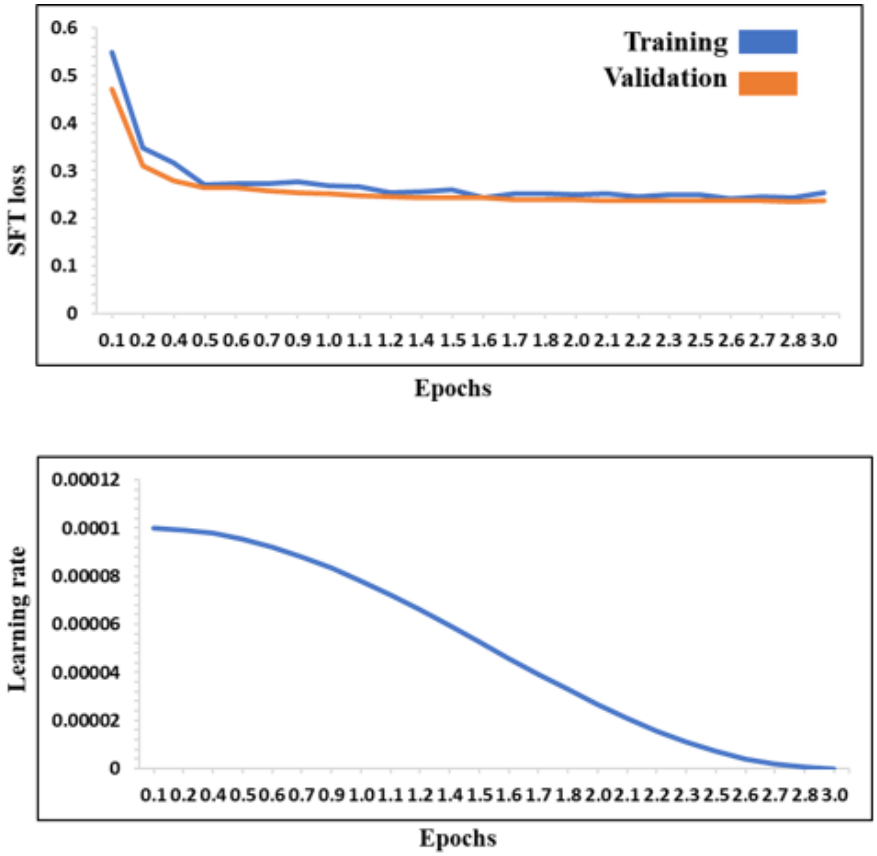
* Answer N



Initially, GPT-4 evaluation was used to assess the performance of AceGPT-7B-Chat, InfectA-Chat (based on AceGPT-7B), and InfectA-Chat (based on AceGPT-7B-Chat). Subsequently, the model demonstrating superior performance in the first phase underwent evaluation against Arabic LLMs, including Jais-13B-Chat and AceGPT-13B-Chat, in the second phase. Finally, building upon the results of the second phase, the selected model was evaluated against state-of-the-art LLMs, such as GPT-3.5, GPT-4, and Gemini, in the last phase. Furthermore, to assess the generalizability of the superior model from the InfectA-Chat suite (comprising AceGPT-7B and AceGPT-7B-Chat), we extended our evaluation beyond the infectious disease domain. We used a broad dataset built for tasks that required common-sense reasoning and Q&A skills. This cross-domain testing enabled us to assess the model's capacity to use its learned information and reasoning skills in a broader environment, offering vital insights into its overall robustness and adaptability. This enabled a full evaluation of model performances.

Experimental Result

Overview



We present the training progress for the InfectA-Chat models (based on AceGPT-7B and AceGPT-7B-Chat), which are visualized in Figures 5 and 6, respectively. Both figures depict a learning rate starting at 0.0001 and gradually decreasing due to the learning rate scheduler used for optimizing convergence. The loss curves in both figures reveal a steady decrease, demonstrating both models effectively learned from the training data and generalized well to unseen data.

Figure 5. Training progress of AceGPT-7B–based InfectA-Chat (training loss, validation loss, and learning rate). SFT: supervised fine-tuning.

RenderX

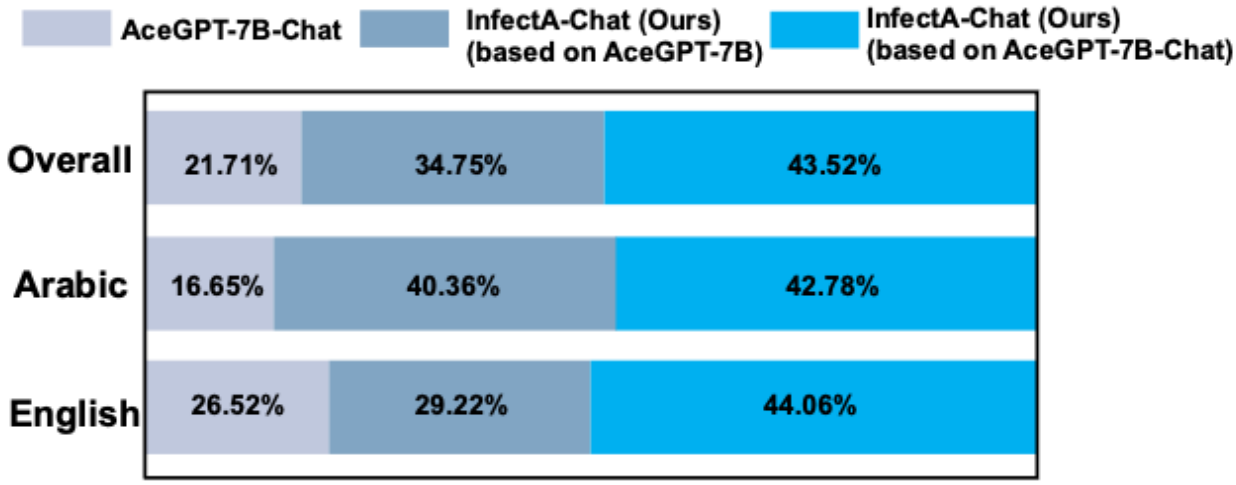

Figure 6. Training progress of AceGPT-7B-Chat–based InfectA-Chat (training loss, validation loss, and learning rate). SFT: supervised fine-tuning.

Performance Comparison of InfectA-Chat in the Infectious Disease Domain

The results of qualitative performance comparisons were conducted across 3 phases using GPT-4 (Figures 7-9). The decision to exclude base models among Arabic LLMs during GPT-4 evaluation was motivated by the number of errors observed in the base models. During the GPT-4 evaluation on AceGPT-7B, 102 errors occurred. In terms of AceGPT-13B and Jais-13B evaluation process, 41 and 669 errors occurred, respectively. Due to the generation of improper answers, GPT-4 could not process during the evaluation. The inclusion of the AceGPT-7B, AceGPT-13B, and Jais-13B models in the comparison study may have a negative impact on the performance analysis's accuracy. Therefore, these 3 base models were omitted from the GPT-4 evaluation to enable a more accurate assessment of model performance. The performance results represent the average accuracy of the 5-step GPT-4 evaluation, which is depicted in Table 2.

Figure 7. Qualitative performance comparison for AceGPT-7B-Chat, AceGPT-7B–based InfectA-Chat (ours), and AceGPT-7B-Chat–based InfectA-Chat (ours) by GPT-4 evaluation.

RenderX

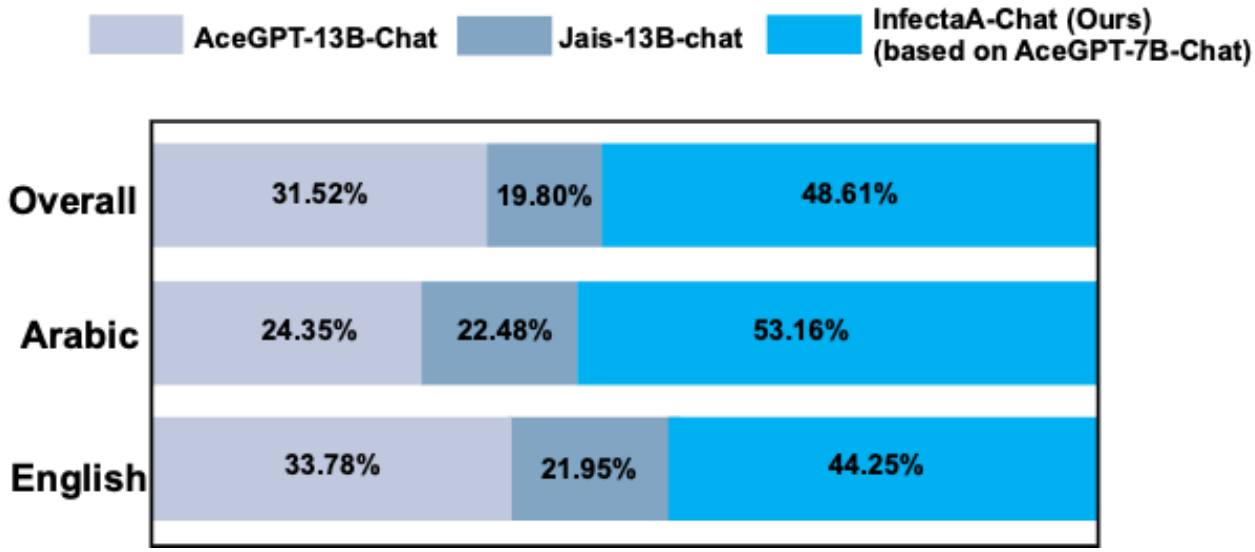

Table 2. Qualitative performance analysis of 5-step GPT-4 evaluation process.

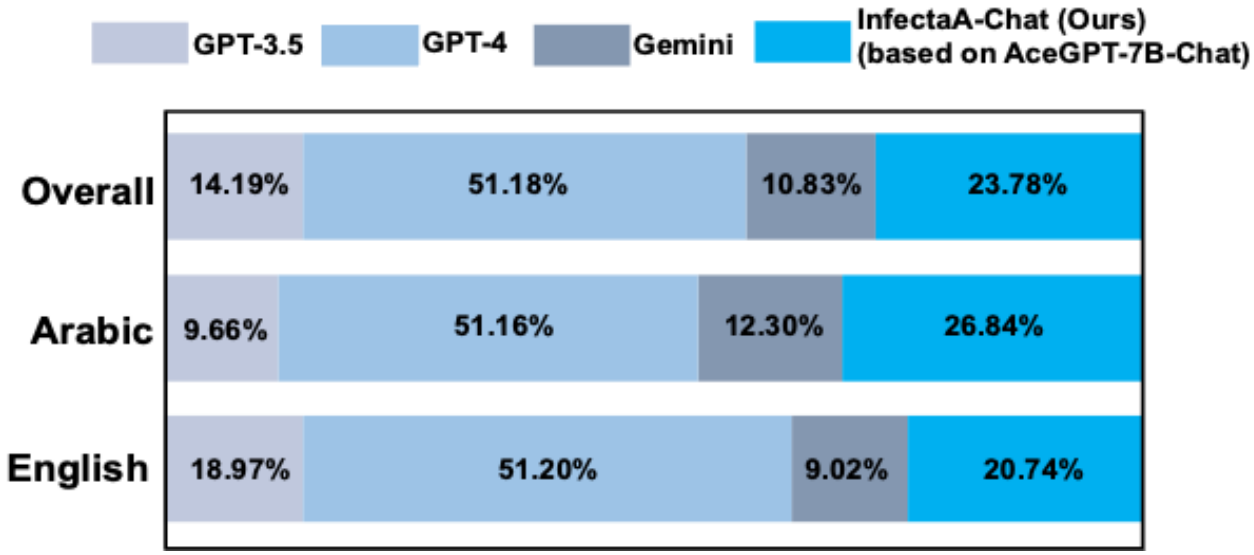
Evaluation phases and models	Accuracy					
	Step 1	Step 2	Step 3	Step 4	Step 5	Mean (SD)
Phase 1 (%)						
InfectA-Chat (based on AceGPT-7B-Chat)	43.86	43.93	42.77	43.61	43.46	43.52 (0.46)
InfectA-Chat (based on AceGPT-7B)	34.99	34.22	35.66	34.51	34.40	34.75 (0.58)
AceGPT-7B-Chat	21.15	21.85	21.57	21.88	22.12	21.71 (0.37)
Phase 2 (%)						
InfectA-Chat (based on AceGPT-7B-Chat)	47.44	51.27	50.37	46.53	47.76	48.61 (0.20)
AceGPT-13B-Chat	32.35	31.37	31.22	32.82	29.86	31.52 (0.11)
Jais-13B-Chat	20.21	17.36	18.41	20.65	22.38	19.8 (0.19)
Phase 3 (%)						
InfectA-Chat (based on AceGPT-7B-Chat)	24.08	23.21	23.93	24.33	23.36	23.78 (0.47)
Gemini	10.43	11.12	10.76	10.52	11.33	10.83 (0.38)
GPT-3.5-Turbo	14	13.54	14.56	14.18	14.70	14.19 (0.46)
GPT-4	51.49	52.13	50.76	50.97	50.61	51.18 (0.62)

In the initial phase, InfectA-Chat (based on AceGPT-7B-Chat) demonstrated superior performance compared to AceGPT-7B-Chat and InfectA-Chat (based on AceGPT-7B), achieving an accuracy of 43.52% on the overall instruction-following dataset (Figure 7). Notably, for English and Arabic instruction–following data, InfectA-Chat (based on AceGPT-7B-Chat) surpassed other models, achieving performance rates of 44.06% on 614 of 1393 English test cases and 42.78% on 589 of 1377 Arabic test cases, respectively. In addition, the performance gap between AceGPT-7B-Chat and InfectA-Chat (based on AceGPT-7B-Chat) can also be observed in their answers to Arabic and English queries (Multimedia Appendix 1).

In comparison to other Arabic LLMs such as AceGPT-13B-Chat and Jais-13B-Chat, InfectA-Chat (based on AceGPT-7B-Chat) showed better performance, achieving an overall performance rate of 48.61% on 1346 of 2770 overall test cases in the instruction-following dataset (Figure 8). Particularly, its performance in English and Arabic instruction–following data, where InfectA-Chat (based on AceGPT-7B-Chat) surpassed other models, achieving rates of 44.25% (616/1393 English test cases) and 53.16% (732/1377 Arabic test cases), respectively. These results prove the capability of InfectA-Chat (based on AceGPT-7B-Chat) not only to outperform similar-scale Arabic LLMs but also to compete favorably against larger models with up to 13 billion parameters.

Figure 8. Qualitative performance comparison for AceGPT-13B-Chat, Jais-13B-Chat, and AceGPT-7B-Chat–based InfectA-Chat (ours) by GPT-4 evaluation.



As the final step, in addition to comparing with open-source Arabic LLMs, the InfectA-Chat (based on AceGPT-7B-Chat) model was evaluated against state-of-the-art closed-source models, including GPT-3.5, GPT-4, and Gemini (Figure 9). These comparisons revealed that the InfectA-Chat (based on AceGPT-7B-Chat) model substantially outperformed GPT-3.5

XSL•FO
RenderX

and Gemini, achieving a performance rate of 23.78% on 656 of 2770 test cases while competing closely with the GPT-4 models, which attained a performance rate of 51.18% (1417/2770 test cases) against other models. This highlights the competitive edge of InfectA-Chat (based on AceGPT-7B-Chat) against top-tier closed-source models in the field of infectious diseases.

Figure 9. Qualitative performance comparison for InfectA-Chat (ours), GPT-4, GPT-3.5, and Gemini.

As demonstrated, we used GPT-4 as an evaluation metric. However, since GPT-4 can show variability during generating answers based on our prompts, we used SD to ensure the trustworthiness of this evaluation method. To do that, we applied GPT-4 evaluation 5 times to our 3-step evaluation process and we compared each model's accuracy in each evaluation step and observed their SD. The further details of this analysis are depicted in Table 2.

As we can see in the SD results from Table 2, the SD of each model in each phase is quite low. This proves the consistency of our GPT-4 evaluation method that reflects our comparison model's performance.

Performance Comparison of InfectA-Chat in the General Domain

To evaluate the generalizability of the best-performing InfectA-Chat model (based on AceGPT-7B-Chat), we conducted cross-domain testing on the Arabic Massive Multitask Language Understanding (MMLU) [54] benchmark (Table 3). This dataset assesses common-sense reasoning and Q&A capabilities, crucial for tasks beyond the infectious disease domain. The Arabic MMLU dataset comprises 40 tasks and 14,575 multiple-choice questions in Modern Standard Arabic, meticulously constructed in collaboration with native Arabic speakers. This dataset covers a wide range of subjects, including science, technology, engineering, and mathematics (STEM); social sciences; humanities; and others, ensuring its relevance as a source of common-sense knowledge. The questions are designed to assess a spectrum of knowledge levels, from primary education to university-level understanding. Because the dataset is specifically tailored to evaluate models' real-world knowledge, we chose to use the Arabic MMLU dataset to assess our model's performance on practical data. We evaluated InfectA-Chat and other models' performance in a multiple-choice Q&A task in 4 different domains, such as STEM, humanities, social sciences, and others, as reflected in Table 3. In the STEM domain, InfectA-Chat achieved a performance score of 40.84% on 1315 of 3220 STEM data, outperforming the LLaMA models (LLaMA-7B and LLaMA-13B) as well as the Jais base models (Jais-13B and Jais-30B) and Bloomz. Its performance was on par with that of the more advanced AceGPT chat models (AceGPT-7B-Chat and AceGPT-13B-Chat), Jais chat models (Jais-13B-Chat and Jais-30B-v3-Chat), and GPT-3.5-Turbo, indicating its strong capabilities in technical subjects. In the humanities domain, InfectA-Chat scored 46.94% on 1715 of 3655 humanities data, demonstrating higher accuracy than LLaMA models, Bloomz, Jais base models, AceGPT base models, and GPT-3.5-Turbo. Its results closely approach those of the AceGPT chat models (48.54% for AceGPT-7B-Chat and 50.91% for AceGPT-13B-Chat, with the following 1774 and 1861 data points out of 3655) as well as the Jais chat models. In the social sciences and other general domains, InfectA-Chat achieved scores of 45.58% (1613/3540 social sciences-related data) and 49.48% (1751/3540 general domain data), respectively, surpassing LLaMA models, AceGPT base models, Bloomz, and Jais base models. Instruction tuning is one of the primary factors limiting the generalizability of InfectA-Chat. Despite this, our model, which is specifically focused on the infectious diseases domain, demonstrates performance comparable to that of the AceGPT and Jais chat models, highlighting its adaptability and strong performance across a wide range of disciplines. On average, across 4 domains, InfectA-Chat achieved a strong overall score of 45.71% on 6662 of 14,575 general domain data, positioning it competitively among large multilingual models such as Bloomz (34.53% of 14,575 data), LLaMA-7B (30.78% of 14,575 data), and LLaMA-13B (37.27% of 14,575 data). Notably, InfectA-Chat outperformed leading Arabic pretrained models, such as AceGPT-13B and the Jais-series base models (Jais-13B-base and Jais-30B-base), with a performance gap ranging from 2.99% to 12.28% of 14,575 data. This suggests that InfectA-Chat is especially effective at handling common-sense multiple-choice

XSL•FO
RenderX

Q&A tasks compared to other prominent Arabic models. Its performance also closely approaches that of instruction-tuned models such as AceGPT-7B-Chat (47.58% performance rate on 6934/14,575 data) and AceGPT-13B-Chat (50.81% performance rate on 7405/14,575 data) while remaining competitive against advanced Jais-series chat models (Jais-13B-Chat and Jais-30B-v3-Chat), which scored between 55.11% and 61.14% of 14,575 data, respectively. This underscores InfectA-Chat's significant performance not only in the domain of infectious diseases but also in real-world common-sense data, outperforming both English and Arabic base models while maintaining competitive results with a small performance gap with Arabic chat models.

Table 3. The results of testing Arabic large language models on the Arabic Massive Multitask Language Understanding benchmark dataset (accuracy).

Model	Mean (%)	STEM[a] (%)	Humanities (%)	Social sciences (%)	Others (%)
Bloomz	34.53	33.35	29.29	37.58	34.53
LLaMA2-7B	30.78	30.30	29.33	27.46	30.78
LLaMA2-13B	37.27	32.94	32.30	33.42	37.27
Jais-13B-based	33.43	30.51	31.25	33.74	33.43
Jais-30B-based	39.60	32.67	30.67	42.13	39.60
AceGPT-7B-based	34.42	29.73	30.95	33.45	34.42
AceGPT-13B-based	42.72	36.60	38.74	43.76	42.72
AceGPT-7B-Chat	47.58	42.41	48.54	47.03	52.33
AceGPT-13B-Chat	50.81	47.10	50.91	50.97	54.27
Jais-13b-Chat	55.11	49.98	56.73	54.05	59.66
Jais-30b-v3-Chat	61.14	54.59	63.45	59.10	67.43
GPT-3.5-Turbo	49.07	43.38	44.12	55.57	53.21
InfectA-Chat	45.71	40.84	46.94	45.58	49.48

Advanced InfectA-Chat Performance With RAG Pipeline

Traditionally, recurrent fine-tuning of models with additional data incurs significant time and computational costs, making it an inefficient strategy. To address this issue, the implementation of the RAG pipeline is critical. In our study, we validated the necessity by applying the RAG pipeline to InfectA-Chat alongside cutting-edge models such as GPT-3.5 and GPT-4, using a set of 50 recent instruction-following data. The results illustrated the efficacy of the RAG pipeline when incorporating recent data (Figure 10). The results in Figure 10 were obtained by averaging the inference accuracy of each model across 5 runs in English and Arabic data to prove the consistency of model performances. Across all datasets, InfectA-Chat exhibited a remarkable performance of 90.08% on 45 of 50 RAG test data, with an SD of 1.7%. Particularly in the Arabic dataset, InfectA-Chat demonstrated superior performance at 86.4% (43/50 RAG test data), and in the English dataset, it excels at 96% on 48 of 50 RAG test data, outperforming both GPT-3.5 and GPT-4 models, which have SD of 0.8% (4/50 RAG test data) and 0.16% (8/50 RAG test data), respectively. These findings highlight the capacity of RAG to obviate the need for repetitive instruction tuning by integrating the model with up-to-date information, particularly crucial in domains such as public health and infectious diseases.

Following the results of the RAG pipeline with the up-to-date dataset, to delve deeper into the influence of information retrieval on factual language models like InfectA-Chat, we investigated the impact of the top-k parameter within the RAG pipeline. This parameter controls the number of top-ranked documents passed from the retrieval stage to the generation stage. Our experiments with RAG using top-1, top-3, and top-5 settings demonstrated a positive relationship between increasing the top-k value and the accuracy of retrieval (Figure 11).

This implied that exposing InfectA-Chat to a greater range of potentially relevant information during retrieval can considerably improve its factual language modeling capabilities. As observed, this translated to a substantial performance improvement for InfectA-Chat, with an accuracy of 80.05% on 40 of 50 RAG test data, achieved using the top-5 parameter compared to the top-1.

Discussion

In conclusion, the critical need for real-time disease monitoring, particularly in regions like the Middle East, has exposed a gap in accessible, multilingual resources. Regional public health agencies, such as the US Centers for Disease Control and Prevention [55] and the Chinese Center for Disease Control and Prevention [56], play an important role in protecting public health by conducting research and offering disease surveillance and prevention programs in their regions. In addition, there has been a rise in innovative platforms providing daily alerts, such as the CIDRAP [45] and the Program for Monitoring Emerging Diseases [57]. Apart from these platforms, with the rise of LLMs, LLMs started to play a role in delivering information in various domains, including infectious disease tracking. Given our focus on Arabic-speaking countries within the MENA region, there remain a limited number of Arabic language models specifically tailored for the medical and public health domains. While the development of medical LLMs is expanding globally, only a few models, such as BiMediX [38] and Apollo [39], have been created with a focus on Arabic language capabilities. Although these models are valuable for supporting societal and medical initiatives, they still face limitations, especially in monitoring infectious diseases, due to the limited

XSL•FO
RenderX

availability of infectious disease surveillance data for training. InfectA-Chat addresses this challenge by delivering up-to-date information on infectious diseases in both Arabic and English. Moreover, the exceptional performance of InfectA-Chat in handling instruction-following data in Q&A tasks across languages sets a new standard in the field of infectious disease monitoring. By leveraging the power of LLMs, InfectA-Chat positions itself as a pioneer for bridging the information gap and promoting public health awareness compared to other existing LLMs. However, even though InfectA-Chat has significant performance, it still shows limitations itself.

First, while InfectA-Chat demonstrates significant performance in Arabic and English understanding, it may still face challenges due to limited computing resources and data availability. The limitation in the amount of data available in English and Arabic in the field of infectious diseases create a barrier to the model's performance. In addition, because the training of LLMs requires more computational resources, such as GPUs, this would make the development process faster and more efficient. Due to our limited computational resources, the process becomes slower, restricting us to using smaller model sizes. As the accessibility of computational resources and instruction-following data continue to grow, InfectA-Chat can achieve greater performance.

Second, in some scenarios, the model may generate inconsistent answers based on the given questions, such as incorrect information about specific diseases, known as the hallucination problem. Although this issue was mitigated by implementing a RAG pipeline, InfectA-Chat may still exhibit a small likelihood of hallucination. Applying RAG with a larger volume of data could further reduce the hallucination rate to nearly 0.

Future work efforts should focus on mitigating these limitations to unlock the potential of InfectA-Chat. With larger datasets and more computational resources, the performance of InfectA-Chat can be increased. In addition, we will focus on how to improve the performance of our model in the general domain by mitigating the disadvantages of instruction tuning. We aim to establish InfectA-Chat as a truly transformative tool in the fight against infectious diseases by enhancing our target regions and obtaining massive data in different languages.

Acknowledgments

This research was supported by the Korea Institute of Science and Technology Information (KISTI; K24L4M2C6). This research was also financially supported by the Government-wide Research and Development Fund project for infectious disease research, Republic of Korea, in the form of a grant (HG23C1624). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript. The authors are grateful to all members of this project for their invaluable contributions. The authors particularly extend their thanks to Dr Donghun Yang at KISTI for his crucial support in giving ideas and supporting the resolution of errors during training. Their expertise and dedication were important during the development of InfectA-Chat.

Abstract

Background: The recent introduction of generative artificial intelligence (AI) as an interactive consultant has sparked interest in evaluating its applicability in medical discussions and consultations, particularly within the domain of depression.

Objective: This study evaluates the capability of large language models (LLMs) in AI to generate responses to depression-related queries.

Methods: Using the PubMedQA and QuoraQA data sets, we compared various LLMs, including BioGPT, PMC-LLaMA, GPT-3.5, and Llama2, and measured the similarity between the generated and original answers.

Results: The latest general LLMs, GPT-3.5 and Llama2, exhibited superior performance, particularly in generating responses to medical inquiries from the PubMedQA data set.

Conclusions: Considering the rapid advancements in LLM development in recent years, it is hypothesized that version upgrades of general LLMs offer greater potential for enhancing their ability to generate "knowledge text" in the biomedical domain compared with fine-tuning for the biomedical field. These findings are expected to contribute significantly to the evolution of AI-based medical counseling systems.

KEYWORDS

artificial intelligence; biomedical; large language model; depression; similarity measurement; text validity

Introduction

Overview

The COVID-19 pandemic has brought significant transformations to health care systems worldwide [1]. Additionally, the utilization of artificial intelligence (AI) in the biomedical field has surged [2], and the adoption of natural language processing (NLP) techniques for analyzing or predicting medical data has notably increased [3-5]. Ong et al [6] utilized machine learning techniques on radiographic text to identify the presence, location, and acuity of ischemic strokes. Since the advent of ChatGPT (OpenAI), numerous studies have highlighted the potential impact of generative models across medical domains, including medicine, medical devices, and medical education. Large language models (LLMs) are anticipated to become a cornerstone in the future of health informatics research [7-12].

The COVID-19 pandemic has exacerbated depression, which is widely acknowledged as a significant social and medical concern [13-15]. During the pandemic and the resultant lockdowns, social isolation and withdrawal became prevalent worldwide, leading to the coining of the term "Corona Blue" to describe depression caused by the pandemic, particularly related to self-isolation and social distancing [16]. Even before

XSL•FO
RenderX

the pandemic, depression was recognized as a societal issue and a mental health concern with substantial economic implications in many countries [17-22].

Generative AI has recently been employed as an interactive consultant, sparking interest in evaluating its applicability in medical discussions and consultations, particularly in the context of depression. This study aims to assess the suitability of generative AI by comparing the similarity between responses generated by AI models and those provided by humans to depression-related questions. To this end, we collected a set of depression-related questions and corresponding human answers and utilized 4 LLMs—BioGPT [23], PMC-LLaMA [24], ChatGPT [25], and Llama2 [26]—to generate responses.

Questions about depression or depressive disorders can arise from various sources, including validated inquiries recommended by professionals and questions posted online by individuals seeking to understand their symptoms. Furthermore, when selecting an LLM, it is essential to consider 2 key factors. First, is the model domain-specific? This pertains to a fine-tuned pretrained model tailored to the medical domain. Second, is the model a general-purpose intelligent system known for its proficient question-answering capabilities?

Building on this foundation, we designed a basic experiment in which medical questions related to depression were sourced from diverse origins and presented to LLMs for answers. Specifically, we explored the fundamental concepts underlying LLMs and examined the attributes of fine-tuned models within the medical domain. The primary objectives of this study were to evaluate the LLMs' ability to respond to medical queries, assess the similarity between their answers and those provided by humans, and investigate the differences between domain-specific and general-purpose models.

The main contributions of this study are as follows. First, semantic similarity analysis highlights discrepancies between human expert answers and the knowledge outputs of LLMs. Second, it enables researchers to evaluate the quality of LLM-generated responses by comparing them with human answers. Finally, the experiments show that the latest versions of LLMs outperform earlier iterations, particularly when fine-tuned on specific topics.

Background and Related Work

Large Language Models

The Transformer architecture [27] has significantly influenced the proliferation of LLMs, giving rise to 2 prominent pillars in NLP: GPT and bidirectional encoder representations from transformers (BERT). Qiu et al [25,28] assessed ChatGPT as heralding a new era in the development and deployment of large AI models. Additionally, they observed that the size, generalization, and scale of training/pretraining for general-domain models have increased, thereby enhancing the capacity of a single model. ChatGPT [25], introduced in 2022, offers notable advantages by producing human-like results and being user-friendly and accessible. The development and dissemination of LLMs began in late 2022 with ChatGPT [25], and numerous models followed in 2023 after the release of Llama, which was freely distributed by Meta. Additionally, Meta announced and distributed Llama-2, which is also available for commercial use [26,28,29]. Furthermore, Google introduced its chatbot BARD [30], which was swiftly followed by Alpaca 7B [31], Vicuna [32], and others, all built upon the free Llama model.

Health Care Domain Large Language Models

ChatGPT, powered by the GPT-3 model, has successfully navigated all stages of the United States Medical Licensing Examination (USMLE) [11,33]. Concurrently, there has been a rise in LLMs fine-tuned for specific domains, designed to maximize performance in general domains. Specialized models, such as BioBERT and PubMedBERT, which fine-tune existing BERT models using extensive medical domain data, have seen increased development.

LLMs initially introduced in the general domain can undergo additional training with health care domain data (biomedical or biomedicine), resulting in pretrained language models. These pretrained models, tailored to the health care domain, are specialized for tasks such as answering health care–related questions [23,24,34,35] and have evolved to facilitate medical diagnoses through the analysis of medical images.

Furthermore, alongside the development and deployment of LLMs, ongoing research evaluates the performance of both pretrained and general-domain LLMs. For instance, studies have compared the performance of GPT-4, a general-domain LLM, with its predecessor GPT-3.5 and Med-PaLM, a model pretrained specifically in the medical domain [11].

Recent research in the field of medicine, particularly focusing on depression, has explored the application of LLMs such as ChatGPT and Claude, developed by Anthropic. Several publications have introduced methods for evaluating the potential use of LLMs in depression treatment and screening [36-39]. Heston [40] discussed the risks associated with using LLMs in mental health support, particularly for depression. These studies have demonstrated that LLMs can accurately categorize symptoms of depression and anxiety, highlighting their potential for integration into the health care field.

Methods

Overview

This section is divided into 3 parts: (1) an overview of the design of experiments; (2) an introduction to medical question-answer data sets and the outputs from our experiments; and (3) a comparison between GPT and Llama models. A detailed process was developed in this study to evaluate the similarity between the answers or outputs generated by LLMs and the original answers. Our methodology consisted of 2 main steps: first, we constructed a data set of depression-related questions and answers sourced from various outlets; second, we segregated the questions to be input into the fine-tuned model from those intended for the general LLMs, based on the data set's source.

Ethics Considerations

All data used in this study were from public literature data obtained from PubMed and Quora data. Therefore, ethical approval was not required.

XSL•FO
RenderX

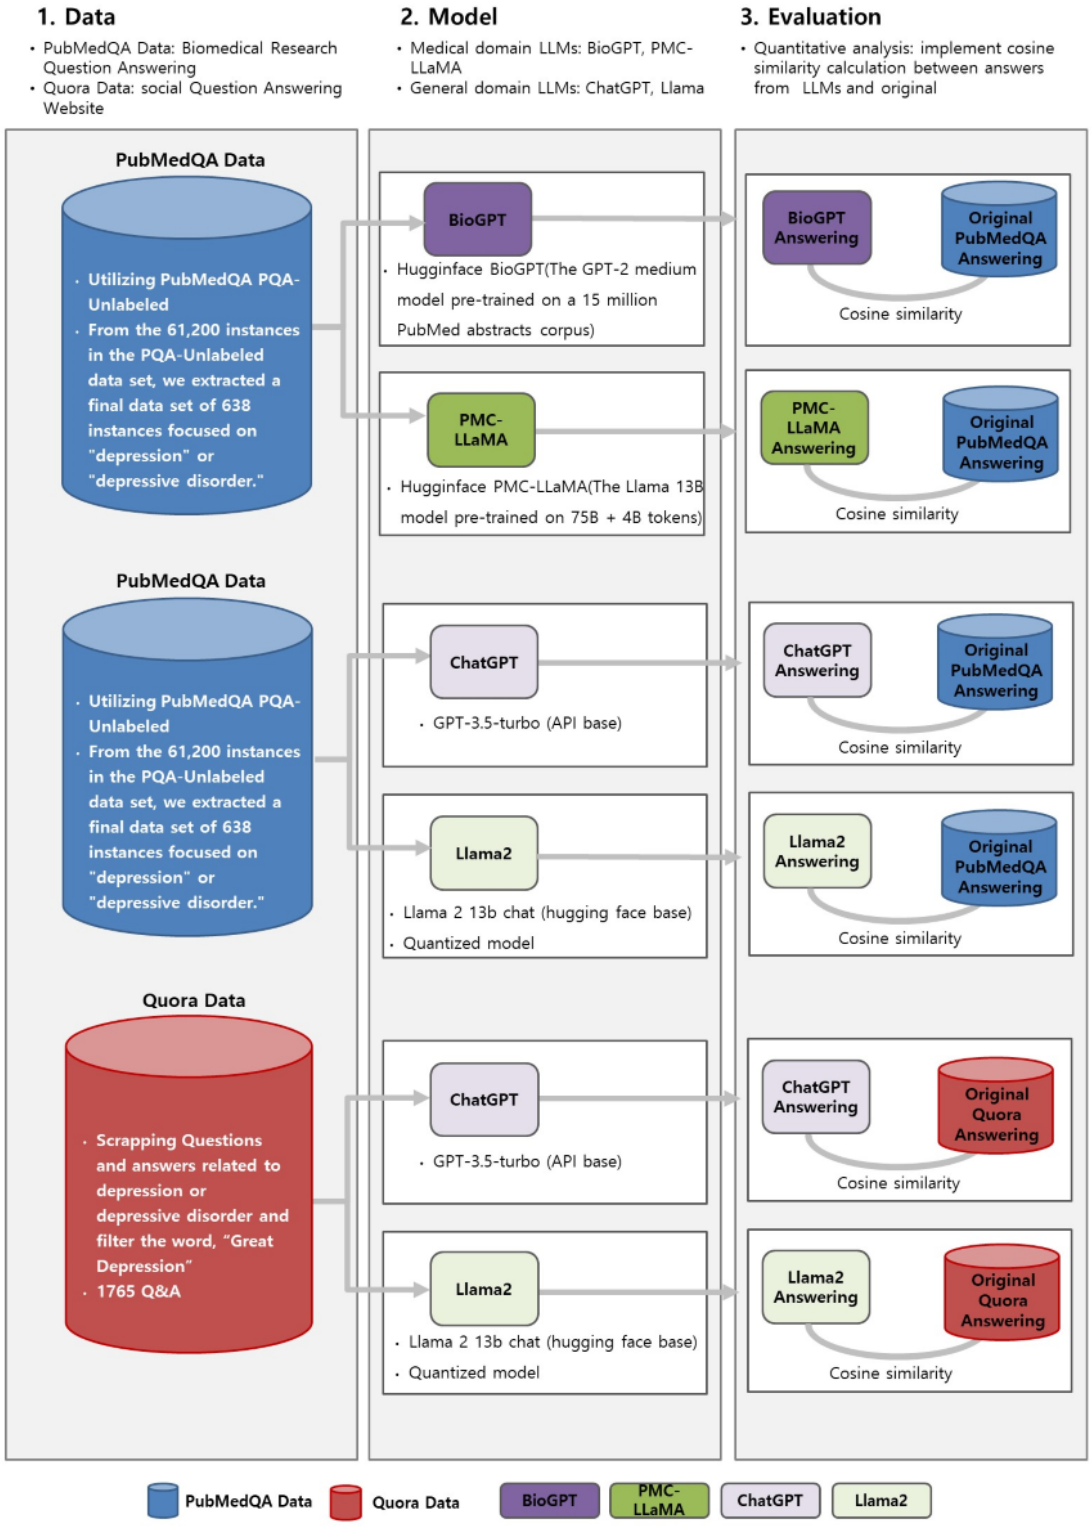
Experimental Design

Figure 1 provides a schematic overview of the study design. This study comprised 3 components: data, model, and evaluation. The model varied based on the type of data, while the evaluation method remained consistent throughout. The data were categorized into 2 types: PubMedQA, derived from medical research abstracts, and question-and-answer data extracted from Quora [41-43], a social platform where users ask and answer questions. The models used in the experiment included 2 types: a basic model that had undergone pretraining and a model fine-tuned with medical data. To evaluate the generated answers from each model, we examined both the quantity and quality of the responses in relation to the input questions. Subsequently, we evaluated the similarity of the generated answers to the correct answers. BERT similarity [36] and SpaCy similarity [37] were used to measure contextual similarities between the human-provided original answers and the LLM-generated responses for each depression-related question.

Various validation metrics can be applied to text generation experiments. He et al [44] introduced common evaluation metrics, including ROUGE, BLEU, METEOR, SACREBLEU, and BERTScore, to assess the quality of LLMs' responses for electronic health records and laboratory test results. ROUGE, BLEU, and METEOR evaluate similarity in tasks such as full-text comparison, translation, and summarization [38,39,45,46]. By contrast, BERTScore emphasizes semantic similarity rather than relying solely on word matches, such as n-gram overlap. However, this study was designed to quantify similarity within specific contexts and nuances. Therefore, we relied on semantic similarity measures such as BERT and SpaCy as automatic and quantifiable metrics.

Semantic similarity is a relative measure of how similar or dissimilar a new word is to established words. The assumption that semantically related words behave similarly allows for the generalization of user semantic similarity. In the vector space model, similarity is calculated using the cosine measure or normalized correlation coefficient. This is known as vector similarity or cosine similarity [47]. Based on the Euclidean dot product formula, cosine similarity can be defined as follows:

where  are given n-dimensional vectors of attributes and *i*th components of vectors , respectively.



Normalized cosine similarity, like other correlation coefficients, is transformed into a value within the range of –1 to 1. A value of –1 indicates that the 2 vectors are diametrically opposed (180° apart), while a value of 0 indicates that the vectors are orthogonal (perpendicular at 90°). Conversely, a value of 1 denotes that the vectors are perfectly aligned in the same direction (horizontal) [47,48].

Furthermore, utilizing automatic context evaluation can replace real human expert feedback. Murty et al [49] suggested that LLM-generated novel personas could be used in data construction. Additionally, Ficler and Goldberg [50] introduced a Delphi expert AI–infused panel, demonstrating its potential to complement human expertise. These studies proposed substituting a real human expert with a persona expert. In this study, a persona expert evaluated the results from LLMs beyond semantic similarity. The persona expert prompt includes the following:

The input Excel (Microsoft Corporation) file contains a question about depression (QUESTION), along with the following columns: expert answer (ANSWER), answer generated by generative AI PMC Llama (PMC_LLAMA_Answer), answer generated by generative AI BIOGPT (biogpt_answer), answer generated by generative AI GPT (GPT_ANSWER), and answer generated by generative AI Llama2 (Llama2_Answer). The question is as follows: "Please compare the answers generated by the generative AI models with the expert answer (ANSWER) using 3 persona agents in the field of mental health, and provide your expert evaluation in an Excel file." Expert evaluations will be categorized into 3 significance levels: high medical, moderate, and low.

Figure 1. Schematic overview of the data, model, and evaluation in the designed experiment. LLM: large language model.

Data

As summarized in Table 1, PubMedQA contains 638 depression-related questions, while 1763 depression-related questions were extracted from Quora. PubMedQA is a data set of medical questions and answers collected from the text of articles indexed in the PubMed database. If an article's title poses a question and its abstract is structured with sections such as "Introduction," "Results," and "Conclusion," the abstract can be considered as addressing the question posed in the title. PubMedQA is curated by extracting medical questions and answers from article titles and structured abstracts based on these characteristics. For this study, we extracted 638 and 1764 question-and-answer pairs containing the keywords "depression" or "depressive disorder" from PubMedQA and Quora, respectively. Quora allows community users to freely provide answers, resulting in multiple responses to a single question. We used the "upvotes" feature on Quora to pair each question

XSL•FO
RenderX

with the answer that received the highest number of upvotes, selecting the most favored answer as the representative. Both data sets are categorized into 10 major categories and 4 subcategories, as shown in Table 2.

Table 1. Summary of the medical question-answers data sets.

Summary	PubMedQA	QuoraQA
Number of questions used in this study, n	• 638	• 1763
Source (question-answers)	• List of questions and answers containing depression-related keywords in questions from PubMedQA	• List of questions and answers containing depression-related keywords in questions from Quora
Prompt (explanations)	• Prompt engineering was applied. • Question: You are a doctor and I am a patient. Please answer the question within 500 words for length, and as a dialog for format, and professionally. “QUESTION”	• None • Question: You are a doctor and I am a patient. Please answer the question within 500 words for length, and as a dialog for format, and professionally. “QUESTION”

Table 2. Detailed categories of the data sets (same categories applied to both data sets).

Type	Group and subgroup names	Definition
1	Suicide and Risk Factors	Questions about suicide attempts, suicide prevention, and associated risk factors
2	Medications and Treatment Effects	Discussions on the effectiveness of antidepressants, therapeutic interventions, and treatment outcomes
3	Role and Awareness of Health Care Professionals	Insights into how medical professionals diagnose, treat, and improve access to mental health care
4	Inflammation and Immune Response	The relationship between inflammation, immune system activity, and depression
	Comorbid Disorders	
5	Anxiety Disorders	Co-occurrence of depression with anxiety or panic disorders
	Bipolar Disorder	Interrelation between depression and bipolar disorder
	Physical Illnesses	Links between depression and chronic conditions such as diabetes or cardiovascular diseases
	Other Mental Disorders	Depression alongside posttraumatic stress disorder, obsessive-compulsive disorder, or schizophrenia
6	Economic Impact	The financial burden of depression, including treatment costs and workplace productivity
7	Clinical Symptoms	The manifestation, severity, and variations in symptoms of depression
8	Physical Impact	Effects of depression on physical health, such as weight changes and somatic complaints
9	Psychological Factors	The influence of genetic predisposition, family history, and environmental factors on depression
10	Brain and Biological Mechanisms	Studies of structural changes in the brain, neurotransmitter imbalances, and biological pathways related to depression
11	Others	Questions that do not belong to any of the aforementioned categories

Models

Medical Domain LLMs

As outlined in the “Background and Related Work” section, 2 primary types of LLMs were utilized in this study. First, we used medical domain LLMs, which are basic language models (such as Llama or GPT) pretrained for general language tasks and then fine-tuned with a biomedical domain–specific model. Among the various models, BioGPT [23] and PMC-LLaMA [24] were selected for their specialized focus on biomedical text generation and mining.

BioGPT underwent prompt-based fine-tuning using biomedical knowledge and a data set of 15 million PubMed abstracts to perform downstream tasks in NLP, such as relation extraction, question answering, and document classification, based on the GPT-2 model [23].

However, PMC-LLaMA underwent a 2-step training process. First, the Llama 13B model was trained using medical academic papers and medical books for knowledge injection. Subsequently, it underwent instruction tuning for the medical domain. Biomedical papers with PubMed Central IDs were extracted from S2ORC [51], an English-language data set of academic papers, and text content was extracted from PDF versions of books to refine the data set. RedPajama-Data, a general language corpus, were combined with the aforementioned data sets in a ratio of 15:4:1 (books:papers:general) to create a comprehensive medical domain data set for training a medical-specific knowledge base. Following this, medical-specific instruction tuning was performed, utilizing data from medical conversations, medical rationale question answering, and medical knowledge graph prompting.

Given that BioGPT and PMC-LLaMA are prompt-based models, we employed a prompt engineering format to fully leverage their capabilities. When inputting PubMedQA questions into BioGPT and PMC-LLaMA, the following prompt was appended: "You are a medical doctor. Answer the following question as a medical doctor."

General LLMs

For the comparison group in the biomedical domain, we selected the GPT-3.5-Turbo model and the Llama2 chat model, which were among the most advanced models available from the GPT and Llama series at the time of the experimental design.

GPT-3.5-Turbo (deprecated by OpenAI as of May 2024) is a closed-source, human-like natural language text generation model developed by OpenAI. While the detailed training process is not publicly disclosed, it is known to have a knowledge level sufficient to pass examinations such as the US Bar Examination and the USMLE. The GPT-3.5-Turbo model has been extensively used in ChatGPT and has demonstrated exceptional abilities across various domains, including mathematical reasoning, coding, and human interaction, such as understanding language and engaging in conversation [33,52,53].

Llama2, developed by Meta, consists of a collection of open-source pretrained and fine-tuned LLMs, ranging in size from small to large, with parameters spanning from 7 billion to 70 billion. Unlike the previous Llama model, which was available only for research purposes, Llama2 can be used for commercial applications. Meta has released a version of Llama2-Chat specifically designed for dialogue use cases. Llama2-Chat is available in 7B, 13B, and 70B parameter configurations, with the 13B model used in this study. According to a study by Touvron et al [29], the Llama2-Chat model (published by Meta) was rated as more useful and helpful by human evaluators compared with other LLMs such as Google's PaLM, OpenAI's ChatGPT, LMSYS's Vicuna, MosaicML's MPT, and TII's Falcon. The study also asserted that Llama2-Chat surpasses other commercial models in terms of safety. In this experiment, the GPT-3.5 model was accessed via the API, while the chat version of the Llama2 model was utilized.

Input-Output Framework

We provide a detailed explanation of the prompts listed in Table 1, using examples to illustrate their structure. Each prompt includes a brief introductory paragraph before the question to clarify the system's role and the expected format of the response. As prompt engineering skills can influence the outcomes of this study, we established a basic experimental condition and constructed the prompts accordingly. First, we expected the LLMs to generate accurate answers as medical experts would. Second, the dialogue was designed to mimic a face-to-face consultation format, such as a medical expert providing counseling to a patient. We limited the answers to 500 characters and anticipated that the responses would be well-balanced, providing complete context. Without constraints on sentence length or when suggesting overly lengthy word counts, the answers generated by the LLMs became incoherent and muddled. For example, "Does depression influence symptom severity in irritable bowel syndrome? ANSWER: Yes, depression can influence symptom severity in Irritable Bowel Syn PMC-LLaMA" or "In a 1994 cost-effectiveness study, Hays and colleagues (1994) concluded that treatment of major depression was not cost-effective relative to no treatment when only the direct costs of health care are considered. However, when indirect costs (lost productivity) were considered, the average cost of usual care was more costly than the average cost of pharmacologic treatment with tricyclic antidepressants. In another study, Carmin and associates (2002) found that the total cost of treatment of depressed Medicare beneficiaries could be reduced by 4,481 per patient if treatment of depression is carried out according to practice guidelines established by the Agency for Healthcare Research and Quality in 1999. Thus there are indications that appropriate treatment of de." After several trials and errors, we determined that a length of 500 characters was optimal. Additionally, we tested various parameters to ensure consistent responses from the LLMs, including temperature, Top K, and Top P. The temperature parameter controlled the randomness of the responses, while Top K limited the model's sampling options. Possibilities were calculated using the Softmax formula after applying temperature, with the model having thousands of tokens to choose from [49,50]. The model then selected the best tokens for a repeatable response [49]. Meanwhile, Top P employed nucleus sampling, offering more control than Top K by providing an intuitive, cumulative probability cut-off for token selection. For the implemented settings, PMC-LLaMA and BioGPT had a temperature of 1.0, Top K of 50, and Top P of 0.7. For GPT-3.5-Turbo, the parameters were set to a temperature of 1.0, Top K of 40, and Top P of 1.0, while for Llama 2 Chat 13B, the settings were a temperature of 0.7, Top K of 0, and Top P of 0.9. With these settings, we were able to generate consistent answers from the LLMs with minimal variation.

Results

In the biomedical domain, the models generally responded to 638 PubMedQA questions, though there were instances where responses were not provided. As shown in Table 2, BioGPT exhibited a higher response rate compared with PMC-LLaMA. The questions in this study were structured into prompts designed to elicit responses in complete sentences. However, the answers generated by each model often consisted of short responses, such as "yes" or "no," or excerpts from articles or books that did not align with the content. Specifically, PMC-LLaMA demonstrated a response rate of only 52.9% (338/638), with only 171 (26.8%) responses forming meaningful sentences.

Figure 2A-D illustrates the examples of questions and answers generated by the biomedical domain LLMs. Figure 2A and 2B

XSL•FO
RenderX

showcases answers extracted from each model, focusing on instances where the responses were deemed appropriate. As different models produced different answers to the same question, we independently and randomly selected examples of suitable responses rather than repeating the same question across models. Figure 2C and 2D displays examples of invalid answers. During the assessment of answer similarity, responses deemed invalid—such as those shown in Figure 2C and 2D—were excluded from the analysis.

Figure 2. Assessment of answer validity by large language models (LLMs) in a question and answer task: (A) valid answer by BioGPT, demonstrating accurate information retrieval; (B) valid answer by PMC-Llama, showing comprehension of complex medical queries; (C) invalid answer by BioGPT, unrelated to the posed question; and (D) invalid answer by PMC-Llama, illustrating a failure to understand the query context.

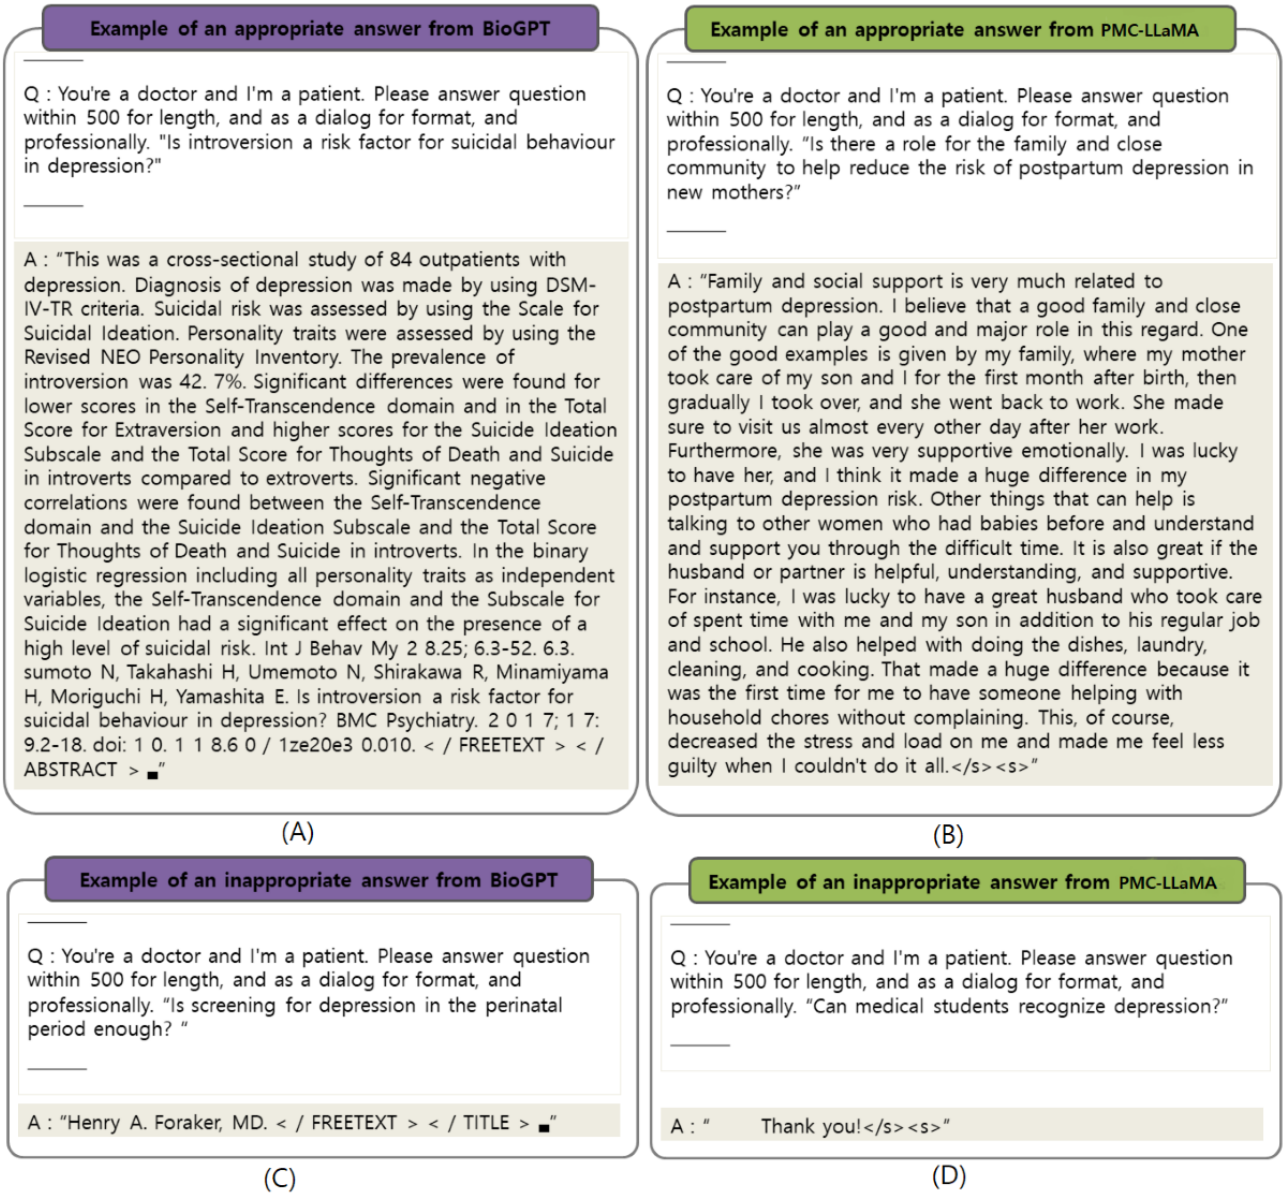

Figure 3A presents the results of measuring the similarity between the answers generated by BioGPT and PMC-LLaMA, compared with the original answers sourced from PubMedQA. Similarity values range from –1 to 1, where a value closer to –1 indicates greater dissimilarity between the model-generated answer and the original, while a value closer to 1 indicates higher similarity. A value of 0 denotes no discernible relationship between the answers.

According to Figure 3A, the answers generated by BioGPT and PMC-LLaMA exhibit a similarity of over 0.4 compared with the original answers. BioGPT shows a distinct similarity peak in the range of 0.4-0.6 when compared with BERT, while achieving a higher similarity score of 0.855 with SpaCy similarity. Negative similarity values, ranging from –0.2 to 0, were also observed. For PMC-LLaMA, although there are fewer valid answers, the similarity values predominantly range from 0.4 to 0.8 with BERT and from 0.8 to 1.0 with SpaCy.

XSL•FO
RenderX

Table 3 presents the overall mean and SD values of similarity for all model answers. The average similarity value is slightly higher for BioGPT, whereas the SD is slightly higher for PMC-LLaMA. This discrepancy is attributed to the smaller number of valid answers generated by PMC-LLaMA (as shown in Table 2), which results in a relatively larger variation in the similarity between PMC-LLaMA's answers and the original answers.

Regarding QuoraQA's questions, both the GPT-3.5 and Llama2 models exhibited high response rates and similarity in their answers, with GPT-3.5 demonstrating particularly strong comprehension and response consistency. Figure 4A and 3B showcases examples of answers generated by both GPT-3.5 and Llama2. Notably, GPT-3.5 demonstrated an ability to handle errors within questions effectively, often responding with statements like "I do not understand your question" when encountering errors. By contrast, Llama2's responses were typically more detailed and longer. However, the Llama2 model had a higher number of unanswered questions compared with the GPT-3.5 model.

There were no invalid answers generated by GPT-3.5, whereas Llama2 produced valid answers with high similarity to the original responses, except in cases of nonresponse, as shown in Figure 3C.

Therefore, as in the previous experiment, we computed the similarity between the answers generated by the LLMs and the original answers from QuoraQA. The distribution of similarity is shown in Figure 3C.

In Figure 3C, the responses generated by the GPT-3.5 and Llama2 models were evaluated using cosine similarity. Notably, there were no negative similarity values (<0). The majority of the similarity values fell within the range of 0.4-0.6.

Table 3 presents the means and SDs of the distributions shown in Figure 3C. In contrast to the previous experiments, where the 2 biomedical domain models exhibited an average similarity between 0.456 and 0.489 with BERT and approximately 0.8 with SpaCy, the average similarity in the general LLMs experiment ranged between 0.590 and 0.632 with BERT and around 0.9 with SpaCy. Additionally, the SDs in this experiment were smaller compared with those observed in the biomedical domain LLMs experiments.

We conducted 6 rounds of experiments: 2 PubMedQA sessions with bio-specific LLMs, 2 PubMedQA sessions with general LLMs, and 2 Quora sessions with general LLMs. The results, presented in Table 4, show that the GPT-3.5 model responded to all questions, while the Llama2 model answered all but 5. This demonstrates a significantly higher response rate compared with the previous biomedical domain models.

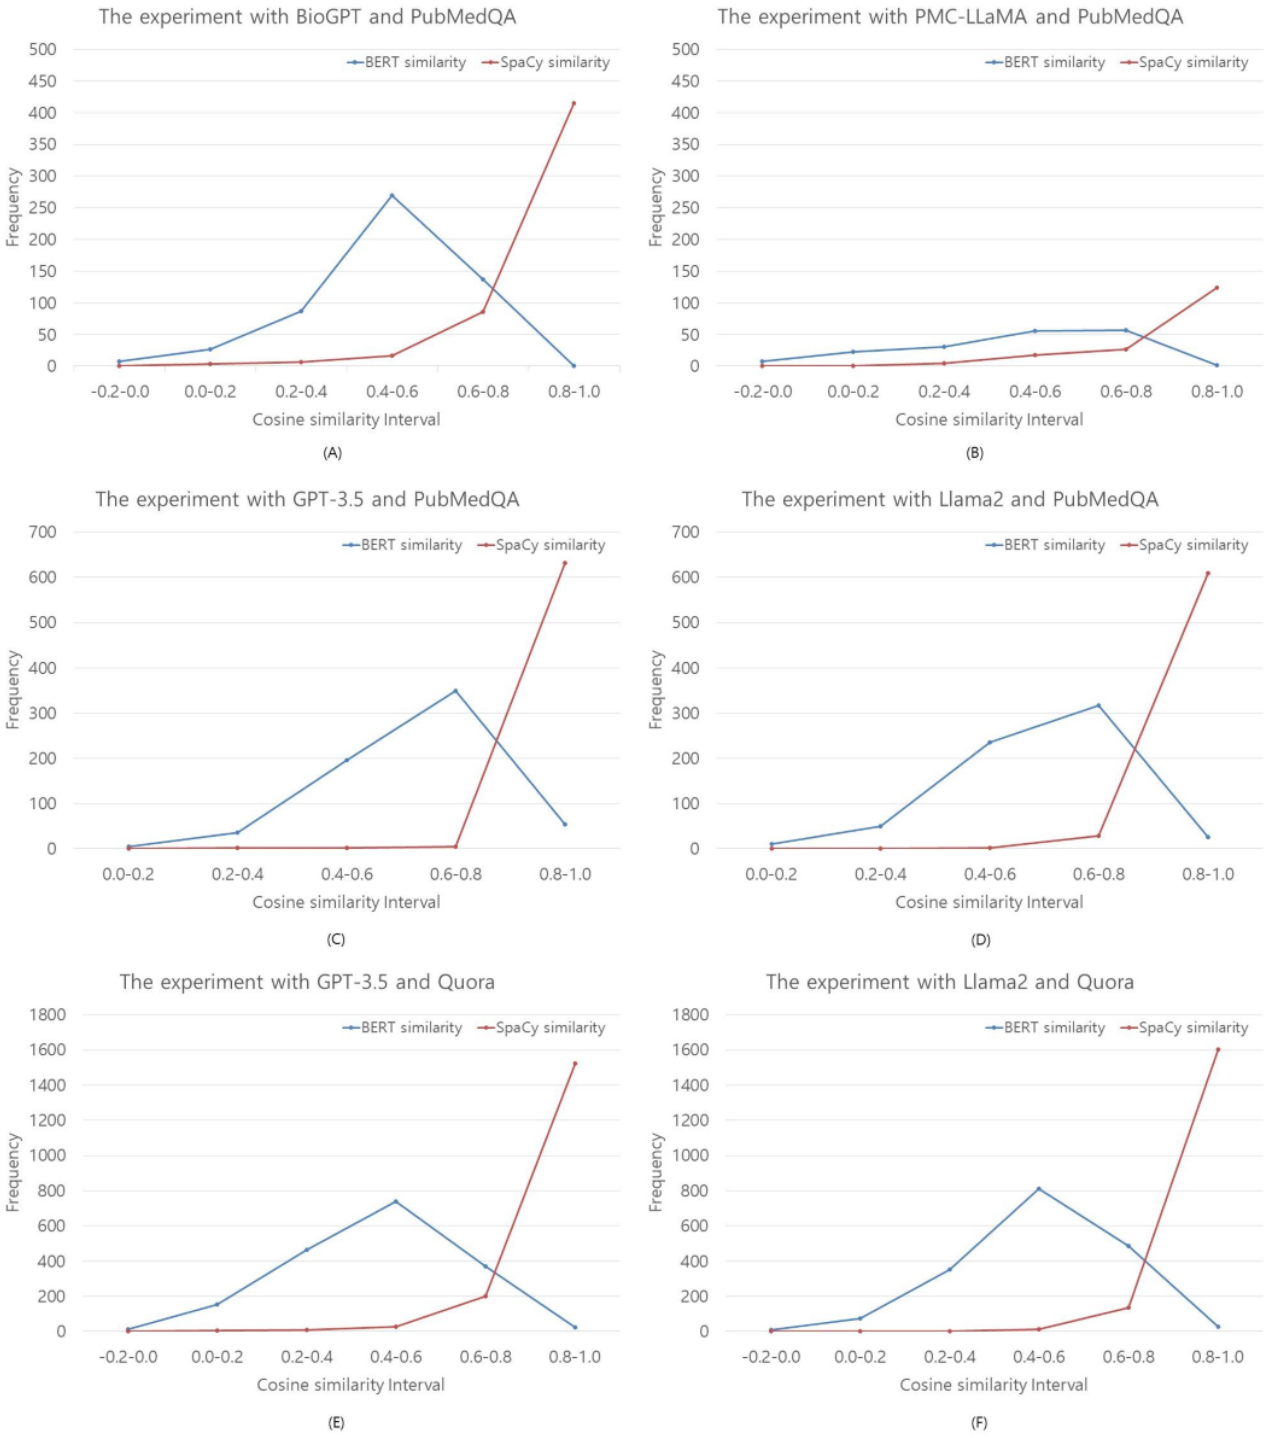
Figure 3B illustrates the distribution of cosine similarity values between the answers generated by the GPT and Llama2 chat models for PubMedQA questions, compared with the correct answer. The highest similarity between the answers generated by both models and the original answer falls within the range of 0.4-0.8. This indicates a positive similarity between the responses generated by the general LLMs and the correct answers. Unlike the biomedical domain LLMs in previous experiments, which produced some answers with negative similarity, the general LLMs consistently generated positively similar answers. Additionally, Table 4 shows that the answers generated by GPT-3.5 exhibit higher similarity and lower deviation compared with those generated by Llama2. Although the answers generated by the Llama2 model show increased similarity compared with those in previous experiments, they still exhibit lower similarity than those generated by GPT-3.5.

Upon comparing the data in Table 3, it is evident that for QuoraQA, the average BERT similarity of answers generated by GPT-3.5 and Llama2 to the original answer is 0.455 and 0.503, respectively. Similarly, for PubMedQA, the average similarity of answers generated by GPT-3.5 and Llama2 to the original answer is 0.632 and 0.590, respectively. The SDs for each experiment are 0.140 and 0.145, respectively. From Table 3, the mean BERT similarities of the answers generated by BioGPT and PMC-LLaMA to the original answer for PubMedQA are 0.489 and 0.456, with SDs of 0.160 and 0.225, respectively.

However, SpaCy similarity exhibits much higher mean values and smaller SDs than BERT. From Table 3, the mean SpaCy similarities of the answers generated by BioGPT, PMC-LLaMA, GPT-3.5, and Llama2 to the original answers for PubMedQA are 0.855, 0.820, 0.922, and 0.911, with SDs of 0.124, 0.154, 0.050, and 0.054, respectively. Similarly, for QuoraQA, the average SpaCy similarity of answers generated by GPT-3.5 and Llama2 to the original answers is 0.876 and 0.897, with SDs of 0.101 and 0.088, respectively.

We observed that the best performance was achieved by general LLMs, such as GPT-3.5 and Llama2, when generating answers to medical questions sourced from PubMedQA.

Figure 5 presents error bar charts for all experiments, illustrating the numerical evaluations of each model's performance. The charts display the mean values of 2 similarity measures per model, along with their respective SDs. Table 5 presents the persona expert evaluation according to LLMs.



According to the evaluation of the expert persona agent in Table 3, the "high significance" in the PubMedQA experiment is generally low, whereas the "moderate significance" is confirmed to be over 0.4. For PMC-LLaMA and Llama2, the sum of high significance and moderate significance is over 0.5, and for BioGPT and GPT-3.5, the low significance is high. Nevertheless, in the QuoraQA experiment, GPT-3.5 exhibits a high significance of 0.7689, whereas Llama2 shows a lower level of significance. Except for the notably high rate of low significance observed in the PubMedQA and BioGPT experiments, an overall moderate level of medical significance is achieved.

We expanded the previous evaluation to gain a deeper understanding of the data set. Tables 6 and 7 present the PubMed and Quora data sets, respectively, categorizing the questions and showing the BERT and SpaCy similarities of the generated answers. In Table 6, the questions in PubMedQA predominantly relate to Medications and Treatment Effects, Comorbid Disorders, and Clinical Symptoms, which are associated with relatively high BERT and SpaCy similarities in the generated

XSL•FO
RenderX

answers. Meanwhile, there are fewer questions in the "Etc." category, and the answers to these questions exhibit very low-average BERT similarity. Most of the questions in QuoraQA fall under the categories of Anxiety Disorders or Comorbid Disorders, as the platform allows the general public to post questions freely. The BERT and SpaCy similarities of the generated answers in QuoraQA are generally lower compared with PubMedQA, indicating that language models perform better at understanding medical content than general questions.

Figure 3. Assessment of answer validity by large language models (LLMs) in a question and answer task: (A) valid answer by GPT-3.5, correctly interpreting the user's question; (B) valid answer by Llama2, providing a detailed and relevant response. (C) invalid answer by Llama2, unable to generate a relevant answer to the question.

[a]BERT: bidirectional encoder representations from transformers.

Discussion

Principal Findings

Recent studies [44,54,55] on using LLMs to test health care question-answering data have found that GPT models may outperform other LLMs, despite occasionally providing incorrect answers. Additionally, fine-tuning LLMs may not effectively consolidate new knowledge, as they tend to rely more on preexisting knowledge [56]. These findings align with our experimental results.

In this study, we conducted experiments with BioGPT, PMC-LLaMA, GPT-3.5, and Llama2 to generate answers to questions from PubMedQA, and with GPT-3.5 and Llama2 for questions from QuoraQA. We then measured the semantic similarity between the generated answers and the original answers. Our findings indicate that general LLMs, such as

XSL•FO
RenderX

GPT-3.5 and Llama2, perform best when generating answers to medical questions sourced from PubMedQA. Notably, the depression-related questions from PubMedQA are professional medical inquiries, whereas those from QuoraQA are posed by the general public, highlighting a difference in question sophistication. Although we expected biomedical domain LLMs to perform better on professional medical questions, we found that newer versions of general LLMs, such as GPT-3.5 and Llama2, generated answers that more closely and contextually resembled the original answers. Furthermore, we initially anticipated that GPT-3.5 and Llama2 would perform better on questions from laypersons compared with professional medical inquiries. However, our findings revealed that the answers provided for professional medical questions were more closely aligned with the original answers.

In summary, the study provides several key insights. It evaluated the performance of both general-purpose (GPT-3.5 and Llama2) and domain-specific (BioGPT and PMC-LLaMA) LLMs in generating medically relevant responses to depression-related queries. The findings demonstrate that general-purpose models outperform domain-specific ones in both response rate and semantic similarity to human-provided answers, highlighting their versatility across specialized domains. Notably, GPT-3.5 consistently delivered higher-quality responses with greater similarity and lower variability.

Despite their specialization, domain-specific models exhibited inconsistencies, with BioGPT generating more responses that were often less relevant. This underscores the need for more refined fine-tuning approaches to enhance reliability. Furthermore, evaluations using persona experts revealed that while many answers had moderate relevance, domain-specific models frequently produced less relevant responses, pointing to the need for improved evaluation and training strategies.

The performance variations between data sets (PubMedQA vs QuoraQA) highlight the impact of query structure, with general LLMs performing better on formal, structured questions. Informal or user-generated content presents more challenges, suggesting the need for enhanced data set design and prompt engineering.

These insights underscore the potential of LLMs in mental health applications while highlighting the importance of addressing limitations, such as response accuracy and relevance, to ensure their effective deployment in sensitive fields.

Conclusions

This study compared several LLMs, including BioGPT, PMC-LLaMA, GPT-3.5, and Llama2, using question-and-answer data sets from PubMedQA and QuoraQA. The goal was to assess how well these models generated answers to depression-related questions. The results indicated that GPT-3.5 and Llama2, the latest general LLMs, outperformed the other models in generating responses to medical inquiries from PubMedQA. Surprisingly, despite expectations that biomedical domain LLMs such as BioGPT and PMC-LLaMA would outperform in professional medical questions, GPT-3.5 and Llama2 showed greater similarity to the original responses. This suggests that advancements in general LLMs have improved their ability to generate accurate biomedical domain text. Additionally, contrary to expectations, GPT-3.5 and Llama2 performed better on professional medical inquiries than on layperson questions. This study provides a foundation for future applications, highlighting the potential of LLMs in developing accessible, AI-driven mental health support systems that enable real-time consultations for users with limited access to professional care. Insights from this study, specifically in the context of depression-related medical questions and answers, can also inform the development of more specialized LLMs tailored to depression and other mental health domains, thereby enhancing their applicability in clinical decision support and personalized care. Additionally, the methodologies and evaluation frameworks used in this study can inform the broader use of LLMs across mental health domains, including depression, and potentially extend to other medical fields, facilitating the integration of AI technologies into health care systems. With continued refinement and ethical safeguards, these applications have the potential to enhance the accessibility and quality of mental health care worldwide.

This study is limited by the absence of expert validation to assess the accuracy of the generated answers. To address this, the study evaluated expert persona agents as a substitute for direct expert validation. While expert personas generated using LLMs are being utilized in various studies and their potential has been demonstrated, they are not yet capable of fully replacing human experts. Nevertheless, this study highlights the significance of creating and utilizing expert personas in the medical field. Addressing this limitation in future research involves incorporating expert textual validation to verify the generated answers, particularly regarding crucial topics in the realm of depression. Moreover, research is needed that simulates real-time discussions and consultations involving the models and human experts, rather than solely focusing on a straightforward exchange of questions and answers. Additionally, further analysis should explore how rapid engineering can improve performance and provide a detailed comparative analysis of various metrics.

Ethical considerations also emerge as critical factors in deploying LLMs for medical applications. Ensuring the accuracy and relevance of responses is paramount, as errors or inappropriate outputs could have significant consequences for users seeking medical advice. Additionally, the potential misuse of LLMs for self-diagnosis or reliance on automated systems without professional oversight raises concerns about user safety and accountability. Further research should delve into these ethical considerations.

In conclusion, the rapid development of LLMs in recent years suggests that version upgrades of general LLMs are more effective in enhancing their capacity to generate “knowledge text” in the biomedical domain compared with fine-tuning for this specific domain. The responses generated by GPT-3.5 and Llama2 to questions from PubMedQA demonstrated a high degree of similarity to the original answers. This underscores the potential for future advancements in prompt engineering and interactive process modeling to further enhance the ability of general LLMs to generate responses to biomedical questions.

Abstract

Background: Pulmonary embolism (PE) is a critical condition requiring rapid diagnosis to reduce mortality. Extracting PE diagnoses from radiology reports manually is time-consuming, highlighting the need for automated solutions. Advances in natural language processing, especially transformer models like GPT-4o, offer promising tools to improve diagnostic accuracy and workflow efficiency in clinical settings.

Objective: This study aimed to develop an automatic extraction system using GPT-4o to extract PE diagnoses from radiology report impressions, enhancing clinical decision-making and workflow efficiency.

Methods: In total, 2 approaches were developed and evaluated: a fine-tuned Clinical Longformer as a baseline model and a GPT-4o-based extractor. Clinical Longformer, an encoder-only model, was chosen for its robustness in text classification tasks, particularly on smaller scales. GPT-4o, a decoder-only instruction-following LLM, was selected for its advanced language understanding capabilities. The study aimed to evaluate GPT-4o's ability to perform text classification compared to the baseline Clinical Longformer. The Clinical Longformer was trained on a dataset of 1000 radiology report impressions and validated on a separate set of 200 samples, while the GPT-4o extractor was validated using the same 200-sample set. Postdeployment performance was further assessed on an additional 200 operational records to evaluate model efficacy in a real-world setting.

Results: GPT-4o outperformed the Clinical Longformer in 2 of the metrics, achieving a sensitivity of 1.0 (95% CI 1.0-1.0; Wilcoxon test, $P<.001$) and an F_1-score of 0.975 (95% CI 0.9495-0.9947; Wilcoxon test, $P<.001$) across the validation dataset. Postdeployment evaluations also showed strong performance of the deployed GPT-4o model with a sensitivity of 1.0 (95% CI 1.0-1.0), a specificity of 0.94 (95% CI 0.8913-0.9804), and an F_1-score of 0.97 (95% CI 0.9479-0.9908). This high level of accuracy supports a reduction in manual review, streamlining clinical workflows and improving diagnostic precision.

Conclusions: The GPT-4o model provides an effective solution for the automatic extraction of PE diagnoses from radiology reports, offering a reliable tool that aids timely and accurate clinical decision-making. This approach has the potential to significantly improve patient outcomes by expediting diagnosis and treatment pathways for critical conditions like PE.

Introduction

Pulmonary embolism (PE) is a serious medical condition where a blood clot blocks one of the pulmonary arteries in the lungs, typically originating from a vein in the lower limbs [1-3]. This blockage can significantly impede blood flow, leading to reduced oxygen levels in the blood and potential lung tissue damage. PE is critical because it can cause sudden, life-threatening complications such as cardiac dysfunction and other acute admissions [4,5]. Prompt diagnosis and treatment are crucial to improve outcomes and reduce the risk of mortality [6,7].

Clinical imaging techniques commonly used for diagnosing pulmonary embolisms include pulmonary computed tomography angiography, combined computed tomography venography and pulmonary angiography, and multidetector computed tomography angiography [8-10]. The analysis and outcomes of these modalities are recorded in radiology reports which describe the presence or absence of emboli, their location, size, and impact on pulmonary circulation. Radiology reports are structured documents that capture the conditions observed from radiology images [11,12]. Typically, the most important parts of these reports are the findings and impression sections [13]. The impression section provides a clinically precise summary of the patient's status, typically summarizing the key findings and diagnoses from the findings section [14]. Therefore, the diagnosis of PE is highly likely to be mentioned in the impression section. Early documentation of PE and its extraction in the electronic medical record system, and consequently in clinical workflows, is crucial for improving patient outcomes. In this study, we aim to develop an advanced transformer-based text classification model to extract PE diagnoses from the impression section of radiology reports, expediting structured data availability and enhancing the quality of care through evidence-based practices.

Natural language processing (NLP) techniques have been increasingly used in the field of radiology, particularly in extracting critical information from radiology reports such as diagnoses [15]. Studies have shown that NLP, combined with machine learning and deep learning algorithms, can effectively extract relevant information from radiology reports [16-18]. These techniques enable the automatic identification and extraction of critical findings such as pleural effusion, pulmonary infiltrate, and pneumonia, aiding in the classification of reports consistent with bacterial pneumonia [19]. Furthermore, NLP algorithms have been developed to detect specific findings like acute pulmonary embolism in radiology reports, showcasing the potential of NLP in enhancing diagnostic processes [20,21].

The application of NLP in radiology reports extends to various medical conditions, including pulmonary embolism. Studies have demonstrated the effectiveness of NLP in structuring the content of radiology reports, thereby increasing their value and aiding in the classification of pulmonary oncology according to the tumor, nodes, and metastasis classification system, a standard for staging cancer [22]. In addition, NLP has been used to identify ureteric stones in radiology reports and to build cohorts for epidemiological studies, showcasing the versatility of NLP in medical research [23].

Recent studies have demonstrated the effectiveness of Clinical Longformer in various clinical NLP tasks. For instance, it has been used to identify incarceration status from medical records, showcasing good sensitivity and specificity compared to traditional keyword-based methods [24]. In addition, Clinical Longformer has been successfully applied in the classification of clinical notes for automated *ICD* (*International Classification of Diseases*) coding, where it outperformed other models in accuracy [25,26]. This capability to accurately interpret and classify clinical text is crucial for improving health care delivery and ensuring proper coding for reimbursement purposes.

On the other hand, advanced versions of the GPT family like GPT-4 and GPT-4o, generative language models, have been recognized for their versatility in clinical applications, particularly in generating, summarizing, classifying, and extracting clinical information [27-33]. Its multimodal capabilities allow it to process not only text but also images and audio, enhancing its utility in diverse clinical settings [34]. GPT-4 has been used in clinical trial matching, where it automates eligibility screening, thus streamlining the recruitment process for clinical studies [35].

This study aims to develop an large language model (LLM)–based extraction system to automatically extract pulmonary embolism diagnoses from radiology report impressions. The key contributions of this study are mentioned in Textbox 1.

Textbox 1. Key contributions.

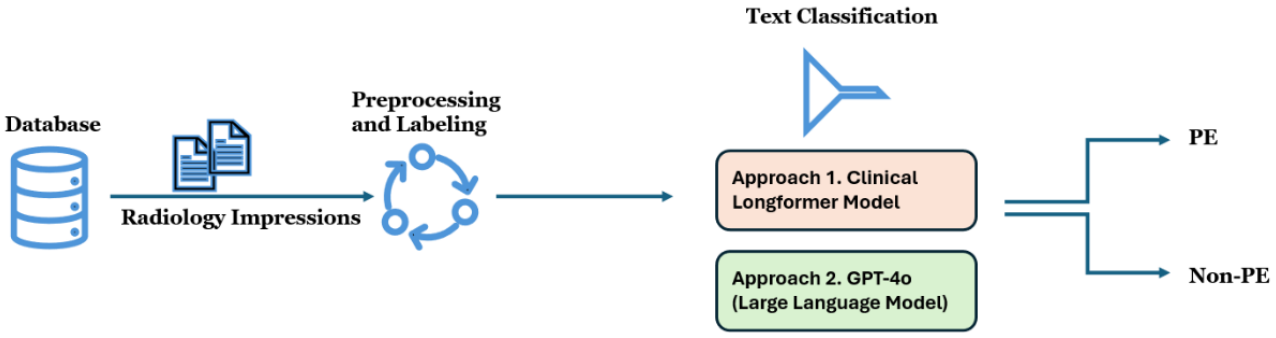
- Enhance and accelerate clinical data availability to improve the quality of care through evidence-based approaches.
- Develop a reliable diagnoses extraction system, which examines 2 technologies: Clinical Longformer and GPT-4o.
- Deploy the developed system as a cloud-based web application, addressing a gap often found in clinical artificial intelligence research.
- Evaluate the model both before and after deployment.

Methods

Overview

In this section, we provide a comprehensive overview of the study's methodology. Subsequently, we explore the text classification approach, followed by a detailed description of the dataset used. We then describe the models applied in this research. In addition, we discuss the deployment pipeline of the selected model. Finally, we outline the evaluation metrics used to assess the model's performance.

XSL•FO
RenderX



The primary objective of this study is to develop and deploy an artificial intelligence (AI) solution capable of extracting PE diagnoses from radiology report impressions. After defining this goal, the research proceeds through 4 distinct phases. In the first step, for collecting training and validation datasets, we determined the appropriate data tables in the Virtua Health clinical database and extracted radiology impressions data. This is followed by preprocessing and transforming the data to make it suitable for model development. The second step involves creating and testing 2 models (Clinical Longformer and GPT-4o), then choosing the one with the best results to proceed. The selected model is then implemented during the third step. In the final step, the performance of the model was tracked in real-world conditions and evaluated on how it affected operational outcomes.

Radiology Impressions Text Classification

Text classification is a fundamental task in NLP that involves categorizing text into predefined labels based on its content. This task is widely used in applications such as sentiment analysis, spam detection, and medical report classification. Text classification models typically preprocess the data by tokenizing the text and transforming it into numerical representations suitable for machine learning. An NLP approach is then used to make predictions based on patterns in the text.

Figure 1 illustrates the process of classifying radiology report impressions to identify PE cases, which is adopted in this study. The workflow begins with the extraction of radiology impressions from a clinical database. The impressions are preprocessed by consolidating line-wise text, removing unnecessary spaces, and applying labels to prepare the data for analysis. Following this, 2 different text classification models are used: Approach 1 uses a Clinical Longformer Model, while Approach 2 involves GPT-4o, a LLM. Both models classify the impressions into 2 categories: PE and non-PE. The goal is to determine whether a diagnosis of PE is present in each radiology report impression.

Figure 1. Radiology impressions text classification. PE: pulmonary embolism.

Data

The data used in this study was sourced from the electronic medical record relational database of Virtua Health, New Jersey, with the primary data element being the impressions of radiology reports. These impressions, which contain key diagnostic information, were consolidated from line-wise data and cleaned to remove extraneous spaces. This process ensured that the data were formatted appropriately for analysis and modeling.

The training dataset consists of 1000 samples, which were randomly selected from radiology reports generated between January 1, 2024, and June 30, 2024. For the validation dataset, 200 samples were randomly drawn from radiology reports collected in July 2024. In addition, a separate testing dataset, consisting of 200 observations, was sampled randomly from operational data received between August 1, 2024, and August 31, 2024. The characteristics of the training and validation datasets are outlined in Table 1. The testing dataset characteristics will be discussed in the following section.

Table 1. Training and validation data characteristics.

Metric	Training dataset	Validation dataset
Number of observations	1000	200
Average number of words (a token is approximately three-fourths of a word)	43.64	40.18
Number of pulmonary embolism-positive cases	36	100
Number of pulmonary embolism-negative cases	964	100

As shown in Table 1, the training dataset contains 1000 observations, with an average of 43.64 words (or 32.73 tokens, where a token is approximately three-fourths of a word) per report impression. The training data includes 235 occurrences of pulmonary embolism term, with 36 positive cases for pulmonary embolism and 964 negative cases. The validation dataset, consisting of 200 observations (1:1 ratio of classes), has a slightly lower average word count per report impression, at 40.18 words.

Fine-Tuned Clinical Longformer Classifier

The Clinical Longformer is a specialized transformer model designed to handle long clinical documents, overcoming the typical limitations of standard transformer models such as

XSL•FO
RenderX

Bidirectional Encoder Representations from Transformers (BERT), which can process sequences up to 512 tokens [36]. Clinical Longformer incorporates a sparse attention mechanism that allows it to efficiently process sequences up to 4096 tokens, making it ideal for handling lengthy clinical narratives. Pretrained on large clinical datasets, it is particularly effective in capturing long-term dependencies in medical text. In this study, the Clinical Longformer is fine-tuned to classify radiology impressions for identifying pulmonary embolism, leveraging its ability to process comprehensive radiology report impressions without truncating important contextual information.

We fine-tuned (full fine-tuning) the Clinical Longformer model on a graphics processing unit server with 48 GB of memory. The fine-tuning hyperparameters were mentioned in Textbox 2.

Textbox 2. Clinical Longformer fine-tuning hyperparameters.

- Batch size: 4
- Gradient accumulation steps: 8
- Learning rate: 2e-5
- Number of epochs: 5
- Optimizer: AdamW
- Learning rate scheduler: Linear

GPT-4o Classifier

The methodology for using GPT-4o in the text classification of radiology impressions, specifically for PE diagnosis, is based on a combination of chain-of-thought (COT) reasoning and few-shot learning techniques. As outlined in Textbox 3, the process begins by initializing an empty list to store the generated labels. GPT-4o is then prompted using a COT and few-shot learning template, where relevant examples of radiology impressions with their corresponding labels (PE or non-PE) are presented to the model. The temperature parameter is set to zero to minimize randomness in the model's predictions. For each radiology impression in the dataset, the system inserts the impression into the prompt, calls the GPT-4o API, and receives a response that indicates whether a PE diagnosis is present. The resulting labels are appended to the list for further analysis and validation.

As shown in Figure 2, the prompt includes a persona where GPT-4o is defined as a clinical AI assistant proficient in radiology, capable of interpreting complex medical language. The prompt further provides detailed steps, starting with studying example impression-label pairs, followed by reading through the target impression to extract potential diagnoses. The model is tasked with determining whether PE is indicated in the impression and returns the output as a structured JSON object. This methodology leverages GPT-4o's advanced language comprehension capabilities to classify radiology reports efficiently, using both clinical reasoning and context learned from the few-shot examples.

Textbox 3. Extraction of pulmonary embolism diagnosis using GPT-4o-based chain of thought (COT) and few-shot learning algorithm.

Input: List of impressions

Output: List of labels ("Yes" if PE presents and "No" otherwise)

1. Initialize an empty list for extracted labels.

   labels = []
2. Initialize chain of thought and few-shot learning prompt template.
3. Set the temperature parameter to 0.0.
4. For each item in the list of impressions do
5. Insert the current impressions item in the prompt.
6. Send the formatted prompt and temperature parameter to the GPT-4o model (API call).
7. Parse the response.
8. Append the generated label: *labels.append(response["answer"])*.
9. End for
10. Return the list of generated labels.

Figure 2. Extraction of pulmonary embolism diagnosis prompt template.

```
prompt_template = '''
# Persona
You are a clinical AI assistant who is expert in radiology. You are capable of annotating clinical text.

# Steps:
- Study the impression-label examples.
    - Examples
        Example 1:
            Impression: No acute inflammatory process is present within the thorax.
            Label: No
        Example 2:
            Impression: 1. No evidence for noncalcified pulmonary nodule or thoracic  adenopathy.
            2.    Evidence of prior granulomatous disease. 3. Stable 1.2 x 1.3 cm left adrenal adenoma.
            LUNG-RADS CATEGORY:  1, Negative (risk of malignancy < 1%). MANAGEMENT:
            If the patient continues to meet the criteria for lung cancer screening,
            recommend annual screening LDCT in 12 months.
            Label: No
        Example 3:
            Impression: 1.  Multiple right-sided pulmonary emboli .
            No findings to suggest right ventricular strain. Other findings as above.
            Label:Yes
- Read through the clinical impression of the radiology report.
- Extract possible diagnoses.
- Determine if the impressions has pulmonary embolism or not.
- Return the answer in JSON object with an 'answer' key that labels the following impression with:
    * Yes (if the impression has a pulmonary embolism diagnosis)
    * No (if the impression does not indicate pulmonary embolism diagnosis)

Impression: {impression}
'''
```

Deployment Pipeline

The deployment pipeline for the PE classification model, illustrated in Figure 3, integrates a combination of on-premises and Azure cloud services to create a streamlined and scalable system. The process begins with data being sourced from an on-premises SQL server, which stores radiology report impressions. These impressions are transferred to an Azure SQL database, where they are stored and prepared for further analysis. This architecture uses direct interaction between Azure SQL, an Azure Web App, and the Azure OpenAI service. The Azure OpenAI service, hosting the GPT-4o model, is invoked by the Azure Web App to perform text classification on the radiology impressions and return pulmonary embolism classification results. These results are then stored back in the Azure SQL database. The web app fetches the results from Azure SQL and displays them for end users.

As shown in Figure 4, the web app was built using Python Flask for the backend, along with HTML, CSS, and JavaScript for the frontend. The interface allows users to query the system by submitting a patient's medical record number to retrieve the corresponding PE classification result. Users can also refresh the data or download the results for further analysis. The table on the right displays relevant patient information, including patient IDs, encounter IDs, admission times, and PE classification results. This interface serves as a convenient tool for health care professionals to quickly identify patients with a PE diagnosis, improving clinical decision-making and patient outcomes by providing prompt, automated insights. The Web App has been operationalized at Virtua Health, New Jersey.

Evaluation Metrics and Statistical Testing

To evaluate the performance of the PE classification model, we used several commonly used metrics (Textbox 4).

Textbox 4. Classification evaluation metrics.

- Sensitivity (Recall): The proportion of actual PE cases that the model correctly identified. It measures the model's ability to detect positive cases (PE) and is defined as the ratio of true positives to the sum of true positives and false negatives.
- Specificity: The proportion of actual non-PE cases that the model correctly identified. It reflects the model's ability to avoid false positives, calculated as the ratio of true negatives to the sum of true negatives and false positives.
- F_1-score: A harmonic mean of precision and recall, which provides a balanced measure of the model's performance, especially in cases of imbalanced data. It is particularly useful for evaluating the trade-off between precision and recall in the context of PE classification.

XSL•FO
RenderX

To rigorously evaluate and compare model performance, we used nonparametric bootstrap sampling with 1000 iterations on both the validation and postdeployment datasets. In each bootstrap iteration, samples were drawn with replacement from the dataset, and standard evaluation metrics—sensitivity, specificity, and F_1-score—were calculated. This process yielded 1000 metric estimates per model (GPT-4o and Clinical Longformer), providing an empirical distribution for each metric.

From these distributions, the mean and 95% CI were derived using percentile-based estimation. This approach enables robust quantification of performance uncertainty without assuming normality.

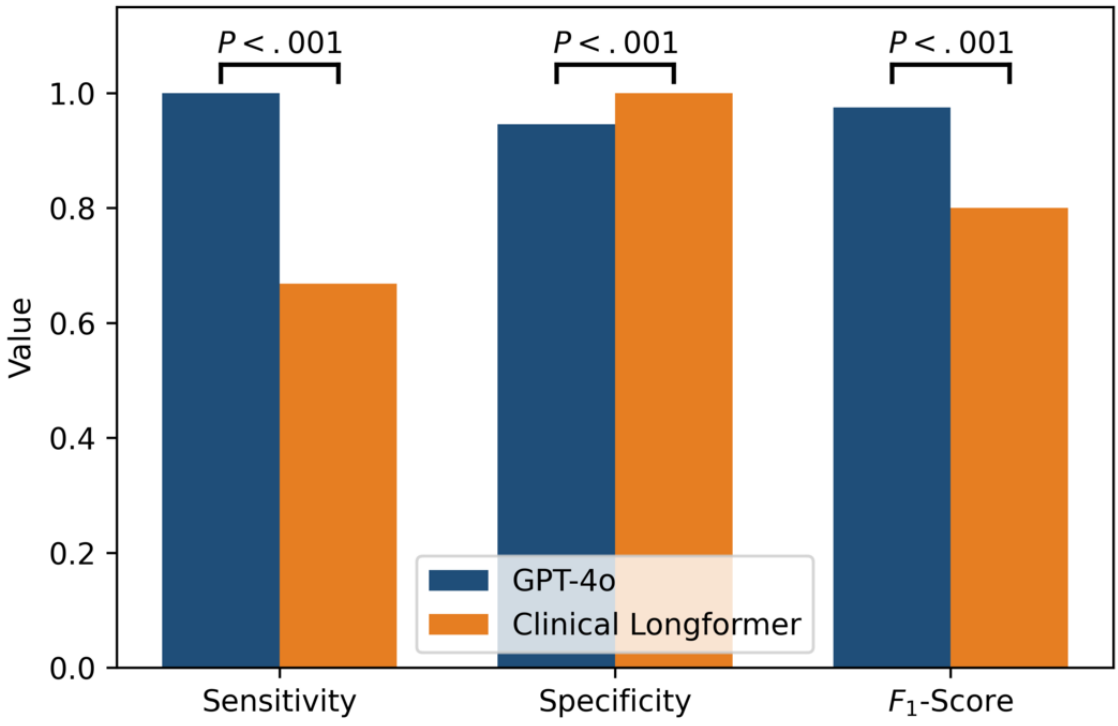
To statistically compare the models, we conducted paired, 2-sided Wilcoxon signed rank tests on the bootstrapped metric distributions. This nonparametric test assesses whether the differences in paired metric values across bootstraps are statistically significant. A significance level of α=.01 was used to determine the threshold for significance.

The same bootstrapping procedure was applied to the postdeployment dataset to calculate mean metric values and corresponding 95% CI. However, statistical significance testing was conducted only on the validation dataset to ensure controlled model comparisons under consistent evaluation conditions. In the postdeployment setting, only the GPT-4o model was in use.

Ethical Considerations

The studies involving humans were approved by Virtua Health institutional review board (FWA00002656). The studies were conducted in accordance with the local legislation and institutional requirements. The ethics committee or institutional review board waived the requirement of written informed consent for participation from the participants or the participants' legal guardians or next of kin because the research involved no more than minimal risk to subjects, could not practically be carried out without the waiver, and the waiver will not adversely affect the rights and welfare of the subjects. This requirement for consent was waived on the condition that, when appropriate, the subjects will be provided with additional pertinent information about participation.

Results



Overview

This section presents the research findings. First, we evaluate the Clinical Longformer and GPT-4o models using the validation dataset during the development phase. Then, we assess the performance of the deployed GPT-4o model post deployment.

Models Evaluation

Figure 5 presents a comparative analysis of evaluation metrics, including sensitivity, specificity, and F_1-score, between GPT-4o and Clinical Longformer. The results demonstrate statistically significant differences across all 3 metrics (P<.001), as determined by the Wilcoxon signed-rank test.

Figure 5. Evaluation metrics comparison of Clinical Longformer (baseline model) and GPT-4o.

XSL•FO
RenderX

GPT-4o exhibits superior sensitivity, achieving a perfect sensitivity of 1.0 (95% CI 1.0-1.0), in contrast to Clinical Longformer, which attains a sensitivity of 0.6684 (95% CI 0.5644-0.7604). This indicates that GPT-4o captures all positive cases correctly, whereas Clinical Longformer has a notable false negative rate. For specificity, Clinical Longformer achieves a perfect score of 1.0 (95% CI 1.0-1.0), slightly surpassing GPT-4o, which attains a specificity of 0.9456 (95% CI 0.9022-0.989). Although both models perform well in distinguishing negative cases, GPT-4o exhibits a marginally higher false positive rate. Regarding the F_1-score, GPT-4o significantly outperforms Clinical Longformer, with an F_1-score of 0.975 (95% CI 0.9495-0.9947) compared to 0.8002 (95% CI 0.7215-0.8639) for Clinical Longformer. This improvement reflects GPT-4o's higher balance between precision and recall, leading to superior overall classification performance.

The statistically significant differences across all 3 metrics underscore GPT-4o's robust generalization and enhanced performance in comparison to Clinical Longformer, suggesting its potential for improved clinical applications.

Postdeployment Performance

Based on GPT-4o's excellent performance during the validation phase, where it achieved superior metrics, it was selected for deployment in the operational setting. The postdeployment evaluation of the GPT-4o model was conducted using a dataset of 200 records, which was selected using stratified sampling from the operational data. Table 2 provides a summary of the dataset characteristics, including 100 positive cases of pulmonary embolism and 100 negative cases.

Table 2. Postdeployment testing data characteristics. A stratified random sample of 200 records was taken from the operational dataset for postdeployment evaluation.

Metric	Values
Number of observations	200
Average number of words (a token is approximately three-fourths of a word)	43.76
Number of pulmonary embolism-positive cases	100
Number of pulmonary embolism-negative cases	100

In postdeployment, sensitivity remains at a perfect 1.0 (95% CI 1.0-1.0), demonstrating the model's ability to correctly identify all positive cases without false negatives. Specificity, however, shows a slight decrease compared to predeployment values, with a point estimate of approximately 0.94 (95% CI 0.8913-0.9804), suggesting a modest increase in false positives. The F_1-score remains high at approximately 0.97 (95% CI 0.9479-0.9908), indicating a strong balance between precision and recall. While GPT-4o maintains robust predictive performance postdeployment, with high sensitivity and a stable F_1-score, the slight decline in specificity highlights a potential area for further refinement.

Discussion

Principal Findings

This study underscores the efficacy of GPT-4o in automating the extraction of PE diagnoses from radiology report impressions. GPT-4o demonstrated excellent performance across sensitivity, specificity, and F_1-scores during both validation and postdeployment evaluations. These findings suggest that GPT-4o's advanced language understanding capabilities allow it to capture subtle contextual and semantic nuances in radiology impressions, which are often critical for accurate diagnosis.

This success is attributed to GPT-4o's ability to leverage large-scale training on diverse datasets, which enhances its generalizability and adaptability. In addition, its deployment as a cloud-based tool offers scalability, making it accessible to health care systems of varying sizes. These attributes make GPT-4o a transformative tool in clinical AI, setting a benchmark for future applications in radiology and other diagnostic domains. This success has also been recognized in various studies, as GPT-4o has demonstrated promise in addressing critical tasks across different areas of radiology [37-41].

Error Analysis

As indicated in the Results section, GPT-4o scored 1.0 (95% CI 1.0-1.0) on sensitivity. However, the specificity was 0.94 (95% CI 0.8913-0.9804), hinting at a false positive rate of around 6%. Here, we look at 3 of these false positives to uncover any commonality.

The first sample, labeled as "Yes" while the ground truth (human labeler) says otherwise, has the following impressions text: "Mild right upper lobe infiltrate. Heterogeneous density of the pulmonary artery, which could represent pulmonary embolus." This is a borderline case, where the text indicates a likelihood of PE without firm confirmation. The model was able to bring attention to this case for further evaluation. Also, ground truth labeling may suggest the need for further validation.

The second sample's impressions text states "(1) Limited examination as mentioned above, particularly further evaluation of the pulmonary arteries in the right lung. Questionable subsegmental pulmonary embolism may be present in the right middle lobe. Follow-up would be helpful as clinically indicated. (2) Large right pleural effusion. Adjacent lung consolidation suggests atelectasis. (3) Mild ground glass infiltrates in the right upper lobe and left lower lobe. This may represent mild pneumonitis. (4) Small left pleural effusion. (5) Incidental findings as above." The model indicated the presence of PE. If we look at the text, we can see that the radiologist indicated a questionable PE. This case is similar to the previous one, in which the model labels likelihoods and questionable diagnoses

XSL•FO
RenderX

as indicative of PE, which could be a useful way to bring clinicians' attention to the case for further evaluation.

The third sample impressions text is "(1) Small linear filling defects involving the right lower lobe, left upper lobe, and left lower lobe, likely sequela of chronic pulmonary embolism. No convincing findings of acute pulmonary embolism. No imaging findings of right heart strain. (2) Interval enlargement of multiple pulmonary nodules measuring up to approximately 12 mm. Further correlation with PET/CT versus follow-up computed tomography in 3 months is recommended. (3) Areas of mild subpleural atelectasis or scar with mild interstitial thickening that may be related to chronic change, although mild pulmonary edema or infection would be difficult to entirely exclude." The text indicates that "No convincing findings of acute pulmonary embolism." This resulted in a negative ground truth label. However, the model interpreted the "likely sequela of chronic pulmonary embolism" as an indicator of PE. The latter suggests that filling defects were a result of a past medical condition. Thus, this might be a definite false positive.

In summary, analyzing some of the false positives indicates the model's ability to bring attention to borderline cases that might hint at the presence of PE, allowing for further clinical validation. However, the model sometimes results in definite false positives when the radiology text ambiguously discusses PE in the context of past conditions.

Operational and Clinical Implications

The postdeployment results of GPT-4o show several important operational and clinical implications. First, the model's sensitivity and specificity in a real-world setting indicate that it can help distinguish between subjects who have pulmonary embolisms and those who do not, without many false positives or negatives. This is important in a clinical setting where missing cases of pulmonary embolism have implications for patient outcomes, and false positives can lead to unnecessary further investigation or treatment. At Virtua Health, the model successfully identified over 700 positive PE cases in 2024.

From an operational perspective, the model's excellent accuracy on both the validation and postdeployment testing datasets means that the model can be operated in an autonomous manner which would help reduce the workload of radiologists and other health care professionals. As a result, it can classify cases correctly, thus taking some of the pressure and time off clinicians and their ability to concentrate on other, more challenging or time-consuming cases. Furthermore, the model's high precision means that health care resources are used more effectively, with fewer unnecessary interventions and therefore better patient care.

Clinically, the use of GPT-4o increases the decision support that clinicians can receive by offering a correct answer to the question regarding the presence of pulmonary embolism based on the information presented in the radiology reports. This early recognition can result in early diagnosis and management and therefore better patient results and possibly reduced mortality. Moreover, the stability of the performance of GPT-4o in identifying pulmonary embolisms in various datasets suggests robustness and generality, which could be useful in various clinical settings.

Ethical Issues in the Use of AI Models in Health Care

The employment of AI models in health care induces multifaceted ethical issues that need to be deliberated on. The first and foremost concern is the privacy of the patients and the security of the information because medical information is private. This includes strong network security, policy compliance with laws like HIPAA (Health Insurance Portability and Accountability Act) and General Data Protection Regulation, and data exposure minimization during training and use of the model. It is crucial to ensure that AI systems work within these legal and ethical parameters to ensure the credibility of their use.

Another important factor is compliance with regulations because the application of AI in health care has to be compatible with the standards that are set on a regional and international level. This includes making sure that the process of training, validation, and integration into the clinical workflow of the model is well documented. These processes are easily understandable and can be explained to health care providers, patients, and regulators, thus establishing the ethical and legal sustainability of technology.

Another important issue is bias and fairness as AI models trained on small and biased datasets are likely to emit biased output. For instance, if the training data is biased then the predictions of the model may be unfair to some patients and thus lead to unequal care. This is particularly a concern in health care where discrimination can have severe impacts on minority populations, stressing the need to ensure that datasets are inclusive, and model evaluation focuses on fairness.

Finally, it is important that in using AI in the various fields of life, transparency and accountability are considered to create confidence in the use of AI. The results of the model must be easy to understand and explain to the clinicians and patients, hence the need for explainable AI. Moreover, it is crucial to subject the models to routine assessments and performance tracking to provide evidence of accountability and trustworthiness in the long run.

To address these ethical issues, there is a need for ongoing assessment, open reporting, and interaction between AI creators, health care deliverers, and regulators. Thus, the main aspects that can be improved are the aspects that when improved will help achieve the best possible results with the use of AI in health care while at the same time adhering to ethical principles and protecting the rights of patients.

Bias Evaluation

LLMs are generally pretrained on large corpora of texts from the internet. As a result, inherent biases in human language can influence model outputs. Recent LLMs, such as GPT-4o, undergo posttraining alignment to reduce biased responses. This serves as the first line of defense against bias. Second, in our case, the LLM is instructed to return a single label (yes or no), which may further reduce the potential for hallucinations and bias. LLMs typically require more tokens to reveal their

XSL•FO
RenderX

underlying tendencies, which can include bias from the pretraining stage. Finally, we evaluated the model's performance using the F_1-score across different age groups and gender profiles.

Table 3 summarizes the F_1-score across different sex and age groups to assess the consistency of the model's performance across demographic subpopulations. The model demonstrates comparable F_1-scores for both female (0.970, 95% CI 0.930-1.000) and male (0.972, 95% CI 0.937-1.000) groups, indicating no apparent sex-based disparity in classification performance.

Table 3. F_1-score across sex and age groups.

Variable and group	Values, n (%)	F_1-score (95% CI)
Sex		
Female	98 (51)	0.970 (0.930-1.000)
Male	102 (49)	0.972 (0.937-1.000)
Age		
Under 30 years	10 (5)	1 (1-1)
30-50 years	25 (12.5)	0.963 (0.867-1.000)
50-70 years	93 (46.5)	0.982 (0.951-1.000)
70-90 years	62 (31)	0.966 (0.906-1.000)
90 years and older	10 (5)	0.823 (CI 0.500-1.000)

Across age groups, the F_1-scores remain generally high, with minor variations. The highest score is observed in individuals under 30 years old (F_1-score=1.000), although this group comprises only 5% of the sample, suggesting potentially limited generalizability due to the small sample size. The model performs well for the majority age groups—50-70 years (F_1-score=0.982, 95% CI 0.951-1.000) and 70-90 years (F_1-score=0.966, 95% CI 0.906-1.000)—which collectively represent over 75% of the dataset. However, performance decreases slightly for individuals aged 90 and above (F_1-score=0.823, 95% CI 0.500-1.000), likely due to a smaller sample size and increased clinical complexity in this cohort. Overall, the model demonstrates robust and consistent performance across most demographic groups, with slight variation observed at the extremes of age distribution.

Explainability

GPT-4o is an LLM built on transformer architecture, a type of neural network that uses an attention mechanism to learn semantics. Due to its complexity, the model is inherently a black box. However, since the model generates output by continuing the input text based on user instructions, the output can be interpreted as the most probable completion (especially when the temperature parameter is set to 0.0).

In our case, the instructions are to analyze radiology impressions and return a "Yes or No," indicating the presence or absence of PE, respectively. In real-world decision-making, users are informed that the LLM generates responses based on the most likely continuation of the input text according to the instructions provided. The generated label is returned to users along with the corresponding impressions for validation and confirmation.

Exploring explainable artificial intelligence methods is highly encouraged to better understand how input text influences LLM output, improving predictability and transparency. Techniques such as Shapley Additive Explanations (SHAP) and attention mechanism analysis can support this effort. In our case, implementation was challenging due to the use of a large proprietary LLM (ie, GPT-4o), for which we do not have access to the model architecture needed for such analyses. Therefore, leveraging open-source LLMs in the future could enable the application of these techniques.

The GPT-4o-based PE classifier is delivered through a web application, requiring user involvement to confirm the model's results. In summary, our application adopts a human-in-the-loop approach. While this supports practical use, the broader explainability of LLM output remains an ongoing area of research aimed at better understanding the underlying mechanisms of next-token prediction.

Limitations

As the study shows promising results, there are important limitations, and their implications cannot be overlooked. A major limitation is the size of the dataset used in this study, which is 1000 training samples, 200 validation samples, and 200 postdeployment testing samples. Another limitation is the data imbalance in the training dataset (for the Clinical Longformer). With such a restricted number of examples, the model may not be able to generalize its learning to the full extent of the clinical scenarios that are likely to be encountered in the real world. This could lead to it being less accurate in real-world use, where report structures can differ significantly, and larger datasets are usually used to increase model confidence and stability.

Another limitation has to do with the model's generalization. The training data was collected from a single health care organization, Virtua Health, which means that the language and cultural features that are unlikely to be encountered in reports from other hospitals or countries may not be well-represented in the model. As a result, this may restrict the applicability of

XSL•FO
RenderX

the model to other settings unless it is retrained (or prompt-engineered) with local data.

The study also found that the Clinical Longformer, which was used as a baseline, could not grasp some of the semantic details, resulting in the misclassification of 2 positive PE cases. This suggests that future work should build on this study to enhance the architecture of transformer models specific to clinical tasks, especially those that entail processing medical text with sophistication.

Some issues may occur when implementing the model in the real world even though GPT-4o performed excellently in controlled experiments. Real-world data often contains errors, omissions, or other noise that the model may not be able to handle properly. In addition, there are potential threats to consistency in reporting practices that may lead to inconsistencies in the information captured by the model.

Future Work

To overcome these limitations, future work should focus on the growth of the dataset, which should be expanded to include a bigger and more complex set of samples that would encompass different types of radiology reports, patients, and institutions. This will increase the size of the dataset and the variety of the samples, which in turn will increase the model's coverage and stability. Data imbalance in the training dataset of the Clinical Longformer should be tackled by using data augmentation techniques to test the impact of validation performance. Furthermore, the model must be tested in different health care contexts to determine its effectiveness, which means that external validation is critical. External validation can be achieved through collaborations with other health systems or testing on publicly available datasets. To mitigate real-world operationalization challenges, future implementation should include routine performance audits to monitor model accuracy over time, periodic retraining with updated real-world data to maintain robustness, and regular human validation checks to ensure data quality and reflect evolving documentation practices. These strategies can help maintain reliability despite variability in data quality and reporting standards. Overall, these measures will assist in ensuring that the model is not only efficient but also easily implementable in various health care environments.

Conclusions

In conclusion, this study features an effective LLM-based approach to the automation of the extraction of PE diagnoses from radiology report impressions. We then compared the performance of a fine-tuned Clinical Longformer and GPT-4o and found that GPT-4o outperformed in terms of sensitivity, specificity, and overall accuracy both before and post deployment. The integration of GPT-4o into clinical practice has several operational and clinical benefits, including decreasing the need for manual review, improving clinical decision support, and detecting cases of PE more quickly. Furthermore, the model's capability to lighten the load of manual review to a great extent is a key contributor to improving the workflow of the diagnostic process, thereby allowing clinicians to channel their efforts toward more challenging problems. These qualities make it suitable for application in other clinical settings with the potential to go beyond PE diagnosis to other medical conditions that require comprehensive and accurate analysis of radiology reports. Not only does its integration enhance efficiency but also the quality of clinical decision-making processes. Future work may involve expanding this approach to other medical conditions and improving the integration of NLP-based models into clinical workflows to keep on enhancing the quality of health care delivery.

Data Availability

The data analyzed in this study are subject to the following licenses or restrictions: data in this study are not available due to agreements made with the institutional review board of Virtua Health.

Abstract

Background: Social media is acknowledged by regulatory bodies (eg, the Food and Drug Administration) as an important source of patient experience data to learn about patients' unmet needs, priorities, and preferences. However, current methods rely either on manual analysis and do not scale, or on automatic processing, yielding mainly quantitative insights. Methods that can automatically summarize texts and yield qualitative insights at scale are missing.

Objective: The objective of this study was to evaluate to what extent state-of-the-art large language models can appropriately summarize posts shared by patients in web-based forums and health communities. Specifically, the goal was to compare the performance of different language models and prompting strategies on the task of summarizing documents reflecting the experiences of individual patients.

Methods: In our experimental and comparative study, we applied 3 different language models (Flan-T5, Generative Pretrained Transformer [GPT], GPT-3, and GPT-3.5) in combination with various prompting strategies to the task of summarizing posts from patients in online communities. The generated summaries were evaluated with respect to 124 manually created summaries as a ground-truth reference. As evaluation metrics, we used 2 standard metrics from the field of text generation, namely, Recall-Oriented Understudy for Gisting Evaluation (ROUGE) and BERTScore, to compare the automatically generated summaries to the manually created reference summaries.

Results: Among the zero-shot prompting–based large language models investigated, GPT-3.5 performed better than the other models with respect to the ROUGE metrics, as well as with respect to BERTScore. While zero-shot prompting seems to be a good prompting strategy, overall GPT-3.5 in combination with directional stimulus prompting in a 3-shot setting had the best results with respect to the aforementioned metrics. A manual investigation of the summarization of the best-performing method showed that the generated summaries were accurate and plausible compared to the manual summaries.

Conclusions: Taken together, our results suggest that state-of-the-art pretrained language models are a valuable tool to provide qualitative insights about the patient experience to better understand unmet needs, patient priorities, and how a disease impacts daily functioning and quality of life to inform processes aimed at improving health care delivery and ensure that drug development focuses more on the actual priorities and unmet needs of patients. The key limitations of our work are the small data sample as well as the fact that the manual summaries were created by 1 annotator only. Furthermore, the results hold only for the examined models and prompting strategies, potentially not generalizing to other models and strategies.

Introduction

Background

For many patients, the World Wide Web plays an important supporting role in coping with their condition. In fact, social media sites, digital support groups, and forums as well as social networks play an important role in the life of patients as sharing and consuming experiences with peers provides emotional, informational, and psychological support [1]. It has been indeed shown that sharing health-related experiences in online communities has an effect of empowerment on patients, increasing their subjective and psychological well-being, leading to increased self-management and control [1].

In addition to being used for receiving support, social media is increasingly used by patients to educate themselves on a disease and to find the hospitals or physicians most capable of treating their condition [2]. When engaging with social media, users are willing to disclose very intimate information [3]. In fact, it has been shown that the anonymity of many social media sites increases the level of self-disclosure [4]. The consumer survey by the PwC Health Research Institute [5] has indeed shown that >30% of respondents would be comfortable having their social media conversations monitored if those data could help identify ways to improve their health. In a study with adults presenting to an academic, urban emergency department, Padrez et al [6] found that, among patients with a social media profile, 71% consented to sharing their social media data to compare it to their electronic medical records. These figures convey that a substantial proportion of patients are willing to share their social media data for research purposes if the data contribute to improving their condition and those of their peers. A recent study confirmed these previous results, showing that participants would be willing to donate some of their digital data to researchers and clinicians in pursuit of health-related insights [7].

Against this background—the World Wide Web and social media playing an empowering role in patients' lives and, at the same time, patients being willing to donate their data if this contributes to improving their and others' health condition—an important question is how relevant insights can be obtained from the data. The Food and Drug Administration has identified social media data as one important source of "patient experience data," that is, data that can foster understanding of the unmet needs and priorities of patients as a basis to design more effective clinical studies; support Outcomes Research activities; and, ultimately, develop better drugs that actually improve patients' lives, well-being, and functioning [8]. In fact, methodologies for patient listening are quite mature and are widely used in patient-focused drug development to automatically analyze social media content as a basis to understand which symptoms are most burdensome to patients; how they experience existing treatments, which outcomes matter to them, and, overall, how their quality of life is affected by the disease [9].

However, these methodologies mostly provide quantitative insights as they rely on the automatic analysis of social media content using techniques from natural language processing (NLP), extracting key information and summarizing it statistically to obtain an understanding of trends at the level of an entire patient population or patient cohort of interest. A frequent problem is how to obtain a more qualitative understanding of how the disease affects patients' daily functioning and living. Most NLP methods, in fact, can extract single entities or concepts from textual data, but there is a lack of methods to analyze textual data at a more qualitative level in terms of the key messages that can be derived from a collection of texts. Summarization techniques, especially from abstractive summarization, can be used for this purpose, but so far research on how well posts from patients in online communities can be faithfully summarized is missing. While it is possible to manually analyze sample posts, there is the risk of missing relevant aspects, and the task of summarizing all the content manually is infeasible. Thus, there is a need for more scalable methods to derive qualitative insights from online patient experience data.

Considering recent developments in the field of large language models (LLMs), in this paper, we ask the question of to what extent existing pretrained LLMs can be used to aid the analysis and summarization of patient-authored social media content. LLMs are machine-learned models that have been "pre-trained" on large amounts of text [10] and later either fine-tuned for specific tasks [10-12] or trained to determine a suitable response to a certain instruction. The latter has been referred to as "alignment" and is typically done using reinforcement learning [13]. Overall, LLMs have been shown to perform very well on tasks such as summarization [14,15], sentiment analysis [16], question answering [17], and machine translation [12]. While excelling at many tasks, LLMs have also been shown to lack robustness and react too sensitively to small perturbations in the input and to be misled by so-called "adversarial examples" [18]. Furthermore, they have been shown to extrapolate too creatively in some cases, generating output that is factually wrong. This phenomenon has been sometimes referred to as "hallucination" [19].

Objectives

On the basis of the need for advanced methods to summarize the patient experience to yield qualitative insights and the promise of LLMs for many tasks, in this paper, we explicitly address the following question: can state-of-the-art LLMs be used to accurately summarize the experience of patients as shared in online data sources?

For this purpose, we experimentally compared different pre-trained LLMs: 2 from the Generative Pretrained Transformer (GPT) family (GPT-3 and GPT-3.5 [OpenAI]) and Flan-T5 (Google). While our focus was on using pretrained language models (LMs) that are prompted via instructions, we also carried out fine-tuning experiments to examine the impact of fine-tuning. We experimentally investigated several prompting strategies—zero-shot, 1-shot, and 3-shot learning—both alone and in combination with directional stimulus prompting (DSP) and chain of thought (CoT) prompting.

For this study, we focused on breast cancer and collected self-reported patient experience data from 5 forums, grouping the documents according to mentions of key symptoms and

XSL•FO
RenderX

treatments. The data collected comprise user posts from 5 leading web forums in which patients with breast cancer discuss their experiences with peers. The 5 sources were manually identified in a search process with the aim to identify the most relevant breast cancer forums.

The texts generated by the LLMs were evaluated with respect to a dataset of 127 manually produced reference summaries that were provided by one of the authors with years of expertise in analyzing patient experience data from social media. The generated texts were evaluated in terms of standard text generation metrics, including the Recall-Oriented Understudy for Gisting Evaluation (ROUGE) metrics and BERTScore. These metrics essentially compute the overlap between the automatically generated texts and the manually created references and, thus, provide an estimate of the quality of the summaries. In a case study, we discuss the output of different LLMs to obtain a sense of how these models are actually able to summarize the conversations.

Our results show that advanced prompting techniques substantially improve the ability of generative LMs to summarize online patient comments efficiently.

Methods

Overview

The research design corresponds to an experimental and comparative study. It corresponds to an experimental study in that it involved experiments in which the ability of LLMs to adequately summarize patient posts was experimentally evaluated by comparing automatically generated summaries to manually created summaries in a series of experiments. This study was also comparative as it evaluated the performance of different LLMs and prompting strategies in comparison to each other. The statistical validity of the results was assessed by computing their statistical significance using a 2-tailed *t* test and reporting *P* values comparing the significance of the results of the best-performing approach to that of the results of the other approaches. While, in most settings, we relied on off-the-shelf pretrained LLMs, we also tested the effect of fine-tuning on the task.

Dataset and Task Description

For this experimental and comparative study, data were crawled from different web-based forums in which patients with breast cancer discussed their disease experience with peers. The data were collected from the following public forums based on a search by the authors for the most prominent forums related to breast cancer available on the web: breastcancer.org, HealthUnlocked, her2support.org, and Macmillan Cancer Support. Data were automatically obtained via Socialgist [20] as a data provider and automatically analyzed to identify posts of individuals who had self-disclosed being patients with breast cancer using the methodology described previously by Spies et al [21]. The processing consisted of anonymization; entity extraction and linking via a knowledge graph; detection of symptoms, treatments, and quality of life mentions; detection of the severity of the symptoms; and detection of the impact of symptoms on the quality of life of the patients. In addition, demographic information involving age and gender was extracted if explicitly mentioned in the posts.

This yielded a dataset comprising 145,460 documents from 1146 patients. The preprocessing revealed the most frequent symptoms (n=8) and most frequent treatments used (n=119). They are listed in Multimedia Appendix 1. The data originated from a time frame between August 2016 and July 2022. As expected from a population with breast cancer, 99.5% (1089/1146) of the patients were female (male individuals can develop breast cancer in rare cases).

Before analysis, the data were automatically anonymized to remove mentions of person names, emails, URLs, telephone numbers, and addresses. A sample analysis showed that the accuracy of anonymization was 99.5%. For this purpose, we relied on the anonymization solution provided by Private AI [22].

The summarization corpus underlying this study was constructed as follows. For each topic in the dataset (where “topic” refers to one of the key symptoms of breast cancer or one of the existing breast cancer treatments as listed in Multimedia Appendix 1), all documents containing at least one mention of the topic were collapsed into a topic-specific subcorpus. If multiple topics were mentioned within a document, it became part of several subcorpora accordingly. This resulted in 127 topic-specific subcorpora derived from 8 key symptoms and 119 treatments. The number of documents per topic-specific subcorpus varied between 1 and 44, with a median of 12.

The summarization task can be seen as an instance of multidocument summarization as it consists of generating a concise summary for each of the 127 topic-specific subcorpora in the summarization corpus. The main challenges for multidocument summarization are, in addition to the fact that the input can be very long, the fact that the content of the documents to be summarized might be overlapping, complementary, or even inconsistent in the worst case [23].

As a gold standard for reference, 1 coauthor of this paper, SV, who is trained in the annotation of online patient conversations, provided a manual summary of each topic-specific document collection in the summarization corpus. With respect to symptom-related document collections, the annotator was instructed to focus on summarizing the impact of symptoms on patients’ daily functioning and quality of life. Regarding treatments, the goal was to summarize outcomes of the treatment as well as side effects or any other aspect related to the experience with these treatments. Consequently, the gold standard comprised 127 manual summaries of the symptoms and treatments listed in Multimedia Appendix 1. Given the substantial effort required in creating such summaries (approximately 3.5 hours per summary, >400 hours in total), it was not feasible to summarize each set of documents by several annotators. We discuss this further in the *Discussion* section while highlighting limitations.

The manual summary for the *rash* symptom, for instance, was as follows:

> *Patients perceive rashes as being horrible and uncomfortable, yet common. They are a great*

XSL•FO
RenderX

impairment for many patients since they are often painful and itchy. Some patients report that they cover multiple parts of the body, while others report it being localized to body parts, such as the face or the breast. They also report on the color and feel of the rash: pink, red, photosensitive, raised, large, hive-like, warm, etc. The appearance of the rashes changes with time, for some patients it became better (e.g. less itching), while for others worse (e.g. redder and hotter). Rashes can have different causes: they can be the side effect of treatments, such as chemotherapy, allergic reactions or symptoms. The cause for the rash is often unclear among patients, but it is often said that usually a rash is just a rash.

For the texts to fit the input size of the LLMs used in the study, the length was truncated to 1024 tokens. From the 127 manually generated reference summaries, 3 (2.4%) were used as examples for few-shot training, whereas the remaining 124 (97.6%) were used for evaluation only. For the fine-tuning experiments, the dataset was divided into 3 nonoverlapping sections: train, validation, and test. The resulting data sizes followed an 80:10:10 ratio, resulting in 79.5% (101/127), 9.5% (12/127) of the summaries for the train, validation, and test portions, respectively.

Models Used for Patient Comment Summarization

For the task of summarizing texts, we relied on pretrained LLMs. On the one hand, we relied on encoder-decoder architectures (Flan-T5), as well as on decoder-only architectures (GPT models). As our focus lay on the experimental testing and comparison of different prompting techniques (instructions in the form of natural language), we used LLMs that have the capability to follow textual instructions. Flan-T5 and the family of GPT-3 models have this property as they have been trained on data to generate answers for instruction-like prompts using reinforcement learning, a process known as alignment [24]. We relied on the following 3 models in particular: Flan-T5-base, GPT-3, and GPT-3.5. Flan-T5 is an enhanced version of T5 that has been fine-tuned on a mixture of tasks using the Flan collection of datasets [25]. For this study, the Flan-T5 base model was used along with GPT-3 and GPT-3.5. GPT-3 is an advanced iteration of the GPT model that operates as an auto-regressive LM featuring an impressive 175 billion parameters [26]. GPT-3.5 is a refined version of its predecessor and boasts an enhanced ability to adapt to diverse prompts and instructions, making it a versatile tool for various applications. Together, these models are a good cross-section of the current LLM landscape and were well suited for our task.

Prompting Techniques for Summarization

To explore the capabilities of LLMs to summarize patient comments, we compared various prompting strategies. We started with a prompt without examples or guidance on how to solve the task, called zero-shot prompting. As further methods, we enhanced the prompt by introducing examples of summarized patient comments (few-shot prompting); giving hints by DSP; and, finally, guiding the model by asking for intermediate results invoked by a set of self-defined questions (CoT prompting). By combining different techniques (few-shot prompting with DSP and zero-shot prompting with CoT prompting), we investigated the most effective prompting technique for summarizing patients' comments.

One-shot prompting closely resembles the few-shot approach, differing in that a single demonstration is permitted along with the natural language task description [26]. The corresponding prompt template used can be found in Figure S1 in Multimedia Appendix 2.

To facilitate our experiment, we adopted this 1-shot prompt template. Within the template, (text) signifies the patient comments or experience regarding a symptom or treatment drawn from the example set, and (summary) represents the corresponding reference summary. Multimedia Appendix 2 contains other prompt templates that we exploited in our study.

Few-shot prompting introduces *k* examples consisting of a text and a summary provided by a human expert followed by the final text, which should be summarized by the model. For this study, *k* was set to 3 due to token limit constraints [26].

DSP is a framework that uses an adjustable LM to offer guidance to a black-box, frozen LLM to enhance its performance. Specifically, a policy LM is trained to generate discrete tokens acting as directional stimuli for each input of the LLM. These stimuli, such as keywords extracted from an article for summarization, are then integrated into the original input and fed into the LLM, steering its generation toward the intended target. DSP uses a customizable policy LM to produce the stimulus—in the case of summarization, keywords—to direct the LLM in generating a desired summary with improved metrics such as higher ROUGE scores or aligning more closely with human preferences. The policy LM can undergo training through supervised fine-tuning from annotated data and reinforcement learning from offline and online rewards, allowing for the exploration of directional stimuli that better align LLMs with human preferences. This adaptable framework is applicable to various LMs and tasks [27]. For this study, instead of a policy LM, KeyBERT [28] was used with the default parameters along with Keyphrase Vectorizers to extract accurate keywords for each patient comment that are given as hints to the summarizing LLM. KeyBERT is a straightforward and user-friendly approach to extracting keywords using Bidirectional Encoder Representations From Transformers (BERT) embeddings to generate keywords and key phrases that closely match the important content of a document [28]. Combining key phrase vectorizers with KeyBERT for key phrase extraction leads to a PatternRank approach, enabling the extraction of grammatically accurate key phrases that closely align with the document's content. In this process, the vectorizer initially extracts candidate key phrases from text documents, and KeyBERT then ranks these candidates based on their similarity to the document. The top *n* most similar key phrases can be regarded as document keywords. The use of Keyphrase Vectorizers alongside KeyBERT offers the advantage of obtaining grammatically correct key phrases as opposed to simple *n*-grams of predefined lengths [29]. In this study, both keywords extracted using KeyBERT with Keyphrase Vectorizers and frequent terms occurring in the patient comment were combined to form a single set that was used as hints or directional stimuli for each

XSL•FO
RenderX

patient comment to generate summaries. For example, the hints retrieved and used for the rash symptom were given as follows: severe rash; hives rash; rash hives; simple rash; red rash; cause; have; describe; impair; increase.

CoT prompting fosters reasoning capabilities by incorporating intermediate reasoning steps. The fundamental concept of this method is straightforward. By introducing phrases such as "Let's think step by step" or a similar instruction, it triggers the model to reason step by step, outputting intermediate results that are combined with other intermediate results into an overall summary. In our study, CoT prompting for the patient comment summary generation was done based on the element-aware summarization approach in the zero-shot setting. In the element-aware summarization approach using CoT, as part of element extraction, we first asked the LLMs to extract important elements mentioned in the patient comment using the following manually set guiding questions: (1) What is the main health- or medical-related topic discussed in this patient comment? (2) What are the important topics mentioned in this patient comment? (3) What are the symptoms and diseases mentioned in this patient comment? (4) What are the recovery methods or treatments mentioned in this patient comment?

Next, we concatenated the extracted elements (ie, the answers to the aforementioned 4 questions [A]) with the following prompt (P)—"Let's integrate the above information and summarize this patient comment:"—along with the patient comment (C) to prompt the LLM for patient comment summary generation. The input to the LLMs was [A; P; C], and the output was the final summary.

The advanced prompting techniques used in this study were applied in combination with each instruction-based model. Here, we tailored the use of these prompting techniques to the specific characteristics and insights derived from the data and task setup. For instance, with DSP, keywords extracted from patient comments were used as hints for generating summaries. Similarly, in CoT prompting, guiding questions were manually set to extract important elements from patient comments for summary generation. The prompt templates for summary generation, initially published by Google Research for Flan-T5 [30], were adopted as the baseline prompt template for implementing zero-shot, 1-shot, and few-shot prompting across all 3 models in our study. The same prompt template for different prompting techniques was followed for all 3 models except for CoT prompting. Together, this is a comprehensive collection of common prompting techniques, allowing for both a broad overview of the field as well as detailed insights into advantages and disadvantages of single techniques with respect to our task of summarizing patient experiences.

Experimental Setup

For our experiments, we used the pretrained model versions of all the models (Flan-T5, GPT-3, and GPT-3.5), as shown in Table 1. The table also shows the decoding parameters that were used for all the models across all prompting techniques. For all the models, the summarization length was set to 300 tokens to balance efficiency and completeness while remaining reasonably close to the maximum token length of the ground-truth summaries (377 tokens). Following previous work [31], the temperature was set to 0.97 to limit the randomness of the generated text in combination with our sampling-based decoding strategy. High temperature values decrease the deterministic behavior of the text generation model. A value of 0.97 corresponds to a moderate level of randomness, representing a trade-off between avoiding repetitive and blank summaries and allowing for too much randomness and unfaithful generated texts.

Table 1. Pretrained model versions and decoding parameters of all the models used in the experiment.

Model	Pretrained model version	Decoding parameters
Flan-T5	flan-t5-base	• min_length=150 • max_length=300 • do_sample=True • Temperature=0.97 • repetition_penalty=1.2
GPT-3	text-davinci-003	• Temperature=0.97 • max_tokens=300 • top_p=0.9 • presence_penalty=1
GPT-3.5	gpt-3.5-turbo-0301	• Temperature=0.97 • max_tokens=300 • top_p=0.9 • presence_penalty=1

To test the effect of fine-tuning, the Flan-T5 model was trained using the preprocessed train split of our dataset with the following training parameters: batch size of 1, a total of 10 training epochs, a learning rate of 0.00002, and weight decay of 0.01.

The chosen hyperparameters were set to fine-tune the Flan-T5 model effectively while minimizing the risk of overfitting. A small batch size helps manage memory limitations and adds implicit regularization. The 10 training epochs allow the model to learn from the data without excessive training, whereas the low learning rate (0.00002) ensures stable updates to pretrained weights, preventing drastic changes that could lead to overfitting. The weight decay of 0.01 acts as regularization by penalizing large weights, further preventing overfitting. In

XSL•FO
RenderX

addition, by using the same decoding parameters for both fine-tuned and non–fine-tuned Flan-T5 models, consistency in evaluation was maintained. To prevent overfitting, the model's performance was monitored on a validation set, ensuring that it did not memorize the training data.

The fine-tuned Flan-T5 model was used to generate the summaries with the same decoding parameters as shown in Table 1 for the non–fine-tuned Flan-T5 model.

Automatic summaries were generated for all models using the 7 prompting strategies. This was done for the 7 symptoms and 117 treatments as 1 symptom and 2 treatments were used as examples in the prompt in the few-shot cases, yielding a total of 2604 summaries (124 summaries per 7 prompting strategies for 3 models). In addition, for further experiments exploring the influence of fine-tuning, Flan-T5 was trained and validated on 113 summaries (n=101, 89.4% of the summaries for training and n=12, 10.6% of the summaries for validation) across 8 symptoms and 105 treatments. The remaining 11% (14/127) of the summaries for 14 treatments were used to measure performance in our automatic evaluation.

Automatic Evaluation

To evaluate the generated texts automatically, we relied on state-of-the-art evaluation metrics used in text generation research, in particular, the token-based ROUGE and BERTScore. These metrics allowed us to compare the similarity of the generated texts to the manually created reference. The token-based ROUGE metrics essentially compute the overlap of phrases between the automatically generated summarization and the reference summarization, thus estimating the similarity of both summaries. BERTScore relies on embeddings and, thus, compares the summaries at a more semantic level, abstracting from the specific words or phrases that appear.

In this study, the generated summaries from all 3 models were evaluated using ROUGE, and the rescaled F_1-score of BERTScore was calculated using the hidden representation states of the 17th layer of RoBERTa Large without inverted document frequency–weighting for the generated summaries. For ROUGE, we used 3 variants: ROUGE-1, ROUGE-2, and ROUGE-L. We used these 3 ROUGE variants to thoroughly evaluate the generated summaries. Each variant served a specific purpose: ROUGE-1 measures unigram (single-word) overlap to assess the occurrence of keywords without looking at the context, ROUGE-2 evaluates bigram (pair of consecutive words) overlap to capture context and word associations, and ROUGE-L analyzes the longest common subsequence to evaluate fluency and structural coherence [32]. These metrics collectively provide a nuanced assessment of the generated summary's content, coherence, and adherence to the reference summary.

We present the average score considering all 124 test instances by computing the ROUGE and BERTScore values for each reference summary compared with the generated texts. A case study was conducted involving 2 summaries that were analyzed qualitatively and discussed in more detail, comparing the different generated versions of it in all model settings. In addition to the experiments with LLMs, we calculated the ROUGE and BERTScore values for a baseline using the concatenation of all input texts as a trivial summarization baseline that does not summarize anything.

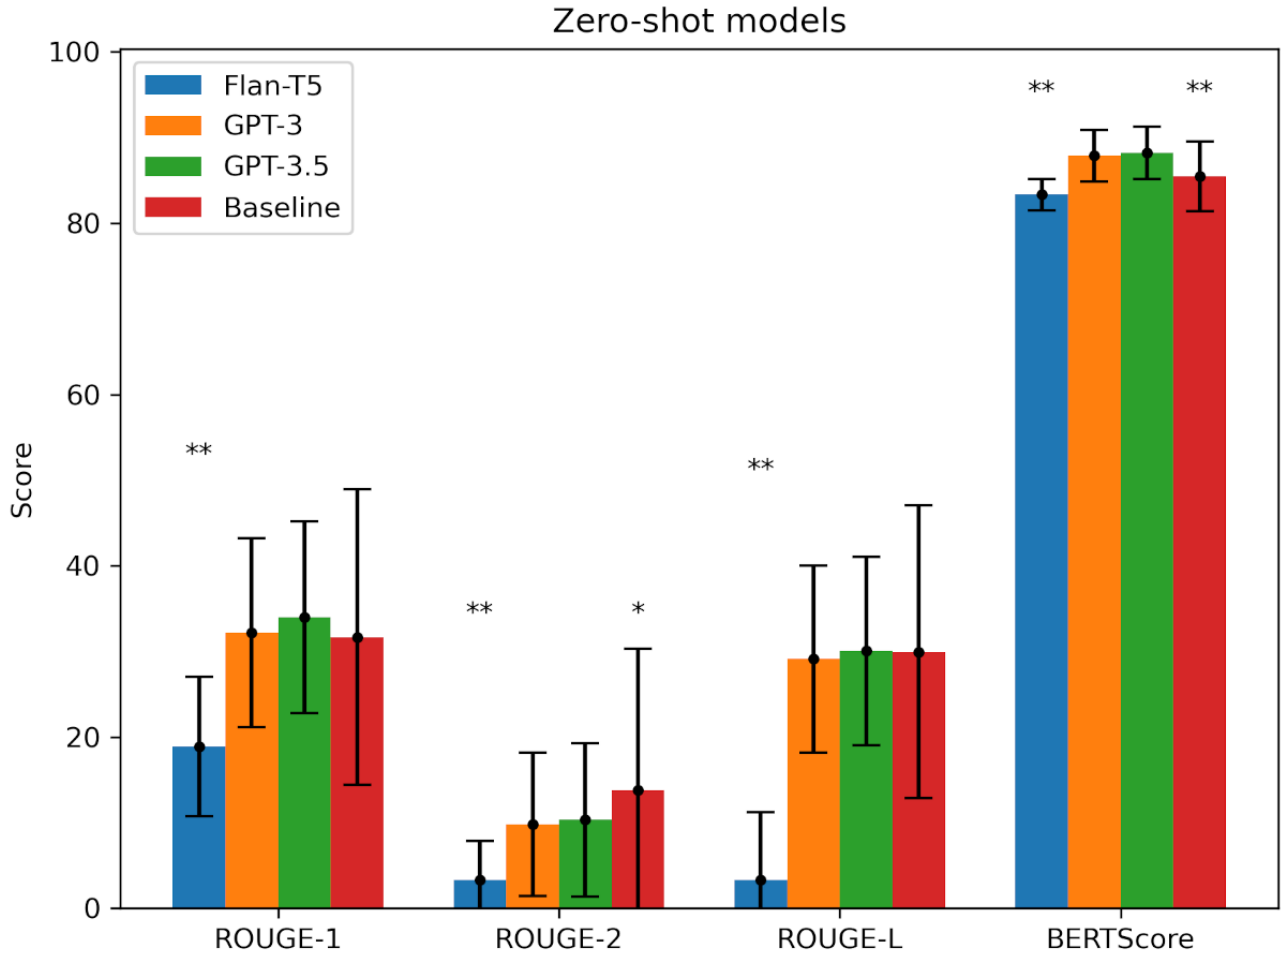
Ethical Considerations

Following recommendations on ethical methods to analyze data using NLP [33], the data were automatically anonymized by removing user IDs, personal names, addresses, and telephone numbers to minimize the risk of identification of a natural person to ensure compliance with the General Data Protection Regulation (GDPR). While the collected data still represent personal information, given the fact that we only analyzed data that had been made manifestly public by users without further provisions to protect the data, the use for research purposes can be argued to be acceptable given that there is a public interest in using these data to improve health care and that other means to collect such insights (eg, surveys) would represent a higher burden for patients [33]. On the other hand, the harm caused to patients by analyzing the data can be argued to be minimal as the content is already publicly available and no new information is released as part of the process.

According to the GDPR, there is a trade-off between the legitimate interests of data processors to process data that need to be balanced against the data protection rights of data subjects. In this particular case, there is a legitimate interest by society to rely on public data shared by patients as these data can contribute to improving the standard of care as well as the development of drugs that are relevant and address outcomes of relevance to patients. Furthermore, given that patients made their data "overtly and explicitly public" without any additional protection, we can assume that the sensitivity of the shared data is not that critical, and so exploiting them for the legitimate purpose of improving health care services is acceptable. The GDPR foresees that consent has to be obtained from data subjects to process their data. Given that the data were anonymized, patients cannot be directly contacted to obtain consent. In this respect, we processed the data making use of the exemption mentioned in the GDPR for processing data without explicit consent in case obtaining consent is not possible "with a reasonable effort." Obtaining consent would, in our case, not represent a reasonable effort as each patient would have to be contacted individually, and some patients might not even be active anymore on the forums or sites in question. Contacting specific users would require registering on the platform in question, which in many cases would violate the terms and conditions of the platform as only patients are allowed to register. On many forums, direct messages cannot be sent to users, so they could not be directly contacted. In general, it has been a matter of debate whether observational studies can be ethical without patient consent and which conditions would need to be met for the absence of patient consent to be ethical. The United Kingdom's Economic and Social Research Council, for instance, considers ethical the forgoing of patient consent as long as a study is not "undertaken lightly or routinely." It is only justified if important issues are being addressed and if matters of social significance that cannot be uncovered in other ways are likely to be discovered [34]. A broader review of ethical recommendations [33] suggests that social media listening (SML) for health research can be ethical without informed consent in cases in which anonymization is ensured,

XSL•FO
RenderX

harms are minimized, and there is a clear public benefit resulting from the analysis. As argued previously, all 3 criteria were fulfilled for our study.



Results

Overview

The evaluation was guided by three research questions: (1) Which model has the best performance compared to the reference summaries? (2) Which prompting techniques are most successful? (3) Does fine-tuning increase the models' performance in generating patient comment summaries by only using a small amount of training data?

Regarding the performance of the different models, Figure 1 shows the average ROUGE and BERTScore values for 124 summaries generated using zero-shot prompting on 3 models. Flan-T5 performed worst for all metrics and with very high significance as well (P<.001).

Figure 1. Mean scores per model and metric with corresponding SDs as error bars. Recall-Oriented Understudy for Gisting Evaluation (ROUGE) scores and BERTScore were obtained for all zero-shot models without fine-tuning; P values were obtained by comparing the mean scores for each model to the overall best-performing model (ie, Generative Pretrained Transformer [GPT], GPT-3.5). The figure shows that GPT-3.5 performed best for all metrics except ROUGE-2, for which the baseline performed best. *P<.05; **P<.001.

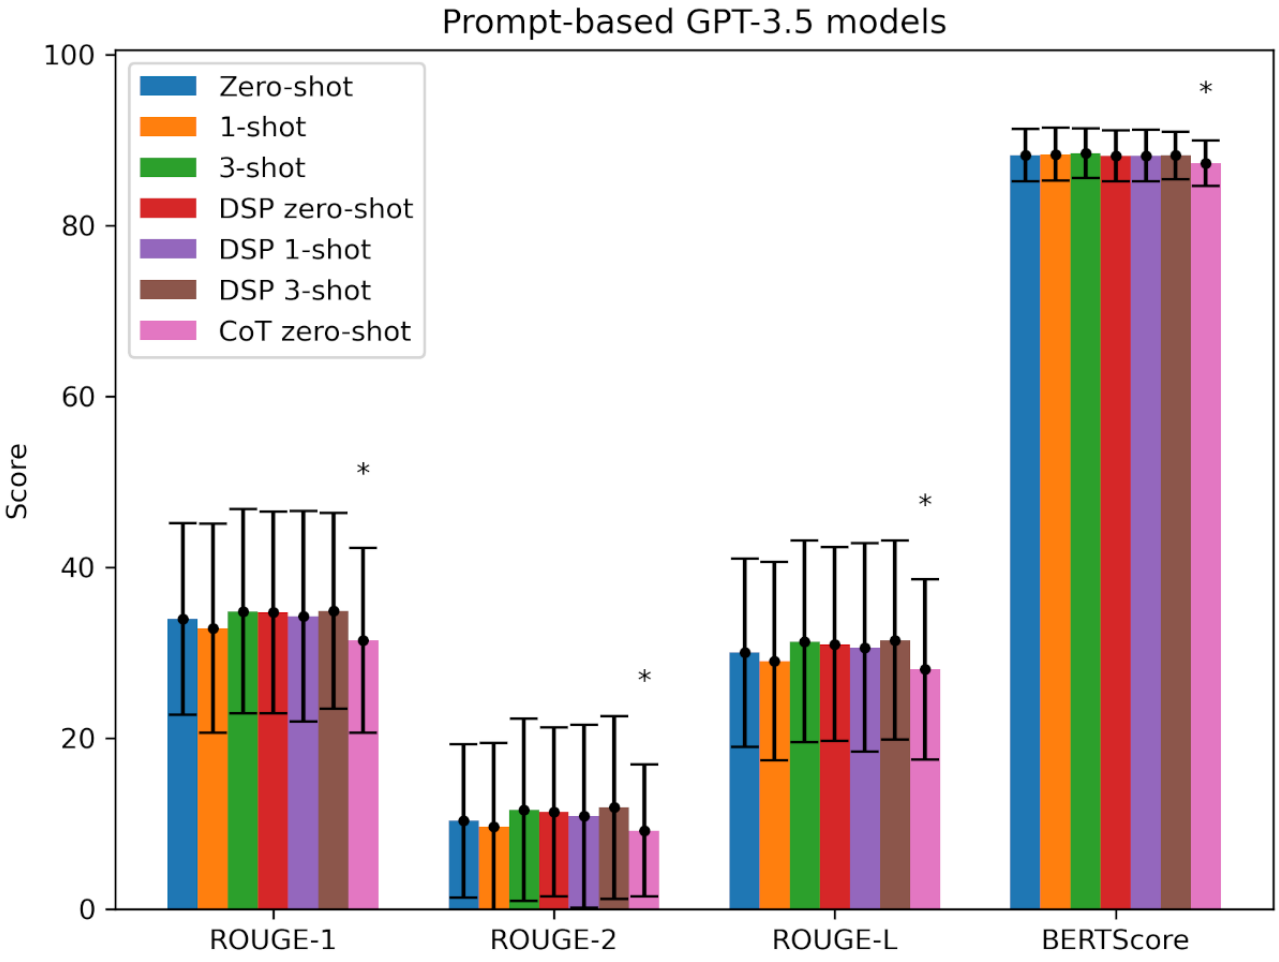
In contrast, GPT-3.5 performed better than all the other models (including the baseline) for all metrics, with a margin ranging from 0.4% to 79.8% except for ROUGE-2, where the baseline performed significantly better (P<.05). GPT-3 in all cases performed slightly worse than GPT-3.5 but better than Flan-T5.

The average text length of the input text (and, hence, the output of the baseline) was 4199 (SD 7809) words, which was much higher than the average text length of the GPT-3.5–generated summaries, which was 446 (SD 214) words. Therefore, the count of bigrams was higher in general for the baseline when compared to the GPT-3.5 summaries due to its high average text length, which is not suitable for an actual summary. However, in contrast to the baseline, GPT-3.5 generated reader-friendly summaries that were shorter than the original text, having a higher semantic closeness to the reference than the baseline (+2.8 points in BERTScore). A t test was carried out comparing all other model variants to GPT-3.5 to confirm the significance of the results. The exact results can be found in Table S1 in Multimedia Appendix 2.

Focusing on GPT-3.5 as the best overall model for zero-shot prompting, we proceeded to investigate the impact of different prompting strategies on the summarization performance. Figure 2 shows the average ROUGE-1, ROUGE-2, ROUGE-L, and BERTScore values for 124 summaries generated using the 7 different proposed prompting techniques. Again, the exact results can be found in Table S2 in Multimedia Appendix 2. Regarding the ROUGE score, the obtained evaluation scores show that DSP using 3 examples outperformed other prompting

XSL•FO
RenderX

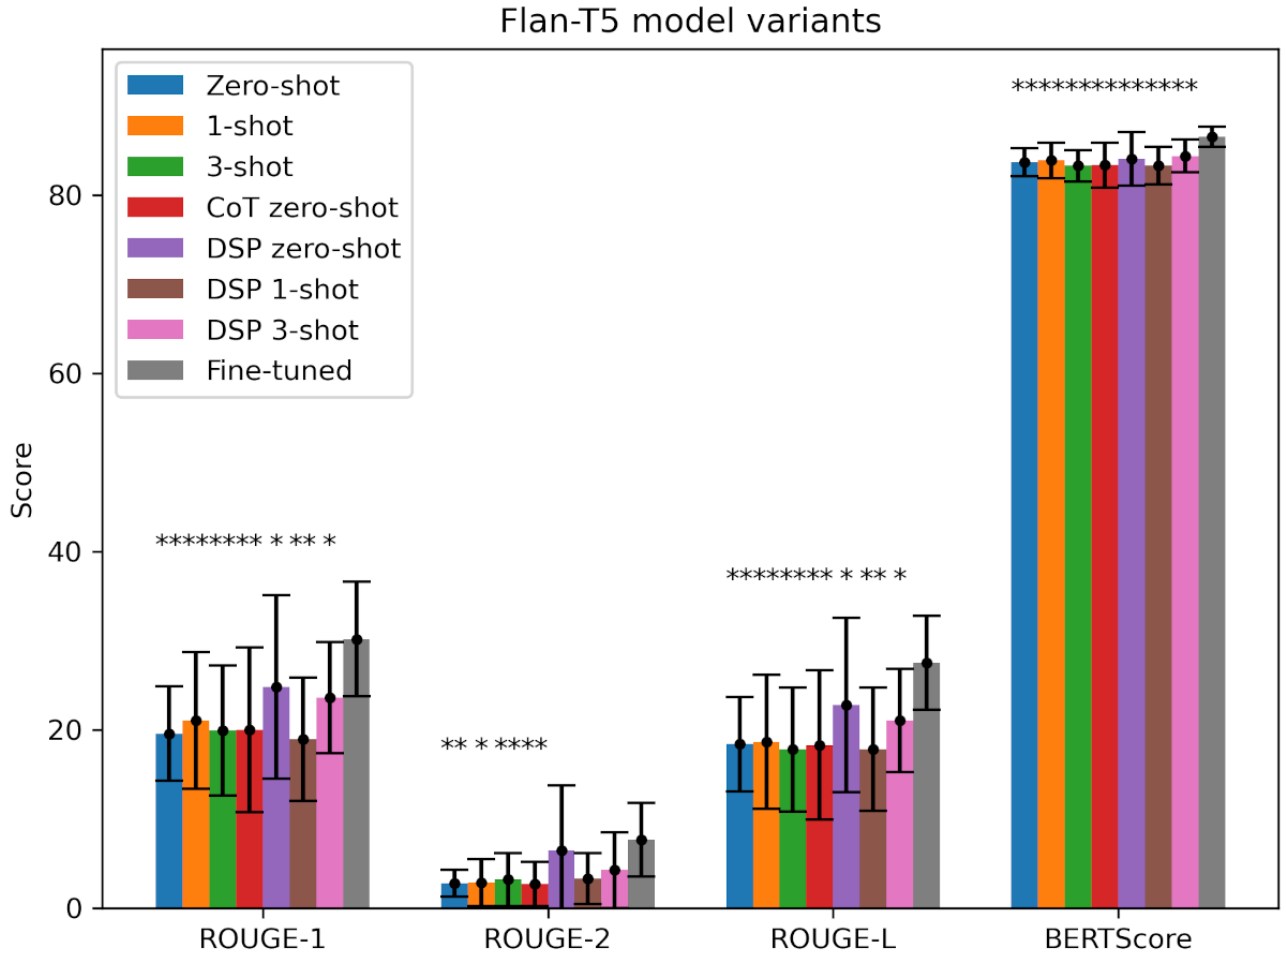
techniques. For BERTScore, 3-shot prompting without DSP outperformed all the other models. However, the differences among the different prompting techniques regarding their performance were only minor and not significant in most cases, especially for BERTScore. The only significant (P<.05) result was that CoT zero-shot prompting performed worse than all other prompting techniques.



Multimedia Appendix 2 provides tables detailing the results of the 7 prompting strategies for the Flan-T5 and GPT-3 models.

To explore the effect of fine-tuning under the restriction of having only a small amount of training data, Figure 3 shows the average ROUGE-1, ROUGE-2, ROUGE-L, and BERTScore values obtained for the fine-tuned Flan-T5 compared with the prompt-instructed Flan-T5 model for 14 test instances (we only considered Flan-T5 for fine-tuning as, given that GPT-3 and GPT-3.5 are closed source, they cannot be fine-tuned locally with a full control over the training process and involved data). Again, the exact results can be found in Table S3 in Multimedia Appendix 2. The fine-tuned Flan-T5 model outperformed the non–fine-tuned Flan-T5 model in all cases, with the non–fine-tuned variants performing worse with normal (P<.05) or even very significant (P<.001) results in almost all cases. Only for the ROUGE-2 scores of the 3 DSP strategies the results were not significant. Thus, upon evaluating the obtained scores, it is evident that fine-tuning—even with only a small amount of training data—is more effective than any prompting strategy for the Flan-T5-base model.

It is important to note that the fine-tuned Flan-T5 model cannot be directly compared to the prompt-based GPT models; it can only be compared to the prompt-based or non–fine-tuned Flan-T5 models, as shown in Figure 3.



All in all, among the tested models, GPT-3.5 performed best. The best-performing prompting strategy was DSP 3-shot prompting for the ROUGE scores and 3-shot prompting for BERTScore. For Flan-T5, the fine-tuned version performed better than all prompting strategies on non–fine-tuned Flan-T5 models.

Figure 2. Mean scores per prompting strategy and metric for Generative Pretrained Transformer [GPT], GPT-3.5 with corresponding SDs as error bars—Recall-Oriented Understudy for Gisting Evaluation [ROUGE], ROUGE-1, ROUGE-2, ROUGE-L, and BERTScore scores for prompt-based GPT-3.5 models, with P values obtained by comparing all prompt-based GPT-3.5 models to the best-performing GPT-3.5 directional stimulus prompting (DSP) 3-shot model. The figure shows that the DSP 3-shot model performed best. However, none of the results was significant except for the worst performance of chain-of-thought (CoT) zero-shot training. *P<.05; **P<.001.

XSL•FO
RenderX

Figure 3. Mean scores per prompting strategy and model variant and metric for Flan-T5 with corresponding SDs as error bars—Recall-Oriented Understudy for Gisting Evaluation [ROUGE] ROUGE-1, ROUGE-2, ROUGE-L, and BERTScore scores for the Flan-T5 model variants, with *P* values obtained by comparing all Flan-T5 models to the fine-tuned Flan-T5 model. The figure shows that the fine-tuned model outperformed all non–fine-tuned models no matter what prompting strategy was used. *P<.05; **P<.001; CoT: chain of thought; DSP: directional stimulus prompting.

Case Study

To discuss the performance of the approach in a more qualitative manner, we analyzed the different summaries provided by the different models in comparison to the reference summary for 1 treatment (Carboplatin) and 1 symptom or phenotype (neoplasm). We selected examples in which the ROUGE scores were highest. While it might seem unfair to select the topics with the best results, the case study is not meant as a proper evaluation but only to provide examples of how the summaries differed across methods.

Textbox 1 shows the different summaries of the patient experience with Carboplatin, including the reference summary and the GPT-3.5 zero-shot, GPT-3.5 three-shot, and GPT-3.5 DSP 3-shot summaries. The reference summary emphasizes that Carboplatin, being a new treatment and a good option to treat triple negative breast cancer, has good study results and better tolerability and is becoming increasingly popular. It emphasizes the side effects, such as hair loss and heart damage. It mentions that side effects might increase in combination with other drugs, such as Taxol and Gemcitabine.

The GPT-3.5 zero-shot summary highlights the efficacy (although not a good study performance explicitly), side effects (hair loss but also hearing loss and tinnitus), and popularity of the treatment. In addition, it highlights better tolerability of Carboplatin and Taxol in comparison to Carboplatin alone. It provides further details on dosage and scheduling and even goes as far as talking about the mechanism of action.

The GPT-3.5 three-shot summary highlights that Carboplatin has had good study results, as well as the side effects, mentioning hearing loss and tinnitus. The summary misses heart damage but includes an additional side effect not mentioned in the reference summary (ie, tinnitus). The summary goes further than the human-generated summary in terms of discussing the regimen and scheduling in addition to discussing outcomes in combination with other drugs.

The GPT-3.5 DSP 3-shot summary emphasizes the side effects (again, hearing loss and tinnitus) as well as better tolerability. It highlights that Carboplatin has shown promising results in clinical trials. Beyond that, it provides more detail on how patients deal with the side effects by using other treatments.

Overall, the 3 summaries cover the most important points highlighted by the human reference summary, providing some additional details (eg, dosage, mechanisms of action, other side effects, and combination with other drugs or treatments to reduce side effects).

XSL•FO
RenderX

Textbox 2 shows different summaries of the patient experience with neoplasm, including the reference summary and the GPT-3.5 zero-shot, GPT-3.5 three-shot, and GPT-3.5 DSP 3-shot summaries. The reference summary highlights patients' experiences with neoplasm, focusing on tumor size, aggressiveness, and growth rate. It discusses tumor structure, including receptors and mutations and varied treatment responses. Patients reported problems such as fluid retention; lymphedema; tissue damage; severe pain; and complications from spinal spread, such as vertebral fractures and bone marrow impairment. Treatment outcomes varied, with some tumors decreasing, staying stable, or growing despite interventions.

The GPT-3.5 zero-shot summary discusses patient experiences with neoplasms, covering tumor characteristics, treatment options, and responses. It distinguishes between benign and malignant tumors and mentions the potential for immunotherapy. However, it lacks details on specific patient-reported problems and complications highlighted in the reference summary, such as fluid retention and bone marrow impairment due to spinal spread.

The GPT-3.5 three-shot summary echoes the reference summary's emphasis on patients' experiences with tumor characteristics, including size, grade, and aggressiveness. It acknowledges the importance of postsurgical treatments such as chemotherapy and radiation in preventing cancer recurrence. It also discusses tumor markers and lymph node involvement. However, it provides a more concise overview, focusing on patients' concerns about tumor growth and aggressiveness and the importance of treatment in improving survival rates.

The GPT-3.5 DSP 3-shot summary delves into patients' tumor descriptions, covering size, stage, grade, and lymph node involvement. It acknowledges larger, aggressive tumors necessitating postsurgical treatments such as chemotherapy or radiotherapy. In addition, it recognizes benign tumors and the significance of tumor markers such as estrogen receptor, progesterone receptor, and HER2 in treatment decisions. The summary also discusses tumor flare after biopsy and size fluctuations over time, stressing the uniqueness of each patient's tumor and the need for personalized treatment plans, echoing the reference summary's focus on varied tumor responses and patient challenges.

Overall, the 3 summaries cover the key points highlighted in the reference summary while providing additional details such as genetic mutations, treatment responses, and the importance of individualized treatment plans.

Textbox 1. Reference summary, GPT-3.5 zero-shot summary, GPT-3.5 three-shot summary, and GPT-3.5 directional stimulus prompting (DSP) 3-shot summary about Carboplatin. The textbox shows that all summaries mention the most important points.

Reference summary

- "Carboplatin is a more recent treatment, deemed by patients as a good option to treat TNBC, having encouraging results in studies and a better tolerability. The treatment is more novel, yet becoming more popular. But it also causes side effects such as hair loss, heart damage. When combined with other drugs such as Taxol and Gemcitabine, the side effects increase."

GPT-3.5 zero-shot summary

- "The patient comment covers a variety of topics related to Carboplatin, a chemotherapy drug used to treat Triple Negative Breast Cancer (TNBC). The comment discusses the efficacy of Carboplatin in treating TNBC even without HER2 positivity, potential side effects such as hearing loss and tinnitus, and its popularity as a treatment option. The comment also touches on the dosing schedule and suggests that weekly carbo taxol is easier to tolerate than every 2 weeks IV carbo. Some comments mention hair loss and other side effects associated with Carboplatin. The comment also highlights the role of calcium carbonate in reducing the absorption of other medicines from the gut."

GPT-3.5 three-shot summary

- "Carboplatin is a chemotherapy drug used to treat Triple Negative Breast Cancer (TNBC), even if the patient does not have Her 2 positivity. Patients report that Carboplatin has been shown to have good results in trials and may be a better option than other treatments such as AC. However, some patients also report potential side effects of Carboplatin, such as hearing loss and tinnitus. Carboplatin can be given as a weekly regime or every two weeks, but the latter may cause a decrease in hemoglobin levels. Despite this, Carboplatin is still seen as an effective treatment option for high-grade TNBC. There is also ongoing research into the use of Carboplatin with other drugs to improve treatment outcomes."

GPT-3.5 DSP 3-shot summary

- "Carboplatin is a commonly used chemotherapy drug for treating TNBC, although it can cause side effects such as hearing loss and tinnitus. Patients report mixed experiences with the drug, with some finding it tolerable and others experiencing difficulty with its side effects. Carboplatin has shown promising results in clinical trials and is being studied in combination with other agents such as leronlimab. It is not clear why some patients are prescribed Carboplatin over other chemotherapy drugs, but it may be preferred for high-grade TNBC or in combination with radiotherapy. Patients also report using bicarbonate and calcium carbonate to manage side effects and improve blood pH levels during treatment."

XSL•FO
RenderX

Textbox 2. Reference summary, GPT-3.5 zero-shot summary, GPT-3.5 three-shot summary, and GPT-3.5 directional stimulus prompting (DSP) 3-shot summary about neoplasm. The textbox shows that, again, all important details are mentioned in the summaries, such as genetic mutations and treatment responses.

Reference summary

- "Regarding neoplasm, patients often describe the size of their tumors, how aggressive they are and how fast they grow. Furthermore, they also describe their structure, which receptors, mutations they have and how fast or slow they respond to treatments. There were many varied responses in these regards, e.g. many small but also many large treatments, responsive and non-responsive treatments and different types of tumors. Neoplasms caused an array of problems for patients such as fluid retention, lymphedema, acidity, tissue dama, a concave chest after removal of the tumor and chest muscle, inflammation, compression of nerves, severe pain and an immunosuppressive environment. For some patients where it spread to their spine, it impaired their bone marrow, caused complications, broke vertebrae and aggravated nodes. Some neoplasms decreased with treatment, but others either decreased and then came back, stayed stable or even grew despite treatment."

GPT-3.5 zero-shot summary

- "The patient comments mention various sizes and stages of tumors, as well as the presence or absence of lymph node involvement and markers such as HER2. Some tumors are benign while others are malignant, and treatment options include surgery, chemotherapy, and radiotherapy. Response to treatment varies, with some tumors showing complete response and others being slow-growing. In some cases, genetic mutations may be acquired under the selective pressure of therapy, and hot tumors with inflammation may respond to immunotherapy. Some tumors contain a mix of different cell types, and there may be concordance or discordance between cell-free DNA and tissue samples. Overall, the comments suggest that cancer diagnosis and treatment can be complex and individualized, and it is important to trust medical professionals while seeking support from others who have gone through similar experiences."

GPT-3.5 three-shot summary

- "Patients share their experiences with tumors, including their size, grade, and aggressiveness. They also mention the importance of postsurgical treatments, such as chemotherapy and radiation, in preventing cancer recurrence and improving survival rates. Patients highlight the difference between benign and malignant tumors and share their tumor markers and lymph node involvement. Some patients express concern about the growth and aggressiveness of their tumors, while others report slow-growing tumors."

GPT-3.5 DSP 3-shot summary

- "Patients describe their tumors in terms of size, stage, grade, and involvement of lymph nodes. Some patients report having larger and more aggressive tumors, which require postsurgical treatments such as chemo or radiotherapy to manage them. However, some tumors are benign and do not necessarily indicate cancer. Patients may also have a combination of different tumor markers such as ER, PR, and HER2, which may affect the aggressiveness of the cancer and the recommended treatment options. Tumor flare is a real phenomenon that can occur after biopsy, and tumor size can fluctuate over time. Some patients also report elevated tumor markers in their blood. Ultimately, each patient's tumor is unique and requires an individualized treatment plan."

Discussion

Principal Findings

Our evaluations of different models on the task of generating summaries about the patient experience revealed that GPT-3.5 was the best-performing model. This is no surprise as it is the model with the most parameters (approximately 375 billion) of the set of models examined. GPT-3 has 175 billion parameters, and the smallest model was Flan-T5 with 0.2 billion parameters in the version we used. As the training data sources for the GPT models are not made public, we cannot attribute the differences in performance to differences in the training data.

Taking GPT-3.5 as the best-performing model (see research question 1), we examined in detail the impact of different prompting strategies. For the 3 ROUGE metrics, DSP 3-shot prompting emerged as the best strategy, whereas few-shot prompting with 3 examples received the best scores according to BERTScore (see research question 2). In any case, the results clearly show that providing at least 3 examples helps the model generate more tailored summaries. DSP 3-shot prompting benefits particularly from the fact that key relevant topics are provided as guidance to the model, which helps generate better summaries.

Our fine-tuning experiments with Flan-T5 showed that fine-tuning can have a positive effect in principle (see research question 3). However, we assume that the amount of data was still too low. Therefore, the fine-tuned Flan-T5 setting was not really comparable to the other settings that were not fine-tuned with a comparable number of examples. In particular, the results of Flan-T5 were, irrespective of fine-tuning, quite low compared to those of the other models. However, the results show the potential of fine-tuning within a particular model class.

Our case study using GPT-3.5 as the best-performing model with the best prompting strategies showed that the summaries produced by GPT-3.5 are reasonable, covering most of the aspects of the manually generated summaries while including some additional details or background. Our results demonstrated that such models can be used to speed up qualitative research by being able to summarize large amounts of text automatically. In addition, we confirmed a positive correlation between the quality of the summaries and the models' size on the one hand and fine-tuning on the other hand. In March 2023, OpenAI released GPT-4, as well as the possibility to fine-tune models using a fee-based application programming interface. These new developments are promising and should be investigated further, yet they were not available at the time the experiments described in this paper were carried out.

XSL•FO
RenderX

Taken together, our results suggest that state-of-the-art pretrained LLMs can be a valuable tool to provide qualitative insights about the patient experience to better understand unmet needs, patient priorities, and how a disease impacts daily functioning and quality of life to inform processes aimed at improving health care delivery and ensure that drug development focuses more on the actual priorities and unmet needs of patients. In particular, the insights would allow for the focus of drug development and clinical development to be on outcomes that are relevant to patients and have the potential to substantially improve their quality of life. The insights provided by our method could be used to develop a more detailed understanding of patient journeys as a basis to improve patient care by focusing on the actual problems and unmet needs that patients face in different phases of their journey. The insights could further help in developing support programs that provide relevant information to patients when they need it to empower them to make better decisions. Finally, such qualitative insights could also inform the design and conceptualization of digital apps for patients.

As a notable limitation of this study, our manually created test set for the quantitative evaluation of the different approaches had a limited sample size. Although we presented an experiment with a fine-tuning approach, after splitting the small dataset into training, development, and test sets, we noticed that each split was too small to derive representative results for each setting. Having a larger dataset (at least by 1 order of magnitude) would enable more experiments with respect to fine-tuning. While the sample size was small, it is a remarkable result that fine-tuning had a positive impact on the task. A larger dataset would possibly have yielded even stronger results. However, as the focus of this study was on experimenting with (unsupervised) prompting approaches, we keep the experiments with a larger dataset for future work. A further important limitation is the fact that the reference summaries were created by only 1 annotator, which might bias the results to the perspective of this single annotator. The huge effort involved in creating these summaries did not make it possible to have multiple annotators providing the summaries. A larger dataset could be obtained via crowdsourcing platforms such as CrowdFlower or Prolific; however, a drawback of these platforms is that we cannot reliably control for the (domain) expertise of the labelers.

The summaries could not be directly compared using standard annotation metrics such as the Cohen κ but could have been compared in terms of ROUGE to each other to have an upper baseline for the scores.

Another limitation arises from the nature of our applied automatic metrics. The average text length of the output of the baseline approach (mirroring its input) was substantially higher (contradicting the idea of a summary that should be concise) than that of the GPT-3.5–generated summaries. However, in terms of our automatic metrics, this discrepancy in text length impacted the count of bigrams, favoring the baseline compared to the GPT-3.5 zero-shot summary. The automatic evaluation metric we used, for example, ROUGE-2, does not consider the text length, which may bias the results toward the longer text. Thus, while the baseline appeared to perform better according to ROUGE-2, it is important to interpret these results cautiously considering the difference in text length.

We compared the different LLMs and the different prompting strategies on our own dataset consisting of 127 reference summaries. The dataset might not be completely representative of all sorts of summarization tasks, possibly limiting the generalizability of the results to other related tasks. The comparison of the different methods and the results obtained are specific to the particular summarization task considered. It is an open question whether the results generalize to other summarization tasks. However, our focus was on determining whether LLMs can reliably and accurately summarize the experience of patients as shown on online posts. A question for further research is to better understand why the performance of models differs and which underlying factors are responsible for the differences. Understanding whether the differences in ROUGE and other scores represent semantically meaningful differences is also an important question for future work. Indeed, future work might strive for a more semantic assessment of the generated summaries by manual coders who could rate the generated text in terms of variables such as clarity, comprehensiveness, completeness, and readability.

Beyond this, since the time our experiments were carried out, newer LLMs have been released, in particular also GPT-4 and GPT-4o, which could also be tested. Other open-source models such as Llama could also be investigated.

To the best of our knowledge, our dataset is the only dataset consisting of manually created summaries of patient experience. Thus, we cannot evaluate our method on existing datasets. To allow researchers to compare their methods on our dataset, we will provide the dataset to anyone interested upon request.

Beyond improving the methodology, data basis, and models used, future research should show that the insights derived via summarization methods can indeed impact our understanding of what unmet needs and priorities patients have and positively impact drug development and optimization of patient journeys. This question is clearly out of the scope of this study but could be pursued in follow-up work. While we focused only on posts from patients with breast cancer, we see no reason why this approach could not generalize to other patient populations. However, this needs to be validated in future work.

Related Work

We briefly discuss related work on using LLMs in health care in general, deep diving into work on using NLP for analyzing patient experiences on social media. We discuss the application of summarization in health care as well.

LLMs in Health Care

Very recently, LLMs have been considered for different tasks and use cases in health care. In a recent overview paper, Clusmann et al [35] described the main areas in which there is the potential to apply LLMs in health care: research, patient care, and education. The use of LLMs to summarize patient discussions falls into the area of patient care as it has the potential to uncover unmet needs of patients that can contribute to improve drug development and patient care.

XSL•FO
RenderX

Beyond text summarization tasks, LLMs have also been investigated on use cases related to drug discovery [36] and have been tested on tasks such as helping discover new targets as well as predicting characteristics of drugs, including molecular pharmacodynamics, pharmacokinetics, and toxicity [37]. They have also been shown to be able to support the discovery of drug-drug interactions [38]. A recent review has even highlighted the opportunities, limitations, and barriers regarding the use of LLMs in medical diagnosis [39].

LLMs for SML

SML has been established as a mature methodology to extract key insights about the patient experience as a way to inform drug development and improvement of patient care. A recent review analyzed 63 publications that performed SML [9]. Of the 63 publications analyzed, 38 carried out some computer-assisted analysis. The methods used covered a wide range of NLP methods to detect topics and concepts within textual data. While some published research used keywords and dictionaries to identify topics in some cases [40], other methods comprised binary matrix factorization, Bayesian estimation, and Latent Dirichlet Allocation [41]. Several of the reviewed publications stated that custom-trained NLP algorithms were used [42,43], and neural networks were also reportedly used to identify certain topics or expressions [44]. A total of 25 out of the 63 publications covered in the aforementioned review performed manual analysis, relying on the manual coding of small data samples. The methods that analyze social media posts automatically by using NLP typically extract certain predefined aspects of the patient experience, including key symptoms, their severity, and experiences with treatments. While they support the scalable analysis of large amounts of text, they are typically not suited to analyze open topics, nor do they provide detailed qualitative insights. Manual analysis methods that rely on the development of a specific coding can be used to answer very specific research questions from a qualitative perspective. However, they are not designed to scale and are necessarily limited to analyzing a smaller sample. The method proposed in this paper can be understood as a sweet spot between these 2 methodological ends of the spectrum. The automatic summary of patient experience conversations allows for the scaling to larger amounts of data and text while also allowing for the succinct summarization of the data to support qualitative understanding.

Automatic Text Summarization in Health Care Applications

Summarizing texts is an important field in the area of NLP, aiming to condense a verbose text into a shorter version while preserving the essence of its meaning. While previous research started with extractive summarization (ie, selecting fragments from the text to be summarized that are concatenated to yield a summary), with the rise of LLMs, research has shifted toward abstractive summarization, in which a model generates a text instead of copying text fragments [45], resulting in a fluent text that helps the reader obtain an overview with minimal time investment. To this end, the input text is encoded into an internal representation that is enrolled by a decoder into natural language. By massive pretraining of LLMs [14], fine-tuning models toward summarization [12], or tailoring them toward instructions asking for summarizations [13], this task is becoming a deeply explored field in NLP.

In the domain of health care, automatic summarization of patient data has emerged as a vital area of research. In this section, we explore the recent advancements in summarization techniques of patient data and other types of data, highlighting the models and methodologies used in alignment with our research.

It has been previously investigated how LLMs can support tasks related to medical documentation and information summarization. LLMs have been particularly evaluated on the summarization of radiology reports, patient questions, progress notes, and doctor-patient dialogue [46]. The objectives of the study by Van Veen et al [46] were similar to those of ours in that the goal was to evaluate the effectiveness of LLMs on the task of summarizing clinical text. In contrast to our focus on patient experience reports from social media or patient forums, their work focused on other types of data (radiology reports, patient questions, progress notes, and dialogues). They used similar metrics for the evaluation of the automatically generated summaries compared to manual summaries (ie, ROUGE-L and BERTScore in addition to Bilingual Evaluation Understudy (BLEU). While they also examined similar models—Flan-T5 as well as GPT (using version 4 instead of 3.5)—they did not examine an exhaustive set of prompting strategies as we did. They also concluded that GPT had the best performance, generating summaries that were more complete on average than human summaries. These results are in line with the results of our study.

A recent study testing the ability to summarize medical evidence using LLMs has shown clear limits of these technologies as factual inconsistencies produced by LLMs are critical in some applications such as summarizing medical evidence, which requires increased care and accuracy as such results might inform the decision-making of many [47]. In their study, Tang et al [47] focused on the task of medical evidence summarization, referring to the process of extracting and synthesizing key information from a large number of medical research studies and clinical trials into a concise and comprehensive summary. They also used automatic evaluation metrics, including ROUGE-L, BLEU, and METERO to evaluate the automatically generated texts with respect to expert-created Cochrane reviews. They explored models from the GPT family only (GPT-3.5 and ChatGPT) but did not analyze the impact of different prompting strategies, relying only on zero-shot prompting. In terms of ROUGE-L scores, GPT-3.5 performed better than ChatGPT, although this was not the case for other metrics.

A study by Pal et al [48] investigated the effectiveness of various neural network architectures in generating hospital discharge summaries from electronic health records within the health care domain. They applied different models (BART, Longformer, T5, and Flan-T5) and examined the impact of fine-tuning on the results, relying on similar automatic evaluation metrics to those we used (ROUGE-1, ROUGE-2, and ROUGE-L). In contrast to our work, they did not use any instruction-following models from the GPT family, so they could not investigate the

XSL•FO
RenderX

impact of different prompting strategies. In line with our results, their study showed that fine-tuning can consistently improve results.

Another research study by Nair et al [49] proposed a multistage approach that leveraged few-shot prompting techniques to generate summaries of patient-provider dialogues within the health care domain. They relied on GPT-3 as a model for their multistage approach and validated their method with respect to 100 clinical encounters. They examined in particular the impact of the number of examples provided in the prompt, varying among 1, 3, and 5 examples.

The effectiveness of pre-trained models for text summarization is further supported by the work by Ay et al [50]. Their work demonstrates the successful application of the T5 model pretrained on news data for abstractive text summarization of Turkish text documents. In contrast to our work, they did not focus on summarization of health-related texts and only relied on 1 sequence-to-sequence model, T5. In contrast, we also examined auto-regressive models from the GPT family and investigated the impact of different prompting strategies.

The study by Wang et al [51] introduced a novel element-aware summarization approach using GPT-3 and CoT prompting for abstractive text summarization. While they worked on a completely different domain (news texts rather than health-related texts), they followed a similar methodology, relying on the same evaluation metrics (ROUGE-1, ROUGE-2, and ROUGE-L as well as BERTScore), also examining the impact of fine-tuning BART and T5 compared to using GPT-3 with zero-shot prompting. Their results were mixed depending on the dataset. As a general trend, they showed that the larger models such as GPT-3 performed better than the smaller (but fine-tuned) models. This study is the only one in addition to ours investigating more advanced prompting strategies such as CoT.

Li et al [27] introduced DSP, which we used in our experiments, as a method to guide LLMs for text summarization tasks. They evaluated their proposed method on the task of summarizing news and also evaluated the suitability of the generated summaries using BLEU, ROUGE, Metric for Evaluation of Translation With Explicit Ordering (METEOR), and BERTScore. In terms of models, they also focused on instruction-following models such as GPT-3, InstructGPT, and ChatGPT. They showed that all the models can benefit from the use of directional stimuli, which is in line with our results.

Taken together, we see that none of the existing works has actually focused on summarizing patient reports from social media or forums. Most studies have also used automated metrics such as ROUGE, BLEU, METEOR, and BERTScore as we did, in some cases complementing this with a manual evaluation by experts. In terms of the models investigated, our study is similar to others in the sense that, in most studies, encoder- or decoder-based sequence-to-sequence models were investigated, including T5 and Flan-T5 in particular, as well as auto-regressive pretrained decoder-only models from the GPT family (GPT-3, GPT-3.5, GPT-4, and ChatGPT). In line with our results, most studies showed the superiority of the GPT family models. Our work is the only one that has investigated the impact of very different prompting strategies, showing in particular the impact of using direct response stimuli in combination with few-shot training. In terms of comparison, it is not possible to directly compare our results to those of other studies as none of the aforementioned studies focused on patient reports.

Conclusions

Exchanging information with peers on social media sites, support forums, or social networks, as well as receiving emotional support from them, is important for patients in coping with their conditions and being empowered. However, the information they share on public sites is unstructured and vast, not accessible for those interested in using it to improve health care. Methodologies for generating qualitative information at a large scale from these datasets have so far been missing.

Toward closing this gap, this study shows that it is possible to accurately and reliably summarize the content shared by patients on social media sites, social networking sites, discussion forums, and support groups automatically. Our study explored the feasibility of automatically summarizing experiences shared by patients online using generative LLMs combined with different prompting strategies. Our comparative study highlights the effectiveness of different advanced prompting techniques used with generative LMs in summarizing online patient comments. Notably, few-shot models, particularly the 3-shot variants, exhibited superior results compared to their zero-shot and 1-shot counterparts. Within the few-shot category, GPT-3.5 stood out with higher evaluation scores compared to those of the other models. In the context of DSP models, DSP few-shot (3-shot) models, specifically GPT-3.5, delivered the most favorable results. Upon comprehensive comparison, DSP-based 3-shot models emerged as the most efficient prompt-based models for summarization tasks, especially in the context of patient comment summarization. Although our experiments fine-tuning the smaller model Flan-T5 increased its performance by 50% in terms of the longest subsequence common to the reference, our advanced prompting techniques using larger models such as GPT-3.5 were superior in the explored domain.

Our results open up the possibility of using the qualitative insights generated at a larger scale to inform processes of drug development, design of clinical trials, development of patient journeys, public policy making, and informing the development of digital health apps. Information about unmet needs; symptoms; and their impact on the quality of life of patients, disease burden, and experiences with existing treatments provides valuable insights to inform the aforementioned processes and, ultimately, improve the state of care for patients.

Abstract

Background: Electroencephalography (EEG) has been widely used to measure brain activity, but its potential to generate accurate images from neural signals remains a challenge. Most EEG-decoding research has focused on tasks such as motor imagery, emotion recognition, and brain wave classification, which involve EEG signal analysis and classification. Some studies have explored the correlation between EEG and images, primarily focusing on EEG-image pair classification or transformation. However, EEG-based image generation remains underexplored.

Objective: The primary goal of this study was to extend EEG-based classification to image generation, addressing the limitations of previous methods and unlocking the full potential of EEG for image synthesis. To achieve more meaningful EEG-to-image generation, we developed a novel framework, Neural-Cognitive Multimodal EEG-Informed Image (NECOMIMI), which was specifically designed to generate images directly from EEG signals.

Methods: We developed a 2-stage NECOMIMI method, which integrated the novel Neural Encoding Representation Vectorizer (NERV) EEG encoder that we designed with a diffusion-based generative model. The Category-Based Assessment Table (CAT) score was introduced to evaluate the semantic quality of EEG-generated images. In addition, the ThingsEEG dataset was used to validate and benchmark the CAT score, providing a standardized measure for assessing EEG-to-image generation performance.

Results: The NERV EEG encoder achieved state-of-the-art performance in several zero-shot classification tasks, with an average accuracy of 94.8% (SD 1.7%) in the 2-way task and 86.8% (SD 3.4%) in the 4-way task, outperforming models such as Natural Image Contrast EEG, Multimodal Similarity-Keeping Contrastive Learning, and Adaptive Thinking Mapper ShallowNet. This highlighted its superiority as a feature extraction tool for EEG signals. In a 1-stage image generation framework, EEG embeddings often resulted in abstract or generalized images such as landscapes instead of specific objects. Our proposed 2-stage NECOMIMI architecture effectively extracted semantic information from noisy EEG signals, showing its ability to capture and represent underlying concepts derived from brain wave activity. We further conducted a perturbation study to test whether the model overly depended on visual cortex EEG signals for scene-based image generation. The perturbation of visual cortex EEG channels led to a notable increase in Fréchet inception distance scores, suggesting that our model relied heavily on posterior brain signals to generate semantically coherent images.

XSL•FO
RenderX

Conclusions: NECOMIMI demonstrated the potential of EEG-to-image generation, revealing the challenges of translating noisy EEG data into accurate visual representations. The novel NERV EEG encoder for multimodal contrastive learning reached state-of-the-art performance both on *n*-way zero-shot and EEG-informed image generation. The introduction of the CAT score provided a new evaluation metric, paving the way for future research to refine generative models. In addition, this study highlighted the significant clinical potential of EEG-to-image generation, particularly in enhancing brain-machine interface systems and improving quality of life for individuals with motor impairments.

Introduction

Background

Electroencephalography (EEG) is one of the ancient techniques for measuring neuronal activity in the human brain [1,2]. EEG records electrical activity from the scalp, offering exceptional temporal resolution and high sensitivity to neural processes. Its application has significant value in clinical practice, especially for diagnosing conditions such as epilepsy, depression, and sleep disorders [3-5], as well as assessing dysfunctions in sensory transmission pathways [6,7]. Historically, the analysis of EEG signals was limited to visual inspection of changes in amplitude and frequency over time. However, with the advent of digital technology, the methodology has undergone significant evolution, enabling a more comprehensive analysis of both the temporal and spatial characteristics of these signals [8]. As a result of these advancements, EEG has become recognized as a powerful tool for capturing real-time brain activity, particularly in the subsecond range. Despite these advantages, EEG traditionally suffers from low spatial resolution, which makes it difficult to precisely identify the brain areas responsible for the observed neuronal activity at the scalp [9]. In recent years, there has been growing interest in leveraging EEG for more advanced applications such as image recognition and reconstruction [10]. These developments have led to significant improvements in the accuracy of image recognition tasks, highlighting EEG's potential as a bridge between neural activity and visual representation [11,12]. The appeal of using EEG for image recognition lies in its ability to capture the temporal dynamics of neuronal activity, although its spatial resolution remains a major challenge. To address this, innovative methodologies, including deep learning techniques and generative models such as generative adversarial networks (GANs) [13] and diffusion models [14], have enhanced the accuracy and effectiveness of EEG-based systems, allowing for the generation of photorealistic images from neural signals [12,15,16].

Recent studies have demonstrated the feasibility of decoding natural images from EEG signals by aligning EEG responses with paired image stimuli [17]. However, most of the existing works claiming to generate images from EEG signals are still primarily image-to-image transformations. In these approaches, EEG information is typically used to slightly alter the input image, often by adding noise rather than generating new images directly from the brain signals [17-19]. In a typical experiment designed to study brain responses related to visual processes, participants view a series of images while their brain signals are recorded by a brain scanner or other recording device for subsequent analysis. Various noninvasive methods, such as functional magnetic resonance imaging (fMRI), EEG, and magnetoencephalography, can be used to capture these brain responses, each offering different sensitivity levels. Despite the availability of these techniques, there is still limited understanding regarding the precise interpretation of the data and, more importantly, the mechanisms underlying these responses. A pioneering study explored the possibility of generating impressions of what participants saw by using fMRI data based on a large image dataset sourced from YouTube [20]. However, this method faces significant challenges, including the complexity and high costs associated with using fMRI scanners. To overcome these limitations, much of the recent research has shifted toward using electrophysiological responses, particularly EEG. Although EEG offers a lower spatial resolution than fMRI, it provides much higher temporal resolution, making it a more accessible and cost-effective method. This shift to EEG is further supported by its ability to capture rapid, real-time neural dynamics. However, EEG data present their own set of challenges. The inherent noise and susceptibility to external factors complicate the accurate reconstruction of the original visual stimulus, limiting its effectiveness in image recognition and generation tasks. As a result, fMRI remains the preferred method in many studies focusing on image recognition or generation from brain signals [21], whereas EEG is used less frequently due to its noisier nature. Previous efforts such as Brain2Image and EEG-GAN have explored EEG-guided image reconstruction using variational autoencoders (VAEs) and GAN frameworks, respectively. However, most of these approaches relied heavily on paired image inputs and did not fully explore direct EEG-to-image synthesis.

To address these limitations and achieve more meaningful EEG-to-image generation, we introduced Neural-Cognitive Multimodal EEG-Informed Image (NECOMIMI), an innovative framework that focuses on EEG-based image generation. This framework integrates advanced diffusion model techniques to enhance the accuracy and realism of images generated from EEG signals. In this study, we first proposed a novel EEG encoder, Neural Encoding Representation Vectorizer (NERV), which achieved state-of-the-art (SOTA) performance in multimodal contrastive learning tasks.

Related Work

The concept of using EEG signals for image-related tasks has evolved over time. Initially, efforts focused on decoding visual categories from EEG signals [11], demonstrating the feasibility of EEG-based image classification using deep learning models. While these early studies laid the groundwork, the datasets used were small, limiting the generalizability of the findings. However, subsequent advancements in generative models, such as VAEs and GANs, paved the way for more sophisticated EEG-to-image generation. The VAE, as proposed by Kingma and Welling [22,23], provided a means of generating and reconstructing data by learning latent data distributions. Similarly, the GAN framework introduced by Goodfellow et al [13] leveraged adversarial training between a generator and a discriminator to produce realistic images. Building on these ideas, Brain2Image [12] became the first to apply VAEs to guide image generation from EEG features. Later, EEG-GAN [18] introduced the first EEG-based image generation model using long short-term memory [24] to extract EEG features and guide the GAN's image generation process.

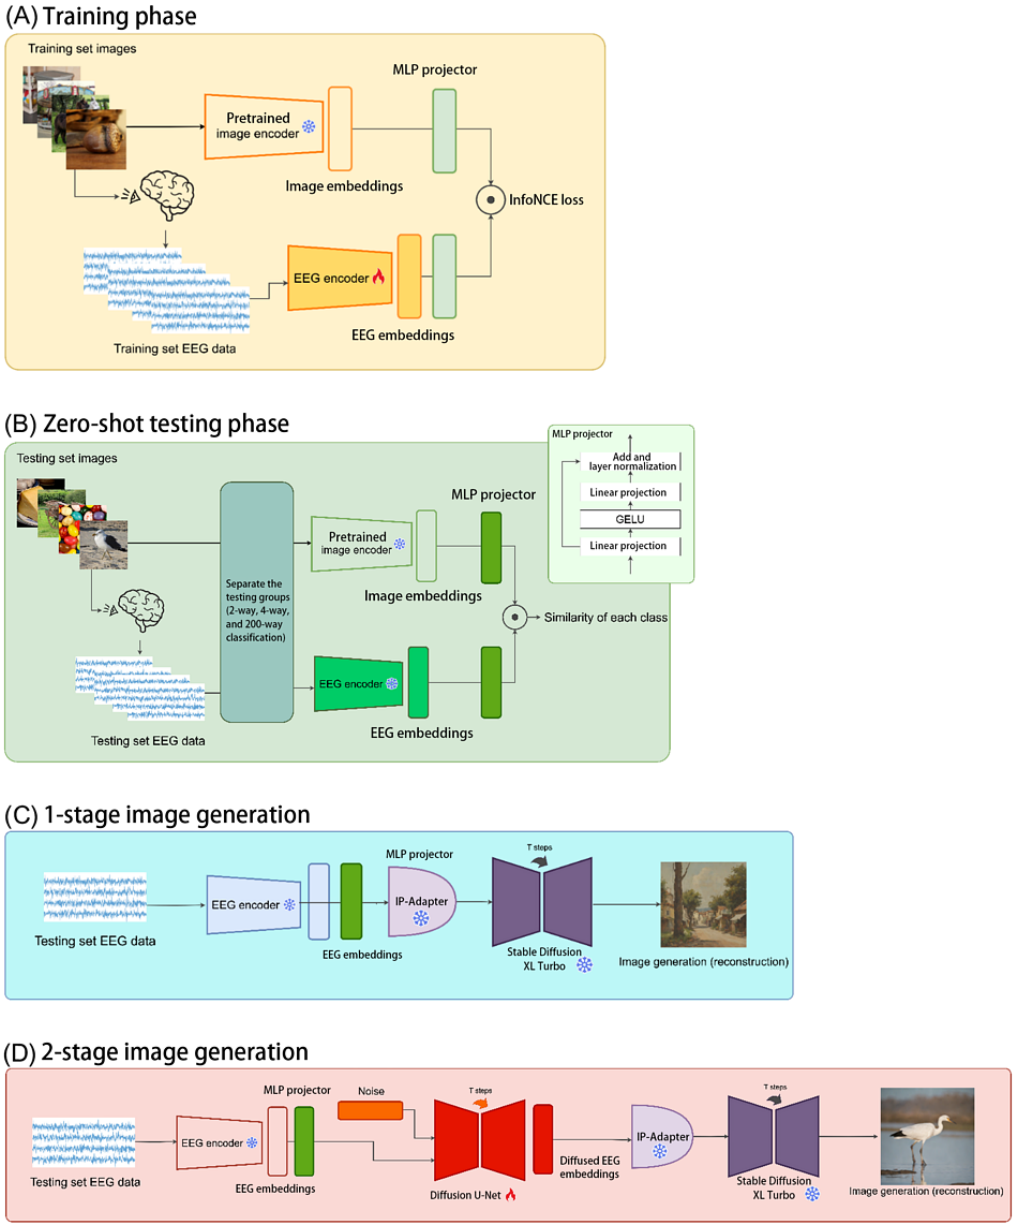
Several works based on GANs, such as ThoughtViz [25], visual-guided GAN with visual-consistent term [26], BrainMedia [27], and EEG2IMAGE [16], have emerged, each focusing on improving the interaction between the EEG encoder and the GAN architecture. Despite these advancements, a common challenge remains in effectively using EEG data to guide image generation and reconstruction. This challenge persisted until the advent of Contrastive Language-Image Pretraining (CLIP; OpenAI) [28], which provided a better solution by enabling more reliable alignment between EEG and image data. EEG-CLIP [29] was the first framework to use contrastive learning to align EEG and image data. However, it was largely exploratory, and its framework was not extended for downstream tasks such as zero-shot image recognition. The next step in this evolution was to design more effective EEG encoders for contrastive learning, leveraging the rich image embeddings extracted from CLIP-based pretrained models. Recent efforts such as Natural Image Contrast EEG (NICE), Multimodal Similarity-Keeping Contrastive Learning (MUSE), Adaptive Thinking Mapper, and others [30-33] have explored this direction. In addition, some researchers have ventured into quantum-classical hybrid computing using a quantum EEG encoder [34], aiming to perform quantum contrastive learning [35]. Currently, many studies focus on zero-shot classification, where the model is tested on unseen EEG data and images, aiming to assess its ability to generalize to novel data. This is a challenging task that involves computing similarity scores between EEG and image data for recognition purposes. The evolution of contrastive learning techniques for EEG-based image recognition has improved the generalization performance of models, particularly when tested on out-of-sample data.

Despite the significant progress, the use of diffusion models to generate EEG-based images remains a relatively new area. While there are several EEG-based image reconstruction models that use diffusion models, such as NeuroVision [19], DreamDiffusion [17], diffusion model for the reconstruction from EEG to image [36], BrainViz [37], NeuroImagen [38], and EEGVision [39], most of these approaches rely on image-based features and treat EEG data as supplementary information. However, these methods primarily use images as input and are not designed to process nonvisual signals such as EEG directly. To address this gap, we proposed NECOMIMI, a flexible and modular framework explicitly designed for EEG-to-image generation. Unlike previous methods that focus on recognition or classification, NECOMIMI leverages modern diffusion models using EEG signals as the primary prompt, enabling direct generation of images from neural features. This shift represents a crucial step forward, reframing EEG not merely as a support signal but as a core semantic driver for brain-conditioned multimodal generation.

On the basis of the trajectory of prior work, it becomes clear that the field is moving from EEG-assisted image recognition toward more ambitious goals such as direct image generation conditioned solely on EEG signals. Although recent studies have explored advanced paradigms, including contrastive learning frameworks and hybrid quantum models, most still relegate EEG to a secondary role. In contrast, our preliminary investigations into quantum-enhanced EEG processing, such as quantum machine learning for enhanced EEG encoding and quantum contrastive learning [35], demonstrate how EEG can serve as the central signal in generative tasks. Quantum machine learning for enhanced EEG encoding [34] uses variational quantum circuits to enrich EEG representations with greater expressive capacity, whereas quantum contrastive learning integrates quantum projections into contrastive learning pipelines to improve cross-modal alignment. These findings underscore a critical limitation in current literature: the lack of a dedicated generative framework that places EEG at the forefront of image synthesis. Our work aimed to fill this void by shifting the paradigm from recognition to generation, positioning EEG not as an auxiliary cue but as a rich, semantic prompt capable of guiding diffusion-based image creation. This reorientation opens new avenues for decoding cognitive states through generative modeling and facilitates the development of brain-native, multimodal artificial intelligence systems.

In this study, we developed a comprehensive 2-stage EEG-to-image multimodal generative framework, which extended previous contrastive learning between EEG and images and applied it to image generation. Unlike previous works that have focused primarily on image-to-image generation with EEG features serving as guidance, our framework offered a more holistic approach to leveraging EEG data for image creation. While EEG data are traditionally characterized by high temporal but low spatial resolution, our goal was not to recover precise pixel-level representations. Instead, we treated EEG as a high-level cognitive modulator that captures semantic concepts, which can be used to guide image generation via latent diffusion models. To address the conceptual differences between EEG-to-image and traditional text-to-image tasks, we introduced a new evaluation metric, the Category-Based Assessment Table (CAT) score. This score assessed image generation performance based on semantic concepts as opposed to merely evaluating image distribution. We further established a CAT score benchmark using a vision language model on the ThingsEEG dataset. Finally, our study uncovered several notable findings

XSL•FO
RenderX



and phenomena that shed light on the EEG-to-image generation process.

Methods

Datasets and Preprocessing

The ThingsEEG dataset comprised a large set of EEG recordings, which were obtained using a rapid serial visual presentation paradigm [40]. The rapid serial visual presentation is a commonly used experimental protocol where participants are shown a series of visual stimuli in quick succession, typically at rates of ≥10 Hz, to evoke reliable neural responses. Responses were collected from 10 participants, each of whom viewed a total of 16,740 natural images sourced from the THINGS database [41]. The dataset includes 1654 training categories, with each category containing 10 images, as well as 200 test categories, each featuring a single image. The EEG data were recorded using 64-channel Easycap equipment, and preprocessing involved segmenting the data into trials that spanned 0 to 1000 milliseconds after the stimulus was shown, with baseline correction applied based on the prestimulus period. EEG responses for each image were averaged over multiple repetitions. The workflow and models used in the EEG-based image generation system are shown in Figure 1.

NERV EEG Encoder

As the foundational component of the NECOMIMI framework, we first describe our novel EEG encoder, NERV, which served as the foundation for EEG signal representation and embedding. As illustrated in Figure 2, NERV was designed to address the unique spatiotemporal complexity of EEG signals, which differ from natural images or text due to their nonstationary nature, simultaneous temporal dynamics, and spatial dependencies across multiple electrodes. To effectively capture these

XSL•FO
RenderX

characteristics, NERV adopted a hierarchical architecture that combined convolutional and attention-based modules. The input EEG data, flattened and linearly projected, first underwent positional encoding to preserve temporal order. It then flowed through 2 complementary convolutional branches: a *spatial-temporal convolution*, which extracted spatial features followed by temporal ones, and a *temporal-spatial convolution*, which performed the reverse. These dual-pathway 2D convolutions operated across the EEG channel dimension, allowing the model to learn localized patterns in both directions. This design enabled NERV to generate robust and semantically meaningful embeddings from EEG signals, laying the groundwork for high-quality image generation in the NECOMIMI pipeline.

Figure 2. The overall structure of the Neural Encoding Representation Vectorizer electroencephalography encoder model. Fp1: frontal pole 1; Fp2: frontal pole 2; FpZ: frontal pole Z; MLP: multilayer perceptron; O1: occipital 1; O2: occipital 2; OZ: occipital midline; POZ: parieto-occipital midline.

The output of these branches was passed through multihead self-attention layers, allowing the model to capture long-range dependencies across time and channel dimensions. Unlike conventional EEG encoders that treat all channels uniformly, NERV incorporated an EEG attention module at an early stage. This module used a transformer encoder across the channel axis to explicitly model interchannel relationships and assign adaptive importance weights to different brain regions. Such a design leveraged the structured spatial geometry of EEG electrode placement, enabling the model to generalize more effectively across participants. To further enhance discriminability, particularly in zero-shot settings, a cross-attention block was incorporated, enabling the class token to selectively attend to latent spatial-temporal features. The resulting feature sequence was flattened and passed through a fully connected layer, yielding a 1440D intermediate representation. Following this, a participant-specific linear transformation adjusted the temporal resolution to accommodate interindividual variability in EEG patterns. Finally, a residual projection head, composed of a Gaussian error linear unit activation and dropout, mapped the features into a 1024D latent space, providing a compact yet expressive representation for the downstream generative module.

The model was trained using a contrastive learning objective, aligning EEG embeddings with paired image embeddings from a pretrained CLIP model. This approach enabled robust multimodal representation learning, bridging neural signals and visual semantics. By combining structured convolution, channel-aware attention, and semantic alignment mechanisms, the NERV encoder effectively captured both the signal dynamics and spatial layout of EEG signals, significantly outperforming previous models in low-data and cross-participant scenarios. The EEG attention module explicitly modeled interchannel relationships and assigned adaptive importance to each channel based on its functional relevance, ensuring that different EEG channels are weighted according to their significance in the image generation process. By adopting this approach, NERV can effectively capture the unique spatial dependencies inherent in EEG data, leading to more accurate and contextually relevant representations for downstream image generation tasks.

Framework Architecture and Experiment Setting Details

To ensure a fair comparison of various EEG encoders and minimize external factors, all experiments in this study were rerun using a unified CLIP–vision transformer (ViT) environment, leveraging the available open-source code [30-32].

XSL•FO
RenderX

CLIP is a deep learning model by OpenAI that uses contrastive learning to map both image and text into a shared embedding space, enabling the model to understand their relationship. It trains separate image and text encoders and supports zero-shot tasks such as image retrieval based on text. CLIP-ViT is a variant that uses ViT as the image encoder, which improves performance by processing images as patches. Given that contrastive learning is sensitive to batch size, a batch size of 1024 was used for all experiments. The final results were averaged across the best outcomes from 5 random-seed training sessions, each running for 200 epochs. We used the AdamW optimizer (The PyTorch Foundation) with a learning rate of 0.0002, and the β1 and β2 parameters were set to 0.5 and 0.999, respectively. The contrastive learning parameter τ was initialized with log(1/0.07). In terms of model architecture, the NERV model performed optimally with 5 multiheads, whereas the transformer layer used 1 multihead and the cross-attention layer used 8 multiheads. The time step for the diffusion model was set to 50. All experiments, including EEG encoder training and prior diffusion model processing, were conducted on a machine equipped with an A100 graphics processing unit.

Using the ThingsEEG dataset, we developed an advanced EEG-to-image generation model that leverages deep learning techniques and diffusion models. Initially, the framework included a 1-stage image generation phase. However, we observed that its performance was suboptimal. As a result, we adapted the model to a 2-stage process. The overall structure of the model was composed of 4 phases: training, zero-shot testing, 1-stage image generation, and 2-stage image generation (Figure 1). Each phase played a crucial role in transforming raw EEG data into meaningful visual outputs.

Diffusion Model Implementation Details

To enhance the reproducibility and transparency of our EEG-to-image generation pipeline, we further describe the technical configuration of the diffusion model used in both the 1-stage and 2-stage NECOMIMI frameworks. We adopted the Stable Diffusion XL (SDXL) Turbo (Stability AI) [42,43] as the backbone generative model. SDXL Turbo is an optimized variant of the original Stable Diffusion architecture designed to produce high-quality images using significantly fewer sampling steps. This model is based on a U-Net structure with cross-attention mechanisms and operates in the latent space of a VAE, allowing for efficient and photorealistic image generation. For the denoising process, we applied a cosine noise schedule [14]. This schedule gradually adjusted the amount of noise during reverse diffusion, which helped improve image diversity and ensured smoother training convergence by avoiding sudden changes in noise levels across time steps. During inference, we used 50 sampling steps, which provided a good balance between generation speed and visual quality. This step count was well suited to SDXL Turbo's low-latency design and has been empirically verified to maintain satisfactory image fidelity.

To condition the image generation on EEG signals, we used the IP-Adapter module [44]. Although originally developed for visual feature prompts, we adapted it to accept EEG embeddings. These embeddings were projected into the appropriate feature space and injected into the cross-attention layers of the U-Net at both low and middle resolutions, enabling the EEG signals to influence multiple stages of the generation process. Furthermore, we applied a classifier-free guidance strategy during image generation. This involved generating both conditional and unconditional outputs and blending them in a controlled manner to improve the relevance of the generated images to the input EEG signal while still preserving sample diversity. In our implementation, the guidance strength was set to a moderate value to maintain a balance between controllability and visual variation. In the 2-stage generation framework, the EEG embeddings were first processed by a lightweight diffusion prior network. This network, implemented as a 6-layer U-Net, was trained to transform noisy EEG embeddings into clean, CLIP-like image embeddings [30-32]. A dropout rate of 0.1 was used during training to encourage robustness. The resulting embeddings were then passed through the IP-Adapter into the SDXL Turbo model for final image synthesis. By integrating these components, the NECOMIMI framework effectively bridges the gap between EEG signals and generative models, enabling high-quality image synthesis guided purely by brain activity.

Training Phase

In the initial training phase, both visual image $\in$ $h \times w \times ch$ and EEG data $\in$ $e \times d$ were processed in parallel to establish a shared embedding space. Here, denotes the image height, *w* is the image width, and *ch* refers to the number of channels (eg, RGB channels). Similarly, *e* represents the number of electrodes (channels), and *d* corresponds to the number of data points (time samples) in the EEG signal. Training set images were initially passed through a pretrained image encoder, which transforms the images into latent representations, referred to as image embeddings *I*. In this work, we used a pretrained ViT [45] from the CLIP model [28] as the image encoder, producing embeddings of size 1×1024 for each image. Simultaneously, the corresponding EEG signals are processed by a custom EEG encoder, generating EEG embeddings *E*. For the EEG encoder, this work extended several existing approaches, including NICE, MUSE, Nervformer, and Adaptive Thinking Mapper, to enable EEG-to-image capabilities [30-32]. Moreover, we introduced a novel EEG encoder, NERV, specifically designed for noisy, multichannel time-series data such as EEG that leveraged a multi-attention mechanism. The image and EEG embeddings were projected into a shared latent space using a multilayer perceptron projector, where they were optimized using the information noise-contrastive estimation (InfoNCE) loss function. This contrastive learning loss function ensured the alignment of corresponding image and EEG embeddings in the latent space, thereby improving the model's capacity to associate neural patterns with visual stimuli. The InfoNCE loss, commonly used in contrastive learning, is defined as follows [28,46,47]: . (1), where $S_{E,I}$ represents the similarity score between the EEG embeddings *E* and the paired image embeddings *I* and τ is the learned temperature parameter.

XSL•FO
RenderX

Zero-Shot Testing Phase

Once trained, the model proceeded to the zero-shot testing phase, which evaluated its ability to generalize to unseen data. During this phase, the EEG signals and images from the test set were encoded using the pretrained encoders, and their respective embeddings were projected through the multilayer perceptron projector. The test data were divided into several groups, including 2-way, 4-way, 10-way, 50-way, and 100-way classification, facilitating a structured comparison between the EEG and image embeddings. The final similarity scores between the embeddings determine the model's classification accuracy, enabling an evaluation of how well the model generalizes to new EEG data without requiring additional training.

One-Stage Image Generation

In the 1-stage image generation process, EEG embeddings from the test set were directly used as inputs to reconstruct images. By incorporating the IP-Adapter [44], originally designed to use images as prompts, the compact design enhanced the flexibility of image prompts within pretrained text-to-image models. In this study, we adapted the IP-Adapter to transform EEG embeddings into *feature prompts* for the image generation process. These vectors were injected into the cross-attention layers of the U-Net at both low- and midresolution blocks, enabling the EEG embedding to modulate generation across multiple stages. These conditioned embeddings were then processed by the SDXL Turbo model [42,43]. This approach offered a streamlined method for EEG-based image generation, relying on a single transformation stage to produce meaningful visual outputs from neural signals. The commencement of the EEG-conditioned diffusion phase was crucial for generating images from EEG data. During this phase, a classifier-free guidance method was used, which paired CLIP embeddings and EEG embeddings (I and E). Specifically, we generated both conditional and unconditional outputs and combined them using the following formula: . (2), where $w \geq 0$ is the guidance scale (set to 3.5 in our experiments). This technique improves controllability while preserving diversity.

By applying advanced generative techniques, the diffusion process was tailored to use the EEG embedding E to model the distribution of the CLIP embeddings $p(I|E)$. The CLIP embedding I, generated in this stage, served as the foundation for the subsequent image generation phase. The architecture integrates a simplified U-Net model, denoted as $\in_{prior}(I^t, t, E)$, where I^t represents the noisy CLIP embedding at a specific diffusion step t. The classifier-free guidance method refined the diffusion model by conditioning it on a specific EEG input E. This approach synchronized the outputs of both the conditional and unconditional models. The final model equation was expressed as follows: . (3).

Where $w \geq 0$ was used to control the guidance scale, this technique allowed for training both the conditional and unconditional models within the same network, periodically replacing the EEG embedding E with a null value to introduce variation in the training process (approximately 10% of the data points). The primary goal was to improve the quality of the generated images while maintaining their diversity. However, we were surprised to find that when EEG embeddings were directly used as prompts for the diffusion model, the generated images predominantly consisted of landscapes regardless of the intended category. As a result, we explored a 2-stage approach for image generation.

Two-Stage Image Generation

The prior diffusion stage played a crucial role in generating an intermediate representation [48], such as a CLIP image embedding, from a text caption [49]. This representation was then used by the diffusion decoder to produce the final image. This 2-stage process not only enhanced image diversity but also maintained photorealism, allowing for efficient and controlled image generation [50]. The 2-stage image generation process introduced a more sophisticated and refined method for synthesizing images from EEG data. In this approach, the EEG embeddings were initially processed by a diffusion prior network consisting of a 6-layer U-Net trained using cosine schedule and dropout (P=.10). After passing through the U-Net, the modified EEG embeddings were input into the SDXL Turbo model assisted by the IP-Adapter. This 2-step transformation ensured a more nuanced generation process, potentially leading to higher-quality images through deeper layers of refinement. The reverse diffusion process used a cosine noise schedule [42], which smoothly adjusts the variance over diffusion steps to stabilize training. This scheduling strategy improved sample diversity and convergence by avoiding abrupt noise scale changes across time steps. The time step t=50 referred to the number of reverse sampling steps used during inference. We found that 50 steps achieved a good trade-off between speed and quality, especially under the SDXL Turbo architecture, which was optimized for low-step generation.

The first step of stage 1 involved training the prior diffusion model. The primary goal of this training phase was to enable the model to recover the original embedding from noisy embeddings. The specific steps are detailed in Multimedia Appendix 1. Briefly, in the first phase of training, the model learned to reconstruct the original EEG embedding from a noisy version. Some EEG embeddings were randomly replaced with null values to introduce variability, and random noise was added and perturbed over multiple time steps. The model was trained to predict and remove this noise, effectively recovering the original EEG embedding. Once trained, the model entered the generation phase. It started with random noise, progressively refining it at each time step by predicting and removing noise. Both conditional and unconditional noise predictions were made and combined using a guidance mechanism to generate the final clean EEG embedding. In the second phase, the clean EEG embedding was passed through a specialized adapter, preparing it as a prompt for the image generation model. The final EEG embedding was then input into the SDXL Turbo model, which generated the final image based on the EEG data.

Classification Task and Evaluation Strategy

We designed a participant-dependent zero-shot classification task to assess the semantic generalization ability of our EEG-to-image model. In this setting, the model was evaluated separately for each participant—a subset of image categories

XSL•FO
RenderX

was used for training, whereas a disjoint set was held out for testing, ensuring a strict zero-shot scenario where the model must generalize to entirely unseen classes. Notably, no participant-specific adaptation methods (eg, participant embeddings or normalization layers) were used, and both training and testing were conducted on a within-subject basis. To align EEG and image features in a shared embedding space, we adopted the InfoNCE loss, a contrastive objective that encourages the model to pull matching EEG-image pairs closer while pushing apart nonmatching pairs within the same batch. This facilitates learning fine-grained semantic associations between brain activity and visual representations. We evaluated the model's retrieval performance under zero-shot conditions using an *n*-way retrieval framework, where each test EEG sample was matched against *n* candidate image embeddings, including the correct one and $n - 1$ distractors sampled from unseen categories. A prediction was considered correct if the ground-truth image ranked highest in similarity. Retrieval difficulty was varied across 3 levels: 2-way task (1 distractor), 4-way task (3 distractors), and 200-way task (199 distractors from the full test set). This evaluation protocol provided a realistic and stringent benchmark for assessing semantic generalization and robust retrieval performance in EEG-to-image understanding.

CAT Score

Unlike traditional image-to-image or text-to-image models driven by image representations, EEG-to-image models face unique challenges. In the current NECOMIMI architecture, the model can only capture broad semantic information from EEG signals rather than fine-grained details. For example, suppose the EEG data are recorded while a participant is viewing an aircraft carrier. When different EEG encoders are used in the NECOMIMI framework, they may lead to different outputs. Specifically, one EEG encoder could generate an image of a jet, whereas another EEG encoder might produce an image of a sheep. Therefore, to objectively assess performance, it was necessary to establish a standard that would score the encoder generating the jet image higher than the one generating the sheep image in such cases. Existing evaluation metrics were not suitable for this purpose. Traditional metrics such as the structural similarity index [51] measure structural similarity between the ground truth and the generated image, whereas the inception score [52] and Fréchet inception distance (FID) [53] focus on the accuracy of image categories and their distribution. However, EEG captures more abstract semantic information, and there was no guarantee that the participants' thoughts during EEG recording would perfectly align with the ground-truth image. This made traditional evaluation methods unfair for EEG-to-image tasks. To address this issue, we proposed the CAT score, a new metric specifically designed for EEG-to-image evaluation (Multimedia Appendix 2). In the ThingsEEG test dataset, which contained 200 categories with 1 image per category, each image was manually labeled using 2 tags for broad categories, 1 for a specific category, 1 for background content, and 1 for object attribute, resulting in a total of 5 tags per image. The tags were extracted using ChatGPT-4o (OpenAI) [53]. The entire test dataset thus consisted of 200 images × 5 tags, totaling 1000 points. Using manual annotation, we were able to determine whether the categories of generated images matched these labels, providing a fair assessment for EEG-to-image models.

While FID remains a widely used metric for evaluating image fidelity by comparing feature distributions of generated and real images, it does not consider semantic alignment between the source EEG signal and the generated output [53]. In contrast, the CAT score directly evaluates whether the generated image aligns with the cognitive concept inferred from EEG signals. Therefore, the CAT score and FID served as complementary evaluation tools in our study. FID captures the visual quality, whereas the CAT score emphasizes semantic correctness, which is particularly crucial for EEG-driven generation where pixel-level supervision is unavailable. Further details on the ThingsEEG categories and scoring scheme are provided in Multimedia Appendix 2.

Ethical Considerations

This study used publicly available datasets, and no personal or sensitive information was collected directly. All data were deidentified before analysis. As the study involved only publicly available data and did not involve the collection of personal data or clinical trials, institutional review board approval was not required per the Chang Gung University's Academic Ethics Series [54].

Results

Classification Results

Table 1 presents the classification accuracy results for the 2-way and 4-way zero-shot tasks across 10 participants. Our proposed model, NERV, consistently outperformed other methods, particularly excelling in the 2-way classification task, where it maintained the highest accuracy across most participants. Specifically, NERV achieved an average accuracy of 94.8% (SD 1.7%) in the 2-way task and 86.8% (SD 3.4%) in the 4-way task, surpassing competing models such as NICE, MUSE, and Adaptive Thinking Mapper ShallowNet (ATM-S). While NICE and MUSE demonstrated strong performance in certain participants, they fell short of NERV's overall performance. NICE achieved an average accuracy of 91.3% (SD 3.1%) in the 2-way task and 81.3% (SD 5.9%) in the 4-way task, whereas MUSE achieved averages of 92.2% (SD 2.3%) and 82.8% (SD 5.0%), respectively. ATM-S, while comparable to NICE and MUSE in some participants, showed weaker results on average, with an accuracy of 86.5% (SD 4.9%) in the 4-way task. In the more challenging 200-way zero-shot classification task (Table 2), NERV also outperformed all other methods, particularly in terms of top-1 accuracy. Although ATM-S and NERV performed similarly overall, NERV demonstrated superior performance in most participants. NERV achieved an average top-1 accuracy of 27.9% (SD 5.8%) and an average top-5 accuracy of 54.7% (SD 6.5%), leading all other models. In contrast, Nervformer exhibited a significantly weaker performance, particularly in the top-1 accuracy, with averages of 19.8% (SD 4.9%) and 44.3% (SD 8.7%) for top-1 and top-5 accuracy, respectively. The results showed that NERV consistently outperformed its competitors across all tasks, demonstrating the strongest zero-shot classification performance,

XSL•FO
RenderX

particularly in distinguishing between a large number of categories.

Table 1. Overall accuracy of 2-way and 4-way zero-shot classification using Contrastive Language-Image Pretraining–vision transformer as the image encoder. The average accuracy was reported along with the SD across 10 participants to reflect the statistical robustness of each method.

Performance Comparison of Different Generative Models

Table 3 shows the results of our newly proposed CAT score method, which quantified and evaluated the quality of EEG-generated images based on their alignment with semantic concepts rather than pixel-level details. The specific CAT score labels are provided in Multimedia Appendix 2. Interestingly, although our NERV method achieved SOTA performance on the CAT score, no EEG encoder surpassed a score of 500 out of a possible 1000 points in this evaluation. This result underscored both the rigor of the CAT score and the inherent challenges associated with the pure EEG-to-image generation task.

Table 3. Overall Category-Based Assessment Table (CAT) score out of 1000 of the Neural-Cognitive Multimodal Electroencephalography (EEG)–Informed Image EEG-to-image generation using several EEG encoders. Average accuracy with SD across 10 participants was reported to indicate statistical reliability.

The FID results for EEG-to-image generation using the NECOMIMI framework with several SOTA EEG encoders are shown in Table 4. This metric evaluated the similarity between generated images and real ones based on deep feature distributions, with lower scores indicating better visual fidelity. To assess the robustness and consistency of each method, we reported the average FID alongside its SD across 10 participants. As expected, the “Pure Test Image” baseline, which did not involve EEG input, achieved an ideal FID of 106.1. Among EEG-based approaches, our proposed NERV (2-stage) model outperformed all competitors, with the lowest mean FID being 183.8 (SD 13.3), significantly surpassing other 2-stage pipelines such as NICE (mean 218.7, SD 7.5) and ATM-S (mean 197.1, SD 18.9). This consistent superiority suggested that NERV may be more effective in learning semantically aligned and visually coherent representations from EEG signals. Notably, even the best EEG-based models exhibited a noticeable gap from the ideal FID score, highlighting the intrinsic difficulty of reconstructing high-fidelity images solely from brain signals. These findings collectively validated the effectiveness of our NERV architecture in capturing and translating complex neural patterns into meaningful visual outputs while also revealing the need for continued improvements in EEG-based generative modeling.

Perturbation Study on Visual Cortex EEG Channels

We further conducted a perturbation study to investigate whether the model disproportionately relied on EEG signals from the visual cortex, particularly in generating scene-based images. In EEG analysis, the visual cortex corresponds to posterior regions of the scalp, particularly the occipital and parieto-occipital areas. Accordingly, we identified 6 key EEG channels: occipital 1, occipital 2, occipital midline, parieto-occipital 3, parieto-occipital 4, and parieto-occipital midline, which are commonly associated with visual perception and spatial integration. These channels are known to play critical roles in visual information processing. Occipital 1 and occipital 2 are located over the left and right occipital lobes; these channels are strongly associated with early-stage visual perception and processing. Occipital midline is situated along the midline of the occipital region; this channel captures central visual cortex activity and contributes to basic visual field representation. Parieto-occipital 3 and parieto-occipital 4 are positioned at the parieto-occipital junction; these channels reflect integrative processing of spatial and visual information such as visuospatial attention. Parieto-occipital midline is a midline parieto-occipital channel involved in high-level integration of visual input and attentional modulation. In this experiment, we replaced the

XSL•FO
RenderX

signals from these 6 channels with Gaussian noise while keeping the remaining EEG data unchanged. This allowed us to isolate the contribution of visual cortex–related signals to the image generation process. We then evaluated the quality of the generated images using the FID. Table 5 shows a significant increase in FID scores compared to the unperturbed condition, confirming that the model heavily depends on signals from the visual cortex to generate coherent and semantically meaningful images. These findings highlight the spatial sensitivity of our EEG-to-image model and further validate its biological plausibility in capturing relevant neural representations for visual imagination.

Table 5. Fréchet inception distance (FID) of the Neural-Cognitive Multimodal Electroencephalography (EEG)–Informed Image EEG-to-image generation using Neural Encoding Representation Vectorizer (NERV) EEG encoders with and without perturbation applied to visual cortex EEG channels. The average accuracy alongside its SD calculated over 10 participants was reported to demonstrate the consistency of each method.

Findings on EEG-to-Image Generation

We observed several noteworthy findings in the pure EEG-to-image generation process (Figure 3). Figure 3A shows the original images shown to participants during EEG recording (ground truth). Figure 3B serves as an ideal baseline, demonstrating the model's capacity when guided by semantically rich CLIP embeddings. As shown in Figure 3C, the images generated by the diffusion model from embeddings derived from EEG signals predominantly consisted of landscapes, which deviated substantially from the original (ground truth). Due to the inherently noisy and low-dimensional nature of EEG signals, these results often default to generic or landscapelike images, where outputs deviate significantly from the intended object categories. This suggested that EEG signals may not directly correspond to specific objects in images. As a result, the model tended to generate "safe options," such as landscapes, which may have constituted a significant portion of the training data. This phenomenon, often referred to as "hallucination," occurs when the model generates content that does not accurately represent the intended visual stimuli. Consequently, in the 1-stage image generation framework, EEG embeddings often led to abstract or generalized images such as landscapes rather than specific objects. In contrast, the 2-stage NECOMIMI architecture (Figure 3D) was able to effectively extract semantic information from noisy EEG signals. This additional transformation improved semantic alignment and supported more accurate object-level synthesis (eg, a cat in column 3 or a caterpillar in column 4). Nonetheless, failure cases still occurred, underscoring the challenge of decoding high-level visual semantics from EEG data. Overall, this figure shows the enhanced specificity and visual relevance achieved by the 2-stage pipeline compared to the 1-stage approach. Moreover, Figure 4 shows the NECOMIMI model's ability to reconstruct images solely from EEG data without relying on "seen" images (ground truth) as embeddings during the generation process. The bottom row of images in Figure 4, generated exclusively from EEG input, highlights NECOMIMI's potential to approximate the content of the "seen" images in the top row even without direct visual references or embeddings. Figure 5 illustrates the performance of NECOMIMI's 1-stage and 2-stage EEG-to-image generation pipelines under perturbation of visual cortex channels. The reconstructed images show clear differences in visual fidelity and semantic alignment, emphasizing the model's spatial sensitivity and its dependence on visual cortex activity for generating coherent visual representations.

Discussion

Principal Findings

In this study, our NERV EEG encoder demonstrated SOTA performance in various zero-shot classification tasks, including 2-way, 4-way, and 200-way classification, solidifying its role as an effective feature extraction tool for EEG signals. However, when applied in a 1-stage image generation framework where EEG embeddings from the encoder were directly used to generate images, the results often turned out to be abstract or overly generalized (eg, landscapes) rather than depicting specific objects. This suggests that EEG signals may reflect more abstract, high-level concepts or emotional responses related to viewing the images rather than concrete objects or specific details. These abstract concepts are likely associated with broader aspects of the scene or the brain's generalized perception of the environment. Consequently, the model may be more inclined to generate generalized images such as landscapes than to focus on specific objects. This limitation underscores the inherent challenges of using EEG signals for precise image generation, primarily due to their noisy and low-resolution nature. Another contributing factor could be insufficient training of the model on EEG signals. The diffusion model might not yet be fully optimized to interpret and generate images from EEG data, particularly in cases in which the available data fail to adequately map EEG signals to specific visual representations. In addition, the significant gap between the visual modality and the neural modality (EEG) could further contribute to these challenges. Several factors may explain the noticeable discrepancies between the images generated from EEG signals and the ground truth, particularly in the failure to recognize specific objects.

Furthermore, this study highlights the critical role of visual cortex activity in EEG-based image generation. Our perturbation analysis, which involved replacing EEG signals from key occipital and parieto-occipital channels with Gaussian noise, led to a significant degradation in image quality, as reflected by increased FID scores. These results indicate that the NECOMIMI framework strongly depends on signals from visual cortical regions to generate semantically coherent images. This observation aligned with previous findings emphasizing the role of occipital areas in visual perception and EEG-based image reconstruction [55]. Importantly, this dependency also reveals potential limitations of such models in cases in which visual cortex function is impaired. Overall, these results further validate

XSL•FO
RenderX

the biological grounding of our approach, demonstrating its ability to capture neural patterns linked to visual imagination.

To address these challenges, we proposed the 2-stage NECOMIMI framework, which combines the NERV EEG encoder with a diffusion-based generative model. The 2-stage NECOMIMI architecture effectively extracts semantic information from the noisy EEG signals, showing its ability to capture and represent underlying concepts derived from brain wave activity. In this framework, we introduced the CAT score, a new evaluation metric specifically designed for EEG-to-image generation. Unlike traditional image evaluation metrics, such as those that assess image distribution, the CAT score focuses on measuring the alignment between the generated images and the underlying semantic intent captured by EEG signals. This evaluation method provides a more accurate reflection of how well the generated images correspond to the cognitive state represented by the EEG data.

Interestingly, our analysis revealed a complex relationship between the encoder's performance in classification tasks and the quality of the generated images. While a high-performing EEG encoder provides robust feature representations, the fidelity and specificity of the generated images were also influenced by other factors such as the generative model's capacity to interpret the EEG embeddings. These findings underscore the challenges of bridging EEG signal processing with image generation and suggest that successful EEG-to-image translation requires both strong feature extraction and sophisticated generative modeling. Our perturbation study further reinforced the biological plausibility of the NECOMIMI framework. The model's responsiveness to disruptions in specific EEG regions indicated its ability to extract spatially meaningful neural patterns, especially those critical for scene-level image synthesis. These results underscore the importance of spatial channel specificity and suggest that leveraging region-targeted EEG signals could further enhance generative performance in future applications.

While the primary focus of NECOMIMI was image generation, its potential extends far beyond this task, particularly in clinical applications for individuals with motor impairments. This section explores how NECOMIMI could be integrated into existing brain-computer interface (BCI) systems and enhanced assistive technologies. One of the applications of NECOMIMI is its ability to function as a visual feedback module in noninvasive BCI systems. Current BCIs for individuals with motor impairments primarily rely on classification-based intent detection methods, such as motor imagery or steady-state visual evoked potentials [56,57]. In contrast, NECOMIMI introduces a novel interaction modality, visual synthesis directly from thought. This approach could enable individuals with severe motor or speech impairments, such as those with locked-in syndrome, to communicate by visualizing concepts through their brain activity. Compared to traditional methods, this offers a more intuitive and flexible interface, allowing users to draw or visualize their thoughts, thereby enhancing their ability to express needs and emotions.

NECOMIMI could also play a critical role in neurofeedback therapies. In this context, real-time EEG-to-image generation may be used to reflect users' mental states, such as emotions or imagined visual scenes, back to them as visual feedback. This feedback loop could be particularly beneficial in therapies targeting attention regulation, anxiety management, or exposure-based interventions [58]. By providing visual stimuli derived from brain activity, NECOMIMI may help users better understand and regulate their mental states, potentially leading to an effective therapeutic outcome. Moreover, NECOMIMI holds strong potential in the field of virtual rehabilitation. The framework could be integrated into immersive virtual environments where patients engage in therapy tasks. Rather than relying on conventional controllers, users could interact with the virtual world by generating images that represent specific tasks or intentions. This offers a more natural and intuitive input method, especially for users with motor disabilities who may struggle with standard navigation tools. EEG-driven image generation could enhance patient engagement and contribute to more personalized and effective rehabilitation processes. As the technology continues to evolve, integration with existing BCI platforms and assistive systems may broaden NECOMIMI's impact, ultimately improving quality of life for individuals with motor and speech impairments. Although still in its early stages, EEG-driven image generation presents a promising direction for enriching user interaction in virtual rehabilitation. By enabling thought-driven image-based communication, NECOMIMI could lower the barrier to access for patients with limited motor control, paving the way for more inclusive and engaging therapy solutions.

Overall, our research presents a novel framework for EEG signal–to-image generation, which expands the application of existing BCI technologies and demonstrates its potential to improve quality of life for individuals with motor impairments. Traditional EEG-based control systems, particularly in clinical settings, often fail to meet expected outcomes. Although our study did not directly evaluate the effectiveness of EEG-controlled devices, it highlighted the promising clinical applications of EEG-to-image conversion. This technology could assist patients in controlling external devices (eg, prosthetics, wheelchairs, and smart environments) through EEG-generated images, thereby offering more opportunities for performing daily tasks and enhancing the accuracy and reliability of EEG-based control systems. Moreover, this approach allows for the transformation of brain sensory signals into realistic visual images, which could be presented in virtual environments, enabling patients to engage in visual perception and interaction based on EEG signals. This not only has the potential to enhance motivation and engagement during the treatment process but also offers possible benefits for rehabilitation therapy and anxiety management. Despite the significant clinical potential, the technology faces several challenges. Future research will need to address how to extract accurate and specific control commands from low-resolution, noise-prone EEG signals while ensuring their stability and reliability in real-world applications.

Understanding the CAT Score Ceiling

The moderate CAT score observed across all EEG encoders, with no model exceeding a score of 500 out of 1000, raised an important question about the underlying limitations of EEG-to-image generation. This result reflected both inherent

XSL•FO
RenderX

challenges of the EEG modality and technological constraints in current generative modeling approaches. Fundamentally, EEG signals are characterized by low spatial resolution, high temporal variability, and a strong susceptibility to noise, making it difficult to extract detailed, object-specific information from brain activity. Compared to neuroimaging modalities such as fMRI, EEG primarily captures global cortical dynamics and abstract cognitive states, which limits its capacity to convey fine-grained visual representations. From a technical perspective, existing diffusion models, even those enhanced with learned priors, are not fully adapted to decode such noisy and semantically diffuse embeddings. The reliance on vision language models such as CLIP may introduce additional complications as these models were trained on natural images and text, not on neural signals, leading to a mismatch in modality and representation [28]. The observed plateau around a CAT score of 500 was largely due to the structure of the scoring system, where each image was evaluated based on 5 semantic tags. Because the EEG embeddings often only weakly reflected specific visual features, the generated images typically aligned with only 1 to 3 of the intended tags. This partial semantic alignment resulted in midrange scores, often between 400 and 500. Furthermore, the generation outputs frequently exhibited generic or overly broad content such as landscapes or blurred objects, reflecting the limited conditioning power of EEG inputs. To overcome these limitations and improve performance beyond this ceiling, several strategies can be considered. Incorporating multimodal physiological signals such as eye tracking or electromyography may provide complementary information that helps disambiguate user intent and improve semantic grounding. In addition, training generative models specifically on EEG-to-image tasks rather than relying on pretrained vision language priors could reduce the modality gap and enhance fidelity. Building large-scale EEG-specific datasets and pretraining encoders on diverse cognitive states may also improve generalization. These directions highlight the importance of tailoring both model architecture and data curation to the unique characteristics of neural signals and point toward a future where EEG-based generative systems can achieve more accurate and reliable visual reconstructions.

Limitations

Despite the promising results of the NECOMIMI framework in EEG-to-image generation, several key limitations remain that must be addressed in future research. One of the primary challenges in EEG-to-image research is the scarcity of publicly available, large-scale EEG-image pair datasets. Unlike text-to-image tasks, which benefit from extensive datasets such as LAION-5B, EEG-to-image studies are constrained by the limited availability of paired EEG and image data. While the ThingsEEG dataset is one of the largest of its kind, it still lacks the diversity and scale necessary to train highly generalized EEG-to-image models. This limitation hinders benchmarking efforts and prevents the development of robust generative models capable of generalizing across different EEG recording conditions, participants, and experimental paradigms. In addition to the dataset scarcity, EEG recordings exhibit significant interparticipant variability, meaning that neural responses to identical visual stimuli can vary considerably between individuals. This variability complicates the generalization of models across different participants. Furthermore, EEG-based datasets are often collected under controlled experimental conditions, which limits their applicability to real-world scenarios. Consequently, without access to larger, more diverse datasets, EEG-to-image models remain constrained in their ability to generalize across a wide range of neural and visual domains.

Another challenge arises from the fact that, although our NERV EEG encoder demonstrated SOTA performance in zero-shot classification tasks, this high classification accuracy did not necessarily translate into higher-quality image generation. This suggests that feature representations optimized for classification tasks may not be equally effective for generative tasks. The gap between feature extraction and image generation remains an open challenge, indicating the need for future models to explore alternative training strategies that better align EEG embeddings with the generative process. Optimizing NECOMIMI for real-time image generation could unlock new possibilities for applications in BCIs and neurofeedback systems. Furthermore, expanding training datasets to include more diverse and larger-scale EEG recordings will be essential for improving model generalization. Incorporating additional data modalities such as eye tracking, electromyography, or functional near-infrared spectroscopy could also provide complementary information to enhance image generation. Finally, future work should aim to improve the model's resilience to signal noise and variability, particularly in the visual cortex. Multimodal integration and training protocols that encourage distributed cortical representation may reduce the model's dependency on any single brain region, ultimately enhancing stability, interpretability, and generalization across individuals and tasks.

Conclusions

The NECOMIMI framework expands previous work on EEG-image pair contrastive learning classification by enabling image generation, filling a gap in previous research and opening up new possibilities for EEG applications. We introduced the SOTA EEG encoder NERV, which achieved top performance in 2-way, 4-way, and 200-way zero-shot classification tasks, as well as in the CAT score evaluation, demonstrating its effectiveness in EEG-based generative tasks. A key finding was that the model often generated abstract images rather than specific objects. This suggests that EEG data, being noisy and low resolution, captured broad semantic concepts rather than detailed visuals. The gap between neural signals and visual stimuli remained a challenge for precise image generation. In addition, we proposed the CAT score, a new metric tailored for EEG-to-image generation, and established its benchmark on the ThingsEEG dataset. Surprisingly, we found that EEG encoder performance may not strongly correlate with the quality of the generated images, providing new insights into the limitations and challenges of this task. NECOMIMI demonstrates the potential of EEG-to-image generation while highlighting the complexities of translating neural signals into accurate visual representations. Furthermore, the perturbation experiment revealed that the NECOMIMI model strongly depends on EEG signals from the visual cortex, particularly the occipital and parieto-occipital regions. This reliance not only

XSL•FO
RenderX

supports the biological plausibility of our model's design but also emphasizes the critical role of spatial EEG features in accurate image reconstruction. These insights may guide future improvements in region-aware modeling strategies for EEG-based generative tasks. Future work should prioritize improving EEG representation learning, refining generative modeling techniques, and developing more robust evaluation frameworks to enhance the reliability and realism of EEG-generated images.

Acknowledgments

The authors gratefully acknowledge the National Science and Technology Council for their generous financial support of this research, provided under contract NSTC 113-2221-E-182-045. The authors would like to thank Aidan Hung-Wen Tsai for brainstorming this fascinating title with them, which originated from a conversation in Silicon Valley about NeuroSky's cat-ear electroencephalography product, Necomimi. They also appreciate Neuro Industry, Inc, for providing A100 computational resources on the Google Cloud Platform. The authors extend special thanks to Dr Guan-Ying Chen for proofreading and providing valuable feedback on revisions.

Abstract

Background: The presence of stigmatizing language within electronic health records (EHRs) poses significant risks to patient care by perpetuating biases. While numerous studies have explored the use of supervised machine learning models to detect stigmatizing language automatically, these models require large, annotated datasets, which may not always be readily available. In-context learning (ICL) has emerged as a data-efficient alternative, allowing large language models to adapt to tasks using only instructions and examples.

Objective: We aimed to investigate the efficacy of ICL in detecting stigmatizing language within EHRs under data-scarce conditions.

Methods: We analyzed 5043 sentences from the Medical Information Mart for Intensive Care–IV dataset, which contains EHRs from patients admitted to the emergency department at the Beth Israel Deaconess Medical Center. We compared ICL with zero-shot (textual entailment), few-shot (SetFit), and supervised fine-tuning approaches. The ICL approach used 4 prompting strategies: generic, chain of thought, clue and reasoning prompting, and a newly introduced stigma detection guided prompt. Model fairness was evaluated using the equal performance criterion, measuring true positive rate, false positive rate, and F_1-score disparities across protected attributes, including sex, age, and race.

Results: In the zero-shot setting, the best-performing ICL model, GEMMA-2, achieved a mean F_1-score of 0.858 (95% CI 0.854-0.862), showing an 18.7% improvement over the best textual entailment model, DEBERTA-M (mean F_1-score 0.723, 95% CI 0.718-0.728; P<.001). In the few-shot setting, the top ICL model, LLAMA-3, outperformed the leading SetFit models by 21.2%, 21.4%, and 12.3% with 4, 8, and 16 annotations per class, respectively (P<.001). Using 32 labeled instances, the best ICL model achieved a mean F_1-score of 0.901 (95% CI 0.895-0.907), only 3.2% lower than the best supervised fine-tuning model, ROBERTA (mean F_1-score 0.931, 95% CI 0.924-0.938), which was trained on 3543 labeled instances. Under the conditions tested, fairness evaluation revealed that supervised fine-tuning models exhibited greater bias compared with ICL models in the zero-shot, 4-shot, 8-shot, and 16-shot settings, as measured by true positive rate, false positive rate, and F_1-score disparities.

Conclusions: ICL offers a robust and flexible solution for detecting stigmatizing language in EHRs, offering a more data-efficient and equitable alternative to conventional machine learning methods. These findings suggest that ICL could enhance bias detection in clinical documentation while reducing the reliance on extensive labeled datasets.

Introduction

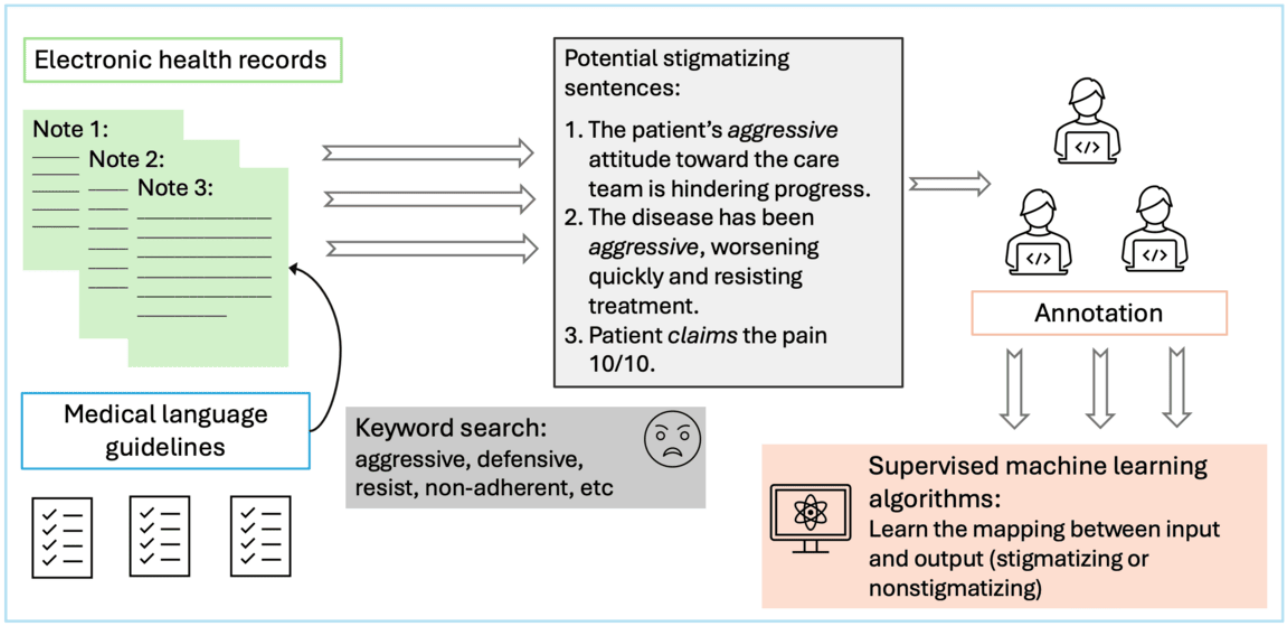
Background

Electronic health records (EHRs) are comprehensive digital systems that capture, store, and facilitate the retrieval and analysis of detailed longitudinal information about a patient's health status [1]. As a central repository of patient information, EHRs are indispensable for facilitating efficient communication and collaboration among medical professionals [2,3]. Given the widespread adoption of EHR systems in health care settings globally and their vital role in streamlining health care communication [4,5], concerns have emerged regarding the prevalence of stigmatizing language within these records [6-9]. Specifically, a recent large-scale study [10] reported that stigmatizing language appears in a substantial proportion of clinical notes, with prevalence ranging from 42.8% to 59.1% in history and physical notes, consultation notes, and discharge summaries.

Stigmatizing language in health care refers to language that carries negative connotations, labels patients negatively, attributes blame, or renders judgment based on their social identities, medical conditions, or personal experiences [11]. Such language can be explicit, as in the use of derogatory terms such as "junkie" or "alcoholic" [8]. However, it also frequently manifests in more implicit forms, including subtle judgments embedded in tone, phrasing, or contextual framing [7]. Research in social psychology has demonstrated that implicit biases, which refer to unconscious attitudes or stereotypes, can be reflected through people's language [12,13]. In health care, implicit biases may surface through the language used to describe patients. For instance, labeling a patient as "noncompliant" may seem clinically objective, but it can implicitly stigmatize their behavior by suggesting poor self-management, rooted in preconceived notions or stereotypes, without considering contextual factors such as mental capacity, available resources, or external circumstances. Implicit biases reflect broader systemic inequities, as institutional practices and cultural norms often perpetuate and normalize the use of stigmatizing language in clinical settings [14,15]. Stigmatizing language has been frequently observed in clinical specialties such as substance use disorders, mental health conditions, diabetes, and obesity, where it has shaped both clinical terminology and professional attitudes [8,16-18]. This systemic perpetuation of stigmatizing language reinforces negative stereotypes and creates barriers to equitable health care, undermining patient trust and treatment outcomes. By embedding biased language into clinical notes, these unconscious attitudes influence immediate clinical decisions and may perpetuate negative stereotypes over time [15,19], as subsequent clinicians rely on prior documentation [20]. These patterns were confirmed in a recent analysis of 754 clinical notes containing stigmatizing language [21], which found that stereotyping accounted for 41.2% of instances, followed by labeling patients as difficult (15.3%), disapproval (9.6%), unilateral decision-making (7.3%), and questioning patient credibility (5.3%). Such findings underscore the importance of mitigating bias to advance health care equity.

The presence of stigmatizing language can profoundly impact the quality of care. A study [18] found that clinicians exposed to the stigmatizing term "substance abuser," as opposed to the more neutral phrase "person with substance use disorder," were more likely to view the patient as personally culpable and deserving of punitive action rather than treatment. In addition, a national survey of 655 emergency physicians, those who used the stigmatizing label "sickler" to describe patients with sickle cell disease, demonstrated lower compliance with national treatment guidelines and were less likely to prescribe appropriate medications [17]. Complementing these findings, previous research has also shown that physicians who read notes containing stigmatizing language are more likely to develop negative attitudes toward the patient and to provide less aggressive pain management [22]. Notably, only 18% of inpatient progress notes are manually entered, with the majority being imported or copied from previous documentation [20]. The reliance on previous documentation raises concerns about the potential perpetuation of stigmatizing language, which could reinforce negative biases and influence clinical decision-making over time. With the implementation of the 21st Century Cures Act in 2021 in the United States, patients have gained access to their EHRs [23], making these records increasingly integral to the clinician-patient relationship. A large survey study [24] found that 10% of patients feel judged or offended due to labeling and evidence of disrespect in EHRs. Another study [16] reported that 19% of patients indicated they would avoid future medical appointments if their physicians used stigmatizing language toward them, while 21% stated they would seek a new physician. There is also substantial evidence that stigmatizing language in EHRs can jeopardize the therapeutic relationship, leading to distrust, delayed care, and reduced treatment engagement [7,25,26].

Given the detrimental effects of stigmatizing language in EHRs and the substantial resources required for its manual identification, there is a growing interest in developing automated detection methods. Manual detection typically necessitates annotators possessing extensive clinical expertise to accurately interpret context, as well as linguistic proficiency to discern subtle indicators of stigma [15,27]. In current practice, manual annotation typically involves experienced physicians reading and classifying individual sentences or notes from EHRs, an approach that is labor-intensive and costly, particularly when scaled across large datasets [15,27,28]. To overcome these challenges, researchers have increasingly explored machine learning approaches for the automated detection of stigmatizing language within EHRs. For instance, Sun et al [15] developed a logistic regression classifier to assess whether sentences in EHRs convey stigmatization, using a proprietary dataset, while Harrigian et al [27] conducted a comparative analysis of logistic regression and Bidirectional Encoder Representations from



XSL•FO
RenderX

Transformers (BERT) classifiers for the detection of stigmatizing language. However, these studies have all used supervised learning approaches, which generally require thousands to tens of thousands of annotated data points to achieve optimal performance. The assumption that such large volumes of annotated data are readily available is often unrealistic, as the acquisition of labels for stigmatizing language detection presents significant challenges. Stigmatizing language is frequently subtle, covert, and highly contextual. Consequently, acquiring annotated data for stigmatizing language detection can be demanding and resource intensive. The previous studies' heavy reliance on supervised machine learning approaches has highlighted a significant limitation in addressing scenarios where annotated data may be scarce.

In-context learning (ICL) is an emerging paradigm for addressing natural language processing (NLP) tasks in data-scarce settings [29-32]. ICL enables general-purpose large language models (LLMs) to adapt to new tasks by incorporating instructions and either zero or a few examples directly within the input prompt, thereby reducing reliance on extensively annotated datasets [29,33,34]. By leveraging the robust contextual understanding capabilities inherent in general-purpose LLMs, the ICL approach is particularly well-suited for detecting stigmatizing language, a task that requires the identification of subtle nuances and a high level of contextual comprehension. To the best of our knowledge, no study has systematically examined the efficacy of the ICL approach for stigmatizing language detection, underscoring a significant gap in the current research landscape.

The effectiveness of the ICL approach is contingent upon prompt engineering, which involves crafting precise, informative, and contextually relevant prompts to guide the LLM in executing specific tasks [29,35,36]. Therefore, the efficacy of the ICL approach could be enhanced by a tailored prompting strategy for stigmatizing language detection. Previous studies on detecting stigmatizing language typically involve a 2-stage process (Figure 1): first, the extraction of sentences containing potentially stigmatizing words or phrases in accordance with medical language guidelines, followed by the development of the supervised machine learning model with the annotated data set [15,27]. The potentially stigmatizing words or phrases identified during the extraction process can provide valuable information that can be incorporated into the prompting strategy. By explicitly prompting the LLM to focus on these terms, we anticipate an improvement in its sensitivity to detecting stigmatizing language. Furthermore, given that stigmatizing language is often covert and subtle [27,37], incorporating common linguistic characteristics associated with such language may further increase the model's accuracy in identifying instances of stigmatization. Customizing prompts to address the unique aspects of stigmatizing language presents a valuable opportunity to enhance detection precision.

Figure 1. Workflow for developing a supervised machine learning model in stigmatizing language detection.

While developing effective machine learning models to detect stigmatizing language is important, it is equally critical to ensure that these models do not introduce or perpetuate existing biases [38]. Numerous studies have demonstrated that machine learning classifiers can exhibit algorithmic bias, resulting in performance disparities across groups of patients with different protected attributes, such as sex, race, age, and socioeconomic status [39,40]. For example, Seyyed-Kalantari et al [41] found that a leading machine learning classifier for detecting chest X-ray pathologies exhibited a higher false negative rate for Hispanic female patients. In the context of stigmatizing language detection, algorithmic bias can lead to uneven identification and correction of stigmatizing language, disproportionately affecting certain groups and potentially exacerbating health disparities. To the best of our knowledge, no previous studies have specifically examined the fairness of classifiers in detecting stigmatizing language within EHRs, highlighting the need for further investigation into how these models perform across diverse patient populations. By rigorously evaluating the fairness of these models, we can identify potential disparities and ensure that they equitably benefit patients from diverse backgrounds.

XSL•FO

Study Objectives

We aimed to investigate the effectiveness of the ICL approach for detecting stigmatizing language in EHRs under data-scarce conditions. First, we evaluated the performance of the ICL approach against established approaches in zero-shot (no annotated data) and few-shot settings (a small amount of annotated data), including the textual entailment [42] and SetFit [43]. For the ICL approach, we used 4 distinct prompting strategies, including more sophisticated strategies, such as the chain of thought (COT) [44] and the clue and reasoning prompting (CARP) [30]. We also introduced a novel prompting strategy, termed "stigma detection guided prompt," specifically designed to enhance the precision and effectiveness of detecting stigmatizing language. Second, to further contextualize ICL's performance, we conducted a comparative analysis of supervised fine-tuning and ICL to evaluate the extent to which ICL can achieve competitive performance under data-scarce conditions relative to a well-established method that leverages a large corpus of annotated data. This comparison provides valuable insights for hospitals, enabling them to assess the cost-benefit trade-offs associated with investing in annotated datasets for detecting stigmatizing language in clinical documentation. Third, we assessed the fairness dimension of the classifiers used for detecting stigmatizing language in this study by comparing their performance across diverse patient groups characterized by various protected attributes, including sex, age, and race.

Methods

Dataset Description

In this study, we used an open-source stigmatization detection dataset prepared by Harrigian et al [27]. The dataset consists of 5043 sentences, of which 3249 (64.4%) are labeled as stigmatizing and 1794 (35.6%) as nonstigmatizing. The original creators randomly sampled these sentences from 4710 discharge summaries associated with 4259 patients within the Medical Information Mart for Intensive Care (MIMIC)–IV database and subsequently annotated them. The MIMIC-IV is an EHR dataset that comprises 331,794 discharge summaries from the Beth Israel Deaconess Medical Center in Boston, Massachusetts, United States, from 2008 to 2019 [45]. The observed prevalence of stigmatizing language in this dataset is notably higher than previously reported estimates, such as the 42.8% identified by Weiner et al [10]. This difference is attributable to the broader scope of stigmatizing expressions captured in the dataset prepared by Harrigian et al [27], which encompasses a wider range of terminology than earlier studies.

Discharge summaries were selected because they provide detailed documentation of the patient's clinical course, including diagnoses, treatments, and physician observations, which are particularly relevant for investigating stigmatization in clinical notes. Sentences were extracted based on the presence of potentially stigmatizing words or expressions, such as "noncompliant" and "agitated." A symmetric context window of 15 tokens on either side of each sentence was applied to preserve surrounding context and enhance model interpretation. If fewer than 15 tokens were available on either side, the context window was shortened as needed to fit the available text. Each sentence was independently annotated by 2 members of an annotation team comprising 1 clinician and 2 research assistants based on a predefined framework [27]. Any disagreements were resolved through discussion among all 3 annotators. The annotation process achieved a high level of interrater agreement, with an average pairwise Cohen κ exceeding 0.9. The annotation of stigmatization was determined based on framing and intent of the sentence with its surrounding context (ie, whether the sentence implies that the patient's behavior is cast in a negative light). Sentences that did not describe patient behavior, or that neutrally described patient behavior, acknowledged structural or clinical barriers, or conveyed empathy from health care providers were not considered stigmatizing. The demographic information of the dataset, including patient sex, age, and race, is presented in Table 1. The "other or unknown" race category included individuals who did not report their race. A more detailed description of the dataset is provided in Multimedia Appendix 1 [15,18,19,22,27,37].

Table 1. Demographic information of the stigmatizing dataset used in this study.

Demographic attributes	Stigmatizing sentences, n (%)	Nonstigmatizing sentences, n (%)
Sex		
Male (n=2600)	1731 (66.6)	869 (33.4)
Female (n=2443)	1518 (62.1)	925 (37.9)
Age (y)		
0-25 (n=468)	303 (64.7)	165 (35.3)
26-50 (n=1639)	1184 (72.2)	455 (27.8)
51-75 (n=2005)	1249 (62.3)	756 (37.7)
>75 (n=931)	513 (55.1)	418 (44.9)
Race		
Asian (n=125)	69 (55.2)	56 (44.8)
Black (n=945)	676 (71.5)	269 (28.5)
Hispanic (n=246)	159 (64.6)	87 (35.4)
Other or unknown (n=522)	305 (58.4)	217 (41.6)
White (n=3205)	2040 (63.7)	1165 (36.3)

Ethical Considerations

This study used a publicly available dataset consisting of EHR sentences. All patient records were anonymized by the dataset's original creators, ensuring that no individual identifiable information was accessible to the research team [45]. As such, the study is exempt from research ethics board review in accordance with Article 2.2 of the Tri-Council Policy Statement [46]. The original collection of data was approved by the institutional review boards of the Beth Israel Deaconess Medical Center, Boston, Massachusetts, and the Massachusetts Institute of Technology, Cambridge, Massachusetts (2001P001699). The institutional review boards also granted a waiver of informed consent and approved the sharing of the research resource, thereby permitting secondary analysis of the deidentified data without additional consent.

No compensation was provided or required for the use of this secondary data. No identification of individual participants or users in any images of the manuscript or supplementary material is possible. To access this dataset, the lead author fulfilled all necessary regulatory requirements, including the completion of the course "CITI data or specimens only research training" (certification number 62353094). In addition, the lead author signed a data use agreement to ensure the appropriate use of the data in compliance with relevant policies and regulations.

Comparative Analysis for Stigmatizing Language Detection

Zero-shot and few-shot learning are machine learning paradigms that allow models to perform tasks with either no labeled data or with only a minimal set of labeled examples, respectively [47,48]. Zero-shot learning enables a model to perform a task without any previous examples, relying solely on its pretrained knowledge. In contrast, few-shot learning operates by providing the model with a limited number of labeled examples, typically ranging from 10 to 100.

In this study, we conducted a comprehensive evaluation of the effectiveness of the ICL approach for detecting stigmatizing language in EHRs under conditions of limited data availability. We compared the performance of ICL against the textual entailment approach [42] within a zero-shot learning context and the SetFit approach [43] within a few-shot learning context, specifically analyzing scenarios involving 4, 8, and 16 annotated examples per class. For the few-shot learning experiments, data points were randomly selected as examples. To ensure reproducibility and mitigate potential variability in performance due to random sampling, the selection process was repeated 5 times using distinct random seeds. The final performance results reported in this study represent the average across these 5 runs, providing a more robust and stable assessment of model performance.

In addition, we extended our comparative analysis to include a fully supervised fine-tuning approach. This broader comparison allows us to rigorously assess the strengths and potential limitations of the ICL approach in the detection of stigmatizing language within EHRs. All approaches used in this study adhered to the framework established in previous studies (Figure 1), wherein sentences were extracted based on potentially stigmatizing words or phrases identified from medical language guidelines, followed by the development of detection approaches (ie, ICL).

Textual Entailment Approach

The textual entailment approach conceptualizes zero-shot text classification as an entailment task [42]. This method is among the most widely adopted for zero-shot text classification and has demonstrated state-of-the-art performance across various benchmarks [49,50]. In this approach, the input text is interpreted as a premise, and the model assesses whether this premise logically entails the corresponding class label. Specifically, in the context of stigmatizing language detection, the model first considers a sentence from an EHR as the premise

XSL•FO
RenderX

and then evaluates whether it entails stigmatization or nonstigmatization. The textual entailment approach relies on the knowledge embedded in pretrained language models, which have been trained on natural language inference datasets [51]. This training effectively enhances the model's capability for sentence comprehension. In our study, we used a selection of widely recognized pretrained language models for natural language inference to assess the effectiveness of the textual entailment approach in detecting stigmatizing language (Table 2). These models were selected due to their widespread use in zero-shot classification tasks [50,52,53] and their representation of a diverse range of transformer architectures, enabling us to fully explore the potential of the textual entailment approach for detecting stigmatizing language.

SetFit Approach

SetFit is a popular few-shot text classification approach that has been applied across various domains [50,54,55]. The SetFit approach consists of a two-step process [43]. First, a pretrained sentence transformer is fine-tuned in a contrastive Siamese manner using pairs of labeled data. The objective of this contrastive fine-tuning is to ensure that embeddings of semantically similar sentences are close together in the feature space while embeddings of semantically dissimilar sentence pairs are maximally distanced. This process aims to generate meaningful representations that accurately capture the semantic relationships between sentences. In the second step, a classification head is trained using the representations produced by the fine-tuned sentence transformer. For this study, we used 6 pretrained sentence transformers to evaluate the effectiveness of the SetFit approach in detecting stigmatizing language (Table 3). MPNET-V2 and MINILM-V2 were the sentence transformers used in the original work that proposed SetFit [43], while the more contemporary E5-V2 and ROBERTA-V2 were included due to their superior performance on various NLP benchmarks [56,57]. We also incorporated 2 sentence transformers pretrained on medical domain knowledge: BERT-BIO-ST and BIOLORD. The inclusion of these models was based on the hypothesis that domain-specific pretraining may enhance the model's ability to capture contextually relevant medical terminology and nuances, thereby improving its effectiveness in detecting stigmatizing language [58].

Fully Supervised Fine-Tuning Approach

The fully supervised fine-tuning approach involves adapting a pretrained language model to a specific task by fine-tuning it on a labeled dataset, where each instance is associated with its corresponding label [29]. In this study, we used 5 pretrained language models to examine the efficacy of a fully supervised fine-tuning approach for detecting stigmatizing language (Table 4). ROBERTA, ROBERTA-XLM, and BERT were selected due to their extensive adoption and strong performance across text classification tasks in different domains [50,59-61]. BERT-BIO and BERT-biomed were included for their pretraining on biomedical text corpora, making them particularly well-suited for NLP tasks involving medical terminology [58,62]. We excluded certain contemporary medical pretrained language models, such as Gatortron [45] and ClinicalBERT [46], from our analysis. These models were omitted because they were pretrained on the MIMIC dataset, which could introduce data leakage and potentially lead to an overestimation of the model's effectiveness. We specifically focused on fine-tuning encoder-based language models, such as BERT, rather than decoder-based models (ie, LLAMA) for 2 primary reasons. First, previous research has demonstrated that encoder-only models typically achieve superior or comparable performance to decoder-based models in text classification tasks with relatively small, labeled datasets, which aligns with our study setting [63,64]. Second, BERT-based models currently represent the state-of-the-art for supervised stigmatizing language detection [27]. Thus, using these models as a benchmark allows for a more rigorous evaluation of ICL performance against established methodologies.

We fine-tuned these pretrained language models on 3543 labeled sentences from EHRs, representing approximately 70% of the total data. The supervised fine-tuning approach was included to provide a robust benchmark for comparison with the ICL approach in detecting stigmatizing language. Hyperparameters were tuned using a validation dataset of 500 data points, representing approximately 10% of the total dataset. Hyperparameter tuning was conducted for key parameters using grid search, including learning rate, batch size, and weight decay rate, to optimize model performance and mitigate overfitting. We used the AdamW optimizer [65] with default betas set to 0.9 and 0.999 and an epsilon of 1×10^{-6} to ensure numerical stability. The number of epochs was determined using an early stopping criterion, where training was terminated if the validation loss did not decrease for 5 consecutive epochs. The final hyperparameter settings were selected based on the model's best performance on the validation dataset before being evaluated on the held-out test dataset.

ICL Approach

The ICL approach leverages general-purpose LLMs through prompting techniques to rapidly adapt to a wide range of NLP tasks [29]. The approach has demonstrated exceptional performance in applications such as question answering, machine translation, text summarization, and text classification [29,32-34]. In this study, we used 5 widely used open-source general-purpose LLMs to evaluate the efficacy of the ICL approach in detecting stigmatizing language (Table 5). We refer to models such as LLAMA-3 as general-purpose LLMs to emphasize their broad applicability across various NLP tasks without extensive task-specific fine-tuning. We specifically selected instruction fine-tuned models, as previous research has shown that instruction fine-tuning significantly enhances model performance across a range of NLP tasks, particularly in zero-shot and few-shot settings [66,67]. In addition, we included BIO-LLAMA-3, a domain-specific model that has undergone instruction fine-tuning on a large biomedical dataset [68], to assess the potential benefits of domain adaptation in stigmatizing language detection. Due to the constraints of the MIMIC-IV data use agreement, we were unable to use newer cloud-based models, such as GPT-4 or Claude 3.5, as their use would necessitate sharing data with external parties. Previous studies have demonstrated that general-purpose LLMs are highly sensitive to subtle variations in prompt formatting [69,70]. To optimize the performance of the ICL approach, we devised a validation data set for prompt format tuning, which included adjustments such as the wording and positioning of instructions. A random sample of 30 data points was selected to construct this validation set, designed to replicate a data-scarce scenario consistent with previous research [71,72].

Prompting Strategies for the ICL Approach

The effectiveness of the ICL approach relies heavily on the design of a well-structured prompting strategy that delivers clear and precise task instructions. A prompting strategy refers to the specific approach used to organize instructions, examples, and guiding principles within a prompt to elicit accurate and reliable outputs from the LLM. These prompts are often accompanied by either zero or a few illustrative examples to guide the model in performing downstream tasks effectively [29,32]. In this study, we evaluated 4 distinct prompting strategies: generic, COT [44], CARP [30], and a new customized prompting strategy we developed, referred to as the stigma detection guided prompt. The prompting template for each strategy is provided in Table 6. Figure 2 provides examples of the prompting strategies used in this study.

Clue and reasoning prompting	"First, list clues (e.g., keywords, phrases, contextual information, semantic relations, tones, references) that support the determination of stigmatization in the input. Second, deduce the diagnostic reasoning process from the premises (i.e., clues and input) that support the stigmatization determination. Third, based on the clues, reasoning, and input, determine whether the input conveys stigmatization. Input: '{input sentence}.' Answer with 'yes' or 'no'. Answer:"
Stigma detection guided prompt	"Stigmatizing language can exhibit the following characteristics: 1) Questioning credibility: Implication of physician disbelief in patient reports of their own experiences or behaviors. 2) Disapproval: Highlights poor reasoning, decision-making, or self-care, often in a way that suggests the patient is unreasonable. 3) Stereotyping: Quoting incorrect grammar or unsophisticated terms. 4) Difficult patient: Inclusion of details with questionable clinical significance that portray the patient as belligerent or otherwise suggest that the physician is annoyed. 5) Unilateral decisions: Language that emphasizes physician authority. Input: '{input statement}.' Keyword: "{keyword}." Does the keyword in the input convey stigmatization? Answer with 'Yes' or 'No'. Answer:"

XSL•FO
RenderX

Figure 2. Examples of 4 distinct prompting strategies used in this study. CARP: clue and reasoning prompting; COT: chain of thought; LLM: large language model.

The generic prompting strategy involves providing the model with minimal context, thereby relying primarily on its pretrained knowledge to perform the task [69]. In this approach, the prompt consists of a brief instruction about the task at hand, without incorporating reasoning steps or specific domain knowledge. For example, in the context of detecting stigmatizing language, the prompt might simply query the model with "Choose your answer: On the basis of the above sentence, does the text convey stigmatization? Yes/No." This strategy serves as a baseline for comparing its performance with that of more advanced prompting techniques, such as COT, CARP, and the stigma detection guided prompt. In the few-shot scenario, a limited number of example sentences accompanied by their corresponding labels are embedded within the generic prompt to guide the model in making informed predictions.

The COT prompting strategy is designed to enhance the reasoning capabilities of general-purpose LLMs by guiding them to generate intermediate reasoning steps before arriving at a final prediction [44]. This approach leverages the LLM's capacity to systematically reason through complex tasks, thereby improving the reliability and accuracy of its outputs. For instance, the prompt can be appended with "Let's think step by step" to induce the model to break down the problem into logical and incremental steps. By explicitly instructing the model to articulate its reasoning, the COT strategy encourages more thoughtful predictions. In the zero-shot setting, the COT strategy involves prompting the model twice before making a prediction [33]. The first prompt encourages the model to produce intermediate reasoning by appending "Let's think step by step" to the end of the prompt. This intermediate reasoning is then incorporated into a second prompt, which is used to generate the final prediction. In the few-shot setting, the model was first prompted to generate reasoning steps for randomly selected data points. These data points, along with their corresponding reasoning steps, were incorporated into the prompt as examples to enhance the model's performance.

The CARP prompting strategy is specifically designed for text classification tasks. It uses a progressive reasoning approach to handle the linguistic complexities inherent in such tasks. This strategy first prompts the model to identify superficial clues within the input text, such as keywords, tone, semantic relations, and references, which provide initial indicators for classification. Once these clues are identified, the model engages in a diagnostic reasoning process to infer the final prediction in a logical manner [30]. For example, the presence of a negative tone combined with specific keywords may collectively suggest the presence of stigmatizing language. In the few-shot setting, the model was first guided to generate clues and reasoning for

XSL•FO
RenderX

randomly selected examples. These examples, along with their associated clues, reasoning, and labels, were then incorporated into the prompt to enhance the model's performance [30]. The detailed code implementation for the prompting strategies is provided in Multimedia Appendix 2.

Design of the Stigma Detection Guided Prompt

In this study, we introduce a novel prompting strategy for detecting stigmatizing language, termed the stigma detection guided prompt. While prompt engineering has shown promise in improving LLM performance, there is no universally established framework for systematically designing prompts tailored to specific tasks [32]. The design of the proposed prompting strategy is inspired by recent research indicating that incorporating task-tailored instructions and domain knowledge can enhance the performance of the LLMs on downstream medical tasks [73,74]. Our proposed strategy consists of two key components: (1) explicitly directing the LLM to assess potentially stigmatizing words or phrases and (2) incorporating linguistic characteristics commonly associated with stigmatizing language to enhance the model's ability to identify subtle instances of stigmatization in clinical text. In the subsequent section, we outline the rationale behind these components and their contributions to improving stigma detection in clinical documentation.

In the stigma detection guided prompt, we specifically instruct the LLM to assess potentially stigmatizing words or expressions. For instance, in the sentence "Patient became more intrusive and confrontational with other patients," the model is specifically instructed to assess whether the term "confrontational" conveys stigmatization based on its surrounding context (Figure 2). We intentionally designed the prompt to focus on sentences containing expert-identified terms that are frequently used to convey stigmatization in clinical documentation (ie, aggressive and noncompliant). In this task formulation, the model is not asked to detect stigmatization broadly, but rather to assess whether the use of a known high-risk term conveys stigmatization in context. This reflects a practical and clinically relevant problem, as the same term may be neutral or stigmatizing depending on how it is used. In addition, this keyword-based approach aligns with prevailing practices in the literature. Previous studies have typically developed machine learning models or conducted analyses using sentences containing specific terms that are frequently flagged as stigmatizing according to medical language guidelines [15,75]. This approach remains widely adopted, in part because standardized definitions of stigmatizing language are still underdeveloped, and the topic remains sensitive within health care contexts. Therefore, focusing on predefined terms in the prompt offers a consistent and pragmatic approach for studying stigmatizing language across datasets and research settings. Conventional prompting strategies do not effectively leverage this information. By explicitly integrating this task-tailored instruction, our approach aims to enhance the LLM's ability to detect stigmatizing language with greater contextual awareness.

Within the proposed prompting strategy, we also integrate linguistic characteristics commonly associated with stigmatizing language to enhance the model's ability to detect subtle and implicit stigmatization. Stigmatizing language in EHRs frequently manifests in indirect ways, where certain words or phrases acquire negative connotations depending on the context in which they are used [19,76]. For instance, the term "claims" in the phrase "Patient claims pain is 10/10" may suggest disbelief, thereby contributing to stigma [7]. Previous work has identified five recurring linguistic patterns associated with stigmatizing language in clinical documentation, including (1) questioning patient credibility, (2) expressing disapproval of patient reasoning or self-care, (3) stereotyping based on race or social class, (4) portraying patients as difficult, and (5) emphasizing physician authority over the patient [37]. By incorporating these linguistic markers into the prompting strategy, our approach aims to enhance the LLM's sensitivity to context-dependent cues, improving its overall accuracy in detecting stigmatizing language. In the few-shot setting, we incorporated examples within the prompt, following a similar approach to that used in the generic prompting strategy.

Performance Evaluation and Comparison

In this study, stigmatizing language detection was framed as a binary text classification problem. To evaluate the performance of various approaches, we randomly sampled 1000 data points to create a test dataset, ensuring no overlap with training or validation datasets. We used 5 standard classification metrics: accuracy, precision, recall, area under the receiver operating characteristic curve (AUC-ROC), and F_1-score. Accuracy indicates the percentage of EHR sentences that are correctly classified. Precision measures the proportion of sentences identified as stigmatizing that are stigmatizing, reflecting the model's ability to avoid false positives. Recall, also known as sensitivity, assesses the proportion of actual stigmatizing sentences that are correctly identified, highlighting the model's capacity to capture true positives. The AUC-ROC evaluates the model's ability to distinguish between stigmatizing and nonstigmatizing sentences across different classification thresholds, with higher values indicating better discriminatory power. The F_1-score, which ranges from 0 to 1, is computed as the harmonic mean of precision and recall, offering a balanced measure of classification performance. The F_1-score is particularly critical for evaluating stigmatizing language detection due to the highly imbalanced nature of the dataset. Notably, the AUC-ROC metric was not computed for the ICL approach, as it does not produce the probabilistic classification required for the metric.

To obtain a robust estimate of the model's performance, we computed 95% CIs by training, tuning, and evaluating each model on 10 different train-validation-test splits, each generated using a different random seed. These test datasets were designed to have no overlap with the training or validation datasets, thereby minimizing potential biases in performance estimation. To compare the top-performing models, we conducted paired 1-tailed t tests on F_1-score, precision, and recall. Because each model was evaluated on the same test splits, the paired t test was chosen as it accounts for the dependency between paired observations, reducing variance and increasing statistical power compared to an independent t test. In the zero-shot setting, we compared the highest-performing models based on F_1-score in

XSL•FO
RenderX

both the textual entailment and ICL approaches. In the few-shot setting, we compared the best models when different numbers of annotations were available in the SetFit and ICL approaches. In addition, we compared the top-performing supervised fine-tuning model with the best ICL model. To mitigate the risk of inflated type I error due to multiple comparisons, we applied the Bonferroni correction to adjust the significance threshold. Given that a total of 15 comparisons were conducted, the adjusted significance level was set at P=.003 (.05/15).

Fairness Evaluation

The notion of machine learning fairness in health care can be broadly classified into equal allocation and equal performance considerations [39]. Equal allocation pertains to the equitable distribution of health care resources across different patient subgroups. For instance, in the context of kidney transplantation, a fair machine learning model would ensure that transplants are allocated proportionally among patient groups, thereby mitigating disparities in access to care [77]. In contrast, equal performance requires that a model achieves comparable predictive accuracy across both protected and nonprotected groups. This can be quantified using metrics such as the true positive rate (TPR) and false positive rate (FPR), among others [39-41]. In the context of stigmatizing language detection, the equal performance criterion is more suitable as it ensures that the model identifies stigmatizing language consistently across different demographic groups.

For the fairness evaluation, we used the criterion of equal performance, assessing the model across 3 key performance metrics: TPR, FPR, and F_1-score. A classifier is considered fair under this criterion if its performance remains consistent across subgroups defined by protected attributes. The TPR, also commonly referred to as recall, quantifies the proportion of EHR sentences containing stigmatizing language that the model correctly identifies. This metric is critical for fairness evaluation, as a lower TPR for certain demographic subgroups means the model fails to detect stigmatizing language in their clinical records at the same rate as others, potentially allowing harmful biases to persist unnoticed in medical documentation. This could lead to disparities in patient advocacy efforts, as undetected stigmatizing language may influence health care provider perceptions and contribute to differences in the quality of care received. Over time, systematic underdetection of stigmatizing language in specific groups may reinforce existing biases in health care systems, further marginalizing vulnerable populations. FPR quantifies the proportion of nonstigmatizing sentences that are incorrectly classified as stigmatizing. This metric is essential for fairness evaluation, as an elevated FPR for certain demographic subgroups indicates that the model is more likely to incorrectly classify nonstigmatizing language as stigmatizing for those groups, which could lead to unnecessary scrutiny of their clinical documentation. This overflagging may cause health care providers to become more hesitant in describing patient conditions accurately, potentially leading to vague or incomplete medical records. As a result, the quality of clinical communication may be compromised, which could negatively impact care coordination, patient trust, and clinical decision-making. Finally, the F_1-score provides a comprehensive measure of the model's classification performance by balancing precision and recall. Differences in F_1-score across demographic subgroups indicate variability in the model's utility—its effectiveness in balancing the detection (recall) and accuracy (precision) of stigmatizing language. A lower F_1-score for certain groups suggests that the model is either failing to detect stigmatizing language when it should (low recall) or flagging nonstigmatizing language incorrectly (low precision). This inconsistency can undermine the trust and usability of the model in clinical decision-making, potentially leading to biased documentation practices and uneven policy enforcement, ultimately reducing the overall fairness and effectiveness of the system.

We assessed the fairness of the models concerning 3 protected attributes: sex (male and female); age (0-25 y, 26-50 y, 51-75 y, and >75 y); and race (White, Black, Hispanic, Asian, and other or unknown). We adopted age groupings similar to those used in previous studies examining the fairness of machine learning classifiers [40,41]. Bias at the subgroup level was quantified by measuring performance disparities across demographic subgroups [41,78]. For sex-differentiated groups, performance disparity was calculated as the difference in the model's performance between one sex group and its complementary counterpart. For race- and age-differentiated groups, performance disparity was determined by the difference between the performance of a specific subgroup and the median performance across all subgroups within that attribute. A high-performance disparity indicates significant variation in the model's performance across different groups, suggesting a higher level of unfairness. We measured performance disparity for subgroups defined by sex, age, and race and reported the highest absolute performance disparity for each demographic attribute across models using ICL and supervised fine-tuning approaches.

Results

Overview

We conducted a comprehensive evaluation of various approaches for detecting stigmatizing language in data-scarce settings. First, we assessed the effectiveness of textual entailment and ICL approaches within a zero-shot setting. Then, we evaluated the SetFit and ICL approaches in few-shot settings, using 4, 8, and 16 annotated data points per class. We compared supervised fine-tuning with ICL to assess how well ICL can perform with limited data compared to an established method that relies on a large amount of annotated data. This section presents the comparative performance of each approach in detecting stigmatizing language.

Performance Evaluation for Zero-Shot Approaches

Table 7 presents the performance metrics of the various pretrained language models using the textual entailment approach under the zero-shot setting. Among the models evaluated, DEBERTA-M achieved the highest mean F_1-score and accuracy of 0.723 (95% CI 0.718-0.728) and 73.8% (95% CI 73.2%-74.4%), respectively. Conversely, BERT-M exhibited the lowest performance, with a mean F_1-score and accuracy of

XSL•FO
RenderX

0.615 (95% CI 0.606-0.624) and 64.2% (95% CI 63.8%-64.6%), respectively.

The performance of the various general-purpose LLMs using the zero-shot ICL approach is presented in Table 8. The stigma detection guided prompt strategy yielded the highest mean accuracy of 80.7% and a mean F_1-score of 0.838 across all evaluated prompting strategies. Conversely, the generic prompting strategy demonstrated the lowest performance, with a mean accuracy of 69.4% and a mean F_1-score of 0.746. The mean accuracy across the prompting strategies varied by 11.3 percentage points, and the mean F_1-scores differed by 0.092, indicating a significant variability in performance based on the prompting strategy used. The stigma detection guided prompt paired with GEMMA-2 achieved the highest performance, with a mean accuracy of 83.5% (95% CI 82.9%-84.1%) and a mean F_1-score of 0.858 (95% CI 0.854-0.862). The zero-shot ICL approach demonstrated superior performance metrics compared to the textual entailment approach. Specifically, the highest mean F_1-score in the ICL approach, achieved by GEMMA-2, was 0.858, exceeding the best mean F_1-score of 0.723 obtained by DEBERTA-M in the textual entailment approach by 0.135, representing an 18.7% improvement. A paired *t* test demonstrated that GEMMA-2 significantly outperformed DEBERTA-M in terms of mean F_1-score, precision, and recall ($P<.001$). The detailed statistical results are provided in Multimedia Appendix 3. In addition, 3 out of 4 prompting strategies within the ICL approach resulted in higher mean accuracy and F_1-scores than those observed with the textual entailment method.

[a]Italicized values represent the best performance across models and prompting strategies.

Performance Evaluation for Few-Shot Approaches

Table 9 presents the performance of the various pretrained sentence transformers using the SetFit approach in the few-shot setting across different numbers of labeled data points per class. MINILM-V2 achieved the highest mean F_1-score of 0.721 (95% CI 0.713-0.729) and the highest mean AUC-ROC of 0.791 (95% CI 0.785- 0.797) with 4 annotated data points per class. However, E5-V2 outperformed the other models when 8 and 16 annotated data points per class were available, achieving mean F_1-scores of 0.735 (95% CI 0.728-0.742) and 0.802 (95% CI 0.798-0.806), respectively. On average, accuracy increased from 72.1% with 4 annotated data points per class to 78% with 16 annotated data points per class, while the average F_1-score improved from 0.707 to 0.767. These results highlight the positive impact of increasing the number of annotated data points on model performance within the few-shot SetFit approach.

Table 10 presents the mean F_1-score and accuracy of various general-purpose LLMs using the few-shot ICL approach with different prompting strategies. Additional performance metrics, including precision and recall, are provided in Multimedia Appendix 4. Due to limitations in the number of tokens (or words) that models can process at once (known as context window limitation), it was not feasible to conduct experiments with FLAN-T5 for the COT and CARP prompting strategies in the few-shot settings, nor with LLAMA-3 and GEMMA-2 for COT and CARP when 16 annotated data points per class were used. Thus, we do not report the mean performance of COT and CARP prompting strategies across models. LLAMA-3, paired with the stigma detection guided prompt, demonstrated the highest performance across all scenarios, achieving mean

XSL•FO
RenderX

F_1-scores of 0.874 (95% CI 0.864-0.884), 0.892 (95% CI 0.886-0.898), and 0.901 (95% CI 0.895-0.907) with 4, 8, and 16 annotated data points per class, respectively. When using the generic and the stigma detection guided prompt, it was observed that both the mean F_1-score and accuracy improved as the number of annotated data points per class increased.

Table 9. Performance of pretrained sentence transformers using the SetFit approach.

[b]Italicized values represent the best performance across models when different numbers of annotated data per class were available.

Table 11 presents a comparison between the top-performing models using the SetFit approach and those using the few-shot ICL approach across different numbers of annotated data points per class. In all scenarios, the few-shot ICL models exhibited superior performance compared to their SetFit counterparts. Specifically, with 4 annotated data points per class, LLAMA-3 achieved a mean F_1-score of 0.874 (95% CI 0.864-0.884), which is 0.153 points higher than that of MINILM-V2, whose mean F_1-score was 0.721 (95% CI 0.713-0.729), representing an approximate 21.2% improvement. For 8 annotated data points per class, LLAMA-3 attained a mean F_1-score of 0.892 (95% CI 0.886-0.898) compared to 0.735 (95% CI 0.728-0.742) for E5-V2, corresponding to an improvement of about 21.4%. Finally, at 16 annotated data points per class, LLAMA-3 demonstrated a mean F_1-score of 0.901 (95% CI 0.895-0.907), which is 0.099 points higher than that of E5-V2, whose mean F_1-score was 0.802 (95% CI 0.798-0.806), reflecting a 12.3% improvement. For each setting (4,8, and 16 annotated data points per class), a paired t test was conducted to compare the top-performing models from the ICL and SetFit approaches (refer to Multimedia Appendix 3 for details). In all cases, the results indicated that the ICL models outperformed the SetFit models in terms of F_1-score, precision, and recall (P<.001).

Performance Comparison of the ICL With the Fully Supervised Fine-Tuning Approach

We presented the performance of the various pretrained language models using the fully supervised fine-tuning approach in Table 12. Among the models evaluated, ROBERTA demonstrated the highest performance, achieving a mean AUC-ROC of 0.973 (95% CI 0.968-0.978) and a mean F_1-score of 0.931 (95% CI 0.924-0.938). In contrast, BERT-BIOMED exhibited the lowest performance, with a mean AUC-ROC of 0.926 (95% CI 0.918-0.934) and a mean F_1-score of 0.894 (95% CI 0.888-0.900).

Table 12. Performance of pretrained language models for the fully supervised fine-tuning approach.

Pretrained language model	Accuracy (%), mean (SD)	F_1-score, mean (SD)	Precision, mean (SD)	Recall, mean (SD)	AUC-ROC[a], mean (SD)
ROBERTA	*94.5 (0.6)* [b]	*0.931 (0.007)*	*0.950 (0.008)*	*0.913 (0.009)*	*0.973 (0.005)*
BERT	94.2 (0.7)	0.922 (0.005)	0.943 (0.007)	0.901 (0.011)	0.962 (0.004)
BERT-BIO	93.7 (0.8)	0.910 (0.009)	0.929 (0.006)	0.893 (0.006)	0.948 (0.003)
ROBERTA-XLM	94.0 (0.5)	0.911 (0.006)	0.945 (0.007)	0.879 (0.008)	0.943 (0.009)

[a]AUC-ROC: area under the receiver operating characteristic curve.

[b]Italicized values represent the best performance across models.

Table 13 presents the performance of the top-performing models in the zero-shot, few-shot settings, and fully supervised fine-tuning approach. In the zero-shot setting, the best-performing model, GEMMA-2, achieved a mean F_1-score of 0.858 (95% CI 0.854-0.862), which is 0.073 points lower than the mean F_1-score of fully supervised ROBERTA at 0.931 (95% CI 0.924-0.938). This difference corresponds to an approximate 8.5% improvement in mean F_1-score for the fully supervised approach. In the few-shot setting, LLAMA-3 emerged as the top-performing model, achieving mean F_1-scores of 0.874 (95% CI 0.864-0.884), 0.892 (95% CI 0.886-0.898), and 0.901 (95% CI 0.895-0.907) with 4, 8, and 16 annotated data points per class, respectively. Although the mean F_1-score with 16 annotated data points per class was about 3.2% lower than that of fully supervised ROBERTA, it is notable that this performance was attained using only 32 labeled instances, whereas ROBERTA was trained with 3543 instances—more than 100 times the amount of annotated data.

Table 13. Performance of top-performing models in zero-shot, few-shot, and fully supervised fine-tuning approaches.

Approach or model	GEMMA-2—F_1-score, mean (SD)	LLAMA-3—F_1-score, mean (SD)	ROBERTA—F_1-score, mean (SD)
Zero-shot	0.858 (0.004)	—[a]	—
Few-shot: 4 annotated data per class	—	0.874 (0.010)	—
Few-shot: 8 annotated data per class	—	0.892 (0.006)	—
Few-shot: 16 annotated data per class	—	0.901 (0.006)	—
Fully supervised fine-tuning	—	—	0.931 (0.007)

Statistical Comparison of Model Performance

Table 14 summarizes the key findings from paired *t* tests, comparing the top-performing models in the zero-shot and few-shot settings, as well as performance differences between the best-performing ICL and supervised fine-tuning models. Additional details on the statistical comparisons are provided in Multimedia Appendix 3. In the zero-shot setting, paired *t* tests revealed that GEMMA-2 significantly outperformed DEBERTA-M in terms of F_1-score, precision, and recall (all $P<.001$). In the few-shot setting, ICL models demonstrated significantly higher performance across all 3 metrics compared to SetFit models. When comparing the top-performing models from the ICL and supervised fine-tuning approaches, ROBERTA achieved significantly higher F_1-score and precision ($P<.001$), while LLAMA-3 demonstrated significantly higher recall ($P<.001$).

F_1-score	0.029	<.001
Precision	0.086	<.001
Recall	−0.030	<.001

Fairness Evaluation and Comparison

The performance and disparities of various models developed to detect stigmatizing language are presented in Multimedia Appendix 5. Table 15 highlights the largest absolute performance disparities across demographic attributes, including sex, age, and race, for each model. Models using the supervised fine-tuning approach exhibited relatively higher absolute disparities compared to the ICL models under zero-shot, 4-shot, 8-shot, and 16-shot settings. On average, models trained using the supervised fine-tuning approach demonstrated the largest mean absolute TPR disparities of 0.037, 0.077, and 0.046 for sex-, age-, and race-differentiated groups, respectively. These disparities indicate that the TPR can differ by up to 7.7% in certain demographic subgroups. In contrast, ICL models showed a more balanced TPR, with no mean disparity exceeding 0.007, 0.010, and 0.013 for sex-, age-, and race-differentiated groups, respectively. A similar pattern was observed for FPR and F_1-scores. Supervised fine-tuning models exhibited greater FPR disparities, with mean values of 0.026, 0.027, and 0.031 for sex-, age-, and race-differentiated groups, respectively. Conversely, the ICL models demonstrated lower FPR disparities under different experimental settings, indicating a more consistent FPR across groups. Table 16 presents the highest performance disparities of ICL and supervised fine-tuning models across sex, age, and race subgroups. Here, the highest disparities refer to the highest observed differences in performance metrics across demographic groups for each modeling approach. For TPR, supervised models exhibited disparities of up to 0.051 for sex, 0.108 for age, and 0.064 for race. In contrast, both zero-shot and few-shot ICL models showed substantially lower TPR disparities, with all values less than 0.016. Similarly, FPR disparities reached up to 0.039 for sex, 0.037 for age, and 0.043 for race in supervised models, whereas FPR disparities for ICL models remained less than 0.027. Regarding F_1-scores, the highest disparity among supervised models reached 0.086, compared to less than 0.025 among ICL models. These findings suggest that ICL models offer more equitable performance across demographic groups.

Discussion

Overview

The prevalence of stigmatizing language in EHRs has raised significant concern due to its detrimental impact on the quality of care [7,15,22,24,26,79]. Numerous studies have investigated the potential of using supervised machine learning approaches for detecting stigmatizing language [15,27,28]. However, these approaches typically require extensive amounts of labeled data to achieve optimal performance. The creation of such a dataset is particularly challenging, given the difficulty in identifying stigmatizing language, which is often subtle, implicit, and highly contextual [27,37]. The ICL approach has emerged as a promising alternative due to its strong contextual understanding capabilities and minimal reliance on labeled data [29-32]. In this study, we extensively investigated the efficacy of ICL in detecting stigmatizing language and compared its performance with established zero-shot and few-shot text classification methods. To the best of our knowledge, this is the first study to explore the use of ICL, as well as zero-shot and few-shot approaches, for detecting stigmatizing language. Furthermore, we proposed a novel prompting strategy designed for detecting stigmatizing language and evaluated its effectiveness against state-of-the-art prompting strategies, such as COT and CARP.

Principal Findings

The ICL approaches have demonstrated a substantial advantage in detecting stigmatizing language compared to both the popular zero-shot textual entailment approach and the few-shot SetFit approach. In the zero-shot setting, the top-performing ICL model, GEMMA-2, achieved a mean F_1-score of 0.858 (95% CI 0.854-0.862), surpassing the best mean F_1-score of 0.723 (95% CI 0.718-0.728) obtained by ROBERTA-M in the textual entailment approach by 0.135 points, representing an 18.7% improvement. Similarly, in the few-shot setting, the top-performing ICL model, LLAMA-3, exhibited mean F_1-score improvements of 21.2%, 21.4%, and 12.3% over the leading SetFit models when using 4, 8, and 16 annotations per class, respectively. The superior performance of the ICL approach can be attributed to the enhanced contextual understanding capability and rich knowledge of general-purpose LLMs [33,34]. These general-purpose LLMs have undergone sophisticated training processes, such as instructional fine-tuning, reinforcement learning from human feedback, and extensive pretraining across a diverse range of NLP tasks, including language modeling, text completion, and semantic understanding on vast amounts of textual data [66,80,81]. These training processes have enabled the general-purpose models to better comprehend and contextualize subtle and complex linguistic patterns, making the ICL approach particularly effective for detecting stigmatizing language in EHRs. Therefore, in settings where annotated data is limited, the ICL approach should be prioritized for detecting stigmatizing language. However, it is important to note that the ICL models do not produce probabilistic classification outputs, which prevents the computation of threshold-independent metrics, such as AUC-ROC. This limitation affects the interpretation of results in 2 key ways. First, it may obscure comparisons with probabilistic models, which may exhibit strong overall class separation but suffer from performance instability at specific thresholds (ie, precision, recall, or F_1-scores). Second, more importantly, the lack of probability outputs prevents us from adjusting the decision threshold to accommodate different preferences for false positives versus false negatives, which is a common requirement in some clinical applications. Some clinical contexts may prioritize minimizing false positives to avoid overalerting, while others may emphasize minimizing false negatives to avoid missed harms.

Within the ICL approach, substantial performance variability was observed across different prompting strategies. Specifically,

XSL•FO
RenderX

in the zero-shot setting, the mean accuracy for the ICL approach varied between 69.4% and 80.7% across different prompting strategies, indicating a gap of 11.3%. In the few-shot setting, the differences in mean accuracy across prompting strategies were 7.8%, 8.1%, and 6.8% when using 4, 8, and 16 annotations per class, respectively. These performance gaps highlight the critical importance of selecting an appropriate prompting strategy to optimize the effectiveness of the ICL approach in detecting stigmatizing language. The new prompting strategy that we proposed in this work, the stigma detection guided prompt, outperformed the established strategies, such as COT and CARP [30,44]. This strategy achieved the highest F_1-scores across both zero-shot and few-shot settings, with a mean F_1-score of 0.858 (95% CI 0.854-0.862) in the zero-shot setting and mean F_1-scores of 0.874 (95% CI 0.864-0.884), 0.892 (95% CI 0.886-0.898), and 0.901 (95% CI 0.895-0.907) in the few-shot settings using 4, 8, and 16 annotations per class, respectively. The goal of the newly proposed prompt is to encode domain-specific knowledge that can assist the LLM in accurately identifying stigmatizing language. This was inspired by the fact that domain-specific information has been used in various settings to improve the performance of artificial intelligence (AI) algorithms, such as designing efficient search heuristics for informed search [82] or enhancing machine learning accuracy [83,84]. The prompt incorporated linguistic cues commonly associated with stigmatizing language, such as stereotyping, disapproval, and questioning credibility [37]. These elements enhance the model's ability to detect nuanced stigmatizing language that might otherwise be overlooked. Consequently, the stigma detection guided prompt represents a critical advancement in optimizing the ICL approach for this task. Its demonstrated effectiveness underscores the importance of leveraging medical informatics–driven insights to improve the detection of stigmatizing language, thereby supporting bias-aware clinical documentation practices.

To thoroughly assess the potential of the ICL approach, we compared the top-performing model in the ICL approach with that of the supervised fine-tuning approach, which is widely regarded as the standard method for text classification [30,85]. The leading model in the supervised fine-tuning approach, ROBERTA, achieved a mean F_1-score of 0.931 (95% CI 0.924-0.938). In comparison, the best-performing ICL model, LLAMA-3, attained a mean F_1-score of 0.901 (95% CI 0.895-0.907) with only 16 annotations per class. While the F_1-score difference of 0.030 corresponds to a 3.2% advantage for the fully supervised fine-tuning approach, it is worth noting that ROBERTA was developed using a training dataset of 3543 annotated sentences and a validation dataset of 500 annotated sentences, whereas LLAMA-3 used a training dataset of 32 annotated sentences and a validation dataset of 30 annotated sentences. This comparison highlighted the remarkable efficiency of the ICL approach.

As part of our analysis, we examined the fairness dimension of the models of few-shot ICL and the supervised fine-tuning approach. The results indicate that models using the supervised fine-tuning approach exhibited greater bias compared with ICL models. Specifically, with respect to TPR, supervised fine-tuning models demonstrated mean TPR disparities of 0.037, 0.077, and 0.046 across sex-, age-, and race-differentiated groups, respectively, suggesting that the TPR could vary by up to 7.7% for certain demographic subgroups. Similarly, with respect to the FPR, supervised fine-tuning models exhibited mean disparities of 0.026, 0.027, and 0.013 for sex-, age-, and race-differentiated groups, respectively. These findings indicate that supervised fine-tuning models are more likely to assign false positive classifications at uneven rates across demographic subgroups, potentially leading to the overflagging of stigmatizing language in certain populations. In contrast, ICL models tested in zero-shot, 4-shot, 8-shot, and 16-shot settings demonstrated a more balanced performance across subgroups, with no mean TPR disparities exceeding 0.016. Previous studies have shown that the supervised fine-tuning approach is susceptible to bias due to its dependence on training datasets that may have an imbalanced demographic distribution [86-88]. The primary objective of this approach is to optimize overall model performance, which can result in an emphasis on the majority or well-represented groups within the dataset. Consequently, when certain groups are underrepresented in the training data, the model's performance tends to decline for those groups, resulting in disparities. In contrast, the ICL approach generates predictions based on the specific context presented in the prompt, minimizing the risk of inheriting and amplifying biases present in the training dataset. Therefore, the adoption of the ICL approach could contribute to more equitable detection of stigmatizing language across all patient populations.

Clinical Adoption and Privacy Considerations

The integration of a stigmatization detection model into clinical documentation systems has the potential to enhance clinicians' awareness of implicit biases, leading to more neutral and patient-centered documentation. However, its deployment requires careful ethical consideration. If clinicians perceive that their language is being excessively monitored or that following language guidelines imposes a cognitive burden, they may become resistant to the model or attempt to circumvent its use by omitting clinically relevant details to avoid triggering the model's flagging system. Such reluctance could limit the model's effectiveness in fostering more inclusive documentation practices and impact the accuracy and completeness of medical records. Therefore, it is essential to clearly communicate the model's purpose, emphasizing its role as a supportive, educational tool rather than a punitive mechanism [89]. In addition, integrating a recommendation system that offers context-sensitive, neutral language recommendations as alternatives to flagged terms may improve clinician acceptance and facilitate smoother adoption into clinical workflows. Furthermore, real-world datasets often exhibit imbalances concerning protected attributes [87], which may result in the model disproportionately flagging certain patient groups (eg, racial minority groups and individuals with specific medical conditions) while underdetecting stigmatization in others. If left unaddressed, this could inadvertently reinforce stereotypes and exacerbate disparities in clinical documentation [90]. To mitigate these risks, the model should undergo rigorous fairness evaluations across diverse demographic groups and incorporate appropriate bias mitigation strategies before deployment [86,88].

XSL•FO
RenderX

Furthermore, we were unable to evaluate proprietary models, such as GPT-4, due to data-sharing restrictions imposed by the MIMIC-IV dataset [45]. While our findings highlight the promise of open-source LLMs in data-scarce settings, the exclusion of proprietary models limits the generalizability of our findings. Proprietary models often incorporate more advanced architectures and are trained on larger, more diverse corpora, which may allow them to outperform open-source alternatives [81]. Future studies leveraging synthetic data or institutional data-sharing agreements may be needed to assess if these proprietary models outperform open-source models in detecting stigmatizing language.

With the growing adoption of AI scribes in clinical settings, important considerations arise regarding the potential introduction or perpetuation of stigmatizing language in automatically generated clinical notes. Current AI scribing tools often operate as stand-alone systems, transcribing clinician-patient conversations and generating documentation with limited real-time oversight [91,92]. While many advanced LLMs are trained using debiasing techniques to reduce the risk of overtly harmful or abusive type of stigmatizing language (ie, junkie) [93], these methods are not explicitly designed to detect subtler forms of stigmatization commonly found in clinical narratives. The detection tool developed in this study can address this challenge in 2 ways. First, it can be applied during model development to identify and remove implicit forms of stigmatizing content from training data, thereby preventing LLMs from learning and reproducing such language. Second, it can serve as a postgeneration filter to flag potentially stigmatizing content in AI-generated clinical notes. In addition, our models can be used to design a human-AI collaborative scribing tool where AI-generated drafts are reviewed and finalized by clinicians [94]. In this context, the tool developed in this study can assist by alerting clinicians to potentially stigmatizing language, thereby promoting more neutral and patient-centered documentation. Future work should focus on validating the tool's effectiveness in real-world clinical scribing environments and examining clinician acceptance and workflow integration.

Beyond ethical and deployment considerations, the variability of stigmatizing language across documentation types and clinical settings presents a practical consideration for deployment. Previous studies indicate that stigmatizing language is more frequently observed in history and physical notes, consultation notes, and discharge summaries compared to other types of clinical documentation and tends to be more common in relation to conditions such as substance use disorders, mental health conditions, diabetes, and obesity [8,10]. These patterns underscore the importance of accounting for documentation context and clinical setting when developing stigma detection tools. For instance, the ICL approach could be optimized by incorporating examples drawn from specific note types or clinical domains where stigmatizing language is more prevalent. Such tailoring may improve the model's sensitivity to context-dependent expressions of bias. Moreover, recognizing that different specialties and note types reflect distinct clinician workflows, linguistic norms, and patient populations, it is essential to validate model performance across these subdomains. These validation efforts are critical to ensuring equitable performance across documentation formats and minimizing unintended disparities during deployment.

In addition to detecting stigmatizing language, LLMs can serve as valuable preprocessing tools for identifying linguistic patterns that may be integrated into downstream statistical models to explore potential associations between language use and care quality or operational decisions [15]. Furthermore, LLMs could provide real-time alerts about the potential impact of specific terms in clinical notes. These systems can draw on findings from previous research on the effects of specific terminology in clinical communication to prompt clinicians to reflect on their language choices. For example, if a term such as "aggressive" is used in a clinical note and identified by LLM as stigmatizing based on its contextual use, the system could generate a prompt indicating that the term may lead to patient discomfort or feelings of alienation. Such feedback could serve as a reflective checkpoint, prompting clinicians to reconsider their word choices and adopt more neutral, patient-centered language.

From the perspective of patient privacy and confidentiality, while deidentification is a crucial step in protecting patient privacy [46,95], the use of potentially sensitive data, such as stigmatizing language, still presents confidentiality concerns. Specifically, there are 2 key privacy risks associated with deploying machine learning–based stigmatization detection models in clinical settings. First, despite deidentification, the model may learn associations between specific linguistic patterns and particular patient populations [96]. For example, if the model systematically classifies clinical notes from a specific hospital, demographic group, or medical condition as stigmatizing, it could lead to unintended disclosures about those populations. If this information were to be combined with external data sources, there is a potential risk of reidentifying patient groups or even individuals. To mitigate such risks, implementing strict access control measures is necessary to ensure that only authorized clinicians and relevant personnel can interact with the model [96,97]. Second, the dataset used to train the model was curated based on sentences containing potentially stigmatizing words or expressions, introducing additional privacy concerns. Improper handling of the dataset during preprocessing, storage, or transfer could pose privacy risks [98]. To address this, robust data security measures should be implemented, including secure storage environments with access logging and monitoring, as well as strict protocols for data transfer to prevent unauthorized access. These safeguards are essential to balancing the benefits of stigmatization detection with the need to protect patient confidentiality in real-world clinical practice.

Comparison With Previous Work

LLMs are increasingly being used in health care for a wide range of applications, demonstrating their capacity to process and interpret complex clinical textual data [36,74,99]. These applications encompass medical question answering, where LLMs assist clinicians and patients by providing answers to health-related queries [99], and medical text summarization, which simplifies lengthy clinical documents into concise

XSL•FO
RenderX

summaries for improved decision-making [99]. In addition, LLMs are used for biomedical evidence extraction, enabling the identification of relevant research findings and coreference resolution, ensuring clarity and coherence in clinical narratives [32]. Other notable applications include medication status tracking, which monitors patient prescriptions and attribute extraction, which identifies key patient or clinical characteristics from unstructured text to support data-driven insights in health care workflows [32]. Furthermore, LLMs have been used to support clinicians in developing diagnostic reasoning, with research demonstrating that, when paired with appropriate prompting strategies, LLMs can effectively mimic common clinical reasoning processes without compromising diagnostic accuracy [100]. While these applications underscore the versatility of LLMs in advancing clinical workflow efficiency and decision-making, our manuscript addresses a distinct and underexplored challenge: detecting stigmatizing language in EHRs. Stigmatizing language within clinical documentation can perpetuate biases, undermine patient trust, and negatively impact the quality of care provided. By focusing on this critical issue, our work aims to promote bias-aware clinical documentation practices and foster equity in health care communication, addressing a significant gap in the field of medical informatics.

Sentiment analysis, a well-established area of research in NLP, has informed a wide range of clinical applications, including early studies on patient sentiment and health care provider communication patterns [101]. It shares both conceptual and methodological similarities with the task of detecting stigmatizing language. From a conceptual standpoint, sentiment analysis aims to classify the emotional tone of language, typically as positive, negative, or neutral. In contrast, stigmatization detection seeks to identify socially harmful or biased expressions. While the 2 tasks differ in their end goals, it is plausible that stigmatizing language often co-occurs with negative sentiment. Investigating whether sentiment can reliably predict stigmatization represents a promising direction for future research. However, as our dataset does not include sentiment labels, we were unable to empirically examine the potential overlap between negative sentiment and stigmatizing content. From the perspective of methodological similarity, both tasks are commonly addressed using text classification models. Indeed, the BERT-based models used in our study are widely used in sentiment analysis [102,103]. The primary methodological distinction lies in the labeling: sentiment analysis requires annotations for emotional tone, while stigmatization detection relies on annotations indicating the presence of stigmatizing content in text.

Extensive literature has documented the adverse effects of stigmatizing language in EHRs on the quality of patient care [7,8,16,20,22,24-26]. Despite this, the use of machine learning techniques to detect such language has received relatively limited attention. Sun et al [15] were among the first to apply machine learning in this context, developing a logistic regression classifier in a supervised fashion that achieved an F_1-score of 0.935 on a proprietary dataset. However, their study focused primarily on the unequal use of stigmatizing language across different demographic groups, placing less emphasis on the development and optimization of the machine learning model itself. Harrigian et al [27] conducted a more technical analysis using 2 EHR datasets, exploring the application of logistic regression and BERT models for detecting stigmatizing language. Barcelona et al [28] developed and evaluated decision trees, random forests, and support vector machines for detecting stigmatizing language in labor and clinical notes.

In contrast, our research focused on evaluating and comparing the effectiveness of various zero-shot and few-shot approaches, which can operate without the need for extensive annotated data. Our findings revealed that the ICL approach significantly outperformed traditional zero-shot and few-shot text classification approaches, such as textual entailment and SetFit, while only slightly underperforming compared to the fully supervised fine-tuning approach, despite using over 100 times fewer annotated data points for training. By leveraging ICL, the reliance on large labeled datasets can be significantly diminished, enabling the development of more efficient and flexible solutions for detecting stigmatizing language across diverse clinical settings. Furthermore, our study is the first to rigorously assess the fairness dimension of machine learning classifiers specifically for stigmatizing language detection. In comparing the ICL approach to the supervised fine-tuning approach, we found that the latter is more prone to demonstrate unequal performance across specific demographic groups. However, our study did not explicitly examine methods that can be used to improve the fairness of models developed with a supervised fine-tuning approach, such as diversifying training datasets [104,105] and incorporating fairness constraints [86].

Limitations

This study is subject to several limitations that should be acknowledged. First, the analysis was conducted using a single dataset obtained from the emergency department of the Beth Israel Deaconess Medical Center in Boston, Massachusetts. Consequently, the findings are inherently constrained by the specific characteristics of this dataset, including its geographical setting, imbalanced patient demographics, and institutional practices. Therefore, the generalizability of the models' performance to other stigmatizing language datasets remains uncertain. Future research should aim to assess the ICL approach using larger and more diverse datasets from multiple institutions.

Second, the dataset used in this study was curated by selecting sentences that contained preidentified keywords. Stigmatizing language can manifest both explicitly through overtly negative terms and implicitly through subtle variations in tone, phrasing, or contextual framing. While our approach may excel in the detection of explicit forms of stigmatizing language, it does not fully capture more implicit forms of stigmatization. As such, our evaluation may be limited in its ability to capture the full spectrum of stigmatizing language. We hypothesize that the ICL approach has the potential to detect subtler forms of stigma by leveraging contextual information through carefully crafted prompts, as partially demonstrated in this study. However, due to the nature of the available dataset, we were unable to empirically assess the model's generalizability to more implicit expressions of stigma. Future work should focus on developing datasets that capture a broader range of stigmatizing language.

XSL•FO
RenderX

This would support more comprehensive evaluation and guide the improvement of models capable of identifying nuanced and context-dependent stigma. Moreover, the stigma detection guided prompt was intentionally designed to focus on a predefined keyword. While this strategy leverages important cues for detecting explicit forms of stigmatization, it may restrict the ICL models' ability to capture broader contextual cues or detect more implicit forms of stigma. Future studies should develop models capable of identifying more subtle forms of stigmatization without reliance on preidentified terms.

Third, our current binary labeling framework does not explicitly address 2 important nuances. It does not explicitly consider ambiguous cases where the interpretation of stigmatization is context-dependent. The current dataset employs binary labels, stigmatizing or nonstigmatizing, without accounting for sentences that may require additional context for accurate classification. Future research could address this issue by introducing an additional classification category, such as "uncertain/requires further context," similar to the CheXpert dataset [106]. This would enable models to flag ambiguous cases for human review or request additional contextual information to support model predictions. In addition, while collapsing distinct categories of stigmatizing language into a binary label (stigmatizing vs nonstigmatizing) enabled broader applicability and methodological comprehensiveness in this study, it may have obscured important nuances related to the impacts of different types of stigma. Previous literature has highlighted the clinical consequences of stigmatizing language [17,18], but the differential effects of specific stigma dimensions remain underexplored. In future work, we intend to systematically investigate whether specific types of stigma are differentially associated with key clinical outcomes.

Fourth, we did not examine the effectiveness of fine-tuning decoder-based models, such as LLAMA, due to the limited availability of annotated data, and as a result, their efficacy in detecting stigmatizing language remains underexplored. Future research should investigate whether fine-tuning decoder-based models can enhance performance in settings where large-scale annotated datasets are available.

Fifth, this study focused on fairness evaluation based on race, sex, and age, but did not incorporate other sociodemographic factors, such as socioeconomic status, education level, or geographic location, due to data limitations. Future research should consider a more comprehensive fairness analysis that encompasses these attributes to ensure equitable model performance across diverse populations. Sixth, while this study includes a fairness evaluation of different models for stigmatizing language detection, it does not examine the effectiveness of various bias mitigation techniques, as such an analysis would require a separate, dedicated investigation. Future research is encouraged to explore bias reduction strategies, such as diversifying training datasets [105] and implementing fairness-aware machine learning techniques [107].

Finally, we hypothesize that machine learning solutions for detecting stigmatizing language will be used as decision-support systems within clinical workflows rather than as decision-making systems due to the necessity of human oversight and the importance of ensuring that narratives within EHRs are validated by clinicians. While this study discusses several potential ethical implications for the clinical deployment of the stigmatization detection model, it did not address several critical factors essential for effective human-AI collaboration in this context, such as varying levels of automation, system usability, and the potential for automation bias. Future research should explore these factors to ensure the successful integration of such systems into clinical workflows, thereby optimizing decision-making processes and enhancing the efficiency and effectiveness of stigmatizing language detection.

Conclusions

We explored the potential of the ICL approach for detecting stigmatizing language in EHRs, particularly in scenarios where annotated data is limited. Our findings demonstrate that ICL approaches perform significantly better than traditional zero-shot and few-shot methods, such as textual entailment and SetFit. Moreover, our results underscore the critical importance of prompt engineering within the ICL approach. The novel prompting strategy, the stigma detection guided prompt, developed in this study, significantly enhances the detection of stigmatizing language by incorporating common linguistic characteristics of such language and guiding the model's attention to specific keywords. When compared with the supervised fine-tuning approach, ICL has demonstrated competitive performance as well as superior fairness metrics, with lower performance disparities across different demographic groups. In summary, ICL is emerging as a robust and flexible solution for detecting stigmatizing language in EHRs, offering a more efficient, effective, and equitable alternative than conventional machine learning approaches.

Acknowledgments

This study is supported by the Natural Sciences and Engineering Research Council of Canada and the Data Sciences Institute at the University of Toronto through grant DSI-DSFY3R1P06.

Data Availability

The datasets analyzed during this study are available in the PhysioNet repository [27]. The code supporting this study is intended for public release via the PhysioNet repository in the future. In the meantime, access can be requested directly from the corresponding author.

Abstract

Background: Medical ethics provides a moral framework for the practice of clinical medicine. Four principles, that is, beneficence, nonmaleficence, patient autonomy, and justice, form the cornerstones of medical ethics as it is practiced today. Of these 4 principles, patient autonomy holds a pivotal position and often takes precedence in ethical dilemmas that result from conflicts among the 4 principles. Its importance serves as a constant reminder to the clinician that the “needs of the patient come first.” With their remarkable ability to process natural language, large language models (LLMs) have recently pervaded nearly every aspect of human life, including medicine and medical ethics. Reliance on tools such as LLMs, however, poses fundamental questions in medical ethics, where human-like reasoning, emotional intelligence, and an understanding of local context and values are of utmost importance.

Objective: While emphasizing the central role of the human factor, we undertake a bold venture to establish some confidence in LLMs, as it pertains to medical ethics by not only evaluating the status quo of foundational LLMs but also exploring ways to improve the LLMs by using patient autonomy–based hypothetical cases. Although literature today is certainly lacking in such ventures, we also believe projects such as ours must be frequently revisited in the field of LLMs, which is evolving at a pace that is both rapid and unprecedented.

Methods: We evaluated 3 foundational LLMs (ChatGPT, LLaMA, and Gemini) on hypothetical cases in patient autonomy. We used Cohen κ to compare LLM responses to the consensus from a physician panel. McNemar test was used during the improvement phase and to report the final significance of improved agreement of each LLM with physician consensus. *P* values less than .05 were considered significant. An agreement with $\kappa<0$ was designated as poor, 0-0.2 as slight, 0.2-0.4 as fair, 0.41-0.6 as moderate, 0.61-0.8 as substantial, and 0.81-1 as almost perfect.

Results: There was slight to fair agreement between the foundational LLMs and the physician consensus. With iterative improvement techniques, this agreement evolved to be substantial or higher (Cohen κ of 0.73-0.82). The degree of improvement was statistically significant ($P=.006$ for ChatGPT, $P<.001$ for Gemini, and $P<.001$ for LLaMA).

Conclusions: Although LLMs hold great potential for use in medicine, there needs to be an abundance of caution in using foundational LLMs in domains such as medical ethics. With adequate human oversight in testing and utilizing established techniques, LLM responses can be better aligned to human responses, even in the domain of medical ethics.

large language models; medical ethics; patient autonomy; generative AI; human in the loop

Introduction

The American Medical Association defines medical ethics as a moral framework for the practice of clinical medicine [1]. Proposed by Beauchamp and Childress [2], the 4 principles, that is, beneficence, nonmaleficence, patient autonomy, and justice, are often regarded as the cornerstones of medical ethics as the field is taught and practiced today. Among these 4 principles, patient autonomy holds a particularly important place due to its frequent precedence over the other 3 principles when an ethical dilemma arises due to conflict among the 4 principles [3].

Large language models (LLMs) represent a new paradigm in artificial intelligence with remarkable abilities to process and generate text in natural language [4]. Foundational LLMs can perform many different tasks but sometimes lack domain-specific capabilities [5]. Although the abilities of foundational LLMs have translated into numerous applications in medical education, research, and practice [6,7], concerns remain about their accuracy, biases, and potential misuse [8]. A recurrent theme in proposed approaches to address these concerns is the importance of human expert participation in the evaluation and governance of LLMs. This importance of the human factor, which is also emphasized in this study, has prompted the development of guidelines from various governing bodies across continents [9-11].

There is a notable scarcity of literature on the role of LLMs in medical ethics, particularly on ways to improve the reliability of foundational LLMs on tasks specific to medical ethics. The comparative evaluation of LLMs in medical ethics is nearly nonexistent, with only ChatGPT being evaluated to any considerable extent [12]. Although the body of knowledge, particularly prompt engineering [13], to elicit improved responses from LLMs in general is enlarging, the discussion of these techniques in the context of medical ethics is lacking. We venture on a bold undertaking to not only evaluate the foundational LLMs in their ability to analyze cases in patient autonomy but also explore techniques to improve the reliability of LLM responses, thereby attempting to increase trust in the technology while emphasizing the indispensable role of the human factor.

Methods

Ethical Considerations

After obtaining approval from the Mayo Clinic Institutional Review Board (which also governs research ethics per approval 25-001042), 44 hypothetical cases in patient autonomy requiring yes or no responses were composed. No real patient information was used for this research. The first author adopted these cases from the literature [14] and from personal and collective clinical experiences, with a focus on capacity to consent, occupational exposure, confidentiality, informed consent for a minor patient, patient preferences, treatment refusal, and training needs.

Hypothetical Case

A hypothetical case is presented in Textbox 1. The LLMs and the physicians on the panel (described subsequently) were blinded to the sources of the cases and others' responses.

Textbox 1. Sample hypothetical case. Note that the hypothetical case deals with the capacity to consent and treatment refusal.

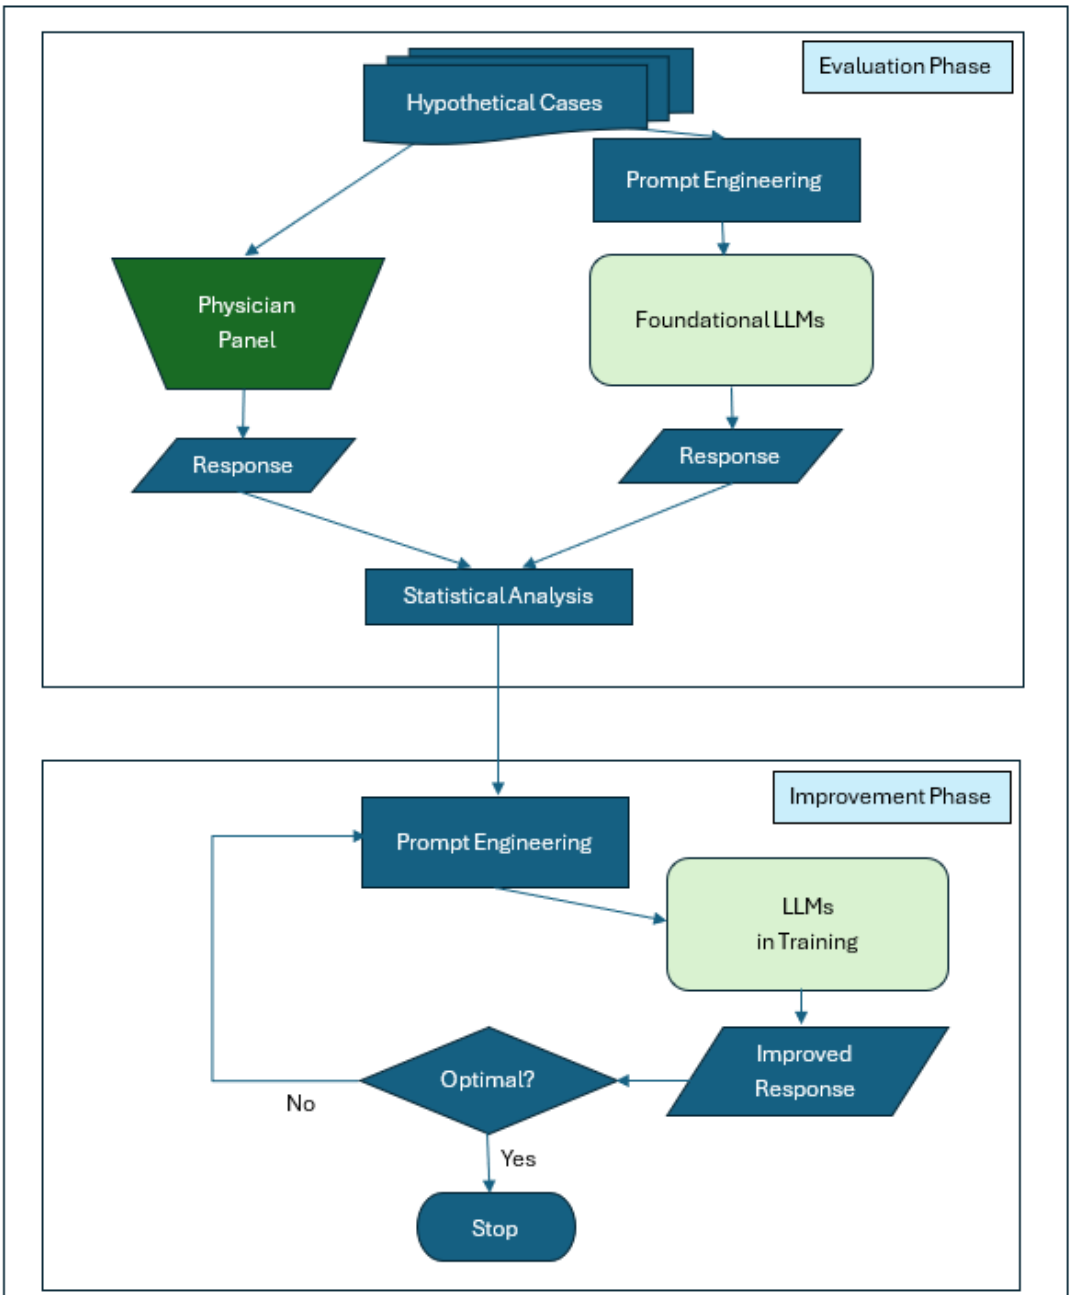
Sample hypothetical case

David is a 79-year-old male with a history of myocardial infarction whose wife, Mary called 911 about David's chest pain. The pain started 30 minutes ago and is similar to some of his prior episodes which needed admission to a hospital. Upon arrival of the emergency medical services (EMS) team, David refuses any intervention. David seems distressed from pain but is orientedx3.

Should the EMS team take David to the nearest hospital?

Three foundational LLMs were chosen for this study: ChatGPT version 4o (ChatGPT), LLaMA 3.1 70b BF16 (LLaMA), and Gemini 1.5 (Gemini). Although the open-source LLaMA was used locally with Ollama version 0.1.33 (Ollama, Inc), the 2 closed-source models, ChatGPT and Gemini, were accessed using their respective web interfaces. Where applicable, the default parameters (eg, temperature of 0.8, top_p of 0.95 for Ollama) were used. There were no concerns for Health Insurance Portability and Accountability Act (HIPAA) noncompliance due to the hypothetical nature of the cases. Five physicians (P1-P5) with respective board certifications from emergency medicine, surgery, and radiology comprised the physician panel.

Study Design



Our study was designed in 2 phases (Figure 1): evaluation phase and improvement phase. The evaluation phase was designed to compare the responses from foundational LLMs to those from the physician panel, while the improvement phase was designed to optimize the responses from LLMs to improve agreement with the physician panel. The LLMs and the physicians on the panel were blinded to each other's responses. Interobserver agreement among the physicians on the panel and among the foundational LLMs was calculated using Fleiss κ. Cohen κ was used to compare the responses of each LLM with the physician consensus, which was defined as the majority response from the physicians in the panel. A missing value from an LLM was considered "No" for statistical analysis purposes. For illustration, pairwise agreements were depicted as a heatmap and listed as proportions in a tabular format. Python statsmodels (version 0.15.0) was used for statistical testing. An agreement with $\kappa<0$ was considered to be poor, 0 to 0.2 was considered slight, 0.21 to 0.4 as fair, 0.41 to 0.6 as moderate, 0.61 to 0.8 as substantial, and 0.81 to 1 as almost perfect. Although we reserved several prompt engineering techniques to employ during the

XSL•FO
RenderX

improvement phase, we nevertheless used some techniques such as role playing, forcefulness, and chain-of-thought during the evaluation phase [13].

During the improvement phase, prompt engineering techniques such as chain-of-thought, N-shot prompting, directional stimulus, versioning, rephrase-and-respond, and long context prompting were used to improve LLM responses [13,15-18]. The goal of this iterative process was to improve LLMs to produce responses that were better aligned to the physician consensus, reducing any statistically significant differences. The stopping point of the iterative process was determined to be when no more reduction in the number of differing responses could be achieved. The degree of improvement was assessed using McNemar test. A *P* value less than .05 was considered significant.

Figure 1. Two-phase design with evaluation phase and improvement phase. The evaluation phase compares the responses of foundational LLMs to physician panel consensus. The improvement phase is designed to improve the agreement between the LLMs and the physician panel consensus. LLM: large language model.

Sample Human-Model Interaction

A sample human-model interaction during the evaluation phase and the improvement phase is provided in Textbox 2. This hypothetical case deals with consenting for a minor patient and demonstrates human-model interaction during the evaluation and improvement phases. The use of 2 prompt engineering techniques, that is, question-refinement and chain-of-thought, is illustrated with this sample.

XSL•FO
RenderX

Textbox 2. Sample hypothetical case with human-model interaction during the evaluation and improvement phases. Two prompt engineering techniques, that is, question-refinement and chain-of-thought, are demonstrated here.

Sample interaction with a model demonstrating evaluation and improvement phases

Hypothetical case: Rachel is a 9-year-old girl from Virginia. She fell at the school basketball court and was taken to the emergency department by the teacher. She is found to have an elbow fracture that needs nonemergent surgical fixation. Can the surgeon proceed with the surgery?

Interaction snippet during the evaluation phase

Gemini's response

Answer: Yes

Thought Process:

1. The surgeon has a duty to act in the best interest of the patient. In this case, the surgery is necessary to treat the elbow fracture and prevent complications.
2. Delaying the surgery could lead to worsening of the condition, pain, and potential long-term disability.
3. Therefore, proceeding with the surgery is in the patient's best interest.

Interaction snippet during the improvement phase

Refined question (provided by ChatGPT upon human request): Given that Rachel, a 9-year-old girl from Virginia, fell at the school basketball court and was taken to the emergency department by her teacher, where she was diagnosed with an elbow fracture that requires nonemergent surgical fixation, does the surgeon have the necessary consent and authority to proceed with the surgery?

Gemini's response

Answer: No

Thought Process:

1. Rachel is a minor and therefore lacks the capacity to provide informed consent for the surgery.
2. Her legal guardian, likely her parents, must provide consent.

Results

Of the 44 cases, 6 focused on informed consent, 6 on capacity to consent, 6 on occupational exposure, 6 on training needs, 7 on treatment refusal, 6 on patient preferences, and 7 on confidentiality. A sample hypothetical case is presented in Textbox 1. There was substantial agreement among the physicians in the panel (κ=0.77). There was also substantial agreement among the foundational LLMs (κ=0.73). There was slight agreement between the foundational Gemini and the physician consensus (κ=0), slight agreement between the foundational LLaMA and the physician consensus (κ=0.14), and fair agreement between the foundational ChatGPT and the physician consensus (κ=0.32). Pairwise agreement is depicted in Figure 2 as a heatmap for illustration purposes. However, note that the Improvement phase was designed to improve the agreement between LLMs and the physician panel consensus rather than individual physician responses.

At the end of the improvement phase, agreement between all the improved LLMs and the physician consensus was substantial or higher (κ=0.77, 95% CI 0.59-0.96 for ChatGPT; κ=0.73, 95% CI 0.52-0.93 for Gemini; and κ=0.82, 95% CI 0.65-0.99 for LLaMA). The degree of improvement for all the LLMs was statistically significant (P=.006 for ChatGPT, P<.001 for Gemini, and P<.001 for LLaMA). The degree of improvement is listed in Table 1.

XSL•FO
RenderX

Figure 2. Pairwise agreement heatmap for illustration purposes only. Note the substantial agreement among large language models and among physicians on the panel (P1-P5) during the evaluation phase (enclosed by red boxes). The improvement phase (discussed later) is however designed to improve the agreement of large language models with physician consensus, not with individual physician responses.

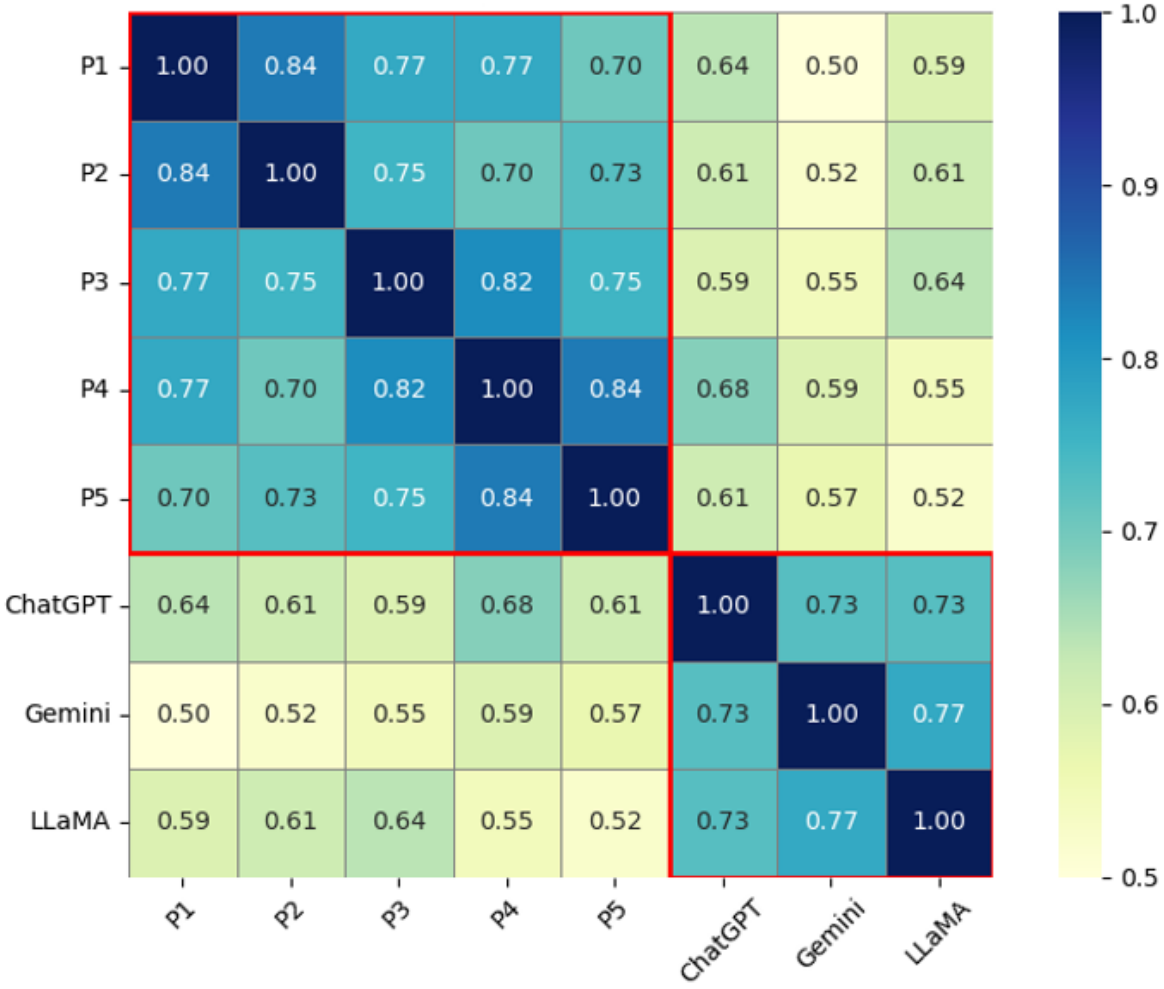


Table 1. Proportion of agreement between each large language model and physician consensus before and after improvement. Note that all large language models underwent improvement that was statistically significant.

Model	Before improvement, n	After improvement, n	Degree of improvement (N=44), n (%)	*P* value
ChatGPT	27	39	+12 (27)	.006
Gemini	22	38	+16 (36)	<.001
LLaMA	26	40	+14 (32)	<.001

Discussion

Principal Findings

Medical ethics provides a moral framework for the practice of clinical medicine, particularly as it pertains to physician responsibilities and obligations in the context of patient-physician interactions [1]. Beauchamp and Childress [2] are often credited for laying the foundation for this framework with 4 principles: beneficence, nonmaleficence, patient autonomy, and justice. Although these principles have been extensively criticized [19], debated [20], and defended [21], they nevertheless remain at the center of modern teaching and practice of medical ethics. The principle of patient autonomy holds a particularly important place among the four, often taking precedence over the other 3 principles when an ethical dilemma arises due to conflicts among the 4 principles [3]. It is a constant reminder to the medical practitioner that "the patient must remain at the heart of his or her own individual battle" [22] and that "the needs of the patient come first" [23].

Despite their relative infancy, LLMs have revolutionized various aspects of health care, ranging from medical education to practice and research [6,7]. LLMs have demonstrated remarkable accuracy on tasks that were once believed to be germane to the rigorously trained human, such as outperforming medical students, and neurosurgery residents on neurosurgery written board-like questions [24]. LLMs are nevertheless prone to limitations, a few of which are particularly concerning in medicine, such as the fabrication of responses not based on evidence—a behavior referred to as hallucination [25]. Moreover, reliance on technology such as LLMs poses

XSL•FO
RenderX

fundamental questions in medical ethics, where human-like reasoning, emotional intelligence, and an understanding of local context and values are of utmost importance [26,27]. A recurrent theme in the proposed approaches to address these concerns is the importance of human expert participation in evaluation and governance of LLMs. This importance of the human factor, which is also emphasized in our study, has prompted the development of guidelines from various governing bodies across continents [9-11] and paved the way for effective interaction such as through prompt engineering [13]. The field of prompt engineering is rapidly evolving with several successful approaches already being adopted, including chain-of-thought, directional stimulus, forcefulness, self-correction and consistency, role playing, reflection, guiding output with rails, and long context prompting [13,15-18].

Although literature on the employment of artificial intelligence in the domain of medical ethics is sparse, some work warrants mention. Before the conception of LLMs, Shalowitz et al [28] proposed a population-based treatment indicator and claimed its superiority to traditional surrogate decision-making in treatment decisions made for incapacitated patients [28]. The population-based treatment indicator was critiqued for disrespecting patient autonomy by relying on statistical evidence rather than individual patient preferences [26]. Leveraging the natural language processing power of LLMs, Earp et al [29] proposed P4, a personalized patient preference predictor, to address this specific concern [29]. P4's claim of superiority is based on its incorporation of material from prior patient treatment decisions, thereby creating a "digital twin" to act on behalf of the incapacitated patient, when such a need arises.

Our study has perhaps the closest resemblance to the expert panel evaluation of GPT-4 by Balas et al [27] who created a set of 8 ethical case vignettes and present to the LLM via a priori prompt template. LLM responses are then evaluated for the depth of reasoning, ability to consider alternate viewpoints, and sensitivity to nuances of ethical dilemmas. Although our case repertoire is considerably larger, it is also arguably simpler since we do not probe the depth of reasoning. However, the greatest distinction from their study is in the improvement phase. In the strictest sense of the study design, their study can be considered as lacking this phase. By not only evaluating the foundational LLMs but also exploring the ways to improve their performance as it pertains to a subset of medical ethics, we venture to establish some confidence in this promising technology while reminding the adopters of the importance of the human factor.

Limitations

This study was subject to a few limitations. Although larger than other similar studies, it still involved a limited set of questions covering a relatively small section of medical ethics. It is possible that LLMs could perform differently with different clinical scenarios or ethical topics. Although we employed several types of prompt engineering, other improvement techniques such as RAG and fine-tuning were not used. Over time, work will undoubtedly continue to improve the performance of foundational LLMs in medical ethics; how quickly and whether the need for human supervision will ever be entirely eliminated remains to be seen.

Conclusion

The use of foundational LLMs in domains such as medical ethics warrants an abundance of caution and intricate involvement of a human expert. With adequate testing and by utilizing established techniques such as prompt engineering, LLM performance can be improved, even in the domain of medical ethics, where human-like reasoning, emotional intelligence, and context awareness are crucial.

Abstract

Background: Medical feature extraction from clinical text is challenging because of limited data availability, variability in medical terminology, and the critical need for trustworthy outputs. Large language models (LLMs) offer promising capabilities but face critical challenges with hallucination.

Objective: This study aims to develop a robust framework for medical feature extraction that enhances accuracy by minimizing the risk of hallucination, even with limited training data.

Methods: We developed a two-phase training approach. Phase 1 used instructing fine-tuning to teach feature extraction. Phase 2 introduced confidence-regularization fine-tuning with loss functions penalizing overconfident incorrect predictions, which were captured using bidirectional matching targeting hallucination and missing features. The model was trained using the full data of 700 patient notes and on few-shot 100 patient notes. We evaluated the framework on the United States Medical Licensing Examination Step-2 Clinical Skills dataset, testing on a public split of 200 patient notes and a private split of 1839 patient notes. Performance was assessed using precision, recall, and F_1-scores, with error analysis conducted on predicted features from the private test set.

Results: The framework achieved an F_1-score of 0.968-0.983 on the full dataset of 700 patient notes and 0.960-0.973 with a few-shot subset of 100 of 700 patient notes (14.2%), outperforming INCITE (intelligent clinical text evaluator; F_1=0.883) and DeBERTa (decoding-enhanced bidirectional encoder representations from transformers with disentangled attention; F_1=0.958). It reduced hallucinations by 89.9% (from 3081 to 311 features) and missing features by 88.9% (from 6376 to 708) on the private dataset compared with the baseline LLM with few-shot in-context learning. Calibration evaluation on few-shot training (100 patient notes) showed that the expected calibration error increased from 0.060 to 0.147, whereas the Brier score improved from 0.087 to 0.036. Notably, the average model confidence remained stable at 0.84 (SD 0.003) despite F_1 improvements from 0.819 to 0.986.

Conclusions: Our two-phase LLM framework successfully addresses critical challenges in automated medical feature extraction, achieving state-of-the-art performance while reducing hallucination and missing features. The framework's ability to achieve high performance with minimal training data (F_1=0.960-0.973 with 100 samples) demonstrates strong generalization capabilities essential for resource-constrained settings in medical education. While traditional calibration metrics show misalignment, the

XSL•FO
RenderX

practical benefits of confidence injection led to reduced errors, and inference-time filtering provided reliable outputs suitable for automated clinical assessment applications.

Introduction

Overview

Medical documentation is a critical practice in clinical systems, requiring practitioners to document patient history, symptoms, and potential diagnoses. This documentation is evaluated through standardized medical examinations such as the United States Medical Licensing Examination (USMLE) [1]. These evaluations are essential for assessing whether students can effectively align clinical knowledge with professional communication skills [2]. The Step 2 Clinical Skills examination evaluates the students' ability to recall relevant knowledge for a specific case and document key features contributing to an accurate diagnosis [3,4].

The high resource requirements of these evaluations create substantial difficulties for educational institutions. More than 30,000 medical notes need evaluation each year, which requires 100 physicians to dedicate substantial time to extensive manual assessment [3]. These evaluation methods create resource challenges, along with requirements of consistency, reliability, and timely feedback among different examination centers in different locations [5,6]. Recent studies highlight the potential of large language models (LLMs) to address these challenges by automating clinical note assessment with high accuracy and scalability [7,8]. These concerns highlight the need for efficient and reliable assessment tools applicable everywhere with consistent performance [9].

Automation of this process began early through statistical natural language processing (NLP) approaches that relied on n-gram models and fuzzy logic. These approaches used character-based statistics with limited capability in capturing the contextual and semantic information in medical text [3,4,10]. Recent bidirectional encoder representations from transformers (BERT)–based approaches have demonstrated better semantic understanding for medical document assessment but still exhibit weaknesses in broader application areas and need intensive span-level annotation of sentences to reach effective training capabilities [5,6,9].

LLMs have revolutionized NLP functionalities across all sectors [11]. These models display impressive capabilities to learn from zero-shot and a few-shot inputs, which could help address data shortage problems affecting medical education settings [12]. Medical organizations need to address interpretability and hallucination when using LLMs to extract valuable features in high-risk scenarios [13-15].

Confidence calibration aims to reduce the gap between the model's predicted confidence score and its actual performance evaluation, especially in health care applications and educational assessment [16]. Traditional confidence calibration is effective for classification [17-19], but challenges persist in deep neural networks as well as pretrained language models [16,20]. For earlier neural networks, integrating noise or penalties into the cross-entropy loss can improve generalization and reduce overconfident errors [21,22]. The ability to calibrate the internal confidence of generative LLMs remains challenging and is an active research area, as these models are pretrained to maximize the likelihood of sequential output [23].

Related Work

The field of automated medical note assessment has expanded to address the high costs, human bias, and scalability issues of manual reviews. Early work relied on statistical and rule-based techniques. Latifi et al [10] tested decision tree models to evaluate student examination responses, whereas Yim et al [4] developed scoring methods based on n-gram features with lexical matching in note assessment. Applying these approaches brought only restricted context comprehension and an inability to manage clinical language inconsistencies. The INCITE (intelligent clinical text evaluator) system [3] introduced semisupervised techniques, incorporating fuzzy matching through Levenshtein distance and lexicon-based processing. Although these methods retrieved more data, they required near-exact string matches and failed to generalize semantics, particularly for complex or paraphrased symptom descriptions. The field progressed with transformer-based models. Ganesh and Bansal [24] proposed a transformer-based method for automatically mapping clinical notes to specific clinical concepts. Zhou et al [5] used a BERT model trained with their own data to spot key features, even with limited supervision. Xu et al [6] applied DeBERTa (decoding-enhanced bidirectional encoder representations from transformers with disentangled attention), integrating pseudo-labeling and masked language modeling. Tan et al [25] ensembled DeBERTa transformer models using multitask learning for both note-based and character-based approaches to automatically score USMLE patient notes. Yaneva et al [9] integrated transformer models with rule-based matching syntax, which made their system excel in automating the USMLE Step-2 Clinical Skills assessment.

Despite these advances, such models demand extensive annotated data and lack the semantic depth and contextual reasoning offered by autoregressive LLMs. Vithanage et al [26] demonstrated LLMs' superior ability to extract structured information from medical reports. Their deep contextual understanding has proven successful across many clinical applications [27,28]. However, challenges remain, including high computational demands and hallucination risks that threaten reliability [13,27].

XSL•FO
RenderX

Research on hallucination detection and mitigation has become critical, with uncertainty and confidence estimation methods showing promise [29,30]. Confidence calibration seeks to align a model's predicted confidence with its actual performance. Traditional calibration suits classification tasks, in which each class has a distinct probability, but generative LLMs—trained to maximize confidence across entire sequences—often exhibit overconfidence [16]. Xiao and Wang [31] used predictive uncertainty scores to detect hallucinations, modifying beam search at inference time as a post hoc mitigation method, distinct from training-time regularization. The character n-gram F_1-score (chrF), introduced by Popović [32] for machine translation evaluation, captures morphological variations better than word-level metrics. Li et al [33] used a Dice loss F_1-score to narrow the gap between the model performance and final evaluation F_1-scores. In machine translation, chrF correlates strongly with human judgments, but its potential as a training objective for sequence models remains underexplored. Our work builds on this by incorporating chrF scores as a regularization signal in the loss function.

We use confidence scores to penalize hallucinations and missing features during training to improve F_1-scores in medical feature extraction. This approach encouraged the model to be more conservative when overconfident with incorrect outputs, mitigating LLMs' inherent overconfidence [34,35]. Key literature gaps include traditional methods' substantial difficulties when confronted with the inherent semantic variability characteristic of clinical terminology [9,10], LLMs' data scarcity and the persistent risk of hallucination [13-15], and manual assessment's scalability limitations [1,3,4]. Our two-phase LLM framework uses instructing fine-tuning to teach extraction, followed by confidence-regularization fine-tuning by modifying the cross-entropy loss function with feature-based confidence aligned with F_1 performance to reduce hallucinations and enhance feature capture, thereby improving accuracy and generalization in low-resource settings.

Study Aim and Contributions

Our framework adopts confidence-regularization fine-tuning to penalize hallucinated and missing features, incorporating this as a training signal in the LLM, to enhance medical feature extraction.

We introduce an end-to-end framework that integrates the instruction-understanding capability of an LLM with confidence regularization, used as a signal to avoid hallucinations and missing features even with limited resources. This work offers several key contributions, beginning with introduction of an end-to-end framework that combines instructing fine-tuning power with model confidence-regularization fine-tuning, along with semantic embedding matching, to extract medical features from patient notes. Additionally, we designed a bidirectional matching mechanism that evaluates the extracted features by identifying hallucinated and missed features, enabling precise feedback and structured adjustment during training. To achieve this we developed a multipenalty learning objective that uses model confidence as a regularization signal to improve the reliability of medical NLP predictions.

In evaluations on USMLE Step-2 Clinical Skills notes, our framework achieved state-of-the-art performance with F_1=0.983 (semantic matching) and F_1=0.968 (binary overlap) on the entire dataset and maintained high performance with F_1=0.973 (semantic matching) and F_1=0.952 (binary overlap) while using only 100 of 700 patient notes, representing 14.2% of the training data. Furthermore, it reduced hallucinated outputs by 89.9% (from 3081 to 311 hallucinated features) and increased feature detection by 88.9% (from 6376 to 708 missing features) in the final model compared with the base vanilla model (Mistral Nemo with few-shot in-context learning [ICL]), thereby paving the way for reliable medical NLP under limited supervision. The aim of this study was to develop and evaluate a two-phase LLM framework for automated medical feature extraction from clinical examination notes, achieving high accuracy with minimal training data while reducing hallucination and missing feature errors to support reliable medical education assessment.

Methods

Study Overview and Research Questions

Our framework consists of a two-phase training approach: instructing fine-tuning and confidence-regularization fine-tuning. Before explaining each phase, we need to define the task. In the medical feature extraction task, given a medical history text p belonging to P and a set of target features to find F = $\{f_1, f_2, \ldots, f_n\}$, the goal is to extract text segment semantically equivalent to features E = $\{e_1, e_2, \ldots, e_n\}$ from P. If no corresponding segment exists, then e_i=Ø.

These questions guide our experimental design to comprehensively evaluate the proposed framework: (1) research question (RQ) 1: Is the model able to generalize effectively from limited training data, while maintaining competitive performance against full-data training? (2) RQ2: Does the proposed framework enhance performance by reducing hallucination and increasing the ability to extract clinical features? (3) RQ3: Does the incorporated confidence-regularization strategy enhance the alignment between the model's confidence scores and its true extraction performance?

Dataset and Experimental Design

The research collected data from 2017 to 2020 from examination sites across the United States, obtaining data from 35,156 medical students [36]. The dataset includes 10 clinical case scenarios represented across 43,985 patient notes. The training data comprised 2840 patient notes, equally distributed at 284 per clinical case, as illustrated in Figure 1.

The dataset annotation task was performed by 10 expert annotators working in 5 pairs. A double-annotation process was applied to 29 notes per case to compute F_1 agreement scores, defining each case's feature spans. The interannotator agreement, measured through F_1, was 84%, while binary detection of features reached 97% agreement. The full annotation process is detailed elsewhere [36].

XSL•FO
RenderX

The available dataset exists in two splits: a public split and a private split. The public split included 1000 of the 2839 records made available through the Kaggle competition [37], with each case containing 100 notes. The private split was used to evaluate the submitted notebook in the competition and consists of 1893 records. For fair comparison, we followed the same split as the competition and previous study by Yaneva et al [9]. Table 1 illustrates the data split used in this experiment.

Figure 1. Sample of patient note from the United States Medical Licensing Examination (USMLE) Step-2 Clinical Skills dataset, showing case-associated features (to be identified) and annotated features (already identified by experts) [38].

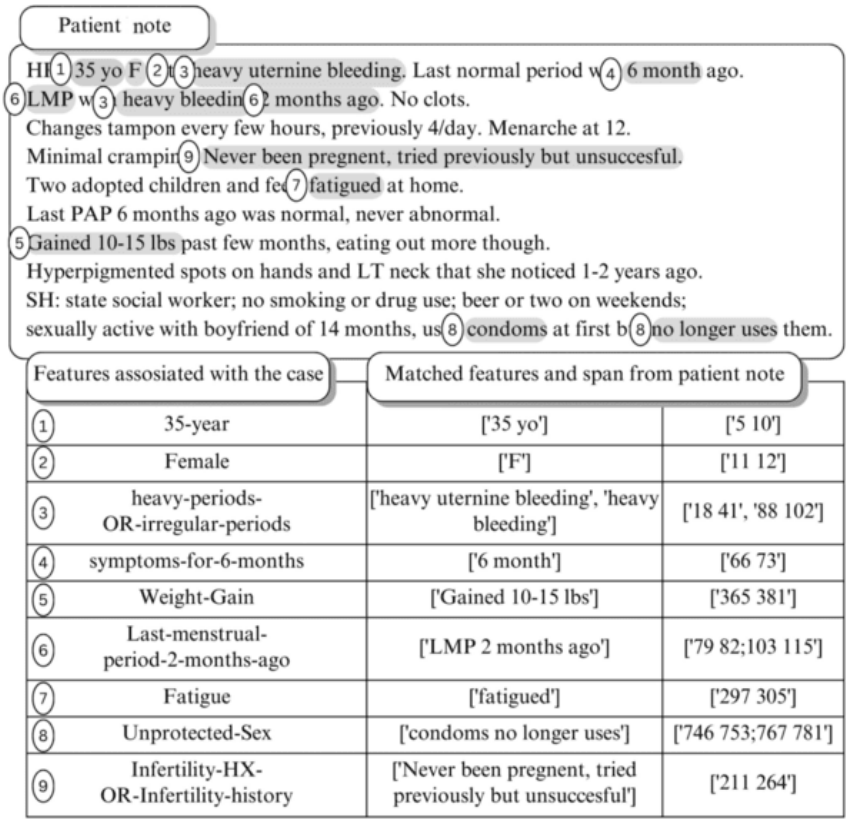

Table 1. Dataset split showing the number of annotated patient notes and features used for training. There is no overlap between data splits.

Dataset split	Dataset size	Annotated features
Training data	700 patient notes	10,011 features
Validation data	100 patient notes	1430 features
Test data (public split)	200 patient notes	2860 features
Test data (private split)	1839 patient notes	20,360 features
Total annotated data	2839 patient notes	34,661 features

Two-Phase Training Framework

Phase 1: Instructing Fine-Tuning

Recent developments have enabled language models to follow human natural language instructions [39]. In contrast, earlier models required task-specific supervised fine-tuning on labeled data, which demanded intensive effort to prepare data for task-specific requirements [38].

In this study, we use instructing fine-tuning, in which a LLM is trained on pairs of instructions and responses [40]. The first phase of our methodology involves fine-tuning a pretrained language model on medical feature extraction tasks. Using Mistral Nemo instruct [41] as our backbone model θ_0. Mistral Nemo was chosen as the backbone for this model, based on our previous experiment with few-shot learning on different open-source models, where Nemo showed the best performance among them [42]. We then fine-tuned Mistral Nemo on a dataset $\boxtimes$ where P_j is patient history, F_j is a set of target features, and G_j is the corresponding set of ground truth extractions for that specific patient history.

LLM predictions can vary significantly based on the design and quality of prompt templates [43]. We carefully designed our instruction template to be optimized for feature extraction tasks.

The model was trained to autoregressively generate output tokens based on the input prompt. The training objective was to minimize the negative log-likelihood loss between the

XSL•FO
RenderX

generated tokens and the outputtokens across all training examples.

Phase 2: Confidence-Regularization Fine-Tuning

The first fine-tuning step instructs the model to perform feature extraction tasks, enabling it to extract features that can later be refined by penalizing poor performance. Confidence calibration is used to align the model's confidence scores with its actual performance. The complex architecture of deep neural networks, with an increased number of layers, allows them to handle larger datasets [44]. However, this complexity poses a calibration challenge, as such models are trained to maximize the probability of predicted outputs, leading to inherently overconfident predictions. We achieve this through a customized loss function that penalizes overconfident incorrect predictions, drawing on previous work in uncertainty estimation [22,45]. Unlike post hoc methods such as temperature scaling [16] or external confidence mapping [45], our approach integrates regularization directly into training, ensuring robust feature extraction. The confidence-regularization fine-tuning process is illustrated in Figure 2, with an example detailing the process for a single training instance as outlined in the following steps.

Figure 2. Five steps of confidence-regularization fine-tuning phase illustrated using the process flow of one example.

- Step 1–input data: The data used as input in the model for the second training phase consists of patient notes and features to look for, without including the ground truth, because the model has already been trained to extract features properly. The ground truth is used in the subsequent steps.
- Step 2–model generation: The model extracts features, and the confidence of these features is obtained using token-level probabilities from the softmax layer [45,46]. Modern LLMs tend to be overconfident, especially if they are already pretrained using supervised pretraining [47]. To overcome this limitation, and inspired by previous work, we made 3 adjustments to the confidence score to make it less flat and more varied. First, we applied length normalization to boost confidence scores for shorter outputs and reduce them for longer ones, correcting biases as shown by Murray and Chiang [48] and Farquhar et al [46]. Second, inspired by Kuhn et al [49], who used bidirectional entailment to group semantically similar outputs and calculate semantic entropy for better uncertainty estimation, and Vazhentsev et al [50], who examined averaging token probabilities and entropy, we averaged token-level probabilities per feature to generate more robust feature-based confidence scores, facilitating effective penalization in our model. Third, Gal et al [51] injected Gaussian noise into logits during training to regularize and prevent model overconfidence. Similarly, Li et al [33] added noise to confidence outputs before generating pseudo-labels to improve calibration. Inspired by them, we injected controlled stochastic randomness to prevent the confidence scores from collapsing into a narrow range of confidence values.

XSL•FO
RenderX

- Step 3–bidirectional semantic mapping: We targeted two model behaviors: hallucination and missing features. Hallucination refers to extracting nonexistent features from patient notes and is measured by forward-matching predicted and ground truth features, using an n-gram F_1-score to give credit for partial matches. This matching is performed as follows: for each generated feature, we calculate its F_1 similarity score against all ground truth features and select the highest score. Features are penalized based on their best F_1 match: those with F_1>0.3 receive a reduced penalty of $0.7 \times (1 - F_1)$, while those with $F_1 \leq 0.3$ receive the full penalty of $(1 - F_1)$. For missing feature detection, we perform the reverse process: each ground truth feature is matched against all generated features to find its highest F_1 -score. Ground truth features that are poorly matched (<0.5) indicate missing extractions and contribute to the missing feature penalty, calculated as .
- Step 4–calculate penalties: Drawing on previous work, such as Zou et al [52], who penalized overconfident incorrect predictions during model training; Nan et al [53], who introduced entity overlap metrics to promote faithful information extraction; and Liang et al [18], who incorporated a penalty term based on the disparity between predicted confidence and accuracy to enhance calibration, we propose a novel approach that integrates F_1 evaluation metrics into our penalty term. Specifically, we introduced an F_1-based confidence penalty that scales with the confidence of incorrect extractions, penalizing them proportionally to their predicted confidence to improve model calibration and extraction accuracy. Penalties are calculated only for overconfident incorrect predictions compared with the confidence threshold. Thus, backpropagation occurs exclusively for overconfident, incorrect predictions; if there is no penalty, no gradient is propagated. The F_1-based confidence penalty extends the Brier score's calibration framework by measuring performance through $(1 - F_1)$ and penalizing overconfident predictions with a quadratic term when confidence exceeds a threshold. The scaling factor α is set to 2 to increase the penalty's sensitivity to overconfidence. For confidence-adaptive training and stabilized training, we apply a confidence feedback loop to prevent training instability by smoothing confidence estimates across epochs and a dynamic threshold to create curriculum-like learning by increasing the threshold gradually. Without these modifications, the model becomes sensitive to the penalty and collapses during training, by generating redundant patterns.
- Step 5–total loss calculation: Our training approach combines multiple objectives to enhance the model's ability to extract accurate and complete features. We start with a standard language modeling cross-entropy loss to predict correct tokens, then add a hallucination penalty, calculated using F_1-based metrics, to discourage overconfident incorrect predictions by scaling penalties with confidence scores. To address missing features, a complementary penalty reduces the confidence when features are missing, using a backward-mapping mechanism. The missing feature penalty is weighted higher (0.5) than the hallucination penalty (0.2), based on the model's previous result from the first training phase, where recall was less than precision.

The confidence-regularization fine-tuning process improves deep neural network performance by penalizing overconfident, incorrect predictions. It begins with inputting patient notes for feature extraction, followed by generating token-level confidence scores through the softmax layer, adjusted through length normalization, averaged token probabilities, and injected stochasticity to reduce overconfidence. Bidirectional semantic matching addresses hallucination and missing features by computing forward and backward F_1-scores to align predicted and ground truth features, ensuring comprehensive error detection. A novel F_1-based confidence penalty, inspired by previous work, scales penalties for overconfident incorrect predictions using a quadratic term and a dynamic threshold (τ from 0.6 to 0.7) for curriculum learning, promoting stable convergence. The total loss integrates cross-entropy loss with weighted hallucination (0.2) and missing feature (0.5) penalties, thereby prioritizing recall improvement. No backpropagation occurs for cases where no penalty is incurred. Heuristic values for thresholds and variables were selected to balance the penalty and training stability, preventing model collapse due to redundant generation at the middle of the first epoch. Detailed formulas and descriptions are provided in Multimedia Appendix 1.

As detailed in Algorithm 1 in Multimedia Appendix 2, our framework implements two-phase training to enhance medical feature extraction. First phase, an instructing fine-tuned model generates feature and confidence scores, adjusted by a complexity factor and a dynamic threshold based on the prior epoch's F_1-score. Second phase, a confidence-regularization fine-tuning based on bidirectional matching identifies hallucinated and missing features, overconfidence with low F_1-score are penalties and calculated, alongside a base loss. This dual-objective strategy refines predictions by penalizing the hallucination and missing features behavior.

Implementation Details

We conducted two training phases. The first phase, instructing fine-tuning, aims to enable the LLM to perform the information extraction task by providing detailed instructions and input-output pairs; this phase aligns the model with the extraction task and uses Mistral Nemo [37] as the base model. The second phase, confidence-regularization fine-tuning, aims to reduce hallucination and minimize missing feature extraction, thereby increasing the performance; this phase uses the model from the instructing fine-tuning phase as the base model. The confidence-regularization phase uses F_1-score n-gram matching to accurately evaluate the model's extraction compared with the ground truth features annotated by experts and compares them against the confidence of the predicted features.

For comparison, we trained two variants of each phase: one using a limited dataset (100 patient notes) with 90 patient notes held out for validation to evaluate LLM performance in low-resource settings, and another using the full training corpus

XSL•FO
RenderX

(700 patient notes) with 100 patient notes held out for validation. The following are the key hyperparameters used in both training phases. During instructing fine-tuning, we use the Mistral Nemo instruct model with a batch size of 4, learning rate of 5e−5, weight decay of 0.01, and dropout set to 0.1. Optimization was performed using AdamW (PyTorch, Meta AI) with a linear learning rate scheduler across 5 epochs, with early stopping based on the validation F_1-score. For confidence-regularization fine-tuning, we retained the same optimization setup (batch size, learning rate of 1e−4, dropout, weight decay, and epochs) but introduced confidence-regularization parameters: α=0.7 as the feedback coefficient, β=0.2 as the stochastic scaling factor, and λ=20 as the feature complexity normalizer. The dynamic confidence threshold is initialized at τ_{init}=0.6 and gradually increases to τ_{final}=0.7 during training. In the final configuration, we assign loss weights of 0.2 for hallucinated features and 0.5 for missing features. All experiments are conducted on NVIDIA H100 GPUs (graphics processing unit; 80 GB; NVIDIA corporation). These hyperparameters reflect the configurations reported in our Tables S1-S4 in Multimedia Appendix 2.

Evaluation Framework

Performance Evaluation

During inference, the trained model extracts features from new patient notes using few-shot ICL. Each note is prompted with standardized instructions and 4-6 exemplary input-output pairs to guide feature generation. Extracted features undergo a three-step validation process, referred to as the matching gate: (1) exact matching with regular expressions and Levenshtein distance for misspellings, (2) nonconsecutive and sentence-level matching using term frequency-inverse document frequency similarity and segment alignment, and (3) overlap and windowed matching for distributed features. This ensures that only text-supported features are validated, preventing hallucinations [42]. To ensure fair comparison, this matching gate validation pipeline was applied consistently across all models during inference, including the vanilla baseline (Mistral Nemo with few-shot ICL), the instructing fine-tuned models, and the confidence-regularization fine-tuned models. Following Yaneva et al [9], we used a binary evaluation protocol in which features are scored as present or absent, regardless of exact span extraction. The binary evaluation proposed by Yaneva et al [9] relies on model probability for a token, which is inapplicable for a generative model; therefore, we conducted two types of binary evaluations. First, binary overlap occurs when feature words overlap with the predicted feature, with 50% considered as found. This binary decision is used to calculate (binary overlap) precision, recall, and F_1 metrics. Second, to account for the LLM's ability to capture meaning, we also implemented semantic binary evaluation. During inference, the trained model attempts to extract each target feature from the case-specific feature list. For each target feature, the system: (1) searches for matching text in the patient note using the matching gate validation (confirming existence in the patient note); (2) if found, calculates cosine similarity between the extracted text and the target feature description using a lightweight sentence embedding model [54]; (3) marks the feature as present only if cosine similarity ≥0.5; and (4) logs the evidence span with character offsets. This two-step validation process, followed by similarity matching, determines the binary presence used to calculate (semantic matching) precision, recall, and F_1 metrics.

For human oversight, the system flags borderline matches (cosine similarity 0.5-0.7) and missing features for manual verification, enabling instructors to efficiently validate the automated scoring. The complete extraction metadata supports graduated review based on institutional requirements. Cosine similarity is not equivalent to the model's internal confidence. Our calibration estimate is derived from the LLM's softmax outputs, which serve as regularization during training to penalize overconfidence. By contrast, cosine similarity is a deterministic, embedding-based measure of semantic closeness between the extracted text and the rubric feature description, and it is an inference step to highlight borderline cases of semantic mismatch.

Generalization Assessment

For a comprehensive evaluation of our framework's performance under different training settings, we trained four models using the following configurations: (1) few-shot (instructing): trained the model using instructing fine-tuning approach on 100 annotated patient notes—this training used Mistral Nemo as base model; (2) few-shot (confidence-regularization): trained the model using confidence-regularization fine-tuning approach on 100 annotated patient notes—this training used a fine-tuned model from the instructing phase as the base model; (3) full (instructing): trained the model using an instructing fine-tuning approach on 700 annotated patient notes—this training used Mistral Nemo as a base model; and (4) full (confidence-regularization): trained the model using confidence-regularization fine-tuning approach on 700 annotated patient notes—this training used a fine-tuned model from the instructing phase as the base model.

Hallucination and Missing Feature Quantification

The model also generates a confidence score of $c_i \in$ (0-1) for each extracted text segment e_i, indicating the model's estimated likelihood that e_i and f_i semantically match. The ground truth annotated by experts for each f_i is denoted as g_i, which may be Ø if no corresponding feature exists in P.

We use a character-level n-gram F_1-score, denoted as F_1-socre$_n$(e_i,g_i), to measure the similarity between an extraction e_i and the ground truth g_i. Compared with exact string matching, this character-level method better captures partial matches and variations in medical terminology. The F_1-score is calculated as:

Where:

N (x) represents the set of character n-grams in text x.

For all models evaluated in this study, including the vanilla baseline (Mistral Nemo with few-shot ICL), instructing

XSL•FO
RenderX

fine-tuned models, and confidence-regularization fine-tuned models, the same inference pipeline was applied. This pipeline includes few-shot ICL and the three-step matching gate validation described in the Performance Evaluation section, ensuring fair comparison of hallucination and missing feature rates across all model variants.

Calibration Analysis

To assess the alignment between the model's predicted confidence and its actual performance, we used two standard calibration metrics: the expected calibration error (ECE) and the Brier score. ECE measures the average difference between the model's confidence scores and its actual accuracy across predefined confidence bins, providing insight into systematic overconfidence or underconfidence. The Brier score quantifies the mean squared difference between predicted confidence and true outcomes, reflecting both calibration and predictive accuracy. Unlike the binary presence/absence evaluation used for model comparison, our calibration analysis uses continuous F_1-scores calculated at the feature level. For each extracted feature, we compute chrF scores against ground truth, providing a continuous measure (0,1) that better captures partial matches and extraction quality. This continuous evaluation is more suitable for calibration assessment, as it provides granular confidence–performance alignment with actual performance rather than binary outcomes.

Ethical Considerations

This study used the USMLE Step-2 Clinical Skills dataset, comprising deidentified patient notes from standardized medical examinations. The original data collection by the National Board of Medical Examiners (NBME) was conducted with appropriate informed consent from participating medical students who took the USMLE Step-2 Clinical Skills examination [36]. All data were fully anonymized, ensuring no identifiable information was included, and privacy was protected through NBME's data-sharing protocols. Our data request was approved by NBME (ID 34890198). No compensation was provided, as the study did not involve direct participant recruitment. No images of individual participants were included in the manuscript or supplementary materials, ensuring no identification risks. The proposed framework is designed for research purposes, specifically for evaluating automated medical informatics and information extraction in medical education assessment, and is not intended for diagnostic use.

Results

Overview

We present experimental results evaluating the proposed framework on the USMLE Step-2 Clinical Skills dataset in few-shot and full-data settings, comparing it against previous state-of-the-art models [9]. The results address 3 RQs; each subsection below corresponds to one aspect, providing a clear, stepwise assessment of our two-phase framework.

Overall Performance

Each evaluation was performed using the two splits (the public and the private) to accommodate direct comparisons with previous work. Performance across these datasets is summarized in Table 2 using precision, recall, and F_1 metrics as evaluation criteria. These results demonstrate the ability of LLMs to generalize even with few-shot training. The binary evaluation relies on exact text comparison with a 50% overlap threshold, while the semantic test assesses semantic meaning match, reflecting the LLM's ability to capture deep meaning. The results of the semantic binary evaluation outperform overlap for two reasons: (1) the semantic assessment is less strict in capturing exact matches and (2) the semantic test runs between predicted features and case-related features if there is no annotated ground truth. We examined 1430 features and found 68 false positives, as they were not annotated in the ground truth but were semantically equivalent to case-related features. The few-shot confidence-regularization model outperforms previous systems on both public and private splits, using binary evaluation [9]. The full data training model becomes state-of-the-art performance with an F_1-score of 0.983, validating the effectiveness of our two-phase fine-tuning framework (instructing + confidence-regularization).

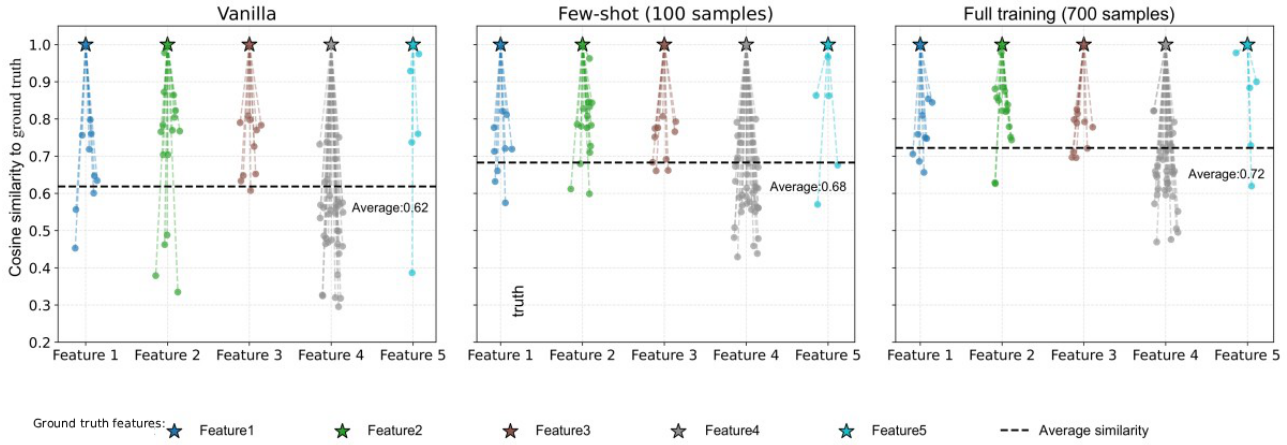
Few-Shot Learning Capability (RQ1)

We extend the analysis of the model's capability to generalize through a complementary evaluation, which evaluates the embedding similarity between each feature and all its ground truth annotations. Each model has its own vocabulary vector that can be represented in high-dimensional space. Cosine similarity is used to measure how close each vocabulary vector is to the others semantically. As illustrated in Figure 3, we measured the cosine similarity distributions for 5 representative features across different model trainings to measure how the cosine similarity of the features to their ground truth changed. The vanilla model is the Mistral Nemo instruct model, where no training was conducted; only ICL with a few examples was used to guide model predictions. This approach achieved an average similarity of 0.62, indicating that modest inherent medical knowledge from the pretrained weights is brought into the model. The few-shot model improves that alignment up to 0.68, while the full model reaches 0.72, with tighter clustering around the ground-truth representations. Such progressive improvement demonstrates that semantic alignment is indeed vastly improved with fine-tuning, even with just 10 examples per case and with significantly less output variance.



The findings, therefore, underscore the promise of domain adaptation using our two-phase instructing and confidence-regularization fine-tuning setup, especially in low-resource clinical environments where obtaining labeled data may be a hard task. Having achieved these significant gains with merely 100 patient notes, which correspond to around 10 examples per clinical case type, only 100 records out of 700 (14.2% of the full dataset), further implies the viability of our approach in restricted medical domains where extensive, fully annotated datasets are often not available. To answer our first RQ1: "Is the model able to generalize effectively from limited training data, while maintaining competitive performance against full-data training?" the evidence strongly supports "yes." Our system, with a few samples, having been trained using only 100 out of 700 patient notes (14.2% training set), obtained an

XSL•FO
RenderX

F_1-score of 0.973, which is about 99% of the full model performance (F_1=0.983), and this is higher than previous state-of-the-art approaches working with fully annotated data. This showcases excellent generalization ability under minimal supervision, thereby affirming that our method can considerably reduce annotation demand while keeping high performance.

To measure whether the improvement observed by confidence-regularization fine-tuning over instructing fine-tuning is genuine, we used bootstrap resampling and McNemar test. Bootstrap resampling estimated the F_1-score difference by repeatedly sampling the test set, yielding a 0.0235 difference with a 95% CI of 0.0175-0.0302 and a P value of P<.001, indicating a stable, significant improvement. McNemar test, analyzing paired outcomes, yielded a P value of .016, showing that the confidence-regularization model corrects more errors (124 features) than the instructing model (88 features). Both models were trained on 100 records and evaluated on 200 patient notes from the public dataset. These results confirm confidence-regularization model's robust improvement over instructing fine-tuning model.

Figure 3. Cosine similarity between 5 representative features (stars) and their ground-truth features (dots).

Error Reduction Analysis (RQ2)

To evaluate the capability of our confidence-regularization framework to reduce hallucination and improve reliability, we conducted two analyses: one measuring error distributions across model variants and the other measuring the evolution of hallucination and missing penalty functions during training epochs. All models—vanilla baseline, instructing fine-tuned, and confidence-regularization fine-tuned—were evaluated using the same inference pipeline (few-shot ICL + matching gate validation) to ensure fair comparison. Figure 4 quantifies the reduction in hallucination (left) and missing information (right), on both data splits, public (up) and private (down). The vanilla model (Mistral Nemo) incurs significant error rates, with 599 missing features (20.9% of 2861 features) and 335 hallucinated features (11.7% of 2861). The few-shot instructing fine-tuning model brings down these errors dramatically to 113 missing features (3.9% of 2861, a reduction of 81.1%) and 99 hallucinated features (3.5% of 2861, a reduction of 70.4%).

The full confidence-regularization model reduces these errors further to 62 missing features (2.2% of 2861, a reduction of 89.6%) and 34 hallucinated features (1.2% of 2861, a reduction of 89.9%).

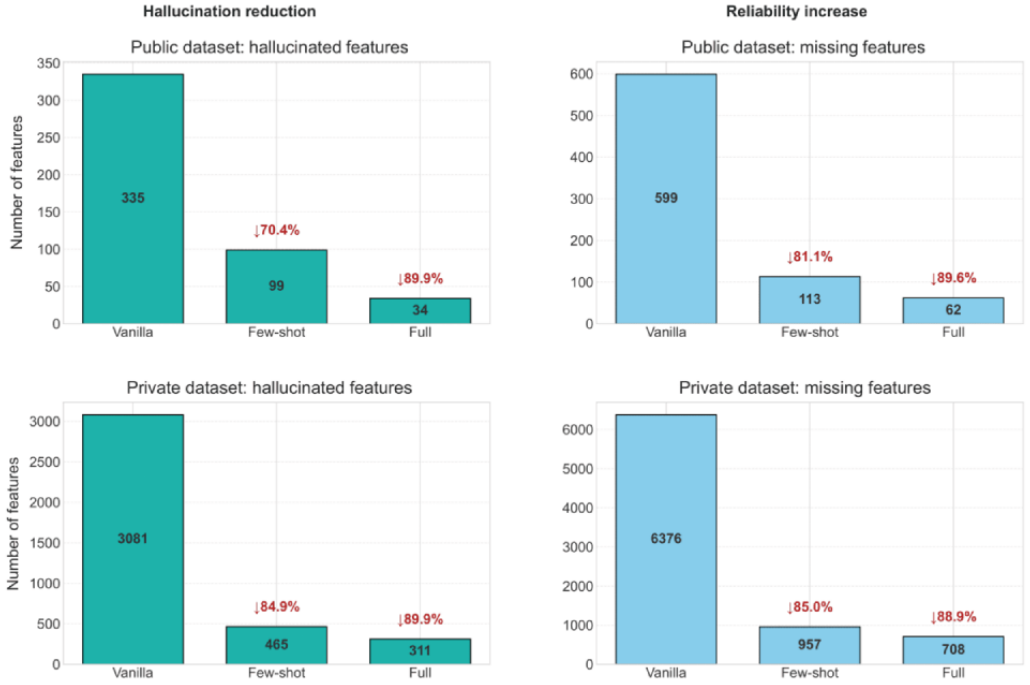
In this respect, the pattern is consistently extended to the much larger private dataset (20,360 features), which misses a total of 6376 features (31.3% of 20,360) in addition to 3081 hallucinated features (15.1% of 20,360) using the vanilla model. The few-shot instructing fine-tuning model reduces the missing features to 957 (4.7% of 20,360, a reduction of 85%) and 465 hallucinated features (2.3% of 20,360, a reduction of 84.9%), while the full model misses only 708 features (3.5% of 20,360, a reduction of 88.9%) and 311 hallucinated features (1.5% of 20,360, a reduction of 89.9%).

To better understand the underlying mechanisms, Figure 5 presents the penalty trends across training epochs for all 10 clinical cases. The hallucination penalty (blue lines) consistently decreases as training progresses, with most cases showing a steep decline during epochs 1-3. Several interesting patterns emerge in the penalty curves: (1) missing feature penalties (yellow lines) often start higher than hallucination penalties, particularly in complex cases (cases 2, 5, 7, and 8), indicating an initial model bias toward precision over recall; (2) by epoch 5, nearly all cases demonstrate convergence to low penalty states (<0.05), showing the model has effectively handled feature detection and hallucination avoidance; and (3) the balanced convergence of both penalty types validates our bidirectional mapping approach, which prevents optimization from favoring one error type over another.

Being able to significantly reduce missing features and hallucinated features and, maintain similar reductions in penalty convergence across clinical cases proves beyond a doubt that our confidence-regularization framework robustly addresses RQ2. The proposed framework has been successful in minimizing hallucination problems prevalent to LLMs in medical contexts and in improving the reliability of extraction even in extremely low supervision (few-shot instructing fine-tuning).

XSL•FO
RenderX

Figure 4. Comparison of missing and hallucinated features across model types. The vanilla model (Mistral Nemo with few-shot in-context learning [ICL]) shows the highest error rates, while the full model minimizes both error types.



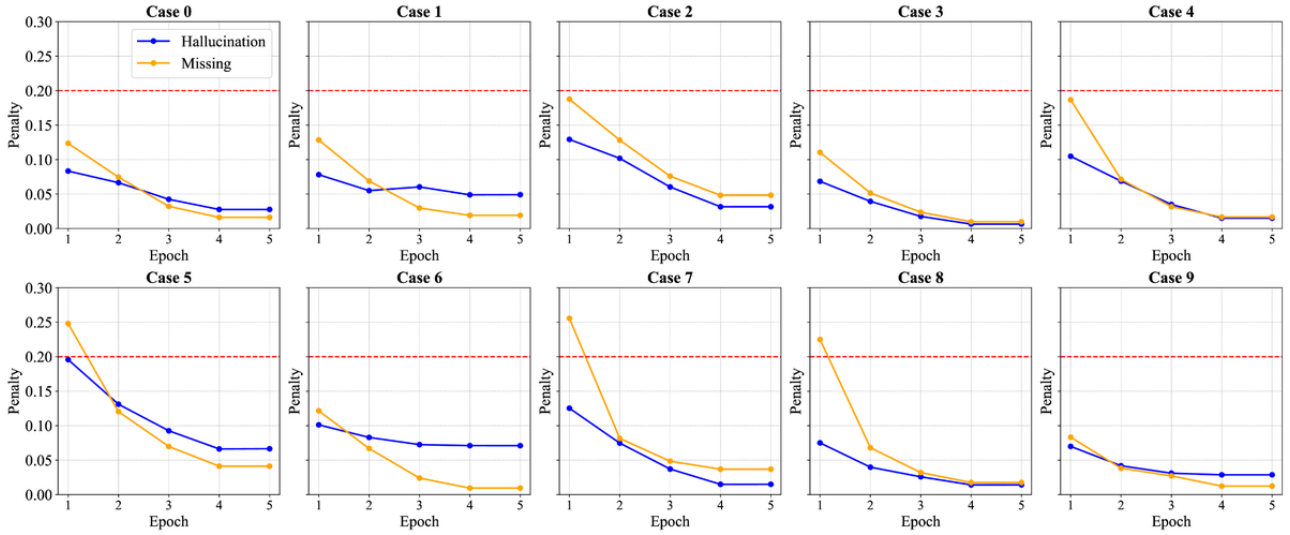


Figure 5. Evolution of hallucination (blue lines) and missing feature (yellow lines) penalty values over 5 training epochs for 10 clinical cases on the training dataset. The convergence of penalties illustrates the effectiveness of bidirectional semantic matching in balancing error types. The red line serves as a visual aid, highlighting where most penalties are <0.2.

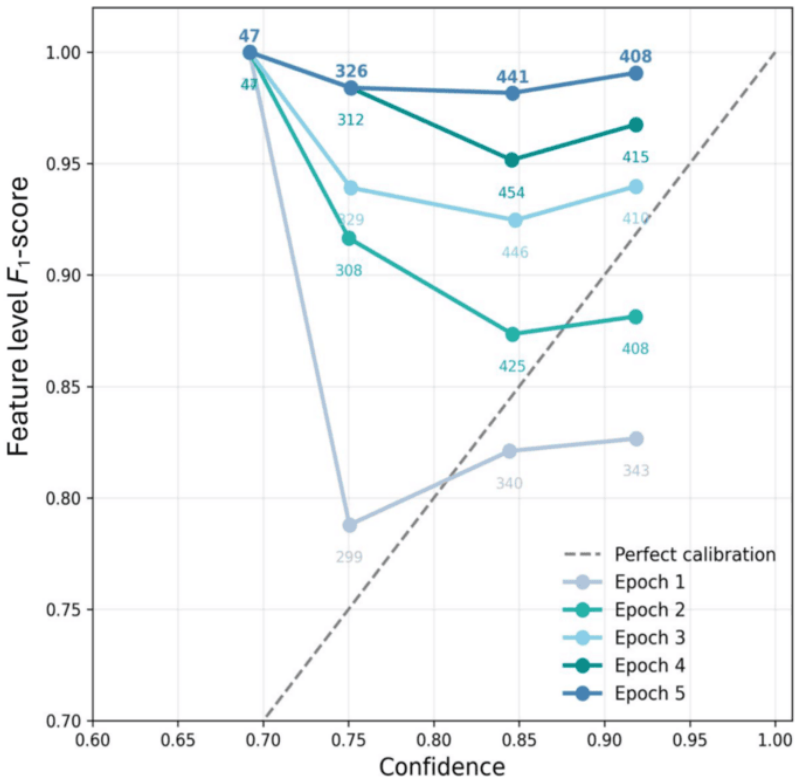
Calibration and Reliability (RQ3)

LLMs have proven to be powerful tools, with inherent deep contextual understanding capabilities, to process and generate human-like text. These models are often poorly calibrated due to their complex architecture and large number of parameters. Many previous works report that further instructing fine-tuning for specific task can improve accuracy but harm calibration, causing LLMs to become overconfident [55,56]. Our confidence-regularization framework reveals an unexpected calibration pattern. Rather than the typical confidence inflation seen in fine-tuned LLMs, our approach maintains stable average confidence (0.84, SD 0.003) while achieving dramatic performance improvements (F_1 improved from 0.819 to 0.986). This creates a unique scenario where ECE increases not due to overconfidence, but from the growing misalignment between conservative confidence estimates and exceptional performance.

Figure 6 presents the reliability diagrams for our confidence-regularization model across 5 training epochs. Following the standard approach established by Guo et al [16], we partition predictions into 4 confidence bins (0.6-0.7, 0.7-0.8, 0.8-0.9, and 0.9-1.0) and compare the mean confidence within each bin against the actual F_1 performance. Perfect calibration would result in all points lying on the diagonal line (y=x). As training progresses from epoch 1 to epoch 2, the model shows mixed calibration with significant underconfidence in the 0.6-0.7

XSL•FO
RenderX

bin; the gap between the average F_1 score of this bin and optimal performance can be calculated as 0.692−1=−0.308 (negative mean underdominance). From epoch 3 to epoch 5 as F_1 performance improves to 0.94-0.98, stable confidence becomes increasingly conservative. The 0.8-0.9 bin shows growing underconfidence (gap evolving from −0.077 to −0.136), while the highest confidence bin (0.9-1.0) transitions from slight overconfidence to underconfidence (gap evolving from 0.092 to −0.072). The distribution of predictions shifts toward higher confidence bins (from 683 to 849 predictions in the 0.8-1.0 range), but this reflects improved feature extraction quality rather than confidence inflation. In the highest confidence bin, F_1-scores reach 0.98 by epoch 5, yet the model maintains conservative confidence estimates (SD 0.003). Despite the degradation in calibration, the model achieves remarkable performance improvements. F_1-scores in the highest confidence bin (0.9-1.0) increase from 0.81 to 0.98, demonstrating that while calibration worsens, the model performance increases.



Our ECE increases from 0.060 to 0.147 across epochs, while the Brier score improves from 0.087 to 0.036. This is explained by our stable confidence mechanism: ECE measures the gap between confidence and performance, which naturally widens as performance improves while confidence remains constant. The improved Brier score indicates better probabilistic predictions despite the calibration mismatch. Contextualizing within medical NLP literature, Oliveira et al [57] reported ECE values for entity and relation extraction tasks ranging from 0.12 to 0.44, depending on the dataset and strategy. Our final ECE of 0.147 falls within this expected range. The increasing ECE aligns with findings from another study [20], which show that pretrained language models do not learn to become calibrated during training; they become increasingly overconfident. In our case, penalties lead to conservatism rather than overconfidence.

This “stable confidence with improving performance” pattern addresses (RQ3) in an unexpected way. The confidence-regularization strategy has not yet achieved tight calibration; instead, it prevents the overconfidence seen in fine-tuned LLMs. Following the framework of Xiao et al [58], our model operates in what they term the “non-calibratable regime,” where performance increases as ECE increases. However, unlike typical models in this regime that exhibit severe overconfidence, our approach maintains conservative, stable confidence estimates.

For medical applications, this represents a desirable trade-off. Conservative confidence estimates (underconfidence) are preferable to overconfidence when errors have serious consequences.

Given the reliability diagram and rising ECE, our findings corroborate a growing body of published evidence that alignment improves task quality at the expense of calibration. It enters the “non-calibratable regime” described by Xiao et al [58], where further accuracy gains cannot be matched by improvements in calibration. Our inference-time gating offers a viable, low-cost alternative when the task requires matching with existing references, as the case in feature extraction for this specific task.

Figure 6. Reliability diagram showing feature-level performance as F1-score with softmax confidence per feature.

RenderX

Qualitative Error Analysis

We analyzed our model's predictions on a private dataset containing 26,297 features. The hallucination rate is defined as precision (FP/[TP+FP]) and the miss rate as recall (FN/[TP+FN]) per feature. The heatmap in Figure 7 shows these features, with darker colors indicating higher hallucination (precision) and missing feature (recall) error rates. Our analysis shows that hallucination errors occur less frequently than missing feature errors, with the highest hallucination rates at 7%, while missing features showed an even higher occurrence, up to 23%.

Upon closer examination of these features (detailed examples provided in Multimedia Appendix 2), we identified several consistent patterns, as illustrated below.

Figure 7. Heatmap showing hallucination and omission (missing features) rates for all clinical features in the private test set, where darker red indicates higher error rates and light yellow indicates lower error rates.

Hallucination Error Patterns

Overview

Annotation inconsistencies: many features categorized as hallucinations stem from inaccuracies in the ground truth annotations. For example, the feature "worsened 3 weeks ago" was not in the ground truth of one patient note, while an equivalent feature, "symptoms worsened 3 weeks," was annotated as ground truth in another note belonging to the same case number.

Specificity requirements

Certain features demand exact descriptions of symptoms to be identified accurately. For example, the feature "Epigastric-discomfort," where epigastric specifically refers to the upper central region of the abdomen, was annotated in ground truth as "pain in the middle of his stomach." On the other hand, the model's prediction of a nonspecific "stomach pain," lacking details on the precise location, caused the predictions to fail similarity matching and be registered as hallucinations.

Redundant documentation

In several cases, features were listed twice in patient documentation using varied phrasing but were annotated only once. For example, the predicted feature "Denies dyspnea" was present in the text but not considered during inference because annotators had only marked "negative shortness of breath."

Knowledge limitations

A significant error example represents a fundamental knowledge gap inherent in the LLM, such as "No-relief-with-asthma-inhaler," predicted as "tylenol did not help." Tylenol is a pain reliever, not an asthma medication.

Missing Feature Error Patterns

Predicting complex features proved consistently challenging for the model. As shown in Tables S3 and S4 in Multimedia Appendix 2, for compound features like "No-hair-changes-OR-no-nail-changes-OR-no-temperature-intolerance," the model predicted only "denies change in weight," while the actual annotation for this patient was "Denies any sweating." Similarly challenging was the feature "Lack-of-other-thyroid-symptoms," which lacks standardization and was inconsistently captured by annotators.

Our analysis identified 4 key limitations: annotation constraints, where human annotators showed inconsistencies in the annotated data, as evidenced by the agreement percentage [36], affecting model evaluation; semantic depth disparity, where the model's deep semantic understanding was sometimes interpreted differently from the annotation team's standardized approach, leading to instances of false positive results; feature ambiguity, where some features were rather generic in nature and lacked a clear set of well-defined boundaries, making consistent annotation and prediction difficult; and model internal knowledge gaps, where the model's knowledge limitations caused errors such as confusing medication classes (eg, pain relievers vs bronchodilators) or anatomic localizations (eg, epigastric vs general stomach pain). The error analysis underscores that the annotation process lacks comprehensiveness and standardization, in addition to being subject to human error bias and the complexity of annotating large text volumes, making it a challenging task. LLMs, highly sensitive to data quality, require consistent, standardized training data for optimal performance, and the model's medical domain knowledge limitations could be improved with accurately annotated data and continuous training on domain-specific medical data to significantly enhance performance.

Discussion

Overview

Our framework efficiently extracts medical features from patient notes by integrating diverse training approaches, multidimensional confidence-regularization, and embedding similarity evaluation. It achieves a state-of-the-art F_1-score of 0.983 (semantic matching) and 0.968 (binary overlap) on the full dataset, and 0.973 (semantic matching) and 0.952 (binary overlap) with only 100 patient notes, outperforming benchmark models INCITE (F_1=0.888) and DeBERTa-based models (F_1=0.958). The framework provides a transformative solution for automated medical education assessment, addressing data scarcity, semantic variability, hallucination risks, and interoperability.

The framework's strength lies in its strong generalization, retaining 99% performance with only 100 out of 700 patient notes (14.2% of the training data) through instructing and confidence-regularization fine-tuning. Semantic embedding matching captures variable clinical expressions (eg, "worsen 3 wks ago" vs "symptoms worsened 3 weeks"), unlike token-level probability methods. Our framework ensures performance stability, reducing overfitting in data-scarce settings—crucial for resource-constrained environments where manual annotation is costly.

Unlike traditional n-gram, fuzzy logic, or BERT-based methods, which struggle with semantic variability in clinical notes, our framework adapts semantic embedding matching and lightweight sentence embedding for cosine similarity, capturing deeper semantic meaning.

Our confidence-regularization fine-tuning phase significantly enhances feature extraction performance, reducing hallucinations by 89.9% (from 3081 to 311) and missing features by 88.9% (from 6376 to 708). However, this phase does not improve the ECE, which increases from 0.060 to 0.147 over 5 training epochs. This trade-off arises not from overconfidence but from the growing misalignment between conservative confidence estimates and exceptional performance. Despite the well-documented overconfidence and the miscalibration of LLMs [55,56], our approach maintains stable, conservative confidence, which becomes underconfident as performance improves.

With near-human performance, the framework evaluates 200 notes in 30 minutes on a high-performance GPU, reducing manual effort for USMLE Step-2 Clinical Skills examination preparation. Its few-shot learning and modular architecture eliminate the need for span annotation (interrater agreement of 84%) and enable customization. The framework shows promise for extracting structured data from electronic health records, diagnostic reports, and discharge notes, improving decision-making in health care.

Compared to lexicon-based INCITE, BERT-based models, or DeBERTa with pseudo-labeling, our framework achieves higher precision and recall through two-phase fine-tuning, with both semantic matching (0.988 vs 0.961 precision; 0.978 vs 0.963 recall) and binary overlap evaluation. Our inference-time matching gate effectively replaces traditional calibration needs through context-aware filtering. Unlike post hoc calibration requiring held-out data (which would reduce our already limited training set), our approach validates extractions against case-specific feature lists. This addresses a unique challenge in medical feature extraction: identical text (eg, "fever") may be correct for case 1 but incorrect for case 2, making global calibration inappropriate.

Our framework generates output that supports human-in-the-loop deployment in medical education assessment. During inference, for each case-specific feature that needs to be identified, the system produces: (1) a matching gate decision indicating whether the feature was found in the patient note (present/absent), (2) the extracted text segment and its offset, and (3) a cosine similarity score (0-1 range) between the extracted text and ground truth during testing, which can also be applied to the case's target feature during deployment. These outputs enable medical instructors to review the output by identifying weakly matched extracted features with low cosine similarity scores that may need manual rechecking. Missing features for features from the case list that the model could not find (marked absent) are highlighted for instructor review to confirm they are truly missing. Potential hallucination occurs when the model predicts a feature that could not be found by the matching gate, indicating incorrect extraction. For deployment, institutions can customize review thresholds based on their requirements. High-stakes examinations might mandate manual review of all extractions with cosine similarity >0.8 to their target features, while formative assessments could limit review to missing features only. This flexibility ensures the system augments rather than replaces human judgment in educational assessment.

Alignment With Artificial Intelligence Trustworthiness Framework

CONSORT-AI (Consolidated Standards of Reporting Trials–Artificial Intelligence) guidelines provide a complete checklist for any artificial intelligence (AI)–based clinical intervention, ensuring transparent and reproducible reporting of AI usage during clinical practice [59]. In the following subsections, we detail how the proposed framework meets important key requirements of CONSORT-AI.

Clear Description of AI Intervention (Item 5)

CONSORT-AI requires a detailed description of the AI intervention, such as how it is used and integrated into clinical workflows. Our framework is used for automating the assessment process of medical feature extraction from clinical examination notes written by medical students. The framework's two-phase approach is clearly described, with detailed algorithms (Algorithm 1) and hyperparameters in Multimedia Appendix 2 to ensure reproducibility. Its intended use is to support automated assessment in medical education, reducing the burden on human evaluators while maintaining high accuracy (F_1=0.983). This framework is considered as part of the examination, where the examiner must also evaluate other communication skills.

XSL•FO
RenderX

Input and Output Specification (Item 7)

CONSORT-AI requires clarification of the input data and output format of the AI system. Input data are described in (Phase 1: Instructing Fine-Tuning section), detailed data collection and annotation prepared by NBME [36]. To prepare data for training the model, notes were descoped and formatted using standardized instructions and few-shot ICL (4-6 exemplar pairs, as described in the section Phase 1: Instructing Fine-Tuning). The output consists of patient notes, features associated with patient note cases, extracted features validated through the matching gate, similarity score, and the matched part within patient notes, ensuring outputs are structured and clinically relevant.

Reproducibility and Code Availability (Items 10-11)

Based on CONSORT-AI, details ensuring reproducibility and providing access to code and data are required. The complete source code, including training and inference code, is available in a GitHub repository [62]. Model weights and training protocols are fully documented. The dataset is accessible through Kaggle and NBME data-sharing agreement. Computational requirements are specified (NVIDIA H100 GPUs).

Performance and Error Reporting (Item 12)

CONSORT-AI encourages comprehensive reporting of performance metrics and error types. Our proposed model provides detailed performance metrics (precision, recall, and F_1-score) across public and private dataset splits (Table 2), achieving F_1=0.983 with full data and F_1=0.973 with 100 notes. Error analysis investigating the pattern and reasons of hallucination and missing features is provided in the Qualitative Error Analysis section.

Handling of Errors and Failures (Item 19)

CONSORT-AI requires describing how errors and failures are managed. During training, errors are detected using bidirectional semantic matching (in step 3 of the Phase 2: Confidence Regularization Fine-Tuning section), targeting hallucinations and missing features. The inference-time matching gate ensures filtering of nonexistent predictions, supporting reliable clinical outputs. During deployment, the model extracts features and displays the relevant feature numbers, allowing human intervention by tracking the extraction process.

Human-AI Interaction (Item 20)

CONSORT-AI stresses the role of human oversight in AI systems. Our framework supports human oversight through a cosine similarity score for each extracted feature, along with the number and text of the feature associated with the case, enabling experts to prioritize review of features below a set low cosine similarity threshold. The matching gate facilitates verification by eliminating mismatched features. All extracted features are matched with patient note text then approved to be passed. This creates oversight transparency where the errors can be tracked in text. Integration with electronic health record systems could further allow clinicians to accept, reject, or flag model outputs prior to downstream use. At present, this capacity is not implemented in the prototype but is identified as a key future development for clinical deployment.

Validation in Clinical Context (Item 22)

CONSORT-AI requires validation of AI performance in intended clinical contexts. The proposed framework's evaluation on the USMLE Step-2 dataset (2839 notes) demonstrates applicability in medical education assessment. Its ability to maintain high performance with minimal data (100 notes, 14.2% of training data) supports scalability in resource-constrained settings.

By following CONSORT-AI guidelines, the proposed framework ensures transparency, reliability, and applicability, making it a trusted option for automated medical feature extraction in clinical education environments.

Limitations

While our framework demonstrated strong performance, the evaluation shows several shortcomings that highlight potential areas for improvement.

First, inconsistencies in human-annotated ground truths, such as ambiguous boundaries, subjective symptom consideration, and missing annotations, led to hallucination and missing feature errors. Developing standardized annotation methodologies and clear clinical feature definitions is essential to enhance annotator agreement.

Second, the LLM backbone demonstrates general medical knowledge by performing well with only few-shot fine-tuning but struggles with specific medical logic, such as medication-symptom relationships. Continual pretraining on medical domain data, integrating structured medical ontologies (eg, Systematized Nomenclature of Medicine–Clinical Terms, Unified Medical Language System), or using retrieval-augmented generation could address these gaps.

Third, designing model training on medical datasets may further improve extraction performance. Testing on USMLE Step-2 Clinical Skills notes provided a controlled case collection, but the framework lacks evaluation on unstructured or multilingual health care records, such as electronic health records or notes from psychiatry and pediatrics. Future work could consider semantic adjustments for multilingual records to enhance global applicability by incorporating continual pretraining or multitask fine-tuning.

Fourth, despite the competitive performance of our framework, it demonstrates the typical calibration-accuracy trade-off observed in fine-tuned LLMs [20,55,56,58]. ECE increases from 0.060 to 0.147 during training. Although this pattern aligns with existing literature showing that task-specific fine-tuning often harms calibration [61], our model shows stable confidence, which contrasts with literature observations that LLMs tend to be overconfident. The model's inability to adjust confidence upward as performance improves from 0.82 to 0.98 suggests that our regularization may be overly restrictive, representing a limitation for applications requiring well-calibrated confidence scores.

Fifth, while our framework and baseline models [9] both use binary feature-detection F_1 metrics for evaluation, the method of determining feature presence differs between approaches. The baseline models use token-level probability thresholds

XSL•FO
RenderX

(≥0.5) from span-extraction architectures, which is inapplicable to generative models that produce textual descriptions. We therefore implemented two adapted evaluations: (1) binary overlap using token overlap ≥0.5 between generated and ground truth text, providing the closest equivalent to baseline methodology, and (2) semantic matching using cosine similarity ≥0.5 to capture semantic equivalence. The semantic approach is inherently more lenient than token-based methods, which may introduce a positive bias. However, our binary overlap results (F_1=0.968) still demonstrate improvements over baselines (F_1=0.958), confirming performance gains independent of evaluation methodology.

Sixth, our framework is specifically designed for structured extraction tasks with predetermined feature lists, as demonstrated in the USMLE Step-2 Clinical Skills evaluation. The framework's evaluation pipeline requires both matching gate validation and cosine similarity comparison (≥0.5) against target feature descriptions to determine feature presence. Without predefined target features, the cosine similarity component cannot function, invalidating our current evaluation methodology. While the core confidence-regularization training objective could potentially be adapted to open-ended named entity recognition tasks through span-level token overlap F_1 scoring, this would require a fundamental redesign of the validation pipeline and evaluation framework. Such adaptation represents a distinct research direction requiring substantial methodological changes rather than a straightforward extension of the current work.

Seventh, future work should systematically investigate the sensitivity of confidence-regularization parameters across diverse medical domains and backbone architectures. While our configuration (α=0.7, β=0.2, λ=20, τ=0.6-0.7) achieved stable convergence on the USMLE dataset, understanding the parameter sensitivity ranges would provide practical guidelines for adapting this framework to new clinical NLP tasks with different precision–recall characteristics and error distributions.

Eighth, we demonstrate our two-phase framework on the Mistral-NeMo-Instruct-2407 backbone. Our choice of this backbone was task-driven, based on preliminary experiments on this dataset [37]. While this open model supports reproducibility, we did not perform systematic cross-backbone evaluation (eg, public Mistral-7B-Instruct, Llama-3-Instruct). Thus, the extent to which our gains translate to other model families remains to be quantified and is a direction for future work.

Future Directions

Building on the proposed framework's foundation, future research will focus on advancing its architectural capabilities to enhance the precise identification of clinical features in text, a limitation that has sparked significant interest across the LLM community. While traditional autoregressive models are effective for semantic generation, they struggle with determining exact token positions, reducing their effectiveness in span-sensitive tasks such as named entity recognition and clinical information extraction. This has motivated a wave of research investigating alternative training approaches that can use bidirectional generation, encoder-decoder, and matching-based retrieval models.

We plan to investigate accurate token-level positional grounding while exploring architectures focused on matching and training objectives that can enhance token-level grounding between input and output. Domain-specific pretraining on clinical corpora such as Medical Information Mart for Intensive Care III [60] can further support the model's understanding of medical terminologies.

We will further evaluate our framework across a wider range of clinical settings, such as unstructured electronic health records, radiology reports, and multilingual patient records. Using standardized medical ontologies, such as Unified Medical Language System and Systematized Nomenclature of Medicine–Clinical Terms, can enhance annotation uniformity and boost span-level accuracy. An in-depth study of poor calibration in LLMs is warranted, which may involve architectural adjustments to address persistent overconfidence. Such changes could entail revising attention mechanisms or implementing dedicated calibration layers to more effectively model uncertainty estimates for feature extraction tasks that depend on contextual features that change for each case.

Conclusions

This study developed and evaluated a two-phase LLM framework for automated medical feature extraction from clinical examination notes. Our approach consisted of two training phases: instructing fine-tuning, followed by confidence-regularization fine-tuning, to address the critical challenges in medical NLP applications, including data scarcity, semantic variability, and hallucination risks.

The framework achieved an F_1-score of 0.983 (semantic matching) and 0.968 (binary overlap) on the USMLE Step-2 Clinical Skills dataset with full training data and maintained an F_1-score of 0.973 (semantic matching) and 0.952 (binary overlap) using only 100 out of 700 training samples (14.2% of the full dataset). Through the two-phase training approach, hallucinated outputs were reduced by 89.9% (from 3081 to 311) and missing features decreased by 88.9% (from 6376 to 708) compared to the baseline LLM model with few-shot ICL. While the confidence-regularization fine-tuning improved extraction accuracy, it increased the ECE from 0.060 to 0.147, reflecting the documented calibration–accuracy trade-off in fine-tuned LLMs. Our inference pipeline's semantic similarity validation provides practical calibration by filtering predictions based on feature matching rather than raw confidence scores.

This framework provides a practical solution for automated medical education assessment, reducing the burden on human evaluators while maintaining quality standards for clinical competency evaluation. The demonstrated ability to achieve strong performance with minimal training data positions this approach as a valuable tool for scaling medical education assessment in resource-constrained environments.

Abstract

Natural language processing techniques are useful for identifying stigmatizing language in electronic health records but require careful consideration. This commentary article builds on "*Efficient Detection of Stigmatizing Language in Electronic Health Records via In-Context Learning*" by Chen et al, which highlights the importance of incorporating situational and temporal contexts in annotation and modeling efforts. We emphasize the need for researchers to explicitly articulate their paradigms and positionality, particularly when working with populations disproportionately affected by stigmatizing language. We also explore the differences arising from conflicting preferences across communities about what constitutes destigmatizing language. We discuss participatory and trust-centered approaches for model development to work toward unbiased impact. Such strategies have a crucial role in raising awareness and fostering inclusive health care.

(JMIR Med Inform 2025;13:e82484) doi:10.2196/82484

KEYWORDS

context modeling; health equity; NLP; inclusive language; natural language processing

Introduction

Stigmatizing language in electronic health records contributes to perceptions, influences care decisions, and unintentionally perpetuates socially constructed power dynamics, resulting in bias. There is growing interest in using natural language processing to identify stigma in electronic health records, not only to assess fairness and bias, but also to detect implicit and context-dependent language. Recently, Chen et al [1] demonstrated how large language models can be leveraged to detect stigmatizing language in clinical notes by applying in-context learning, using a custom prompt to guide automated identification of stigma. However, detecting stigma is not only a technical challenge, but also a social and ethical one.

This commentary builds on their work, outlining the key considerations for future research. We emphasize the importance of contextual modeling to identify stigmatizing language that subtly reinforces bias. We also emphasize researcher self-awareness and contextual understanding, especially when working with marginalized communities. We discuss the differences in language across clinicians, patients, caregivers, and communities and its impact on model fairness. Finally, we advocate for participatory, equity-centered approaches that foster trust and accountability in the development of bias detection tools.

Considering the Context and Mode of Implicit Stigmatizing Language

Annotating a training/benchmarking corpus for stigmatizing language can help to identify subtle and contextually dependent instances (eg, homonyms). However, a focus on explicit mentions may miss some forms of implicit stigmatizing language. For example, "Patient discussed using tobacco in cultural ceremonies and has been advised on the dangers of smoking to her health" may not be flagged as stigmatizing with a bias toward explicit mentions. However, one could argue that this sentence stigmatizes both the patient's beliefs and a cultural practice by labeling this tobacco use as potentially unhealthy.

The authors acknowledge this limitation and reveal an opportunity for future work to explore implicit or implied stigma, an inherently difficult task that responds to 3 central

XSL•FO
RenderX

features of stigmatizing language: subtle, implicit, and highly contextual.

Addressing these features requires a broader contextual window around a given sentence and consideration of situational, relational, and temporal factors. The authors used a 15-word symmetric window on either side of the input sentence, suggesting this can be expanded with improved modeling approaches and additional resources.

However, understanding subtle instances of stigmatizing language may require context that lies beyond the clinical note. These include multimodal elements such as tone, body language, identities, and relationship dynamics between clinician and patient. Capturing this richer context may require incorporating audio, video, or self-reported data and a reflexive understanding of how power relationships shape clinical interactions. These added data sources require ethical considerations beyond current protected health information guardrails; for example, can one objectively identify tone and body language? How and when should information be extracted from video and audio if it was not deemed clinically relevant by a clinician? How can patients request to edit their video or audio data?

Acknowledging the Positionality of Researchers

The ontological and epistemological leanings of the research team can influence assumptions about stigmatizing language in clinical notes. Research can be strengthened and the audiences better informed if research teams outline their guiding paradigms and assumptions. Additionally, research into stigmatizing language could benefit from positionality statements where factors that influence decision-making are acknowledged, better enabling the identification of limitations and future directions.

For example, was the research process informed by views from patients from specific populations, cultural backgrounds, socioeconomic status, or groups more likely to experience stigmatizing language? Similar to outlining methodological assumptions and approaches, describing what positions influenced the research process can improve its rigor, transparency, and application.

Accounting for Patient Perspectives and Conflicting Values

Chen et al discuss the importance of transparent communication about the model's purpose and recognize the risk of enforcing stereotypes of historically marginalized groups. Strategies such as decision-support alerts and prompted artificial intelligence scribing [2] aim to encourage reflection about this risk among clinical teams.

However, we must account for the patients and caregivers affected by the model's outputs and resulting care decisions. Although the authors acknowledge variations in how stigmatizing language materializes in different types of clinical documentation and health contexts, it is equally important to recognize tensions between what clinicians, patients, caregivers, and communities deem an appropriate health care interaction. What one group interprets as destigmatizing language may be perceived differently by another group. Within a group, individuals can have conflicting preferences for what language best reflects their shared identity.

Plurality—the concept that there is no "correct" form of destigmatized language—requires us to consider alternative and potentially contradictory values when refining the sensitivity of models [3,4]. In recognizing the limitations of a binary stigmatizing versus destigmatizing framework, Chen et al point us to avenues for future work: (1) elicit these contradictory values and explore how model parameters should be tailored to account for and address each community's unique challenges and (2) examine ethical ways to engage communities in this work while minimizing privacy risks.

Building Trust and Equity

Given nuanced views of what is considered destigmatized language, researchers must leverage strategies to build trust and center marginalized communities as they develop and implement models. For example, recent human-computer interaction work has outlined concrete steps to address racial gaps in participatory methods, providing guidance for health equity–focused artificial intelligence design, implementation, and decision-making [5]. Theoretical and practical frameworks can provide an equity lens for technology research and implementation [6,7].

Applying this knowledge can help avoid historical patterns of research exploitation while ensuring the model's purpose, outputs, and implementation are driven by and aligned with the values of the communities they are intended to benefit.

Conclusion

Standalone technologies cannot completely eliminate stigma and bias in health care interactions. However, with evolving social norms and forward cultural progress, these technologies offer critical ways to minimize harmful impact and address root causes of health inequity. Importantly, Chen et al affirm that the intention of bias-detection models is not to surveil or punish the use of stigmatizing language; instead, the goal is to increase bias awareness in the daily practice of delivering and receiving care. With greater awareness, we can remove barriers to health equity and achieve improved health outcomes.

Abstract

Background: Early diagnosis and intervention in glottic carcinoma (GC) can significantly improve long-term prognosis. However, the accurate diagnosis of early GC is challenging due to its morphological similarity to vocal cord dysplasia, with the difficulty further exacerbated in medically underserved areas.

Objective: This study aims to address the limitations of existing technologies by designing a vision-language multimodal model, providing a more efficient and accurate early diagnostic method for GC.

Methods: The data used in this study were sourced from the information system of the First Affiliated Hospital of Sun Yat-sen University, comprising laryngoscopy reports and 5796 laryngoscopic images from 404 patients with glottic lesions. We propose a vision-language–guided multimodal fusion network (VLMF-Net) based on a large vision-language model for the early automated diagnosis of GC. The text processing module of this model uses the pretrained Large Language Model Meta AI (LLaMa) to generate text vector representations, while the image processing module uses a pretrained vision transformer to extract features from laryngoscopic images, achieving cross-modal alignment through the Q-Former module. By leveraging a feature fusion module, deep integration of text and image features is achieved, ultimately enabling classification diagnosis. To validate the model's performance, the study selected contrastive language-image pretraining (CLIP), bootstrapping language-image pretraining with frozen image encoders and large language models (BLIP-2), a large-scale image and noisy-text embedding (ALIGN), and vision-and-language transformer (VILT) as baseline methods for experimental evaluation on the same dataset, with comprehensive performance assessment conducted using accuracy, recall, precision, F_1-score, and area under the curve.

Results: We found that on the internal test set, the VLMF-Net model significantly outperformed existing methods with an accuracy of 77.6% (CLIP: 70.5%; BLIP-2: 71.5%; ALIGN: 67.3%; and VILT: 64.3%), achieving a 6.1-percentage point improvement over the best baseline model (BLIP-2). On the external test set, our method also demonstrated robust performance, achieving an accuracy of 73.9%, which is 4.6 percentage points higher than the second-best model (BLIP-2: 69.3%). This indicates that our model surpasses these methods in the early diagnosis of GC and exhibits strong generalization ability and robustness.

Conclusions: The proposed VLMF-Net model can be effectively used for the early diagnosis of GC, helping to address the challenges in its early detection.

glottic carcinoma early diagnosis; multimodal deep learning; large-scale foundation model; computer-aided diagnosis; clinical decision making

Introduction

Glottic carcinoma (GC) is a common malignant tumor of the head and neck [1]. According to GLOBOCAN, China reported 29,500 new cases and 16,900 deaths from laryngeal cancer in 2022 [2], posing heavy burdens on health care systems. Approximately 60% of patients are diagnosed at an advanced stage [3], leading to significant impairment of vital physiological functions and compromising both physical and mental health. Early diagnosis of malignant tumors has been increasingly

XSL•FO
RenderX

emphasized in clinical practice due to its potential to improve cure rates and organ function preservation [4]. Therefore, optimizing diagnostic methods for GC and enhancing early detection capability are urgent tasks for otolaryngologists.

Laryngoscopy is the primary diagnostic tool for GC [1], offering direct visualization of lesion shape, extent, and surface texture. When combined with narrow band imaging, it enhances early tumor detection by identifying neovascularization [5], making it a valuable tool for early diagnosis. However, vocal cord dysplasia (VCD), a precancerous condition situated between normal epithelium and squamous cell carcinoma, is characterized by a small lesion with clinical and laryngoscopic features similar to early GC [6]. Therefore, it is challenging for the human eye to distinguish between them. In addition, the lesion is often covered by "leukoplakia-like" substance, which interferes with the ability of narrow band imaging to reveal submucosal vasculature [7], increasing the risk of misdiagnosis. Laryngoscopy reports provide textual descriptions of lesion morphology observed dynamically during the examination, supplementing static images and assisting in diagnostic decision-making. Studies have demonstrated a correlation between morphological grading and malignancy risk [8-10], underscoring the diagnostic value of textual reports. Furthermore, reports authored by experienced clinicians serve as valuable references, facilitating more accurate diagnoses by less experienced clinicians. Histopathology examination remains the gold standard for diagnosis [1]. However, biopsy is invasive, painful, and carries procedural risks [11], impeding its widespread application in large-scale clinical screening. To address this issue, it is necessary to develop an efficient and noninvasive method to improve the diagnostic accuracy of early GC.

Recently, significant progress has been made in deep learning techniques for tackling real-world classification tasks in computer vision and natural language processing [12-14]. Many researchers have sought to apply these models to the detection of laryngeal cancer, yielding promising outcomes. However, most existing methods only use laryngoscopic images as input, including UC-DenseNet [15], MTANet [16], Dlgnet [17], RedFormer [18], and SAM-FNet [19]. Although these methods have demonstrated promising performance in laryngeal cancer detection and other tasks, they neglect certain latent information present in other modalities. Such information is typically inaccessible through unimodal approaches, thereby highlighting the advantages of multimodal methodologies [20,21].

Therefore, this study proposes a novel method named vision-language–guided multimodal fusion network (VLMF-Net) for early diagnosis of GC. Addressing the limitations of traditional single-modality diagnostic methods, our approach integrates the images and reports text of laryngoscopy to provide a more comprehensive representation of lesion characteristics. Using a pretrained vision transformer (ViT) [22] model for image feature extraction and a LlaMa3 [23,24] model fine-tuned for text processing, we achieve effective multimodal feature fusion. Compared to single-modality methods, our approach significantly improves the diagnostic accuracy and robustness, achieving an accuracy of 0.776 on real clinical datasets. This study highlights the potential of multi-modal fusion in clinical auxiliary diagnosis and provides new insights for reducing misdiagnosis rates and improving patient treatment outcomes.

Methods

Dataset

In our study, we constructed 2 datasets for model development and validation. First, we built an internal dataset for model training, validation, and testing. For the internal dataset, we collected data from 404 patients with glottic lesions at the First Affiliated Hospital of Sun Yat-sen University in Guangzhou, China. This dataset consists of 5799 professionally annotated image-text pairs, covering two types of lesions: VCD and GC. Each sample includes a laryngoscopic diagnostic report written by an experienced otolaryngologist and its corresponding laryngoscopic image.

In addition, to assess the model's generalization ability and robustness, we constructed an external dataset. The external dataset was collected from the First People's Hospital of Zhaoqing, consisting of data from 47 patients with glottic lesions between January 1, 2018, and August 31, 2024. This dataset includes 308 image-text pairs and strictly follows the principle of isolation from the training data, serving only for final performance evaluation. For detailed information on internal and external datasets, please refer to Figure 1 and Table 1.

Model Architecture

Overview

Figure 2 illustrates the overall architecture of our proposed VLMF-Net model, which consists of 3 main modules: the laryngoscopic image encoder, the clinical report encoder, and the laryngeal feature fusion module. Specifically, the laryngoscopic image encoder is responsible for extracting visual feature representations from laryngoscopic images, while the clinical report encoder captures textual feature representations from the patient's laryngoscopic examination findings. These features are then fused through the laryngeal feature fusion module. Finally, the fused features are passed through a fully connected layer to complete the classification task. The detailed implementation of each module in our proposed VLMF-Net model is as follows:

XSL•FO
RenderX

Figure 2. The overall architecture of our proposed vision-language–guided multimodal fusion network (VLMF-Net) model.

Laryngoscopic Image Encoder

The laryngoscopic image encoder is an adapted version of a pretrained ViT [22] model. Considering that a single ViT model may introduce cross-modal discrepancies in multimodal tasks, potentially affecting model accuracy, we incorporated an additional Q-Former [25] module into the ViT model to mitigate the impact of modality differences and bridge the gap between image and text features. Q-Former is a trainable module based on Transformer that extracts and condenses visual features through alternating stacking of self-attention and cross-attention. Specifically, we first use ViT to extract features from the image, and then we input the extracted image features into a Q-Former module with frozen parameters to reduce modal differences.

Formally, let fenc(·) denote the image encoder and fq(·) denote the Q-Former module. Given an image xi, first resize the image to 224×224×3, then the image feature vi is obtained as follows:

(1)vi=fq(fenc(xi·θenc);θq)

where θenc and θq are the weight parameters of the image encoder and the Q-Former module, the shape of vi is 1×1024. It is worth noting that in terms of the weights of the pretrained model, we adopt the transfer learning strategy: we directly use the pretrained weights of the BLIP-2 [25] model as the weight parameters of the laryngoscope image encoder, because a large number of studies have demonstrated the effectiveness of BLIP-2 in downstream tasks [26-28]. Such operations can ensure that the extracted image features and text features are in the same scale space, thus effectively avoiding catastrophic problems caused by modal differences.

Clinical Report Encoder

In the clinical report encoder module, we use LLaMA3 [23], an advanced large language model, as the text feature extractor to obtain textual feature representations from the patient's laryngoscopic examination findings. This model is renowned for its exceptional ability to understand long-form text.

Formally, let fLLaMA3(·) denote the clinical report encoder function. Given a clinical report ri, the process of obtaining the text feature ti can be formulated as follows:

(2)ti=fLLaMa3(ri;θq)

where θqrepresents the weight parameters of the clinical report encoder, the shape of ti is 1×4096. Notably, we adopt the same transfer learning strategy for the clinical report encoder's weight parameters as we did for the laryngoscopic image encoder. Furthermore, considering that the text in our dataset is in Chinese, we use a fine-tuned LLaMA3 model trained on a Chinese dataset as the encoder's weight source [24]. This approach effectively addresses the original LLaMA3 model's limitations in Chinese language understanding.

Laryngeal Feature Fusion

In the 2 modules described above, we obtained image and text features. To effectively fuse these 2 modalities, we introduced the laryngeal feature fusion module, which aligns, maps, and integrates the features from both modalities. Specifically, we first use the vision projector fvp(·) and the text projector ftp(·) to map the image feature vi and text feature ti into a unified feature space:

(3)vi′=fvp(vi;θvp)

(4)ti=ftp(ti;θtp)

Where vi` and ti` represent the mapped image and text features (their shapes are 1×512 and 1×2048), respectively, and θvp and θtp are the learnable parameters of the projectors fvp(·) and ftp(·) .

Next, we apply L2 normalization to both features to ensure consistency, obtaining:

vi``=vi`||vi`||2and ti``=ti`||ti`||2. Thenvi`` and text featureti`` along the feature dimension to form a vision-language joint representation, denoted as:gi=Concatvi``,ti``. This joint feature is then fed into a classifier, which consists of multiple fully

XSL•FO
RenderX

connected layers, dropout layers, and ReLU activation functions. The classification process is formulated as:

(5)y^i=ffc(gi,θfc)

where θfc represents the learnable parameters of the classifier.

Model Training

The internal dataset is divided at the patient level into training, validation, and test sets in a ratio of 8:1:1, strictly following the principle of data isolation. Regarding the loss function during training, we use the cross-entropy loss function Lce and the contrastive loss functionLct, which are formulated as follows:

(6)LCE=−∑i=1cyilog (y^i)

(7)LCT=−log exp (sim(zi,zj)τ)∑k=12N1[k≠i]exp (sim(zi,zk)τ)

In Lce, *C* represents the total number of classes, yi denotes the ground-truth class label in one-hot encoding, and yi^ is the predicted probability for class *I*. This loss function aims to minimize the difference between the model's predicted distribution and the true distribution, thereby guiding parameter updates and optimization. In Lct, sim(·) represents cosine similarity,zi and zj are positive sample pairs, τ is the temperature parameter, and *N* is the number of negative samples. The final loss function Lloss is formulated as follows:

(8)Lloss=Lce+c×Lct

where c=0.1. All training processes and experiments are conducted on a dedicated server equipped with 4 NVIDIA A6000 GPUs with a total of 196GB of VRAM. The system runs on Ubuntu 20.04.5 LTS, and the model is implemented using PyTorch 3.9.0 and Scikit-learn 1.3.1. In this study, we use the AdamW optimizer to optimize VLMF-Net, with an initial learning rate set to 0.00001. A warm-up strategy and cosine learning rate scheduling are adopted to dynamically adjust the learning rate. VLMF-Net is trained for a total of 80 epochs.

Ethical Considerations

This study was approved by the Ethics Committee of the First Affiliated Hospital of Sun Yat-sen University (approval number [2023]755 - 1). Informed consent was waived by the institutional review boards of all participating hospitals due to the study's retrospective design. We implemented stringent measures to protect the privacy of all participants by anonymizing all collected data to remove any personally identifiable information. Throughout the manuscript preparation, we diligently avoided disclosing any details that could reveal the identity of participants. Furthermore, no compensation or indemnity was required as the study did not cause any losses to participants beyond the necessary clinical diagnostic and therapeutic measures.

Results

Result of Our Model

To demonstrate the effectiveness and advantages of our proposed VLMF-Net, we selected 4 classic models as baseline models and performed comparisons on 2 datasets. The 4 models include vision-and-language transformer (VILT) [29], contrastive language-image pretraining (CLIP) [30], bootstrapping language-image pretraining with frozen image encoders and large language models (BLIP-2) [25], and a large-scale image and noisy-text embedding (ALIGN) [31], and the 2 datasets refer to the internal and external datasets mentioned earlier. Tables 2 and 3 present the average results of 5 trials for the 4 baseline models and our proposed model on the internal and external datasets, respectively. Figure 3 shows the receiver operating characteristic curves and corresponding area under the curve values of different models on internal and external datasets. As shown in Table 2, on the internal dataset, our method demonstrates significant advantages, achieving the following evaluation metrics: accuracy (0.776), precision (0.820), and F_1-score (0.776). Notably, compared to the second-best model, our method achieves significant improvements of 0.061, 0.032, and 0.046 in accuracy, precision, and F_1-score, respectively. In terms of class-wise recall, VLMF-Net achieves recall rates of 0.754 and 0.803 for VCD and GC, respectively. Compared to other models, VLMF-Net shows significant improvements across multiple evaluation metrics, indicating its superior ability in recognizing glottic cancer. In addition, as shown in Table 3, on the external dataset, our method also demonstrates significant advantages, achieving accuracy (0.739), precision (0.828), and F_1-score (0.737), with improvements of 0.046, 0.053, and 0.046 over the second-best model, respectively. In terms of class-wise recall, our model achieves recall rates of 0.701 and 0.793 for VCD and GC, respectively. Compared to other models, there is also a significant improvement, which further demonstrates that VLMF-Net possesses excellent generalization ability and robustness. Moreover, as shown in Figure 3, our model demonstrates significant advantages in area under the curve metrics on both internal and external datasets. On the internal dataset, it outperforms the second-best model by 0.026, and on the external dataset by 0.012.

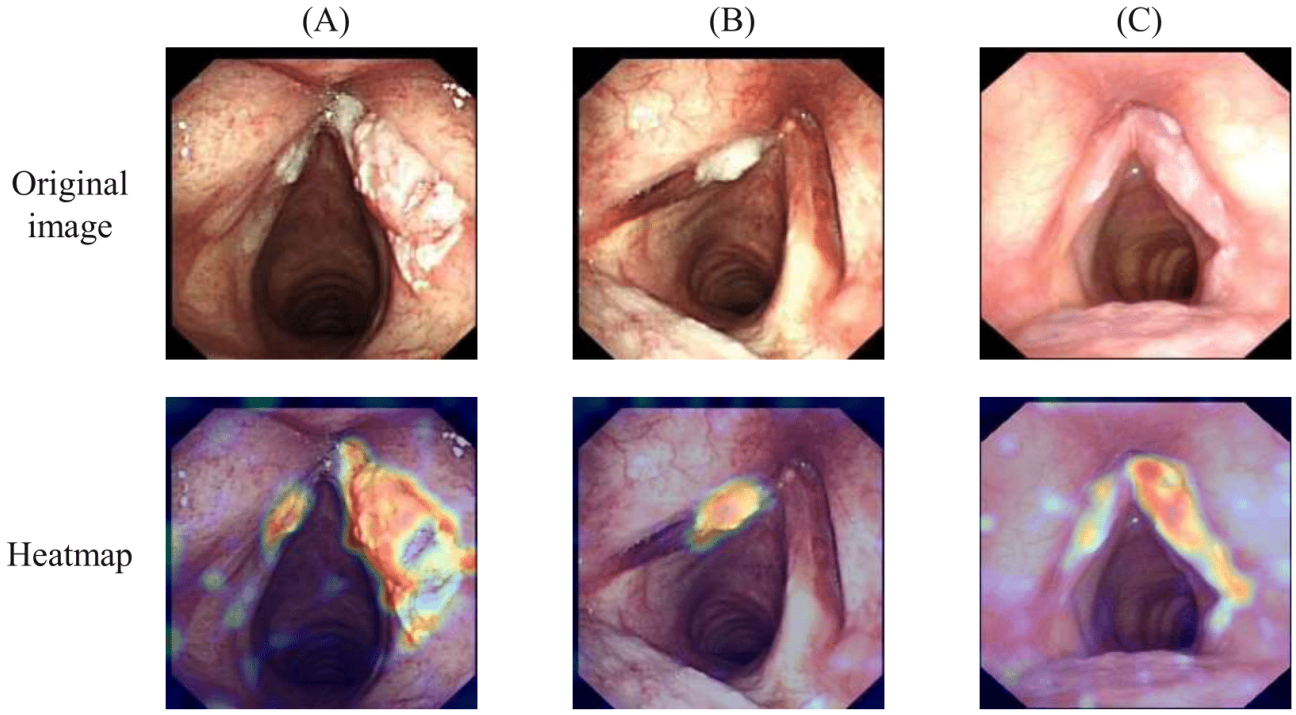
Ablation Studies

To validate the effectiveness of our multimodal approach for early diagnosis of GC, we designed an ablation study to systematically evaluate the performance differences between models using single-modal and multimodal inputs: (1) M1: a single-modal model using only laryngoscopy images; (2) M2: a single-modal model using only laryngoscopy diagnostic reports; (3) M3: a multimodal model combining images and text, but without Q-Former. (4) M4: a multimodal model combining images and text with Q-Former. The experimental results, as shown in Table 4, indicate that the multimodal model M4 significantly outperforms both single-modal models across all evaluation metrics. Specifically, compared to the best single-modal model, M4 achieves improvements of 0.098 in accuracy (0.776), 0.106 in precision (0.820), 0.100 in recall (0.779), and 0.098 in F_1-score (0.776). This demonstrates that the multimodal data fusion strategy effectively integrates visual features and textual semantic information, significantly enhancing the diagnostic performance of the model.

Table . Ablation study on vision-language–guided multimodal fusion network.

Variants	Image	Report	Q-Former	Accuracy, mean (SD)	Precision, mean (SD)	Recall, mean (SD)	F_1-score, mean (SD)
M1	√	0.678 (0.02)	0.714 (0.03)	0.679 (0.03)	0.678 (0.03)		
M2	√	0.673 (0.01)	0.711 (0.02)	0.675 (0.01)	0.673 (0.01)		
M3	√	√	0.722 (0.02)	0.708 (0.01)	0.723 (0.01)	0.722 (0.03)	
M4	√	√	√	0.776 (0.01)	0.820 (0.02)	0.779 (0.02)	0.776 (0.01)



In addition, to verify the effectiveness of the Q-Former module, we designed ablation experiments related to the Q-Former module. The experimental results are shown in Table 4. M4 outperforms M3 in all indicators. Specifically, M4's accuracy (0.776) increased by 0.054, precision (0.820) increased by 0.112, recall (0.779) increased by 0.056, and F_1-score (0.776) increased by 0.054. This indicates that the Q-Former module effectively reduces the impact of cross-modal differences.

Visualization for Model Prediction

To enhance the interpretability of the VLMF-Net model's predictions, we used the Grad-CAM (Gradient-Weighted Class Activation Mapping) [32] algorithm to generate class activation heatmaps. The visualization results are shown in Figure 4. In the heatmap, we can see that VLMF-Net focuses on the lesion area of the patient when analyzing the laryngoscopy image. This indicates that the model is able to correctly classify based on the features of the lesion area, enabling early diagnosis of GC.

Figure 4. The heatmaps generated by the vision-language guided multimodal fusion network (VLMF-Net) model on patient laryngoscopic images, where (**A**) represents glottic carcinoma and (**B**) and (**C**) represent vocal cord dysplasia.

Discussion

Main Findings

In our study, we developed a novel model for the early diagnosis of GC named VLMF-Net, which leverages multimodal fusion technology guided by vision-language information. When tested on an internal dataset, VLMF-Net achieved accuracy, precision, recall, and F_1-score of 0.776, 0.820, 0.779, and 0.776, respectively, outperforming all baseline methods. These results demonstrate the feasibility and effectiveness of VLMF-Net in the early diagnosis of GC. Ablation studies further reveal that VLMF-Net significantly outperforms unimodal models. By integrating both laryngoscopic images and clinical text reports, VLMF-Net captures complementary diagnostic information, thus mitigating the risk of information loss inherent in single-modality systems. Notably, the textual modality meaningfully guides the extraction of image features; for instance, textual cues explicitly describing the lesion's location (eg, "anterior-middle segment of the left vocal cord") can help the model focus on the relevant visual regions. This form of cross-modal interaction may enhance the model's ability to detect subtle pathological patterns that might otherwise be overlooked.

Moreover, Grad-CAM–based visualizations demonstrate that VLMF-Net consistently attends to clinically significant lesion areas. These attention heatmaps show strong alignment between the model's focus and expert-defined pathological regions, enhancing interpretability. Such interpretability is crucial in clinical contexts, where transparency in decision-making processes fosters trust and facilitates integration of AI systems into diagnostic workflows.

Finally, these findings validate the design philosophy of VLMF-Net and highlight the broader potential of multimodal fusion strategies in medical AI. In particular, the ability to synthesize visual and contextual clinical information allows for more robust and informed diagnostic decisions. This work not only advances the state of the art in GC diagnosis but also lays a foundation for extending vision-language multimodal techniques to other complex diagnostic tasks where rich multimodal data is available.

Deep Learning Challenges in Early GC Diagnosis

Early GC lesions are usually small and exhibit complex morphological characteristics, making it challenging for deep learning models to capture fine-grained lesion features. As a result, important details related to the lesions may be missed, significantly affecting the model's diagnostic accuracy. Furthermore, most existing mainstream models rely solely on laryngoscopic images as input. While these models have achieved some progress in a unimodal setting, they overlook information from other modalities, which is often beyond the reach of image-based models [15-19]. This limitation constrains the model's comprehensive understanding of lesion characteristics and ultimately affects diagnostic accuracy.

Strengths and Limitations

To the best of our knowledge, this is the first study to apply multimodal techniques to the early diagnosis of GC. In our model, we fully utilize patients' laryngoscopy reports and laryngoscopic images to extract relevant information about GC, enabling the model to comprehensively understand the patient's condition and thereby improve its performance. However, this study still has some limitations. First, the VLMF-Net, based on a pretrained large language model, relies heavily on powerful computational resources, particularly high-performance GPUs, during training, which may result in slower training and inference speeds. Second, the data used in this study underwent quality checks, but in real-world scenarios, more complex

XSL•FO
RenderX

situations may arise, such as poor image clarity due to imaging devices or challenging shooting angles, which could affect the model's diagnostic accuracy.

Conclusions

In this paper, we propose a VLMF-Net for the early diagnosis of GC. Extensive experiments on 2 datasets demonstrate that VLMF-Net achieves superior accuracy and robustness, effectively addressing the challenges of early GC diagnosis.

Acknowledgments

We note that a shorter conference version of this paper appeared in the 2024 China Health Information Processing Conference (CHIP 2024). In our initial conference paper, we did not investigate whether the vision-language guided multimodal fusion network (VLMF-Net) model maintains its effectiveness across different datasets and consistently outperforms baseline models. This manuscript addresses these issues while further optimizing the originally proposed model through approaches such as hybrid loss function training. In addition, we use the Grad-CAM (Gradient-Weighted Class Activation Mapping) methodology to analyze the interpretability of VLMF-Net. Abstract

Background: Drug–target interaction (DTI) prediction is crucial in drug repositioning, as it can significantly reduce research and development costs and shorten the development cycle. Most existing deep learning–based approaches employ graph neural networks for DTI prediction. However, these approaches still face limitations in capturing complex biochemical features, integrating multilevel information, and providing interpretable model insights.

Objective: This study proposes a heterogeneous network model based on multiview path aggregation, aiming to predict interactions between drugs and targets.

Methods: This study employed a molecular attention transformer to extract 3D conformation features from the chemical structures of drugs and utilized Prot-T5, a protein-specific large language model, to deeply explore biophysically and functionally relevant features from protein sequences. By integrating drugs, proteins, diseases, and side effects from multisource heterogeneous data, we constructed a heterogeneous graph model to systematically characterize multidimensional associations between biological entities. On this foundation, a meta-path aggregation mechanism was proposed, which dynamically integrates information from both feature views and biological network relationship views. This mechanism effectively learned potential interaction patterns between biological entities and provided a more comprehensive representation of the complex relationships in the heterogeneous graph. It enhanced the model's ability to capture sophisticated, context-dependent relationships in biological networks. Furthermore, we integrated multiscale features of drugs and proteins within the heterogeneous network, significantly improving the prediction accuracy of DTIs and enhancing the model's interpretability and generalization ability.

Results: In the DTI prediction task, the proposed model achieves an AUPR (area under the precision-recall curve) of 0.901 and an AUROC (area under the receiver operating characteristic curve) of 0.966, representing improvements of 1.7% and 0.8%, respectively, over the baseline methods. Furthermore, a case study on the KCNH2 target demonstrates that the proposed model successfully predicts 38 out of 53 candidate drugs as having interactions, which further validates its reliability and practicality in real-world scenarios.

Conclusions: The proposed model shows marked superiority over baseline methods, highlighting the importance of integrating heterogeneous information with biological knowledge in DTI prediction.

Introduction

Background

Drugs play a crucial role in treating diseases by interacting with multiple targets and modulating their functions. Accurately predicting drug–target interactions (DTI) is essential for understanding drug mechanisms [1], discovering new targets, and facilitating drug repositioning. Traditional methods rely heavily on large amounts of labeled data and often suffer from label noise in negative samples. In recent years, positive-unlabeled learning has been effectively applied to alleviate this issue [2]. Meanwhile, self-supervised learning strategies integrated with heterogeneous biomedical networks have improved the accuracy of DTI prediction by leveraging multimodal information [3]. With the rapid advancement of large language models (LLM), their applications in the biomedical domain have expanded significantly. Due to their powerful sequence representation and semantic understanding capabilities, LLMs are driving DTI prediction methods toward a higher level of performance [4].

Currently, DTI prediction methods are primarily categorized into three types [5,6]: ligand similarity–based methods [7,8], network-based methods [9,10], and structure-based methods [11]. Ligand similarity–based methods predict DTIs by comparing the structural similarity of drugs. These methods are computationally efficient but often overlook complex biochemical properties and molecular characteristics, which may lead to inaccurate predictions [12]. Network-based methods rely on large amounts of high-quality interaction data and are computationally intensive [13-15]. They typically lack structural information about drugs and targets, resulting in poor performance on sparse networks. Structure-based methods usually depend on the three-dimensional structures of target proteins and drugs [16]. However, these methods exhibit limited efficacy for proteins with unknown structures.

To address the above issues, we propose a heterogeneous network (HN) model based on multiview path aggregation for DTI (MVPA-DTI) prediction. MVPA-DTI enhances prediction capability through a multiview feature extraction and fusion mechanism. First, the molecular attention Transformer model is used to extract the three-dimensional spatial structure information of drugs, while the protein-specific LLM Prot-T5 is leveraged to deeply explore the biophysical properties of protein sequences, forming two feature views based on structure and sequence. Subsequently, a HN is constructed by incorporating multisource heterogeneous information from proteins, drugs, diseases, and side effects. This approach effectively integrates the previously defined feature views into the message-passing framework of the HN, thereby forming a comprehensive biological network relationship view. The multiview path aggregation mechanism allows the model to dynamically synthesize feature information from multiple perspectives. By introducing a meta-path aggregation mechanism, the model dynamically synthesizes feature information across different perspectives, capturing underlying drug–target associations at multiple hierarchical levels through both feature-oriented views and biological network relational contexts. During the message-passing process, MVPA-DTI optimizes the weight distribution by incorporating both network topology and biological prior knowledge. By extracting node-level feature embeddings from heterogeneous data, the model is capable of accurately predicting new DTI. Experimental results show that MVPA-DTI outperforms existing advanced methods across multiple evaluation metrics. Additionally, for the voltage-gated inward-rectifying potassium channel KCNH2 target, which is related to cardiovascular diseases, MVPA-DTI was used for candidate drug screening. Among 53 candidate drugs, 38 are predicted to interact with this target (10 of which are already used in clinical treatment). This finding not only validates the effectiveness of MVPA-DTI in predicting DTI but also further demonstrates its application potential and practical value in real drug development. The main contributions of this paper are as follows:

1. We employ a molecular attention Transformer network that extracts three-dimensional structural information from molecular graphs through a physics-informed attention mechanism, establishing a structural feature perspective of the drug.
2. The sequence-level features are extracted from protein sequences using Prot-T5, a protein-specific LLM. The model maps sequence features to functional relevance, establishing a sequence feature perspective of proteins.
3. We integrate the drug structural view and protein sequence view into a multi-entity HN to construct a biological network relationship view. The meta-path information aggregation mechanism captures higher-order interaction patterns among different types of nodes.
4. We propose a multiview path aggregation–enhanced HN model that integrates protein and drug biological knowledge to accurately identify critical drug–target relationships. Benchmark tests show that the model exhibits a significant advantage in prediction performance.

Related Work

DTI prediction plays a significant role in drug discovery and drug repositioning. With the rapid advancement of deep learning technologies, an increasing number of deep learning–based DTI prediction methods emerge. These methods, particularly those combining big data with deep learning, gradually overcome the limitations of traditional approaches. Based on different prediction strategies, DTI prediction methods are generally categorized into three types [5,6]: ligand similarity–based methods [7,8], network-based methods [9,10], and structure-based methods [11]. In recent years, prediction methods based on LLMs also bring remarkable breakthroughs to the DTI field, opening new pathways for its development.

Ligand Similarity–Based Methods

In DTI prediction, ligand similarity–based methods estimate potential interactions by comparing the structures or chemical similarity of drug molecules. These methods typically rely on the SMILES (simplified molecular input line entry system) representation or molecular fingerprints of drugs to calculate drug–drug similarities and infer potential target interactions based on these similarities. For instance, Thafar et al [17] proposed the DTiGEMS model, which integrates drug–drug

XSL•FO
RenderX

similarities and employs a similarity selection and fusion algorithm to enhance the accuracy of DTI predictions. Additionally, Shim et al [18] introduced a similarity-based convolutional neural network method. This method calculates the outer product of the similarity matrix between drugs and targets and employs a two-dimensional convolutional neural network to capture potential relationships between them. These methods have improved DTI prediction accuracy to some extent, but they often overlook the dynamic interactions and complex spatial structures between molecules. Moreover, ligand similarity–based methods operate under the assumption that similar drug molecules share similar targets. However, this assumption does not always hold, especially when dealing with molecules that exhibit significant structural differences.

Network-Based Methods

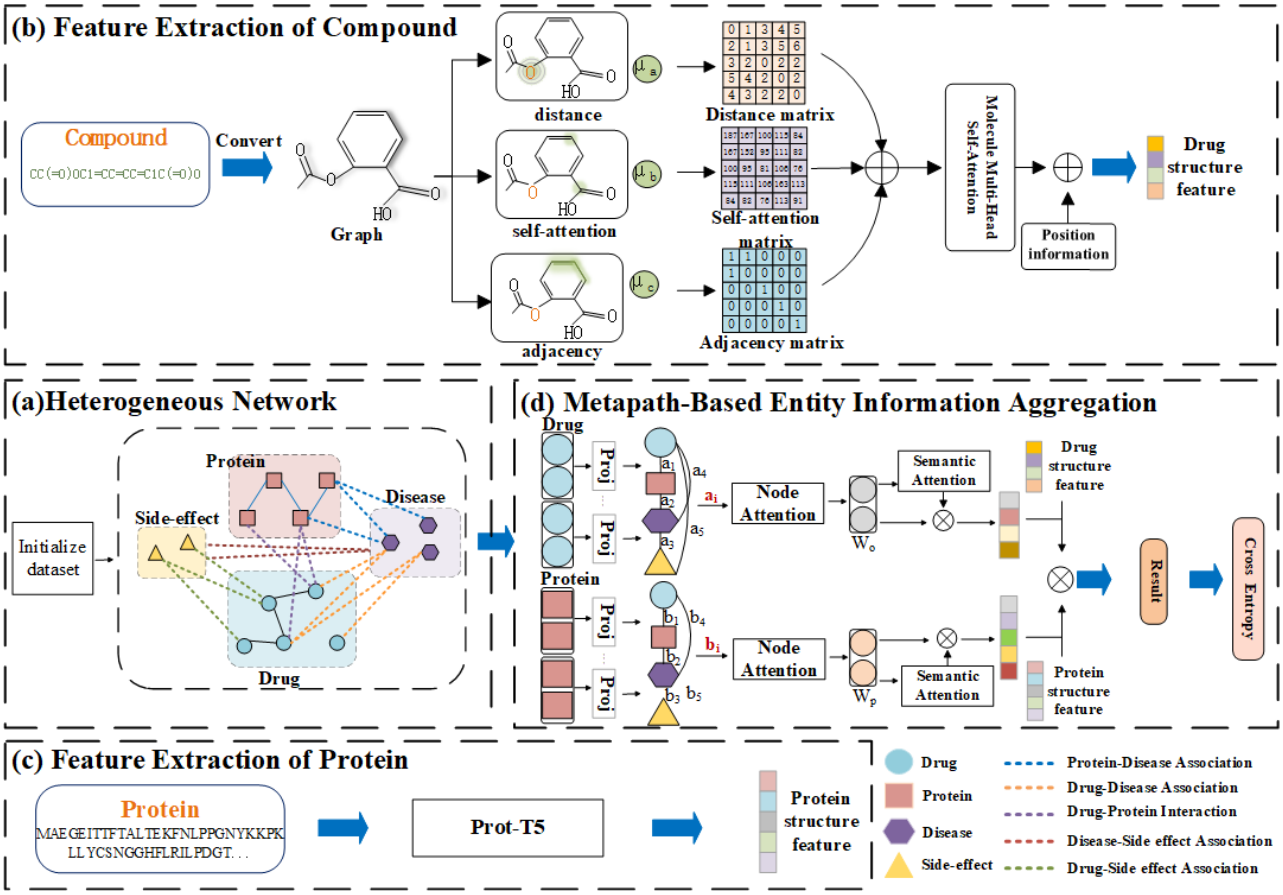
Network-based methods typically rely on large amounts of known DTI data and utilize graph algorithms for modeling. In these methods, drugs and targets are represented as nodes in a graph, while the interactions between them are represented as edges. Additionally, drug–drug similarity networks, protein–protein similarity networks, and known DTI networks are often integrated into a HN. Examples of such approaches include DTI networks, multisimilarity collaborative matrix factorization, and HN models. On this basis, researchers used graph structures to explore potential interaction patterns and promoted the development of tasks such as drug repositioning.

In recent years, with the development of graph representation learning [19,20], network-based methods have achieved deep fusion modeling of structural and semantic information. For example, Zhao et al proposed a regulation-aware graph learning method that enhances drug representation by integrating gene regulation information, thereby improving the prediction effect of drug repositioning [21]. GNN methods mostly rely on the direct adjacency structure of nodes, which easily ignores the rich high-order semantic information and cross-modal associations in biological networks. To this end, some studies have proposed information fusion methods that combine low-order and high-order graph structures. For example, Zhao et al jointly modeled direct neighbor relationships and high-order network path features to effectively enhance the discriminability of drug and target representation [22]. At the same time, in order to more comprehensively model the heterogeneous relationships between multiple entities such as drugs, proteins, and diseases, Zhao et al constructed a heterogeneous information network using semantic paths and attention mechanisms to achieve the integration and discrimination of multimodal information, thereby improving the accuracy and generalization ability of DTI prediction [23]. The iGRLDTI introduced edge weight regulation mechanisms and regularization terms in GNN, further improving the model's ability to learn potential interactions in heterogeneous biological networks [24].

Structure-Based Methods

Traditional structure-based methods typically use molecular docking techniques, combined with molecular dynamics simulations, to accurately predict the binding patterns between drugs and targets. With the development of deep learning methods, an increasing number of studies have integrated structural information with neural networks. For example, DeepDTA [25] and DeepDrug3D [26] have enhanced the modeling capability of the drug–target binding process by incorporating three-dimensional structural information of proteins and drugs, further improving prediction accuracy. Although deep learning models can handle structural information, they generally require large amounts of labeled data for effective training, and obtaining high-quality drug–target binding data remains a challenge.

The application of language models is particularly crucial in the absence of molecular structural information. Drawing on techniques from the field of Natural Language Processing, pretrained language models (such as BERT [27] and MolBERT [28]) are used to deeply characterize drug and protein sequence data. By automatically learning latent features and semantic information within sequences, these models enhance the accuracy of DTI predictions. A key advantage of LLMs is their ability to process large-scale, unlabeled data and improve model generalization through transfer learning. For instance, MolBERT [28] and ChemBERTa [29] achieve high-quality molecular representations by pretraining on massive drug molecular datasets. Transformer-based protein language models, such as ProtBERT [30], TAPE [31], and ProtT5 [32], are pretrained on large protein sequence databases. This enables them to capture hierarchical and context-rich sequence representations, enhancing the understanding of protein characteristics. These models can efficiently and accurately characterize proteins using only sequence data, without relying on three-dimensional structural information.



Methods

Framework

MVPA-DTI combined multiple types of heterogeneous data. It extracted structural and sequential features from drug molecules and protein sequences. It also optimized the weight distribution for information propagation in a heterogeneous graph neural network. As illustrated in Figure 1, the process consisted of four steps: (a) First, an HN is constructed, incorporating drugs, proteins, diseases, and drug side effects. (b) Next, a molecular attention Transformer [33] network is used to extract 3D structural features from the SMILES [34] representations of drugs, which are then assigned to drug nodes. (c) Then, the Prot-T5 model is employed to analyze key biophysical features of protein data, which are subsequently assigned to target nodes in the graph. (d) In the final step, a Heterogeneous Graph Attention Network (HAN) [35] is utilized to analyze network topology, unify node embeddings, determine node importance using meta-paths, and integrate node features through semantic attention. Ultimately, MVPA-DTI predicted potential DTI by optimizing the drug–protein reconstruction loss and the cross-entropy loss.

Feature View

Feature Extraction of Compound Structures

The MVPA-DTI model utilized SMILES sequences as input for drug molecules to learn effective representations of their structural features. Since SMILES sequences shared structural similarities with natural language, contextual information can be effectively leveraged to analyze molecular features. However, traditional methods often struggled to capture long-range atomic relationships when processing molecules. To overcome this limitation, this study employed an improved Transformer architecture.

First, we employed the RDKit toolkit [36] to convert SMILES sequences into molecular graph structures. Since the lengths of SMILES sequences vary across different molecules, a maximum length of 100 is selected to construct reasonable molecular representations. This setting covered at least 90% of the compounds in the dataset. For sequences exceeding this length, truncation is applied, while shorter sequences are padded with zeros to maintain consistent input formatting.

For feature extraction, we employed the Molecule Attention Transformer (MAT) [33] for encoding. Its core idea is to replace the self-attention layer of the traditional Transformer [37] with an enhanced molecular self-attention mechanism. By integrating adjacency information from molecular graphs and interatomic distance information, MAT comprehensively captured the feature representation Sdrug of drug structures. The attention mechanism integrated interatomic distance and molecular topology. This enhancement allowed the attention distribution to more precisely capture internal molecular relationships. The calculation formula for molecular multihead self-attention is as follows:

$$(1)A(i)=(\mu b\rho(QiKiTdk)+\mu ag(D)+\mu cA)Vi$$

where $A\in\{0,1\}Natoms\times Natoms$ represented the adjacency matrix of the molecular graph and $D\in RNatoms\times Natoms$ denoted the distances between atoms. The query, key, and value vector matrices are defined as Qi=XWiq, Ki=XWik, and Vi=XWiv, respectively, where *W* represented learnable parameters. In the attention calculation, μα, μb, and μc corresponded to the weights of different attention components, with specific meanings as follows: μα measured the importance of interatomic distances in the attention mechanism; μb adjusted the influence of self-attention on the overall attention mechanism; and μc controlled the role of the adjacency matrix in the attention computation.

Feature Extraction of Protein Structures

The MVPA-DTI model employed Prot-T5 to extract features from protein sequences. By treating sequences as natural language, it used Transformer-based self-supervised learning to capture biological insights. During the data preprocessing

XSL•FO
RenderX

stage, protein sequences are treated as text data composed of 20 standard amino acids (along with a few unknown amino acids, such as X). To adapt to the input format of Natural Language Processing tasks, each protein sequence is treated as a token sequence of individual amino acids, with spaces inserted between each amino acid to ensure the Transformer can correctly parse the sequence information. Additionally, to enhance the model's generalization capability, all uncommon or unresolved amino acid symbols (eg, B, O, U, Z) are mapped to the universal token X, ensuring data consistency.

Prot-T5 is based on the Text-to-Text Transfer Transformer (T5) [38] architecture, which employs an encoder–decoder structure. However, for the task of protein feature extraction, only the encoder part of T5 is utilized to map protein sequences into a high-dimensional feature space. Prot-T5 adopted the Span Masking language modeling strategy, where during training, continuous segments of amino acids in the sequence are randomly masked, and the model is tasked with reconstructing the masked portions based on the context. This enabled the model to learn long-range dependencies and semantic information within protein sequences. As shown in Equation 2, given a protein sequence S=(S1,S2,...,Sn), it is first embedded into a high-dimensional space ES and then fed into the Transformer to compute the hidden representations:

(2)H=Transformer(E(S))

Finally, the global representation of the entire sequence is obtained through average pooling, as calculated by the following formula:

(3)Sprotein=1n∑i=1nHi

where Hi represented the hidden states output by the Transformer and Sprotein served as the global feature of the protein.

Relational View of Biological Networks

Heterogeneous Networks

The HN is described as an undirected graph G = (V, E), where V={υ1,υ2,...,υn} represented the set of nodes and E={E(1),E(2),...,E(k)} denoted the set of ktypes of edges, with each E(i)={ei1,ei2,...,eim} representing a specific type of edge.

As shown in Figure 1A, this paper constructed a comprehensive heterogeneous information network, which included drug–drug interactions, drug–protein interactions, drug–disease associations, drug–side effect associations, protein–protein interactions, and protein–disease associations. In the network, entities such as drugs, targets, diseases, and side effects are represented as nodes, while the relationships and interactions between nodes are represented as edges. In the proposed framework, each node belonged to only one type of entity, and all edges are undirected and have nonnegative weights. Node messages are first sent to their first-order neighbors and then propagated to higher-order neighbors through the network edges, a process known as message passing.

The message-passing process in the HN is divided into multiple stages. First, nodes transmitted their information to first-order neighbors. This information is then propagated to higher-order neighbors through network edges, forming more complex information dissemination. Message passing is not limited to directly connected nodes but also includes information transmitted through multihop paths. This enabled the model to integrate features across a broader neighborhood, thereby better capturing long-range dependencies and multilevel network structures.

Metapath-Based Entity Information Aggregation

In heterogeneous graph representation learning, our goal is to learn effective feature representations for each node in the HN. However, the challenge of this task lies in not only integrating information from different types of nodes and edges in the heterogeneous graph but also considering the heterogeneous features and content of each node. To address this issue, we employed HAN [35] as the topological feature extraction method for the heterogeneous information network. HAN modeled the structural relationships in the HN through a hierarchical attention mechanism. Specifically, node-level attention learned meta-path-based neighborhood weights and aggregates them to generate semantically specific node embeddings, while semantic-level attention assigned weights across different meta-paths to obtain the optimal task-specific representation, as illustrated in Figure 1D. In terms of meta-path selection, we selected two biologically meaningful paths: D-P-D (Drug–Protein–Drug) and P-D-P-D (Protein–Disease–Protein–Drug). D-P-D is used to capture the semantic relationship between drugs connected by common targets, which helped the model identify drug pairs with similar functions or related potential mechanisms of action, while P-D-P-D further explored the multi-hop indirect connections between proteins formed by disease associations, thereby reflecting a more complex biological network structure. We selected these two meta-paths based on their good semantic interpretability and biological relevance, which helps the model more effectively model the potential interactions between drugs and targets.

After obtaining the node embeddings, we further proceeded with the message-passing process. Assuming the initial node embeddings are defined as f0:V→Rd, where f0(v) represented the mapping of node v in the d-dimensional space, the information aggregation process for node v can be expressed as:

(4)fv=σ(1K∑k=1K∑u∈ Nvαuv W f0(u))

(5)αuv=exp(AconC(α[Wf0(u)//Wf0(v)]))∑k∈Nvexp(AconC(α[Wf0(u)//Wf0(k)]))

where σ represents a nonlinear activation function, K denotes the number of attention layers, Nv represents the set of neighboring nodes of node v, W is the shared weight parameter, auv is the edge weight computed by the attention mechanism, and AconC(∗) [39] is an adaptive activation function.

Based on obtaining the graph structure representation, we further integrated the structural information of each node to construct the final drug and protein representation. For drug nodes, its representation integrates the meta-path structure features, the original embedding representation, and the molecular structure features, which is specifically expressed as:

(6)fdrug=L2Norm(ReLU([mateDPD,Edrug+L2Norm(Sdrug)]W0+b0))

XSL•FO
RenderX

Similarly, the protein node representation combined its meta-path structure features, original embeddings, and sequence representations and is expressed as:

(7)protein=L2Norm(ReLU([matePDPD,Eprotein=L2Norm(Sprotein)]W0+b0))

Among them, W0 and b0 are learnable linear transformation parameters, which are used to uniformly map the concatenated multiple features to a common low-dimensional semantic space, and implicitly model the importance weights of each feature subspace during the training process to improve the discriminative ability of the final representation.

After completing the representations of drugs and proteins, we used the inner product to calculate the interaction probability between them, as shown in Figure 1D. For a drug node u and a protein node v, their interaction probability is calculated as follows:

(8)puv=σ((fu)Tfv)

where σ is the sigmoid function and puv represents the interaction score between node u and node v.

To optimize the model, we employed multiple loss terms for joint training. Among them, the cross-entropy loss is used to supervise the interaction prediction task, defined as follows:

(9)£CEL=∑r∈ R−yrlog(pr)−(1−yr)log(1−pr)

where R is the set of relationships, yr is the ground truth label of sample r (1 for positive samples and 0 for negative samples), and pr is the predicted probability.

In addition, to enhance the model's structural perception of node features, we introduced reconstruction losses for drugs and proteins, which are defined as follows:

(10)£recdrug= ‖ A^drug−Adrug ‖ F2

(11)£recprotein= ‖ A^protein−Aprotein ‖ F2

Among them, Adrug and Aprotein are the adjacency matrices of drug and protein nodes in the original HN, respectively. A^ represents the adjacency matrix reconstructed by the model through node embedding and ·F represents the Frobenius norm. The final optimization target is the weighted sum of three losses:

(12)£=£CEL+λ1£recdrug+λ2£recprotein

where £recdrug and £recprotein represent the reconstruction losses for drugs and proteins, respectively, while λ1 and λ2 are weighting coefficients used to balance the contributions of different loss terms. Through joint optimization, we can improve the accuracy of DTI prediction while ensuring that the generated feature representations possess robust structural information and discriminative capabilities.

Results

Dataset

This study conducted DTI prediction experiments on the Luo dataset [9], which was assembled by Luo et al. To better capture biological characteristics, we incorporated the SMILES sequences of drug molecules and the structural sequence data of proteins into the dataset. Tables 1 and 2 present the relevant statistical information of nodes and edges in the dataset. The dataset comprises six independent drug–protein interaction networks, with all edge weights being binary values.

Table . Statistics of node information in the dataset.

Node type	Count
Drug	708
Protein	1512
Disease	5603
Side effect	4192

Table . Statistics of association information between nodes in the dataset.

Edge type	Count	Source
Drug–protein interaction	1923	DrugBank version 3.0 [40]
Drug–drug interaction	10,036	DrugBank version 3.0 [40]
Protein–protein interaction	7363	HPRD Release 9 [41]
Drug–disease association	199,214	Comparative Toxicogenomics Database [42]
Protein–disease association	1,596,745	Comparative Toxicogenomics Database [42]
Drug–side-effect association	80,164	SIDER Release 2 [43]

Experimental Settings

Building upon the study by Luo et al [9], 90% of the positive and negative samples from the dataset were used to construct the HN and train MVPA-DTI, while the remaining 10% were reserved for testing. In this study, we adopted a data preprocessing process consistent with NeoDTI, including negative sample sampling strategy, drug–target similarity calculation method, and similarity threshold setting to eliminate redundancy. Subsequently, the model's performance was evaluated through 10-fold cross-validation, with the

XSL•FO
RenderX

effectiveness of the method being measured using AUROC and AUPR metrics.

MVPA-DTI consists of three modules: Prot-T5, MAT, and HAN, with the parameter settings detailed in Table 3. During the training process, we employed the Adam optimizer to update the network weights.

Table . Parameter settings in the experiment.

Parameter	Value
Number step	3000
Batch size	128

Comparison With Prior Work

In this study, to better simulate real-world scenarios, we randomly sampled negative samples while retaining all positive samples, setting the ratio of positive to negative samples at 10:1. This ratio aims to reflect the imbalance between positive and negative samples in the real world. Subsequently, we compared the performance of MVPA-DTI with several benchmark models to evaluate its effectiveness in DTI prediction tasks; they are briefly described as follows:

- MSCMF [44]: MSCMF effectively predicts DTI by utilizing multiple similarity matrices of drugs and targets through collaborative matrix factorization.
- HNM [45]: HNM integrates disease, drug, and target information via a HN, aiming to enhance the efficiency and accuracy of drug repositioning.
- DTINet [9]: DTINet predicts interactions between new drugs and targets by integrating heterogeneous data and learning low-dimensional feature representations.
- NeoDTI [46]: NeoDTI automatically generates feature representations by integrating diverse information from HN.
- EEG-DTI [47] : EEG-DTI is an end-to-end learning framework based on heterogeneous graph convolutional networks, capable of effectively learning features from multiple biological entities.
- SHGCL-DTI [48]: SHGCL-DTI combines semi-supervised learning with graph contrastive learning, enhancing the model's adaptability.

The performance of MVPA-DTI was compared with various models, and the experimental results are shown inTable 4. MVPA-DTI achieves the best performance, demonstrating significant improvement over other DTI models. It achieves an AUPR of 0.901, which is 1.7% higher than the second-best method, and an AUROC of 0.967, representing a 0.9% improvement over SHGCL-DTI. MSCMF employs matrix transformation to optimize prediction results through network inference and the topological structure of data. However, compared to the recent outstanding performance of deep learning methods, MSCMF does not fully exploit the latent information in data matrix embeddings or the features of adjacent nodes, thereby limiting its predictive performance. HNM does not adopt mainstream heterogeneous data embedding methods for feature representation and information integration, resulting in insufficient generalization ability and lower prediction accuracy. In contrast, DTINet, NeoDTI, and EEG-DTI further extract hidden features by combining matrix transformation with neural networks, enabling more accurate modeling of node relationships and improving prediction performance. SHGCL-DTI employs a graph contrastive learning strategy to capture the structural information of heterogeneous graphs. This is achieved by enhancing the similarity of positive sample pairs and reducing the similarity of negative sample pairs. However, SHGCL-DTI fails to fully utilize the rich semantic information and complex interaction patterns in heterogeneous graphs, presenting certain limitations when processing biological data.

XSL•FO
RenderX

Table . The AUPR and AUROC evaluation results for each model.

Model	AUPR[a]	AUROC[b]
HNM[c]	0.579	0.834
MSCMF[d]	0.603	0.856
DTINet[e]	0.818	0.916
NeoDTI[f]	0.855	0.943
EEG-DTI[g]	0.847	0.952
SHGCL-DTI[h]	0.884	0.958
MVPA-DTI (ours)[i]	0.901	0.966

[a] AUPR: area under the precision–recall curve.

[b]AUROC: area under the receiver operating characteristic curve.

[c]HNM: heterogeneous network model.

[d]MSCMF: multiple similarities collaborative matrix factorization.

[e]DTINet: drug–target interaction prediction network.

[f]NeoDTI: neural integration of neighbor information for DTI prediction.

[g]EEG-DTI: end-to-end graph for drug–target interaction prediction

[h]SHGCL-DTI: semi-supervised heterogeneous graph contrastive learning for drug–target interaction prediction.

[i]MVPA-DTI: multi-view path aggregation for drug–target interaction.

Existing methods fail to fully exploit critical biochemical information in drug molecular structures and protein sequences, potentially leading to information loss during the node embedding process. In contrast, MVPA-DTI integrates a graph attention network that incorporates all types of adjacent nodes, enhancing the extraction of composite structural information. Furthermore, it employs HAN to model the potential relationships between different types of nodes. Additionally, the method dynamically fuses features extracted from sequences and graph to update the embedding representations of drug and protein nodes. Through this process, it progressively strengthens the weight of node information and optimizes the feature representation of different types of nodes, thereby improving the predictive accuracy.

Robustness Experiment

To further validate the stability of MVPA-DTI, considering the potential presence of redundant information in the dataset, additional experiments were conducted to evaluate the model's predictive performance. First, we removed some samples from the dataset, including DTIs with similar drugs or targets and DTIs involving drugs with similar drug interactions. The details of the removed data are provided in Table 5.

Table . Number of drugs, targets, and DTIs included in the redundant data.

Redundant data	Drug number	Target number	DTI number
DTI of similar drugs or targets	146	78	955
DTI of drugs with similar side effects	17	0	51

[a]DTI: drug–target interactions.

After removing similar drugs and targets, as shown in Table 6, MVPA-DTI achieves a 15.9% improvement over the second-best method, NeoDTI. Meanwhile, Table 6 also demonstrates that after removing drugs with similar side effects, MVPA-DTI outperforms the second-best method by 3.1%.

RenderX

Table . AUPR performance of each model after adjustment of the dataset.

Model	AUPR[a]		
	DTIs[b] with similar drugs and targets were removed	DTIs with drugs with similar side effects were removed	Trained on non-unique dataset and tested on unique dataset
HNM[c]	0.547	0.581	0.233
MSCMF[d]	0.265	0.593	0.206
DTINet[e]	0.611	0.803	0.389
NeoDTI[f]	0.694	0.848	0.432
EEG-DTI[g]	0.686	0.846	0.431
SHGCL-DTI[h]	0.617	0.729	0.443
MVPA-DTI[i]	0.849	0.873	0.46

[a]AUPR: area under the precision–recall curve.

[b]DTI: drug–target interaction.

[c]HNM: heterogeneous network model.

[d]MSCMF: multiple similarities collaborative matrix factorization.

[e]DTINet: drug–target interaction prediction network.

[f]NeoDTI: neural integration of neighbor information for DTI prediction.

[g]EEG-DTI: end-to-end graph for drug–target interaction prediction.

[h]SHGCL-DTI: semi-supervised heterogeneous graph contrastive learning for drug–target interaction prediction.

[i]MVPA-DTI: multi-view path aggregation for drug–target interaction.

The experimental results indicate that although the model's performance declined after removing a significant portion of specific DTI data, MVPA-DTI still maintains the best AUPR, demonstrating its strong robustness. Additionally, this study treats drug–protein interactions as a specific case for experimentation. To objectively evaluate the predictive capability of MVPA-DTI, both special drug–target relationships and conventional drug–target relationships were separately processed. Specifically, the model was first trained on a dataset in which the relationships between drugs and proteins were nonunique and then tested on a dataset with unique interactions. As shown in Table 6, MVPA-DTI significantly outperforms the second-best method, with a 1.7% improvement in AUPR. This result suggests that MVPA-DTI exhibits stronger generalization ability in predicting DTI.

Ablation Experiment

To verify the contribution of each module in MVPA-DTI, we conducted ablation experiments. The experimental results are presented in Table 7, where ProSF represents the protein sequence feature extraction module and DruSF denotes the drug compound structure feature extraction module.

Table . Evaluation of the impact of MVPA-DTI modules on performance.

Method	AUROC[a]	AUPR[b]	F_1-score	MCC[c]
w/o[d] ProSF[e]	0.963	0.886	0.839	0.828

[d]w/o denotes corresponding module was removed.

[e]ProSF: protein sequence feature extraction module.

[f]DruSF: drug compound structure feature extraction module.

[g]protBert-MVPA-DTI replaces the ProSF module with ProtBert processing.

[h]MVPA-DTI: multi-view path aggregation for drug-target interaction.

XSL•FO
RenderX

The Effectiveness of ProSF

As shown in Table 7, the ProSF module improves the model performance by 0.3% in AUROC and 1.5% in AUPR. ProSF effectively extracts deep semantic information from proteins, capturing features related to key physicochemical properties such as secondary structure and solubility, thereby enhancing the model's predictive capability.

The Effectiveness of DruSF

As shown in Table 7, the DruSF module enhances the model's performance, with improvements of 0.2% and 1.0% in AUROC and AUPR metrics, respectively. This enhancement is attributed to DruSF's ability to thoroughly explore the structural features of drugs, thereby assigning higher weights to drugs during the message-passing process and further optimizing the prediction outcomes.

The experimental results demonstrate that the MVPA-DTI model exhibits high effectiveness in extracting the biological structural features of drugs and proteins. By deeply exploring the chemical structures, physical properties, and biological functions of drugs and proteins, the model can accurately capture the complex interaction relationships between them, thereby enhancing DTI prediction performance. Further analysis reveals that protein structural information plays a more critical role than drug structural information in the prediction process. This phenomenon may be attributed to the protein-specific LLM Prot-T5, which more effectively captures evolutionary conservation and functional relevance in protein sequences, thereby providing more discriminative feature representations for DTI prediction.

Discussion

Case Study

In evaluating the practical application of MVPA-DTI, we predicted 53 candidate drugs targeting the voltage-gated inwardly rectifying potassium channel KCNH2 (hERG). The KCNH2 channel, a critical protein in cardiac electrophysiology, plays a central role in regulating ventricular repolarization. Dysfunction or dysregulation of this channel delays ventricular repolarization, manifesting as QT interval prolongation on electrocardiograms. This phenomenon has been extensively documented to correlate with the pathogenesis of various cardiovascular diseases [49]. The results demonstrate that 38 out of the 53 candidate drugs exhibited potential interactions with KCNH2. Among these, 10 drugs have been experimentally validated in published studies to interact with the KCNH2 channel. Although the remaining candidates have not yet been experimentally confirmed, their established associations with cardiovascular pathologies suggest potential therapeutic relevance in cardiovascular disease management. Studies have demonstrated that procainamide interacts with the KCNH2 channel, primarily by inhibiting its function. This inhibition prolongs the duration of potassium ion efflux, leading to QT interval prolongation [50]. Nicotine, as a blocker of the KCNH2 channel, significantly affects the electrophysiological properties of the heart. This interaction may have important clinical implications for assessing the impact of nicotine on cardiac health [51]. Ranolazine is considered to have potential therapeutic effects, as it improves cardiac electrophysiological abnormalities caused by genetic variations by modulating the function of the KCNH2 channel [52].

In this study, AutoDock was used to perform molecular docking simulations on the interaction between procainamide and KCNH2 channel protein. As shown in Figures 2 and 3, procainamide can stably bind to the central cavity region of the KCNH2 channel protein and is embedded in a hydrophobic pocket surrounded by the S6 helix and the lamellar structure. The binding site involves multiple key amino acid residues, including THR 768, TYR 827, etc. These residues have been widely reported in the literature as core sites for regulating drug binding and gating behavior of KCNH2 channels. These binding residues are visually annotated in Figure 2. Binding mode analysis showed that hydrophobic interactions and potential hydrogen bonds were formed between procainamide and the above residues, which may interfere with the open state of the channel and affect its function. As shown in Figure 3, binding energy analysis showed that procainamide interacted strongly with KCNH2, and the binding energy of some conformations was as low as –9 kcal/mol, indicating that it has high binding stability and potential biological activity.

Conclusions

This study proposes a novel DTI prediction method MVPA-DTI, which extracts key biological features from protein and drug sequences and reconstructs them into a heterogeneous graph, enabling the model to capture the most critical biological information during each iteration, thereby optimizing the weight assignment for drugs and targets. Experimental results demonstrate that MVPA-DTI outperforms existing methods across multiple benchmark tests. Although MVPA-DTI effectively captures DTI, the biological mechanisms underlying these interactions are complex, involving multiple factors, which are not yet fully considered by MVPA-DTI. Future improvements should focus on in-depth exploration of the

XSL•FO
RenderX

biological details of DTI to enhance prediction accuracy and applicability. To enhance the ability to model the complex relationship between drugs and targets, in the future, it is possible to consider introducing new graph neural network structures such as FCGCN [53] into the drug–target graph modeling process to more effectively integrate molecular structure, pharmacological properties, and network topology information.

Abstract

Background: A large language model (LLM) provides new opportunities to advance the intelligent development of traditional Chinese medicine (TCM). Syndrome differentiation thinking is an essential part of TCM and equipping LLMs with this capability represents a crucial step toward more effective clinical applications of TCM. However, given the complexity of TCM syndrome differentiation thinking, acquiring this ability is a considerable challenge for the model.

Objective: This study aims to evaluate the ability of LLMs for syndrome differentiation thinking and design a method to effectively enhance their performance in this area.

Methods: We decomposed the process of syndrome differentiation thinking in TCM into three core tasks: pathogenesis inference, syndrome inference, and diagnostic suggestion. To evaluate the performance of LLMs in these tasks, we constructed a high-quality evaluation dataset, forming a reliable foundation for quantitative assessment of their capabilities. Furthermore, we developed a methodology for generating instruction data based on the idea of an "open-book exam," customized three data templates, and dynamically retrieved task-relevant professional knowledge that was inserted into predefined positions within the templates. This approach effectively generates high-quality instruction data that aligns with the unique characteristics of TCM syndrome differentiation thinking. Leveraging this instruction data, we fine-tuned the base model, enhancing the syndrome differentiation thinking ability of the LLMs.

Results: We collected 200 medical cases for the evaluation dataset and standardized them into three types of task questions. We tested general and TCM-specific LLMs, comparing their performance with our proposed solution. The findings demonstrated that our method significantly enhanced LLMs' syndrome differentiation thinking. Our model achieved 85.7% in Task 1 and 81.2% accuracy in Task 2, surpassing the best-performing TCM and general LLMs by 26.3% and 15.8%, respectively. In Task 3, our model achieved a similarity score of 84.3, indicating that the model was remarkably similar to advice given by experts.

Conclusions: Existing general LLMs and TCM-specific LLMs continue to have significant limitations in the core task of syndrome differentiation thinking. Our research shows that fine-tuning LLMs by designing professional instruction templates and generating high-quality instruction data can significantly improve their performance on core tasks. The optimized LLMs show a high degree of similarity in reasoning results, consistent with the opinions of domain experts, indicating that they can simulate syndrome differentiation thinking to a certain extent. These findings have important theoretical and practical significance for in-depth interpretation of the complexity of the clinical diagnosis and treatment process of TCM.

large language model; traditional Chinese medicine; RAG; instruction tuning; TCM LLMs; syndrome differentiation thinking

Introduction

In recent years, the large language model (LLM) has made significant progress in electronic medical record analysis [1], drug discovery [2], clinical decision support [3], and other medical fields [4,5]. As an important part of the health care system, traditional Chinese medicine (TCM) is known for its unique theoretical framework and complex knowledge system [6]. The LLMs offer better means to explore and understand knowledge from classic texts, prescription data, and clinical cases, laying the foundation for the clinical application of TCM.

The core concept of TCM diagnosis and treatment emphasizes a dynamic treatment strategy based on patient characteristics, which requires the LLMs to have profound medical knowledge

XSL•FO
RenderX

and adaptive reasoning ability. To address the specificity of TCM-domain knowledge, the researchers have tried to improve the model performance through domain fine-tuning by leveraging publicly available datasets, including classical TCM literature, educational materials, and clinical case records [6-8].

Some models have also integrated domain-specific pathology data such as TCM formulas and medical record files to enhance specialization and specificity. For example, BianCang [9] added clinical data on cardiology and used a two-stage training method of injecting domain knowledge and alignment to obtain results. Yang et al [10] developed ZhongJing by leveraging a Chinese multi-turn medical conversation dataset of 70,000 authentic doctor-patient dialogues, enabling the model to better capture the nuances and complexity of clinical communication.

Although existing TCM-specific LLMs demonstrated improved performance in some areas of TCM, their effectiveness in handling complex TCM tasks remains inadequate. This limitation stems from the lack of targeted reasoning training for TCM syndrome differentiation thinking. The highly context-dependent and flexible nature of TCM diagnostic reasoning necessitates a deep understanding of the intricate logic underlying disease patterns, placing higher demands on the model's comprehension and reasoning ability [11,12]. LLMs often struggle with knowledge confusion when confronted with the nuanced reasoning required for TCM syndrome differentiation. For instance, the principle of "different treatments for the same disease" is common in TCM, where varying treatment approaches and herbal prescriptions are recommended for the same condition across different texts. Such inconsistencies in the training data significantly hinder the reasoning ability of LLMs in TCM. It is worth noting that Chain-of-Thought (CoT)–based mechanisms exhibit clear limitations in this field, as the reasoning explanations generated by these models frequently devolve into nonsensical or irrelevant outputs [13]. In contrast, the direct application of Retrieval-Augmented Generation (RAG) can provide accurate contextualized hints derived from professional TCM knowledge [14].

To evaluate the capacity of LLMs for performing TCM syndrome differentiation, we developed three core tasks grounded in the foundational theories of TCM: pathogenesis inference (Task 1), syndrome inference (Task 2), and diagnostic suggestion (Task 3). For the evaluation dataset, we extracted 200 medical cases from *Essence of Modern Chinese Medicine Case Studies* [15] and standardized these cases into the corresponding task formats. Furthermore, we developed a methodology for generating instruction data based on the idea of an "open-book exam." Given each task's unique logic, we designed a specialized data template for each task type. To enhance the model's comprehension of the problem, we extracted relevant information from a local knowledge base and inserted it into predefined positions within the templates. Thus, we generated 800 high-quality instruction samples for fine-tuning the model using this approach. This method of embedding RAG content into instruction data enables the model to better understand contextual information unlike models that directly input RAG content.

Methods

Overview

To enhance the ability of existing LLMs in TCM syndrome differentiation thinking, this study proposed an instruction data generation method based on the idea of an "open-book exam." Open-book exams allow candidates to consult materials during the exam, but only those students who have mastered how to obtain and interpret the answers in advance quickly can cope with them efficiently. Similarly, we treated each type of TCM task as an "open-book exam." Incorporating domain knowledge into the instruction template enhances the LLMs' ability to reason information from the materials, enhancing their performance in TCM tasks. The method consists of three core parts: (1) designing core tasks based on TCM theory; (2) constructing domain-specific instruction data templates for different task categories; and (3) designing an evaluation method to compare and analyze LLMs.

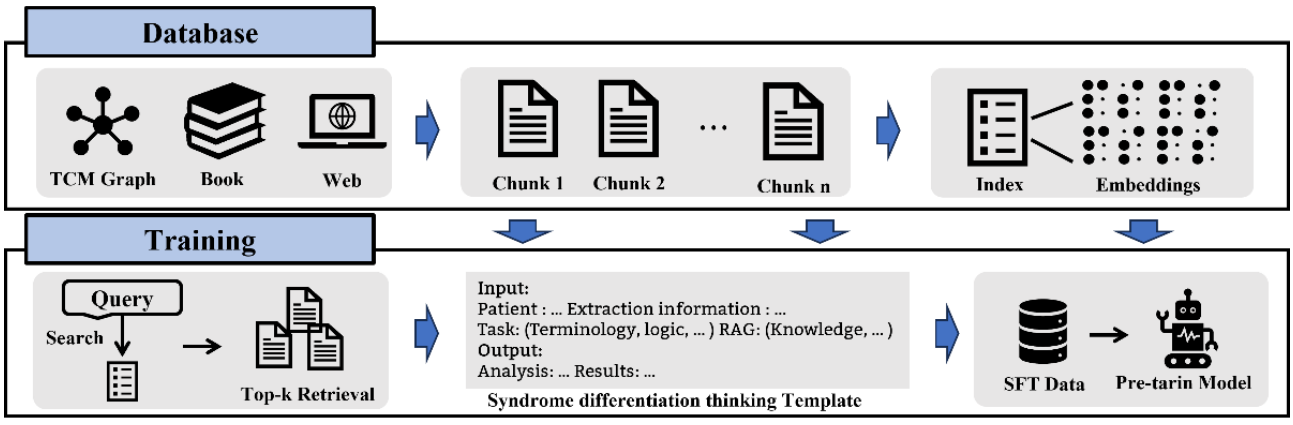
Task Decomposition

According to the TCM pathogenesis theory, the clinical process of TCM syndrome differentiation thinking requires deducing from symptoms to syndromes by analyzing the pathogenesis factors of the surface-level symptoms one-by-one and comparing the relationships between the factors. For clinical application, in addition to analyzing the pathogenesis factors, the patient's judgment also depends on understanding the integrated relationships among these factors. Based on this framework, we have extracted three core tasks: pathogenesis inference, syndrome inference, and diagnostic suggestion. The decomposition of the complex process of TCM identification into clear task modules helps the model in hierarchical analysis of the TCM identification ideas. The three tasks are explained in Table 1.

XSL•FO
RenderX

Table . Comparison of the performance of different models in three tasks.

Task	Explanation	Question format
Task 1: Pathogenesis inference	Pathogenesis refers to the mechanism of disease occurrence, development, change and outcome, including the changes and mechanisms of etiology, nature, location, and course of disease.	Select the most appropriate pathogenesis based on the clinical information. You will choose the most correct answer from options A, B, C, D, E, F, G, H, I, and J. The questions are as follows: "Clinical Information" "Pathogenesis Options"
Task 2: Symptom inference	Symptoms are a pathological summary of the body's overall response to a disease at a particular stage.	Select the most appropriate syndrome based on the clinical information. You will choose the most correct answer from options A, B, C, D, E, F, G, H, I, and J. The questions are as follows: "Clinical Information" "Syndrome Options"
Task 3: Diagnostic suggestion	Diagnostic suggestion forms a comprehensive understanding of the disease's nature. This step emphasizes summarizing the local to the whole and from phenomenon to the essence, thus guiding the formulation of treatment plans.	Write a summary and syndrome differentiation analysis based on the clinical information, core pathogenesis and syndrome. The questions are as follows: "Clinical Information" "Core Pathogenesis" "Core Syndrome"



TCM Instruction Data Generation

We treated each TCM task as an open-book exam scenario, where structured domain knowledge is embedded directly into the prompt templates, in a manner similar to the process of simulating a test-taker's responses on an exam. The model was expected to learn to use this information in specific contexts to generate accurate responses.

As illustrated in Figure 1, the local knowledge base was partitioned into distinct segments, referred to as chunks, and vector models were employed to generate embeddings. Let Q denote the question to be addressed. The knowledge base is represented as D={d1,d2, ,dn}, where di corresponds to a chunk of the document. Embeddings for each chunk are generated using a vector model, denoted as E={e1,e2, ,en}. Each chunk embedding is defined as ei=f(di), with f representing the embedding generation function. The similarity matching is established through cosine similarity, defined as follows:

$$sim(ei,Q)=ei\cdot Q \parallel ei \parallel \parallel Q \parallel$$

Figure 1. A framework for generating instruction data is formed by integrating the local knowledge base into the Syndrome Differentiation Thinking Template.

where ·represents the vector norm, and chunks exhibiting the highest similarity are selected to form the matched document set D`:

$$D'=\{di\in D \mid \sim(ej,Q)\geq\theta\}$$

In this expression, θ represents a predefined similarity threshold. The reference knowledge is then integrated into the instructional data I<Input,Output>, thereby enhancing reasoning capabilities across three tasks during practical evaluations. To incorporate domain-specific knowledge into the reasoning process, we introduce a structured template T, parameterized as Input=TQ,D`.

Data Collection

We analyzed 200 medical cases from *Essence of Modern Chinese Medicine Case Studies* [15] and systematically organized the data into categories, including patient demographics, clinical manifestations, tongue and pulse

XSL•FO
RenderX

diagnoses, etiologic factors, and diagnostic examination findings. To ensure data consistency and accuracy, nonessential or irrelevant details were excluded during the extraction process, retaining only critical information related to clinical reasoning. An illustrative example is presented in Textbox 1.

Textbox 1. Example medical case extracted from books.

The patient is a woman, 18-years-old. Sudden decline in vision of both eyes for 10 days, and blindness in the left eye for 3 days. The patient has a dull headache in the forehead, pulling pain behind the eyeball when moving the eye.

Examination: Visual acuity–Right eye 0.02, no light perception in the left eye. Moderate dilation of pupils in both eyes, sluggish light reflex in the right eye, and absence of direct light reflex in the left eye. Intraocular pressure is 18.86 mmHg in both eyes. The optic discs of both eyes are congested, mildly elevated, with blurred boundaries, disappearance of physiological cupping, dilated retinal veins, and mild edema of the retina near the optic disc in the left eye.

Western medical diagnosis: Acute optic neuritis (both eyes)

Examination as per Traditional Chinese medicine: Depressed mood, dizziness, blurred vision, flank pain, bitter taste in the mouth, and chest tightness; the tongue is red with thin yellow coating, and the pulse is wiry

Pattern differentiation: Sudden blindness (both eyes) – type of liver qi stagnation and obstruction of collaterals.

Treatment principle: It is appropriate to soothe the liver and resolve stagnation, and to unblock the channels and invigorate the collaterals. The prescription used is Shugan Mingmu decoction (an empirical formula).

Commentary: Sudden blindness refers to serious internal ocular disorders where the external appearance of the eye seems normal but there is a sudden and drastic decline in vision, or even blindness, in one or both eyes. Although the external appearance of the affected eye shows no obvious abnormalities, various pathological changes occur inside the pupil, and the etiology and pathogenesis are more complex. Due to the acute onset, early treatment should be initiated. In western medicine, various fundus diseases can cause sudden blindness, the most common being central retinal vascular occlusion and acute optic neuritis.

To enable automatic quantitative scoring, Tasks 1 and 2 were designed as multiple-choice questions, with all disease mechanisms and clinical evidence data aggregated into a standardized dataset. The answer options for these questions were generated by randomly permuting the original option set, with distractor options created by systematically rearranging plausible alternatives. While Task 3 was formatted as open-ended questions, answers were derived from source text, with scores calculated via cosine similarity between answer embeddings.

Ethical Considerations

This study used data from published medical records in publicly available literature, which did not involve human subjects or contain personally identifiable information. Accordingly, ethics committee approval was not required.

Experimental Setup

The base model used in this study was InternLM2-Chat2-20B-SFT [16], which has been pretrained on domain-specific knowledge from TCM. This enables the model to effectively address complex medical scenarios and perform basic TCM question-and-answer tasks without requiring further fine-tuning. Text embeddings were generated using Acge-Text-Embedding [17]. For general LLMs, we used the official API interface, while for TCM LLMs, we deployed reasoning locally. Specifically, the experiments were conducted on a single NVIDIA A6000 GPU (48 GB memory). All model weights were publicly available via the Hugging Face Hub. Instruction tuning was performed using the Llama Factory framework [18], with LoRA integration. The hyperparameters were configured with a learning rate=2×10−4 and training epochs set to 5. After fine-tuning, parameter consolidation of the optimized modules was sufficient for deployment.

Results

We establish scoring criteria for each task. For Tasks 1 and 2, scores were calculated using a proportional multiple-choice method, computed as the ratio of correct responses to the total number of options presented. For Task 3, the cosine similarity between the model output and the standard output was determined. The resulting similarity scores were then linearly scaled to a range of 0 - 100, with higher values indicating greater similarity.

As demonstrated in Table 2, our model achieved superior performance across all three tasks, with accuracy rates of 85.7% and 81.2% for Task 1 and Task 2, respectively, and a similarity score of 84.3 for Task 3. In contrast, the powerful general model, ChatGPT4 performed poorly in Task 1 and Task 2, with accuracy rates of only 24.4% and 36.3%, respectively, but achieved a score of 78.2 in Task 3. Task 3 is an open-ended generative task, evaluated using cosine similarity, which emphasizes linguistic fluency and semantic coherence rather than factual accuracy. This evaluation criterion aligns well with ChatGPT-4's strength in generating natural and coherent language, even when its underlying understanding of TCM is limited. In contrast, Tasks 1 and 2 demand a deeper comprehension of specific TCM concepts, where the lack of specialized training in TCM becomes more evident in ChatGPT-4's performance. Additionally, DeepSeek-v3 and Qwen-max demonstrated more balanced performance across multiple tasks, with scores consistently exceeding the range of 50% to 60%, likely due to their targeted training in TCM-related tasks. Our model demonstrates strong advantages in both accuracy and similarity across structured TCM tasks, highlighting its effectiveness in domain-specific reasoning and output generation.

[a]Task 1: Pathogenesis inference.

[b]Task 2: Symptom inference.

[c]Task 3: Diagnostic suggestion.

Discussion

Comparison With Other Works

To better contextualize our proposed TCM LLM, we compare it with four representative models: ShenNong [24], BianCang [9], HuangDi [25], and ZhongJing [10]. These models were selected due to their prominence in the TCM domain, publicly available methodologies, and diverse approaches to integrating TCM knowledge into LLMs. Each model reflects a distinct strategy in data sourcing, architectural design, or application focus, making them suitable benchmarks for evaluating our method. Specifically, ShenNong compiles an extensive dataset of TCM information and generates a knowledge graph, which serves as a benchmark for creating over 110,000 TCM-related instruction data points to train a foundational model. BianCang integrates a vast collection of ancient TCM texts, modern educational materials, and clinical data, offering users precise TCM knowledge quizzes, diagnostic support, and treatment recommendations. HuangDi is built on the Ziya-LLaMA-13B-V1 base model and incorporates TCM textbooks, website data, and other TCM corpora, demonstrating a notable comprehension of TCM knowledge. ZhongJing enhances the model's proficiency in TCM clinical diagnosis and treatment by training it on classical TCM literature.

As demonstrated in Table 3, BianCang outperforms all other TCM LLMs by achieving accuracy rates of 59.3% and 65.4% on Tasks 1 and 2, respectively, and scoring 69.6 on Task 3. Although BianCang benefits from training on case diagnosis data, thereby enhancing its understanding of syndrome differentiation, it still underperforms compared to our proposed solution across all tasks. These results suggest that relying exclusively on domain-specific training data proves inadequate and significantly constrains a model's capacity for TCM reasoning. These results underscore that our approach not only outperforms existing TCM LLMs but also represents a meaningful advancement in the integration of domain knowledge with deeper reasoning capabilities.

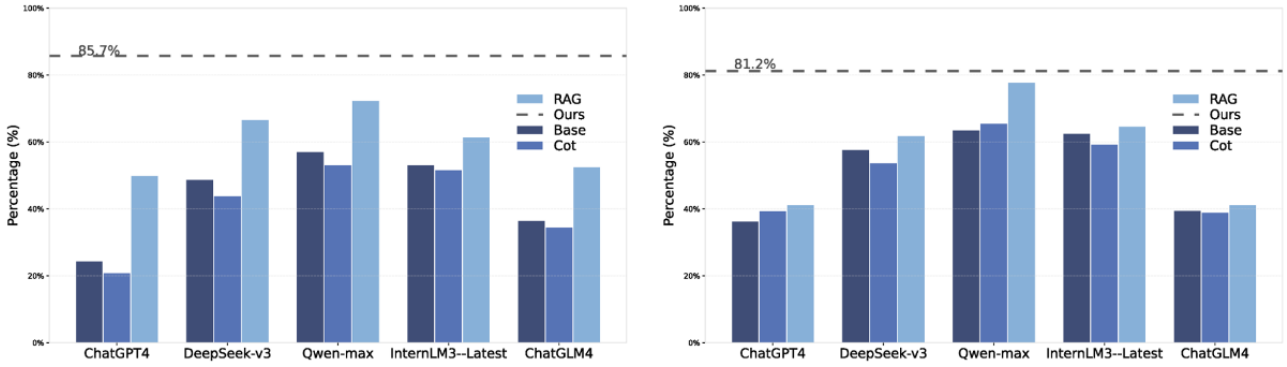
Table . Performance comparison of TCM LLMs across multiple tasks.

Models	Task 1,[a] (%)	Task 2,[b] (%)	Task 3,[c] (score)
ShenNong	42.2	53.3	42.8
BianCang	59.3	65.4	69.6
HuangDi	32.4	45.6	52.4
ZhongJing	38.1	36.5	59.6
Our study	85.7	81.2	84.3

[a]Task 1: Pathogenesis inference.

[b]Task 2: Symptom inference.

[c]Task 3: Diagnostic suggestion.



To more systematically evaluate the performance advantages of the proposed method, we also selected two popular LLMs enhancement methods for comparison: CoT, and RAG. Specifically, CoT significantly improves the model's logical reasoning ability in a step-by-step manner by guiding it to gradually generate intermediate reasoning steps, thereby showing higher interpretability and accuracy in complex tasks. On the other hand, RAG expands the model's knowledge coverage and enhances its contextual understanding and domain adaptability by dynamically retrieving and integrating external knowledge during generation. We retained the base model without any enhancement methods as the baseline control group, referred to as Base, to comprehensively measure the relative performance improvements across different methods.

As illustrated in Figure 2, RAG demonstrated significant performance advantages in both Task 1 and Task 2. The accuracy of all models using RAG exceeded that of the Base and CoT setups. With RAG, Qwen-max showed improvements of 15.3% and 14.2% in Tasks 1 and 2, respectively. This indicates that integrating external knowledge enhances the

XSL•FO
RenderX

overall accuracy of model responses. In contrast, the effectiveness of CoT varied significantly depending on the task type and model characteristics. For instance, in Task 2, the performance of some models using CoT is even lower than that of the Base configuration. For example, ChatGPT4's accuracy drops from 39.4% to 36.3%. This decline may be attributed to the increased complexity of Task 2, where relying solely on the model's internal knowledge is insufficient to meet the reasoning demands.

Figure 2. Performance comparison of RAG, CoT, and Base models across Two Tasks; Task 1 pathogenesis inference (left), Task 2 symptom inference (right). CoT: Chain-of-Thought; RAG: Retrieval Augmented Generation.

To explicitly compare the differences between the three methods, we present the results of a case in Task 3, as shown in Figure 3. The ground truth revealed four key conclusions: (1) the condition was attributed to kidney deficiency; (2) kidney deficiency caused weakness in the lower limbs; (3) the condition was identified as wind-induced paralysis; and (4) blood deficiency contributed to the pathology of "wind."

Figure 3. Comparison of results on Task 3: CoT, RAG and our method. CoT: Chain-of-Thought; RAG: Retrieval Augmented Generation.

Mr. xx, male, 45 years old, experienced weakness in his lower limbs and fell to the ground. After walking a few more steps, his limbs feel heavy, and he is prone to falling. He experiences a feeling of soreness and tenderness in the lumbar region; there are no abnormalities on the surface of the lower limbs, and the sense of touch is normal. Prolonged standing makes him feel like he might fall.
Western medical diagnosis: narrowing of the lumbar vertebrae 4 and 5, with compression on the spinal nerves and descending fibers. He was diagnosed with "spinal stenosis."
TCM Examination: Pulse is deep and fine, tongue is dull, and the coating on his tongue is thin and yellow.

Ground Truth: This condition is caused by kidney deficiency. The lower back is the residence of the kidneys, and the spine is the pathway of the Governing Vessel (Du Mai), which is connected to the kidneys. When kidney qi is insufficient, the Governing Vessel also becomes deficient. The lower limbs are linked to the Lesser Yin meridian network, and the Governing Vessel governs the lower limbs. When the Governing Vessel is weak and empty, the lower limbs lose their support, making it easy to fall. In ancient times, this was referred to as "wind-induced paralysis". When blood is deficient, it generates wind, and "Fei" implies dysfunction, thus resulting in weakness and lack of strength in the lower limbs.

CoT: 1: The patient's primary pathological mechanism is insufficiency of kidney qi and internal heat. This serves as the foundation for understanding the symptoms described. Kidney qi plays a vital role in nourishing the lumbar region. 2: When kidney qi is deficient, the lumbar region lacks proper nourishment. This deficiency leads to soreness and weakness in the lower back, which is one of the key symptoms observed. 3: Internal heat is another component of the pathological mechanism. It typically presents with specific signs, such as a thin, yellow tongue coating. This symptom helps confirm the presence of internal heat in the patient.

RAG: The core pathogenesis of this case is insufficiency of kidney qi, stagnation of qi and blood stasis, and internal heat due to blood deficiency. Based on the key pathological mechanism of kidney qi deficiency and liver wind combined with phlegm, the obstruction of the channels by phlegm turbidity leads to impaired circulation of qi and blood, resulting in qi stagnation and blood stasis. This causes a pattern of lower extremity weakness and upper body symptoms, giving rise to the manifestations of "wind-induced paralysis".

Ous: The chief complaint and clinical manifestations of this patient correspond with the description of "wind-induced paralysis". Combined with the patient's pulse and tongue signs, the condition can be differentiated as insufficiency of kidney qi and wind generated from blood deficiency. The treatment approach should focus on tonifying the kidney and boosting qi, nourishing the blood to calm the wind, while also resolving phlegm and unblocking the orifices, with the aim of restoring limb function.

In the CoT results, the model erroneously inferred the irrelevant factor 'internal heat.' This discrepancy may stem from the limitations of LLMs' knowledge, which cannot fully support the accurate processing of complex dialectical reasoning tasks. On the other hand, most of the conclusions from RAG align with the ground truth. But the method incorrectly proposed the diagnosis of 'blood stasis,' which may be attributed to the increased complexity of the context. Our method successfully derived all key conclusions and effectively mitigated reasoning biases caused by insufficient knowledge, excessive contextual complexity, and challenges faced by other methods.

Limitations and Future Research

The approach proposed in this paper demonstrates significant advantages in TCM syndrome differentiation thinking. However, there remains room for further refinement when addressing highly intricate and dynamic scenarios in TCM diagnosis and treatment. While the current knowledge base draws extensively from classical literature and clinical case studies, potential biases in coverage may exist. This bias stems from the fact that the literature tends to reflect the medical understanding and insights of the time, which may not be fully compatible with the contemporary clinical context or with different patient

XSL•FO
RenderX

populations. In addition, some aspects of diagnostic experience favor specific diagnostic and treatment methods, which can limit their applicability and accuracy in real-world clinical decision-making. Expanding the knowledge base by integrating updated clinical data and interdisciplinary insights could further enhance the LLMs' ability. Future research should explore dynamic task decomposition strategies to deepen the LLMs' understanding and improve its adaptability to the nuances of TCM theories.

Conclusions

In conclusion, this study presents an innovative methodology integrating RAG with instruction fine-tuning to enhance LLMs' syndrome differentiation thinking ability. Our approach achieved state-of-the-art performance in three core tasks: pathogenesis inference, syndrome inference, and diagnostic suggestion, outperforming both general and TCM LLMs. These findings underscore the importance of incorporating domain-specific knowledge and structured task decomposition to address the unique challenges of TCM reasoning. Although the proposed framework demonstrates significant potential, further advancements are necessary to handle complex, dynamic scenarios and improve conversational abilities.

Abstract

Background: Electronic health records (EHRs) contain comprehensive information regarding diagnoses, clinical procedures, and prescribed medications. This makes them a valuable resource for developing automated hypertension medication recommendation systems. Within this field, existing research has used machine learning approaches, leveraging demographic characteristics and basic clinical indicators, or deep learning techniques, which extract patterns from EHR data, to predict optimal medications or improve the accuracy of recommendations for common antihypertensive medication categories. However, these methodologies have significant limitations. They rarely adequately characterize the synergistic relationships among heterogeneous medical entities, such as the interplay between comorbid conditions, laboratory results, and specific antihypertensive agents. Furthermore, given the chronic and fluctuating nature of hypertension, effective medication recommendations require dynamic adaptation to disease progression over time. However, current approaches either lack rigorous temporal modeling of EHR data or fail to effectively integrate temporal dynamics with interentity relationships, resulting in the generation of recommendations that are not clinically appropriate due to the neglect of these critical factors.

Objective: This study aims to overcome the challenges in existing methods and introduce a novel model for hypertension medication recommendation that leverages the synergy and selectivity of heterogeneous medical entities.

Methods: First, we used patient EHR data to construct both heterogeneous and homogeneous graphs. The interentity synergies were captured using a multihead graph attention mechanism to enhance entity-level representations. Next, a bidirectional temporal selection mechanism calculated selective coefficients between current and historical visit records and aggregated them to form refined visit-level representations. Finally, medication recommendation probabilities were determined based on these comprehensive patient representations.

Results: Experimental evaluations on the real-world datasets Medical Information Mart for Intensive Care (MIMIC)-III v1.4 and MIMIC-IV v2.2 demonstrated that the proposed model achieved Jaccard similarity coefficients of 58.01% and 55.82%, respectively; areas under the curve of precision-recall of 83.56% and 80.69%, respectively; and F_1-scores of 68.95% and 64.83%, respectively, outperforming the baseline models.

Conclusions: The findings indicate the superior efficacy of the introduced model in medication recommendation, highlighting its potential to enhance clinical decision-making in the management of hypertension. The code for the model has been released on GitHub.

hypertension medication recommendation; electronic health records; heterogeneous graph; multihead graph attention mechanism; time series selective mechanism

Introduction

Background

Hypertension represents a prevalent chronic condition and serves as a significant contributor to cardiovascular mortality, making timely pharmacological intervention for blood pressure management crucial [1]. With the increasing trend of an aging population, the growing number of patients with hypertension has placed a significant burden on health care systems [2]. Consequently, automated medication recommendation systems for hypertension have been developed.

XSL•FO
RenderX

Prior Work and Limitations

Early hypertension medication recommendation methods were primarily rule-based. For example, Wu and Xie [3] developed a hypertension ontology and reasoning rules to recommend appropriate antihypertensive medications to patients. However, these methods relied only on predefined rules and a limited set of case data, neglecting other critical patient information, which resulted in recommendations that lacked flexibility and personalization. In recent years, numerous neural network models for recommending hypertension medications based on electronic health records (EHRs) have been proposed [4,5]. These models have shown improved outcomes and effectively address many limitations inherent in earlier algorithms.

Nevertheless, the complexity of EHR data continues to present significant challenges for medication recommendation tasks, particularly in 2 critical areas: insufficient synergy among heterogeneous medical entities and neglect of temporal dynamics in the patient's condition.

Insufficient Synergy Among Heterogeneous Medical Entities

EHR data contains heterogeneous but interrelated medical entities—such as diagnoses, procedures, and medications—that jointly influence treatment outcomes. For example, a diagnosis indicates a patient's health status, which subsequently informs procedure and medication decisions. Effective modeling of such cross-entity relationships is essential for generating accurate and personalized treatment recommendations.

Existing approaches like Multilevel Medical Embedding (MiME) [6] and graph convolutional transformer (GCT) [7] attempt to model medical concepts and their causal relations using homogeneous graph structures. However, these structures fail to capture the inherent heterogeneity across EHR entities. The Heterogeneous Information Network for Medical Diagnosis (HeteroMed) [8] introduces semantic associations via metapaths, but it does not model dynamic interentity interactions. CausalMed [9] explores causal inferences between treatment elements but overlooks the reinforcement between medications and procedures. Graph transformers of bidirectional encoder representations from transformers on EHRs (GT-BEHRT) [10] integrates graph transformers with temporal modeling yet does not incorporate contextual synergy among entities.

Further, current models inadequately balance efficacy and safety. For instance, Graph-Augmented Memory Networks (GAMENet) [11] uses a drug-drug interaction (DDI) graph to reduce adverse effects but does not consider diagnostic and procedural inputs. Graph-augmented bidirectional encoder representations from transformers (G-BERT) [12] extends to multientity modeling yet omits DDI-aware safety metrics. Competitive neural network (CompNet) [13] faces issues with computational efficiency and model stability on large-scale datasets. Recent work like that by Yang et al [14] (using medication molecular structure graphs) and Li et al [15] (using contrastive learning) enhance representation power, but they still lack a unified mechanism for modeling both "multientity synergy" and "safety constraints."

Neglect of Temporal Dynamics in the Patient's Condition

As a chronic disease, hypertension evolves over time. In clinical practice, treatment strategies are often adjusted based on both current and historical visit data. Hence, capturing the temporal dynamics of the patient's condition is essential for effective medication recommendation.

Several studies have addressed sequential modeling. Yang et al [16] used dual medical sequences to represent medication history but did not account for intersequence relationships. Liu et al [17] developed 3 long short-term memory (LSTM) variants to model correlations across medical sequences but failed to consider the immediate influence of current clinical status. Although models like the Reverse Time Attention model (RETAIN) [18] use attention mechanisms to prioritize relevant historical visits and An et al [19] introduced hierarchical temporal modeling, these methods primarily focus on general temporal behavior without consideration for hypertension-specific patterns like long-term management or phased treatment adjustment.

Advanced designs have attempted to improve modeling capabilities. Le et al [20] used a memory-enhanced neural network to represent long-term dependencies, while Yang et al [21] adopted a residual mechanism to capture patient status transitions. Wu et al [22] introduced a transformer with a "copy-generate" mechanism to decide whether to reuse previous prescriptions. However, none of these methods fully addresses the task-specific temporal dynamics required for hypertension medication recommendations.

Objective and Contributions

To address the aforementioned limitations, this study proposed CSRec, a novel hypertension medication recommendation framework that integrates the synergistic interactions of heterogeneous medical entities with selective modeling of temporal progression. CSRec is designed to capture cross-entity synergies through both heterogeneous and homogeneous graph construction based on EHR data, model time-aware patient representations using a temporal selectivity module that weighs current versus historical visits, and enhance safety by incorporating DDI information in the recommendation process.

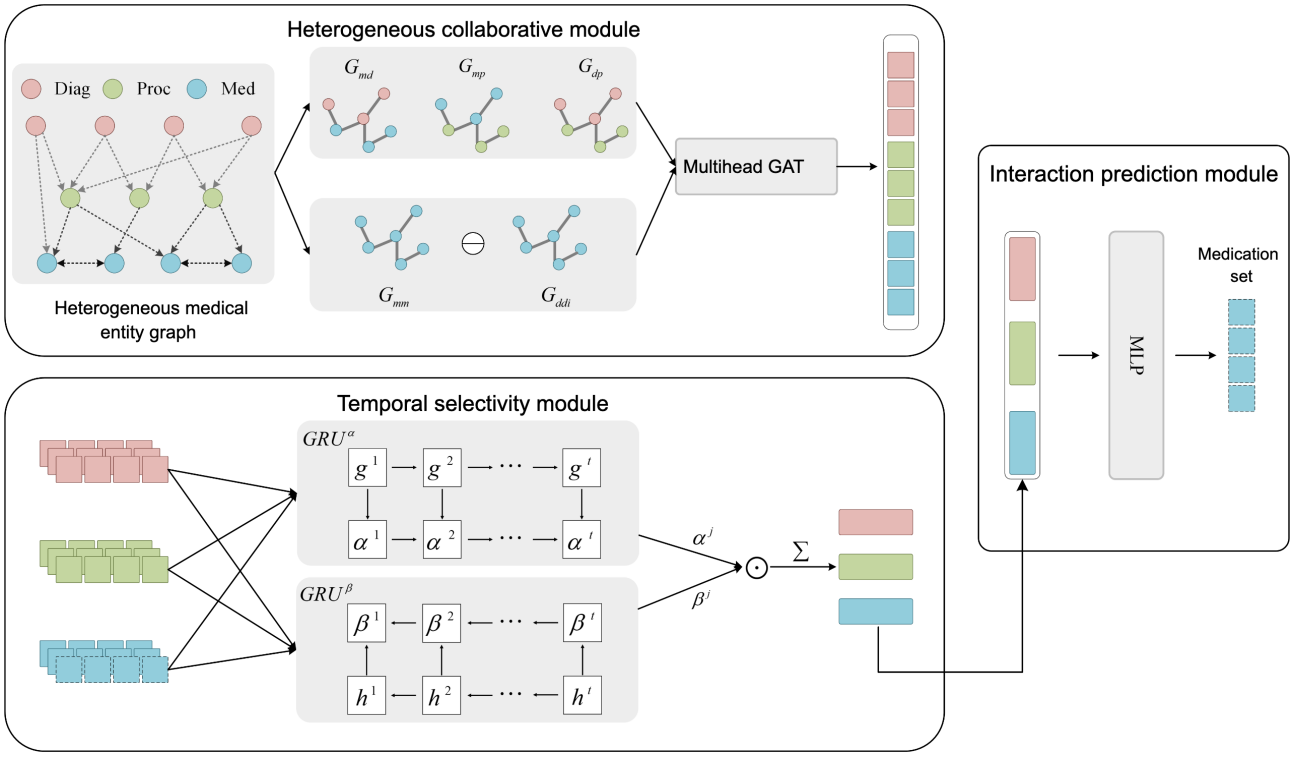
The primary contributions of this paper are summarized in the following paragraphs.

We propose a novel medication recommendation model, named CSRec, specifically designed for hypertension treatment. CSRec effectively integrates the synergistic interactions and selective characteristics among diverse medical entities. By constructing a heterogeneous medical entity graph derived from EHRs, our model utilizes a graph attention mechanism to generate enhanced collaborative embeddings among medical entities. Additionally, a temporal selection mechanism was incorporated to simulate hypertension progression, thereby producing a comprehensive patient representation to facilitate accurate medication recommendations.

To better capture synergistic relationships between medical entities, we innovatively modified the traditional graph attention

XSL•FO
RenderX

network (GAT) to focus more on neighboring node information, thus obtaining a more aggregated representation of the principal nodes.



Extensive experiments on the publicly available datasets Medical Information Mart for Intensive Care (MIMIC)-III [23] and MIMIC-IV [24] were conducted to validate the superiority and effectiveness of our proposed method.

Methods

Overview

In this section, we present a comprehensive description of the CSRec model's structure. As depicted in Figure 1, our model comprises 3 core modules for end-to-end hypertension medication recommendations: (1) The Heterogeneous Collaborative Module, with heterogeneous and homogeneous graph networks, learns entity-level representations by aggregating collaboration patterns between medical entities, which are then passed to the Temporal Selectivity Module; (2) the Temporal Selectivity Module, using a bidirectional selection mechanism, processes these entity-level representations to calculate relevance coefficients between current and previous visits, generating visit-level entity representations that are transmitted to the Interaction Prediction Module; and (3) the Interaction Prediction Module concatenates these visit-level entity representations to enrich entity information, forming a patient representation. This is converted into medication recommendation probabilities, with medications exceeding a threshold output as results.

Problem Formulation

Electronic Health Records

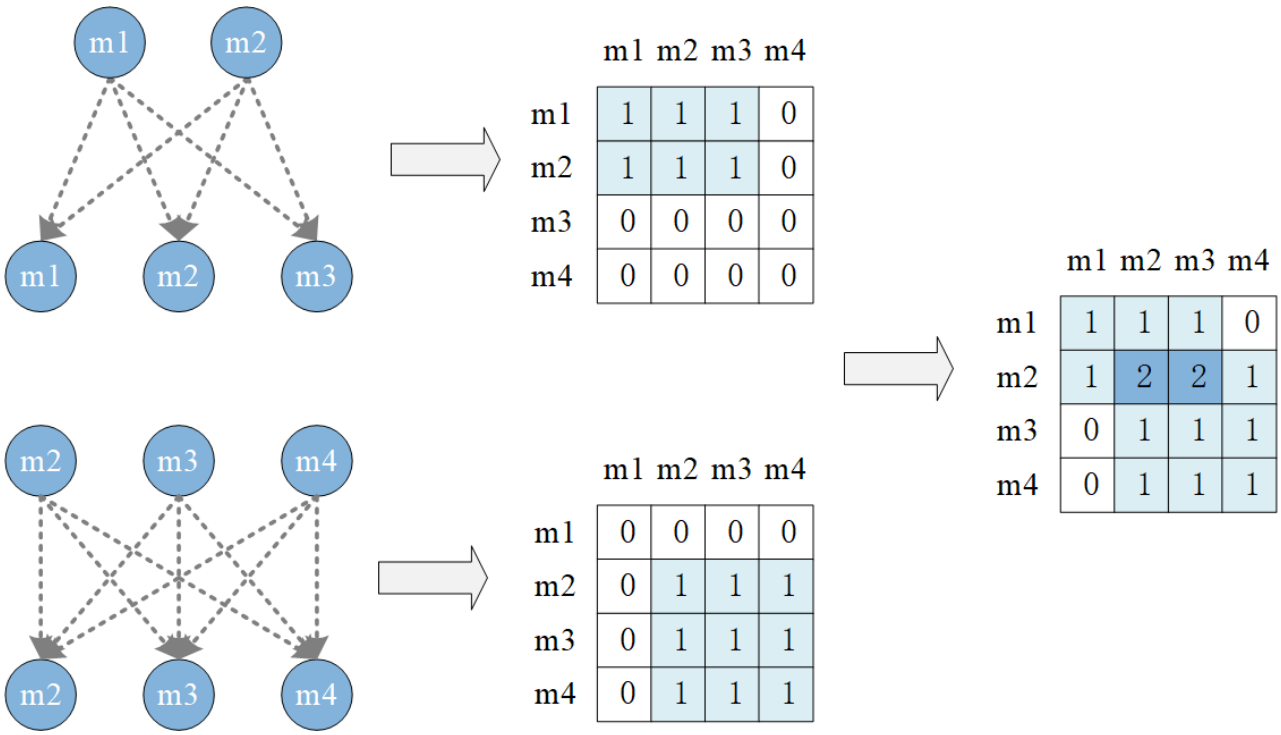
EHRs encompass a variety of medical visit information collected from patients. For a specific patient, EHRs can be structured into a sequence comprising multiple clinical visit records, represented as V=V1,V2, ,VT, where Vt represents the t-th visit and T indicates the total number of visits for that patient. Specifically, each clinical visit Vt can be represented as Vt=Vdt,Vpt,Vmt, in which Vdt∈ 0,1D, Vpt∈ 0,1P, and Vmt∈ 0,1M represent multihot encoded vectors corresponding to diagnosis, procedures, and medications, respectively. Here, the notation indicates the total number of distinct categories within each respective medical entity type.

Heterogeneous Medical Entities

In this paper, distinct medications were modeled as medication entities. Each medication recorded in the EHR corresponds to a unique medication entity, identified by a specific identifier denoted as m1,m2, , and each entity is independently embedded within the model using embeddings of identical dimensionality. Likewise, diagnoses and procedures were categorized into diagnostic entities and procedural entities, respectively. Collectively, these 3 categories of entities were termed heterogeneous medical entities.

Hypertension Medication Recommendation

Based on the patient's current diagnostic information Vdt, procedural data Vpt, historical visit sequence V=V1,V2, ,VT−1, and heterogeneous medical entity graph G, the model recommends appropriate antihypertensive medications y^t∈ 0,1M to the patient.



XSL•FO
RenderX

Heterogeneous Collaborative Module

For a specific patient, we first constructed a medication homogeneous graph, which was explicitly designed to characterize relationships between medications and provide a foundation for subsequent cross-entity modeling. This graph comprised 2 components, both of which take medications as the sole node type.

One component is the medication collaboration graph Gmmt−1=Mt−1,Amm, which serves to capture the patterns of combined medication use in clinical practice. Specifically, Mt−1 denotes the collection of all prescribed medications from the patient's previous visits, and Amm signifies the adjacency matrix representing collaborative interactions among medications. Each entry within this adjacency matrix indicates the initial collaboration weight between the respective medication nodes. The detailed procedure for generating this matrix is illustrated in Figure 2. Initially, Amm is set as a zero matrix. If medication i and medication j co-occur during a specific visit, then Ai,j=1; if medication i and j co-occur across multiple visits, the corresponding value in Amm is incremented, with higher values indicating stronger collaboration between the medications.

Figure 2. The medication-medication synergy matrix construction process.

Each medication node m∈ Mt−1 in the graph corresponds to its initial embedding vector, expressed as:

(1)em=Vmt−1Em

Specifically, Em refers to the embedding matrix associated with medication entities. The selector vector Vmt−1 specifically extracts the relevant embedding from Em for the medication at the previous time step t-1.

Moreover, some medications may have harmful interactions (DDI) and should be avoided when used together. To address this, we integrated the medication collaboration graph Gmm with the medication safety graph Gddi , enhancing the comprehensive representation of the medication nodes. Notably, the methodology used to construct the medication safety graph Gddi closely mirrors that of Gmm. Specifically, we used Addi as the adjacency matrix, where Addii,j=1 signifies that the i-th and j-th medications exhibit a paired harmful medication interaction.

(2)Gm=Gmm−λGddi

Subsequently, we adopted a GAT-based graph neural approach to obtain embeddings for medication nodes within the medication graph Gm.

First, we utilized the attention mechanism to calculate the attention coefficients between a node and its neighbors, followed by normalization:

(3)αij(m)=expgijm∑k∈ Ni(m)expgikm

Here, gijm=LeakyℜLUβmThim // hjm denotes the output of the LeakyReLU activation function applied to the linear transformation of the concatenated feature vectors himand hjm, parameterized by the learnable weight vector βm. The notation Ni(m) represents the neighboring node set of node mi in the graph Gm, while // signifies the vector concatenation operation.

Second, we used the calculated attention coefficients to perform weighted aggregation of neighbor nodes, thereby obtaining the representation of node mi:

(4)eim=σ∑j∈ Nimγijmhjm

To overcome the limitations posed by single-view attention, we further introduced a multihead attention mechanism, using a linear layer to map node representations into multiple subspaces,

XSL•FO
RenderX

then aggregate representations under each subspace. Formally, this operation is expressed as:

(5)eim=// h=1Hσ∑j∈ Nimhγijmhhjmh

In this equation, H denotes the total number of attention heads, the superscript h indicates the current attention head index, and // represents concatenating outputs from different heads. Through this strategy, distinct node-specific information is captured across various dimensions and integrated from multiple subspaces, thereby significantly improving the precision and robustness of the learned node representations.

During the training process, each medication entity is updated according to the aforementioned steps, resulting in an aggregated representation of the medication set Vm=vm1,vm2, vmt−1.

Similarly, to capture the unique clinical relationships of hypertension, such as the interactions between comorbidities, long-term monitoring data, and combination therapy dynamics, we defined 3 heterogeneous complete graphs: diagnosis-procedure graph Gdpt=Dt,Pt,Adp, medication-diagnosis graph Gmdt=Mt−1,Dt,Amd, and medication-procedure graph Gmpt=Mt−1,Pt,Amp. This established an association model that is crucial for accurate hypertension medication recommendations but has low correlation with other medication categories. Following a similar learning approach to the medication graph Gm, we first initialized the diagnosis and procedure nodes in the 3 heterogeneous graphs.

(6)ed=VdtEd,ep=VptEp

Using the approach outlined in equations (3)-(5), we then learned from the diagnosis-procedure graph to obtain aggregated sets of diagnosis codes Vd=vd1,vd2, vdt and procedure nodes Vp=vp1,vp2, vpt.

Finally, based on the aggregated medication nodes from the medication graph Gm and the learned diagnosis and procedure nodes from the diagnosis-procedure graph Gdp, we learned from the medication-diagnosis graph Gmd and the medication-procedure graph Gmp, updating to obtain entity-level representations of the medication, diagnosis, and procedure sets:

VD={Vd1,Vd2, Vdt}

VP={Vp1,Vp2, Vpt}

(7)VM={Vm1,Vm2, Vmt−1}

It is noteworthy that this study used a multihead GAT mechanism to learn and update nodes within the graph. Although traditional GAT models consider intrinsic features and aggregate neighboring features, our proposed heterogeneous graph-based method places greater emphasis on enhancing the embeddings of medications, diagnoses, and procedures by explicitly modeling interactions among diverse medical entities. Consequently, our model focuses more intensively on neighboring nodes to prevent excessive node information merging. To this end, we modified the standard GAT approach to explicitly focus on information derived from neighboring nodes within the heterogeneous graph learning process.

Temporal Selectivity Module

To effectively model the temporal evolution of patient health conditions, this paper introduces a bidirectional temporal selection mechanism using gated recurrent units (GRUs), with 3 key innovations that distinguish it from conventional applications.

First, we adopted a bidirectional temporal architecture to capture multiscale temporal dependencies. Specifically, we first used GRUα to learn the diagnostic sequence, generating forward diagnostic selection coefficients that emphasize the impact of historical visits on current states (eg, past hypertensive crisis records influencing present medication titration):

(8)g1,g2, ,gt=GRUdαVd1,Vd2, ,Vdt

(9)αj=tanhWαgj+bα,j=1, ,t

Concurrently, a backward GRUβ was used in the reverse temporal order to learn the diagnostic sequence, generating backward selection coefficients at different time steps that highlight recent critical changes. For example, recent fluctuations in blood pressure require immediate therapeutic adjustment. This bidirectional design enhances computational stability while overcoming the limitations of unidirectional GRUs or traditional recurrent neural networks (RNNs), which often overlook either long-term or short-term temporal cues:

(10)ht,ht−1, ,h1=GRUdβVdt,Vdt−1, ,Vd1

(11)βj=tanhshrinkWβhj+bβ,j=t, ,1

Second, we proposed an adaptive selection coefficient integration strategy. Based on the generated bidirectional diagnostic selection coefficients, we can capture key visit information and entity information within the visit sequence, rather than relying on static aggregation methods. This allowed us to capture key visit information and entity interactions, thereby obtaining a diagnostic representation that integrates historical context with current needs:

(12)dt=∑j=1tαjβj⊙Vdj

Third, leveraging GRU's inherent advantages, our design achieved computational efficiency without sacrificing performance. Compared with traditional RNNs, GRU effectively mitigates gradient vanishing issues; relative to LSTMs, its simplified gating mechanism reduces parameter complexity by avoiding redundant memory cells, resulting in faster training efficiency, a critical advantage for handling large-scale longitudinal EHR data in medication recommendation tasks. After a series of similar processing steps, we obtained the patient's final procedural and medication representations.

(13)pt=∑j=1tαjβj⊙Vpj,mt−1=∑j=1t−1αjβj⊙Vmj

Interaction Prediction Module

Based upon the outputs generated by the aforementioned modules, for the patient's t-th visit, we concatenated the medical entity sequence to make medication recommendations:

(14)yt=σ([dt;pt;mt−1])

In our approach, the medication recommendation task is formulated as a multilabel classification problem [25,26]. To address the complexities and potential imbalances in medical

XSL•FO
RenderX

datasets, we used a comprehensive strategy during model training. We enhanced the model's generalization capabilities and mitigated overfitting through the use of regularization techniques, which limit the complexity of the parameters learned. Additionally, an early-stopping mechanism was implemented to curtail training based on validation set performance. To optimize parameters, we used the Adam optimization algorithm [27], which minimizes the binary cross-entropy loss function to promote efficient and stable model convergence.

$$(15)L=-\sum t=1T\sum i=1|M|yitlog\ y\hat{}it+(1-yit)log\ (1-y\hat{}it)$$

Ethical Considerations

This study made use of the standardized, publicly available MIMIC-III and MIMIC-IV datasets from the Massachusetts Institute of Technology [23,24] and was therefore deemed exempt from ethical approval requirements. Prior to their release, these datasets underwent comprehensive ethical review and privacy protection processes conducted by the data provider (Massachusetts Institute of Technology). These processes included deidentifying all personally identifiable information in patients' EHRs, such as names, hospital admission numbers, and dates of birth. Additionally, the datasets' usage license explicitly covers secondary analysis scenarios for academic research, eliminating the need for users to obtain additional ethical approval independently. Since this study did not involve independent collection of human subject data and solely relied on the aforementioned publicly available and compliant existing datasets for secondary analysis, we do not possess separate ethical approval documents to provide. The ethical approval statement is published on the official website of the data provider [23,24], and we can be contacted to obtain the original copy of the datasets' usage license.

Results

Dataset Description

Our experiments were conducted using the MIMIC-III v1.4 and MIMIC-IV v2.2 datasets provided by the Massachusetts Institute of Technology. The datasets comprise medical records collected from patients admitted to intensive care units, such as diagnoses, procedures, and medications. The diagnostic and procedural information uses the *International Classification of Diseases, Ninth Revision* (*ICD-9*) coding system. To study medication recommendations for patients with hypertension, this paper extracted relevant data from the aforementioned datasets based on the *ICD-9* hypertension codes under the guidance of clinical experts. Meanwhile, referring to previous research norms [4,21,22], patients who completed at least two visits were included, and medications with a frequency <2000 occurrences were excluded.

During data analysis, we observed that the number of frequently used antihypertensive medications was relatively limited and the recommendations based on overly broad Anatomical Therapeutic Chemical (ATC) categories often lacked the specificity needed for precise clinical decision-making. Given the systematic medication classification framework of the ATC classification system, this study overcame the limitation of previous studies that only focused on the ATC04 level for recommendation. It not only predicted the medication categories at the ATC04 level (such as C02A, anti-adrenergic medications with central effects) but also further refined to the specific medication types at the ATC05 level (such as C02AA, reserpine-like medications).

After data extraction, we carried out meticulous preprocessing. We normalized features to standardize the scale of different variables, which prevented certain features from dominating others during model training. Moreover, we selectively chose variables most relevant to hypertension medications. Finally, the preprocessed dataset was partitioned into training, validation, and testing subsets according to a ratio of 23:16:16.

Detailed information about the dataset used in the experiments and examples from patients are shown in Table 1 and Table 2.

Evaluation Metrics

To validate the effectiveness of CSRec, the evaluation metrics described in the following sections were used.

Jaccard Similarity Coefficient

A higher Jaccard coefficient reflects greater overlap between the predicted medication set and the actual medication set.

(16)Jaccard=1T∑t=1T|yt∩y^t||yt∪y^t|

Area Under the Curve of Precision-Recall

A high area under the curve of precision-recall (PRAUC) indicates that the model recommends appropriate medications while keeping a low error rate.

(17)Δℜcallitalic(i)t=ℜcallitalic(i)t−ℜcallitalic(i−1)t

(18)PRAUC=1T∑t=1T∑i=1|M|Precisionitalic(i)tΔℜcallitalic(i)t

F_1-Score

The elevated F_1-score metric in medication recommendations signifies an optimal equilibrium between minimizing false negatives and maintaining classification specificity.

(19)Precisiont=|yt∩y^t||y^t|, Recallt=|yt∩y^t||yt|

(20)F1=1T∑t=1T2×Precisiont×ℜcalltPrecisiont+ℜcallt

DDI Rate

A lower DDI rate ensures that the recommended combination of medications is safer in clinical practice.

(21)DDI=1T∑t=1T∑j=1|y^t|∑j=i+1|y^t|1{Adjy^it,y^jt}∑j=1|y^t|∑j=i+1|y^j|1

Comparative Models

The following baseline models were selected for comparison with the proposed CSRec:

- Logistic regression (LR) uses L2 regularization.
- Ensemble of classifier chains (ECC) [28] enhances predictions by connecting multiple classifiers, typically applied to multilabel classification scenarios for performance optimization.
- RETAIN [18] implements bidirectional temporal attention architecture designed for sequential clinical prediction tasks like treatment recommendation.
- Learn to Prescribe (LEAP) [29] uses RNNs to extract meaningful representations during current medical visits and generate medication sequences.
- Dual memory neural computer (DMNC) [20] incorporates dual-memory neural components to model asynchronous therapeutic pattern interactions.
- GAMENet [11] adopts graph-based memory architecture combining medication interaction knowledge and querying longitudinal EHR data for medication retrieval.
- MICRON [21] analyzes EHR temporal dynamics to adaptively optimize medication combinations upon symptom evolution.
- SafeDrug [16] evaluates molecular-level medication-patient compatibility to suggest safer therapeutic regimens.

XSL•FO
RenderX

- COGNet [22] implements medication copy or predict strategy integrating historical effective prescriptions into current recommendations.
- MoleRec [14] predicts medication mechanisms and interactions via molecular-patient relationships for personalized, safer recommendations.
- CausalMed [9] identifies medical entity causal relationships via causal discovery, accounting for dynamic health condition differences to generate causally linked recommendations.

Performance Comparison

In this section, we conducted an extensive comparative analysis between CSRec and the previously described baseline medication recommendation models to evaluate its effectiveness. Experimental results on the MIMIC-III v1.4 and MIMIC-IV 2.2 datasets are shown in Table 3 ("↑" indicates a preference for larger values, "↓" indicates a preference for smaller values).

[l]Optimal data.

After detailed analysis, we observed several key findings, as described in the following paragraphs.

The CSRec model proposed in this paper outperformed most comparative models across multiple evaluation metrics, fully

XSL•FO
RenderX

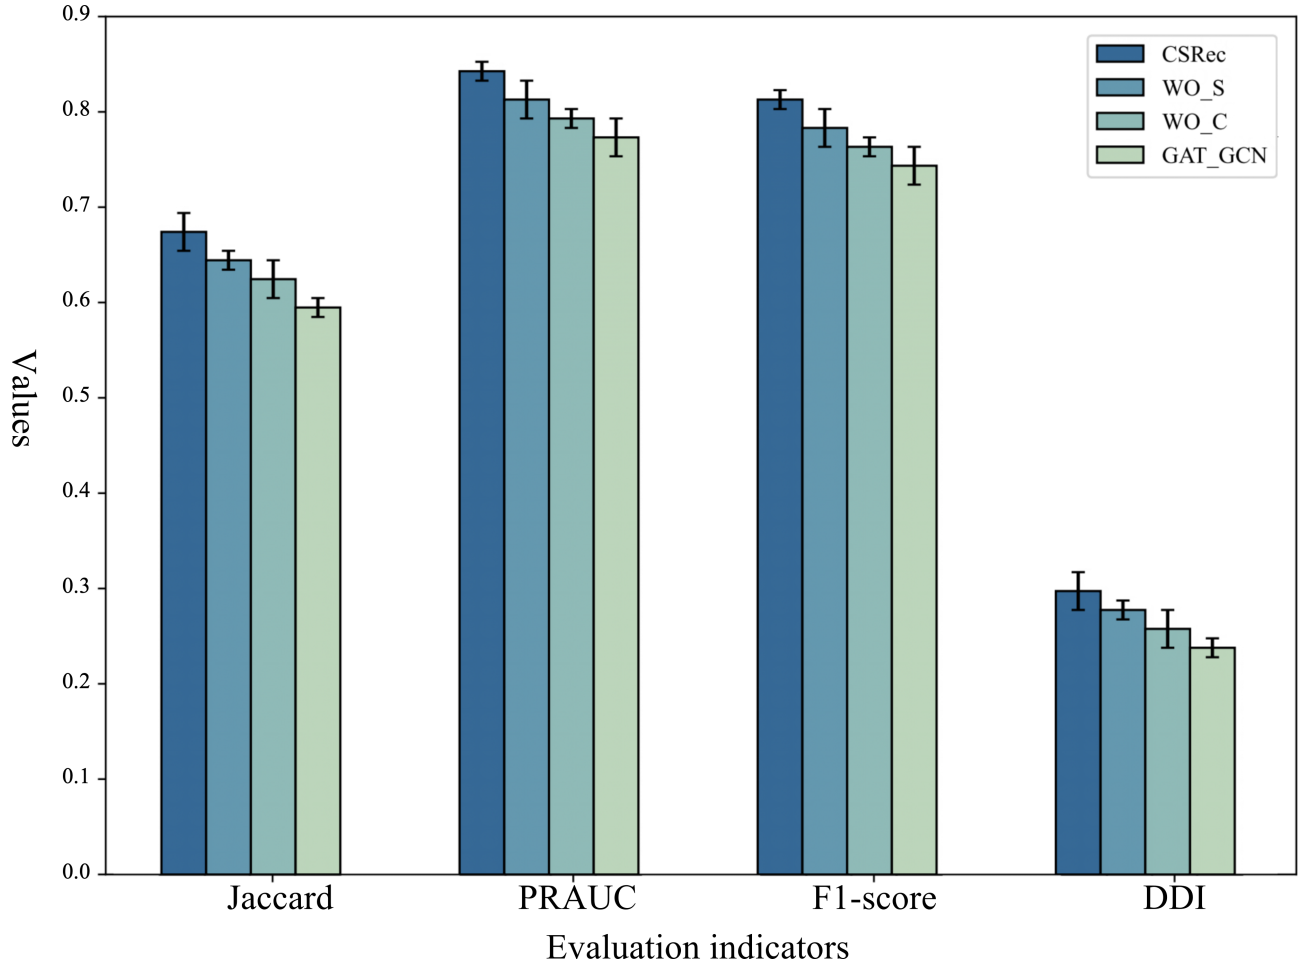
demonstrating its significant effectiveness in hypertension medication recommendation.

LR and ECC performed poorly, primarily because these methods only focus on the patient's current clinical condition, neglecting the influence of historical medical data on present treatment decisions. In contrast, the model presented in this paper, along with RETAIN, GAMENet, and other models integrating longitudinal medical histories, performed better, highlighting the importance of capturing historical medical information in hypertension medication recommendations.

In comparison with longitudinal models such as RETAIN, GAMENet, and COGNet, CSRec maintained superior performance, with a particularly notable enhancement in Jaccard scores. This superiority can be attributed to 2 core architectural advancements. The Temporal Selectivity Module enables accurate simulation of patient disease progression by assigning enhanced weights to clinically critical historical information, thereby ensuring that recommendations adhere to consistent clinical reasoning frameworks. Meanwhile, the Heterogeneous Collaborative Module facilitates effective capture of synergistic relationships among heterogeneous medical entities (diagnoses, procedures, medications), enabling the identification of medication combinations that are clinically coherent and reflective of real-world coprescription patterns. Collectively, these innovations augment the degree of overlap between recommended and actually prescribed medications, as empirically validated by the elevated Jaccard index.

Although the CSRec model introduced in this study does not achieve the highest score on the DDI metric, it still ranks as suboptimal. This is mainly because the best performing LEAP model only considers the patient's present health status, resulting in the recommendation of fewer medications and consequently yielding the lowest DDI scores.

Ablation Study



To systematically assess the contribution and validity of each module within CSRec, ablation experiments were conducted on MIMIC-IV by comparing CSRec with its variants:

- WO_S removes the selection module based on the cyclic mechanism.
- WO_C removes the collaborative module based on the heterogeneous graph.
- GAT_GCN replaces the multihead GAT in the collaborative module with a graph convolutional network (GCN).

The results displayed in Figure 3 indicate that the performance of CSRec declined when any module is removed or replaced, demonstrating that each component of CSRec is indispensable. The observed performance drops in evaluation metrics (Jaccard, PRAUC, F_1-score, and DDI) can be attributed to the unique functional roles of each module: The collaborative module effectively modeled the correlations between different medical events during each visit, and its removal (WO_C) led to incomplete capture of event associations, resulting in a decrease in recommendation accuracy as medical entity representations lost contextual relevance. The selective module globally modeled the patient's historical medical data, and its absence (WO_S) caused the model to fail at emphasizing critical time points in disease progression, leading to a decline in metrics as the temporal continuity of hypertension development was disrupted. When replacing multihead GAT with GCN (GAT_GCN), the loss of the attention mechanism resulted in insufficient differentiation of important medical entity relationships, reducing recommendation precision compared with the original model as convolutional operations cannot dynamically weight heterogeneous graph information.

XSL•FO

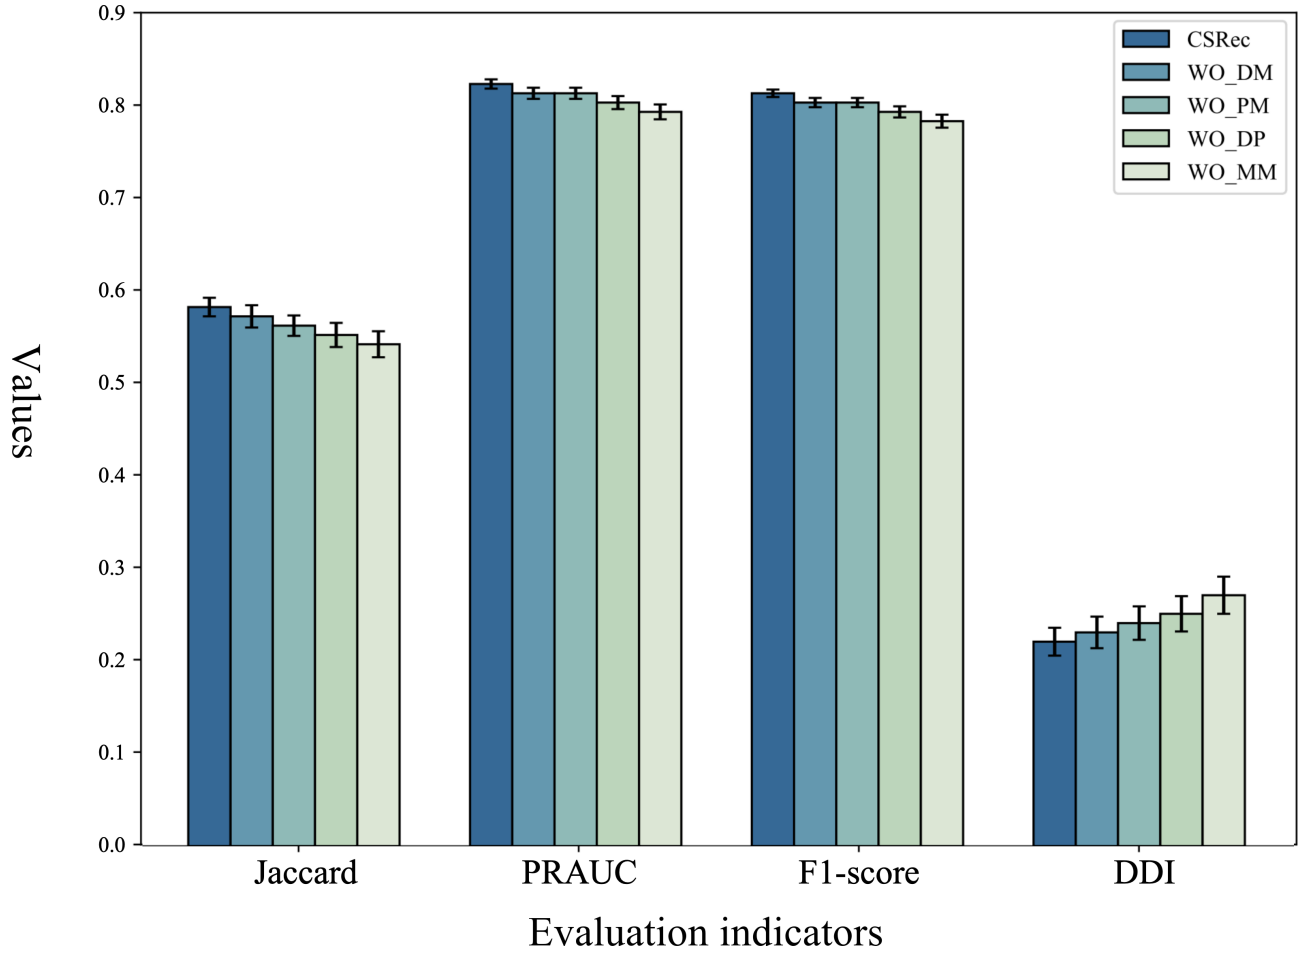
Figure 3. The ablation study of different components. DDI: drug-drug interaction; GAT_GCN: variant replacing the multihead graph attention network in the collaborative module with a graph convolutional network; Jaccard: Jaccard similarity coefficient; PRAUC: area under the curve of precision-recall; WO_C: variant removing the collaborative module based on the heterogeneous graph; WO_S: variant removing the selection module based on the cyclic mechanism.

Additionally, this study further explored the impact of different types of collaborative medical entity information (diagnosis-medication, procedure-medication, diagnosis-procedure, and medication-medication) on hypertension medication recommendations. The variants were designed as follows:



- WO_DM removes diagnosis-medication interaction information.
- WO_PM removes procedure-medication interaction information.
- WO_DP removes diagnosis-procedure interaction information.
- WO_MM removes medication co-occurrence and interaction information.

As illustrated in Figure 4, CSRec's performance decreased when any single type of collaborative medical entity information (WO_DM, WO_PM, WO_DP) was removed, confirming the strong correlation between such information and the medication recommendation task. The specific decline in metric degree corresponded to the clinical relevance of each information type: Removing diagnosis-medication interactions (WO_DM) reduced metrics, as diagnostic information directly guides first-line hypertension medication selection. The WO_PM group's drop stemmed from lost procedure-related medication adjustments (eg, postinterventional anticoagulation needs). For WO_DP, the decline reflects disrupted diagnosis-procedure logical chains that inform therapeutic medication choices.

Notably, removing medication co-occurrence and interaction information (WO_MM) caused a significant decline in the DDI risk rate of the medication recommendation performance. This substantial change is explained by the frequent use of combination therapy in hypertension management. Without medication interaction data, the model cannot avoid contraindicated medication pairs, while the loss of co-occurrence patterns reduces the accuracy of synergistic medication recommendations. This underscores the essential role of medication co-occurrence and DDI information for ensuring hypertension treatment efficacy and safety.

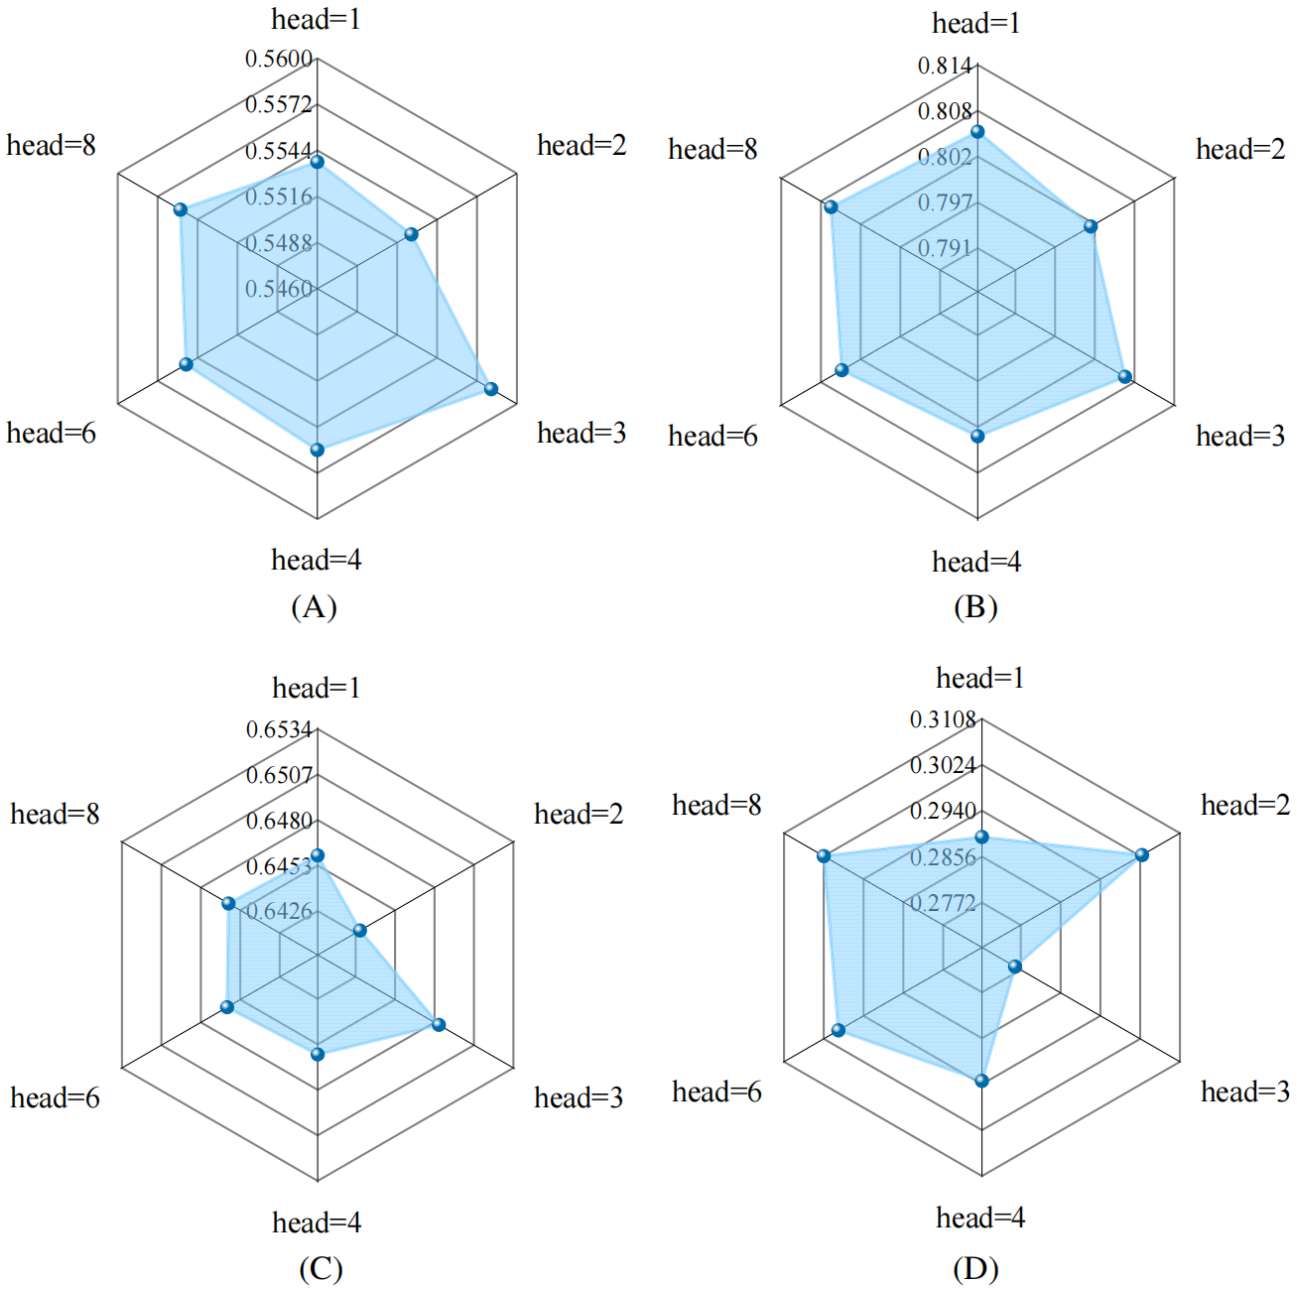
DDI: drug-drug interaction; Jaccard: Jaccard similarity coefficient; PRAUC: area under the curve of precision-recall; WO_DM: variant removing diagnosis-medication interaction information; WO_DP: variant removing diagnosis-procedure interaction information; WO_MM: variant removing medication co-occurrence and interaction information; WO_PM: variant removing procedure-medication interaction information.

Parameter Sensitivity



In order to investigate how varying the number of attention heads in the multihead graph attention mechanism within the heterogeneous collaborative module impacted model efficacy, multiple experiments were conducted on the MIMIC-IV dataset. The outcomes of these experiments, comparing different head counts, are presented in Figure 5.

A setting of 3 attention heads (head=3) achieved optimal performance. Consequently, this configuration (head=3) was adopted consistently throughout the remaining experiments in this study. Moreover, the experimental results illustrated that variations in the number of attention heads led to minimal performance differences, highlighting the stability and reliability of the proposed model.

Furthermore, to investigate the impact of the number of included hypertension medications on model performance, we conducted a sensitivity analysis by varying the minimum occurrence threshold for medication inclusion from 500 to 3000. The number of medications ranged from 26 (≥500) to 9 (≥3000).

XSL•FO
RenderX

Figure 5. The effect of different numbers of heads in the multihead graph attention network (GAT), as measured using (A) the Jaccard similarity coefficient, (B) area under the curve of precision-recall (PRAUC), (C) F_1-score, and (D) drug-drug interaction (DDI) rate.

As shown in Table 4, performance across all 4 metrics—Jaccard, PRAUC, F_1-score, and DDI—remained remarkably stable, with only marginal fluctuations. Notably, the best performance was observed at the 2000 threshold, which is used in our paper. This finding supported our design choice and indicated that our framework remained robust even under different medication inclusion criteria, alleviating concerns regarding limited sample size. In addition, setting a lower threshold introduced lower-frequency medications that may lack sufficient clinical representation, potentially compromising the statistical reliability of training. Thus, the current configuration struck a reasonable trade-off between medication variety and prediction stability.

Case Study

To visualize and validate our core innovations, which included heterogeneous collaborative interaction modeling and the temporal selectivity mechanism, we randomly selected a patient from the test set of the MIMIC-IV dataset for a case study. Taking diagnosis and medication entities as examples, the entire learning process is shown in Figure 6.

Figure 6. Case study. DC: diagnosis code; DS: diagnosis selection coefficient; MC: medication code; MS: medication selection coefficient; Rec: recommended medication; True: prescribed medication.

Initially, in the collaborative process (a), the model's collaborative interaction mechanism was showcased: In the visit-specific level, the model dynamically enhanced the integration of diagnostic information into medication recommendation reasoning by assigning context-aware interaction weights to the interplays between diagnostic codes (DC column) and medication codes (MC column). For the first visit of the illustrative patient, the DC column encompasses comorbidity-related codes, including chronic obstructive pulmonary disease (*ICD-9*: 496), hypothyroidism (*ICD-9*: 2449), atrial fibrillation (*ICD-9*: 42731), and a documented history of cardiovascular disease (*ICD-9*: V1254), while the MC column includes hypertension-targeted agents such as selective β1-receptor blockers (ATC-04: C07A) and dihydropyridine calcium channel blockers (ATC-04: C08C). This aligns with our innovation of capturing disease-specific collaborative patterns, evident in the consistently higher selection coefficients for hypertension-related diagnostic codes in each DC column, which prioritizes the disease context critical for hypertension treatment.

XSL•FO
RenderX

Furthermore, to demonstrate our temporal selectivity mechanism, the case study highlights how the model captures longitudinal EHR dependencies. Given hypertension's chronic nature, recommended medications depend on both current (third visit) diagnoses (DC column) and historical data. As shown in step (b), diagnostic codes from previous visits received higher selection coefficients, while step (c) reveals that historical medication codes were similarly prioritized. This reflects our model's ability to dynamically weight temporal information, addressing the evolving nature of hypertension and representing an advantage over static models.

Discussion

This paper presents the CSRec model for hypertension medication recommendation, which is based on the collaboration and selection of heterogeneous medical entities. By effectively capturing relationships among diverse medical entities and combining the temporal evolution characteristics of clinical entities, the model provides more precise and effective medication guidance for hypertension treatment. Future research will focus on 3 main areas: (1) in-depth exploration of the multilabel imbalance problem existing in the current method, (2) further investigation of the model's performance in addressing the cold-start problem, and (3) exploration of recommendations regarding medication dosages and medication types.

Abstract

Background: Traditional Chinese Medicine (TCM) emphasizes the concept of medicine food homology (MFH), which integrates dietary therapy into health care. However, the practical application of MFH principles relies heavily on expert knowledge and manual interpretation, posing challenges for automating MFH-based dietary recommendations. Although large language models (LLMs) have shown potential in health care decision support, their performance in specialized domains such as TCM is often hindered by hallucinations and a lack of domain knowledge. The integration of uncertain knowledge graphs (UKGs) with LLMs via retrieval-augmented generation (RAG) offers a promising solution to overcome these limitations by enabling a structured and faithful representation of MFH principles while enhancing LLMs' ability to understand the inherent uncertainty and heterogeneity of TCM knowledge. Consequently, it holds potential to improve the reliability and accuracy of MFH-based dietary recommendations generated by LLMs.

Objective: This study aimed to introduce Yaoshi-RAG, a framework that leverages UKGs to enhance LLMs' capabilities in generating accurate and personalized MFH-based dietary recommendations.

Methods: The proposed framework began by constructing a comprehensive MFH knowledge graph (KG) through LLM-driven open information extraction, which extracted structured knowledge from multiple sources. To address the incompleteness and uncertainty within the MFH KG, UKG reasoning was used to measure the confidence of existing triples and to complete missing triples. When processing user queries, query entities were identified and linked to the MFH KG, enabling retrieval of relevant reasoning paths. These reasoning paths were then ranked based on triple confidence scores and entity importance. Finally, the most informative reasoning paths were encoded into prompts using prompt engineering, enabling the LLM to generate personalized dietary recommendations that aligned with both individual health needs and MFH principles. The effectiveness of Yaoshi-RAG was evaluated through both automated metrics and human evaluation.

Results: The constructed MFH KG comprised 24,984 entities, 22 relations, and 29,292 triples. Extensive experiments demonstrate the superiority of Yaoshi-RAG in different evaluation metrics. Integrating the MFH KG significantly improved the performance of LLMs, yielding an average increase of 14.5% in Hits@1 and 8.7% in F_1-score, respectively. Among the evaluated LLMs, DeepSeek-R1 achieved the best performance, with 84.2% in Hits@1 and 71.5% in F_1-score, respectively. Human evaluation further validated these results, confirming that Yaoshi-RAG consistently outperformed baseline models across all assessed quality dimensions.

Conclusions: This study shows Yaoshi-RAG, a new framework that enhances LLMs' capabilities in generating MFH-based dietary recommendations through the knowledge retrieved from a UKG. By constructing a comprehensive TCM knowledge representation, our framework effectively extracts and uses MFH principles. Experimental results demonstrate the effectiveness of our framework in synthesizing traditional wisdom with advanced language models, facilitating personalized dietary recommendations that address individual health conditions while providing evidence-based explanations.

KEYWORDS

Traditional Chinese Medicine; medicine food homology; large language model; retrieval-augmented generation; uncertain knowledge graph; dietary recommendation

Introduction

Background

The concept of "medicine food homology" (MFH) in Traditional Chinese Medicine (TCM) means that certain substances can function as both nutritional food and therapeutic medicines depending on their application and dosage [1]. This ancient philosophy has gained considerable traction in modern health care systems [2], offering approaches to disease prevention and management through dietary interventions [3]. However, the practical implementation of MFH principles remains largely dependent on the expert knowledge of TCM practitioners, leading to inconsistent application and limited accessibility. The absence of automated and systematic approaches to using MFH principles for dietary recommendation generation has hindered its broader integration into contemporary health care frameworks and constrained its potential benefits for public health.

Recent advances in large language models (LLMs) [4] have demonstrated their remarkable performance across a variety of medical tasks [5], including automated clinical decision support [6], medical education [7], and health care information retrieval [8]. These capabilities are primarily derived from extensive pretraining on large-scale corpora, which encode rich knowledge from diverse textual sources. The application of MFH principles heavily depends on the domain knowledge documented in TCM literature, including foods, herbs, and formulations. Given that many LLMs have been pretrained on the corpora, which incorporate such TCM literature, combined with their strong natural language generation abilities, they present promising potential for automating MFH-based dietary recommendations. Nonetheless, LLMs exhibit substantial limitations as they often produce hallucinations that refer to factually incorrect information [9]. This problem is especially evident when generating information related to the medicinal properties of food in the context of TCM. For example, when querying with "I have stomach discomfort recently, can you recommend some summer drinks?" the LLMs respond: "Mung bean soup clears heat and is suitable for heat-related discomfort." However, according to MFH principles, mung beans are cold (yin), and their consumption may aggravate stomach discomfort. Such inaccuracies significantly affect the safety and reliability of LLMs in practical health care applications [10].

Retrieval-augmented generation (RAG) has emerged as a promising strategy to mitigate these limitations by incorporating external knowledge into LLMs, thereby enhancing factual accuracy and reducing hallucinations [11]. However, using TCM knowledge as the retrieval source of RAG presents unique challenges. TCM knowledge is sourced from diverse and heterogeneous materials, including ancient and classical literature, modern TCM literature, food and herbs information, regulatory documents, research papers, and TCM formulations. This multisource nature results in inconsistent knowledge representation, terminological ambiguities, and varying levels of evidence quality. Furthermore, MFH principles inherently involve uncertainties arising from dosage effects, individual variability, and context-dependent applications [12]. Currently, there is no comprehensive and structured knowledge base specifically tailored for supporting RAG grounded in MFH principles, creating a significant gap between traditional wisdom and modern technologies.

Related Work

Dietary Recommendation Systems

Dietary recommendation systems provide personalized food and nutrition suggestions based on individual health status and preferences. Traditional approaches have primarily relied on rule-based methods using expert knowledge and predefined guidelines, often lacking personalization and accessibility. Recent advancements in artificial intelligence have transformed this field through deep learning and knowledge graphs (KGs). Chen et al [13] defined food recommendation as constrained question answering over a food KG, integrating user preferences with health guidelines. PPKG [14] is a cancer-specific dietary recommendation system that combines a KG with time-aware long short-term memory networks to dynamically adjust recommendations for cancer prevention and rehabilitation. Ma et al [15] proposed a nutrition-related KG method based on graph convolutional networks to enhance food recommendation diversity while promoting more healthy eating habits. LLMs have further advanced dietary recommendation capabilities. ChatDiet [16] integrates personal and population models with causal inference to enhance personalization and explainability. Jin et al [17] demonstrated the clinical effectiveness of a GPT-based dietary recommendation system for patients with hemodialysis, successfully reducing serum potassium levels. Kopitar et al [18] created a generative artificial intelligence system for personalized inpatient meal planning that incorporates electronic health records and clinical guidelines.

However, we still do not have methods to integrate MFH principles with LLMs for dietary recommendation. Our framework bridges this gap by combining MFH KG with LLMs to develop more comprehensive and culturally informed dietary recommendations.

The Interplay Between LLMs and KGs

KGs serve as structured representations of factual knowledge, providing an excellent complement to parameterized language models [19,20]. With the emergence of LLMs, research has evolved along 2 complementary trajectories: leveraging LLMs to construct KGs and enhancing LLMs with KG integration. Several approaches have emerged for LLM-assisted KG construction. Extract-define-canonicalize [21] addresses scalability through open information extraction (OpenIE) and

XSL•FO
RenderX

post hoc canonicalization. BEAR [22] leverages LLMs for zero-shot knowledge extraction in service-oriented domains. LLM-TIKG [23] applies few-shot learning for constructing threat intelligence KGs, while Yang et al [24] presented an approach for medical ontology expansion using LLMs to generate competency questions.

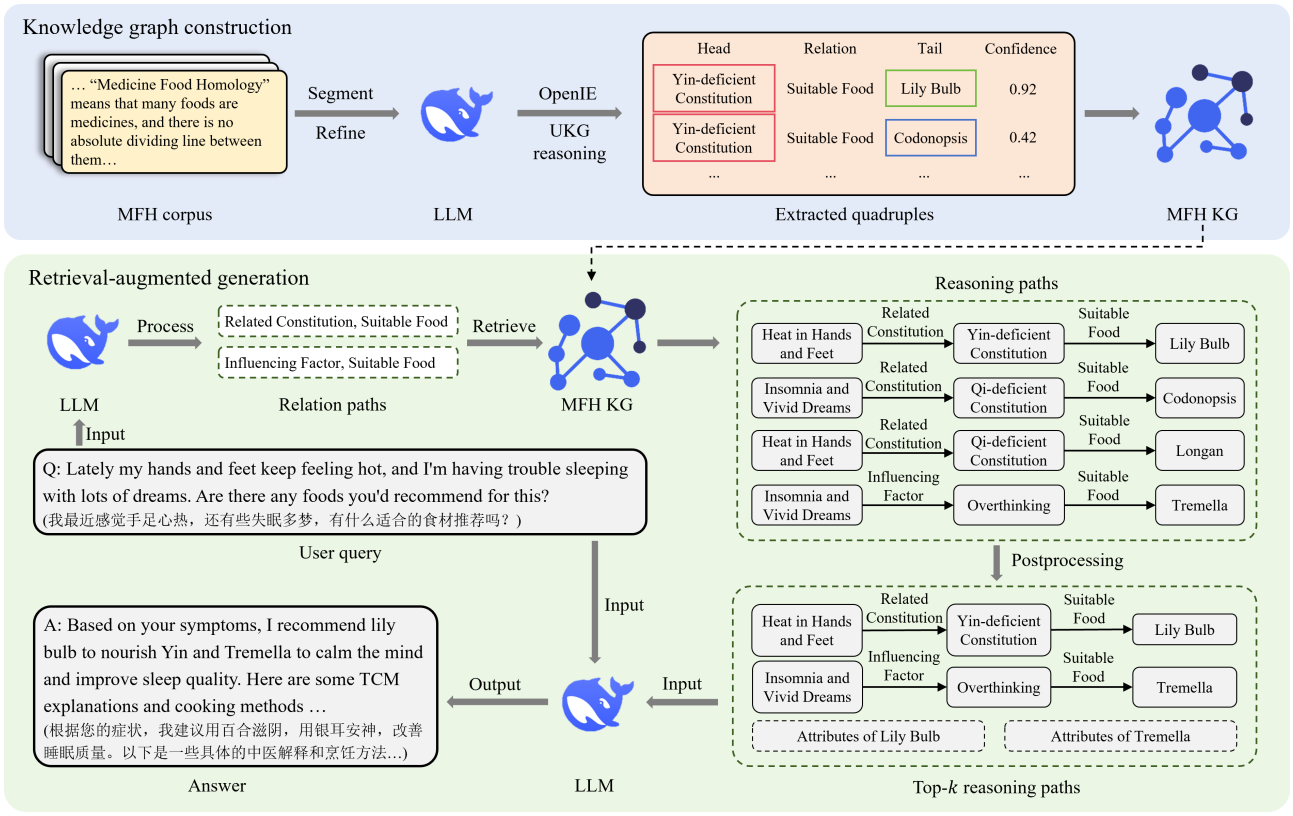
Researchers have also explored integrating KGs to enhance LLMs' capabilities. GraphGPT [25] combines LLMs with graph structural knowledge through instruction tuning. GaLM [26] transforms KGs into text representations to improve reasoning while reducing hallucinations. Think-on-Graph [27] is a training-free framework that uses iterative beam search to enable interactive reasoning, while StructGPT [28] enhances zero-shot reasoning through an iterative Reading-then-Reasoning approach. Our work builds upon these dual research trajectories by proposing a framework that leverages LLMs for KG construction and uses KGs to enhance the capabilities of LLMs specifically within the domain of TCM, thereby providing reliable dietary recommendations grounded in MFH principles.

Objectives

To overcome the limitations of existing methods, we propose a new framework that enhances LLMs' capability to generate MFH dietary recommendations by using an uncertain knowledge graph (UKG) as an external resource. This framework uses multistep LLM calls for OpenIE [29] to automatically construct an MFH KG from unstructured and heterogeneous literature sources. It then implements UKG reasoning to measure the confidence of existing triples and complete missing triples. To improve knowledge retrieval, the framework adopts a reasoning path–based knowledge retrieval strategy, extracting relevant knowledge from the MFH KG and refining the results through ranking and filtering based on triple confidence scores and entity importance. By encoding domain-specific knowledge and addressing uncertainties related to MFH, the MFH KG empowers LLMs to deliver more personalized, evidence-based, and reliable dietary recommendations.

The key contributions of this study are as follows: (1) an integrated framework that leverages KG-augmented LLMs to generate personalized and evidence-based MFH dietary recommendations, (2) an LLM-driven OpenIE methodology for automatically constructing a UKG specifically tailored to TCM's MFH from heterogeneous multisource data, (3) a systematic evaluation of several mainstream LLMs for the generation of MFH dietary recommendations, and (4) experimental results and case studies that demonstrate the capability of the proposed framework to deliver personalized and professional MFH-based dietary recommendations.

Methods



Overview

This study proposed Yaoshi-RAG, an RAG framework designed to enhance LLMs' capabilities in generating evidence-based dietary recommendations based on MFH principles. As illustrated in Figure 1, the framework consists of 2 modules:

1. Knowledge graph construction: A comprehensive corpus was compiled from multiple sources, and an MFH KG was constructed using LLM-driven OpenIE. Then, UKG reasoning was applied to measure the confidence of extracted triples and complete missing triples.
2. Retrieval-augmented generation: Given a user query, the framework first identified and linked query entities to the MFH KG. The LLM then constructed relation paths to facilitate the retrieval of reasoning paths. Subsequently, these candidate reasoning paths were refined through postprocessing, including ranking and filtering, to extract the top-k most relevant reasoning paths, thereby improving retrieval accuracy. The retrieved knowledge was integrated with the user query through prompt engineering, guiding the LLM to generate personalized dietary recommendations that aligned with both the user's needs and MFH principles.

XSL•FO

Figure 1. The architecture of the proposed framework. KG: knowledge graph; LLM: large language model; MFH: medicine food homology; OpenIE: open information extraction; TCM: Traditional Chinese Medicine; UKG: uncertain knowledge graph.

A comprehensive corpus was compiled from multiple sources, and an MFH KG was constructed using LLM-driven OpenIE. Then, UKG reasoning was applied to measure the confidence of extracted triples and complete missing triples. In the following sections, we provide a detailed explanation of both modules, outlining their design, implementation, and contributions to the overall framework.

KG Construction

Corpus Collection

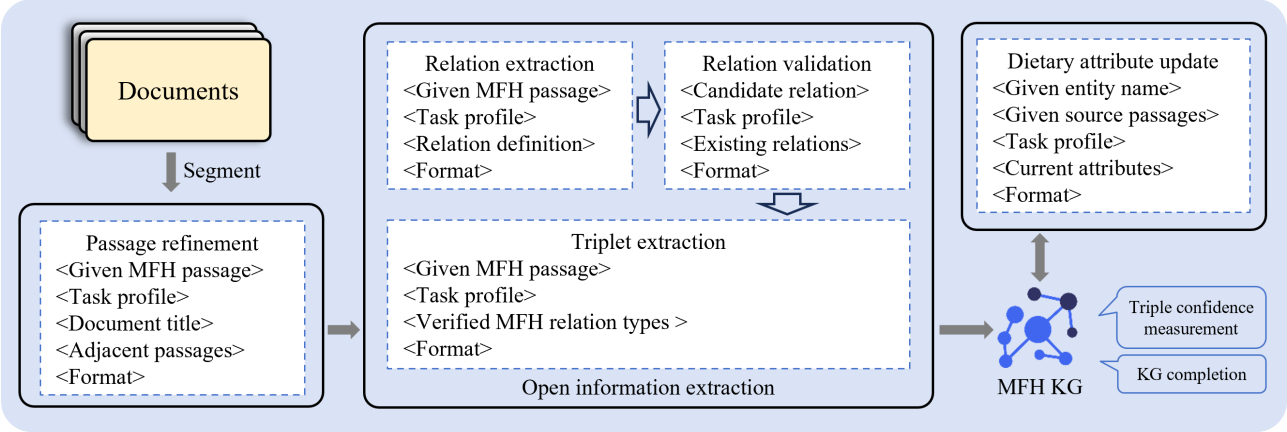
To construct an MFH KG, we systematically constructed a corpus from diverse sources, including ancient and classical literature, modern TCM literature, food and herbs information, regulatory documents, research papers, and TCM formulations. This process results in a corpus of 1359 relevant documents. Table 1 shows the statistical distribution of documents across different source categories.

Table . The statistical distribution of 1359 documents.

Source category	Number of documents
Ancient and classical literature	75
Modern TCM[a] literature	228
Food and herbs information	400
Regulatory documents	42
Research papers	432
TCM formulations	182
Total	1359

[a]TCM: Traditional Chinese Medicine.

To improve the efficiency and accuracy of entity-relation triple extraction, each document was segmented into passages of 300 tokens. These passages were then input into LLMs with a carefully designed prompt (Textbox S1 in Multimedia Appendix 1) to resolve pronominal references by incorporating information from document titles and neighboring passages. Additionally, irrelevant content within passages was filtered out to ensure domain-specific focus.



MFH Knowledge Graph

Based on the collected corpus, we constructed an MFH KG G, as shown in Figure 2, which illustrates the detailed process. Formally, the graph is defined as a triple G=(E,R,F), where E

XSL•FO
RenderX

represents the set of entities, R represents the set of relations, and F⊆E×R×E represents the fact set. Each fact in F is represented as a quadruple (h,r,t,s), where h is the head entity, r is the relation, t is the tail entity, and s is the confidence score reflecting the likelihood that the triple (h,r,t) holds true. For instance, consider the quadruple (h: Insomnia and Vivid Dreams, r: Related Constitution, t: Yin-Deficient Constitution, s: 0.87). This quadruple indicates that Insomnia and Vivid Dreams are associated with the Yin-Deficient Constitution, with a confidence score of 0.87.

Figure 2. The detailed process of medicine food homology knowledge graph construction. KG: knowledge graph; MFH: medicine food homology.

We used LLM-driven OpenIE to extract triples h,r,t from each passage within the corpus. Specifically, we first integrated predefined relation definitions into a prompt (Textbox S2 in Multimedia Appendix 1), guiding the LLM to identify and extract potential relations. These candidate relations, along with existing ones, were subsequently processed using another prompt (Textbox S3 in Multimedia Appendix 1), where the LLM determined whether to retain new relations or filter out redundant ones. This process resulted in the construction of a relation set rsel, which was incorporated into OpenIE prompts, instructing the LLM to extract entity-relation triples. The relations of extracted triples were strictly constrained to the relation set rsel.

Specifically, during the OpenIE, we instructed the LLM to extract attributes of food entities and dish entities (Textboxes S4 and S5 in Multimedia Appendix 1). For food entities, LLMs referenced their source passages to update attributes, including name, primary effects, consumption methods, indications, and contraindications. Similarly, for dish entities, attributes such as name, ingredient composition, cooking method, and dietary benefits were updated.

The automated construction of the MFH KG inevitably introduced noise, incompleteness, and factual inaccuracies, making absolute factual correctness unattainable. To mitigate these issues, we adopted UKG reasoning to measure the confidence of extracted triples and complete missing triples. Specifically, we first used unKR [30], an open-source Python library for UKG reasoning, to learn vector representations of entities and relations. Based on these representations, we applied the triple confidence measurement method [31], integrating heterogeneous evidences to measure confidence of each triple. For each given head entity h and relation r, candidate tail entities were enumerated to construct new triples absent from the current graph. The triples with confidence scores larger than 0.85 were added to the MFH KG.

Retrieval-Augmented Generation

The Retrieval Strategy

Given a user query Q, we first constructed a prompt (Textbox 1) to guide the LLM to extract a set of relevant keywords E from Q. We then encoded both the keywords and all entities from the MFH KG into dense vector representations, denoted as HR and HG, respectively. Considering that SBERT [32] has demonstrated superior performance over BERT [33] and RoBERTa [34] on semantic textual similarity tasks while maintaining lower computational overhead [35], we adopted SBERT for embedding both the extracted keywords and entities. Subsequently, we computed the cosine similarities between the embeddings of each keyword and all entities. For each keyword, we retrieved the top-10 most similar entities from the MFH KG based on cosine similarity scores. These candidate entities were then presented to the LLM, which was instructed to identify the matched entity (Textbox 2). The selected entity corresponding to each keyword constitutes the query entity set EQ={e1,e2,…,en}, which serves as the starting point for subsequent reasoning path retrieval.

Textbox 1. Prompt for keyword extraction.

You are a medical knowledge assistant specialized in Traditional Chinese Medicine. Given a user query, extract a concise set of keywords that represent the user's core health-related intent and information needs. These keywords will be used to retrieve relevant knowledge from a medicine-food homology knowledge graph to answer the user query.

User query: {user_query}

Please return the output as a Python-style set of keywords:

XSL•FO
RenderX

Textbox 2. Prompt for entity linking.

Given a keyword and a list of candidate entities retrieved from the medicine food homology knowledge graph, select the entity that most accurately matches the keyword based on contextual meaning and traditional usage. If none of the entities are appropriate matches, return "None."

Keyword: {keyword}

Candidate entities: {candidate_entities}

Please return the output as a JSON list:

This study used path-based retrieval from the MFH KG rather than retrieving contextual subgraphs for linked entities. This is motivated by the advantages reasoning paths offer in generating MFH-based dietary recommendations. Specifically, reasoning paths provide structured knowledge by capturing direct relations between query entities and answer entities. For example, the reasoning path "(Insomnia and Vivid Dreams, Related Constitution, Qi-deficient Constitution); (Qi-deficient Constitution, Suitable Food, Codonopsis)" enables LLMs to clearly infer the relations between a user's symptoms, their constitution, and the recommended food, thereby enhancing the interpretability. In contrast, subgraph-based retrieval in long-hop reasoning tasks often introduces irrelevant information [36]. This not only leads to significant computational overhead but also hinders LLMs from effectively extracting relevant information from the retrieval results.

Built upon the previous work [37], we first provided the LLM with a structured prompt (Textbox 3) listing all relations in G. The LLM then generated multiple relation paths {prel1, prel2, …, prelk}, where each preli is an ordered sequence of relationsr1,r2,…,rl. These relation paths serve as guides for retrieving knowledge essential to answering user queries. Given that the MFH KG contained considerably fewer relations compared with large-scale KGs such as FreeBase [38], we did not fine-tune the LLM for relation path generation. Instead, we used few-shot prompting to enhance the LLM's ability to generate meaningful relation paths.

Textbox 3. Prompt for relation paths generation.

Task instructions:

1. Please generate multiple relation paths (sequences of relations) based on the existing relation types. Each relation path should contain relations that are connected through the same entity.
2. The purpose of the relation paths is to assist in retrieving relevant entities that can answer the user query.

Relation types: {existing_relations}

User query: {user_query}

Query entities: {query_entities}

Few-shot examples: {examples}

Please strictly follow the task instructions and return only the required JSON list:

Subsequently, starting from each entity in the EQ, we followed each generated relation path preli to retrieve a set of reasoning paths Prea={prea1, prea2, …, pream} from G, where each reasoning path preai={(e1,r1,e2),(e2,r2,e3),…,(el,rl,el+1)} consists of multiple triples ej,rj,ej+1 and represents an instance of one of the relation paths.

Retrieval Result Postprocessing

In our initial experiment, we noticed that the reasoning paths in Preacontained redundant and irrelevant information. To enhance the quality of these reasoning paths, we computed a score for each reasoning path in Preaby considering both the entity importance and the triple confidence within the reasoning path. These scores enabled us to filter out less relevant reasoning paths.

The importance of each entity in the reasoning path was calculated using a weighted PageRank [39] algorithm. Traditional PageRank ignored the confidence of triples, which could lead to equivalent treatment of false and true relations, thus causing inaccuracies in entity importance. To overcome this limitation, we constructed a subgraph using entities from the Preaalong with their one-hop neighbors and incorporated confidence scores of triples as edge weights in the PageRank computation. The weighted PageRank formula is defined as:

$$(1)PR(ei)=(1-d)\cdot 1N+d\cdot \sum ej\subset In(ei)wj\to i\sum kwj\to k\cdot PR(ej)$$

where PR(ei) represents the weighted PageRank score of entity ei, d is the damping factor, and N is the total number of entities in the graph. The term wj→i denotes the edge weight from entity ei to ej, derived from the confidence score of the corresponding triples. When multiple relations exist between ei and ej with different confidence scores, their influence was aggregated by averaging these scores. For scoring the reasoning paths, we integrated entity importance and triple confidence scores to formulate the following path-scoring function:

$$(2)PathScore(P)=\prod i=1nwi-1\to i\times(1n\sum ej\in PPR(ej))$$

where wi-1→i represents the confidence score of the relation from entity ei to ej, n denotes the total number of entities in the path, and PR(ej) is the weighted PageRank score of entity ej within the reasoning path. This scoring methodology captured both the confidence of triples within the reasoning path and the importance of the entities involved, striking a balance between

XSL•FO
RenderX

path reliability and informational importance. Finally, we ranked the reasoning paths based on their scores and retained only the top-k reasoning paths for subsequent inference.

Answer Generation

We used prompt engineering to improve the accuracy and relevance of generated answers of LLM. Prompt engineering involves constructing carefully designed prompts to guide LLMs toward generating high-quality and task-specific responses. Specifically, we constructed a prompt template (Textbox 4) comprising four key components: (1) task specification, (2) user query, (3) retrieved reasoning paths, and (4) attributes of food and dish entities. This structured prompt facilitates the integration of external knowledge, improves the LLMs' comprehension of MFH principles, and supports the generation of more accurate responses.

Textbox 4. Prompt for answer generation.

You are a professional Traditional Chinese Medicine doctor, providing dietary recommendations using the concept of "medicine food homology." Given a user query and the relevant reasoning paths and entity attributes, generate an answer.

Task instructions:

1. Please provide a detailed, accurate, and concise response based on the information provided.
2. The response should be well-structured and ensure logical consistency with the given reasoning paths and entity attributes.
3. Incorporate medicine food homology principles in your recommendations.
4. Output format: {"answer": "(Your answer here.)"}. The answer must be written in Chinese.

User query: {user_query}

Reasoning paths: {reasoning_paths}

Entity attributes: {entity_attributes}

Please strictly follow the task instructions and return only the required JSON format:

LLM Selection

To identify the most suitable LLM for MFH dietary recommendation tasks, we evaluated several mainstream LLMs, including GPT-4 [40], LLaMA2-Chat-7B [41], Qwen2.5-7B [42], and DeepSeek-R1 [43]. Additionally, we considered the influence of model size, incorporating both large-scale models (GPT-4 and DeepSeek-R1) and 7B-parameter models (LLaMA2-Chat-7B and Qwen2.5-7B). During the experiment, we implemented the same prompt set across all models to ensure comparative evaluation under identical input conditions. All models were integrated with our proposed framework for dietary recommendation generation based on the MFH principles.

Evaluation Metrics

Automated Evaluation

To quantitatively assess the effectiveness and accuracy of the model's dietary recommendations, we used 2 evaluation metrics: Hits@1 and F_1-score. Hits@1 measures the proportion of queries where the top-ranked predicted recommendation matches a ground truth answer. This metric evaluates the model's ability to prioritize the most relevant dietary recommendation. F_1-score captures the harmonic mean of precision (P) and recall (R), offering a balanced evaluation of both aspects. This metric is particularly appropriate in scenarios where multiple valid recommendations may exist for a single query. It is defined as follows:

$$F1=2\times P\times RP+R \quad (3)$$

where precision and recall are defined as:

$$P=TPTP+FP,\ R=TPTP+FN \quad (4)$$

In this context, *TP* (true positives) represents the number of dietary recommendations correctly suggested, FP (false positives) indicates inappropriate dietary recommendations incorrectly suggested, and FN (false negatives) refers to appropriate dietary recommendations that the model failed to suggest.

Human Evaluation

While automated evaluation methods are widely applied in natural language processing tasks, they have certain limitations in the context of dietary recommendations. Automated metrics struggle to assess the effectiveness of recommendations, specifically whether the suggested food and their combinations align with MFH principles. Moreover, user acceptability and explainability of the generated dietary recommendations are difficult to accurately assess using automated methods. Therefore, we incorporated human evaluation, integrating subjective ratings from both experts and general users to provide a more comprehensive assessment of the generated dietary recommendations.

Specifically, we assessed the generated dietary plans based on the following five evaluation criteria: (1) rationality, (2) explainability, (3) user acceptability, (4) personalization, and (5) consistency. Rationality assesses whether the recommended dietary plan adhered to both TCM principles and modern nutritional standards. Explainability evaluates whether the recommendations included clear TCM-based justifications. A higher score indicates that the system provided reasonable and understandable explanations rather than simply outputting ingredient combinations. User acceptability measures how well the recommendations aligned with users' subjective preferences, including taste, cultural adaptability, and feasibility. Personalization assesses whether the system provided tailored

XSL•FO
RenderX

recommendations based on an individual's constitution and health conditions. Consistency examines whether the model produced stable recommendations under similar inputs.

Among these evaluation criteria, rationality, explainability, user acceptability, and personalization were assessed using a 5-point Likert scale (1 - 5, where 1 represented the lowest score and 5 represented the highest). Consistency was evaluated using a binary judgment (Yes=5 points and No=0 points).

To conduct the evaluation, we recruited 5 experts with backgrounds in TCM or nutrition, along with 20 general users. Participants followed a structured human evaluation guideline to rate the generated dietary recommendations. The evaluation was conducted using a survey system, where assessors were provided with the user queries along with the corresponding dietary recommendations generated by LLMs. Finally, we computed the mean scores for each evaluation criterion.

Ethical Considerations

Institutional review board approval was not required for this study, as it did not involve direct research with human participants. All corpora used, such as research papers and TCM formulations, were publicly available [44-46], and no identifiable private or sensitive information was accessed or recorded. Annotators involved in the human evaluation participated voluntarily, provided informed consent prior to participation, and were informed of their right to withdraw at any time. No compensation was provided, and no private information was collected.

Results

We constructed an MFH KG comprising 24,984 entities, 22 relations, and 29,292 triples. To evaluate the LLMs' performance in dietary recommendation tasks, we developed a specialized question answering dataset consisting of 2000 queries focused on MFH principles. This dataset was designed to ensure balanced coverage across diverse health conditions and TCM constitutional types.

Table 2 shows a comparative analysis of LLMs with or with no augmentation by the MFH KG on dietary recommendation tasks. Overall, the integration of the MFH KG substantially improved model performance across all evaluated metrics, with an average increase of 14.5% in Hits@1 and 8.7% in F_1-score, respectively. Among the baseline LLMs, DeepSeek-R1 achieved the best performance (Hits@1: 70.4%, F_1-score: 64.1%), followed by GPT-4 (Hits@1: 68.6%, F_1-score: 55.8%), Qwen2.5-7B (Hits@1: 58.7%, F_1-score: 53.2%), and LLaMA2-Chat-7B (Hits@1: 54.1%, F_1-score: 49.3%). The performance ranking remained consistent after MFH KG augmentation, with DeepSeek-R1 outperforming the others (Hits@1: 84.2%, F_1-score: 71.5%). Due to its superior performance in the above automated evaluation, DeepSeek-R1 was selected as the LLM for all subsequent experiments.

Table . The performance comparison between large language models and medicine food homology knowledge graph–augmented large language models on dietary recommendation tasks.

Model	Hits@1	F_1-score
LLMs[a]		
GPT-4	68.6	55.8

[c]KG: knowledge graph.

[d]Values in italics indicate the best performance for each metric.

In human evaluation, we conducted a comparative assessment between LLMs and MFH KG–augmented LLMs across 5 key metrics. As shown in Table 3, the MFH KG–augmented DeepSeek-R1 consistently outperformed the baseline DeepSeek-R1 model across all evaluation criteria. The MFH KG–augmented model achieved substantially higher scores in rationality (4.1 vs 3.2), explainability (4.3 vs 2.9), user acceptability (4.4 vs 3.6), personalization (4.2 vs 3.3), and consistency (4.6 vs 3.4). These results provide compelling evidence that augmenting DeepSeek-R1 with the specialized MFH KG significantly improves the quality of dietary recommendations based on MFH principles.

[b]KG: knowledge graph.

We analyzed the impact of parameter k, which controls the number of retrieved reasoning paths in the RAG module. The evaluation across k values [1, 3, 5, 10, 20, and 30] is shown in Figure 3. The F_1-scores indicate that small increases in k initially improved performance, but after reaching an optimal point (k=10), further increases led to gradual accuracy decline. This pattern demonstrates the effectiveness of our reasoning path postprocessing, as it successfully prioritizes the most relevant reasoning paths while filtering out potentially misleading or irrelevant information.

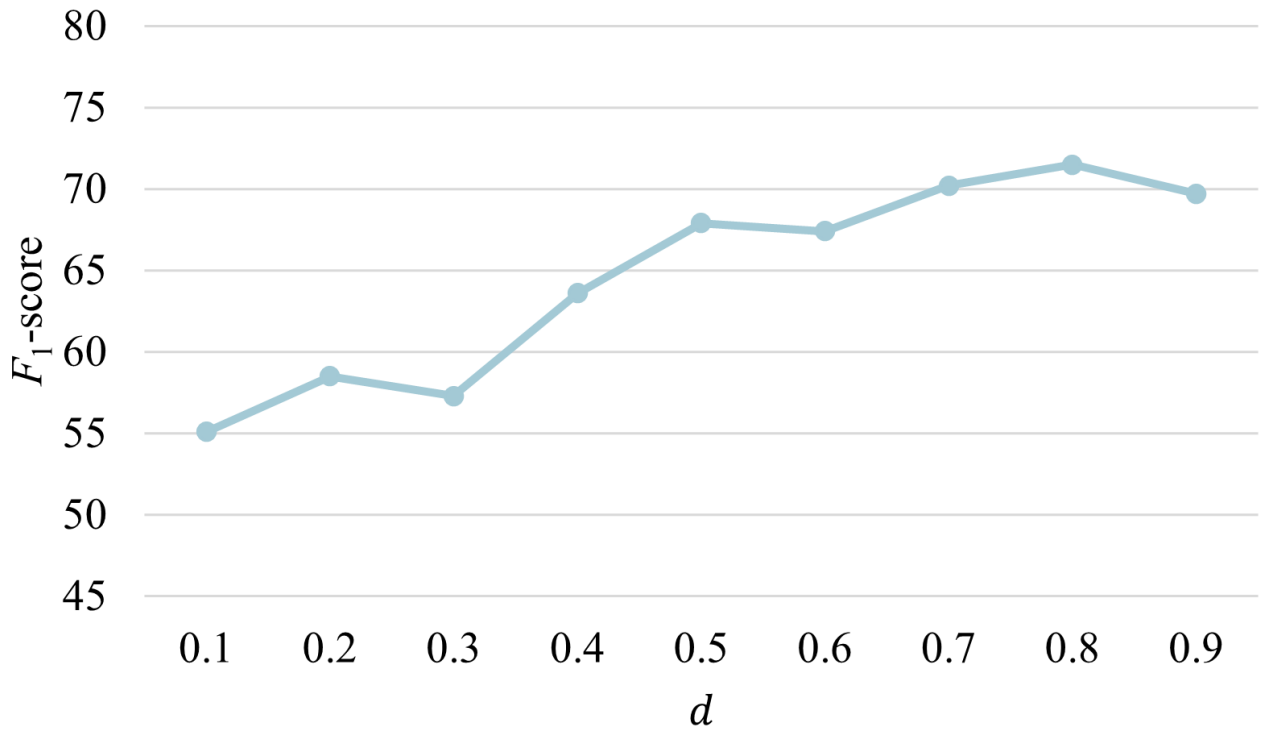

Figure 3. Different knowledge retrieval settings and the corresponding F_1-scores.

To study the impact of the damping factor d, where 1-*d* is the probability of randomly jumping to other nodes, we varied d within the range of [0.1, 0.9]. As shown in Figure 4, the performance of Yaoshi-RAG initially improved with increasing d, reached the peak (d=0.8), and subsequently declined. This trend aligns with the commonly adopted value (d=0.85) proposed by Page et al [47] and is consistent with previous findings [48,49]. Specifically, when d is too small, the resulting PageRank distribution is dominated by random jumps, which weakens the influence of the graph structure and yields less meaningful entity rankings. Conversely, when d approaches 1, the distribution becomes nearly uniform, and the convergence of the power iteration method slows significantly, posing computational challenges.

XSL•FO
RenderX

Figure 4. Different damping factor settings and the corresponding F_1-scores.

We evaluated the effectiveness of Yaoshi-RAG's retrieval strategy against multiple baselines. For sparse retrieval, we used BM25 [50] and followed DecAF [51] by transforming 1-hop subgraphs of topic entities into text. In KG embedding–based methods (TransE [52] RAG and RotatE [53] RAG), we ranked triples by embedding similarity. We also extracted the 2-hop subgraph to prioritize semantically relevant triples from query entities' neighborhood. All baseline methods retained the top 30 triples as retrieval results. Table 4 shows the performance comparison of different retrieval strategies. Yaoshi-RAG achieved superior performance with the highest Hits@1 (84.2%) and F_1-score (71.5%).

Table . The performance comparison of retrieval strategies.

Retrieval strategies	Hits@1	F_1-score
BM25 (2009)	72.8	65.3
TransE RAG (2013)	82.6	69.9
RotatE RAG (2019)	81.9	68.5
2-Hop Subgraph	75.4	67.2
Yaoshi-RAG (Ours)	*84.2* [a]	*71.5*

[a]Values in italics indicate the best performance for each metric.

To evaluate the impact of key modules in Yaoshi-RAG, we compared three variants: (1) a variant replacing the UKG with a deterministic KG, in which all triples were assumed to be fully reliable (ie, confidence scores were set to 1); (2) a variant removing the postprocessing of retrieval results, in which all retrieved reasoning paths from the UKG were directly input into the LLM without ranking or filtering; and (3) a variant randomly generating relation paths to guide the retrieval of reasoning paths.

As shown in Table 5, using a deterministic KG leads to a performance decline, highlighting the importance of incorporating uncertainty information derived from the UKG. Performance degrades further when postprocessing is removed, due to the inclusion of noisy and irrelevant reasoning paths. This confirms the effectiveness of leveraging weighted PageRank and triple confidence scores in identifying relevant reasoning paths. The variant using randomly generated relation paths for retrieval performs the worst among all settings, emphasizing the necessity of a retrieval strategy that generates faithful relation paths.

XSL•FO

Textbox 5 demonstrates an actual case of a dietary question and the answer generated by our proposed framework. The framework delivers a comprehensive response to a patient presenting peripheral heat sensations and sleep disturbances. By leveraging reasoning paths derived from the MFH KG, the framework establishes clear relations between reported symptoms, underlying constitutional patterns, and appropriate dietary recommendations. The framework also enriches its recommendations by incorporating detailed food entities' attributes from the KG into the LLM, thereby enhancing the specificity of guidance regarding consumption methods and other relevant details. This case demonstrates how Yaoshi-RAG effectively translates MFH principles into clear and practical guidance, helping patients better understand the recommendations and adhere to the suggested treatments.

User query:

Lately my hands and feet keep feeling hot, and I'm having trouble sleeping with lots of dreams. Are there any food you'd recommend for this?

我最近手足心热、失眠多梦，请给我推荐一些食材。 Top-3 reasoning paths:

1. (Heat in Hands and Feet, Related Constitution, Yin-deficient Constitution) → (Yin-deficient Constitution, Suitable Food, Lily Bulb)
2. (Heat in Hands and Feet, Related Constitution, Yin-deficient Constitution) → (Yin-deficient Constitution, Suitable Food, White Fungus)
3. (Insomnia and Vivid Dreams, Influencing Factor, Disharmony between Heart and Kidney) → (Disharmony between Heart and Kidney, Suitable Food, Mulberry)

1. (手足心热, 关联体质, 阴虚质) → (阴虚质, 适宜食物, 百合)
2. (手足心热, 关联体质, 阴虚质) → (阴虚质, 适宜食物, 银耳)
3. (失眠多梦, 影响因素, 心肾不交) → (心肾不交, 适宜食物, 桑葚)

Attributes of related food entities:

[Name], [Primary Effects], [Consumption Methods], [Indications], [Contraindications]

Generated answer:

Based on the symptoms you described—Heat in Hands and Feet, along with Insomnia and Vivid Dreams—the following analysis and dietary recommendations are provided according to Traditional Chinese Medicine (TCM) principles:

TCM syndrome differentiation analysisHeat in Hands and Feet is a typical manifestation of "Five-Center Heat" syndrome. When accompanied by Insomnia and Vivid Dreams, the condition may be attributed to three primary constitution types: (1) Yin Deficiency with Excessive Fire: Insufficient Yin fluids in the body lead to internal heat, disturbing the Shen (spirit) and causing insomnia. (2) Disharmony between Heart and Kidney: The inability of Kidney Water to balance Heart Fire results in excessive Heart Fire, affecting sleep quality. (3) Liver Blood Deficiency: A deficiency in Yin and Blood leads to an unsettled spirit, causing frequent dreams and light sleep. These syndromes often intertwine, requiring dietary adjustments to nourish Yin, reduce internal heat, and harmonize the Heart and Kidney.Recommended food and recipes

- Lily, lotus seed, and white fungus soup: Efficacy: Lily calms the mind, Tremella nourishes Yin and moistens dryness, and lotus seed strengthens the kidney and astringes essence. Together, they create a "Metal-Water Mutual Generation" effect. Preparation: Soak 15 grams of Tremella in cold water until fully expanded, then tear it into small pieces. Add 30 grams of fresh lily and 20 grams of decored lotus seeds to 800 mL of water and simmer for 1 hour. Add rock sugar before serving. Best time to consume: Between 3 and 5 PM (Shen Hour), when the bladder meridian is active, enhancing Yin nourishment.
- Mulberry and black sesame paste: Efficacy: Mulberries nourish the liver and kidneys, while black sesame replenishes blood and moisturizes dryness, making them an ideal pairing for dual liver-kidney nourishment. Preparation: Lightly toast 50 grams of black sesame over low heat and then blend it with 20 grams of dried mulberries and 30 grams of glutinous rice with 600 mL of water into a smooth paste. Best time to consume: About 2 hours before bedtime for a calming effect.

Precautions and lifestyle adjustments

- Dietary restrictions: Avoid spicy and heat-inducing food (eg, chili and Sichuan pepper), warming tonics (eg, lamb and longan), and stimulants such as strong tea and coffee.
- Lifestyle recommendations: Prepare for sleep before 9 and 11 PM (Hai Hour). Practice the "Shaking Head and Wagging Tail to Reduce Heart Fire" movement from the Eight-Section Brocade (Ba Duan Jin). Engage in calligraphy or meditation to calm the mind.

The above plan should be followed continuously for at least 2 weeks to see effects. If diarrhea occurs, discontinue the use of Poria. For patients with diabetes, it is recommended to substitute rock sugar with xylitol. If symptoms persist, seek medical attention promptly for tongue and pulse diagnosis.

根据您描述的手足心热、失眠多梦症状，结合中医辨证及食材特性分析如下:

中医辨证分析

手足心热属于"五心烦热"的典型表现，伴随失眠多梦可综合辨证为三类体质问题：其一为阴虚火旺，因体内阴液不足导致虚火内生，上扰心神引发失眠；其二属心肾不交，肾水无法上济心火，致使心火亢盛影响睡眠质量；其三与肝血不足相关，阴血亏虚致使魂不守舍，出现多梦易醒症状。这三种证型常相互交织，需通过滋阴降火、交通心肾的食疗调理。

推荐食材与烹饪方案

- 百合莲子银耳羹：功效配伍：百合清心安神，银耳滋阴润燥，莲子固肾涩精，三者协同形成"金水相生"之效。制作方法：取银耳15克冷水泡发后撕小朵，配鲜百合30克、去芯莲子20克，加水800毫升炖煮1小时，起锅前加冰糖调味。建议申时（下午3-5点）食用，此时膀胱经当令，可增强滋阴效果。
- 桑葚黑芝麻糊：功效配伍：桑葚滋补肝肾之阴，黑芝麻养血润燥，两者搭配实现肝肾同补。制作方法：将文火炒香的50克黑芝麻与20克桑葚干、30克糯米混合，加600毫升水用破壁机打成米糊。适宜睡前2小时温服，有助宁神助眠。

注意事项与生活调摄

XSL•FO
RenderX

- 饮食禁忌：避免辛辣助火之物（如辣椒、花椒）、温热补品（如羊肉、桂圆）及咖啡浓茶等兴奋性饮品。
- 生活建议：保证亥时（21-23点）前准备入睡，日常练习八段锦“摇头摆尾去心火”招式，并通过书法、冥想安神定志。

以上方案需连续食用2周以上见效，若出现腹泻可暂停茯苓，糖尿病患者建议以木糖醇替代冰糖。症状持续者应及时就医进行舌脉诊察。

Discussion

Principal Findings

Evaluation results indicate that our framework improved the performance of all evaluated LLMs, showcasing its robust adaptability. High-performing models, such as DeepSeek-R1, exhibited marked improvements when enhanced by the MFH KG. This suggests that the MFH KG offers valuable context about ingredient relations, therapeutic properties, and dietary principles, which might not be fully captured during the models' pretraining. Remarkably, even LLMs with fewer parameters showed performance improvement when integrated with the MFH KG. These results highlight the effectiveness of the proposed framework, which combines the contextual reasoning capabilities of LLMs with the rich and structured knowledge of KGs, making it a powerful tool for MFH-based dietary recommendations.

The human evaluation results revealed that the KG-augmented LLM demonstrated comprehensive improvements. The augmented LLM exhibited improved rationality through the relations between symptoms and dietary recommendations provided by the MFH KG. It also achieved superior explainability by integrating theoretical reasoning paths. Furthermore, the framework demonstrated increased user acceptability with more clinically applicable suggestions. The augmented LLM also maintained greater consistency across varying inputs. These findings collectively indicate that RAG can effectively enhance LLMs' capabilities with domain-specific knowledge.

The parameter analysis and ablation studies validate the effectiveness of our postprocessing strategy applied to the retrieved reasoning paths. Retrieving more information does not necessarily lead to performance improvement and may instead introduce irrelevant or noisy information [54], thereby degrading the quality of recommendations. By incorporating triple confidence scores from UKG reasoning, the framework prioritizes informative reasoning paths for dietary recommendations. The performance decline beyond k=10 indicates that confidence-based ranking effectively distinguishes informative reasoning paths from less relevant ones. This underscores the importance of uncertainty modeling in TCM knowledge representation, particularly given the heterogeneous quality of evidence. By measuring confidence scores, the inherent uncertainty in MFH principles can be better managed, prioritizing reliable relations while mitigating the influence of less trustworthy ones.

Limitations

Several limitations of this study should be acknowledged. The MFH KG was constructed using OpenIE, which may introduce inaccuracies and cannot cover all knowledge on MFH principles. Besides, we did not fine-tune the LLMs specifically for relation path generation, which may have constrained the retrieval effectiveness of our framework, particularly for complex cases involving multiple symptoms or conditions. Addressing these limitations in the future would likely further enhance the LLMs' clinical uses and recommendation quality.

Conclusions

This study shows Yaoshi-RAG, a new framework that enhances LLMs' capabilities in generating MFH dietary recommendations through the integration of a UKG. This framework uses multistep LLM calls for OpenIE to automatically construct an MFH KG, incorporating UKG reasoning to measure the confidence of existing triples and complete missing triples. Upon receiving user queries, the framework implements a reasoning path–based knowledge retrieval strategy, extracting relevant reasoning paths from the MFH KG and optimizing the retrieval results through a postprocessing mechanism. Experimental evaluations demonstrate that DeepSeek-R1 is the best-performing base model for MFH-based dietary recommendation generation. This framework facilitates dietary recommendations that adapt to individual health conditions and symptom requirements while considering diverse ingredients and dishes, accompanied by comprehensive explanations grounded in MFH principles. In the future, we plan to focus on implementing more effective knowledge extraction methodologies, expanding our KG through additional MFH literature, exploring optimized retrieval strategies, and fine-tuning open-source LLMs to further improve the accuracy and reliability of the generated dietary recommendations.

The article “Diagnostic Classification and Prognostic Prediction Using Common Genetic Variants in Autism Spectrum Disorder: Genotype-Based Deep Learning” [1] is being retracted due to analytical errors and irreproducibility of the results, which led to the overestimation of predictive value. The issues are detailed by the authors of a letter to the editor [2] and were confirmed during investigation by JMIR Publications.

Authors Wang and Avillach responded and expressed neither agreement nor disagreement with the decision.

Abstract

Background: Many institutions are in various stages of deploying an artificial intelligence (AI) scribe system for clinic electronic health record (EHR) documentation. In anticipation of the University of California, Davis Health's deployment of an AI scribe program, we surveyed current patients about their perceptions of this technology to inform a patient-centered implementation.

Objective: We assessed patient perceptions about current clinician EHR documentation practices before implementation of the AI scribe program, and preconceptions regarding the AI scribe's introduction.

Methods: We conducted a descriptive preimplementation survey as a quality improvement study. A convenience sample of 9171 patients (aged ≥18 years) who had a clinic visit within the previous year, was recruited via an email postvisit survey. Patient-identified demographics (age, gender, and race and ethnicity) were collected. The survey included rating scales on questions related to the patient perception of the AI scribe program, plus open-ended comments. Data were collated to analyze patient perceptions of including AI Scribe technology in a clinician visit.

Results: In total, 1893 patients completed the survey (20% response rate), with partial responses from another 549. Sixty-three percent (n=1205) of the respondents were female, and most were 51 years and older (87%, n=1649). Most patients identified themselves as White (69%, n=1312), multirace (8%, n=154), Latinx (7%, n=130), and Black (2%, n=42). The respondents were not representative of the overall clinic populations and skewed more toward being female, ages 50 years and older, and White in comparison. Patients reacted to the current EHR documentation system, with 71% (n=1349) feeling heard or sometimes heard, but 23% (n=416) expressed frustrations that their physician focused too much on typing into the computer. When asked about their anticipated response to the use of an AI scribe, 48% (n=904) were favorable, 33% (n=630) were neutral, and 19% (n=359) were unfavorable. Younger patients (ages 18-30 years) expressed more skepticism than those aged 51 years and older. Further, 42% (655/1567) of positive comments received indicated this technology could improve human interaction during their visits. Comments supported that the use of an AI scribe would enhance patient experience by allowing the clinician to focus on the patient. However, when asked about concerns regarding the AI scribe, 39% (515/1330) and 15% (203/1330) of comments expressed concerns about documentation accuracy and privacy, respectively. Providing previsit patient education and obtaining permission were viewed as very important.

Conclusions: This patient survey showed that respondents are generally open to the use of an AI scribe program for EHR documentation to allow the clinician to focus on the patient during the actual encounter rather than the computer. Providing patient education and obtaining consent before using AI are important components to gain patient trust. Caution about the results is appropriate, given the low response rate and nonrepresentative profile.

Introduction

The use of electronic health records (EHRs) has become ubiquitous in US medical practices [1]. The benefits of EHR for medical documentation include legibility, accuracy of record-keeping, enhanced ability to access laboratory data, placement of physician orders, interactive alerts, clinical pathways, plus timeliness and interoperability between health care institutions. Since the EHR is designed to be comprehensive, there are considerable and growing demands on clinicians for documentation of the myriad aspects of patient encounters. The time to complete EHR for clinic notes commonly exceeds the time associated with face-to-face visits between the patient and clinician, which may contribute to clinician burnout [2,3]. Research has documented that physicians can spend more than 15 hours per week solely on documentation [2].

Many clinical practices have used live human scribes in the last 10 years to address the substantial work required for medical documentation. Existing research finds that this support significantly lessens physician documentation burden and improves physician-patient communication [3]. With appropriate training, live scribes can effectively and efficiently transcribe and summarize the direct interactions between patients and clinicians, as well as integrate important information such as previous medical records, laboratory, and imaging tests [4]. The use of live scribes can markedly decrease the time and effort of the clinicians to document clinical notes, which may result in less time outside of clinic hours for documentation [5]. Since the use of live scribes is very common in current medical practice, patients are both accepting and supportive of their use [6]. However, there are significant limitations to scaling the usage of live scribes, including staff recruitment and cost.

Recently, there has been the emergence of digital scribes, which use generative artificial intelligence (AI) to transcribe human speech and then transform this into a standard progress note format [7]. There are other recent examples of the use of AI in health care delivery, with AI also entering the patient care landscape for patient navigation and medication adherence [8], and analyzing radiological imaging [9].

Use of AI digital transcriptions (also known as ambient voice technology, or “AI Scribes” may also help lessen the burden of clinical documentation, similar to the use of live scribes [10,11]. It may also enhance the patient experience during clinic visits compared to direct documentation by the provider, since the clinician may be able to spend more time interacting directly with the patient rather than documenting in the EHR during the visit. Initial reports about the use of AI Scribes show a strongly positive response from clinicians, since there is often decreased time and cognitive effort required for medical documentation [12-15]. Although most clinicians had a favorable view of their experience with the use of the AI scribe, the accuracy of the note is still problematic with regard to errors, length of the note, and note style requiring clinician effort to edit the note before finalization [11,12].

However, on a cautionary note, patients may be hesitant to accept use of an AI scribe due to a lack of familiarity or information, or preexisting beliefs about the process, accuracy, and integrity of the information shared between the patient and clinician. In anticipation of a planned deployment of an AI scribe program, our patient experience team surveyed our patients who receive primary care at the University of California, Davis ambulatory clinics. The intent of the survey was to understand the preexisting perceptions of our patients about the current state of EHR documentation and to anticipate both the positive and negative reactions that might be experienced before the rollout of an AI scribe program. In addition, this information could influence how we communicate about the AI scribe program, including the opportunity to opt out of participation.

Methods

Overview

We conducted this study from January 31, 2024, to February 12, 2024, at the University of California Davis Health (UCDH) in Sacramento, CA. UCDH is an academic medical center with 11 community medical group locations that provide care to a diverse catchment area of 6 million people across 33 Northern California counties.

A convenience sample of 9171 patients 18 years and older who had a UCDH primary care visit within the last year was recruited through the postclinic visit surveys via an email that was only sent in English. Patients spoke English as a primary language and were not incentivized to participate. Age, as well as self-identified demographic characteristics such as sex, race, and ethnicity, were taken from the electronic medical record (EMR). When available, these EMR data were collated with their email responses.

Survey Design

A 17-question survey was designed by the UCDH Patient Experience Design team to capture patient perceptions and concerns about the anticipated future rollout of an AI scribe technology. The survey questions included a rating scale for some answers and open-ended responses for others.

The survey was developed and coded using Press Ganey’s Forsta Foundation tool, a JavaScript-based survey platform that assists in simplifying the programming of a survey. Once the survey was developed, it went through 5 functionality tests to ensure proper survey function and data collection.

The survey design took place over multiple iterations. With the goal of identifying possible sources of patient frustration or concern, survey design discussions focused on what insight would be needed to develop possible implementation approaches before the launch of an AI scribe technology within UC Davis Health.

A committee was established to provide feedback on survey design that consisted of 5 individuals: our Chief Medical Information Officer, a medical educator attending with patient research experience, a medical educator who leads digital health clinical programs for the health care system, a program manager responsible for patient experience survey design, and a qualitative survey design professional responsible, who facilitated the creation and execution of the survey. The survey

XSL•FO
RenderX

was reviewed by the committee, which provided feedback on question inclusion, removal, and design. The full introduction to the survey and questions is included in Multimedia Appendix 1.

Participants received an email invitation with an option to opt out. Patients were provided the following brief description of the technology.

"To help take notes, UC Davis Health is testing a tool that looks similar to a cell phone. Upon being activated by the doctor, the tool listens to the conversation and automatically creates notes in the system.

As you participate in this survey, please focus on the note-taking capability and how you would like the use of this technology to work better for you. Please keep in mind that:

- The transcribed notes will be reviewed by the physician.
- Patients and families would be informed about the use of this device."

Results were monitored hourly for the first 150 responses to ensure respondents were completing the survey and providing usable responses for open-ended questions. Since the study's goal is to assist in the development of AI scribe deployment, respondents were required to answer all questions before proceeding. For questions seeking a numeric response (ie, 5-point scale), a score of 3 provided respondents the ability to offer a neutral response. Another batch of 150 was sent again to gauge their responses.

After the initial survey responses were reviewed, it was determined that the survey functioned well and did not require any modifications. However, the email request to the remaining patients (about 8800) was slightly modified, and the final version is contained in Multimedia Appendix 2, with the clarifying language involving the last paragraph noting that the "transcribed notes will be reviewed by the physician" and the "patients and families would be informed about the use of the device."

The median length of time to complete the survey was 10 minutes and 33 seconds. The survey was provided via a secure and closed link, which allowed respondents to start the survey and complete it later. The shortest survey response was 2 minutes and 15 seconds. The longest was 256 hours and 25 minutes.

Survey Analysis

The data were reported using descriptive summary statistics. Since this was a convenience sample survey, no statistical comparisons between groups were performed. Descriptive statistics were used to identify broad themes and to help guide the pilot implementation and deployment of the AI scribe program at UC Davis Health. Since the group of respondents may not have been representative of our clinic population, comparative statistical analysis of the respondent groups was deemed not justifiable. Incomplete responses were not used in the final analysis of this study.

An inductive coding framework was used for open-ended questions. The process entailed a review of all responses to a specific question and identifying response themes (which helped generate a code book). Each response was reviewed and assigned a descriptive label from the code book summarizing the basic theme of a response. A separate research team member evaluated the responses for alignment or discussion. Research team members met to ensure consensus on the application of codes, refine dimensions of existing codes, add new codes, develop categories, and identify theoretical direction. Disagreements among the team members were resolved through discussions to understand viewpoints, deliberate, and achieve consensus. An open-ended response could have multiple themes based on the patient's input. Open-ended responses that were singular in nature were categorized as "other." Statements made by patients that did not align with the subject matter were classified as "not applicable or NA" (ie, a question in the survey asks about a patient's opinion regarding a provider taking notes, and the patient responds with negative statements about parking). Both members of the team are professionally trained survey designers.

Ethical Considerations

This quality improvement study was reviewed by the UC Davis Health Institutional Review Board and deemed non–human subjects research, and therefore exempt from review, because the data came from patient surveys. Since this study was exempt from review and the participants were anonymous, we did not obtain informed consent, waivers, or privacy protections. Participants were not compensated for completing this survey.

Results

The survey had an overall completion rate of about 21% (n=1893 respondents out of 9171 surveys). An additional 549 started the survey, but did not complete it. Partial responses were excluded from the survey results. All percentages calculated from 1893 respondents. The age, sex, race, and ethnicity data were extracted from the EMR and collated for each patient response. The respondents' demographics were predominantly female (1205/1893, 64%), ages 51 years and older (1649/1893, 87.1%), and White (1312/1893, 69%; see Table 1). As noted in the Methods section, patients self-identified their race and ethnicity. We compared these percentages to our patient population at UC Davis Health, using our Epic EHR, and accessed the active clinic patient registry for any interactions in the past 2 years. The demographic profile of this group was as follows: female 53.7% (207,947/387,512; total clinic population), ages 50 years and older 44.5% (172,500/387,512), and White (not Hispanic) 37.3% (144,836/387,512).

Sex	
Female	1205 (63.7)
Male	688 (36.3)
Age (years)	
18-30	64 (3.4)
31-40	60 (3.2)
41-50	120 (6.3)
51-60	285 (15.1)
61-70	622 (32.9)
71+	742 (39.2)
Race and ethnicity	
White or Caucasian	1312 (69.3)
Multirace (Ethnicity)	154 (8.1)
Latinx or Hispanic	130 (6.9)
Unknown	105 (5.5)
Asian	86 (4.5)
Other[b]	57 (3)
Black or African American	42 (2.2)
Native Hawaiian or Other Pacific Islander	5 (0.3)
American Indian or Alaska Native	2 (0.1)

[a]Before introducing an AI (artificial intelligence) Scribe program, UC Davis Health primary care patients were sent an email questionnaire about their perceptions to determine how the program should be implemented.

[b]American Indian or Alaskan Native, Native Hawaiian, or other Pacific Islander were combined in the "Other" category for reporting, since those numbers were small.

The survey was performed as a quality improvement project, rather than a scientific investigation. Given the potentially nonrepresentative patient sample, we did not perform comparative statistical analysis between the groups. Thus, these results should be considered as indicating broad informal trends.

Patients' perceptions of current clinician notetaking practices were generally positive, with 71% (1349/1893 responses) feeling very heard or somewhat heard and 79% (1490/1893 responses) indicating their doctors were engaging in their health discussion while taking notes during their primary care provider (PCP) appointment. However, younger patients (ages 40 years and younger) and Asian and Latinx or Hispanic patients expressed more critical views, citing a lack of engagement and limited interest from physicians during notetaking. A review of actual open-ended patient comments revealed that 62 responses were not applicable to the question, leaving 1831 responses. The comments related to clinician EMR documentation demonstrated that 29% (530/1831 responses) were very positive and the patients felt "heard" by their provider, and another 24% (439/1831) reported that the notetaking did not bother them, since this was a normal routine. 21% (385/1831) reported that it was a "necessary evil" because documentation is required. 23% (416/1831) reported that when the provider took notes into the computer during the visit, it felt very impersonal to them, that the physician was distracted, and sometimes they felt disrespected. An example of a typical positive comment was "I feel she is listening and accurately recording my info since she is recording as we speak." Examples of negative comments include: "I feel the need to slow down and even stop talking until my PCP completes her typing," "Feels a bit impersonal, like he's just entering data to tick boxes, etc. rather than really discuss the issue with me," and "I realize it's a necessity – but would rather they just be able to listen."

When asked about how the AI scribe technology would impact the overall clinic visit, 48% (904/1893 responses) of patients responded positively, 33% (630/1893) were neutral, and 19%

XSL•FO
RenderX

(359/1893) felt it would have a negative impact on the patient-physician interaction.

Overall, regardless of age, more patients had a favorable perception about the use of AI scribes than neutral or negative (see Figure S1 in Multimedia Appendix 3). Looking at the trends in perceptions about AI scribe technology suggested some differences by age. Younger patients (aged 18-30 y) appeared to have a higher frequency of concerns about the potential negative impact (31%, 20/64 responses) compared to older groups. Interestingly, patients aged 50 years and older seemed to have the most favorable perceptions and the least skepticism (18%, 300/1649 responses).

Figure S2 in Multimedia Appendix 3 shows the breakdown of perceptions by race and ethnicity, which varied among the groups. The majority of patients had positive perceptions across all groups, ranging from 46% (598/1312) "White" responses to 67% (58/86) "Asian" responses. Patients who identified as "Asian" or "Black" seemed to have more positive perceptions about the use of a voice technology and lower rates of skepticism. Negative perceptions were around 20% (323/1660) for the remaining groups; 20% (257/1312) "White" responses were negative, 19% (30/154) "Multirace (Ethnicity)" responses were negative, 18% (23/130) "Latinx or Hispanic" responses, and 20% (13/64) "Other" responses were negative.

The open-ended comments about the perceived benefits were collated and grouped by themes. Table 2 shows these themes in descending order. The respondents listed the following anticipated benefits for an AI scribe: improve human-to-human interactions (41.8%, 655/1567 comments), accuracy of notes (28%, 435/1567), benefits to doctor and staff (15%, 231/1567), generally positive (6%, 98/1567), and transparency (4%, 58/1567). The listing of potential benefits varied by age, with 57% (28/49 responses) of patients aged between 31 and 40 years listing "improve human elements" as the most frequent. There was less variation when comparing the results by race and ethnicity. Positive open-ended comments about the "improve human elements" included: "It will free up the doctor to read emotion and other non-verbal cues and ask follow-up questions," and "If it allows the doctors to see more patients, it could decrease the time it takes to get an appointment." Positive comments about "accuracy of notes" include: "Better information regarding my complaints and symptoms. Nothing missed," and "It will more accurately reflect our conversation. I often read the notes in the After Visit Summary and find errors…."

Numerous concerns about the AI scribe program were noted by the survey respondents (see Table 3). The most commonly mentioned were related to note accuracy (39%, 515/1330 comments), privacy and security (15%, 203/1330), negative feelings about being recorded (13%, 177/1330), and general feelings that it was bad for the physician and staff (10%, 139/1330), plus others. These concerns were common among those respondents who thought that the digital technology would have a negative impact. Younger respondents expressed the greatest skepticism over note accuracy, privacy, and security. Key comments focused on the risks that the recordings might be discovered by hackers, which would be a violation of privacy. There were both positive and negative comments about the potential accuracy of the digital transcriptions. Some felt that the transcribed clinic notes would be more accurate, while others were worried that there was a higher risk of containing inaccurate statements (transcription errors). Since the survey was done preimplementation, this probably reflects the respondents' best speculations about the effectiveness of the AI scribe technology.

Patients were queried about the best time to be informed about the AI scribe program. It was clear that patients preferred early notification, either when the appointment is made (43%, 809/1893 responses), upon arrival at the examination room (32%, 602/1893), or upon arrival at the clinic (15%, 276/1893). When given choices about how they would be informed, patients preferred verbal discussion (57%, 1085/1893 responses), followed by email (45%, 854/1893), text (28%, 532/1893), and then via brochure (24%, 460/1893), followed by miscellaneous. Patients had fewer clear preferences about who might provide the notifications, with a slight preference to hear from the physician or resident over nursing or support staff. When asked about the preferred method to be informed about the use of AI scribe technology before the clinic visit, the respondents most preferred an email (63%, 130/206 respondents), text message (40%, 82/206 respondents), or verbal discussion (38%, 78/206 respondents).

Table 2. Thematic benefits of artificial intelligence (AI) scribe.

Response themes[a]	Coded comments, n (%)
Improve human elements	655 (41.8)
Accuracy of notes	435 (27.8)
Beneficial to the doctor and staff	231 (14.7)
General positive	98 (6.3)
Transparency	58 (3.7)
Mixed	36 (2.3)
Improve access	28 (1.8)
Other	26 (1.7)

Table 3. Thematic concerns of artificial intelligence (AI) scribe.

Response themes[a]	Coded comments, n (%)
Accuracy of notes	515 (38.7)
Privacy and security	203 (15.3)
Problem with being recorded	177 (13.3)
Bad for the physician and staff	139 (10.5)
Human element	126 (9.5)
Other (technical failure, billing, incorrect *ICD* code, referrals, etc)	58 (4.4)
Transparency (MyChart, Notes summary, etc.)	22 (1.7)
General negative	90 (6.8)

[a]Patients responded to open-ended questions about their concerns related to the implantation of an AI scribe program. These comments were collated and grouped by theme, with the frequency of each theme listed in descending order.

Discussion

Principal Findings

This survey of UCDH primary care patients in anticipation of a deployment of our AI scribe program helped inform our team about the perceived benefits and concerns to shape our implementation. This convenience sample of nearly 1900 patients, with a response rate of about 20% (1893/9171), was sufficient to influence the implementation process. We believe that these results can support other health care institutions to implement patient-centered, culturally competent AI scribe programs.

It is important to note upfront that the demographic profile of the patients who responded to the survey was less representative of the overall outpatient clinic population at UC Davis Health, skewing more strongly to those who were female, were ages 50 years and older, and White compared to our overall clinic population. Thus, interpretation of the survey results should be tempered with this knowledge. Nonetheless, we believe there is value in reporting these results, given the relatively large number of responses and broad trends.

There were several overall trends expressed by the respondents that were supportive of the AI scribe program, as well as cautionary notes. Of the survey respondents (predeployment of an AI scribe program), most patients felt that their physicians were currently attentive during the visit (71% 1349/1893), and patients accepted that EHR documentation was needed to ensure an accurate record of patient encounters. Nonetheless, 22% (416/1893) of respondents were put off when their providers were typing into the computer during the visit, feeling that the clinician was too focused on the documentation and paying less direct attention to the patient. This may reflect different interaction styles between physicians and their patients, rather than a rejection that physicians perform documentation during the clinic visit. Most patients appear to have realistic views about how clinicians must balance their approach to directly interacting and listening to them with the burdens of documentation. Nonetheless, if using an AI scribe during the visit frees the physician to directly interact with the patient, this is likely to be perceived positively.

In support of this interpretation, a plurality of respondents viewed the use of an AI scribe in a positive light (42%, 655/1567 positive open-ended comments), noting that this might enhance the clinician's ability to focus on the patient and less on documentation during the encounter. Other positive benefits included improved note accuracy, reduced workload for the clinician and staff, and improved transparency. Although we are cautious not to overinterpret the differences based on age and race and ethnicity (since the groups were not subjected to formal statistical comparisons), there were interesting trends. For example, in contrast to our expectations, patients aged 50 years and older appeared to be more positive about the potential benefits of use of an AI scribe compared to a younger cohort. The younger patients expressed more concerns about privacy and security with regard to being recorded as part of the AI scribe technology, as well as accuracy. It appeared that non-White patients expressed positive impressions about the use of the AI scribe at least as often as White patients.

Nonetheless, although there were negative comments or concerns expressed, only 19% (359/1893) of respondents thought that the overall impact would be negative, whereas 48% (904/1893) thought that it would be positive. Thus, this may reflect anticipatory anxiety, and this could be readily addressed by both previsit patient education and actual experience.

Comparison to Previous Work

There are currently limited studies that report patient experiences with AI scribe technology, and the responses have been generally favorable. Most research to date has focused on time saved to physicians or on using AI to generate medical advice, while very little has been done to measure patient attitudes about AI scribes during clinic encounters. Cao et al [7] reported their experience with the use of the Dragon Ambient eXperience (DAX; Nuance & Microsoft) system in a dermatology practice. In a limited survey of patients (score 1-5, 5 being "strongly agree"), there was high favorability on the following questions: "The provider spent less time typing on their computer" (mean score 4.5), "My visit felt more like a personable conversation" (mean score 4.4), and "The provider seemed more focused on me during the visit" (mean score 3.9). A group of Northern California Kaiser Permanente physicians and researchers published their initial experience with an AI scribe program

XSL•FO
RenderX

[16]. The primary focus of this paper was on the implementation of the software-based medical dictation technology from a provider standpoint (accuracy of note, usability, and effectiveness). They described their patient-facing educational materials as part of their permission process that included a verbal summary of the AI scribe to the patients, as well as laminated posters. Between October and December 2023, the AI scribe was rapidly implemented, with over 3400 physician users and more than 300,000 patient encounters. In a limited survey of 21 patients from a single clinic site, 71% of respondents noted that they spent more time talking with their physicians, and 81% reported that physicians spent less time looking at their computers during the encounter. The patient responses to early experience with the AI scribe match up well with our patient survey results. In a news article about the Kaiser Permanente study, Feldheim [17] noted that the benefits of the AI scribe extended beyond the time savings for the providers: "they may help restore the fundamental human connection at the heart of medicine."

It is worth considering potential explanations about why there appears to be a difference in attitude between older and younger respondents, even though our survey was not designed to explore these differences in detail. Several papers appear to offer clues about what might be underlying these differential attitudes. Older adults, especially those who are comfortable with technology, are willing to share their personal information with family and hospitals (compared to government agencies) [18]. Older adults are selective about what information they share, but if they perceive that these services are used to maintain and promote health, then they are willing to share that information, even if they have concerns about privacy [18]. Kauttonen et al [19] conducted a web-based survey of Finnish participants to gauge trust and acceptance of artificial intelligence when adapted into health care delivery. They found that age was a factor in the acceptance of the use of AI in health care, but not always a consistent trend. Instead, the combination of familiarity with technology along with age appeared to be more important. For example, those who were less familiar with AI were the least trustful. Interestingly, though, people aged 70 years and older were the most positive about AI when balanced with trade-offs. There were significant confounders based on the type of AI scenario presented to the participant. In a study of German patients at a tertiary care center, more than 50% of participants had positive attitudes about the use of AI in health care, and only about 5% had serious reservations. In contrast to our study results, older patients and women expressed more caution about AI in health care [20]. The key to acceptance is that the patients insist that the use of AI be under the control of their physician.

Younger patients may have a greater understanding of technology, particularly AI. In a survey report offered by Cisco, they found that about 48% of respondents agreed that AI could be useful to improve their lives. However, there were serious concerns, especially about the use of generative AI, even though few were very familiar with this technology. In particular, there was substantial concern about privacy protections, with the youngest consumers (42% of those aged between 18 and 34 y) actively engaged in protecting their privacy, and this was 7 times higher than those aged 75 years and older [21]. A small group of young adults (25-34 years) was provided with a focus group survey about AI-driven mobile health technology [22]. Many expressed enthusiasm (and skepticism) about the emerging technology. Prominent among the perceived risks were concerns about data privacy and the need for human supervision.

These studies seem to highlight several themes relevant to the use of an AI scribe. One is that there is limited familiarity with the new technology. The degree of enthusiasm seems closely aligned with both familiarity with technology and the perception of whether it can enhance health care delivery for the patient. It may be that older patients are more accepting that the AI scribe can unburden the physician's responsibility for clinic documentation, whereas younger patients have greater concerns about privacy and lack of control over their personal information when their data is fed into a generative AI program. As noted in the Conclusions section, education about the process and protections for privacy are key to acceptance and trust.

Strengths and Limitations

There are several strengths to this study. First, is that we received a relatively large number of responses to the survey, representing about 20% (1893/9171) of those who were contacted. Second, we queried about both the current patient-physician interactions as well as anticipating patient responses to the eventual implementation of an AI scribe voice technology for medical documentation. Third, we obtained actionable information that helped modify the future rollout of the program. For example, we prepared our users with information about the system's security and data retention policies so they would be prepared to respond to expected patient concerns. Finally, we identified that patient education (in various manners) would be a critical element for patient acceptance of the AI scribe.

Several important limitations affect the interpretation of the survey results. A primary limitation is that the demographic profile of those who responded was not representative of the clinic population, as determined by the self-identification of the patients noted in our EMR. Since this was a convenience sample and not expected to be fully representative of our patient population, this limits our ability to precisely compare the differing responses among the varying demographics and perform statistical analysis. The survey was only sent to English-speaking patients and was sent by email, so the perspectives of non-English speaking patients and those with limited digital access or literacy on this technology are not known. Given this limitation, the best we could expect was to understand broad themes. It is worth acknowledging that the demographic characteristics of the respondents are probably more representative of who chose to respond to the survey rather than the overall population of patients who receive their health care at our institution. Since survey respondents skewed older and white, we are uncertain whether a younger, more diverse population would actually experience this technology differently. The response rate was only 20%, so this also limits the generalizability of the results. Thus, it will be important to monitor patient reactions to the rollout of the AI scribe over time, since the actual patient experience may vary from the

XSL•FO
RenderX

anticipated one. To that point, we note that this survey had a high nonresponse rate. Finally, we intentionally shared information about the technology with participants that was simple and written for a lower literacy competency. While we believed this was appropriate, some participants may have wished for a deeper explanation of the technology involved.

Nonetheless, the survey provided valuable guidance on how to communicate about the use of AI scribe and gain patient consent for a new technology that some may find uncomfortable or threatening. A recent study by Lawrence et al [23] describes a quality improvement project focusing on determining the best approaches to obtaining patent consent before using the AI scribe during a clinic visit. The keys to successfully obtaining patient consent included establishing patient-physician trust, targeted education (more than a single modality and a flexible approach to answering patient questions), and honest discussions about potential vulnerabilities (risk of security breaches, inaccurate documentation, and risk of medical errors). When basic information about the AI scribe was provided to the patients, 81.6% consented. This study supports the findings that we obtained from our own patient survey, that most patients would accept the AI scribe, if introduced with appropriate education and permission sought beforehand.

Conclusions and Recommendations

We learned that although many patients understand and accept that providers commonly complete their medical documentation during the actual clinic visit to increase efficiency, a significant proportion feel that this interferes with effective and empathetic communication. Using AI Scribe technology may allow clinicians to spend more time in direct dialogue with patients rather than typing into the EHR and staring at a computer screen. Key to the acceptance of an AI Scribe program is to educate the patient about the program in advance (through placard notifications in the clinic, EMR notices, or verbal discussions) and obtain explicit verbal permission from the patient before use. The patient must be allowed the option to opt out. Verbal consent should be documented in the patient's clinic note.

Acknowledgments

We are grateful to Anthony Caso and Shefali Tamakuwala for their assistance with data extracts, data management and analysis, and to Elizabeth Keating for her assistance with manuscript editing. Generative artificial intelligence was not used in any portion of the writing of this manuscript.

The authors received no financial support for the research, authorship, or publication of this article.
