We conducted experiments to estimate the frailty status from speech signals. We used the PDT, which is commonly used for screening cognitive function impairments, to collect speech data. In the PDT process, a picture is shown, and the participants are asked to describe everything visible and explainable in the picture for 2 minutes [15]. The participant's cognitive function is assessed based on which part of the picture the participant observes and how they express the situations in syntactic and semantic terms. The PDT is usually used as a screening tool for Alzheimer disease, one of the types of degenerative brain disease, and we adopted the PDT as a tool to collect voice data for developing an AI model to evaluate frailty status [16,17].

The Boston Cookie Theft picture has been commonly used in the PDT to assess cognitive function; however, it does not fit South Korea's culture [18]. For this reason, we developed a Korean version of the PDT, which contains Korean cultural references and could thus feel familiar to Koreans. The illustration was designed according to the following principles [19]: (1) salience of information, (2) semantic categories, (3) referential cohesion, (4) causal and temporal relations, (5) mental state language, (6) structural language, and (7) general cognition and perception. Detailed descriptions for each principle are represented in Multimedia Appendix 1.

XSL•FO
RenderX

The picture shown in Multimedia Appendix 2 was developed on the basis of these principles for the Korean version of the PDT. In our data acquisition phase, the picture was provided to the participants through an app developed for a tablet, and they were asked to describe it for 2 minutes. While they explained the picture, the participants' voices were recorded using the application.

Short Form of the Comprehensive Geriatric Assessment

The participants completed a short form of the Comprehensive Geriatric Assessment (SF-CGA) to identify comorbidities, functional status, cognitive function, and depressive symptoms. Medical history, including hypertension, diabetes, heart failure, atrial fibrillation, chronic kidney disease, chronic liver disease, respiratory disease, cerebrovascular disease, myocardial infection, Parkinson disease, dementia, and depression, was assessed. Cognitive function was assessed using the Korean version of the Mini-Mental State Examination-2 (K-MMSE-2) [20]. In addition, the Clinical Dementia Rating scale (CDR), a numerical scale used to quantify the severity of dementia symptoms, was assessed [21]. Functional status, including activities of daily living (ADLs) and instrumental ADLs (IADLs), were assessed using the Barthel index and the Lawton and Brody index, respectively [22,23]. Depressive symptoms of the participants were evaluated with the SGDS-K [24].

Outcomes and Definition of Frailty and Prefrailty

Frailty status was defined using the Korean version of the Fatigue, Resistance, Ambulation, Illnesses, and Loss of Weight Scale (K-FRAIL) questionnaire [6]. We considered K-FRAIL scale scores with ≥3 positive items to indicate frailty. K-FRAIL scores of 1 or 2 were classified as prefrail, and a K-FRAIL score of 0 was categorized as robust. In this study, since the prefrail group is considered to exhibit some physiological deficits, the prefrail and frail groups were combined and compared with the robust group, which is consistent with previous research [25-27].

Acoustic Features

Recent AI technologies have been used in speech recognition, generation, and analysis. However, few studies have used speech signals as biomarkers to evaluate frailty using machine learning techniques. In our experiments, we considered using voice recordings to evaluate the frailty. Specifically, we converted raw speech data into acoustic features expressed in the frequency domain for the input of an AI model. The spectral characteristics of speech signals can be expressed using mel-frequency cepstral coefficients (MFCCs) and are well suited for various deep-learning methodologies [28].

In preprocessing using MFCCs, the audio signals are transformed from the time domain to the frequency domain via a Fourier transform after quantization to time-windowing segments. Subsequently, the mel scale is applied to the spectrum to reflect the sensitivity of the frequency band. The first "n" coefficients are then gathered after transforming the mel spectrum through the discrete cosine transform. The gathered coefficients are called MFCCs and represent the unique characteristics of the audio signal. In general, studies using MFCCs have considered not only the coefficients but also their first- or second-order derivatives. In our study, to develop an AI model for identifying frailty using speech signals, we set the number of coefficients "n" to 20 and used the first- and second-order derivatives. Consequently, the acoustic features constructed using the MFCC technique comprised 60 dimensions. To convert the speech signals into acoustic features, we used Python 3.8 (Python Software Foundation) and the Librosa library (Python Software Foundation).

Prediction Model Development and Validation

AI models using demographic and speech data were trained and validated to predict the frailty status. Among the machine learning methods, we trained the models using a supervised learning scheme, and the dataset collected from the prospective cohort was used for training and validation. The entire collected dataset was separated for training and validation purposes; there was no overlap between the training and validation datasets.

We explored and compared three types of machine learning models to predict frailty. The first model, SpeechAI, was constructed to predict the frailty status using only the acoustic features of speech signals. In the second model, DemoAI, demographic data were used to predict the frailty status, and in the third model, DemoSpeechAI, demographic data and acoustic features were combined to predict the frailty status. A total of 3 primary modules were designed to construct these models. One was designed as a classifier to identify frailty status from the data represented in the embedding space. The others were designed to represent demographics and speech data as embedding vectors.

The SpeechAI model was organized to predict frailty using acoustic features extracted from voice signals and was constructed with two modules: speech embedding and classifier. The Transformer structure was used in the speech-embedding module to express the acoustic features in the vector space [29]. The vector expressed via the Transformer model is passed to the classifier module, which consists of one hidden layer to predict the frailty status. The SpeechAI model shown in Figure S1 of Multimedia Appendix 3 had approximately 612,000 deep-learning network parameters to be trained. Among the parameters, approximately 96% (587,520/612,000) belonged to the Transformer architecture, and the classifier module had approximately 25,000 parameters.

The DemoAI model consists of a demographically embedded module that projects demographic information provided as a categorical type in an embedding space and a classifier module that predicts frailty based on the information expressed in the embedding space, as shown in Figure S2 of Multimedia Appendix 3. The demographic embedding module receives chronological age categorized into 10-year intervals and sex as the input among demographic information. They are projected onto 2D and 4D continuous embedding spaces, and the embedding vectors are concatenated to express a joint vector. The classifier module, which consists of one hidden layer, receives the joint vector expressed by the demographically embedded module, and serves as a binary classifier that distinguishes between frailty and robustness. The DemoAI model had approximately 26,000 entire network parameters for training.

XSL•FO
RenderX

The DemoSpeechAI model shown in Figure S3 of Multimedia Appendix 3 was constructed using demographics, speech-embedding modules, and a classifier module. The demographics and acoustic features were projected onto each embedding space through the embedding modules and then combined as a joint embedding vector. Subsequently, the joint embedding vector was passed to the classifier module to estimate frailty. The embedding modules used in the DemoSpeechAI model have the same structure as those used in the DemoAI and SpeechAI models. The parameters of the DemoSpeechAI model were approximately 621,000, consisting of approximately 34,000 for the classifier and 587,000 for the embedding module.

To build and train the deep-learning model, we used the PyTorch (version 2.0.1; PyTorch Team) library for Python, and an early stopping technique was used to prevent overfitting of the models in the training phase [30]. The dataset was split into five folds for 5-fold cross-validation; 4 sets were used for training, and 1 set was used to analyze the performance of the models. Each fold was divided into a balanced number of robust and frail labels.

Pretraining Strategy Using Self-Supervised Learning

We designed and modularized three types of models to predict the frailty status of the participants using deep neural networks. Among the modules constructing each model, the speech-embedding module contained a significant number of parameters to be trained compared with the amount of data collected from participants, accounting for approximately 95% of the parameters in the SpeechAI and DemoSpeechAI models. To address the risk of overfitting due to the limited data, we used a self-supervised learning (SSL) strategy [31,32]. In the SSL strategy, an AI model is pretrained on a different task before being fine-tuned for the primary task. This involves pretraining the model on a different dataset, which helps establish a robust parameter foundation. As a result, there is no need to train the parameters from scratch, allowing effective training with a relatively small dataset. To implement the SSL technique, we used the AIHub dataset from the Open AI Dataset Project (AIHub) for public purposes [33]. The AIHub dataset includes voice recordings of 1002 Korean participants, which we used for pretraining the speech embedding module of the SpeechAI and DemoSpeechAI models. Consequently, only about 5% of the parameters in these models, specifically those in the classifier and demographics embedding modules, were trained using the dataset collected from our prospective cohort.

Results

A total of 127 Korean participants aged ≥50 years were recruited to collect data at Seoul National University Bundang Hospital from June to December 2022. We acquired demographics, SF-CGA results, and voice recordings and developed an AI model for predicting frailty status. Among the participants, 43 out of 127 participants (34%) were female, the average number of years of education was 11.787 (SD 4.732) years, and the mean age was 69.2 (SD 10.9) years.

Among the 65 participants in the frail group (prefrail and frail), 6 out of 65 (9%) had dependent ADLs, and 7 out of 65 (11%) had dependent IADLs. The mean scores for the K-MMSE-2, standard total T-score, and CDR-Sum of Boxes were 25.874 (SD 4.53), 44.748 (SD 13.4), and 0.591 (SD 1.3), respectively. In the CDR, 87 out of 127 participants (68%) had 0 points, 37 out of 127 participants (29%) had 0.5 points, and 3 out of 127 participants (2%) had 1 point or higher. The mean SGDS-K scores were 2.945 (SD 2.89).

According to the K-FRAIL results, 65 out of 127 participants (51%) belonged to the frail group. The participants in the prefrail to frail group were older (73.4 vs 64.9 years; $P<.001$), had lower education levels (10.2 vs 13.5 years; $P<.001$), lower cognitive function (K-MMSE-2, 23.9 vs 27.9; $P<.001$), more depressive symptoms (SGDS-K, 4.1 vs 1.7; $P<.001$), and dependent ADL and IADL levels (Table 1).

We explored and compared 3 AI models for predicting the frailty status using speech only (SpeechAI), demographics only (DemoAI), and a combination of speech and demographics (DemoSpeechAI). In this study, we used 5-fold cross-validation to train and evaluate our models using a dataset corresponding to 127 participants. The entire dataset was randomly divided into 5 subsets, with each fold containing approximately 20% of the total samples. Each fold was used once as the validation set, while the remaining 80% of the samples were combined to form the training set. This process was repeated 5 times so that each fold served as the validation set exactly once. Consequently, all data points were used for validation once, and the performance metrics reported are the average results from these 5 validation runs. This approach ensures that the model's performance is robust and generalizable, avoiding overfitting and clearly defining the proportion of samples used in the validation phase. The accuracy, area under the receiver operating characteristic (ROC) curve (AUC), sensitivity, and specificity were used to analyze the performance of the model.

The mean accuracy of the SpeechAI model for the 5 validation results was 80.4% (95% CI 76.89% - 83.91%), with minimum and maximum values of 75.05% and 86.93%, respectively. The mean AUC was 0.89 (95% CI 0.86 - 0.92), with minimum and maximum values of 0.86 and 0.94, respectively. Furthermore, the average sensitivity and specificity of the SpeechAI model for 5-fold validation results were 0.75 (95% CI 0.67 - 0.83) and 0.86 (95% CI 0.84 - 0.88), respectively (Table 2). ROC curves were observed for 5-fold cross-validation, and the results and means are shown in Figure 1.

XSL•FO
RenderX

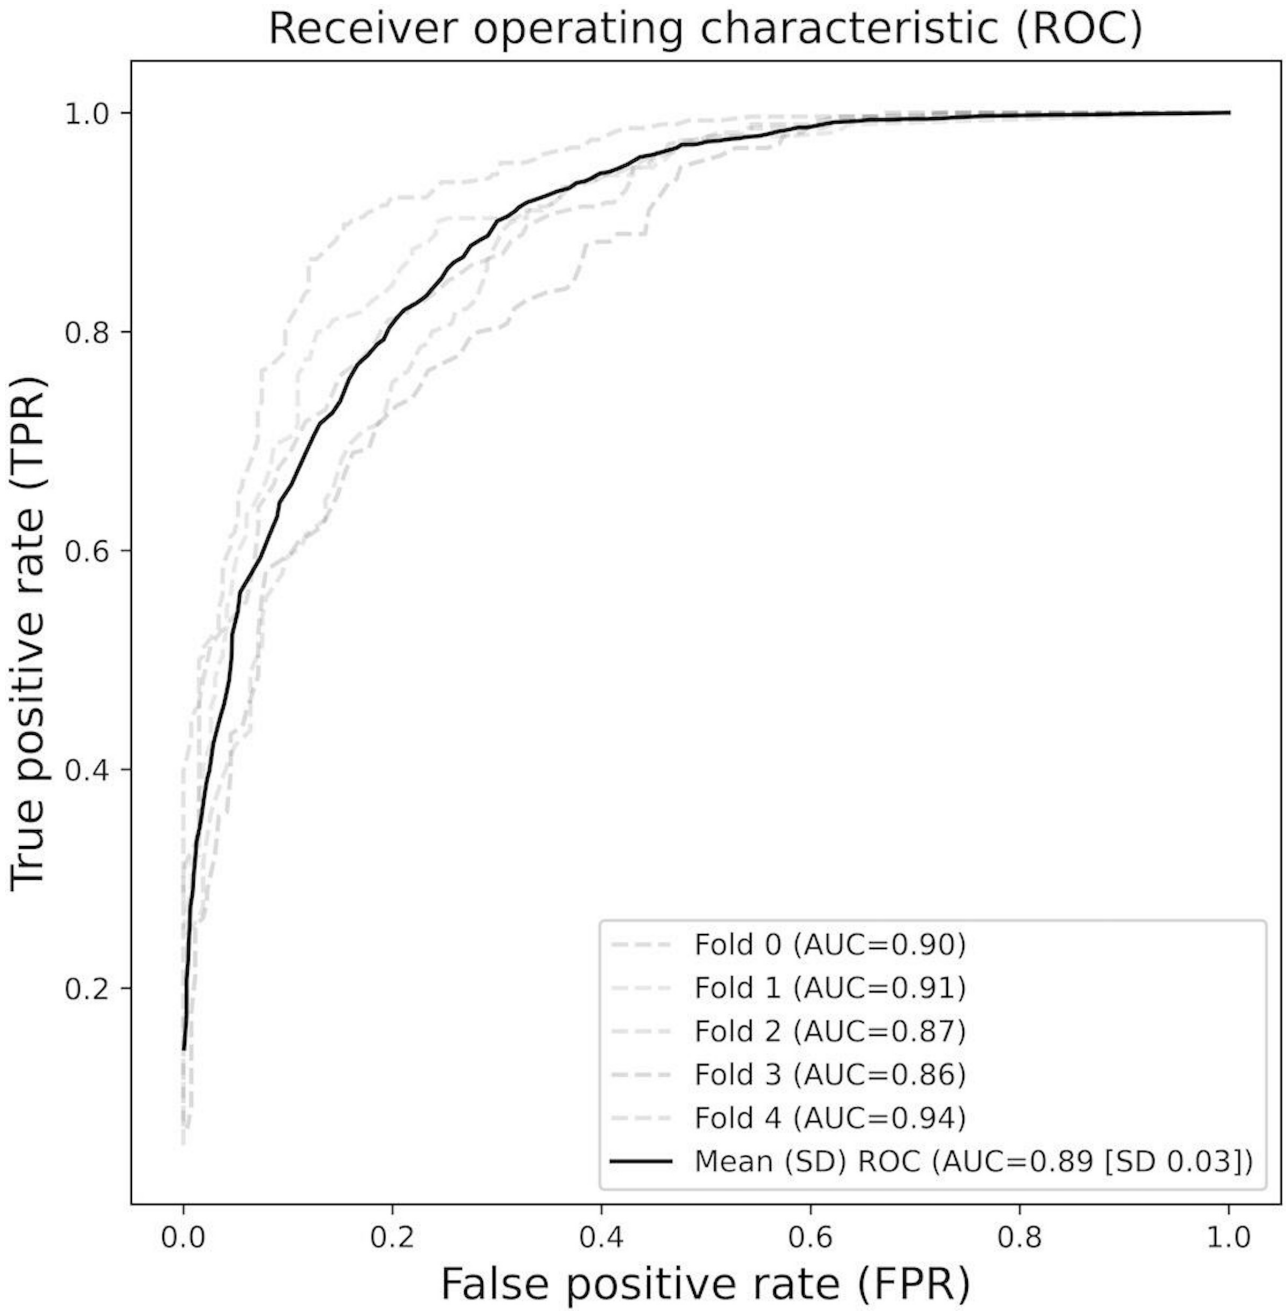

Table . The performance of the SpeechAI, DemoAI, and DemoSpeechAI models by 5-fold cross-validation.

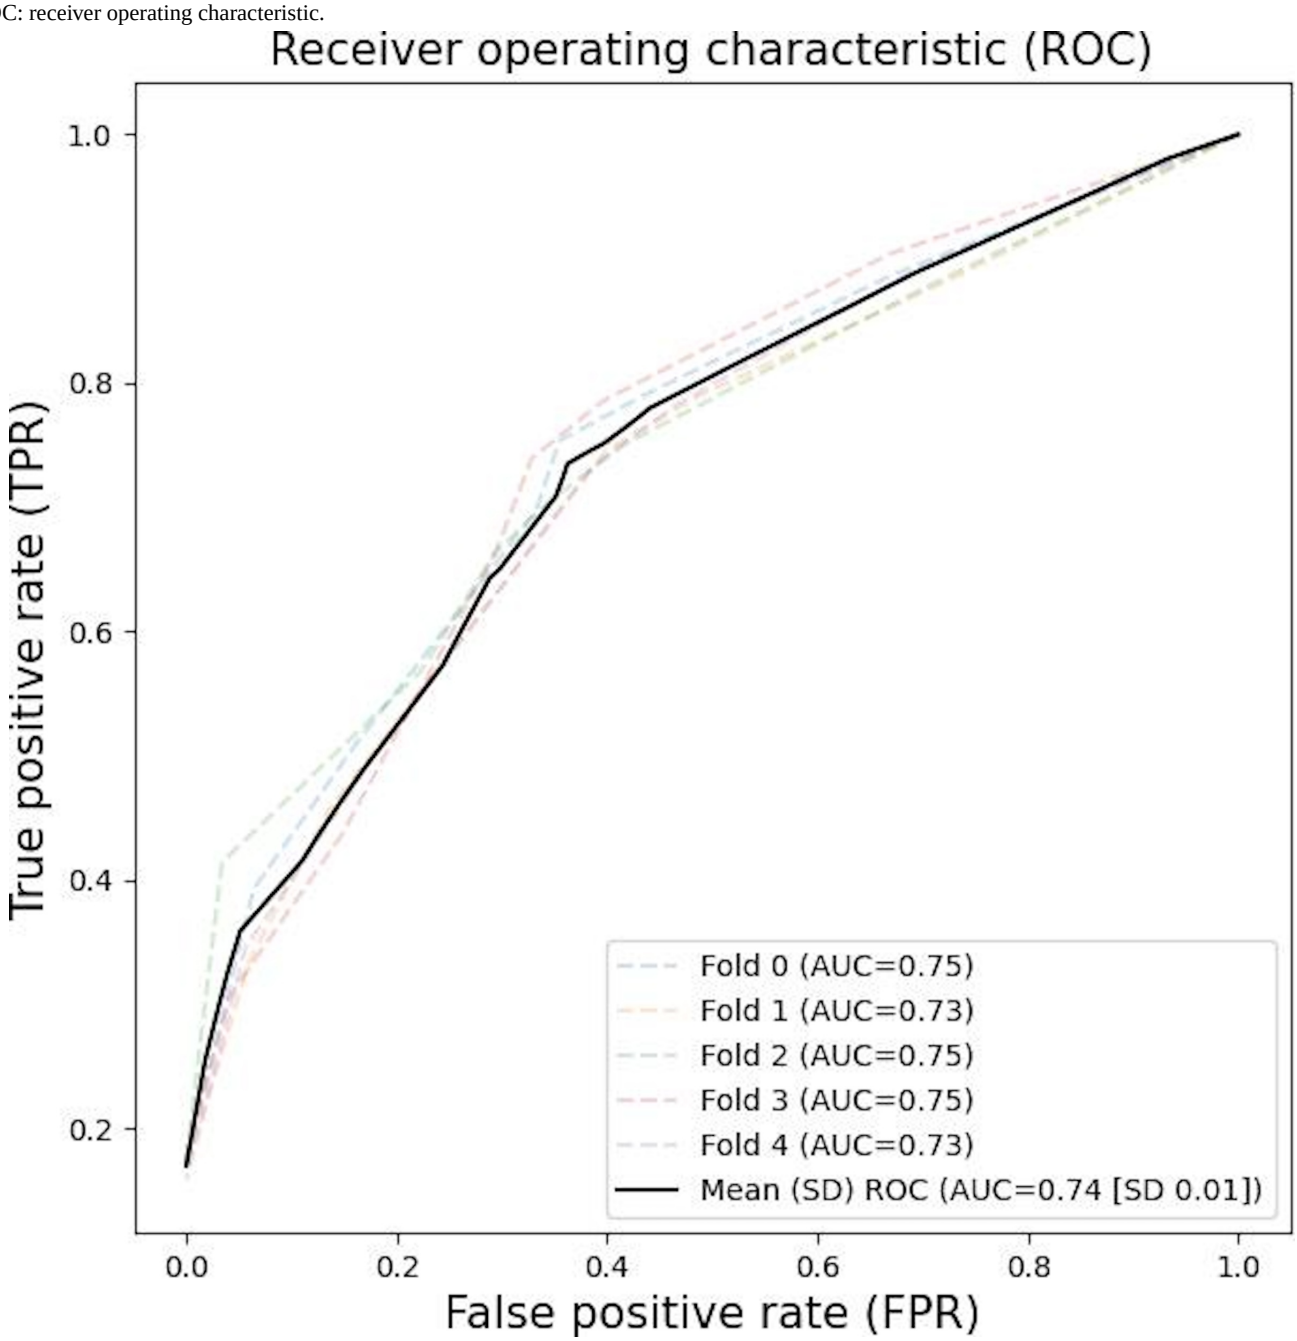
		Accuracy (%)	AUC[a]	Sensitivity	Specificity
SpeechAI					
	Mean (95% CI)	80.40 (76.89 - 83.91)	0.89 (0.86 - 0.92)	0.75 (0.67 - 0.83)	0.86 (0.84 - 0.88)
	Minimum	75.05	0.86	0.62	0.83
	Maximum	86.93	0.94	0.88	0.88
DemoAI					
	Mean (95% CI)	67.96 (67.63 - 68.29)	0.74 (0.73 - 0.75)	0.65 (0.61 - 0.69)	0.71 (0.68 - 0.74)
	Minimum	67.51	0.73	0.60	0.66
	Maximum	68.44	0.75	0.71	0.75
DemoSpeechAI					
	Mean (95% CI)	85.60 (80.03 - 91.17)	0.93 (0.89 - 0.97)	0.89 (0.83 - 0.95)	0.83 (0.77 - 0.89)
	Minimum	74.31	0.83	0.75	0.73
	Maximum	92.29	0.98	0.95	0.91

[a]AUC: area under the receiver operating characteristic curve.

XSL•FO
RenderX

Figure 1. ROC curves for each fold demonstrating the performance of the SpeechAI model. AUC: area under the receiver operating characteristic curve; ROC: receiver operating characteristic.

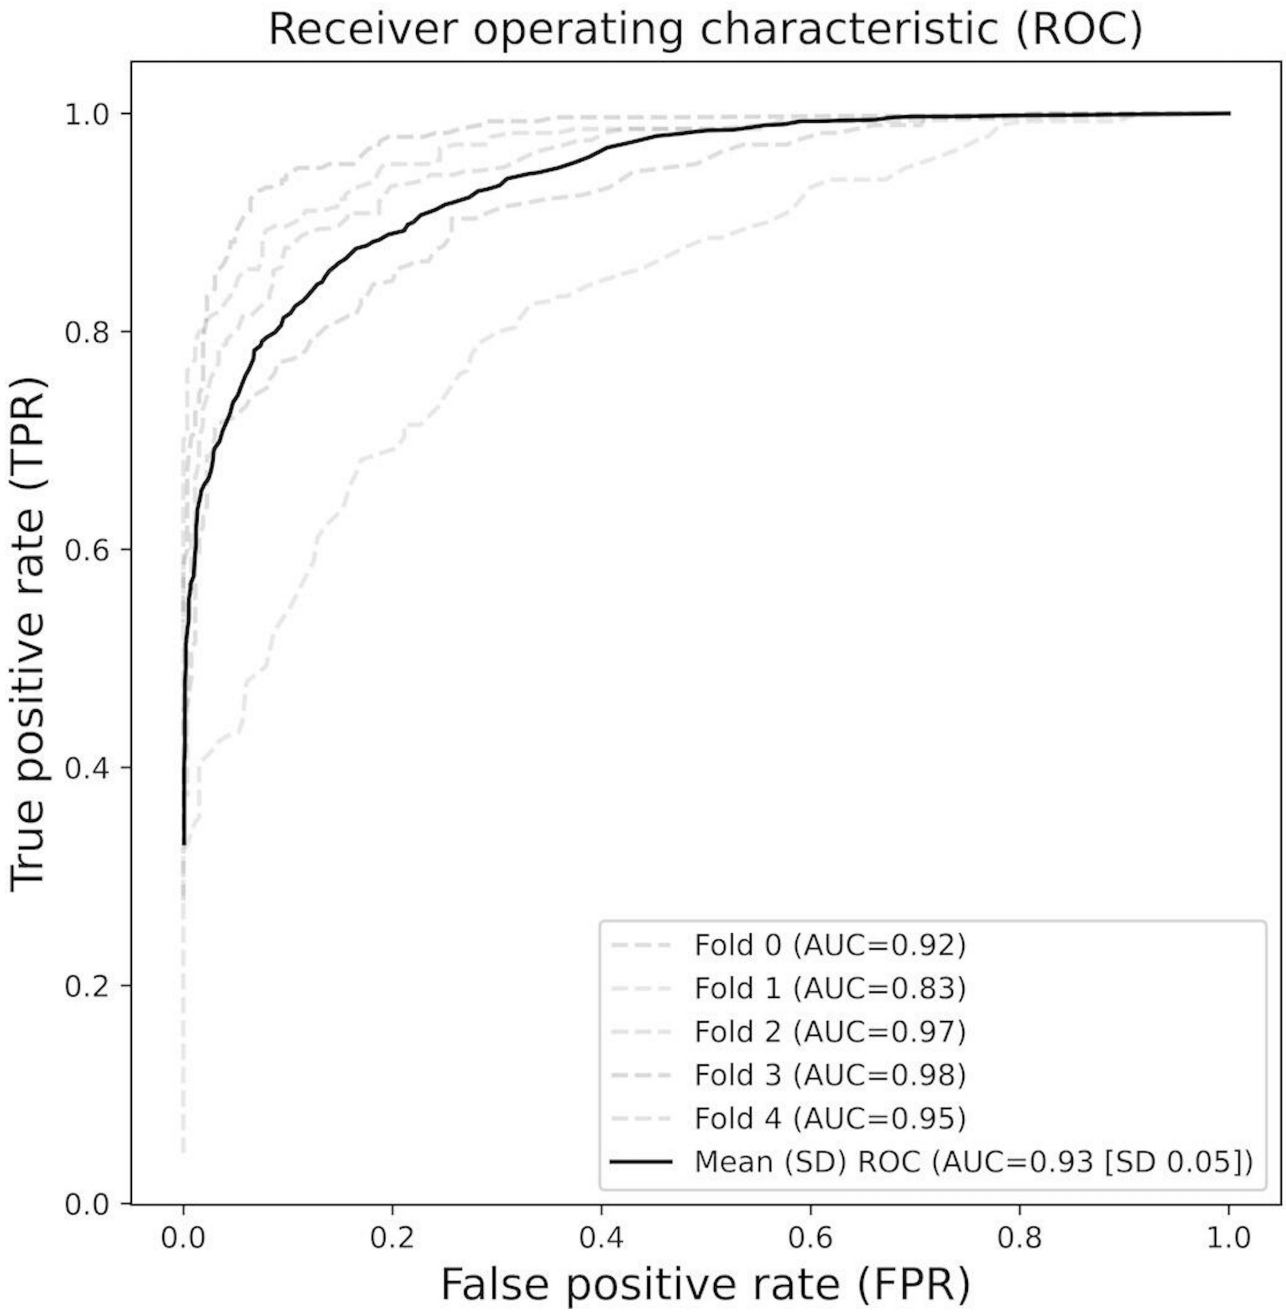


The curves represent the trade-off between true positive and false positive rates across different threshold values. The AUC values reflect the ability to distinguish between indviduals who were and were not frail.

On the other hand, the performance of the DemoAI model using the validation dataset, which was equal to that used for the SpeechAI model validation, was 67.96% (95% CI 67.63% - 68.29%) for the mean accuracy, and its minimum and maximum values were 67.51% and 68.44%, respectively. The ROC curves of each fold by 5-fold cross-validation are shown in Figure 2, and the mean AUC was 0.74 (95% CI 0.73 - 0.75), along with 0.73 and 0.75 for minimum and maximum values, respectively. Moreover, the mean sensitivity and specificity of the DemoAI model elicited from 5-fold cross-validation results were 0.65 (95% CI 0.61 - 0.69) and 0.71 (95% CI 0.68 - 0.74), respectively (Table 2).

XSL•FO
RenderX

Figure 2. ROC curves for each fold demonstrating the performance of the DemoAI model. AUC: area under the receiver operating characteristic curve; ROC: receiver operating characteristic.



The curves represent the trade-off between true positive and false positive rates across different threshold values. The AUC values reflect the ability to distinguish between individuals who were and were not frail.

The mean accuracy of the DemoSpeechAI model for 5-fold cross-validation was 85.6% (SD 6.35%, 95% CI 80.03% - 91.17%), and the minimum and maximum values were 74.31% and 92.29%, respectively. Furthermore, the mean AUC values of the DemoSpeechAI model elicited from 5-fold cross-validation were 0.93 (SD 0.05, 95% CI 0.89 - 0.97), and the mean sensitivity and specificity were 0.89 (SD 0.07, 95% CI 0.83 - 0.95) and 0.83 (SD 0.07, 95% CI 0.77 - 0.89), respectively (Table 2). Figure 3 shows the ROC curves obtained from 5-fold cross-validation and their mean.

XSL•FO
RenderX

Figure 3. ROC curves for each fold demonstrating the performance of the DemoSpeechAI model. AUC: area under the receiver operating characteristic curve; ROC: receiver operating characteristic.

In the comparison between the SpeechAI and DemoAI models, the SpeechAI (AUC 0.89, 95% CI 0.86 - 0.92) model showed superior performance to the DemoAI model (AUC 0.74, 95% CI 0.73 - 0.75) in AUC values (t_4=8.705 [2-tailed]; P<.001), and the DemoSpeechAI model (AUC 0.93, 95% CI 0.89 - 0.97) was superior to the DemoAI model in AUC values (t_4=7.978 [2-tailed]; P<.001). However, there was no significant difference between the SpeechAI and DemoSpeechAI models (t_4=1.057 [2-tailed]; P=.35).

To evaluate the effectiveness of our models using deep learning–based acoustic features, we conducted a comparative analysis with simpler machine learning models, specifically logistic regression, random forest, and decision tree. For this comparison, we used acoustic features extracted using the openSMILE toolkit [34], a commonly used tool for extracting audio features. The extracted features included frequency domain characteristics such as MFCCs, pitch, and loudness.

We trained logistic regression, random forest, and decision tree models using these acoustic features and compared their performance with our model, which use a transformer-based architecture for feature extraction. The results of this comparison are summarized in Table 3.

XSL•FO
RenderX

Table . Performance metrics for machine learning methods using acoustic features extracted by the openSMILE toolkit.

Model	Accuracy (%), mean (95% CI)	AUC[a], mean (95% CI)	Sensitivity, mean (95% CI)	Specificity, mean (95% CI)
Logistic regression	61.45 (46.54 - 76.35)	0.62 (0.47 - 0.77)	0.62 (0.52 - 0.71)	0.62 (0.36 - 0.87)
Decision tree	57.48 (40.11 - 74.84)	0.57 (0.40 - 0.75)	0.59 (0.31 - 0.86)	0.56 (0.41 - 0.72)
Random forest	66.09 (57.69 - 74.50)	0.66 (0.58 - 0.75)	0.69 (0.58 - 0.81)	0.63 (0.42 - 0.84)

[a]AUC: area under the receiver operating characteristic curve.

The results in Table 3 compare with our model, SpeechAI, which uses the deep neural network–based feature extractor. SpeechAI significantly outperforms these traditional features-based models. The performance metrics for SpeechAI are as follows: accuracy: 80.40%, AUC: 0.89, sensitivity: 0.75, and specificity: 0.86. This demonstrates the superiority of our deep-learning approach, particularly in handling the complex and high-dimensional nature of acoustic features. The advanced feature extraction capabilities of the SpeechAI model enable it to capture intricate patterns and nuances in the voice data, which simpler models fail to exploit fully.

While traditional models provide a baseline performance, the deep learning–based model's ability to leverage large-scale pretraining and complex feature extraction processes leads to improved predictive accuracy. These results underscore the effectiveness of deep-learning techniques for this application and highlight their potential for broader adoption in related research fields.

Discussion

Principal Findings

In recent years, several studies have investigated the use of voice data to predict frailty among older adults. One study explored the application of vocal biomarkers for frailty classification, finding significant associations between specific voice parameters and frailty levels [12]. Our study builds on this by using advanced deep-learning techniques to extract more nuanced features from voice data, potentially improving the accuracy and reliability of frailty predictions. In addition, a study demonstrated the feasibility of using voice biomarkers to classify frailty, focusing on various acoustic parameters such as formant frequencies and spectral energy ratios [13]. Our findings align with these results, further validating the effectiveness of voice biomarkers in predicting frailty. However, our approach differs by incorporating a more extensive set of acoustic features and using robust cross-validation methods to ensure generalizability. Our study aligns with the growing body of research that leverages vocal biomarkers to predict cognitive and functional decline. Notably, a study demonstrated the effectiveness of using spontaneous speech analysis to identify cognitive function decline among older adults in a multilanguage cross-sectional study [35]. Their findings highlighted that specific acoustic features could discriminate between healthy individuals and those with mild to severe cognitive impairment with high accuracy, supporting the viability of voice as a noninvasive diagnostic tool.

Using acoustic features to predict frailty is promising, particularly in the context we have adopted, where participants describe and explain a picture. Recent studies have demonstrated that transformer models yield superior results in various speech-related tasks, such as speech recognition, speech synthesis, and speech classification, surpassing traditional methods. Transformer architectures significantly improve the ability to capture complex patterns and long-range dependencies in sequential data, which are crucial for accurate speech processing [36].

In our study, we compared the performance of our transformer-based SpeechAI model with machine learning models that use acoustic features extracted by the openSMILE toolkit, which does not rely on deep neural networks. The openSMILE toolkit is widely used for extracting features such as pitch, loudness, and MFCCs. Our experiments showed that the deep neural network–based model outperformed simpler models using acoustic features, demonstrating the effectiveness of the transformer architecture in extracting and leveraging high-level acoustic features for predicting frailty.

The ability of the transformer architecture to model long-range dependencies and process sequences in parallel contributes to its enhanced performance [37]. This capability allows the transformer-based SpeechAI model to capture intricate patterns and nuances in the voice data, which extractors that do not rely on deep neural networks fail to exploit fully. The abilities can be experimentally observed by the superior performance metrics of SpeechAI, such as higher accuracy and better sensitivity and specificity, compared with models based on traditional acoustic feature extraction methods.

Through this study, the picture, Silvia Train Station, was developed for the Korean version of the PDT. It was designed according to the appropriate principles, containing Korean cultural references that would feel familiar to Koreans. We recruited a prospective cohort that included various clinical, medical, and demographic information and voice data encompassing the frailty status of 127 individuals. We developed and validated a model to predict frailty using AI techniques in conjunction with voice data from a prospective cohort and public AIHub dataset. Our study showed that 3 modularized models can be used to predict the participants' frailty status using deep neural networks, which showed excellent performance.

Evaluation With Imbalanced Validation Set

In our study, we investigated whether speech data could be used to classify frailty and observed meaningful results. We conducted experiments to classify between robust individuals and a combined group of individuals with prefrailty and frailty.

XSL•FO
RenderX

We trained the model using a balanced class distribution between the two groups to ensure effective learning and avoid bias toward the majority class. Balancing the dataset during training is crucial, as it prevents the model from favoring the majority class, leading to improved performance across both classes and enhancing the model's generalization capability. However, recognizing that the real-world prevalence of frailty is approximately 20%, we conducted an additional sensitivity analysis with the SpeechAI model to better reflect real-world conditions by using a validation set where the frailty group constituted 20% of the data. The results showed an accuracy of 74.80% (95% CI 69.36% - 80.25%), an AUC of 0.79 (95% CI 0.71 - 0.88), a sensitivity of 0.77 (95% CI 0.67 - 0.87), and a specificity of 0.63 (95% CI 0.39 - 0.88). These results indicate that the model maintained strong predictive accuracy with the imbalanced validation set, demonstrating its robustness. While this approach provides meaningful insights, future research should aim to include more diverse and representative cohorts to fully validate the model's applicability to real-world scenarios.

Strengths and Limitations

Our study had several strengths. First, we developed and validated a model that successfully estimated the frailty state by showing a picture and obtaining voice recordings that freely described the picture using a tablet. Previous methods to diagnose frailty consumed a lot of time, space, and manpower or required much effort to process existing medical data. According to the methodology used in this study, older adults can check their risk of frailty in a way that can be performed on their own without having to visit a hospital or research institution. Second, voice data predicted frailty well, and it was experimentally confirmed that the acoustic features extracted from the voice recordings played an important role in predicting frailty. Based on these results, we demonstrated the possibility of developing many acoustic feature–derived models that can identify many health-related characteristics of older people, such as cognitive function, certain disease status, morbidity, and mortality. Third, despite statistical challenges, the model was developed and validated using a limited dataset, providing effective performance, even with a small sample size. The model efficiently leveraged voice data, omitted frailty-related variables, and demonstrated robust predictive capability while avoiding unnecessary complexity.

Our study had several limitations. First, in research using voice data, there are inevitable limitations in noise processing. The data collected for this study contained various noises as they were collected in a routine hospital environment. To remove noise, it was necessary to remove sounds other than the participants' voices. So, it is necessary to provide an automatic noise removal process using technologies such as noise canceling, speaker recognition, and voice activity detection in further studies. Second, in the PDT, which was performed in our study, cognitive function could be assessed by the participants' understanding of the causal relationship or the importance of the PDT. However, during the PDT, the participants had some difficulty explaining the given picture for 2 minutes, which made it difficult to collect complete and diverse sound characteristics from the participants. Therefore, if the PDT can be developed to be more specialized and suitable for the older population and to extract acoustic features, the accuracy of AI technology will further increase. Third, the relatively small sample size may not fully represent the diversity of each group, and biases introduced during participant selection could have affected the generalizability of the results. In addition, the study involved only Korean participants, thus caution should be taken in generalizing the results to populations from different regions or ethnicities. Furthermore, there is a significant age difference between the robust and prefrail and frail groups in our cohort. Due to this existing significant difference in age between the two groups, the DemoAI model, which was trained using only age and sex, also showed relatively high performance. Nevertheless, the model using speech data demonstrated statistically superior performance compared with the DemoAI model, highlighting the effectiveness of incorporating vocal biomarkers in frailty prediction. Future work should include more diverse participants to address these limitations and ensure the broader applicability of the findings. In addition, developing advanced noise processing techniques to improve the clarity of voice data collected in natural environments is essential. Expanding the use of vocal biomarkers to predict various health conditions and integrating these models into mobile health apps will make health monitoring more accessible. This approach could lead to noninvasive, efficient, and widely applicable health assessment tools for older adults.

Conclusions

We developed and evaluated 3 types of models, DemoAI, SpeechAI, and DemoSpeechAI, to predict participants' frailty status using deep neural networks with SSL techniques based on voice recordings collected via a tablet during the PDT. This was successfully developed using voice data collected from the recruited participants, assisted by an independently released voice database (AIHub). The next possible step would include applying the model to electronic health records, which can assist in decision-making, additional perioperative evaluation, and supportive care to prevent adverse outcomes after surgery.

Abstract

Background: Postpartum depression (PPD) is a prevalent mental health issue with significant impacts on mothers and families. Exploring reliable predictors is crucial for the early and accurate prediction of PPD, which remains challenging.

Objective: This study aimed to comprehensively collect variables from multiple aspects, develop and validate machine learning models to achieve precise prediction of PPD, and interpret the model to reveal clinical implications.

Methods: This study recruited pregnant women who delivered at the West China Second University Hospital, Sichuan University. Various variables were collected from electronic medical record data and screened using least absolute shrinkage and selection operator penalty regression. Participants were divided into training (1358/2055, 66.1%) and validation (697/2055, 33.9%) sets by random sampling. Machine learning–based predictive models were developed in the training cohort. Models were validated in the validation cohort with receiver operating curve and decision curve analysis. Multiple model interpretation methods were implemented to explain the optimal model.

Results: We recruited 2055 participants in this study. The extreme gradient boosting model was the optimal predictive model with the area under the receiver operating curve of 0.849. Shapley Additive Explanation indicated that the most influential predictors of PPD were antepartum depression, lower fetal weight, elevated thyroid-stimulating hormone, declined thyroid peroxidase antibodies, elevated serum ferritin, and older age.

Conclusions: This study developed and validated a machine learning–based predictive model for PPD. Several significant risk factors and how they impact the prediction of PPD were revealed. These findings provide new insights into the early screening of individuals with high risk for PPD, emphasizing the need for comprehensive screening approaches that include both physiological and psychological factors.

KEYWORDS

postpartum depression; machine learning; predictive model; risk factors; XGBoost; extreme gradient boosting; PPD

Introduction

Postpartum depression (PPD) is a common mental disorder characterized by low mood, loss of pleasure, and sleep disturbance during the postpartum period [1]. The prevalence of PPD ranges from 3% to 38% in different nations and is higher in limited-income countries [2,3]. PPD leads to adverse consequences for the mother and family members, such as emotional strain and increased caregiving burden. Women with PPD may experience prolonged periods of distress and are more vulnerable to recurrent depressive episodes [4]. Previous studies revealed that PPD can impair a mother's parenting ability, such as breastfeeding, potentially resulting in enduring adverse effects on the child's development across emotional, cognitive, and physical domains [5,6]. Moreover, PPD can strain family relationships and impose economic burdens due to increased health care needs and reduced productivity [6].

With such a profound impact, mothers should be routinely screened for PPD, and early interventions should be implemented. However, current screening for PPD is mainly based on existing depressive symptoms such as fatigue and sleep disturbance, which are believed to be overlooked due to

XSL•FO
RenderX

overlap with normal physiological manifestations after delivery [7,8]. In addition, the diagnosis of PPD depends on patients' subjective reporting of personal health conditions [9]. It is urgent to identify individuals with high risk for PPD before clinical symptoms appear, while no effective and validated screening tools are currently available [7,10].

Previous studies have identified several risk factors of PPD such as unplanned pregnancy, lack of social support, and family history of mental disorders [11,12]. However, limited variables in such studies led to a lack of integrity. Machine learning algorithms provide support for the development of predictive models to prevent and intervene adverse health outcomes, offering avenues for personalized prediction and intervention strategies [13,14]. Several studies have adapted machine learning into the prediction of PPD risk in the last few years and achieved impressive performance [15-17]. However, insufficient model explanations leave obstacles for actual implementation. Besides, mental disorders are strongly associated with cultural backgrounds and study populations. Thus, the challenge remains to develop more nuanced and culturally adaptable machine learning models for the early detection and effective management of PPD, bridging the gap in current research and practice.

Given the importance of early screening for PPD and the limitations mentioned earlier, we conducted a retrospective study at our institution. This study comprehensively collected variables from multiple aspects, adopted machine learning algorithms to identify risk factors, and aimed to achieve precise prediction of PPD.

Methods

Participants

Pregnant women who underwent perinatal examinations and delivered at West China Second University Hospital, Sichuan University, from January 2017 to December 2020 were invited to participate in this study. The study cohort was divided into training and validation sets by random sampling. Participants were screened for eligibility. The inclusion criteria were as follows: (1) participants who completed regular examinations and delivered at our institution, (2) participants with a gestational age of ≥28 weeks, and (3) participants who gave consent to participation and be followed up. The exclusion criteria were (1) participants with a psychiatric history in the 6 months before conception and (2) participants with missing data.

Outcome

Participants were assessed for PPD 3 months post partum with the Edinburgh Postnatal Depression Scale [18]. The Edinburgh Postnatal Depression Scale has 10 items concerning depressive symptoms, and each item is evaluated using scores ranging from 0 to 3, constituting a total score of 30. Participants who scored 13 or more were regarded as having PPD [18]. The diagnosis of PPD was confirmed by 2 experienced senior psychiatrists using the Structured Clinical Interview for *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) [19] and the *Chinese Classification and Diagnostic Criteria of Mental Disorders, Third Edition* (*CCMD-3*) [20].

Variable Screening

Demographic variables were collected from the electronic medical record system of our institution. Clinical variables were assessed and documented by qualified clinicians. Relevant laboratory indicators were collected at 28 weeks of gestation from the medical laboratory system of the institution.

Participants were assessed for antepartum depression before delivery with the Zung Self-Rating Depression Scale [21]. The Self-Rating Depression Scale is a self-reported scale with 20 items concerning depressive symptoms, and each item is evaluated with scores ranging from 0 to 4, according to the severity of symptoms. All participants with more than 53 points were regarded as having antepartum depression [22].

Social variables, including education, income, exposure to suspected adverse factors, and family and social relations, were collected using scales and self-administered questionnaires. Income level was assessed using the local minimum income standard. Suspected adverse factors included alcohol consumption and smoking. Family and social relations comprised spouses in good health, only child, planned pregnancy, social support, family satisfaction, adverse marital status, and family history of mental illness. The level of social support was measured using the Social Support Rating Scale, which is widely used to assess social support with great reliability [23]. Scores higher than 35 are considered normal; scores of 35 or lower indicate low levels of social support [24]. Family satisfaction was assessed using the Family Adaptation, Partnership, Growth, Affection, Resolve index [25]. The Family Adaptation, Partnership, Growth, Affection, Resolve index consists of 5 items, each with a score ranging from 0 to 2. It systematically evaluates the level of family care a pregnant woman receives. A total score of 0 - 3 represents a low level of family satisfaction, and a score higher than 4 represents a normal level.

To avoid the potential bias of multicollinearity and overfitting, least absolute shrinkage and selection operator (LASSO) regression was performed to select and filter the variables in the training set. LASSO is a regression-based methodology that can reduce model complexity; multicollinearity and overfitting are avoided by constructing a penalty function [26]. LASSO regression is applied to filter a large number of variables and remove those that are insignificant [27,28]. The 5-fold cross-validation method was used to calculate the optimal λ values, and variables with nonzero coefficients were selected as the final predictive factors. After LASSO regression, the variance inflation factor (VIF) was calculated among the included variables to assess multicollinearity. The VIF was introduced to understand the impact of collinearity in regression models and has since been widely applied in various fields, including medical research [29-31]. VIF helps ensure that machine learning models or statistical models are not adversely affected by collinear predictors [32]. Typically, a VIF value greater than 10 is considered indicative of high multicollinearity, which may necessitate removing or adjusting variables to improve model stability [29,33].

XSL•FO
RenderX

Model Development

We used the following 3 machine learning algorithms to develop the PPD prediction model: extreme gradient boosting (XGBoost), random forest (RF), and gradient boosting machine (GBM). XGBoost is a powerful and efficient machine learning algorithm known for its exceptional performance in regression, classification, and ranking problems. It is an extension of the traditional gradient boosting method that combines multiple weak classifiers to create a strong classifier that minimizes the loss function [34]. RF is an ensemble machine learning algorithm based on decision trees. It creates multiple decision trees, each based on a randomly sampled subset of the training data to create a more accurate and robust output [35]. GBM is a popular machine learning algorithm that combines the principles of boosting and gradient descent to create a powerful predictive model [36]. Additionally, logistic regression, a traditional method, was implemented to predict PPD as a control.

Machine learning models were developed in the training set. To mitigate overfitting and achieve ideal model performance, hyperparameters for each machine learning model were tuned by grid search. In each session of hyperparameter tuning, 3-fold cross-validation was implemented, and the area under the receiver operating characteristic curve (AUC) was the criterion to assess model performance [37]. The combination of hyperparameters with the largest AUC value was further evaluated in the validation set.

Model Evaluation

Predictive models were evaluated with the receiver operating characteristic curve (ROC) and decision curve analysis (DCA) in the validation set. ROC reflects the ability of a model to discriminate PPD [38]. DCA is used to evaluate and compare the clinical utility of different diagnostic or predictive models. It provides a framework for assessing the net benefit of a model by taking into account the potential harms and benefits associated with different decision thresholds [39]. Additionally, accuracy, sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) of each model were calculated for comprehensive evaluation. Based on ROC, the predictive model with the greatest AUC value was considered as the optimal model, which would be further explored for interpretation.

Model Interpretation

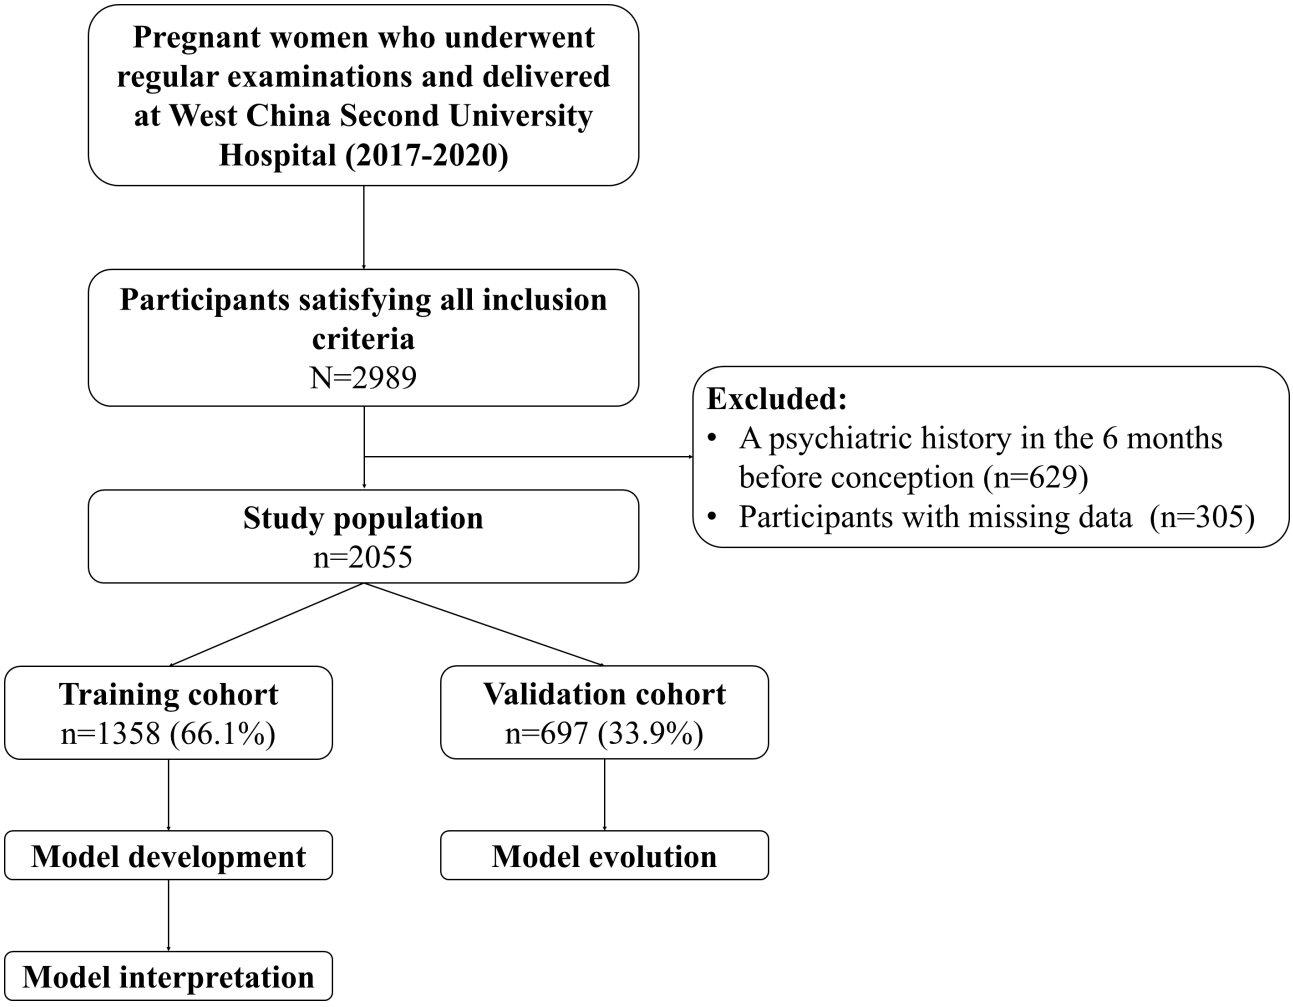
We performed variable importance, partial dependence plot (PDP), and Shapley Additive Explanation (SHAP) to interpret the optimal predictive model. Variable importance assesses the contribution of each input variable by calculating the decrease in error when split by a variable [40]. PDPs calculate the partial dependence of a variable by fixing the values of other variables and observing the variation in the outcome [41]. It helps to explain how the outcome changes with changes in input variables. SHAP measures the contribution of variables in each individual sample [42]. The SHAP values show how much each variable contributes, either positively or negatively, to the outcome.

Statistical Software

All statistical analyses were performed with R software (version 4.3.1; R Foundation for Statistical Computing). LASSO regression was performed using the R package *glmnet*. Logistic regression model was implemented using the R package *glm*. XGBoost, RF, and GBM models were developed and assessed with R package *mlr3*. Model interpretation was performed with R packages *fastshap* and *pdp*. Other involved packages include *xgboost*, *randomForest*, *gbm*, *pROC*, *ggplot2*, and their various dependencies.

Ethical Considerations

This study was approved by the ethics committee of West China Second University Hospital, Sichuan University (approval 2021-186). Informed consent was obtained from all individual participants involved in the study. The original informed consent covered the secondary use of the data without the need for additional consent. All participant data were anonymized to protect privacy and confidentiality. No compensation was provided for participation in this study.



Results

Participant Characteristics

The overall procedure of this study is shown in Figure 1. After eligibility screening, 2055 participants were included in the study cohort. A total of 78 variables were incorporated in our study including 16 psychosocial characteristics, 43 obstetric characteristics, and 19 laboratory indicators. The baseline characteristics were analyzed by χ^2 test and Wilcoxon test for category variables and continuous variables, respectively. The detailed characteristics are shown in Tables 1-3. Of these participants, 697 (33.9%) participants were diagnosed with PPD, 621 (30.2%) participants had antepartum depression, 101 (4.9%) were unemployed, 187 (9.1%) had an income below the local minimum income standard, 1947 (94.7%) pregnant women were the only child of the family, and 45 (2.2%) reported low family satisfaction; the median age of participants was 32 (IQR 29-35) years.

[a]PPD: postpartum depression.

Variable Screening

After LASSO regression, 18 variables with nonzero coefficients were identified as potential predictors of PPD. Among these variables, the 5-minute Apgar (appearance, pulse, grimace, activity, and respiration) score and the 10-minute Apgar score had VIF values over 10, indicating multicollinearity between them. Of these 2 variables, the 5-minute Apgar score had a lower coefficient in absolute value in the LASSO regression, suggesting its lower contribution to the outcome; therefore, it was excluded. Another round of VIF analysis was performed after excluding the 5-minute Apgar score, and the results showed that all remaining variables had a VIF below 10, indicating low multicollinearity. Finally, 17 variables including prenatal depression, ethnics, occupation, income, only child, family satisfaction, adverse marital status, amniotic fluid volume disorder, Rh negative, intrauterine death, fetal distress, age, fetal weight, 10-minute Apgar score, serum ferroprotein, thyroid-stimulating hormone (TSH), and thyroid peroxidase antibody (TPOAb) were identified as features to develop predictive models. The detailed results of the LASSO regression and VIF analyses are presented in Table 4.

[d]N/A: not applicable.

[e]TSH: thyroid-stimulating hormone.

[f]TPOAb: thyroid peroxidase antibody.

Model Development and Evaluation

Predictive models were established in the training set. With optimal hyperparameters, models were evaluated in the validation set. The AUC values obtained in the validation set of all 4 models were above 0.75 (Table 5 and Figure 2A). The XGBoost model outperformed other models with the highest AUC of 0.849 (95% CI 0.828 - 0.871). GBM had the poorest performance with an AUC value of 0.779 (95% CI 0.738 - 0.820). Detailed results of model evaluation were shown in Table 5.

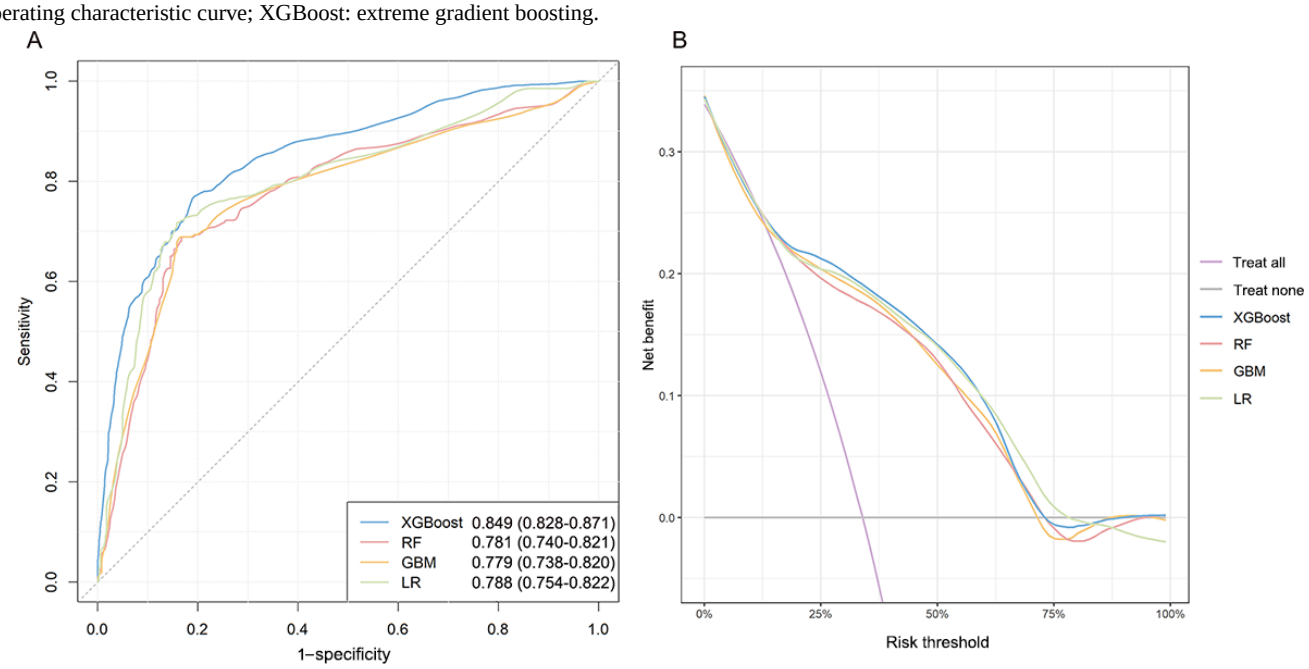
[a]AUC: area under the receiver operating characteristic curve.

[b]PPV: positive predictive value.

[c]NPV: negative predictive value.



[d]XGBoost: extreme gradient boosting.

[e]RF: random forest.

[f]GBM: gradient boosting machine.

[g]LR: logistic regression.

Figure 2. (**A**) The ROC and (**B**) the DCA of predictive models. The area under the curve and the corresponding 95% CI for each model are shown in the legend of Figure 2A. DCA: decision curve analysis; GBM: gradient boosting machine; LR: logistic regression; RF: random forest; ROC: receiver operating characteristic curve; XGBoost: extreme gradient boosting.

DCA (Figure 2B) was performed for 4 models in the validation set to compare the net benefit of the best model and alternative approaches for clinical decision-making. Treatment strategies informed by any of the 4 models are superior to the default strategies of treating all or no patients. The net benefit of the XGBoost model exceeded those of the other models at 20%-60% threshold probabilities.

Model Interpretation

The XGBoost model, identified as the optimal model in terms of AUC value, was further explored for interpretation. Table 6 demonstrates the variable importance of the XGBoost model. Antepartum depression, TSH, fetal weight, serum ferritin, TPOAb, and age were the 6 variables that most influenced the outcome of the model.

PDPs illustrate a visual representation of the relationship between the most influential variables and the predicted response while accounting for the average effect of the other predictors in the model (Figure 3). As our predictive outcome is a binary categorical variable, the impacts of variables on the outcome were presented in the form of predictive probability ranging from 0 to 1. These plots indicate that the probability of PPD increases when participants have antepartum depression, higher TSH, higher serum ferritin, and older age. Likewise, the probability descends when participants have higher fetal weight and higher TPOAb.

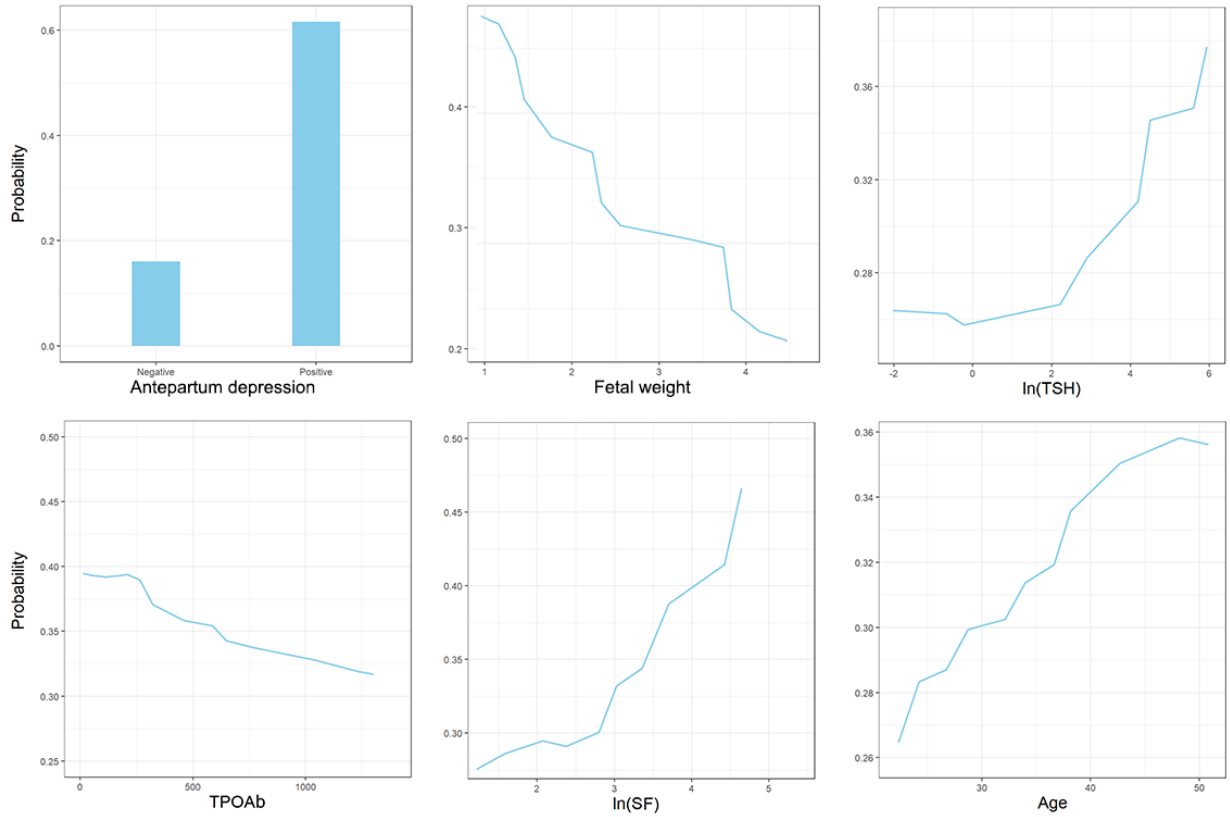
RenderX

Table . Variable importance for extreme gradient boosting model.

Variable	Importance
Prenatal depression	0.268
Fetal weight	0.169
TSH[a]	0.162
TPOAb[b]	0.132
Serum ferritin	0.131
Age	0.063
Apgar[c] 10 minutes	0.024
Income	0.014
Occupation	0.012
Amniotic fluid volume disorder	0.011
Fetal distress	0.010
Family satisfaction	0.009
Only child	0.009
Intrauterine death	0.007
Rh negative	0.005
Adverse marital status	0.002
Ethnics	0.002



[a]TSH: thyroid-stimulating hormone.

[b]TPOAb: thyroid peroxidase antibody.

[c]Apgar: appearance, pulse, grimace, activity, and respiration.

XSL•FO
RenderX

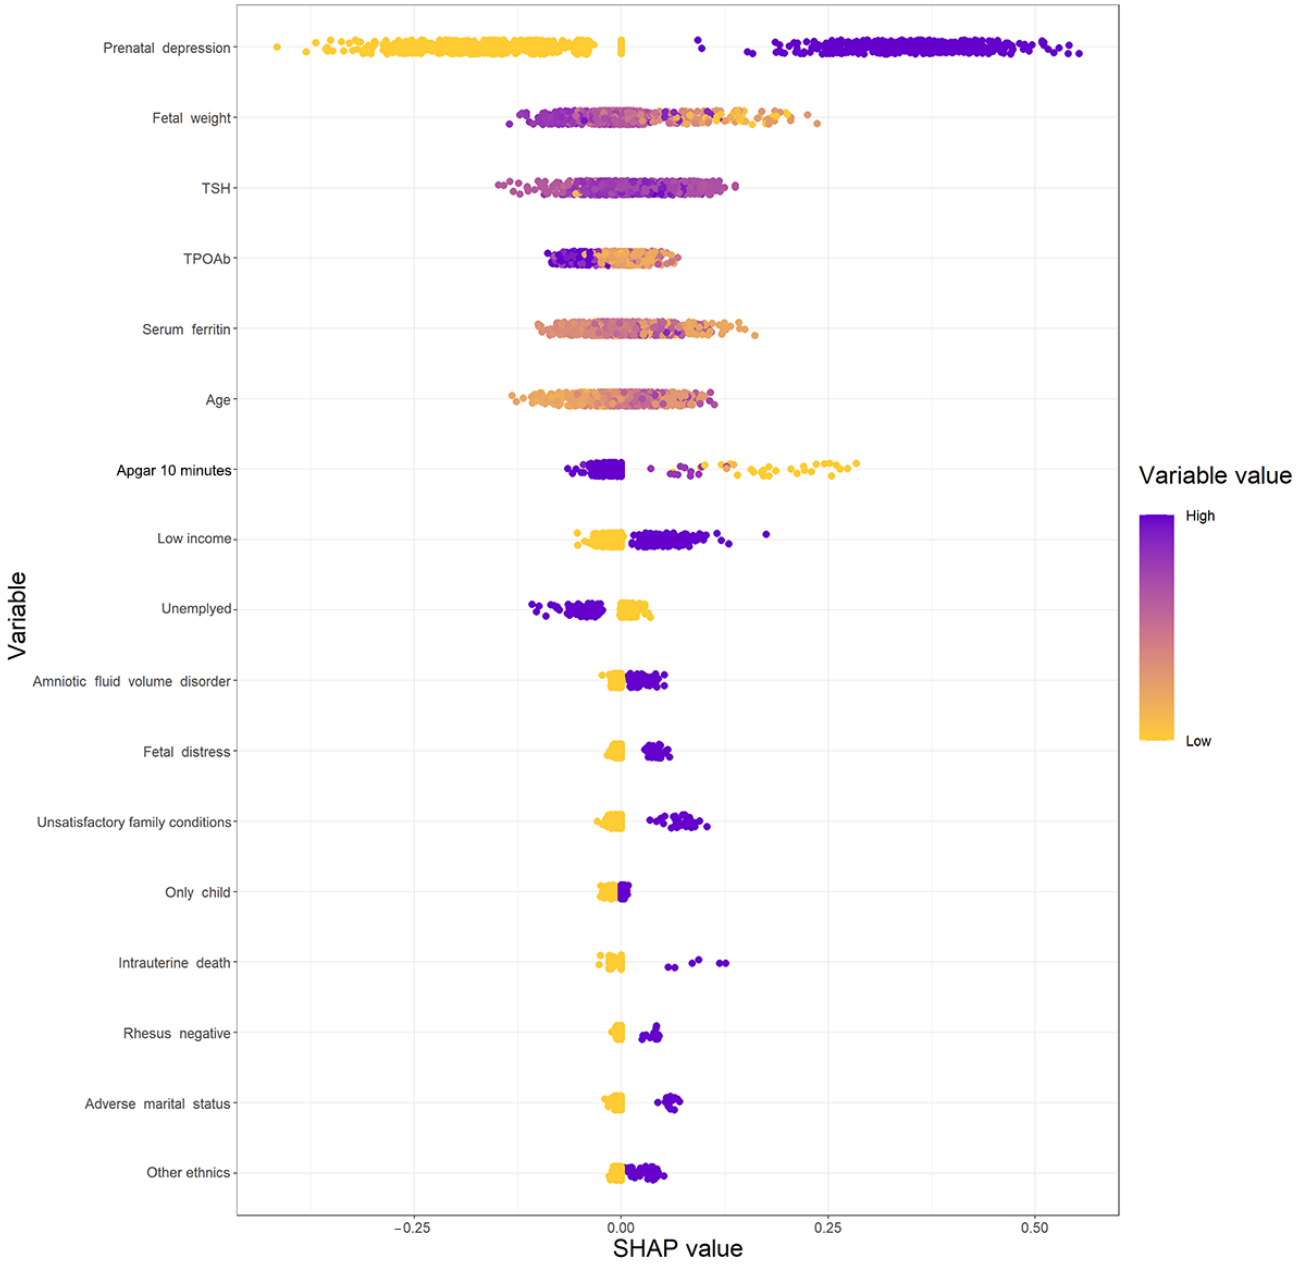


Figure 3. Partial dependence plots for the 6 most influential variables in the extreme gradient boosting model. The y-axis is set on a probability scale since our model was a binary classification model; the values of TSH and SF were on a logarithmic scale to present more pronounced trends in predicted probability as the values of the variables change. SF: serum ferritin; TPOAb: thyroid peroxidase antibody; TSH: thyroid-stimulating hormone.

SHAP provides an insight into how variables influence the prediction in each single sample (Figure 4). It can be concluded that the risk of PPD increases for participants with antepartum depression, lower fetal weight, lower level of TPOAb, elevated serum ferritin, and older age. The overall impact of TSH is not obvious. The interpretation of SHAP was mostly consistent with the interpretation of PDP. A higher risk of PPD is also associated with lower Apgar scores at 10 minutes, low income, amniotic fluid volume disorder, fetal distress, unsatisfactory family conditions, only child in the family, intrauterine death, Rh negative blood type, adverse marital status, and other ethnics.

XSL•FO
RenderX

Figure 4. The SHAP values for the extreme gradient boosting model. Each dot in the figure represents a variable for a single participant. The horizontal position indicates whether that variable has a positive or negative impact on the predictive probability. Greater absolute values of SHAP represent a greater predictive probability of postpartum depression. The color shows the value of the variable for that observation. Purple indicates a higher value, representing the positive contribution of predictive outcome; and yellow indicates a lower value, representing the negative contribution of predictive outcome. A larger absolute value means that the variable has a greater impact on the result. For example, lower fetal weight (yellow dots) caused a negative impact on the predictive outcome. Since the SHAP system only accepts numeric input, binary categorical variables are converted to 0 (negative) and 1 (positive). In this case, low income and fetal distress are associated with a greater probability of postpartum depression. Apgar: appearance, pulse, grimace, activity, and respiration; SHAP: Shapley Additive Explanation; TPOAb: thyroid peroxidase antibody; TSH: thyroid-stimulating hormone.

Discussion

Principal Findings

This study developed and validated a machine learning–based model for prediction of PPD with an AUC of 0.849. Through the model interpretation of our optimal XGBoost model, several significant predictors of PPD were identified. These findings derived from the XGBoost model provide insightful contributions to the understanding of PPD.

Based on variable importance, antepartum depression was the most influential predictor of PPD in our analysis. Women with antepartum depression are likely to extend depressive symptoms into the postpartum period. In an epidemiology study, more than 54% of women with PPD reported depressive symptoms during pregnancy [5]. Several studies excluded participants with antepartum depression to focus on newly diagnosed PPD [16,43]. This might avoid the bias associated with chronic depression but neglect the impact of maternal prenatal mental status on PPD.

In addition, our study identified key biochemical markers of PPD including TSH, TPOAb, and serum ferritin. According to the result of the PDP interpretation, women with elevated serum ferritin levels were prone to PPD. Ferritin serves a critical role

XSL•FO
RenderX

in the synthesis of monoamine neurotransmitters including dopamine [44]. With excessive ferritin, neurotransmitter dysregulation might play a part in the onset of PPD [45]. This finding warns the risks of excessive iron supplementation during pregnancy. Apart from that, elevated TSH and declined TPOAb were associated with a higher risk of PPD in our model interpretation. Elevated TSH often indicates hypothyroidism, whose clinical manifestation includes depression [46]. TPOAb is an autoantibody against the enzyme thyroid peroxidase and is commonly associated with autoimmune thyroid diseases such as Hashimoto thyroiditis [47,48]. A systematic review reported that the association between TPOAb and PPD remains controversial [49]. The specific mechanism of how TPOAb affects PPD requires more investigation.

Additionally, women with older age and lower infant weight were prone to PPD in our findings. This aligns with existing literature [49]. Other commonly recognized predictors like lack of social support, gestational diabetes, and overweight were excluded in the LASSO regression due to potential multicollinearity. These results not only validate some of the existing hypotheses about the pathophysiology of PPD but also open new avenues for research, particularly in the context of developing more effective, holistic screening methods.

Our study offers several advancements over previous research on PPD prediction. Earlier studies predominantly focused on clinical factors, such as obstetric history and comorbidities during pregnancy [50-52]. Our research comprehensively collected variables from multiple domains, including clinical, psychosocial, and biochemical markers. This broader scope allows for a more holistic view of the potential risk factors contributing to PPD, addressing the multifactorial nature of the condition. In addition, many previous studies were limited by relatively small sample sizes, often involving fewer than 1000 participants, which may have restricted the generalizability of their findings [50,51,53]. In contrast, our study included a larger cohort of over 2000 participants, providing greater statistical power and a more reliable basis for identifying significant risk factors. This larger sample size also enhances the model's ability to detect more subtle associations between variables and PPD, which might have been overlooked in studies with smaller sample size. Moreover, previous research has often been limited to populations in Western countries [54,55]. Our study focuses on a Chinese cohort, offering insights that are culturally specific and potentially more relevant for addressing PPD in non-Western settings. This regional focus helps fill a critical gap in the literature, as the risk factors and prevalence of PPD may vary significantly between different cultural and geographical populations. Finally, our inclusion of biochemical markers, such as thyroid function and serum ferritin levels, adds a novel dimension to PPD research. These physiological indicators have rarely been incorporated in prior studies; yet, they may play a crucial role in understanding the biological underpinnings of PPD. By integrating these markers with traditional clinical and psychosocial factors, our study provides a more comprehensive framework for early detection and intervention.

Although our study was conducted on a specific population from Southwestern China, the comprehensive nature of the variables included in the model suggests that it could be adapted to other populations with similar characteristics. Future studies could explore the model's applicability in different regions and cultural contexts, potentially leading to a robust, universally applicable tool for PPD prediction.

Our study offers significant insights into the clinical application of machine learning models for PPD. By integrating a broad spectrum of both biochemical and psychosocial factors, our models offer a more nuanced and accurate prediction compared to traditional methods. Incorporating often-overlooked indicators such as thyroid function and iron metabolism provides insight into the early screening of PPD. The XGBoost model, which demonstrated the highest performance, is particularly valuable for its ability to manage complex interactions between variables, making it universally applicable in a clinical setting where multiple risk factors are at play. This comprehensive approach enhances the understanding risk factors for PPD and supports more effective early interventions. Future research can build on these findings by validating them in larger, more diverse populations, integrating these predictive factors into routine prenatal care, and exploring interventions targeting these risks to reduce the incidence of PPD.

Limitations

This work is not without limitations. First, our analysis is constrained by the retrospective nature of the data, which may introduce biases such as recall bias or selection bias. Additionally, during the process of variable screening, removing variables with collinearity ensured the independence of final predictors, but also eliminated substantial amounts of variables, leading to loss of information. Furthermore, the study's reliance on a specific population from a single institution may limit the generalizability of our findings to broader, more diverse populations.

Conclusions

This study developed and validated several machine learning–based models for predicting PPD, integrating a comprehensive set of clinical, psychosocial, and biochemical factors, and incorporating a larger sample size. The XGBoost model was considered as the optimal model with an AUC of 0.849. Interpretation derived from the predictive model revealed significant predictors of PPD, encompassing antepartum depression, elevated TSH, declined TPOAb, elevated serum ferritin, older age, and lower infant weight. These identified risk factors could be implemented to the early screening of PPD for individuals at high risk. These findings underscore the advantages of integrating diverse predictors and advanced machine learning techniques to improve early screening for PPD. This approach not only enhances prediction accuracy but also provides valuable insights for future research and clinical applications.

Acknowledgments

The authors would like to express their gratitude to all colleagues and individuals at West China Second University Hospital, Sichuan University, who contributed to this research. Their insights and support were invaluable to the completion of this work.

Authors' Contributions

RZ and YL conceptualized the research. RZ, BL, and YL conducted the data acquisition, data analysis, and writing of the manuscript. RZ, ZZ, and RL performed the statistical analyses and created the figures. RZ and ZZ conducted the image optimization. BL revised the manuscript and supervised the project. All authors contributed to and have approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: In data-sparse areas such as health care, computer scientists aim to leverage as much available information as possible to increase the accuracy of their machine learning models' outputs. As a standard, categorical data, such as patients' gender, socioeconomic status, or skin color, are used to train models in fusion with other data types, such as medical images and text-based medical information. However, the effects of including categorical data features for model training in such data-scarce areas are underexamined, particularly regarding models intended to serve individuals equitably in a diverse population.

Objective: This study aimed to explore categorical data's effects on machine learning model outputs, rooted the effects in the data collection and dataset publication processes, and proposed a mixed methods approach to examining datasets' data categories before using them for machine learning training.

Methods: Against the theoretical background of the social construction of categories, we suggest a mixed methods approach to assess categorical data's utility for machine learning model training. As an example, we applied our approach to a Brazilian dermatological dataset (Dermatological and Surgical Assistance Program at the Federal University of Espírito Santo [PAD-UFES] 20). We first present an exploratory, quantitative study that assesses the effects when including or excluding each of the unique categorical data features of the PAD-UFES 20 dataset for training a transformer-based model using a data fusion algorithm. We then pair our quantitative analysis with a qualitative examination of the data categories based on interviews with the dataset authors.

Results: Our quantitative study suggests scattered effects of including categorical data for machine learning model training across predictive classes. Our qualitative analysis gives insights into how the categorical data were collected and why they were published, explaining some of the quantitative effects that we observed. Our findings highlight the social constructedness of categorical data in publicly available datasets, meaning that the data in a category heavily depend on both how these categories are defined by the dataset creators and the sociomedico context in which the data are collected. This reveals relevant limitations of using publicly available datasets in contexts different from those of the collection of their data.

Conclusions: We caution against using data features of publicly available datasets without reflection on the social construction and context dependency of their categorical data features, particularly in data-sparse areas. We conclude that social scientific, context-dependent analysis of available data features using both quantitative and qualitative methods is helpful in judging the utility of categorical data for the population for which a model is intended.

Introduction

Background

Artificial intelligence (AI) promises to transform medical diagnostics and treatment; however, this paradigm change comes with social and ethical challenges [1,2]. One particular challenge is the persistent unreliability of medical machine learning models for diverse populations [3-7]. The variation in performance reliability across populations stems, among other factors, from data scarcity in medical datasets. Publicly available datasets to train medical models, compared to those in other disciplines, are small or have little variation, often featuring populations from a specific area of the world in which the data were collected. When a machine learning model is trained on such a dataset, the results can have limited generalizability to a more diverse population seeking medical care, having disadvantaging or discriminatory effects [8].

Computer scientists increasingly turn to innovative multimodal computational methods to counter data scarcity and leverage the full potential of the limited available information. Recently, (deep) multimodal data fusion algorithms (ie, algorithms incorporating available categorical data such as a patient's medical history and demographics in addition to a main data category such as a medical image) have been developed and successfully used in, for example, dermatology and radiology [9-14]. However, the effects of including categorical data for machine learning training are understudied, particularly regarding models such as medical image classifiers intended to equitably serve individuals from diverse populations. However, understanding the impacts of categorical data on machine learning outcomes is crucial for the development of fairer and more accurate machine learning models.

From a social science perspective, using categorical data for machine learning training is controversial. Categorization, by definition, clusters individuals in groups based on their attributes. Many categories, such as gender, socioeconomic status, and skin color, are used broadly to structure everyday communication and facilitate scientific research. However, these categories are socially constructed, meaning that they are the result of artificial definitions that go beyond biological facts [15]. As a result, socially constructed categories are unstable and can be too broad or narrow for the context they are used in or simply inadequate shorthands [3]. When rendered statistically, such as in a machine learning model, the inexactitude of such categories becomes materially significant and can introduce biases.

This paper proposes a mixed methods approach to assess the qualitative utility of available categorical data before machine learning model training. We first assess data categories' social construction as a major reason behind their context dependency. We then report an exploratory, quantitative examination of the effects of data features from a specific dermatological dataset's [16] unique categorical data features on a vision transformer model. We square the quantitative findings with a qualitative study of the data collection process and inclusion and exclusion logics of the dataset's categorical data for publication.

Our results suggest how data collection practices and publication decisions are roots for the observable effects of categorical data on machine learning model training. This study practically exemplifies how insights into the social construction and context dependency of available categorical data can be derived and used for inclusion or exclusion decision-making during training. This demonstrates how integrating quantitative and qualitative insights to decide on the inclusion or exclusion of categorical data can help incorporate health equity considerations into machine learning–based medical imaging workflows, such as considering who is served or neglected when certain data categories are used or disregarded during training. Such interdisciplinary results, we argue, are pertinent to inform model training accounting for the unavoidable performance differences of machine learning models for different groups.

The Dermatological and Surgical Assistance Program at the Federal University of Espírito Santo 20 Dataset

In dermatology, the primary data category typically consists of images of skin lesions. Additional data often collected include the patient's age, sex or gender, and dermatologically relevant factors such as skin type or the location of the lesion on the body. We base our work on experiments with and analyses of the Brazilian Dermatological and Surgical Assistance Program at the Federal University of Espírito Santo (PAD-UFES) 20 dermatological dataset [16]. The dataset contains 2298 entries in total labeled for 6 skin lesion classes: 3 malignant (basal cell carcinoma [BCC], nevus [NEV], and melanoma [MEL]) and 3 benign (seborrheic keratosis [SEK], actinic keratosis [ACK], and squamous cell carcinoma [SCC]).

The PAD-UFES 20 dataset has a unique combination and a comparatively high number of 21 patient-focused data features. These features are leverageable for machine learning model training. The dataset's data cover the patients' medical information and history (eg, *skin_cancer_history*), medical details about the skin lesion not captured by the image (eg, *itch*, *grew*, *bleed*, and *elevation*), demographics (eg, *age*, *gender*, *background_father*, and *background_mother*), environmental determinants (eg, *pesticide*, *has_piped_water*, and *has_sewage_system*), and lifestyle (eg, *smoke* or *drink*), with many of the data types being categorical (ie, the assignment of individual patients to a category is a matter of definition; Table 1 [15]). This unique combination of data features for each entry, its comparably small sample size for a machine learning context, and its public availability that makes PAD-UFES 20 accessible for researchers worldwide were significant criteria for choosing this dataset for exploring the implications of using categorical data for machine learning training.

XSL•FO
RenderX

Examining the PAD-UFES 20 dataset's categorical data features illuminates its theoretical limitations. Most of the samples in the dataset originate from Brazilian patients of central European ancestry. Prevalent characteristics of this group include a White phenotype and a dominantly disadvantaged socioeconomic status. The combined characteristics of lighter skin tones typical of the White phenotype and their heightened sun exposure during various activities common among those of a disadvantaged socioeconomic status in Brazil, such as fieldwork and domestic labor, make this subgroup particularly susceptible to skin lesions induced by the intense Brazilian sun. While the resulting high prevalence of skin cancer in the dataset renders the PAD-UFES 20 dataset effective for training a skin lesion classifier, especially for skin cancer, it is crucial to recognize that the dataset's population is notably specific and, thus, introduces significant biases. Because the dataset is skewed toward lighter skin tones and a particular socioeconomic status, a model trained using this dataset might, even when trained on image data alone, limitedly generalize to other populations. In the following section, we will consider how data categories are socially constructed and, thus, context dependent, calling their utility for the model training process into question.

Table 1. Description of (categorical) data attributes available with the PAD-UFES 20 dataset (in the metadata CSV file).

Attribute	Description
patient_id	A string representing the patient ID – example: PAT_1234
lesion_id	A string representing the lesion ID – example: 123
image_id	A string representing the image ID, which is a composition of the patient ID, lesion ID, and a random number – example: PAT_1234_123_000
smoke	A Boolean to map if the patient smokes cigarettes
drink	A Boolean to map if the patient consumes alcoholic beverages
background_father and background_mother	A string representing the country in which the patient's father and mother descends. Note: many patients descend from Pomerania, a region between Poland and Germany. Although it is not a country, we decided to keep the nomenclature, since they identify themselves as Pomeranian descendants.
age	An integer representing the patient's age
pesticide	A Boolean to map if the patient uses pesticides
gender	A string representing the patient's gender
skin_cancer_history	A Boolean to map if the patient or someone in their family has had skin cancer in the past
cancer_history	A Boolean to map if the patient or someone in their family has had any type of cancer in the past
has_piped_water	A Boolean to map if the patient or someone in their family has had any type of cancer in the past
has_sewage_system	A Boolean to map if the patient has access to a sewage system in their home
fitspatrick	An integer representing the Fitspatrick skin type
region	A string representing one of the 15 macro-regions previously described
diameter_1 and diameter_2	A float representing the skin lesions' horizontal and vertical diameters
diagnostic	A string representing the skin lesion diagnostic – BCC, SCC, ACK, SEK, MEL, or NEV
itch	A Boolean to map if the skin lesion itches
grew	A Boolean to map if the skin lesion has recently grown
hurt	A Boolean to map if the skin lesion hurts
changed	A Boolean to map if the skin lesion has recently changed
bleed	A Boolean to map if the skin lesion has bled
elevation	A Boolean to map if the skin lesion has an elevation
biopsed	A Boolean to map if the diagnostic comes from clinical consensus or biopsy

The Social Construction of Categorical Data

Data categories featured in publicly available datasets such as the PAD-UFES 20 and used to train medical imaging machine learning models are often assigned to someone or something as biological despite being "socially constructed." Socially constructed categories are historically produced, reproduced, and changed within institutions or cultures [15]. Many demographics, for example, age, race, or gender, are examples of socially constructed categories. They play a key role in shaping and structuring human communication as well as the beliefs we hold about the world, but they are also loaded with meanings that go beyond their biological bases or initial definitions and depend on the working definitions of these categories in a specific assessment setting [15]. Hence, while sometimes appearing universally applicable and comparable, socially constructed categories harbor underlying ambiguities that make them context dependent. When such

XSL•FO
RenderX

context-dependent data are used for machine learning training, their ambiguities create biases and can disadvantage population groups, often those already marginalized [3,5].

In the early nineties, Suchman [17], building on the analysis by Winner [18] of how artifacts have politics, described how categories have politics. The works by both Winner [18] and Suchman [17] drew attention to how moral values are inscribed in human-made constructs, be they artifacts made of concrete, such as bridges that disallow a specific population from entering a public beach [18], or categorial classifications, such as racial categories that group specific individuals and bestow upon these groups value-laden associations [17] that have tangible, measurable impacts on aspects of their lives, such as income, access to health care, and education [19-21]. The category "race" and its experienced disparities constitute an illustrative example of how categories are socially constructed and create social and political struggles for those classified under them. To elucidate, we can juxtapose the official "race" categories used in the census of countries such as the United States, Brazil, and Germany. In the United States, the collection of racial categories has undergone much change since the establishment of racial categories in the country's census in 1790 [22]. Today, the US Office of Management and Budget "requires five minimum categories (White, Black or African American, American Indian or Alaska Native, Asian, and Native Hawaiian or Other Pacific Islander) for race [and] permits the Census Bureau to also use a sixth category - Some Other Race" [23]. Following Statistical Policy Directive 15 in October 1997, "the option to choose multiple racial categories was introduced as part of the U.S. government's routine data-collection mission" [24]. For census data collection in Brazil, on the other hand, "white, brown, black, yellow (amarelo, i.e., of some Asian descent), and...the Indigenous (indígena) category [which was added] in the 1991 census" [25] constitute the "official" racial categories. In Germany, as another contrasting example, the census systematically omitted data collection of ethnic and racial categories after World War II. Instead, the German census collects "related data on foreigners, migrants and their descendants" [26], such as individuals' "migration background."

Note how the different handling of racial categories in a census creates subtle classification differences. Foremost, the categories collected are different. As a result, a single person could be classified differently depending on whether they live in the United States, Brazil, or Germany. Second, the categories themselves are based on different features. For example, "[u]nlike the USA, color or race in Brazil refers primarily to appearance rather than descent" [25]. Third, the approach to collecting the data is notably different. While, in the United States, the categorization was conducted by an authority employee until 1970 [22], "[s]elf-identification has been the official method for recording racial category membership in Brazil since 1950" [25]. Finally, Germany applies a "color blind" approach, collecting neither appearance-based nor self-identified racial data in its official census [26]. The decisions (not) to collect and how to collect the data shape the potential applications of the data on a country-by-country basis and influence the local medical data collection practices. The resulting differences hamper cross-national comparison and complexify the transfer of publicly available datasets that include such categories to different national contexts (it is important to note that the categories used for assessments in the official census do not always translate to the medical sector; for example, in the United States, the census categories are being challenged for the context of medical use by the Agency for Healthcare Research and Quality [27]). In addition to national differences in handling racial data categories, the inexactitude of racial categories and their intertwining with proxies such as skin color have been criticized [28]. In increasingly diverse populations, classifying someone as belonging to a single or even multiple races becomes increasingly complex and, thus, inaccurate. Because assessment strategies and categories can never be defined in a fine granular enough way, the categories are, by default, more descriptive of some than others classified within the same category. Following a recent controversy on a published paper that distinctly depicted human ancestry [29], a coauthor of the paper said that their "analysis reaffirms that race and ethnicity are social constructs that do not have a basis in genetics" [30].

In the context of machine learning models, the nuanced effects of using social constructs as categories can impact performance. Computer scientists who build machine learning and other statistical models "work every day on the design delegation, and choice of classification systems and standards" [24]. Thus, they have immense decision-making power over the specifications of the classification systems implemented. However, as Bowker and Star [24] note, "few see them as artifacts embodying moral and aesthetic choices that in turn craft people's identities, aspirations, and dignity." When, as a result, machine learning models process multiple individuals as classified under a single data category, subtle distinctions crucial for the model's intended use might be overlooked, manifesting inaccuracies and biases. The resulting models will tend to perform better for those who align closely with the mean of their assigned category and less reliably for individuals who fall between or outside of the categories or are placed within a category that is too broad. Famous examples of the effects that the incautious consideration of racial categories can have in practice are the "racist soap dispenser" [31], which would not identify darker-skinned hands and, thus, not dispense soap for them; Google Photo's facial recognition software, which identified darker-skinned individuals in photo postings as gorillas [32]; the perpetuation of discriminatory biases through search engines [33]; and the worrisome automation of decisions on whether someone is worthy of help, for example, when triggering child abuse investigations [34].

In health care, studies accounting for racial differences have reified categorial differences of inexact, socially constructed categories. For example, the hypertension medication BiDil was granted Food and Drug Administration approval after showing efficacy for Americans of African ancestry, whereas earlier, when tested on Americans of European ancestry, it was believed to be ineffective. Duster, a social scientist and critic of using socially constructed categories in genomic research, criticized the parties involved in both the study and its approval for insufficiently accounting for the "complex feedback loop and interaction effect between phenotype and social practices

XSL•FO
RenderX

related to that phenotype" [35]. His work contributed to a large body of science studies scrutinizing the utility of assessing and using race, ancestry, gender, and other data categories in different areas of medical research [36-42]. For example, in precision medicine, scholars claimed that the absence of biomedical significance of categorizations creates shorthands, which are, at most, unhelpful for meaningful statistical inference [43,44]. Despite potentially providing clues for correlations, data categories used in health care are frequently proxies for other factors that matter in the context of diagnosis or treatment. In dermatology, health and its categorial social determinants are particularly intertwined as different skin types have different susceptibilities to skin lesions [45].

Feature Selection: The Current State of the Art to Assess Data Feature Utility for Machine Learning

The fact that data features have different utility for different contexts is well established in the data science community. Hence, so-called feature selection methods have followed the introduction of techniques that use multiple, possibly multimodal (ie, various data types) data features in a single medical machine learning model [46]. Using feature selection in developing a machine learning model, computer scientists test which data features make sense to include for training. To do so, feature selection methods render available data features statistically and rank them regarding their relevance for the intended use of a particular model. In addition to helping choose which data to include for a model, data feature selection methods have been used to create new insights about certain statistical connections of variables and, thus, strengthen the explainability of a model [47] or find clues about the root causes of certain diseases [48].

The feature selection approach effectively provides insights into the statistical relevance of the data features of a particular dataset and its corresponding machine learning model. However, available feature selection methods fail to provide qualitative insights into why a specific data category contributes to a model's reliability, explainability, and performance. An additional limitation of currently used feature selection methods is that they usually look at the relevance of a data category across the entire model and fail to investigate performance increases or decreases due to the inclusion or exclusion of certain data features per class. As a result, the effects of irrelevant data features, or those reducing the performance of a particular class, might be balanced out if another class does correlate with the same data features.

Methods

The methods for this work were a mix of applied computing and qualitative investigations based on grounded theory [49]. For the claims we make, it is necessary to incorporate both computer scientific findings from experimenting with the dataset and qualitative accounts that can shed light on some of the effects we observed in more detail than numbers can.

Quantitative Analysis

The quantitative analysis aimed to investigate the effect that each available data feature, including categorical data, has on a skin lesion classifier model to provide insights into the utility of each data feature. Therefore, we trained multiple similar transformer-based models using the PAD-UFES 20 dataset while randomizing one of the data categories in each case. We then compared the performance of the obtained models per class. Coauthors AW and TC-B led the method and implementation of the quantitative analysis.

For preprocessing, duplicates and entries with 2 images or lacking data were excluded. A total of 64.14% (1474/2298) of the entries remained. Patient data were first converted to categorical data (numerical data entries [age and lesion size] were binned) and encoded into soft one-hot vectors.

We trained identical multi-classifier vision transformer models (with a training, validation, and testing data split of 70%-15%-15%) based on the architecture published in the study by Cheslerean-Boghiu et al [13]. As the feature extractor, we used the "vit_small_patch16_224" vision transformer, which comprises 12 transformer encoder layers and a classification head operating on embedding vectors with 384 elements. The model, loaded via the PyTorch Image Models library [50] with ImageNet-1K (Standford Vision Lab) pretrained weights, operates at an input resolution of 224 × 224 pixels. Positional embeddings were also derived from ImageNet pretraining, and we performed fine-tuning across the entire model without any layer freezing. The framework used for this implementation was PyTorch.

One model was trained using all available data, and one model was trained using randomized values for all data features. For the other 16 models, we randomized the input for 1 data feature in each case: *Fitzpatrick*, *background_father*, *background_mother*, *gender*, *hurt*, *region*, *age*, *smoke*, *drink*, *pesticide*, *has_piped_water*, *has_sewage_system*, *cancer_history*, and *skin_cancer_history*. The data features we tested were selected based on an internal discussion about the potential utility of the data features for the model. These decisions were made before having spoken to the authors of the PAD-UFES 20 dataset.

To solidify our results, all models were trained in 5 separate runs each; the randomized values of the models were set differently in each training run. The seed was set differently in every run. The fixed input dimensions of our vision transformer model constituted the rationale for this process. Feature randomization has been successfully applied in other studies [51]. Leaving out data features instead of randomizing them would alter the model and, thus, impair our analysis of the effects of each data feature.

For the result presentation, we concatenated all runs per model (one model with all data features included, one model with randomized values for all data features, and one model for each randomized data feature). We created receiver operating characteristic (ROC) curve plots for each of the 6 classes (NEV, BCC, MEL, ACK, SCC, and SEK). Each ROC plot shows the performance of all models for one of the classes in color-coded graphs. For each performance representation, we included area under the ROC curve values and CIs calculated using the nonparametric bootstrap method with 10,000-fold resampling at the image level.

XSL•FO
RenderX

The quantitative part of our analysis is an exploratory study; needs replication to substantiate it, including reproduction with combinations of data features included or excluded; and is naturally limited by the small sample size of the dataset, particularly in combination with the transformer model architecture used. This setup was selected not to develop a robust skin lesion classifier but to simulate a real-world application of this dataset [13], highlighting the realistic limitations and implications associated with its use.

Qualitative Analysis

The qualitative analysis featured in this work is based on one-on-one interviews with 3 of the authors of the PAD-UFES 20 dataset. The interviews aimed to gain (unpublished) insights into the dataset and the data therein.

The first author of this paper (TW) approached André Pacheco, assistant professor at the Federal University of Espírito Santo, lead of the PAD-UFES project, corresponding author of the dataset, and presenter of multiple (publicly available) talks on the PAD-UFES 20 dataset, via email, establishing first contact, explaining the context of the study, discussing participation in an interview for the study at hand, leading to the first interview in October 2023. After the initial interview, 2 other authors of the dataset publication were recruited via snowballing: Gabriel Giorisatto, a machine learning student working in André Pacheco's research laboratory when the PAD-UFES project started and who helped gain skin cancer domain knowledge facilitating dialogues with medical colleagues, and Breno Krohling, a machine engineer who was working as an undergraduate student in the laboratory facilitating the PAD-UFES project by helping with data collection. The second and third interviews were conducted in October 2024.

An initial interview was conducted with André Pacheco in October 2023. To solidify the findings, 2 additional interviews were conducted in October 2024 (Breno Krohling and Gabriel Giorisatto). All interviews were conducted by TW via Zoom (Zoom Video Communications) and followed the peer-to-peer interview method [52] using a semistructured interview guide to structure the conversation. The interviews lasted between 40 minutes and 1.5 hours and covered the genesis of the PAD-UFES 20 project; the context in which the dataset was created; the authors' rationale for collecting the data; their rationales for collecting each of the data features; the initial intended use of the dataset; how access to the community centrally featured in the dataset was established; how the dataset was created; and how the authors of the dataset reflected on the public use of the dataset, which, at least in some instances, includes the data features for analysis.

Initial interview transcripts were created with AI assistance [53]. TW double-checked and corrected the transcripts while relistening to the interview audio files. The interview transcripts were analyzed using a grounded theory–inspired coding process that included line-by-line coding and axial coding with sensitizing concept clusters according to initial findings [49]. Initial codes were selectively recoded to inform our analysis and condition our findings. TW created memos based on the codes that later formed the basis for the qualitative accounts in this work. The quotes used in this manuscript have been edited for readability and were returned to the interviewees to double-check that the correctness of meaning stayed intact before publication. The interview data showed strong consistency across participants, suggesting a high level of theoretical saturation.

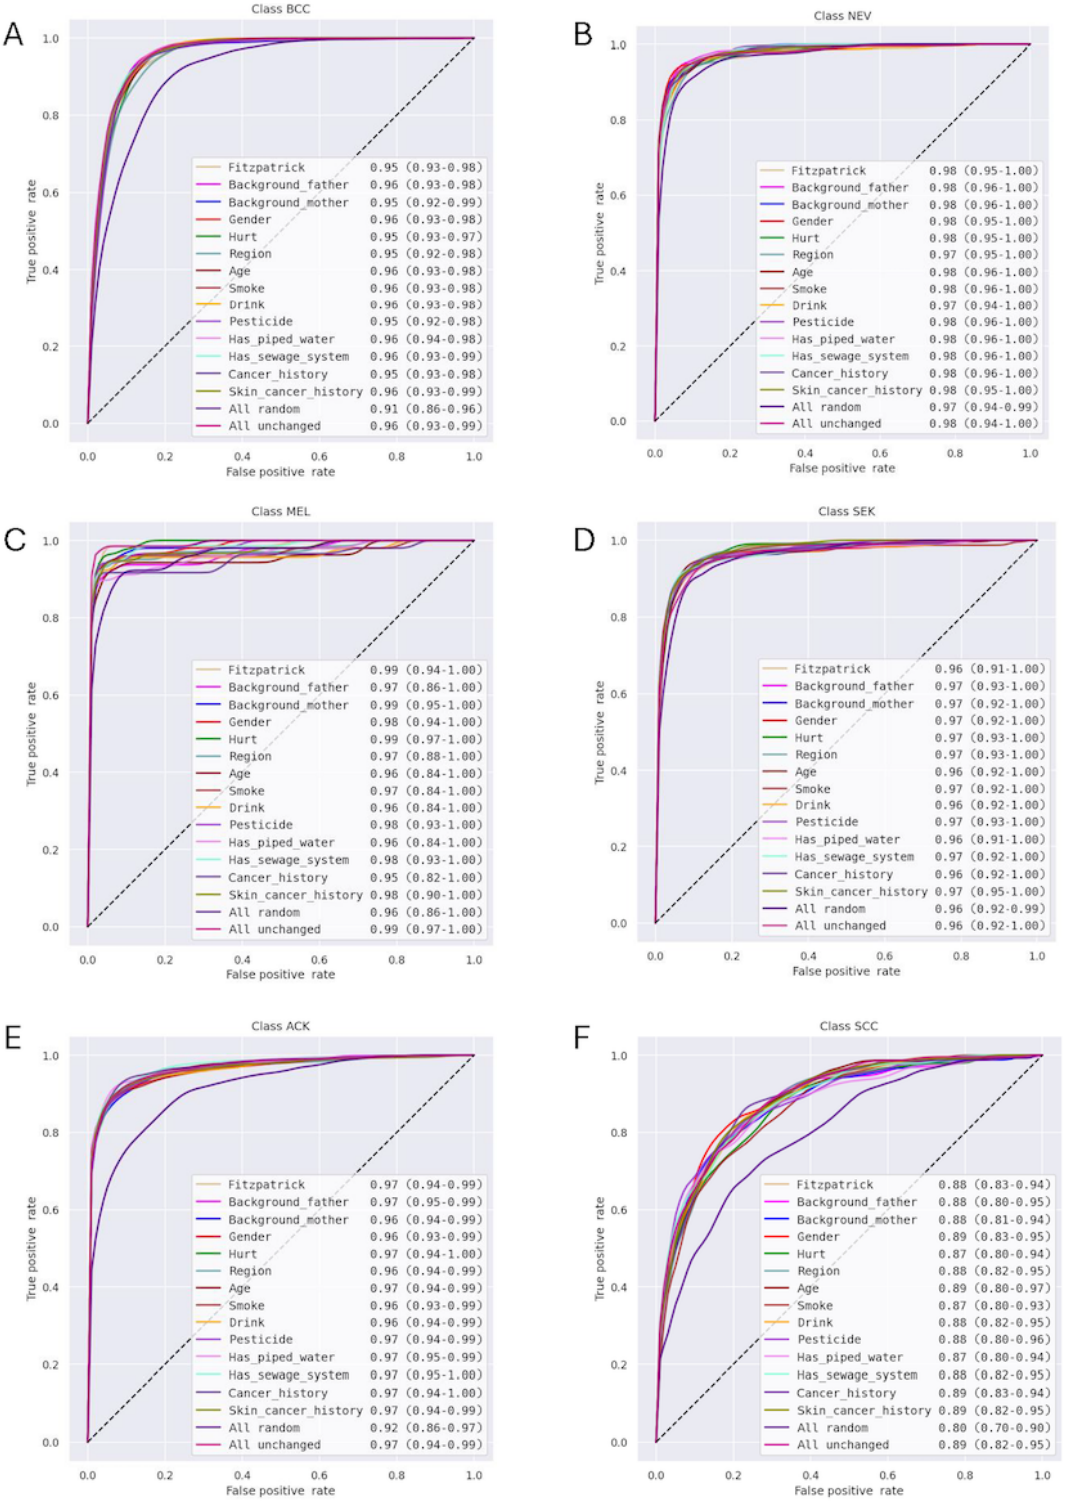
We followed the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist for reporting the qualitative part of this study (Multimedia Appendix 1).

Ethical Considerations

Before each interview, TW explained the reservations about participating in the study, including the interviewees' ability to opt out of the study at any time and the impossibility of granting them pseudonymization. All interviewees gave their written informed consent to participate in the interviews and to be referred to by their real names throughout this manuscript. Interviewees did not receive any compensation for participating in the interviews.

Results

Overview



In the following sections, we present our findings of the experimental inclusion or exclusion of the data features of the Brazilian PAD-UFES 20 dermatological dataset for training a vision transformer multi-classifier and the pairing of these quantitative findings with a qualitative investigation. We observed scattered effects in the quantitative analysis and interpreted them regarding the creation and use practices of publicly available medical datasets. However, combined with our qualitative analysis, the observed scattered effects provide insights into how data collected in or for a particular social context can have adverse effects when used to train models intended for different or broader contexts. On the other hand, our data solidify evidence that the optimization of a model for a social context such as the dataset's by including categorical metadata for training can make the model more precise if data categories are not too broad, narrow, or ambiguous or shorthands. However, there is reason to believe that, in these cases, the precision of the model overfits the dataset's context and, hence, the resulting model might impede the ability of health care professionals to decide whether a particular model will work for a new patient. Our insights advise for interdisciplinary dialogue to assess the data or context fit before model training.

Changes in Model Performance Through Data Feature Randomization

The juxtaposition of the performance of the models, which were trained using all available data features (model 1), using randomized values for all available data features in training (model 2), or randomizing 1 data feature in each case (models 3-16), showed scattered effects for each class (Figure 1).

XSL•FO
RenderX

Figure 1. Performance of the vision transformer models trained on the Dermatological and Surgical Assistance Program at the Federal University of Espírito Santo 20 dataset per class—(A) basal cell carcinoma (BCC), (B) nevus (NEV), (C) melanoma (MEL), (D) seborrheic keratosis (SEK), (E) actinic keratosis (ACK), and (F) squamous cell carcinoma (SCC). Each graph represents the mean performance of 5 similar concatenated models; the color of each graph corresponds to the metadata feature that was randomized for this model's training (see the legend in each of the images) except for the "all random" and "all unchanged" graphs. The "all random" graph represents the model performance when all metadata features were randomized, and the "all unchanged" graph represents the model performance when all metadata features were included in the training as per the dataset.

Randomizing All Data Features

Across all classes, the performance of the models decreased when all data features were randomized for training compared to the model for which we included all data feature values according to the PAD-UFES 20 dataset ("all unchanged"), indicating the predictive utility of the data features for the classes.

XSL•FO
RenderX

The magnitude of the performance drop from the "all unchanged" to the "all random" model varied notably across classes. For example, for SCC (Figure 1F), the performance decreased from 0.89 to 0.80 by 0.09. For other classes, the performance difference was only very slight (eg, 0.01; Figure 1B), or the performance even stayed the same (eg, 0.00 for SEK; Figure 1D) when all data features were randomized. This indicates that the data are more relevant to some classes than others.

Randomizing Individual Data Features

Randomizing individual data features impacted the models. In some instances, the model's performance decreased when a data feature was randomized, indicating that the randomized data feature had predictive utility for the model's performance. For example, randomizing the "cancer history" data feature reduced the average predictive performance for the melanoma class (Figure 1C) by 0.04. Considering the breadth of some confidence intervals (CIs), this effect seems even more pronounced for some of the models created in our experiment. In other cases, the model's performance increased when a data feature was randomized, indicating that the randomized data feature hampered the model's predictive power. For example, when "background father" was randomized, the performance for the SEK class increased by 0.01 compared to that of the "all unchanged" model.

The effects observed in our quantitative analysis coincide with the qualitatively contextualized expectations regarding the relevance of data features to the overall model and some classes (detailed analysis in the following sections). As a general trend, the randomization of data features considered highly medically relevant by the dataset's authors, on average, also decreased the model's performance, indicating that the data features have predictive power. The performance variance varied per class and randomized data feature across those expected to be highly medically relevant (eg, *itch*, *bleed*, and *elevation*) and those expected to be confounded through their social context dependency to the envisaged prediction (eg, *background_mother* and *background_father*, *has_sewage_system*, or *has_piped_water*).

Comparative Analysis of the Randomization of Individual and All Data Features

When all data features were randomized, the model in some cases performed better than a model for which we randomized only 1 data category during training. This suggests that a model trained using all random data features ignored the meta data and took only the image data into account. The fact that the CI reaches (close to) 1.00 in most models supports this hypothesis and further shows that, in our experiment, relatively well-performing models were obtainable even when one or all data features were randomized. Note that, in our experiment, we validated the performance of the models on a split from the training dataset. The performance increased for some models when data were included, which can partially be explained by the heterogeneity of the PAD-UFES 20 dataset, which is largely biased toward a lighter-skinned immigrant population. The model likely overfits this population.

Overall, the quantitative analysis of the models showed a scattered impact of the available data features in the PAD-UFES 20 dataset, making it difficult to quantitatively evaluate the usefulness of including individual data features. However, medical data appeared slightly more pertinent to the model than other categories serving as proxies, whereas demographic, context-dependent variables showed uneven relevance per model class. However, note that the empirical evidence exploratively derived from our quantitative analysis can only provide limited (stand-alone) information about specific impacts of the inclusion and exclusion of data features from the PAD-UFES 20 dataset and is rather meant to showcase the potential of quantitative analysis for the evaluation of data features. Checking whether the results are consistent across other feature selection methods would exceed the scope of this exploratory study. Still, it would be highly relevant to future work to provide further insights into the utility of the PAD-UFES 20 data.

Qualitative Contextualization

Overview

This section features qualitative data from interviews with the authors of the PAD-UFES 20 dataset to show an example contextualization of the quantitative findings using qualitative analysis. The accounts presented provide insights into how the dataset was created and why certain data categories were included in and excluded from the publicly available version. Thus, they provide insights into the quality of the publicly available PAD-UFES 20 data features.

Inclusion: How Data Categories Were Chosen

First, it is essential to understand how the team decided which data categories to include for data collection. Our interlocutors told us that one purpose of the PAD-UFES project was to digitize the university's dermatological data collection process that, at the time, was still conducted manually by medical students. Therefore, an initial set of data categories to collect originated from formerly institutionally established data collection practices. The refinement of the data collection specifications for the PAD-UFES 20 dataset specifically was established while aiming to satisfy multiple actors' interests at the same time:

> *They [the medical colleagues] wanted to have this data to make research on this data, so, for example, the geographic location of the patient, if the patient has clean water, the income of the patient per month...they wanted relevant data for their research about the demography of the patients. This information was initially not relevant to us, we wanted specific information about the lesion. So, we had these two types of data to collect.* [Gabriel]

Hence, some data categories were defined independently by medical students and scholars, whereas the computer scientists leading the data collection were less interested in these.

To determine which data categories would be relevant for machine learning, André and his colleagues referred to the "reporting standard in most medical data sets" (Breno) and consulted additional medical experts. André explained that their

XSL•FO
RenderX

selections of which data features to collect were ultimately related to the following:

> *...specific questions [dermatologists ask their patients], like "does this lesion itch" or "has it bled in the past"..."has this been growing"...this kind of questions. Because they [doctors] try to simulate the algorithm that they have in their head.* [André]

On the basis of the factors that dermatologists reported working with to diagnose a lesion, André and his colleagues created a combination of data categories to potentially accompany the dermatological images. They ran the categories by the dermatologists again before starting the data collection process, asking the following:

> *If you have only this information, can you classify or...provide a diagnosis from this lesion for this lesion? And most doctors said "okay, now I have enough information.*" [André]

Re-Exclusion: Medically Irrelevant Data

Despite basing the choice of which data categories to collect on dermatological clinical practice, it became clear during data collection that not all data categories seemed reasonable to include for analysis:

> *[For the dataset creation] we asked people if they had contact with chemicals. Most of them work on farms. They are peasants...and some doctors say chemicals, you know, when you put them in the food [on the fields], they may have an impact on skin lesions. So, we have this in the data set. But most doctors don't ask [their] patients [about chemicals during skin assessments] because they don't think this is relevant.* [André]

The "pesticide" category serves as a representative example here. Gabriel and Breno shared similar insights regarding the categories "has_sewage_system" and "has_piped_water." They reported that these categories were initially collected for medical students to analyze demographic factors and skin cancer or explore potential causal links between these features and skin cancer that could not be established in a subsequent analysis [54]. Notably, they still chose to publish these data categories despite excluding them from their machine learning analysis after deeming them medically irrelevant:

> *We left this information there [in the dataset] because we thought something like "maybe someone in the world wants to have this information to do something with it," right?* [André]

Re-Exclusion: Unreliable Answers

Some other data categories available in the dataset were unreliable due to ambiguous internal definitions or varying degrees of patient honesty, such as the following:

> *If the patient uses cigarettes or drinks...if they consume alcohol. Those are general questions most people don't like to answer.... Most of them say no, but sometimes they use that.* [André]

André explained that the resulting vagueness of the data features "smoke" and "drink" caused them to disregard these categories in the version of the dataset that they used for training algorithms. However, again, they held onto these features for publication of the dataset in case "someone wants to do some analysis with it," as Breno said. This highlights the importance of critically reflecting on the available data features for their applicability for the intended use of a new model and the integrity of the categories.

Re-Exclusion: "Purposeful" Shorthands

Particularly striking data categories in the PAD-UFES 20 dataset are "background_father" and "background_mother." André and his colleagues included these data categories for data collection for the following reason:

> *...many people in Brazil are descendants from Europe. Immigration. So, you know, this is a complicated feature because if I ask [a patient about their background and they say] "Oh, I'm descended from Germany," we know that they are very white. They probably have Fitzpatrick skin type 1 or 2...because they work on a farm in the sun.... [Sun] exposure and being white is a very, very, um, you know, predisposition for skin cancer.* [André]

Hence, the categories referring to the patients' parents' background are conscious shorthands to assess their skin color. When asked why they collected both the patients' parents' backgrounds and their Fitzpatrick skin type, André answered the following:

> *Because sometimes people don't know from which part of the world they descend. And at the office, they use that for statistics...just to see which region [the patients come from]. And in Brazil, there is a very high miscegenation. It doesn't mean if people descend from, I don't know, Italy, for example, [some might be] very white and [others], they have, you know, Fitzpatrick skin type 3 or 4 because of miscegenation, right? So, it tells us some part of the history, but not the whole history.* [André]

Several noteworthy observations emerge from this and similar accounts that we obtained from our interlocutors. First, it is interesting to highlight the decision to assess the migration background instead of racial categories. The rationale for including the background categories seems closely related to race-related concepts. However, the team hoped to assess who migrated from countries in which lighter skin tones are more prevalent. Second, while race or family origin appears to be an intuitive category to ask about to assess skin tone, its medical relevance in the context of a dermatological classifier seems questionable under closer scrutiny. Individuals descending from a specific region may have a higher likelihood of a particular skin type, yet their actual skin characteristics could deviate significantly, especially if their parents themselves underwent migration. Finally, including the background categories served multiple purposes: assessing the skin type, potentially including genetically important information that goes beyond skin type, and delivering statistics. The assessment of the patients' parents' backgrounds is a shorthand to fulfill all these goals

XSL•FO
RenderX

simultaneously; however, not asking these questions separately compromises the exactitude of the categories.

These nuances suggest that the "fitzpatrick_skin_type" variable might offer greater reliability in assessing the intended parameters of the background data categories. However, according to André, the team included the variable "fitzpatrick_skin_type" only as a backup to the background categories. They did so because they expected that some patients might be unable to provide satisfactory answers regarding their backgrounds or migration history. Furthermore, he argued, "Fitzpatrick is subjective. You know, maybe a doctor may say this person is type two, and another doctor says this person is type three." Moreover, the Fitzpatrick skin type scale, being a social construct in itself, harbors numerous limitations regarding its suitability to assess the intended parameters. For example, the scale has recently been criticized for having a Eurocentric bias toward lighter skin tones [55] and for incorrectly and inadequately reflecting sunburn and tanning risks for skins of color [56]. A useful data category would assess a cause factor of the classes the dataset is used to predict. For example, assessing how much melanin a patient's skin holds might be more expedient in the case at hand.

Therefore, it was not surprising that all interviewees told us that the project team ultimately did not use some of the categorical data features for their analyses. This shows, once again, how limited the utility of some of the data categories included in the publicly available dataset can be. The fact that, in their qualitative analysis, they "didn't find [some features] that useful when compared to the other data features" (André) is in line with the scattered effects of our quantitative results, in which the utility of other data features was much more visible compared to that of the background categories (Figure 1). Again, this emphasizes the necessity for thoroughly scrutinizing the available data categories in publicly available datasets.

Another purposeful shorthand that André and his colleagues used can be found in the categories "has_piped_water" and "has_sewage_system." The team told us that they collected these data for the following reason:

> *...most people [in the dataset] are very poor. They work in farms, you know, this kind of thing. Right? When you collect "has_piped_water" and "has_sewage_system," you can draw some correlations to family income. Usually, people with low family income don't have piped water and don't have a sewage system. And they usually have more skin lesions.* [André]

Our other interlocutors seconded this, and Breno added that "the age was also important because, as...they were farmers, the older they were, the more sun-exposed they were, so they have an increased risk of skin cancer," showing how sometimes combinations of categorical data features were believed to have statistical importance for assessing skin cancer using predictive machine learning models.

However, as André noted, "this is a correlation, not causation.... They [poorer people] usually have more skin lesions because they don't have money to afford the private treatment." While it seems meaningful to assess social determinants of health, such as socioeconomic status, our aforementioned quantitative analysis did not show a particularly pronounced utility of this data feature across classes. In addition, André told us that these categories are not used in their model. Furthermore, because of the specific population in the dataset, correlations between the data categories are expected. For example, during data collection, André and his colleagues recruited heavily among the European immigrant population, creating a dataset predominantly of individuals with lighter skin tones and who were socioeconomically disadvantaged and prone to skin lesions because of their high sun exposure. While the research group is still grappling with mitigating the resulting biases, André pointed out that "it's very hard to see how it could generalize to other groups here in Brazil." When taken into consideration in isolation, some biases of a skin lesion classifier trained using the PAD-UFES 20 dataset might be productive for the accuracy of diagnoses in a population with similar characteristics to those of the population included in the PAS-UFES 20. According to André, the population they use their current model with—which is similar to the population of the dataset—is "98%...skin types under four."

These Fitzpatrick skin types (1 to 3) are very well represented in the dataset; hence, the model they use regarding this aspect presumably works well for the vast majority of the patients they diagnose with the help of the model. This shows how a machine learning model might be locally helpful but hardly transferable to another context, in this case, a more diverse population, providing yet another reason for a context-sensitive assessment of data categories before their inclusion in training. However, what this leaves open is how the remaining 2% of patients in the Brazilian case can be granted fair access to dermatological care, how high the number of individuals who do not have access to this dermatological workflow is, and what skin types they have.

Renomination: Missing Categories Create Missing Values

André and his colleagues not only omitted specific data features from their model during analysis, but in other instances, they also discovered during the data collection process that specific data categories are indeed pertinent yet they had overlooked assessing them:

> *For example, the "elevation" data...one year after the [data] collection started, some doctors said to us, "Oh, the elevation is important, because if the lesion has elevation...it's probably not a melanoma." And we said, "Oh my God, this is very important information. Why haven't any doctors here said that to us before." Right. So, if you check the data set, you will see that elevation is missing for many samples in the dataset.* [André]

When the data features that result from the late inclusion of categories in data collection are included for training a machine learning model, the missing values must be accounted for; otherwise, they could distort the results. We did not explicitly test for the impact of missing values; however, because they are relatively many in the case of the PAD-UFES 20 dataset's

XSL•FO
RenderX

"elevation" category, it seems best to exclude this data category for training or wait for a new version of the dataset, which, according to André at the time of this writing, will be published shortly.

Publication: Making the Data Available to the Public

Our qualitative analysis showed that the authors of the PAD-UFES 20 dataset were aware of the caveats of the dataset. André and his colleagues carefully considered which data to include for the training of their model based on the quantitative analysis they performed and, importantly, the contextual knowledge they had about the population; the ways in which the data were assessed; and the quality of the data features they produced regarding unreliable answers, shorthands, medically irrelevant data, or missing values. However, when prompted about whether they had concerns about how their publicly available dataset might be decontextualized when used in other areas of the world by other developers with less contextual knowledge or applied to different population groups, André answered the following:

> *No, we don't have concerns about that. We just released the data set to, you know, to help the research community. You know, when we started to work in this field, we felt like, "oh, the data, there are just a few open [publicly available] datasets, and it would be great if we could release a data set that people from any part of the world could use." Right. But, of course, that can be used for good or bad. Of course, we cannot control what people do with this data set.* [André]

This account brings together several arguments. Again, it highlights that the team's motivation to publish the PAD-UFES 20 dataset was to counter the frustration within the medical machine learning community regarding the challenge of accessing datasets just above the quantitative threshold for being effective for machine learning applications. While emphasizing the pervasive scarcity of data in health care and the urgent need for comprehensive datasets, all interviewees underscored the dual use potential of datasets—the obtained results can either be advantageous or detrimental for individual patients or society at large depending on the decisions made by those using the dataset.

On the basis of our analysis, the potential damages that uncontextualized datasets might result in are not necessarily due to adverse decision-making of developers but can stem from a challenging-to-bridge gap in contextual knowledge. The significant gap between the pressing need for publicly available data to pursue the promised benefits of AI in health care and the potential for unintended harms highlights the need to exercise caution when dealing with unfamiliar, publicly available categorical data. It prompts important questions about responsible data publication practices.

Discussion

Principal Findings

For this study, we conducted a quantitative analysis and interpreted it regarding the creation and use practices of publicly available datasets. Our results showed that vague data categories, which are medically irrelevant, unreliable, shorthands for other categories, or otherwise distorted (eg, by missing values), can impair the quality of a machine learning model either overall or for specific predictive classes. The second part of our study—a qualitative analysis of an interview with authors of the dataset—provided evidence that the effects observed in the quantitative study are due to the social context dependency of the data categories chosen for a dataset and the medico-social context in which the data were collected.

Our results suggest that the uncritical use of context-dependent categorical data from publicly available datasets can introduce significant biases. These biases are particularly challenging to detect and mitigate because, under current machine learning standards, performance tests—even subgroup-specific performance tests—are typically conducted on a test split derived from the same dataset used for training. As this test split shares its context-dependent categorizations with the training split, these biases can go unnoticed. Such biases pose a particular risk in sensitive fields such as health care, which are challenged by scarce data landscapes combined with high-stakes decision-making in which every false negative and false positive can be detrimental to individual patients. As we demonstrated, a qualitative examination of how categorical data features are defined and an assessment of where categories may be vague, unreliable, oversimplified, or otherwise unsuitable for the model's intended application can help detect these biases.

Limitations

It is important to note that the magnitude of the observed effects of data categories on a machine learning model's performance likely varies depending on the dataset used. We expect, for example, that, if a similar study to ours were conducted using a larger dataset, the impacts of the data categories and washout effects would make the results more challenging to quantify. Conversely, in our experiment, the washout was less pronounced, and thus, the impact of the data categories became visible. However, the fact that we worked with a publicly available medical imaging dataset positions our results to raise significant concerns, particularly for domains such as medicine in which data scarcity frequently results in particularly small datasets being used for machine learning training. However, other studies should replicate our findings and investigate the impact of data categories in different settings.

An established limitation of case-sensitive research is limited generalizability. We would like to highlight that the phenomena observed in this study might not immediately lend themselves to generalization. This work intended to explore the interplay among data collection practices, the social construction of categories, and current use practices of publicly available datasets for machine learning model training in high-risk areas such as health care. While offering insights that might apply to similar cases or broader trends, this work, instead of deriving generalizable claims, exemplifies our research approach. We recommend conducting additional analyses when applying the approach to other scenarios. We made corresponding remarks throughout the manuscript. In line with the trend toward structured assessment of data categories [9-14], our data suggest

XSL•FO
RenderX

that including well-defined and contextually relevant data features in machine learning training can increase the accuracy of a model. However, this renders overfitting likely, and the translation to a more diverse population likely holds potential for harm because the accuracy of a model for any given patient and, therefore, the reliability of the model's outputs become more complex to assess. Further investigations are required to validate these hypotheses.

Relationship to Prior Work and Outlook

Our results deepen concerns raised by scholars about the social construction of attributes and intersectionality, for example, that machine learning puts specific, already marginalized groups at risk of medical under- or overtreatment [3,5-7]. Following the idea that categories have politics [17,18,24], our analysis of the politics of data categories extended established risks of the use of image data [7] and cautions against the inconsiderate use of categorical data accompanying image data in medical machine learning settings and beyond. In light of the context dependency and social constructedness of categorical attributes, such as racial categories used in the official censuses of individual countries [22,23,25-28], our results highlight the need for sociomedical studies to identify more precise data categories tailored to each of the diverse contexts in which medical machine learning models are applied. We believe that an increase in data category quality is essential to fulfill the potential of enhancing machine learning algorithms by incorporating relevant data categories during training. To achieve this, interdisciplinary research that establishes context-dependent data category definitions is needed. Context-dependent definitions should account for the, as Duster [35] put it, "complex feedback loop and the interaction effect between phenotype and social practices related to that phenotype."

As we have pointed out in this paper, the trend toward structured assessment of data categories in medical imaging is accompanied by an increase in data fusion algorithms. Both practices follow a sublime "more data is better" narrative previously reported in the context of publicly available image databases such as ImageNet [57]. This logic incentivizes those collecting data to include categories that fulfill multiple purposes simultaneously and those who develop machine learning models to include more of these potentially vague or too specific data features for training. Feature selection methods [46], the insights of which are based on statistics leveraged from the training dataset and lack qualitative contextualization, seem to be toothless against the context-sensitive limitations of data inclusion and exclusion for training. Additional mechanisms are needed to investigate the suitability of data categories for a new model, its context, and the population to which it will be applied. Consequently, this work advocates for deepening transdisciplinary collaborations in high-risk areas such as machine learning for medical images. We believe that the combination of applied computing and qualitative assessment is pertinent to assessing the contextual dependencies of data assessments and data applications and providing analytical insights into relevant gaps. As demonstrated in this research, considering quantitative and qualitative evaluations together can yield valuable recommendations for using or refraining from using data categories.

Conclusions

This work case-sensitively explored the effects of including categorical data features for training in data-scarce and community-serving areas such as medical imaging. We suggested a mixed methods approach, a blend of quantitative and qualitative analysis, to draw contextual conclusions about the social construction and context dependency of categorical data in publicly available datasets before using them for machine learning training. We exemplified our approach by applying it to the PAD-UFES 20 dermatological dataset, for which we quantitatively observed scattered effects on model performance when comparing scenarios in which we included all available data features for training, randomized all data features, or randomized a single data feature at a time. A qualitative analysis of the genesis of the dataset revealed root causes for the futility of some of the available data features.

Highlighting the nuanced and complex relationship between categorical data features and model performance, our observations suggest the need for an overall cautious use of publicly available categorical data for machine learning training. Our findings showed that data collection and categorization practices are not always intentional (enough) and that data categories' social constructedness and context dependency limit their transferability to new models. This underscores the importance of conducting qualitative, context-dependent analyses when considering integrating categorical data features into model training, particularly in domains in which the impact on diverse populations is paramount.

We further deduce from these findings that, first, interdisciplinary social science and health care scholarship is needed to create more purposeful and context-dependent definitions of data categories to guide data collection. Second, dataset creators should include detailed descriptions of the collection context of each data category. Finally, those using publicly available datasets should assume that more features may be available than are necessarily useful to include in training. Machine learning scientists should further institute robust practices to test available categorical data for their integrity within the context of the intended model application to prevent the perpetuation of biases when too narrow or vague data categories translate to their model. Importantly, the absence of reliable methods to assess and mitigate the adverse effects of context-sensitive data features creates an ethical imperative of refraining from including categorical data features unless proven safe for use in a diverse population related to the model's intended use.

We believe our findings to be particularly relevant for fields such as medicine, where sample sizes are often limited, demanding meticulous scrutiny of available data features for suitability before incorporation into model training. We advocate for an interdisciplinary approach that combines technical rigor with sociological understanding, ensuring that machine learning models are developed with the complexity of categorial attributes in mind. This collaborative effort is essential for

advancing the ethical and effective deployment of AI in a manner that respects the complexities of human societies.

Acknowledgments

This work was supported in part by the German Federal Ministry of Health's program for digital innovations for the improvement of patient-centered care in health care (grant agreement 2520DAT920).

Data Availability

The datasets generated during and analyzed during this study are not publicly available to protect the confidentiality and privacy of the participants but are available from the corresponding author on reasonable request. The Dermatological and Surgical Assistance Program at the Federal University of Espírito Santo 20 dataset analyzed during this study is available in the GitHub repository [58]. The architecture used to perform the analysis is available as a preprint [13].

Abstract

Background: Chronic heart failure (CHF) is a serious threat to human health, with high morbidity and mortality rates, imposing a heavy burden on the health care system and society. With the abundance of medical data and the rapid development of machine learning (ML) technologies, new opportunities are provided for in-depth investigation of the mechanisms of CHF and the construction of predictive models. The introduction of health ecology research methodology enables a comprehensive dissection of CHF risk factors from a wider range of environmental, social, and individual factors. This not only helps to identify high-risk groups at an early stage but also provides a scientific basis for the development of precise prevention and intervention strategies.

Objective: This study aims to use ML to construct a predictive model of the risk of occurrence of CHF and analyze the risk of CHF from a health ecology perspective.

Methods: This study sourced data from the Jackson Heart Study database. Stringent data preprocessing procedures were implemented, which included meticulous management of missing values and the standardization of data. Principal component analysis and random forest (RF) were used as feature selection techniques. Subsequently, several ML models, namely decision tree, RF, extreme gradient boosting, adaptive boosting (AdaBoost), support vector machine, naive Bayes model, multilayer perceptron, and bootstrap forest, were constructed, and their performance was evaluated. The effectiveness of the models was validated through internal validation using a 10-fold cross-validation approach on the training and validation sets. In addition, the performance metrics of each model, including accuracy, precision, sensitivity, F_1-score, and area under the curve (AUC), were compared. After selecting the best model, we used hyperparameter optimization to construct a better model.

Results: RF-selected features (21 in total) had an average root mean square error of 0.30, outperforming principal component analysis. Synthetic Minority Oversampling Technique and Edited Nearest Neighbors showed better accuracy in data balancing. The AdaBoost model was most effective with an AUC of 0.86, accuracy of 75.30%, precision of 0.86, sensitivity of 0.69, and F_1-score of 0.76. Validation on the training and validation sets through 10-fold cross-validation gave an AUC of 0.97, an accuracy of 91.27%, a precision of 0.94, a sensitivity of 0.92, and an F_1-score of 0.94. After random search processing, the accuracy and AUC of AdaBoost improved. Its accuracy was 77.68% and its AUC was 0.86.

Conclusions: This study offered insights into CHF risk prediction. Future research should focus on prospective studies, diverse data, advanced techniques, longitudinal studies, and exploring factor interactions for better CHF prevention and management.

KEYWORDS

machine learning, chronic heart failure, risk of occurrence; prediction model, health ecology

Introduction

Heart failure is a complex clinical syndrome where the ventricular filling or ejection capacity is compromised due to any structural or functional abnormality of the heart [1]. Chronic heart failure (CHF) is a severe manifestation or advanced stage of various cardiovascular diseases. It features high mortality and rehospitalization rates, thus constituting the ultimate battlefield for cardiovascular disease prevention and control [2]. According to the World Health Organization, the global prevalence of heart failure in adults is 1% to 2%, with 25,000-30,000 new cases expected each year [3]. The multiple physical and psychological symptoms endured by patients with CHF not only intensify the burden of the patients and caregivers but also diminish their quality of life [4,5]. Therefore, it has become an inevitable trend to identify risk factors for those who have not developed CHF and patients with CHF, to prevent the occurrence of CHF in a timely manner, and to strengthen the health management of patients with CHF.

Preventive management in current guidelines and practice is mostly based on comprehensive cardiovascular interventions [6]. However, within the framework of the goals of "health for all" and "personalized medicine," early and precise risk stratification takes precedence in cardiovascular prevention and control [7]. Risk factors for heart failure are the primary concern in suspected diagnoses, and the control of risk factors is the top priority in the primary prevention of patients with heart failure. Diagnosis, treatment, and management are based on this. Risk assessment, as the initiating link of precise health management of CHF, particularly needs to recognize the significance of risk factor identification in the face of the disease characteristics of CHF, such as complex etiology, severe condition, rapid progression, and poor prognosis. With the in-depth research of precision medicine and the change in residents' living behaviors, the update of important risk factors and cardiovascular markers is a crucial element in the development of risk assessment programs and the improvement of assessment tools.

The accuracy and comprehensiveness of identifying the risk factors of CHF, as well as the advancement and scientific nature of the modeling techniques, are the keys to guaranteeing the smooth implementation of risk assessment. As for the risk factors, they mainly include personal factors (such as gender, age, weight, etc) [8] and disease-related factors (such as ejection fraction, biomarkers, myocardial imaging, cardiac ultrasound parameters, etc). For instance, Salvioni et al [9] developed a method for integrating Metabolic Exercise Test data combined with Cardiac and Kidney Indexes (MECKI) scores from 2715 patients. It was demonstrated that the MECKI score is a highly efficient tool for facilitating risk stratification and therapeutic decision-making for patients with heart failure. Klimczak-Tomaniak et al [10] conducted repeated measurements of 92 biomarkers that optimally predict adverse clinical events in heart failure and can be used for dynamic risk assessment in clinical practice. However, these risk factor identifications focus only on individual and disease treatment–related factors, ignoring broader social factors that affect health. In terms of modeling techniques, traditional modeling methods such as Cox and logistic regressions cannot well deal with the complex relationships that may exist between variables, and researchers have begun to introduce digital technology into model construction to obtain a large amount of data information in the database after multidimensional interactions. Angraal et al [11] used a random forest (RF) model to predict mortality and hospitalization rates for heart failure in outpatients with preserved ejection fraction. Wang et al [12] used a machine learning model to accurately predict the risk of heart failure in older patients with prediabetes or diabetes using data from the National Health and Nutrition Examination Survey. Although risk assessment models based on big data and artificial intelligence exist, the mainstay of current risk assessment approaches remains the risk factor itself. Moreover, most of the models are predicated on the patient's medical record information from the initial diagnosis and hospitalization, intended for medical and nursing professional evaluations, as well as checks of objective data such as those from laboratories, and a dynamic prediction model that changes with the condition has not been established.

In summary, in the face of the incomplete coverage of clinical risk factors of CHF and the low accuracy of risk prediction modeling, constructing an accurate and convenient heart failure risk prediction model is an important pathway and tool for the identification of accurate risk factors, and fully using the big data resources for the refinement of risk factors and completing the digital modeling is an important guarantee for the effectiveness of the final risk assessment.

Methods

Data Source

This study applied to the Jackson Heart Study (JHS) database through the National Heart Lung and Blood Institute. The database contains data on 3883 individuals. The participants were African American adults aged 35-84 years. Data were collected at baseline (V1: 2000-2004), first follow-up (V2: 2005-2008), and second follow-up (V3: 2009-2013). There were 489 patients with CHF at baseline and 3394 without CHF. The first follow-up V2 (2005-2008) lost 777 cases, leaving 3106 cases; the second follow-up V3 (2009-2013) lost 462 cases, leaving 2644 cases.

XSL•FO
RenderX

Study Population

Patients who did not have heart failure at baseline (V1) of the JHS database were selected for this study (Textbox 1).

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Those who did not have chronic heart failure at baseline
- Those who participated in the first and second follow-up visits, or those who had electronic medical records

Exclusion criteria

- Patients who met the Framingham heart failure diagnostic criteria [13]

Study Variables

The inclusion of study variables was carried out at 5 levels of health ecology. A total of 53 variables were finally included. Among them, the individual trait level, including general information, biological indicators, disease history, family history, and symptoms, had a total of 28 variables; the individual behavioral trait level, including diet, exercise, sleep, and psychology, had a total of 12 variables; the interpersonal relationship level, including family relationship, social relationship, neighborhood relationship, had a total of 4 variables; the work and life level, including working conditions, living conditions, access to health care, had a total of 8 variables; and the macropolicy level had only 1 variable, being health insurance policy. All the variables can be seen in Table S1 in Multimedia Appendix 1.

Statistical Analyses

The study encompassed several crucial steps. In the data preprocessing stage, 2 primary operations were undertaken. First, for data proofreading, a check was made to determine if there were any missing values within the data. In the case of categorized data, values were assigned if necessary. Second, with regard to missing value processing, data with missing values exceeding 30% were directly eliminated. Concurrently, for data with missing values less than 30%, Monte Carlo multiple interpolation was used for interpolation.

Proceeding to the data analysis phase, SPSS 22.0 (IBM Corp) was used for data statistical analysis. For measurement data, if they adhered to a normal distribution, a *t* test (2-tailed) was used for comparison between groups. The *t* test (2-tailed) was a statistical test designed to determine if there was a significant difference between the means of the two groups. In the event that the measurement data did not follow a normal distribution, they were represented as median (IQR). Count data were described by frequency and percentage. Regarding the measured information in the influencing factors, if it satisfied the normal distribution, the independent samples *t* test (2-tailed) was used for testing. The independent samples *t* test (2-tailed) was a method for comparing the means of two independent groups. If the measured information in the influencing factors did not conform to the normal distribution, the Mann-Whitney *U* rank sum test was used. The Mann-Whitney *U* rank sum test was a nonparametric test used for comparing two independent groups. This study consisted entirely of count data, frequency and percentage were used for statistical description, and the chi-square test was used for statistical analysis. The chi-square test was a statistical test designed to determine if there was a significant association between two categorical variables.

Next, in the delineation of the dataset step, this study used randomized splitting to divide the dataset into a training set (70%), a test set (15%), and a validation set (15%).

In the feature selection process, before feature selection, the data were standardized. Then, after the completion of the standardization process, feature selection was carried out. Pycharm (JetBrains Corp) was used. Principal component analysis (PCA) and RF were two methods used to screen the variables, respectively. PCA was a statistical procedure that used an orthogonal transformation to convert a set of correlated variables into a set of uncorrelated variables known as principal components [14]. RF was an ensemble learning method for classification, regression, and other tasks that operated by constructing a multitude of decision trees during training and outputting the class that was the mode of the classes of the individual trees [15]. The two feature selection methods were compared, the importance of the features was ranked, and the visualization of feature importance was also performed.

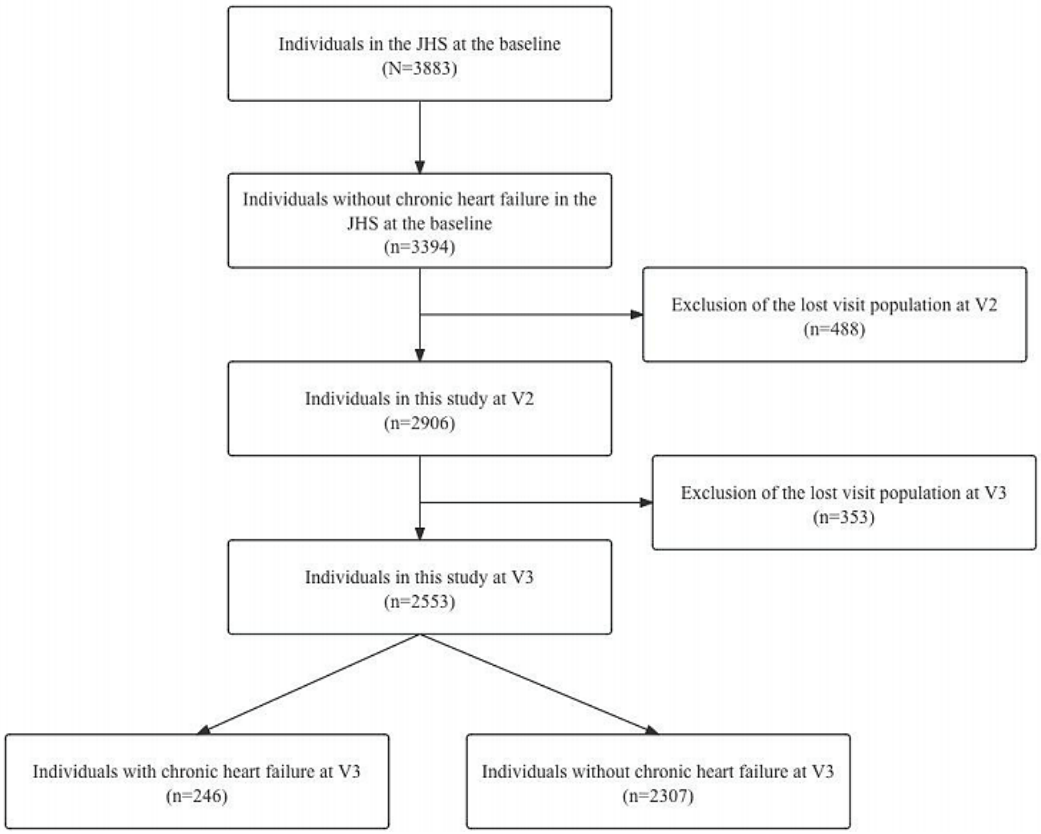
In the imbalance data handling stage, this study used 5 methods for processing unbalanced datasets. These methods included oversampling, undersampling, Adaptive Synthetics Sampling, Synthetic Minority Over-sampling Technique (SMOTE), and Synthetic Minority Over-sampling Technique and Edited Nearest Neighbors (SMOTE-ENN). Models constructed using the original dataset were compared with models constructed from datasets that had been processed by these 5 methods.

Finally, in the model construction stage, 7 models were constructed in this study. They were decision tree, RF, support vector machine, extreme gradient boosting, adaptive boosting (AdaBoost), naive Bayes model, multilayer perceptron, and bootstrap forest. The decision tree was a flowchart-like structure where each internal node represented a test on an attribute, each branch represented the outcome of a test, and each leaf node represented a class or a value [16]. The RF was an ensemble learning method as previously mentioned [17]. The support vector machine was a supervised learning algorithm that analyzed data for classification and regression analysis [18]. Extreme gradient boosting was an efficient implementation of gradient boosting for large datasets [19]. AdaBoost was an iterative algorithm that combined multiple weak classifiers to form a strong classifier [20]. The naive Bayes model was a probabilistic classifier based on applying Bayes' theorem with

XSL•FO
RenderX

strong independence assumptions between the features [16]. The multilayer perceptron was a type of artificial neural network with multiple layers of neurons [21]. The bootstrap forest was an ensemble method that combined multiple bootstrap samples to build a forest of trees. The accuracy, precision, sensitivity, F_1-score, and area under the curve (AUC) of each model were compared, and receiver operating characteristic (ROC) curves of each model were drawn. After selecting the optimal model, a 10-fold cross-validation was performed using the training and validation set. In order to construct a better model, we used hyperparameter optimization to find the best combination of parameters that makes the model perform best on the training set and achieve better results on the test set.

Ethical Considerations



The study was approved by the Ethics Committee of Zhongda Hospital, Southeast University (2022ZDSYLL401-Y01).

Results

Patient Characteristics

Among the 3883 individuals in the JHS, 489 had CHF at baseline and 3394 did not have CHF. Excluding patients who were lost to visit and did not have any electronic medical records, 2553 people did not have CHF at baseline. The mean age of this population was 57.84 (13.45) years, with 1590 female participants (62.2% of the population) and 963 male participants (37.7% of the population). The screening process is shown in Figure 1. The dataset (n=2553) was randomly divided into three parts: 70% (n=1787) of the data for model training, 15% (n=383) for model test and 15% (n=383) for model validation. The amount of missing data for the predictors left ventricular diastolic diameter, left ventricular systolic diameter, left ventricular mass, depression, vitamin D_2, vitamin D_3 derivatives, shortness of breath, walking 100 m with wheezing, and loneliness was greater than 30%, so these predictors were not included in the analysis.

Figure 1. Study flowchart. CHF: chronic heart failure; JHS: Jackson Heart Study; V2: first follow-up; V3: second follow-up.

Univariate Analysis of Variables Influencing the Occurrence of CHF

Alcohol, smoking, health insurance, income, occupation, education, minutes of walking or running, nocturnal sleep dyspnea, ever had swelling of feet or ankles, chest ever sound wheezy without cold, left ventricular regional wall motion, cardiac disease, age, BMI, systolic blood pressure, glycosylated hemoglobin, triglycerides, ultrasensitive C-reactive protein, glomerular filtration rate, heart rate, stress, regional poverty population ratio, the status of favorite food stores within 3 km, status of sports facilities within 3 km, and the ratio of early maximal ventricular filling velocity to atrial maximal ventricular filling velocity were statistically significantly different in the population without heart failure (P<.05). A one-way analysis of the baseline characteristics of the included patients is shown in Tables 1-3.

Machine Learning Analysis of the Occurrence of CHF

Feature Selection

This study made use of PCA and the RF method for feature selection. The model was trained using root mean square error (RMSE) as a criterion. The principle is that each step includes an additional feature with the highest variance as a basis for classification [22]. The number of selected features was used as the horizontal axis and the predicted RMSE score for each fitted model was used as the vertical axis.

PCA offers the advantage of transforming a set of correlated variables into a set of uncorrelated principal components, thereby reducing dimensionality and enhancing interpretability. After feature selection by PCA, a total of 15 features were incorporated. The initial eigenvalues, percentage of variance, and accumulation of these features are presented in Table 4. RMSE results are presented in Figure 2.

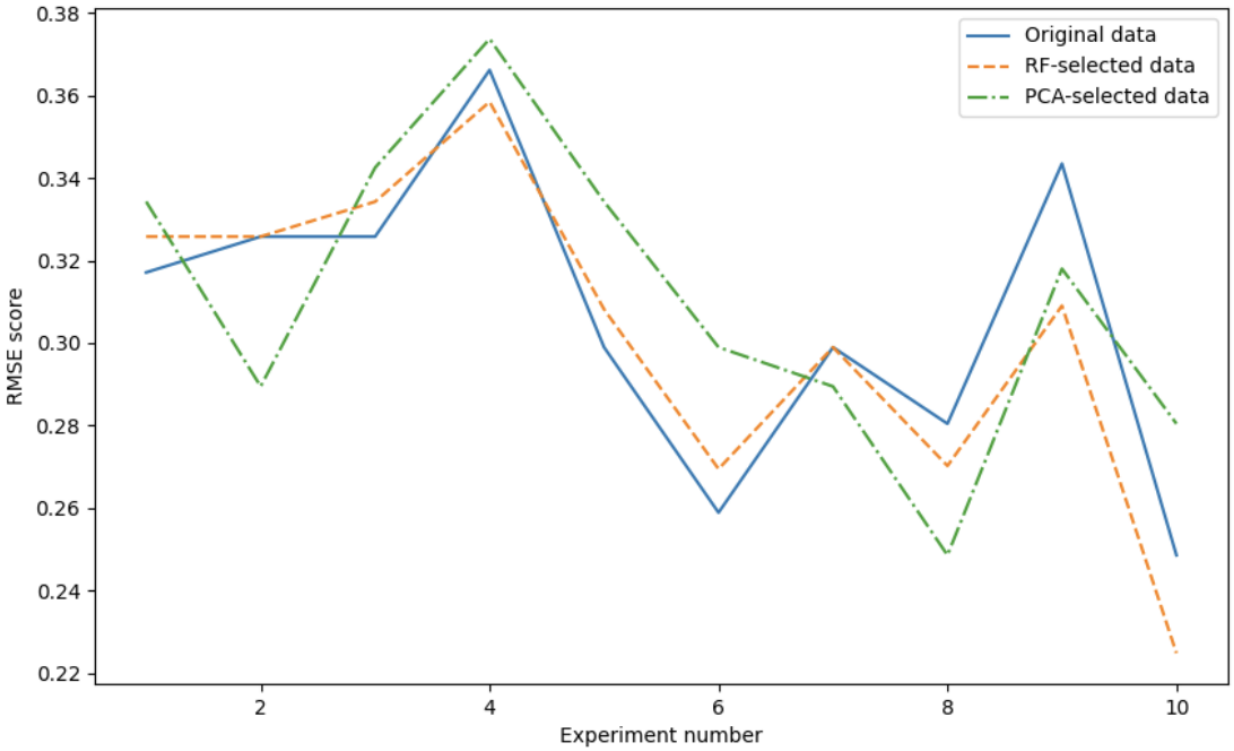

Figure 3. Root mean square error (RMSE) results of the random forest method.

XSL•FO
RenderX

To compare the feature selection methods, this study used 10-fold cross-validation. After calculating the mean RMSE and plotting the image as shown in Figure 4, the results demonstrated that the outcomes after feature selection by RF outperformed those after feature selection by PCA. The average RMSE mean of RF was 0.30. The average RMSE mean of both RF and original data was 0.31. This highlights the superiority of the RF method in terms of providing more accurate and reliable feature selection results.

Figure 4. Root mean square error (RMSE) results of the original data and different feather selection. PCA: principal component analysis; RF: random forest.

Data Balance

This study's analysis of machine learning algorithms using diverse data balancing techniques is presented in Table 6. The result indicated that, in contrast to other data balancing strategies used in this study, SMOTE-ENN consistently surpassed all evaluated models in terms of accuracy.

Development and Performance Comparisons of Machine Learning Models

This study used SMOTE-ENN for oversampling and model construction. The evaluation of each performance metric of the model is presented in Table 7, and the ROC curve of the model is shown in Figure 5. Among the models, the AdaBoost model exhibited the greatest effectiveness, boasting an AUC of 0.86, an accuracy of 75.3%, a precision of 0.86, a sensitivity of 0.69, and an F_1-score of 0.76. Simultaneously, to validate the model's efficacy, the training and validation data in this study were used to carry out validation of the model through 10-fold cross-validation. The results showed an AUC of 0.97, an accuracy of 91.27%, a precision of 0.94, a sensitivity of 0.92, an F_1-score of 0.94, and the ROC curve is presented in Figure 6. We used grid search and random search on the test set to make a better model. Comparing these two methods, random search performed better on the AdaBoost model. The data processed by grid search had an accuracy of 74.79% with an AUC of 0.84. After random search processing, the accuracy and AUC of AdaBoost improved. Its accuracy was 77.68% and its AUC was 0.86.

Discussion

Analysis of Risk Factor Analysis for the Occurrence of CHF Based on the Health Ecology

This study found that 22 risk factors predicting the occurrence of CHF were identified through a machine learning algorithm and hierarchically classified in accordance with the health ecology theory, with the objective of offering a comprehensive perspective for the prevention and intervention of CHF in the future. Health ecology not only takes into account the influence of individual disease factors on health but also conducts an all-round and holistic management of health from aspects such as individual traits, behavior and lifestyle, family and social interpersonal networks, and macropolicies [23].

At the individual trait level, this study identified age, glomerular filtration rate, glycosylated hemoglobin, systolic blood pressure, BMI, the ratio of early maximal ventricular filling velocity to atrial maximal ventricular filling velocity, ever awakened by trouble breathing, fasting triglycerides, heart rate, high-density lipoprotein, peak early diastolic velocity of mitral annulus, ejection fraction, fasting total cholesterol, ultrasensitive C-reactive protein, and low-density lipoprotein, for a total of 14 risk factors. Results from existing population-based cohort studies [24] suggest that despite the lower incidence and absolute risk of heart failure in younger people compared with older people, the associations of modifiable risk factors were stronger, and attributable risks were greater in younger participants, consistent with age factors. Systolic blood pressure, glycated hemoglobin, heart rate, high-density lipoprotein, low-density lipoprotein, ejection fraction, fasting total cholesterol, and ratio of early maximal ventricular filling velocity to atrial maximal ventricular filling velocity are important indicators for evaluating cardiac systolic-diastolic function, blood glucose levels, and glomerular filtration function, along with hypertension, diabetes mellitus, and comorbidities as the traditional independent risk factors for CHF [25-27]. Ever awakened by trouble breathing is used as a typical symptom of nocturnal paroxysmal dyspnea and edema in heart failure [28,29].

At the behavioral and lifestyle level, this study identified vitamin D_3, eggs, and dark-colored green vegetables, a total of 3 risk factors. Diet has a great influence on the development of CHF and is one of the important risk factors for the development of CHF [30].

In the living and working conditions stratum, this study identified the proportion of the population living in poverty in the area, the status of sports facilities within 3 km, and the status of favorite food stores within 3 km, for a total of 3 risk factors. The status of favorite food stores within 3 km reflects the impact of dietary nutrition in at-risk populations; nutrition has been shown to be an important factor in the prevention of heart failure [31]. The status of sports facilities within 3 km could reflect the exercise situation. Studies have shown a strong association between physical inactivity, low fitness, and heart failure and have emphasized the importance of regular physical activity in

XSL•FO
RenderX

the prevention and treatment of heart failure [32], which is consistent with the exercise and activity index factors identified in this study. The proportion of the population living in poverty in the area reflects income and wealth. Yusuf et al [33] conducted a study to explore the risk factors for cardiovascular events and showed that each risk factor varied according to the economic level of the country.

The above risk factor analyses based on the health ecology perspective not only make up for the limitations of the individual factor level of CHF but also provide a researchable direction for the future health management of heart failure.

Analysis of Prediction Model Construction for the Occurrence of CHF Based on Machine Learning

At present, traditional regression methods are mainly used in clinical practice to screen for high-risk factors of CHF, and no conventional prediction methods have been found for the occurrence of CHF. Although traditional regression methods can provide effective prediction results, they still cannot effectively solve the problem of deviation between predicted and actual values, and more advanced technologies are needed to solve it. With the advent of the big data era, the application of machine learning in the medical and health field is becoming increasingly widespread, especially in disease prediction and prognosis evaluation [34]. This study compares different methods for processing unbalanced datasets. SMOTE-ENN is the optimal processing method. SMOTE-ENN combines the SMOTE and ENN methods. SMOTE is first used to generate new synthetic samples, and then the ENN method is used to clean the synthetic dataset to remove the noisy samples and outliers to improve the quality of the dataset and the classification performance of the model [35].

This study found that AdaBoost has a better ability to handle the problem of CHF occurrence, with better performance. Many studies have shown that AdaBoost is able to achieve high accuracy in solving various classification problems [36,37]. AdaBoost focuses on hard-to-classify samples by constantly adjusting the sample weights, allowing the classifier to better learn the features of these samples, thus improving overall accuracy. Currently, AdaBoost has been used in the area of heart disease. Rath et al [38] conducted a study demonstrating that the proposed AdaBoost algorithm has been shown to have an advantage over other algorithms in terms of accuracy when solving the electrocardiogram quality assessment problem. Therefore, AdaBoost is an efficient machine learning algorithm that is particularly suitable for processing large-scale datasets. Its efficient computational performance, excellent prediction accuracy, and flexible model configuration give it natural advantages in the construction of cross-domain models in medical engineering.

Limitations

This study has certain limitations. First, due to the limitations of retrospective research attributes, there are inevitably issues such as insufficient variable collection, missing data, and anomalies. Second, there is a lack of external datasets to further test the generalization ability of the model. Finally, due to some missing data obtained from the National Heart, Lung and Blood Institute in this research database, there is a lack of biological indicators that are highly correlated with CHF, such as N-terminal pro-B-type natriuretic peptide.

Conclusion

In this study, we endeavored to construct a predictive model for CHF occurrence using machine learning and analyze CHF risk from a health ecology perspective. Through a series of comprehensive procedures, including data preprocessing to handle missing values and standardize data, and applying feature selection methods like PCA and RF, we identified relevant factors associated with CHF. The analysis of risk factors based on health ecology provided a holistic understanding. At the individual trait level, multiple factors were recognized, along with several at the behavioral and lifestyle level and the living and working conditions level. Among the machine learning models evaluated, the AdaBoost model showed relatively high effectiveness. However, the study had limitations. The retrospective design led to issues such as incomplete variable collection and missing data, and the lack of external datasets affected the assessment of model generalization.

For future research, prospective studies should be considered to improve data quality and collection. Incorporating more diverse data sources and advanced machine learning techniques could enhance the model’s performance and generalizability. Longitudinal studies could track the changes in risk factors over time to better understand CHF development. In addition, further exploration of the interactions between different levels of health ecology factors could provide deeper insights into CHF prevention and management strategies. By addressing these areas, future research can build on the current work and contribute to more effective approaches to dealing with CHF.

Abstract

Background: Modern lifestyle risk factors, like physical inactivity and poor nutrition, contribute to rising rates of obesity and chronic diseases like type 2 diabetes and heart disease. Particularly personalized interventions have been shown to be effective for long-term behavior change. Machine learning can be used to uncover insights without predefined hypotheses, revealing complex relationships and distinct population clusters. New data-driven approaches, such as the factor probabilistic distance clustering algorithm, provide opportunities to identify potentially meaningful clusters within large and complex datasets.

Objective: This study aimed to identify potential clusters and relevant variables among individuals with obesity using a data-driven and hypothesis-free machine learning approach.

Methods: We used cross-sectional data from individuals with abdominal obesity from The Maastricht Study. Data (2971 variables) included demographics, lifestyle, biomedical aspects, advanced phenotyping, and social factors (cohort 2010). The factor probabilistic distance clustering algorithm was applied in order to detect clusters within this high-dimensional data. To identify a subset of distinct, minimally redundant, predictive variables, we used the statistically equivalent signature algorithm. To describe the clusters, we applied measures of central tendency and variability, and we assessed the distinctiveness of the clusters through the emerged variables using the *F* test for continuous variables and the chi-square test for categorical variables at a confidence level of α=.001

XSL•FO
RenderX

Results: We identified 3 distinct clusters (including 4128/9188, 44.93% of all data points) among individuals with obesity (n=4128). The most significant continuous variable for distinguishing cluster 1 (n=1458) from clusters 2 and 3 combined (n=2670) was the lower energy intake (mean 1684, SD 393 kcal/day vs mean 2358, SD 635 kcal/day; *P*<.001). The most significant categorical variable was occupation (*P*<.001). A significantly higher proportion (1236/1458, 84.77%) in cluster 1 did not work compared to clusters 2 and 3 combined (1486/2670, 55.66%; *P*<.001). For cluster 2 (n=1521), the most significant continuous variable was a higher energy intake (mean 2755, SD 506.2 kcal/day vs mean 1749, SD 375 kcal/day; *P*<.001). The most significant categorical variable was sex (*P*<.001). A significantly higher proportion (997/1521, 65.55%) in cluster 2 were male compared to the other 2 clusters (885/2607, 33.95%; *P*<.001). For cluster 3 (n=1149), the most significant continuous variable was overall higher cognitive functioning (mean 0.2349, SD 0.5702 vs mean –0.3088, SD 0.7212; *P*<.001), and educational level was the most significant categorical variable (*P*<.001). A significantly higher proportion (475/1149, 41.34%) in cluster 3 received higher vocational or university education in comparison to clusters 1 and 2 combined (729/2979, 24.47%; *P*<.001).

Conclusions: This study demonstrates that a hypothesis-free and fully data-driven approach can be used to identify distinguishable participant clusters in large and complex datasets and find relevant variables that differ within populations with obesity.

Introduction

Overwhelming evidence shows that modern unhealthy lifestyle behaviors (eg, physical inactivity, poor nutrition, tobacco consumption) in many parts of the world increase the prevalence and incidence of obesity and chronic illnesses such as type 2 diabetes mellitus (T2DM), coronary heart disease, and some forms of cancer [1]. Prevention of (secondary) diseases and health promotion have been proposed as important solutions to ensure a sustainable health care system for the future [2,3]. Dutch national programs aiming at promoting a healthy lifestyle in a large number of people have, however, not yet led to a decrease in the prevalence of the abovementioned diseases or a decrease in health care consumption [4].

Obesity needs to be considered a complex system problem, influenced by a combination of genetic, biological, behavioral, social, economic, and environmental factors. These factors are intertwined and can reinforce each other. An unhealthy diet can be influenced by, for example, personal factors, cultural habits, the availability of healthy food, and economic conditions. To better understand the multifaceted nature of obesity, a systems approach is needed [5,6].

Research indicates that personalized interventions appear to be more effective than general programs in achieving long-term lifestyle behavior change among various populations [7-9]. Personalized treatment takes the variability among patients into account, considering, for example, genetic, environmental, disease-related, behavioral, and lifestyle-related factors to optimize treatment outcomes. In recent years, growing experience has been gained in applying advanced data analytics and machine learning (ML) in the context of public health [10]. Processing large amounts of data by including ML enables the recognition of patterns and the identification of variables that might play an important role in personalizing programs and interventions, due to the possibility to identify persons in a certain cluster or possibilities in exploring mechanisms underlying the distinctiveness between the different clusters. Moreover, emerging hypotheses may lead to additional opportunities. Recently, data-driven approaches are increasingly being explored on large datasets. ML algorithms can detect patterns in large and complex datasets, which would be difficult to find by more simple, conventional analyses. Clustering algorithms can organize similar data points into groups, uncovering patterns that may not be obvious with traditional statistical methods. Conventional statistical models, which require a priori information, often struggle with these complex systems; this restriction requires thorough data analysis and clear modeling, which can be challenging to manage in large datasets [11]. Interestingly, this kind of exploratory data analysis can be conducted without a predefined hypothesis. With regard to obesity, hypothesis-driven methods may be less suitable for understanding the complexity of this problem because they focus on isolated variables, might miss interactions, overlook broader contexts, and may not capture the multifaceted influences on obesity. Such a hypothesis-free approach provides the chance for exploration and discovery of patterns and relationships in the data without being limited or biased by a priori–defined expectations. In general, emerging patterns may be meaningful in describing complex phenomena; discovering cross-links between different variables; and identifying possible, distinct clusters within a population. Due to recent progress in processing large amounts of intricate and unorganized data, contemporary ML techniques are becoming ever more essential in the realm of personalized medicine [12].

Recently, various data clustering approaches have been applied among different populations. Nagamine et al [13] used a hypothesis-free approach to find patterns within the symptom range mentioned by patients with heart failure (n=25,861) and characterized these clusters in terms of their distinguishing variables in order to generate characteristics and progression patterns of heart failure. Nicolet et al [14] identified clusters for clinical practice to investigate the patient multimorbidity and complexity of Swiss residents aged ≥50 years (n=18,732) in claims data. Elbattah and Molloy [15] clustered older adult

XSL•FO
RenderX

participants in Ireland after a hip fracture into subgroups, in order to better predict the most beneficial care strategy for each patient. Takeshita et al [16] identified 7 clusters of obesity (BMI ≥35 kg/m^2) in order to tailor interventions based on the data in a health care claims database (n=9494). The abovementioned studies show that using unsupervised ML techniques offers unique opportunities to uncover unexpected insights, identify novel patterns, and elucidate previously unknown connections within large data by taking the approach of exploratory, data-driven, and hypothesis-free analysis. All these studies use the k-means clustering technique. Given these promising results and developments in the field of unsupervised ML techniques, we chose to include new developments in this study.

In particular, we explore in this paper the clustering of a large multidimensional dataset provided by The Maastricht Study. The Maastricht Study is an observational, prospective, population-based, cohort study [17]. Contrary to the aforementioned studies, which rely mainly on health care data, The Maastricht Study data include a broader range of potential variables, including etiology, pathophysiology, complications, and comorbidities of T2DM and other chronic diseases, and are featured by a comprehensive phenotyping approach. This dataset is complex due to the high number of variables, which implies high mathematical dimensionality, including noisy data and outliers. To handle these mathematical characteristics of the data, we choose to apply factor probabilistic distance clustering (FPDC) in this study [18].

The main aim of this study is a methodological exploration to identify potential clusters and relevant variables among individuals with obesity among participants in The Maastricht Study, using a data-driven and hypothesis-free ML approach.

Methods

Ethical Considerations

We used cross-sectional data from The Maastricht Study, an observational, prospective, population-based, cohort study. The rationale and methodology were described previously by Schram et al [19]. The Maastricht Study was approved by the institutional medical ethical committee (NL31329.068.10) and the Minister of Health, Welfare, and Sports of the Netherlands (Permit 131088-105234-PG). All participants gave written informed consent.

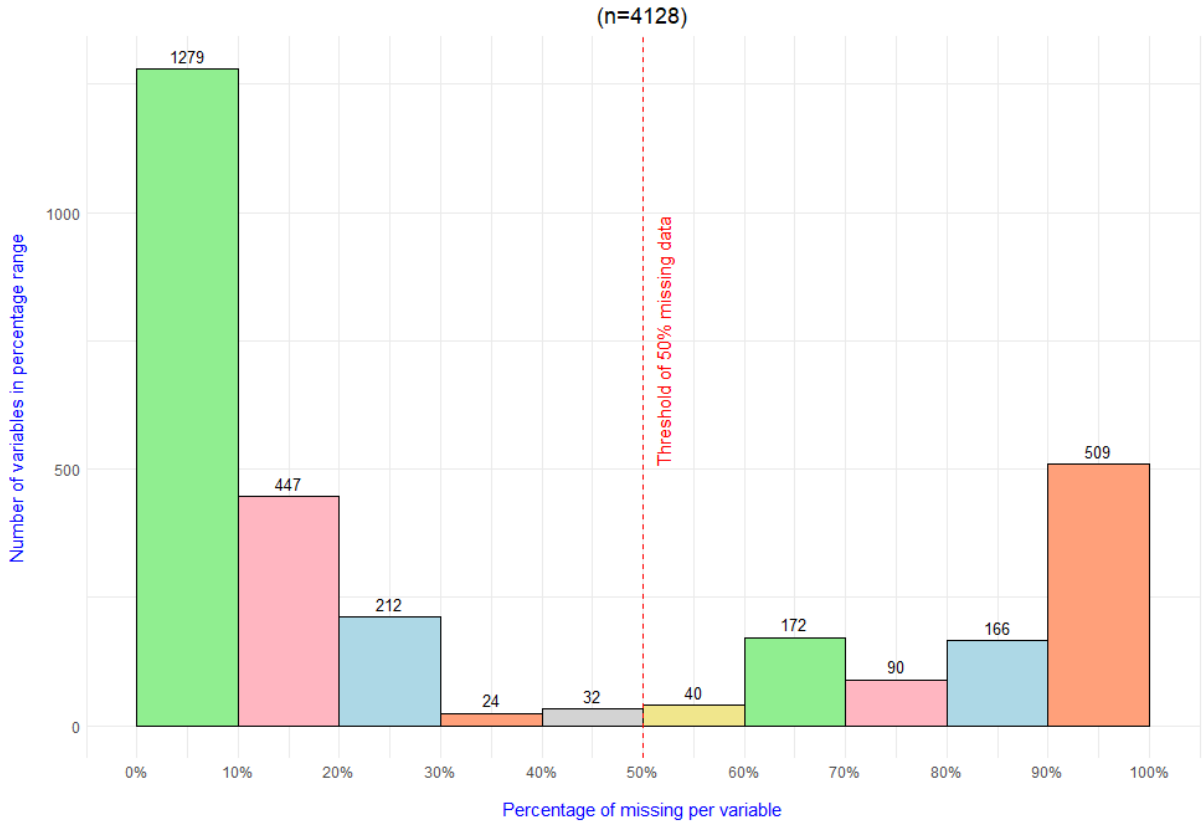
Study Population

Eligible for inclusion into this study were participants of The Maastricht Study with obesity. Within The Maastricht Study context, individuals were enlisted through widespread media outreach efforts and by sending invitations through postal mail to those registered in municipal records as well as the regional Diabetes Patient Registry. Recruitment was structured based on the known status of T2DM, with a deliberate emphasis on selecting more individuals with T2DM to ensure operational efficiency as part of The Maastricht Study.

Measurements

The Maastricht Study dataset includes a wide range of variables disaggregated in various general and disease-specific measurements comprising, for example, questionnaire data, physical examinations, and blood and urine examinations. For a detailed description of all measurements, see Schram et al [19].

In this study, data were included from all measured variables (2971 variables) of the cross-sectional data from the first 9188 participants who were included in the baseline survey between November 2010 and October 2020. For the specific purpose of our study, data from individuals with obesity were selected for our data analysis within this dataset based on the waist circumference variable. Men with a waist circumference higher than 102 cm (about 3.35 ft) and women with a waist circumference higher than 88 cm (about 2.89 ft) can be defined as being abdominal obese [20,21]. For a detailed description of the variables included, we refer to The Maastricht Study Dictionary [20]. This dictionary provides an overview of the variables included in our study.



Statistical Analysis

Overview

All data were assessed for aberrant measurement data and missing data. One of the steps to prepare the data before clustering was to remove variables with more than 50% missing data from the dataset. To provide more detail on the amount of missing data, an overview of the missingness is given in Figure 1. To impute the missing data in the remaining variables, we used the chained random forests (CRF) method [22,23] from the *missRanger* package in R. This package allows the use of predictive mean matching. Predictive mean matching ensures an imputed value that (1) occurs in the variables of interest in the case of categorical values and (2) attempts to bring the variance to a realistic size. In this research, all remaining variables were used to fill in the missing values in the data. Random forests have properties that allow them to impute heterogeneous data, unlike most standard methods, and can handle complex, nonlinear relationships in the data automatically [24], with high imputation accuracy [22]. The strength of the ensemble approach, by using random forest, lies in combining the predictions of multiple trees, which ensures a more reliable usage of the patterns underneath the data. Linear or distance-based methods struggle to capture this data structure and these underlying patterns. This feature of CRF makes the clustering, based on the decomposition into factors, more reflective of the actual data structure and underlying patterns. Another important feature of CRF is the ability to handle high-dimensional data, without overfitting [25]. This is in contrast to methods like k-nearest neighbors, which suffer in high dimensional space [26], and work well when no assumptions are made regarding the different types of missingness [27]. These properties led to the conviction that CRF is a suitable choice to impute this high-dimensional dataset when keeping the aim—to cluster the data—in mind. Further handling of missing data including data imputation is described in Multimedia Appendix 1. Data were standardized before inclusion.

Software

R Studio (version 4.3.0 {2023-04-21}; R Foundation for Statistical Computing) was used as an integrated development environment for the R programming language. R has been used including the packages in Textbox 1.

Textbox 1. List of R packages used in this study

- *missRanger*: An approach using random forests in sequence to fill in missing values within datasets containing a mix of different data types [22,28].
- *FPDclustering*: Factor probabilistic distance clustering is a factor clustering method that involves linear transformation of variables and clusters that optimize the probabilistic distance clustering criterion [18,29,30].
- *MXM*: Many feature selection methods for a wide range of response variables, including minimal, statistically equivalent, and equally predictive feature subsets [31,32].
- *uwot*: The uniform manifold approximation and projection method for dimensionality reduction [33].
- *vtable*: Variable table for variable documentation [34].

Identification of Participant Clusters

A novel unsupervised ML technique developed to handle high-dimensional and complex data was used to identify clusters in data from people with obesity. We applied the FPDC algorithm with the *FPDclustering* package in R. The FPDC algorithm was used to cluster individual cases into *k* clusters after preparing the data as described in Multimedia Appendices 2 and 3. The parameter *k* is required to be established within the algorithm framework. Subsequently, clustering was conducted across a range from 2 to 30 clusters, in line with previous research [13,35]. Followed by the identification of the optimal number of clusters through evaluation criteria, the number of clusters was determined by choosing an adequate number for the practice, but also by aiming for the highest possible average silhouette coefficient (SC) score. In addition, the uniform manifold approximation and projection (UMAP) plot provides insight into the actual distinctiveness of the clustering through visualization.

This algorithm executes a linear transformation of the original variables to reduce the number of variables into orthogonal factors, the so-called Tucker-3 decomposition [36]. Thereafter, these orthogonal factors are clustered with probabilistic distance (PD) clustering [18,30]. PD clustering assigns units to a cluster according to their probability of membership. Different

XSL•FO
RenderX

connections between probabilities and distances can be postulated, leading to diverse methods of clustering the data. In this study, the assumption holds that the product of the probability and the distance from each point to any cluster's center is a constant; thus, it is more probable that a data point is assigned to a cluster when this point is closer to the cluster's center [37,38]. The probabilistic nature of FPDC and its ability to handle transformed data (ie, Tucker-3 decomposition) allow it to be more robust to outliers [18]. Unlike some traditional deterministic methods, FPDC does not rigidly assign outliers to clusters, which can help maintain the integrity of the main clusters. This robustness is particularly useful in real-world applications where data can be noisy or contain anomalies. To overcome unstable results due to a large number of variables and correlated variables, which is a problem with PD clustering, the transformation into orthogonal factors is important. This combination results in a clustering algorithm suitable for high-dimensional datasets [39]. Besides being suited for high-dimensional datasets with correlating variables, the FPDC algorithm is also considered in this study because of the advantages it offers: (1) being a distribution-free clustering method. It outperforms models relying on k-means clustering (eg, factorial k-means) when dealing with non–Gaussian-shaped clusters or when (2) dealing with noisy data. This is due to the probabilistic approach that is more flexible and robust in handling noise in the data. Next to these advantages, the FPDC algorithm is (3) robust to outliers [18], as mentioned before. We believe that in this study the FPDC algorithm is suitable to handle outliers and noisy data, which is an important feature because of the complexity of the data used. Next to this, the FPDC algorithm is also considered because of the vast amount of variables and the amount of correlating variables, which is also a property of this dataset.

Evaluation of the Clustering Algorithm

To assess the outcome of the FPDC algorithm (ie, definition and number of clusters), we used the average SC, which provides a measure of both the cohesion and segregation of each data point [40]. This SC is derived from the probability matrix generated by the FPDC algorithm, which assigns a probability to each point in a cluster. To achieve this, a density-based SC is used [41]. In addition, apart from computing the SC, we depicted the data in 2 dimensions using UMAP. As the SC value approaches 1, the cohesion among data points within one cluster strengthens, while the segregation between data points within that cluster, relative to those in other clusters, increases. In conjunction with this metric, UMAP offers visualization of the data in 2D space, aiding in assessing the effectiveness of the clusters and their separation.

Description of Participant Clusters

In an attempt to take a data-driven and hypothesis-free approach to find and characterize the patterns in the large and complex The Maastricht Study dataset (ie, clusters), a feature selection technique was used to find the most distinguishing variables for each cluster separately. To understand each cluster's unique combination of variables separately, after the FPDC algorithm assigned participants to clusters, we applied a feature selection model (the statistically equivalent signature [SES] algorithm [42]) for cluster C_j with fixed j {1,…,k} based on binary logistic regression as a conditional independence test [32].

The cluster assignment is decoded in such a way that

With this, a binary classification problem was thus created. The data used in this feature selection model consists of N_j data points in C_j and randomly selected data points from cluster subsets other than C_j. To ensure that no class imbalance arises, we drew a simple random sample from the data points in the other clusters, where the ratio of the number of data points from the clusters other than cluster C_j was maintained and the sum of the sampled data points equaled the number of data points in C_j. Refer to Multimedia Appendix 4 for a deeper explanation. By studying the variable importance with the SES algorithm, we can make statements about which variables have a greater impact on the classification performance (ie, which variables can better distinguish C_j from the other clusters). Since we used sampling, we sampled the data points 8 times and thus used the SES algorithm 8 times for each cluster separately to select the variables. We sampled 8 times so that (1) we could capture the loss of information as much as possible and (2) the randomness in selecting variables could be counteracted by being sampled.

Variable Selection

The SES algorithm attempts to identify predictive variables grouped into subsets, which are called signatures of the target variable, while avoiding a high degree of redundancy; it aims for a minimum size of these variable subsets and to maximize the predictive power of the variable subsets over the target variable, that is, trying to predict the binary outcome variable introduced in the previous section. The algorithm identifies multiple predictive variable subsets whose performance, in terms of predictive power, is statistically equivalent [32]. It does this by using conditional independence tests (α=.01) to assess the relationship between variables and the target variable (ie, being in a certain cluster or not) [43]. By applying these statistical tests, with an iterative forward-backward filtering technique on every variable, it will add variables that are significantly related to the target variable, conditional on already selected variables, to the subset of variables (ie, the signature) in the forward phase. It will also remove variables, after selecting a new variable, that have become redundant in their information in the subset by testing whether these variables are still significantly associated with the target variable given all other selected variables. Initially, each variable is selected in its own group. If variables seem to be interchangeable in predicting the target variable, then they will be combined into one group. The SES algorithm will pick one variable from each group to form this so-called signature. By following these steps, the SES algorithm aims to provide a minimal subset of variables that contains all the information needed to predict the target variable without adding variables that do not provide unique information to the subset of variables, considering the variables already in the subset [32,43].

In this algorithm, the use of a conditional independence test, suitable for heterogeneous data and a binary target variable,

XSL•FO
RenderX

makes it possible to extend the SES algorithm to meet the specific requirements of the dataset used in this study. Therefore, we used a conditional independence test, provided in the algorithm, that is characterized by the binary target variable and the heterogeneous predictor variables it can handle, by using the binary logistic regression model to predict the target variable. Variables emerged by the SES algorithm, in terms of differences between the clusters, can be considered as a set of variables that are selected in such a way that the variables are minimally redundant in their predictive information within the subset of variables and that, as a set of variables, have maximum predictive power toward the binary classification of the outcome variable. This property is useful in terms of the aim of this study because it will return a subset of variables that is strongly related to the cluster number without providing redundant information in the subset of variables. When using a conventional statistical test for comparison between the variables in each cluster (eg, the Mann-Whitney *U* test) on all variables, it is difficult to select variables that are very distinguishable under the condition that we do not only report on variables that provide similar information. This would lead to an unsuitable interpretation of the clusters in an attempt to find cross-links between a variety of variables within the clusters. These considerations led to the use of the SES algorithm, which was introduced by Tsamardinos et al [42], on the data used in this study.

Description of Results

We used descriptive statistics to describe the variables of the identified clusters (mean, 5-number summary, SD, and the number and percentages) to indicate whether there is distinctiveness between participants, whether they belonging to a certain cluster or not, and the outcomes in a variable of interest. We used the group differences *F* test for continuous variables and the chi-square test of independence for categorical variables at a confidence level of α=.001. To compute these measures, we used the *sumtable* function from the *vtable* package (version 1.4.4) [34]. To ensure that it is easy to compare statistics, we created separate tables for continuous and categorical variables, resulting in 6 tables. These tables are presented in Multimedia Appendices 5-10. Although all *P* values are denoted as <.001, these values are actually all less than or equal to 1.13×10^{-9}. All these variables were extracted from The Maastricht Study dataset; their explanations are available on the web [20].

Results

Overview of the study population

In total, we included 4128 eligible participants from The Maastricht Study who were obese in our data analysis (Table 1). In total, 1586 variables were included after the data preparation and thus used in the FPDC algorithm.

XSL•FO
RenderX

Table 1. General description of the sample (n=4128)

Variable and category	Value
Sex, n (%)	
Female	2246 (54.41)
Age (years), mean (SD)	60.92 (8.39)
Marital status, n (%)	
Divorced	345 (8.36)
Living together	202 (4.89)
Married	3031 (73.43)
Other marital status	22 (0.53)
Single (not necessarily never married)	308 (7.46)
Widowed	220 (5.33)
Educational level, n (%)	
Higher professional education or university education	1335 (32.34)
Intermediate vocational education, higher secondary education, or higher vocational education	1878 (45.49)

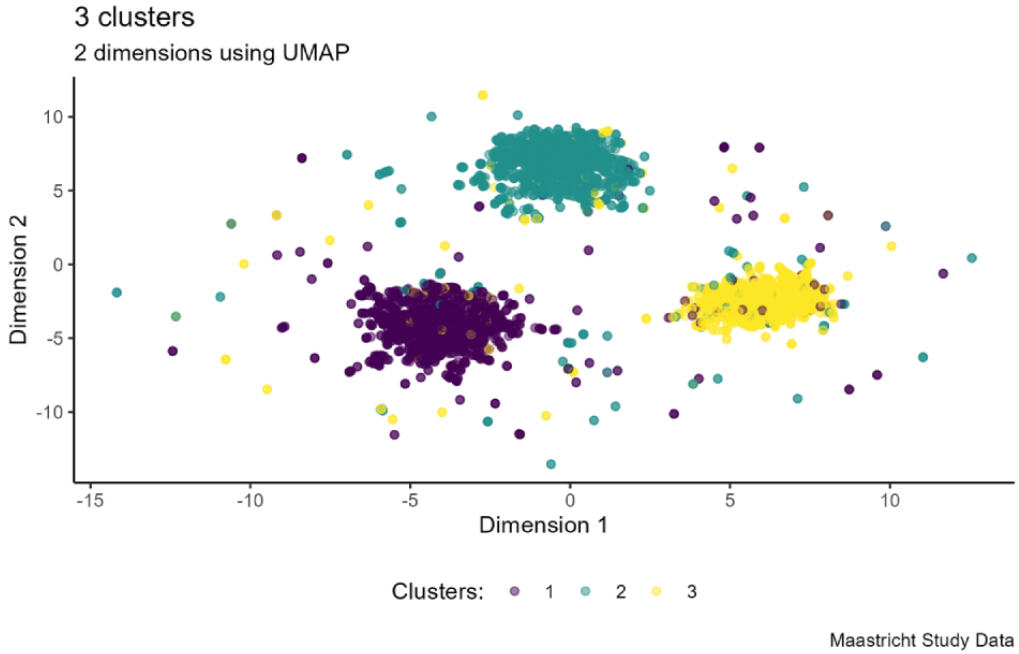
Identification of Participant Clusters

The SC in Multimedia Appendix 11 shows that 2 and 3 clusters were identified as the most optimal clustering number by the FPDC algorithm. Figure 2 shows the results of the FPDC algorithm by a UMAP projection that displays 3 distinct clusters, each with different characteristics.



A comprehensive overview of all selected variables and how the clusters differ from the other two clusters is displayed in Multimedia Appendices 5-10. Pictured next here, a description is given of the 2 variables of each cluster with the highest *F* statistic, for continuous variables, and the highest chi-square statistic, for categorial variables, by which a cluster differed from the other 2 clusters. For more information about these variables, we refer to the online dictionary of The Maastricht Study [20].

Cluster 1 (1458/4128, 35.32%) reported on average a significantly lower energy intake (mean 1684, SD 393 kcal/day; *P*<.001) than the average kilocalorie intake for clusters 2 and 3 combined (mean 2358, SD 635 kcal/day). The most significant (*P*<.001) categorical variable was occupation. A larger proportion of cluster 1 (1236/1458, 84.77%) did not work compared with clusters 2 and 3 (1486/2670, 55.66%); in cluster 1, the proportion of high occupational category (76/1458, 5.21%) was smaller than that in clusters 2 and 3 (420/2670, 15.73%). A similar picture can be seen for the proportion of intermediate occupational class; of the 1458 participants in cluster 1, a total of 31 (2.13%) participants report being in an intermediate occupational class, against 177 (6.63%) of 2670 participants in clusters 2 and 3. Of all participants in cluster 1, 54 (3.7%) out of 1458 reported a low occupational class, against 193 (7.23%) of 2670 participants in cluster 2 and 3. Of 1458 participants in cluster 1, a total of 57 (3.91%) were self-employed; in the other 2 clusters, 389 (14.57%) out of 2670 participants were self-employed. In Figure 3, these results are visualized.

Cluster 2 (1521/4128, 36.85%) included predominantly male participants. Sex was in this cluster the most significant (*P*<.001) categorical variable. A total of 997 (65.55%) of all 1521 participants in cluster 2 were male; this was in contrast to clusters 1 and 3, where 885 (33.95%) of 2607 participants were male. Looking at the most significant continuous variable, cluster 2 reported a significantly higher energy intake (mean 2755, SD 506.2 kcal/day; *P*<.001) than clusters 1 and 3 (mean 1749, SD 375 kcal/day). In Figure 4, these results are visualized.

Cluster 3 (1149/4128, 27.83%) reported significantly higher overall cognitive functioning (mean 0.2349, SD 0.5702; *P*<.001)) than clusters 1 and 2 combined (mean –0.3088, SD 0.7212). Educational level was the most significant categorical variable (*P*<.001). A higher proportion of cluster 3 participants received higher vocational or university education (475/1149, 41.34%) compared with the other 2 clusters combined (729/2979, 24.47%). A substantially lower proportion of cluster 3 attended no education, did not complete primary education, completed only primary education, or had lower vocational education. Of 1149 participants in cluster 3, a total of 281 (24.46%) reported this low educational level. In cluster 1 and 2 combined, 1515 (50.86%) out of 2979 participants reported the same educational level. Participants in cluster 3 received, relatively more often, intermediate vocational education or higher secondary education (393/1149, 34.2%) than the other 2 clusters combined (735/2979, 24.67%). In Figure 5, these results are visualized.

Discussion

Principal Findings

This study aimed to identify distinct clusters and relevant variables on which the clusters differ within a large population of individuals with obesity (n=4128) by applying an unsupervised ML algorithm. We included all available and eligible personal-level variables (2971 variables) from a population-based rich dataset of The Maastricht Study and used a hypothesis-free approach to group the data into clusters, analyzing the variables for their clustered association with obesity, without any previous human selection-based on established hypotheses.

Our novel data analysis strategy, which included (1) the FPDC algorithm, (2) SES feature selection, and (3) statistical testing, appeared valuable and successful for identifying distinct clusters within a population. This conclusion is based on the highly significant *F* and chi-square statistics observed for the selected variables across the clusters (refer to Multimedia Appendices 5-10). In this study, we chose to describe 3 clusters. This choice was based on the results of the SC and the UMAP. In this analysis strategy, we see particular strength in the use of an algorithm, specifically designed to cluster high dimensional data, in combination with the selection of a subset of minimally redundant predictive variables; this subset does not include variables that do not provide unique information in predicting the cluster numbers and has maximum predictive power over the cluster numbers generated by the clustering algorithm. This approach offers the opportunity to find relationships between the most proximate variables for obesity included in the dataset (eg, nutrition and physical activity) and the more distal variables (eg, occupation and education) that come into play in the background. This provides the opportunity to not only address the more proximal factors but also to learn about the importance of the more distal variables within the 3 different clusters. In each cluster, the root of the obesity problem might be a different one.

It should be noted, however, that the extent to which these 3 clusters could be relevant to clinical practice was not investigated in this study. To provide a meaningful interpretation and translate the findings to practical advice and programs, expert researchers, health care professionals, and representatives of those with obesity must be involved as well in field testing.

In comparison with the study of Takeshita et al [16], who also used unsupervised ML, we can point out some differences. The differences in results (eg, 7 clusters) within a population with morbid obesity may be explained by differences in the study population, type of data, and statistical analysis approach. In our study, we included individuals with obesity based on waist circumference, while Takeshita et al [16] included individuals with class 2 obesity (BMI≥35 kg/m^2). We chose not to use BMI as a measure of obesity because BMI does not take into account fat distribution throughout the body. Waist circumference is a measure of visceral fat and is strongly associated with all-cause morbidity and mortality [44]. Even though both studies used unsupervised ML, there are differences in the statistical

XSL•FO
RenderX

approach. We used the SES algorithm to identify the subset of variables that has the strongest predictive power toward the cluster number, resulting in a set of substantial distinguishing variables that are minimally redundant in their predictive information. Despite using the SES algorithm, we report variables that provide similar information (eg, energy intake reported as kilocalorie intake and kilojoule intake). This is due to using this algorithm 8 times and thus creating 8 subsets of variables for each cluster. This approach ensured the clusters were interpreted such that cross-links could be made between a variety of distinct variables within the clusters. Takeshita et al [16], on the other hand, performed a chi-square test to identify clinical variables. Nevertheless, some of our findings seem to be in line with Takeshita et al [16]. In particular, the findings of Takeshita et al [16] indicate that ocular diseases are a significant factor in differentiating cluster 4 from the other 6 obesity subgroups. In our study, we found that ocular measurements were contributing factors in the difference between cluster 1 and the other 2 clusters. In the study of Takeshita et al [16], age and sex are likely among several factors that contribute to the differences observed between the clusters. We see a similar picture in our clustering output. In Takeshita et al [16], cluster 6 is identified with the lowest hemoglobin A_{1c} (HbA_{1c}) level among the clusters. In our study, we found that cluster 3 has a significantly lower HbA_{1c} level in comparison with the other 2 clusters. This suggests that HbA_{1c} is a critical factor in differentiating these clusters from others in both studies. These findings indicate a certain similarity in the cluster characteristics. However, because The Maastricht Study offers more broadly varied data, compared to Takeshita et al [16], we can report on other potential differentiating factors such as dietary intake and energy consumption, and we also can offer insights into factors like cognitive functioning, aggression, and socioeconomic status.

This study primarily centered on the data analysis strategy. In future research, the content of the clusters should be interpreted by experts in the field of obesity and the clinical relevance should be assessed.

Limitations

Even though we used a hypothesis-free approach, data preparation was needed to apply the FPDC algorithm. For instance, The Maastricht Study data collected from participants lacked clear differentiation across all variables due to indistinguishable answer options in some variables. Essentially, these variables had significant overlap, rendering them ineffective for distinguishing between clusters. For example, the variable for ethnicity is divided into 2 categories (Caucasian or other); however, since almost 99% of the participants with obesity reported to be Caucasian, this variable is not useful to cluster on. The use of the FPDC algorithm is subject to some limitations. This algorithm can be computationally intensive, which leads to long processing times on high-dimensional data. Furthermore, this algorithm is sensitive to the choice of the initial parameters used, for example, the choice of the number of factors. In our study, we applied hyperparameter tuning to ensure a valid choice of these parameters. In addition, due to its flexibility with outliers, the FPDC algorithm may have difficulty detecting clustering structures if there is a significant size difference between clusters and the 2 clusters are not far apart. For example, if one cluster has a much larger number of units than another cluster and the clusters are not far apart, the FPDC algorithm may fail to identify the smaller cluster. Given the absence of significant differences in the number of data points across clusters in this study, we anticipate that this issue does not adversely affect our results. In our dataset, individuals diagnosed with T2D were overrepresented. In the Dutch general population, the prevalence with T2D is about 7%, but in this study, the prevalence is almost 35%. We chose not to correct for oversampling of patients with T2D in this study, because we have come to the belief that (1) this study is methodological in nature, (2) the loss of information cannot be compensated for, and (3) the objective of this study does not involve the generalization to T2D patients.

Conclusions

This study illustrates that using a hypothesis-free approach using the FPDC algorithm successfully identified 3 distinct clusters within a complex and extensive dataset concerning a population with obesity. The SES algorithm proved to be adept at uncovering highly discriminative variables that highlight differences between the clusters identified by the FPDC algorithm. Further research and collaboration with clinical experts are needed to interpret the content of the clusters and to assess potential clinical relevance.

Acknowledgments

The authors thank the owners of the data for their contribution to the conversations about the variables that are presented in the results, as their views have highly enriched our study. In particular, we thank Dr. Martijn Zoet, SB, and the Maastricht Study Management Team for their contribution to the beginning of this project. The following respondents opted to have their names acknowledged as members of the Maastricht Study Management Team:

Pieter C Dagnelie, CARIM School for Cardiovascular Diseases, Maastricht University/Department of Internal Medicine, Maastricht University Medical Center, Maastricht, the Netherlands; Marleen van Greevenbroek, Cardiovascular Research Institute Maastricht (CARIM), Maastricht University/ Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands; Sebastian Köhler, School for Mental Health and Neuroscience (MHeNS) Maastricht University/Alzheimer Centrum Limburg Maastricht University Medical Center+ (MUMC+)/Department of Psychiatry and Neuropsychology, Faculty of Health, Medicine & Life Sciences Maastricht University, Maastricht, The Netherlands; Miranda T Schram, School for Mental Health and Neurosciences (MHeNs), Maastricht University/Department of Internal Medicine, Maastricht University Medical Centre/School for Cardiovascular

Disease (CARIM), Maastricht University/Heart and Vascular Centre, Maastricht University Medical Centre, Maastricht, The Netherlands; and Anke Wesselius, Department of Epidemiology Maastricht University, Maastricht, The Netherlands.

This study was supported by the European Regional Development Fund through OP-Zuid, the Province of Limburg, the Dutch Ministry of Economic Affairs (grant 31O.041), Stichting De Weijerhorst (Maastricht, The Netherlands), the Pearl String Initiative Diabetes (Amsterdam, The Netherlands), the Cardiovascular Center (CVC, Maastricht, the Netherlands), CARIM School for Cardiovascular Diseases (Maastricht, The Netherlands), CAPHRI Care and Public Health Research Institute (Maastricht, The Netherlands), NUTRIM School for Nutrition and Translational Research in Metabolism (Maastricht, the Netherlands), Stichting Annadal (Maastricht, The Netherlands), Health Foundation Limburg (Maastricht, The Netherlands), and unrestricted grants from Janssen-Cilag BV (Tilburg, The Netherlands), Novo Nordisk Farma BV (Alphen aan den Rijn, the Netherlands), and Sanofi-Aventis Netherlands BV (Gouda, the Netherlands).

Data Availability

The dataset analyzed in this study is not publicly available due to the availability of these data, which were used under license for this study but are available from the corresponding author on reasonable request and with permission of the Maastricht Study Management Team.

Authors' Contributions

MJMB and MK took responsibility for the acquisition of the data from The Maastricht Study in close consultation with CvdK and AK. MJMB and KVB designed the study. MJMB conducted a quantitative study. MK, IMK, and MJMB conducted conversations with several owners of the data. MJMB wrote the script for the data cleaning, the factor probabilistic distance clustering (FPDC) algorithm, the statistically equivalent signature (SES) algorithm, and the statistical analysis. IMK, SB, and MK discussed and took the choice for the inclusion criteria (ie, using the waist circumference) and discussed the variables in the analyses. IMK and MJMB drafted the manuscript, and MK, SB, and KVB reviewed all versions of the manuscript. All authors read and contributed to editing the manuscript for final submission.

Abstract

Background: Machine learning (ML) systems in health care have the potential to enhance decision-making but often fail to address critical issues such as prediction explainability, confidence, and robustness in a context-based and easily interpretable manner.

Objective: This study aimed to design and evaluate an ML model for a future decision support system for clinical psychopathological treatment assessments. The novel ML model is inherently interpretable and transparent. It aims to enhance clinical explainability and trust through a transparent, hierarchical model structure that progresses from questions to scores to classification predictions. The model confidence and robustness were addressed by applying Monte Carlo dropout, a probabilistic method that reveals model uncertainty and confidence.

Methods: A model for clinical psychopathological treatment assessments was developed, incorporating a novel ML model structure. The model aimed at enhancing the graphical interpretation of the model outputs and addressing issues of prediction explainability, confidence, and robustness. The proposed ML model was trained and validated using patient questionnaire answers and demographics from a web-based treatment service in Denmark (N=1088).

Results: The balanced accuracy score on the test set was 0.79. The precision was ≥0.71 for all 4 prediction classes (depression, panic, social phobia, and specific phobia). The area under the curve for the 4 classes was 0.93, 0.92, 0.91, and 0.98, respectively.

Conclusions: We have demonstrated a mental health treatment ML model that supported a graphical interpretation of prediction class probability distributions. Their spread and overlap can inform clinicians of competing treatment possibilities for patients and uncertainty in treatment predictions. With the ML model achieving 79% balanced accuracy, we expect that the model will be clinically useful in both screening new patients and informing clinical interviews.

Introduction

Overview

As in most areas of human activity, mental health care has seen an increase in the application of artificial intelligence (AI), particularly in assisting the diagnosis and treatment of mental disorders [1]. While the debate between clinical judgment and statistical methods is longstanding in the field of clinical psychology [2], under appropriate conditions, statistical tools can perform as well as—or better than—clinical judgment in diagnosing psychopathologies [3]. To be effective, these statistical tools should be context-based and simple for clinicians to use [3,4].

When assessing patients for treatment in a mental health setting, clinicians consider various screening instruments in addition to demographic and medical information, assessing the scores related to possible diagnoses and treatments based on the patient's answers to questions [5]. Patients with complex clinical scenarios present a challenge for clinicians in assessing the various possible symptoms to arrive at a most likely diagnosis [6]. In diagnosing depression, for example, comorbidity with anxiety disorders and other factors was found to lead to uncertainty in diagnosis in as many as 40% of cases [7]. The consequences of an uncertain diagnosis may be high rates of treatment-resistant depression [7,8].

Early correct intervention may reduce the burden of disease for the individual as well as the society. The global costs of mental disorders were estimated to be US $2493 billion in 2010 and are expected to more than double by 2030 [9]. Wittchen et al [10] deemed mental disorders "the core health challenge of the 21st century." In their key recommendations for future research, they state that "clinically sensitive and economically feasible decision algorithms could be explored to determine what types of interventions should be assigned to which type of patient." Therefore, insight into the underlying factors that characterize a psychopathological diagnosis and the factors that discriminate between alternative diagnoses is valuable and a contribution to solving a larger and urgent health need.

Mental health care has benefited from the ability of AI technologies to analyze data, infer classifications from new data, and communicate insights from data [11]. AI has been recognized as an important tool in clinical decision-making for mental health [12]. In assessment, AI technologies offer the potential to complement the role of clinicians with diagnostic decision support technologies [13,14]. Such diagnostic tools require the AI models to be explainable and interpretable [15], both in terms of the model itself (global) and the individual model predictions (local). Interpretability refers to how a model arrives at a decision, and explainability refers to why the decision is reached [16]. While explainability in AI has been a topic of interest since the 1980s, the recent accelerations in the widespread use of AI have resulted in guidelines on the responsible use of AI. Responsible AI requires a robust model that conveys the confidence and degree of uncertainty in prediction [16-18]. Although confidence and uncertainty estimation are considered a necessity for medical AI models to enable safe clinical deployment [19], it has been claimed that most machine learning (ML) methods in the recent medical literature neglect the important issue of model uncertainty [19].

This paper presents the design of an ML model for psychopathological mental health treatment tailored to the omnipresent questionnaire-type screening instruments. The AI model described here is based on a novel hierarchical structure that aims to meet the needs of clinical interpretability while accounting for decision confidence and uncertainty. The presented approach facilitates the questionnaire instruments that are typically used in mental health care to assess symptom severity, but in a data-driven way [13], while leveraging any other information known about respondents.

This paper first lays out the rationale for explainable AI (XAI) methods in medical models, introducing the important issues of model confidence and uncertainty. Typical ways in which model confidence and uncertainty can be quantified are introduced with an emphasis on Monte Carlo dropout (MCD), the method used in this paper. The model structure is then introduced and shown to provide interpretability by design with confidence and uncertainty estimation provided through the use of MCD. Next, model training and validation on clinical data from a Danish web-based mental health treatment service are detailed and results presented. Finally, the implications of the work are discussed.

Background

After initial interest in the explainability of AI models in the 1980s and 1990s, recent advances in AI and ML, and the increased use of such technologies in safety-critical, socioeconomically and medically impactful applications have driven a renewed interest in XAI [20]. The explainability of AI models is generally understood as the ability for a wider range of users to understand the outputs of a given AI or ML model [21]. The concept of interpretability is closely related and refers to the ability of a person to understand how a given set of inputs results in a model output [22].

As an extension to the explainability of ML models, recent endeavors have put more emphasis on responsible or trustworthy AI [23], with confidence and robustness being important technical prerequisites. The confidence of an ML algorithm is defined as the model's own assessment that the provided inferences are correct. Robustness is defined as the ability of a model to yield consistent results in the presence of uncertainty [16]. In practice, robustness can be evaluated by perturbing the model structure to induce distribution shifts [24], introducing epistemic uncertainty. According to XAI frameworks, robustness extends explainability while increasing stability and user satisfaction [16]. Such measures of confidence and robustness are important for a model aimed at medical decision support systems (DSSs), such as the one presented in this paper [25].

ML Methods in Relation to XAI

Logistic regression is a classification model used in ML that applies a linear combination of the data X, with weights W, to discriminate between classes of the dependent variable Y. It models the probability of an outcome using a logistic (sigmoid) function:

XSL•FO
RenderX

(1)

Since the equation consists of a linear combination of the features transformed by a sigmoid function, each weight of the model directly corresponds to the weight of a feature in determining the output. Because of this linear nature, XAI deems logistic regression to be a white-box model [16,18]. White-box models are also referred to as having the property of transparency [18]. In contrast, gray-box models and black-box models are categories of AI models with less ability to inspect the inner workings of the model (less interpretability and less transparency), but typically with more power to discriminate, and are often used in complex applications such as computer vision. This property of powerful models being black-box is often referred to as the interpretability-performance trade off [26]. Other common white-box ML models include decision trees and K-nearest neighbor models [18]. Deep neural networks are an example of a black-box model due to their many stacked nonlinear layers, typically consisting of millions of weights, which make their operation uninterpretable. Post hoc techniques add interpretability as an additional method or algorithm to the AI model [16]. One such approach is to add an additional, surrogate model that simplifies relevant sections of the AI model to be explained. Local interpretable model-agnostic explanations (LIME) [27] is a method that can explain the prediction of any classifier by building a local model that aims to approximate the original model and its predictions. The new model is chosen to be an interpretable model (such as logistic regression). This allows the user to better understand the relationship between a single input and the corresponding output prediction by providing a local explanation and is, therefore, an explanation by simplification. However, LIME has some drawbacks: it does not inherently provide global explanations of the dataset as a whole and it can experience inconsistency because it requires multiple perturbations of input data and retraining local surrogate models [28]. An alternative XAI method that ranks the importance of features used by the model is Shapley additive explanations (SHAP) [29]. SHAP is a method that calculates an additive feature importance score, which can provide local explanations for individual predictions as well as global explanations for the whole dataset. However, SHAP may experience sensitivity to feature perturbations and to feature correlations and interactions [30]. As a whole, a drawback of post hoc explainability techniques is that they approximate the model's decision-making rather than directly reflecting its internal structure.

Since explaining black-box models requires post hoc techniques, SHAP and LIME have been applied to deep learning models in medical applications, for example, to aid the explainability of complex convolutional neural network medical diagnostic models for chest X-ray classification for COVID-19 infection [31]. SHAP has also been applied as a backend explanation module for a neural network predictor of COVID-19 infection diagnosis in eHealth record data [32], providing both local and global explanations. Post hoc XAI techniques, such as these, represent the vast majority of XAI use cases in health care [33]. To overcome the drawbacks of post hoc methods, our new approach offers an inherently interpretable model for predicting mental health treatment outcomes. Its transparency stems from a logistic regression framework, which, as described earlier, is interpretable as it is possible to make a direct link between the value of an input parameter, its associated weight, and the prediction made by the model. Moreover, by using a hierarchical structure that moves from questions to scores to classification predictions, this design enables users to understand how and why the model makes decisions, both at the questionnaire score level and the individual question level.

Responsible AI

As previously stated, responsible AI requires an understanding of its own confidence and robustness in inferences. The advent of deep learning has resulted in a step change in the performance of models and the associated practical use of AI. However, this has come with disadvantages. Deep learning models can be confidently wrong, especially in case of a shift in the input data, and in recent years, such overconfidence in incorrect inferences has proved fatal, as illustrated by serious accidents caused by machine vision models in cars [34]. Most ML algorithms provide point-estimate predictions, meaning they provide an inference with, at best, a scalar estimate of the model's confidence in the inference. More recently, methods based on the application of Bayesian statistics have been proposed [35]. In such methods, rather than estimating a point estimate, the models provide a probabilistic inference modeled by a probability distribution. This distribution can then be used for a point-estimate inference (eg, by taking the mode of the distribution as the inference) and can also be used to assess the model's uncertainty in this inference by considering the shape of the probability distribution. Distributions strongly peaked around the inference indicate low uncertainty; very wide and flat distributions around the inference indicate high uncertainty.

These models often also provide probabilistic information on the effect of model predictions in the face of perturbations in the input features. For example, Cardelli et al [36] showed that for Bayesian inference with Gaussian processes, a class of algorithms overlapping with deep neural networks that have inherent uncertainty estimates [19], the model's uncertainty in response to perturbations in the input space can be upper-bounded, thus providing a measure for the model's robustness.

If a full Bayesian probability distribution is established for all parameters in the model, with statistics either learned from data or based on existing knowledge, it can then be used to investigate the confidence and robustness of the model. However, a significant drawback of this approach is that it can be compute-intensive [37].

An alternative method called MCD is inspired by using the dropout layers in deep neural networks to improve the ability of a network to "generalize," or provide good quality predictions on yet unseen data [38]. When used to allow the model to generalize well, dropout sets weights of the model to 0 randomly during training only [38]. The result is that the trained model does not become overreliant on any one (potentially spurious) characteristic of the data. In contrast, MCD also uses dropout when new predictions are made. It does so by obtaining repeated

XSL•FO
RenderX

inferences from the trained model, but with different weights dropped out in every iteration of the inference. The result is a distribution of inferences rather than a point-estimate. Such inference distributions can be shown to be equivalent to those obtained by a fully Bayesian model for an important family of probabilistic models, called Gaussian process models, when dropout is applied before every weight layer [39]. Consequently, MCD results in a Bayesian approximation by randomly switching off connections in the network during inference.

MCD has been applied to estimate uncertainty in medical imaging AI convolutional neural network models where the model perturbations allow the estimation of epistemic uncertainty in the prediction of potentially cancerous skin lesions [17] and brain tumors [40]. Using this method, the model is sampled N times with dropout elements set to 0 randomly according to Bernoulli random variables. Given a prediction s^*, the model is sampled N times, with model parameters  at each iteration, to yield the sample distribution y^*. The mean value of class c (μ_c) of the sample is the prediction probability of the class, while the variance of class c (σ_c^2) is the uncertainty measure:

Methods

Overview

This paper presents a methodology to obtain explainable, interpretable models that are robust and provide a reliable confidence score for use with an important class of data in mental health, namely that of sum-score questionnaires. The model uses the answers to individual questions as inputs, but also explicitly represents the traditionally used sum-scores of such questionnaires in the model. Hence, explainability and interpretability are provided both at the question level and at the sum-score level. To also provide robustness and a measure of model confidence in its predictions, MCD is applied as described in the previous section.

The ability of the proposed model to provide interpretable predictions as well as estimates of confidence is demonstrated with a use case aimed at providing clinicians with treatment recommendations for several mental disorders.

Metrics

Precision, recall, F_1-score, balanced accuracy score, weighted F_1-score, and area under the curve (AUC) are relevant metrics for evaluating the predictive model's classification performance. Precision measures the proportion of correctly predicted treatment decisions among all predictions for a given class. A high precision score ensures that the model minimizes incorrect treatment assignments. Recall (or sensitivity) assesses the proportion of correctly predicted treatments among all actual instances of that class, reflecting the model's ability to identify the correct treatment when needed. F_1-score is the harmonic mean of precision and recall, balancing both metrics to provide a single performance measure, particularly useful in cases of class imbalance. The balanced accuracy score is the average of recall across all classes, accounting for imbalanced class distributions by ensuring each class contributes equally to the overall performance evaluation. Weighted F_1-score adjusts the F_1-score by considering class frequencies, preventing minority classes from being overshadowed in imbalanced datasets. The AUC measures the model's ability to distinguish between different treatment classes, with higher values indicating better discrimination. During validation these metrics ensure reliable treatment predictions, minimize incorrect classifications, and balance performance across all treatment options, reducing potential clinical risks.

Data

A dataset comprising patient questionnaire answers and demographics was used to train and validate the model. The data were gathered between November 14, 2019, and December 31, 2022, from patients of the "Internetpsykiatrien" web-based treatment services delivered by the Centre for Digital Psychiatry, Denmark. The center delivers routine care internet-delivered cognitive behavioral therapy with nationwide coverage [41]. The data consisted of answers to the Patient Health Questionnaire-9 (PHQ-9) [42], the Generalized Anxiety Disorder Questionnaire-7 (GAD-7) [43], the Social Interaction Anxiety Scale (SIAS) [44], the Panic Disorder Severity Scale (PDSS) [45], and the Fear Questionnaire [46]. Additional features included demographic information and a brief medical history, such as previously diagnosed conditions.

The ground truth of the dataset was the choice of treatment selected by the psychologists in the clinic for each patient. The treatment decision was reached using multiple steps. First, clinical psychologists or psychologists under the supervision of a clinical psychologist, assessed patients using questionnaires to determine the optimal treatment. This assessment used the same questionnaire and demographic data that was used by the model, except for free text data, which were available to the psychologists, but not to the model. Second, they performed a clinical assessment interview, including the use of the semistructured interview, Mini Neuropsychiatric Interview. Any ambiguities were discussed at a clinical conference.

A total of 91 input features were selected for inclusion in the models (Table 1), with data completeness as the primary inclusion criterion. The dataset (N=1068) was randomly split into a training set (n=801, 75%) and a test set (n=267, 25%). The training data consisted of 4 prediction class categories as follows: (1) depression (n=269, 33.6%); (2) panic (n=269, 33.6%); (3) social phobia (n=193, 24.1%); and (4) specific phobia (n=70, 8.7%). The test set class categories were stratified to match the training set in proportion: 33.7% (90/267); 33.3% (89/267); 24% (64/267); and 9% (24/267) for the 4 classes, respectively.

XSL•FO
RenderX

The percentages of training or test set data per class were: 34% (269/801); 34% (269/801); 24% (193/801); and 9% (70/801) (rounded), respectively. Given this class distribution, we opted against upsampling the underrepresented classes (social phobia and specific phobia) or downsampling the overrepresented classes (depression and panic). While upsampling could mitigate class imbalance, it risks introducing synthetic patterns that may not generalize well to real-world data. In addition, given the relatively small sample size of the latter category (70/801, 9% in training), aggressive upsampling could lead to overfitting, where the model learns artifacts of the duplicated instances rather than underlying patterns in the data.

Conversely, downsampling depression and panic would reduce the total available training data and potentially discard valuable information, impairing the model's ability to capture the full variation within these classes. Furthermore, since the dataset represents naturally occurring clinical distributions, artificial class balancing could distort the real-world relevance of model predictions. Instead, we opted to maintain the original class distribution and address class imbalance using performance metrics robust to class imbalance, such as balanced accuracy, weighted F_1-score, and AUC, ensuring that model evaluation accounts for differences in class representation.

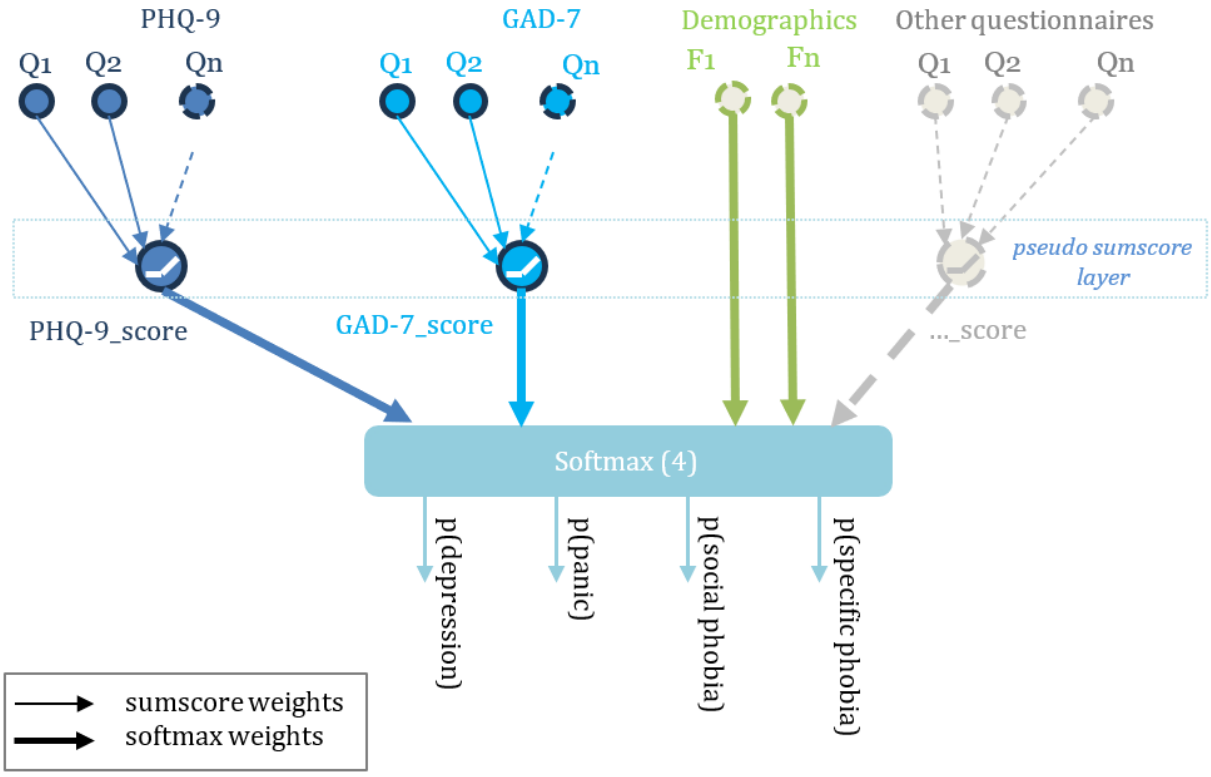
Ethical Considerations

Data were extracted from Internetpsykiatrien after approval from The Regional Council in Southern Denmark. Since this was a secondary data analysis, separate informed consent was not required. However, the Regional Committees on Health Research Ethics for Southern Denmark were informed about the study and were provided with the case number S-20232000-65. In accordance with Danish national ethical guidelines, no additional ethics approval was needed. The study was reported to the Danish Data Protection Agency. Data was anonymized before being provided to the researchers. No compensation was provided.

Model

The proposed model was designed to interpret the traditional sum-score questionnaires used in mental health treatment in a data-driven, explainable fashion. Sum-score questionnaires offer several prespecified answers to each question, with each answer associated with a numeric, typically integer, score. These scores are then summed and in many cases a threshold is then applied, which indicates whether the respondent demonstrates clinically significant symptoms for the disorders tested by the instrument. Hence, such sum-scores play an important role in clinical decision-making. ML models such as logistic regression strongly align with this principle while also offering inherent interpretability due to the nature of the output activation being related to a weighted sum of the inputs. Such inherent explainability is appealing; however, the complexity of the information conveyed when models contain many weights can lead to cognitive overload, hampering decision-making [15] and explainability [16].

To improve the model's explainability while also retaining its inherent interpretability, a hierarchical model was proposed. As can be seen in Figure 1, this model mimics the sum-score models in the hidden layer of the model, in which the responses of each individual instrument are multiplied by their respective weight and then summed to yield pseudosum scores. These scores differ from normal sum-scores by applying a learned weighting to each answer before summing. These pseudosum scores incorporate a rectified linear unit activation function to ensure a linear sum while also ensuring the sum cannot be negative (due to the model learning negative weights during training). These scores and their weights allow inherent interpretability on a per-score basis, which will be familiar to clinical users of traditional questionnaire instruments. These pseudosum scores are then weighted before being combined in the output layer with the weighted sum-score of all other used instruments. In addition to the pseudosum scores, any other features with potentially discriminative power, such as sociodemographical information, can be added. All weights have dropout applied during prediction, consistent with the use of MCD as described previously. A softmax-type activation function is used in the output layer. The softmax activation function ensures that the sum of all the outputs of the model equals 1. Hence, each of the outputs can be interpreted as the probability that the corresponding treatment should be recommended. This output probability is illustrated as p(depression), as shown in Figure 1. Note that the output layer will typically contain 1 output node for each of the treatments considered by the model and that this number is not necessarily the same as the number of screening instruments used as inputs to the model.



With this specific architecture, the model achieved three important goals as follows: (1) the model allows the nonlinear combination of multiple instruments to achieve a treatment prediction, (2) the model allows the explanation of its predictions based on pseudosum score results and thus provides score-level explainability and trust in the model, and (3) at the same time, the model allows for the analysis of model predictions based on the input features, enabling users to understand which particular responses to each questionnaire drive the model predictions. These insights may provide therapists with valuable information on how to personalize the therapy.

The model's structure inherited its interpretability from its foundation in logistic regression, while confidence and robustness of the model were addressed using the

XSL•FO
RenderX

aforementioned MCD. As previously stated, MCD can be shown to approximate the probabilistic results obtained by Bayesian approaches for a class of models called Gaussian Processes. The latter are a generalization of generalized linear models, one of which is the logistic regression model chosen in our approach for its explainability. The hierarchical logistic regression model has dropout applied before every weight layer, since the Bayesian properties of MCD apply for neural networks of arbitrary depth and nonlinearities, as long as dropout is applied in this way [39]. While it is usual for dropout to be applied to neural networks to fulfill the function of regularization during training time [38], as explained, MCD also applies dropout during inference. The probability of a node being dropped, the dropout rate, is a parameter of the dropout layers. In MCD, the dropout rate is typically set heuristically. Extensions to the technique, such as learnable Bernoulli dropout [48], allows the dropout rate to be jointly optimized in the model training phase. When MCD is used in this way, to approximate a Bayesian network, it should not be seen as a regularization method [49]. Therefore, L1 regularization is applied during training to reduce overfitting. L1 regularization attempts to achieve good generalization (ie, good performance on yet unseen data) by forcing the influence of unimportant features to 0. L2 regularization can be applied as an alternative, fulfilling the regularization function without enforcing sparsity in the weights. Further justification for the choice of L1 regularization is provided in the Results section. Multimedia Appendix 1 shows the model details.

Figure 1. Model structure. The structure of the hierarchical model shows the questionnaire input features (Q) being passed to the pseudosum score layer and then to the output layer. The pseudosum layer incorporates a rectified linear unit activation function to ensure the pseudosum scores cannot be negative. The output layer performs a softmax function, predicting the probabilities of the 4 classes. The weights are represented by the arrows, with the thicker arrows representing the weights in the softmax layer. The demographic features (f) pass directly to the output layer with softmax weightings. GAD-7: Generalized Anxiety Disorder Questionnaire-7; PHQ-9: Patient Health Questionnaire-9.

Prediction Explainability and Confidence

The distribution of the softmax output classes over the N samples , are visualized using Violin plots of the output class probability distribution over the N samples of a single patient prediction. A prediction for a single patient is shown in Figures 2 and 3. The outer, colored, “violin” shape visualizes the probability distributions over the N samples of the single patient example, while the embedded box-plots illustrate the medians and IQR of the model’s predictions. The confidence and uncertainty of the prediction can be understood by observing the shape and overlapping of the violin plots. Figure 2 provides an example of depression being predicted with high likelihood and nonoverlapping with the other 3 classes, whereas the predictions for all 3 other disorders have a low median probability. Predictions with low confidence (ie, low probabilities) and high uncertainty (ie, large probability variation), where more than 1 class may credibly be predicted, resulted in outputs, such as shown in Figure 3. This is an example of the relation between XAI concepts [16], using visualization to enhance explainability, contributing to improved interpretability, and the interpretability of the model leading to validation of the explanation.

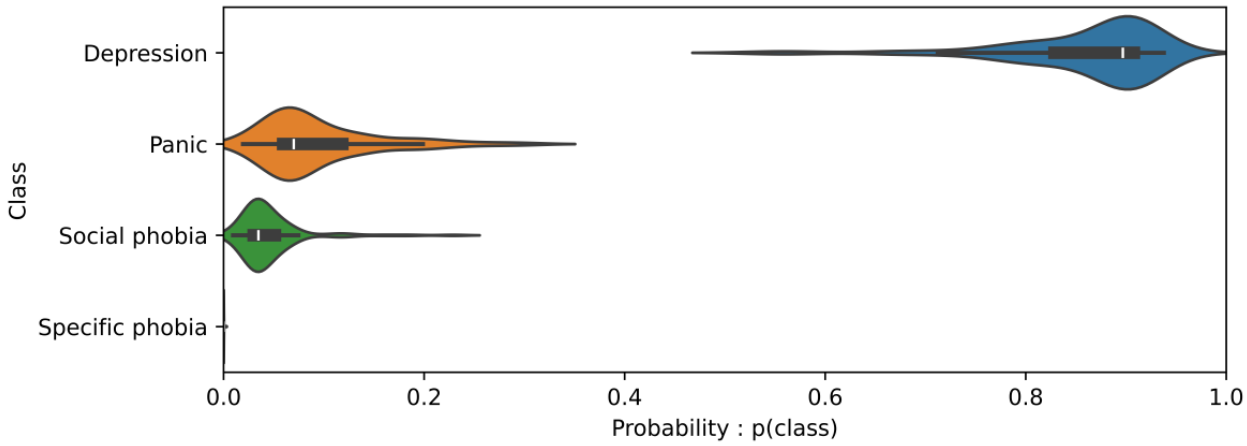
RenderX

Figure 2. A representation of the output class distribution. A violin plot showing the probability distribution of the 4 treatment classes for a single example over N runs (samples) of Monte Carlo dropout. The separation of the probabilities (x-axis) indicates high model confidence in the prediction of depression compared to the other classes. The low dispersion in the predictions indicates low uncertainty.



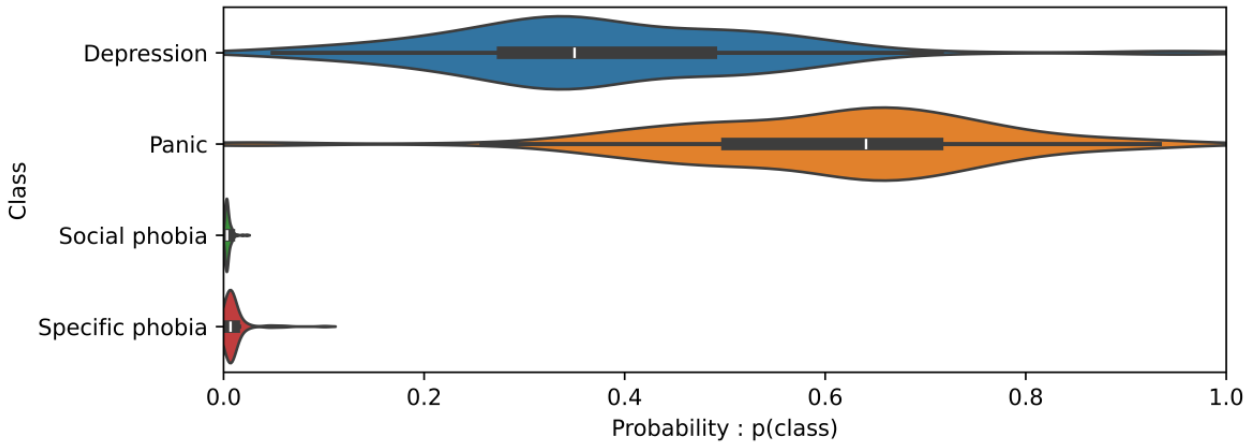


Figure 3. Class distribution of high uncertainty and low confidence. A violin plot showing the probability distribution of the 4 treatment classes for a single example over N runs (samples) of Monte Carlo dropout. The overlap of the probabilities (x-axis) indicates low model confidence in the prediction of panic compared to depression. The high dispersion in the predictions indicates high uncertainty.

Prediction Interpretability and Robustness

Interpretability at the model level is aided by examining the learned weights after training. Since the scores are weighted linear sums of the question inputs W^TX, the learned weights (W) are informative of the importance of each of the question features in determining the score used in the output class predictions in the softmax layer. The softmax layer implements a multiclass logistic regression function for each class (subscript c) and score (subscript s):

(4)

Where σ represents the sigmoid (or logistic) function, X_s is the input coming from the score layer or demographic features, W_c represents the weights in the softmax layer for class c, and B_c represents a bias value for each class.

Determining feature importance is an important aspect of explainability. At the model level, applying L1 regularization to logistic regression tends to force the weights of unimportant features to zero, leaving more important features as nonzero [50]. However, it is important to be aware that collinear features may not be equally important for a model since they can be accounted for by just one of the collinear features, with the others set to 0. Constraining trained weights to be nonnegative in the score layer aids interpretability since traditionally, questions are summed to produce a score. Therefore, the relative weights play a useful role in determining feature importance, provided that the inputs have been normalized to the same scale during training and prediction.

At the model level, standardized coefficients obtained by multiplying the original coefficients by the SD of the corresponding feature, provides a scale-free measure of influence, allowing the comparison of the relative importance of different features [51].

At the prediction level, for a specific patient record, the weights can be interpreted as the feature importance, given the normalized input range and positive weight constraint.

Results

Overview

The model was constructed using the TensorFlow library for Python (Python Software Foundation) and trained over 2000 epochs with a batch size of 32. The Adam optimizer was used at default setting, with L1 regularization of 0.001 and a dropout rate of 0.05 [52].

During development, both L1 and L2 regularization were considered, with evaluations involving 5-fold cross-validation on the training set. The optimal balanced accuracy score for both L1 and L2 corresponded to a regularization factor of 0.001 for both, with L1 and L2 achieving similar cross-validated mean balanced accuracy scores. Since L1 regularization tends to lead to a sparse solution by forcing unrequired weights to 0, it may be favored over L2 for transparent interpretability. However, when there are multiple near-equivalent predictors (eg, correlated measures), small fluctuations in initialization can lead the model to "select" a slightly different subset of features for its nonzero coefficients, eliminating one correlated feature, for example, while retaining the other. In consistency tests over 30 training runs, consistency in the top features was observed, although the order of importance may switch the top positive weight. In the depression class, for example, the top positive feature was PHQ-9 in 70% (21/30) of the runs and DAD_1.0 (previously diagnosed with depression) in 30% (9/30) of the runs. In the panic class, PDSS was always the top positive feature, with GAD-7 taking second place in 40% (12/30) of the runs and fq_total in 30% (9/30) of the runs. Examining the softmax weights, 80% (24/30) of the cumulative sum of the weights for each class were represented in the top 6 factors for L1 regularization, whereas for L2, up to 11 factors were required to represent the 80% (24/30). Therefore, L1 regularization was adopted for interpretability since: (1) both L1 and L2 regularization demonstrated similar accuracy; (2) L1 regularization enforces sparsity, requiring fewer weights to explain the top 80% (24/30); (3) the top weights are consistently in the top 3; and (4) the model transparency ensures the same weights are used in both prediction and explanation.

Following training, the model was evaluated on the held-out test set, achieving a balanced accuracy score of 0.79, indicating good generalization. The validation metrics (Table 2) indicate strong predictive performance across all 4 classes, with F_1-scores ranging from 0.71 to 0.86, which indicates a balanced trade off between precision and recall. Specific phobia achieved the highest precision (0.84) and the highest recall (0.88), suggesting that the model is highly accurate in predicting this class when it does make a prediction. However, social phobia had the lowest recall (0.70) compared to other classes, indicating some difficulty in correctly identifying all cases of this condition. The AUC values, all >0.90, suggest strong discrimination between classes. The aggregated metrics demonstrate an overall balanced accuracy score of 0.79 and a weighted F_1-score of 0.78, confirming that class imbalance did not severely impact overall model performance. The use of these weighted metrics ensures that smaller classes, such as specific phobia, contribute proportionally without distorting the results.

The confusion matrix (Table 3) details the number of treatment recommendations proposed by the model, with correct classifications appearing on the main diagonal of the table. Off-diagonal elements quantify the number of cases in which the model chose a different treatment than the clinician.

Patients assessed with social phobia were misclassified as depression in 4.9% (13/267) cases and as panic disorder in 1.9% (5/267) cases, suggesting that the model struggles to distinguish social phobia from other anxiety-related conditions. This was consistent with the lower recall observed for social phobia in Table 2, indicating that some patients with social phobia were incorrectly classified into other categories.

For specific phobia, the model correctly identified 7.9% (21/267) cases, but 1.1% (3/267) cases were misclassified as panic disorder (2/267, 0.7% cases) or social phobia (1/267, 0.4% case). Given that specific phobia was the least represented category in the dataset, the model's relatively strong performance in this class may be influenced by its high specificity (0.98, Table 2), which suggests that when the model does predict specific phobia, it does so with a high degree of accuracy. However, the smaller sample size in this class may also lead to performance variability.

The model generally performed well in classifying depression and panic disorder, with high agreement between model predictions and clinician labels (72/267, 27% and 69/267, 25.8% correct classifications, respectively). However, 3.7% (10/267) panic disorder cases were misclassified as depression, indicating some overlap in how these conditions were represented in the feature space or possible comorbidities.

Table 2. Validation metrics on the test set.

Treatment	Precision	Recall (sensitivity)	F_1-score	Specificity	Per-class balanced accuracy	AUC[a]
Depression	0.76	0.81	0.78	0.87	0.84	0.93
Panic	0.82	0.77	0.79	0.91	0.84	0.92
Social phobia	0.71	0.70	0.71	0.91	0.81	0.91
Specific phobia	0.84	0.88	0.86	0.98	0.93	0.98

Table 3. Confusion matrix on the test set.

Clinician proposed treatment (ground truth)	Model proposed treatment, n (%)			
	Depression	Panic disorder	Social phobia	Specific phobia
Depression	72 (27)	8 (3)	9 (3.4)	0 (0)
Panic	10 (3.7)	69 (25.8)	8 (3)	3 (1.1)
Social phobia	13 (4.9)	5 (1.9)	45 (16.8)	1 (0.4)
Specific phobia	0 (0)	2 (0.7)	1 (0.4)	21 (7.9)

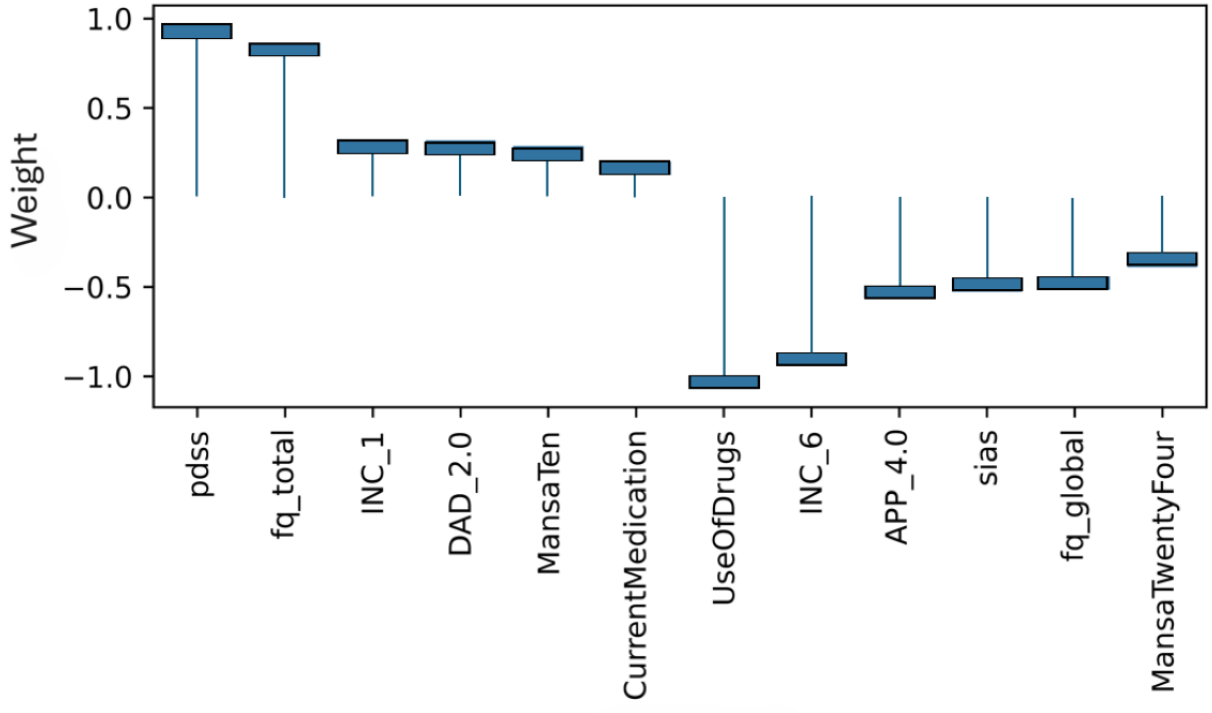
Model Level (Global) Explainability of Classes From Score Totals and Demographics

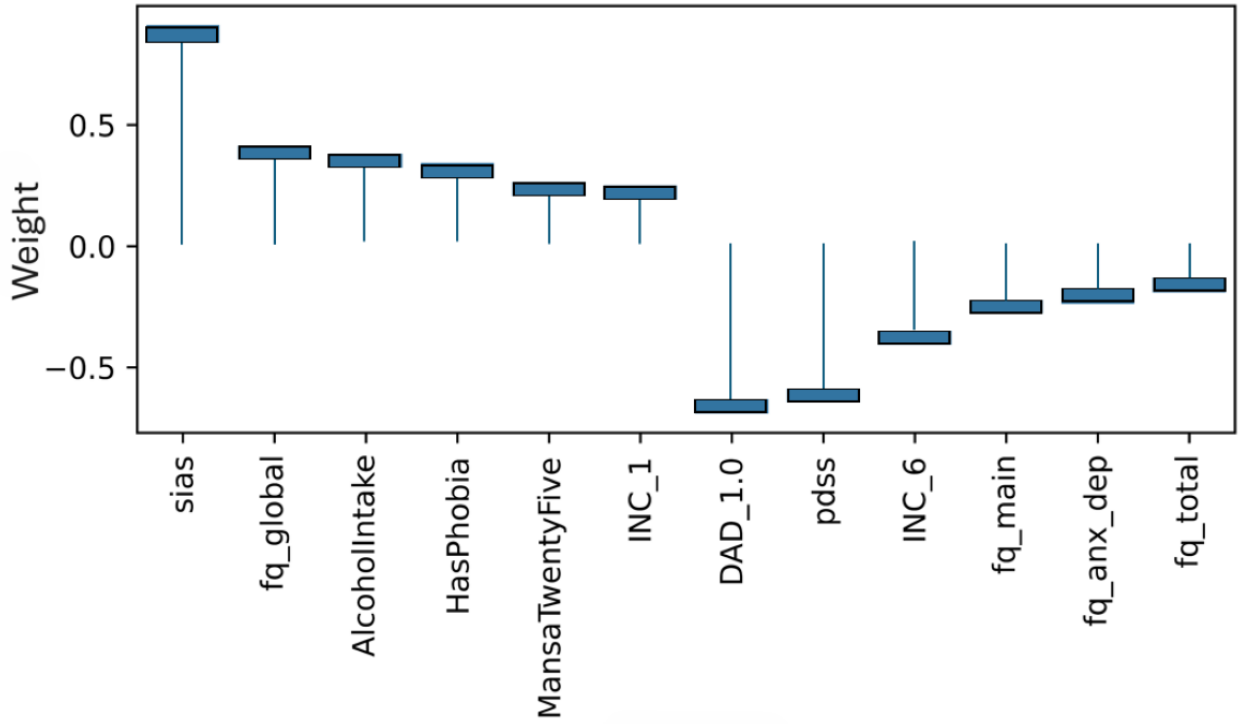
Examining the learned weights of the softmax layer that predicts the class probabilities from the score and demographic features is informative to interpret their relative importance at the model level. Positive weights contribute toward a more probable class prediction, while negative weights detract. Examining the top 6 positive and negative contributions, the depression class (Figure 4), is mostly influenced by the PHQ-9 score, application-related variables (APP_4.0, APP_3.0), and the previous diagnosis of depression (DAD_1.0). The Fear Questionnaire Global Phobia rating (question 18) detracts from this class prediction. The panic class (Figure 5) is most influenced positively by the PDSS score and the Fear Questionnaire total score (fq_total) and most negatively by the use of euphoric drugs or pills (UseOfDrugs), so drug use detracts from this class probability. The social phobia class (Figure 6) is most influenced by the SIAS score and the Fear Questionnaire Global Phobia rating (fq_global). Having been previously diagnosed with depression (DAD_1.0) works against this class. The specific phobia class (Figure 7) is most influenced by the Fear Questionnaire main level of avoidance (item 1), and the Global Phobia rating (fq_global), while having applied for both anxiety and depression treatment (APP_3.0) counts against this class.

Figure 4. Weights of the softmax depression class node (top 6 positive and negative). The chart shows the top 6 positive and negative weights of the softmax output layer with respect to the depression class. The relative magnitude and sign indicate the importance of the feature for the prediction. Positive weights contribute to the class prediction probability. Negative weights detract from it. The chart indicates that the Patient Health Questionnaire (PHQ-9) score (phq), and application-related variables (APP_4.0, APP_3.0) have the most influence on the prediction of the depression class, while the Fear Questionnaire Global Phobia rating (fq_global) has the strongest negative influence.

XSL•FO
RenderX

Figure 5. Weights of the softmax panic class node (top 6 positive and negative). The chart shows the top 6 positive and negative weights of the softmax output layer with respect to the panic class. The relative magnitude and sign indicate the importance of the feature for the prediction. Positive weights contribute to the class prediction probability. Negative weights detract from it. The chart indicates that the Panic Disorder Severity Scale (PDSS) score (pdss), and the fear questionnaire total score (fq_total) have the most influence on the prediction of the panic class, while the use of euphoric drugs or pills (UseOfDrugs) has the strongest negative influence.





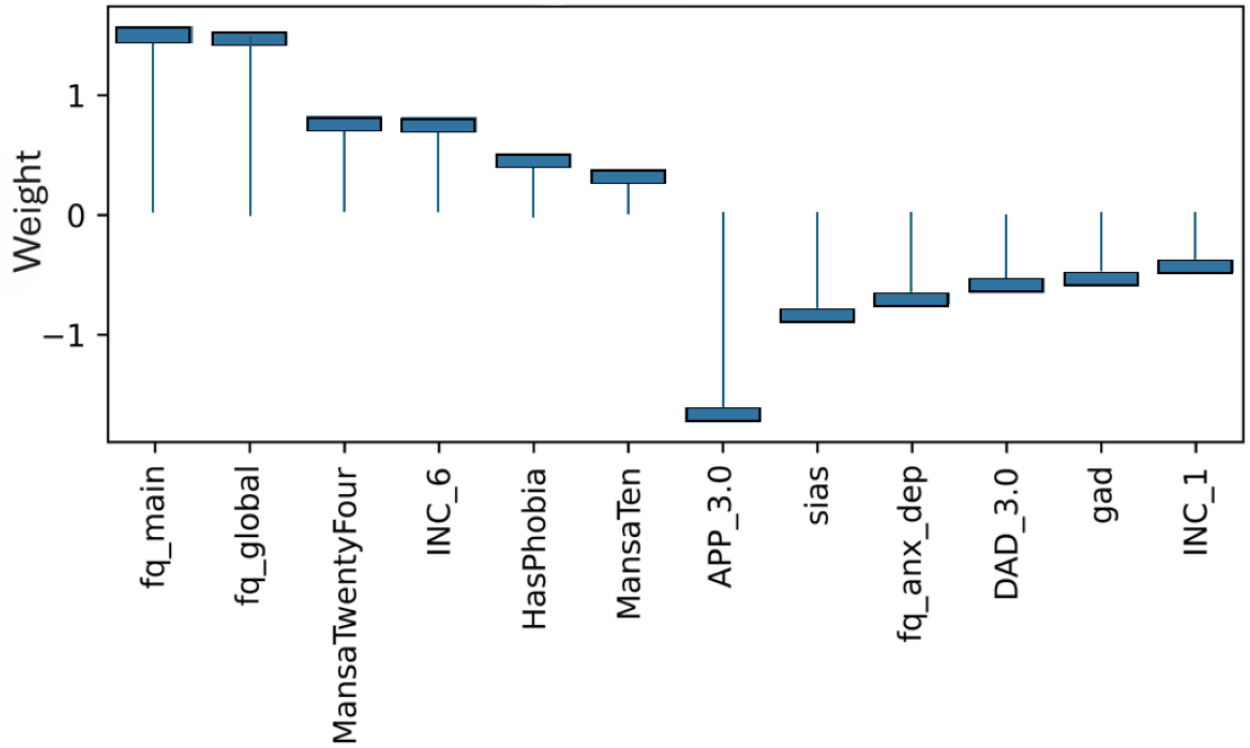


Figure 6. Weights of the softmax social phobia class node (top 6 positive and negative). The chart shows the top 6 positive and negative weights of the softmax output layer with respect to the social phobia class. The relative magnitude and sign indicate the importance of the feature for the prediction. Positive weights contribute to the class prediction probability. Negative weights detract from it. The chart indicates that the SIAS score (sias) and the Fear Questionnaire Global Phobia rating (fq_global) have the most influence on the prediction of the social phobia class. Having been previously diagnosed with depression (DAD_1.0) has the strongest negative influence.

XSL•FO
RenderX

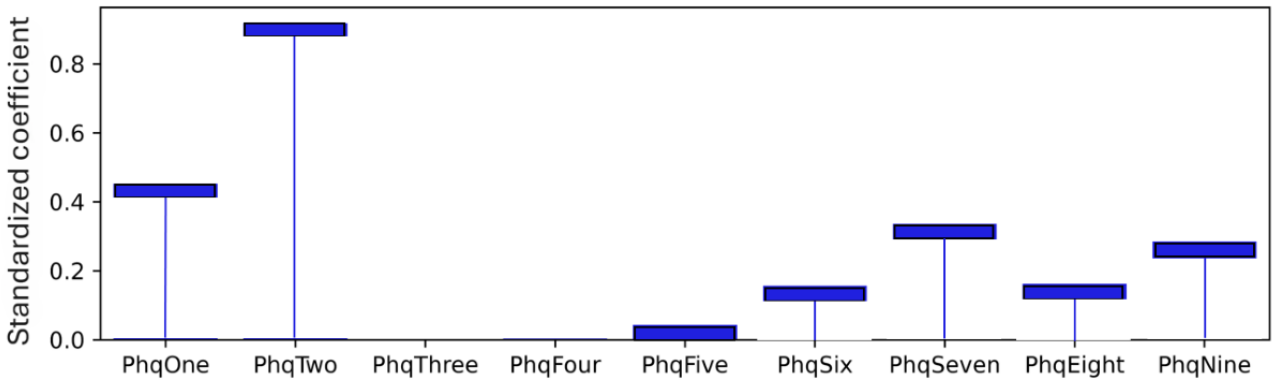

Figure 7. Weights of the softmax specific phobia class node (top 6 positive and negative). The chart shows the top 6 positive and negative weights of the softmax output layer with respect to the specific phobia class. The relative magnitude and sign indicate the importance of the feature for the prediction. Positive weights contribute to the class prediction probability. Negative weights detract from it. The chart indicates that the Fear Questionnaire has the most influence on the prediction of the panic class. The main Phobia Level of Avoidance score (fq_main), and Global Phobia rating (fq_global) are the top 2 positive weights. Having applied for both anxiety and depression treatment, (APP_3.0) has the strongest negative influence.

Model Level (Global) Explainability of Score Totals

As explained, standardized coefficients obtained by multiplying the original coefficients by the SD of the corresponding feature in the dataset provide a scale-free measure of influence, allowing the comparison of the relative importance of different features. The standardized coefficients are shown in Figures 8-12. Examining the PHQ-9 standardized coefficients (Figure 8), questions 1 and 2, the main cognitive factors of the questionnaire [53] are the most important, with all the 5 cognitive factors being represented. The importance of the GAD-7 (Figure 9) is almost exclusively represented by questions 4 (“Trouble relaxing”) and 2 (“Not being able to stop or control worrying”). The most important SIAS questions (Figure 10) were 6 and 1. Question 3, (“How often do you feel anxious about the possibility of having a panic attack?”) was the most important in the PDSS (Figure 11). In the Fear Questionnaire anxiety or depression subscale (Figure 12), question 23, “Feeling you or your surroundings are strange or unreal,” was the most important. The Total Phobia Score from the Fear Questionnaire was defined as the sum of the subscale scores for agoraphobias, blood injury phobia, and social phobia. In this case, only the learned agoraphobia subscore was weighted at nonzero (Figure 13). Question 5 was the most relevant question in the Fear Questionnaire agoraphobia subscale (Figure 14).

Figure 8. Patient Health Questionnaire-9 (PHQ-9) question standardized coefficients. This chart illustrates the relative importance of the PHQ-9 questions with respect to the pseudosum score for the PHQ-9 (phq) after model training.

XSL•FO
RenderX

Figure 9. Generalized Anxiety Disorder Questionnaire-7 (GAD-7) question standardized coefficients. This chart illustrates the relative importance of the GAD-7 questions with respect to the pseudosum score for the GAD-7 (gad) after model training. GAD question 4 “Trouble relaxing” and GAD question 2 “Not being able to stop or control worrying,” are the main nonzero standardized coefficient after L1 regularization pushes unimportant weights to zero.

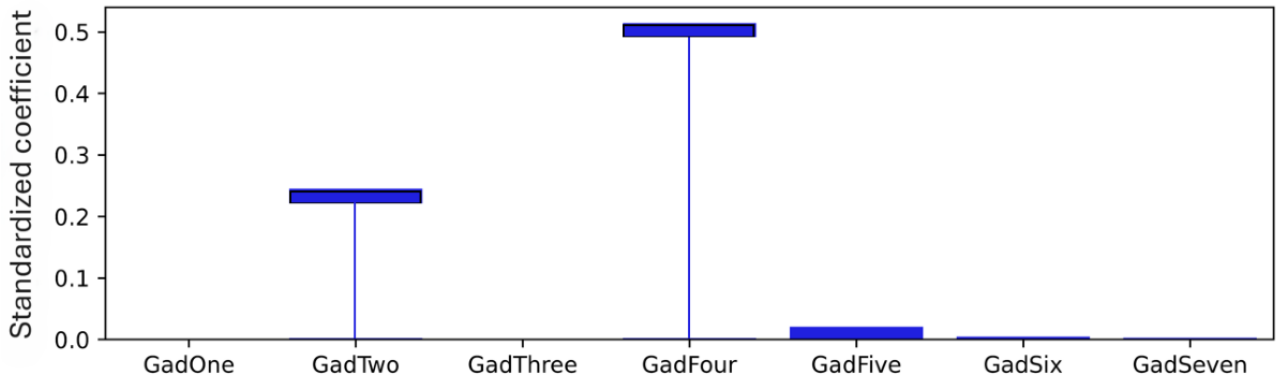

Figure 10. Social Interaction Anxiety Scale (SIAS) question standardized coefficients. This chart illustrates the relative importance of the SIAS questions with respect to the pseudosum score for the SIAS (sias) after model training. Reverse scored features have an R suffix, for example, Sias5R.

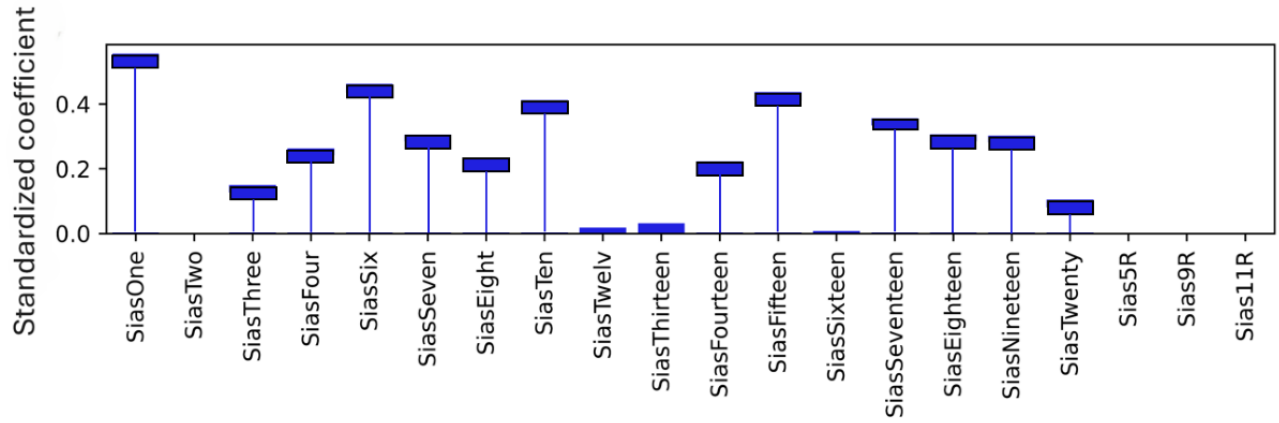

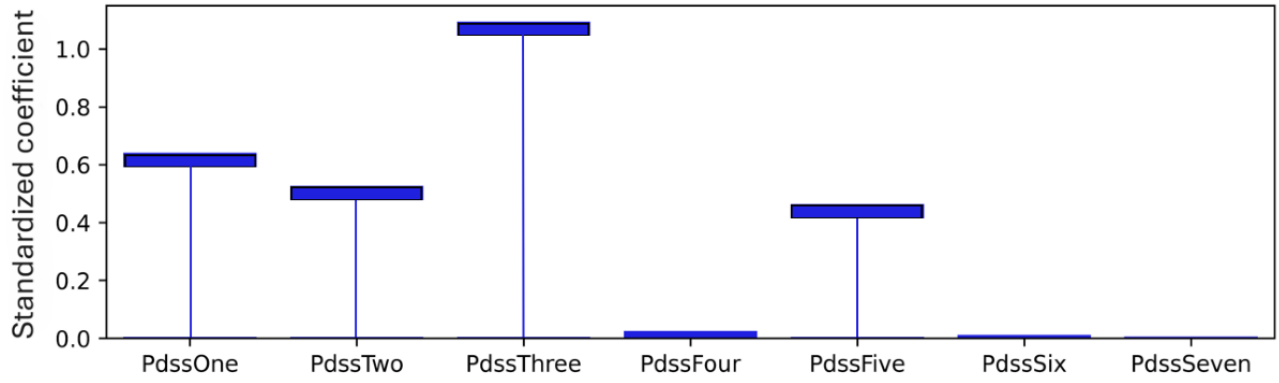

Figure 11. PDSS question standardised coefficients. This chart illustrates the relative importance of the PDSS questions with respect to the pseudo-sum score for the PDSS (pdss) after model training.

XSL•FO
RenderX

Figure 12. Fear Questionnaire (FQ) anxiety depression subscale question standardized coefficients. This chart illustrates the relative importance of the Fear Questionnaire Total Phobia Score questions with respect to the pseudosum score (fq) after model training. Question 23, "Feeling you or your surroundings are strange or unreal." is the largest standardized coefficient after L1 regularization pushes unimportant weights to 0.

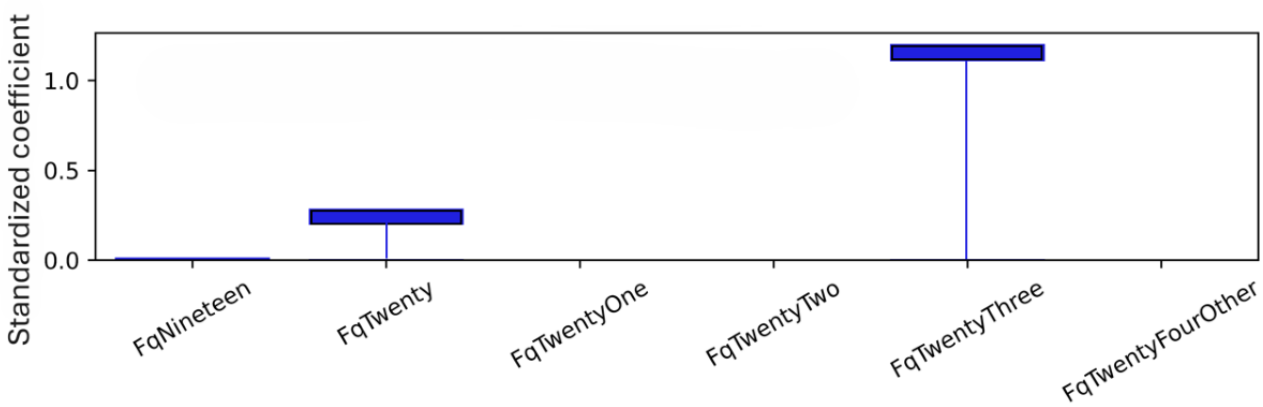

Figure 13. Fear Questionnaire (FQ) total score weighting of the FQ subscales. This chart illustrates how the Fear Questionnaire subscales are weighted in relation to the fear questionnaire total score fq_total. Only the agoraphobia subscale (fq_ago) was learned as being relevant. This is likely to be due to L1 regularization of correlated factors.

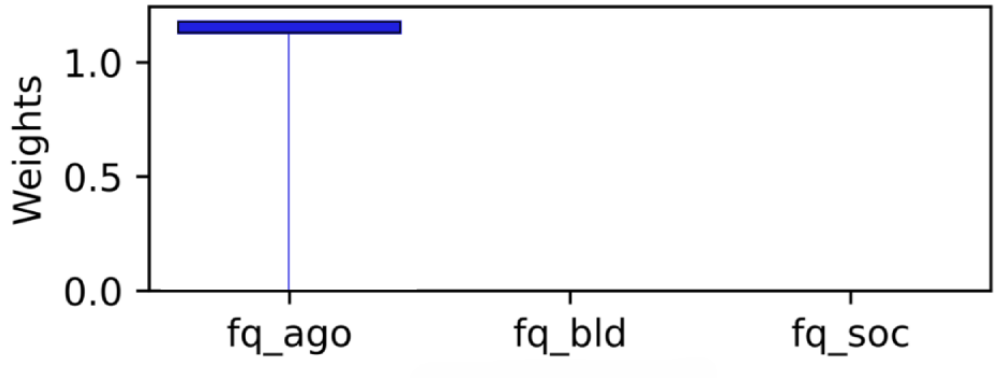

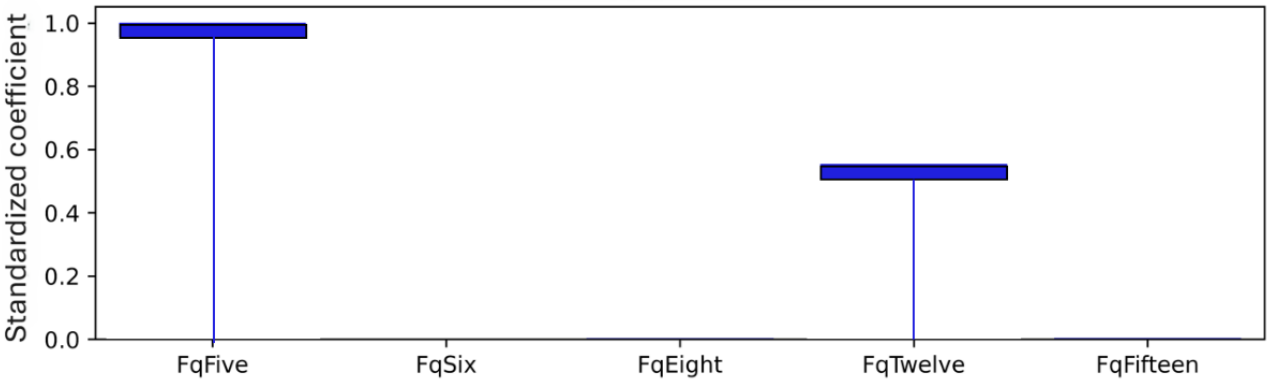

Figure 14. Fear Questionnaire (FQ) agoraphobia subscale question standardized coefficients. This chart illustrates the relative importance of the FQ agoraphobia subscore questions.

Patient Level (Local) Explainability

The relevant questionnaire total score summaries of a test patient (patient 1) are provided here. The PHQ-9 (15) score indicated moderately severe depression [42]. The PDSS score (13) indicated "moderately ill" panic disorder [54]. The GAD-7 score (17) indicated severe anxiety [55]. The SIAS score (22) was lower than the threshold for an indication of social phobia [56]. The clinical assessment (ground truth) of an appropriate treatment was panic. Other scores included Fear Questionnaire total score (6), global score (0), and main score (0).

Examining a local explanation at the individual patient level for patient 1 (Figure 15), the predicted probability distribution of panic (the prescribed treatment), overlapped with depression. The importance was determined from the weighted inputs to the softmax layer, combining both the patient record and the learned weights. Examining the importance associated with the prediction in the softmax layer for the panic class shows the top 6 positive factors (Figure 16), and the top 6 negative factors (Figure 17). Positive values make the class more probable, while negative values make the class less probable. It should be noted that the positive and negative y-values for each class are derived

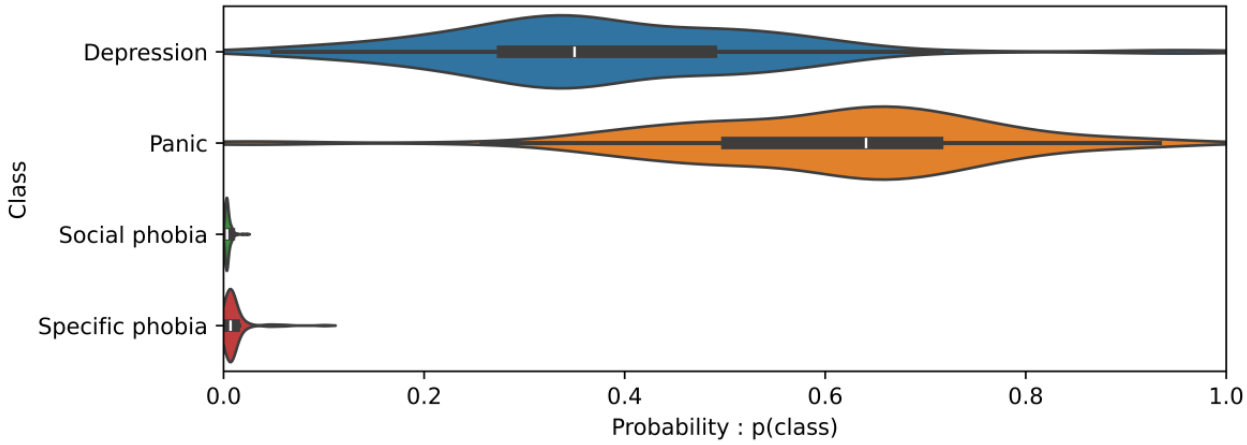
XSL•FO
RenderX

from the same weight layer and, therefore, are suitable for comparative analysis. In the patient 1 example, the PDSS questionnaire score explained most of the probability for the panic class, while the SIAS questionnaire detracted from the probability of the panic class, but to a lesser degree.

The model can also be used to explain any of the class probabilities. It is not limited to explaining the highest probability prediction. Hence, the class prediction for depression can be examined in the same way. This showed the PHQ-9 score as the most important (Figure 18), followed by APP_3 (the patient applied for both anxiety and depression treatment). The PDSS score showed a negative influence on this class (Figure 19), which was important but lower than the positive importance of PHQ-9. It is interesting to note that the negative importances for the depression class (Figure 19) were larger than the negative importances for panic, the highest probability class (Figure 17). This goes some way to explain why panic was predicted to be more probable than depression.

The hierarchical model also allowed a closer examination of the individual questions. For example, an examination of the PHQ-9 questions that contributed to the probability of the depression class (Figure 20), showed PHQ-9 questions 1 and 2 as having the most influence on the model prediction for this class, for this patient.

Figure 15. Prediction for patient 1. A violin plot showing the probability distribution of the 4 treatment classes for the data of patient 1. Although panic has the highest probability, the overlap of the probabilities (x-axis) indicates low model confidence in the prediction of panic compared to depression. The high dispersion in the predictions indicate high uncertainty. Overall, this plot indicates to a clinical user that both panic and depression are credible treatments according to the model.



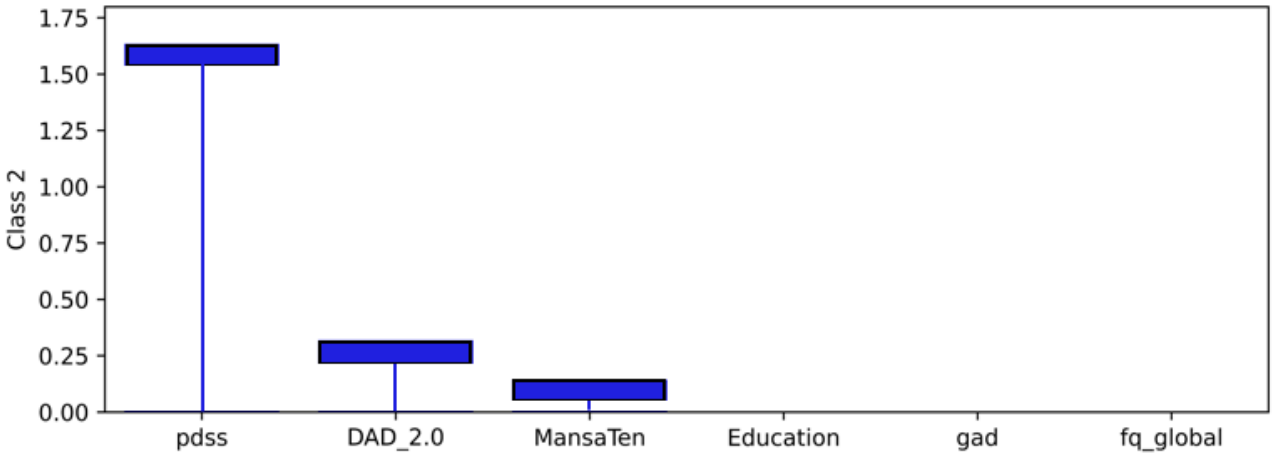


Figure 16. Patient 1 explainability for panic prediction (positive weightings). The product of the weights and the pseudosum score data or demographic data explains the importance of those features in determining the local prediction from a patient record. These positive values contribute to the class probability. The Panic Disorder Severity Scale (PDSS) score (pdss) is the most significant contributor to the probability of the panic class for patient 1.

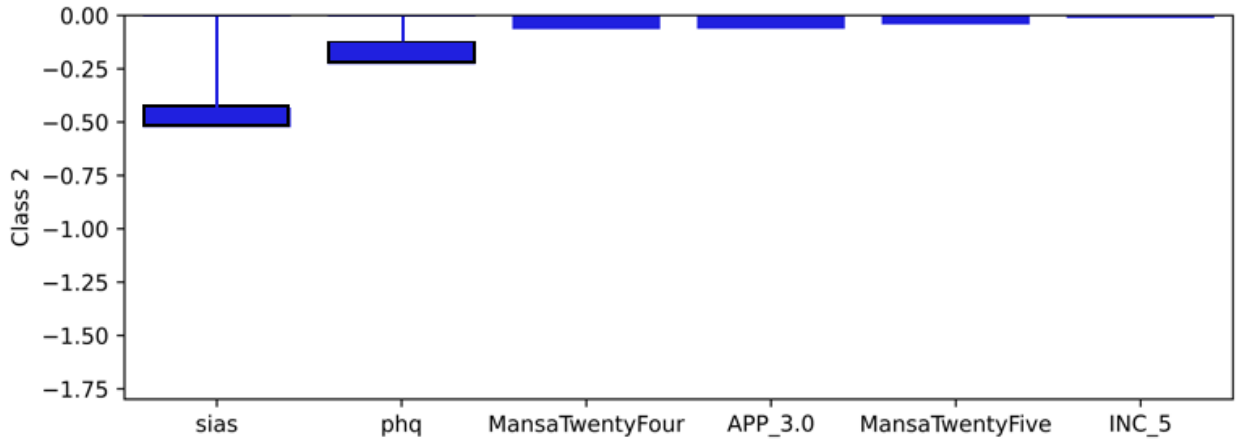
XSL•FO
RenderX

Figure 17. Patient 1 explainability for panic (class 2) prediction (negative weightings). The product of the weights and the pseudosum score data or demographic data explains the importance of those features in determining the local prediction from a patient record. These negative values detract from the class probability. The Social Interaction Anxiety Scale (SIAS) score (sias) is the most significant detractor from the probability of the panic class for patient 1, but at approximately −0.5, it has less contribution than the comparative positive scores.



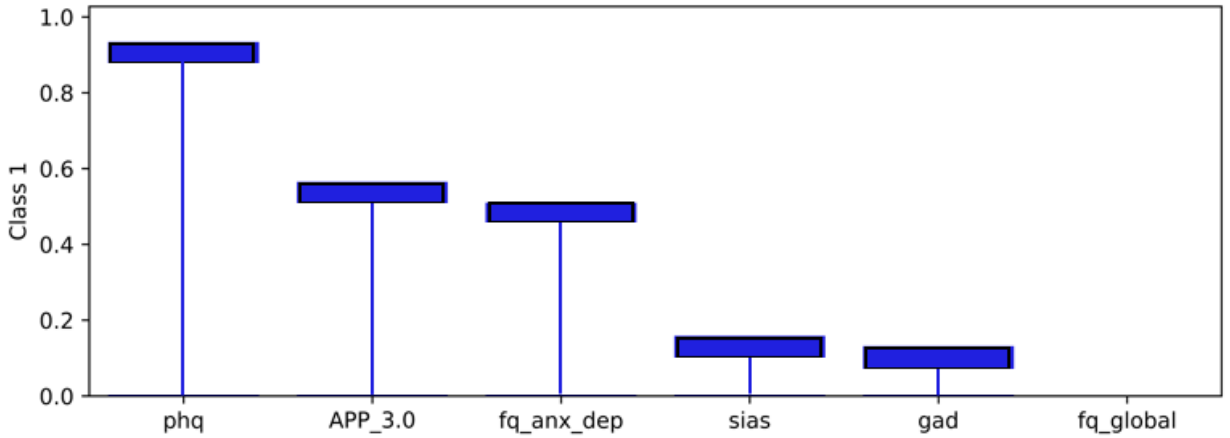


Figure 18. Patient 1 explainability for depression prediction (positive weightings). The product of the weights and the pseudosum score data or demographic data explains the importance of those features in determining the local prediction from a patient record. These positive values contribute to the class probability. The Patient Health Questionnaire-9 (PHQ-9) score (phq) is the most significant contributor to the probability of the depression class for patient 1.

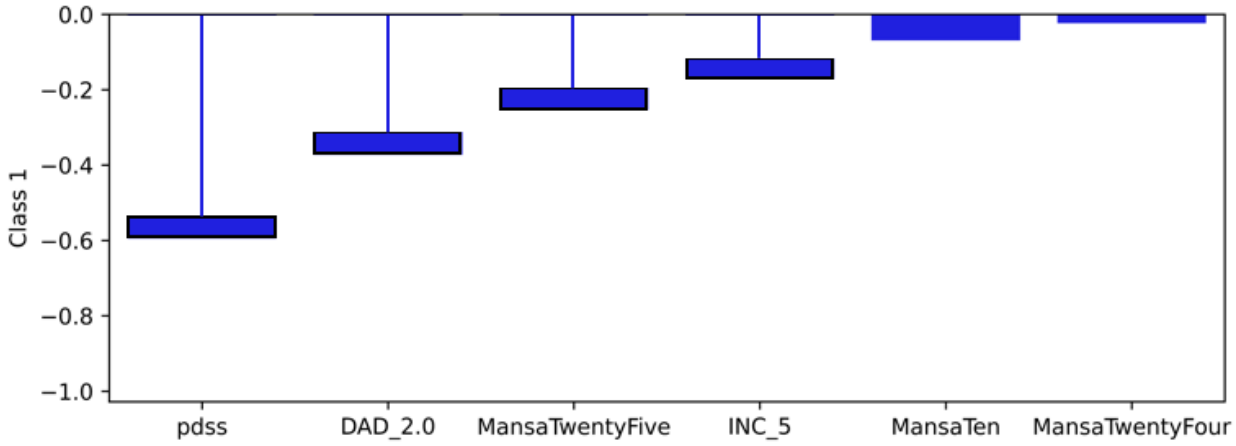
XSL•FO
RenderX

Figure 19. Patient 1 explainability for depression prediction (negative weightings). The product of the weights and the pseudosum score data or demographic data explains the importance of those features in determining the local prediction from a patient record. These negative values detract from the class probability. The Panic Disorder Severity Scale (PDSS) score (pdss) is the most significant detractor from the probability of the depression class for patient 1.



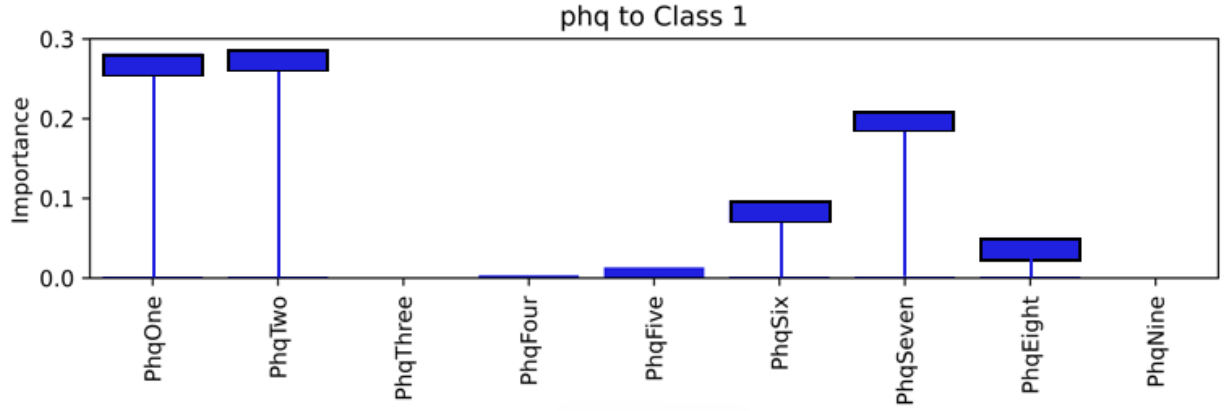


Figure 20. Patient 1 explainability for the Patient Health Questionnaire-9 (PHQ-9) questions in the depression prediction. The product of the weights and the question data explains the importance of the questions in determining the local prediction from a patient record. The PHQ-9 questions 1 and 2 score are the most significant contributors to the phq pseudosum score of depression class for patient.

Discussion

Overview

Uncertainty and lack of confidence in diagnosing psychopathological conditions can present a considerable challenge due to comorbidities and overlapping symptoms [6]. The diagnosis of social anxiety disorder, for example, must be differentiated from major depression, panic disorder, agoraphobia, and generalized anxiety disorder [7,57]. Furthermore, maintaining human involvement in patient assessments involving AI is critical [58]. Therefore, explaining predictions and enabling clinicians to explore the clinical factors associated with the predictions, has been a central aspect of this work.

Principal Findings

We have demonstrated the design and quantitative evaluation of a hierarchical model that aims to aid diagnosis and meet the requirements of providing explainable predictions that are context-based and easy for clinicians to use in questionnaire-based assessments [4]. Issues of confidence and robustness that are important for ML models aimed at medical DSSs [25] have been addressed.

As the model achieved a balanced accuracy score of 0.79 and AUC >0.90, it is expected that it will be clinically useful in both screening a new patient and informing a clinical interview. In patient screening, for example, the graphical interpretation of the class probabilities, their spread, and their overlap can inform the clinician of competing treatment possibilities for the patient. Even in the case where the treatment prediction is unambiguous and agrees with the clinician's assessment, the model may serve as a confirmatory second opinion. At the clinical interview stage, the specific questions that are deemed important for the class prediction may inform the clinician of which areas to probe further in the clinical interview.

Limitations

ML models extract knowledge from data, limiting their applicability to use in scenarios that are statistically similar to the training scenario. The models reported in this study were trained on data obtained from the Internetpsykiatrien web-based treatment with nationwide coverage in Denmark [41]. Hence,

XSL•FO
RenderX

while similar performance for individuals presenting to this service in Denmark can be expected, performance in a different country or otherwise different setting cannot be guaranteed. This can be seen as a limitation of ML models, but also as a strength; retraining the model described in this study is cheap. Hence, it is relatively straightforward for any regional mental health service to train this model on local data and obtain predictions that are sensitive to regional sociodemographics and patient characteristics. Moreover, patient characteristics may well change over time, and such temporal changes can be addressed by retraining the model periodically.

The ground truth is based on clinical judgment and is, therefore, influenced by the subjectivity of the clinicians, interrater variability, and possibly by group dynamics in decision-making clinical conferences. Clinicians have access to free-text provided by the patient, which the model does not have. A future direction may involve the development of a hybrid model that makes use of all the relevant questionnaire and demographic and free-text data for each patient. An additional limitation of the ground truth is that the assessment relies on structured questionnaires and the Mini Neuropsychiatric Interview, which may not capture all relevant patient characteristics, leading to potential gaps in the ground truth.

During training, L1 regularization adjusts the standardized coefficients and model weights toward 0 for features deemed unimportant or redundant, for example, due to having a high correlation with another feature. Consequently, features that clinicians consider relevant may be excluded by the model and thus do not appear in the explanations of predictions. However, it is common for clinicians to prioritize the importance of certain features over others in a diagnostic context [59]. It is anticipated that clinicians will find the specificity of the explanations at the question level to be clarifying and informative, complementing their own clinical judgment. Moreover, L1 regularization may result in model instability in the sense that small changes in the training set may result in a different selection of nonzero coefficients (and thus important features). Hence, a retrained model may yield different explanations to the original model for similar individuals, and this could be confusing to clinicians. However, it should be emphasized that the feature weights that explain the predictions are the same feature weights that the model uses to make the predictions, due to the model's transparency. However, using L1 regularization is not a prerequisite for the use of the proposed approach. L2 regularization, which attempts to achieve good generalization by keeping model weights small (rather than forcing a subset to 0 such as in L1 regularization) can also be used. The result would be that the model contains mostly nonzero weights, and thus, the explainability of model decisions becomes more complex. However, clinicians could choose to focus on the most important features (ie, those with the highest influence on the model). Visualizations, such as those in Figures 16-19, could be constrained to the N most important features with N chosen by the clinician.

The clinical use of the ML model would require the development of a DSS so that clinicians can view and explore the model predictions and explanations when provided with patient records. The lack of such a DSS may be seen as a limitation in demonstrating the clinical effectiveness of the model. While this study does not empirically demonstrate that the aims of clinical interpretability have been met, further work is planned to develop the DSS and study the clinical usefulness of the system incorporating the model.

Overall, the results highlight the key challenges in differentiating social phobia from other anxiety disorders and suggests that future improvements could focus on enhancing feature differentiation for overlapping categories, particularly social phobia and panic disorder.

Future Work

The incorporation of this model into a DSS for mental health treatment prediction will be an important future step for this work. Once developed, assessing its use in a clinical setting will help to validate it for future clinical use. The model itself could be extended to use more input features, especially those that have a potential to enhance feature differentiation for overlapping categories (particularly social phobia and panic disorder). Additional hybrid features may include free-text data input for each patient. Output enhancements can also be foreseen to further build on the model's explainability. For example, a text output of the model's prediction, competing predictions, and explanations in written form could form an important input to clinical notes and provide material for clinical conferences.

Conclusions

This paper presents the design of a model aimed at a DSS for psychopathological mental health treatment. Its basis in standard screening questionnaires will allow seamless adoption in a clinical setting in the future. The AI model incorporated in the system is based on a novel hierarchical structure that aims to meet the needs of clinical interpretability while accounting for decision confidence and uncertainty that are lacking in previous work.

Acknowledgments

This work has been supported by the Innovation Fund, Denmark. The authors wish to thank the clinical staff, administrative staff, and patients at the Centre for Digital Psychiatry, Denmark.

Authors' Contributions

AK conceived the probabilistic model; designed, trained, and verified the models; and drafted the paper. PVdV conceived the hierarchical score model, made significant contributions to the paper's Introduction and Methods sections, and improved all sections of the paper. EMG made contributions to the explainable artificial intelligence literature description. EKJ and KM made

Abstract

Background: Congestive heart failure (CHF) is a common cause of hospital admissions. Medical records contain valuable information about CHF, but manual chart review is time-consuming. Claims databases (using *International Classification of Diseases* [*ICD*] codes) provide a scalable alternative but are less accurate. Automated analysis of medical records through natural language processing (NLP) enables more efficient adjudication but has not yet been validated across multiple sites.

Objective: We seek to accurately classify the diagnosis of CHF based on structured and unstructured data from each patient, including medications, *ICD* codes, and information extracted through NLP of notes left by providers, by comparing the effectiveness of several machine learning models.

Methods: We developed an NLP model to identify CHF from medical records using electronic health records (EHRs) from two hospitals (Mass General Hospital and Beth Israel Deaconess Medical Center; from 2010 to 2023), with 2800 clinical visit

XSL•FO
RenderX

notes from 1821 patients. We trained and compared the performance of logistic regression, random forests, and RoBERTa models. We measured model performance using area under the receiver operating characteristic curve (AUROC) and area under the precision-recall curve (AUPRC). These models were also externally validated by training the data on one hospital sample and testing on the other, and an overall estimated error was calculated using a completely random sample from both hospitals.

Results: The average age of the patients was 66.7 (SD 17.2) years; 978 (54.3%) out of 1821 patients were female. The logistic regression model achieved the best performance using a combination of *ICD* codes, medications, and notes, with an AUROC of 0.968 (95% CI 0.940-0.982) and an AUPRC of 0.921 (95% CI 0.835-0.969). The models that only used *ICD* codes or medications had lower performance. The estimated overall error rate in a random EHR sample was 1.6%. The model also showed high external validity from training on Mass General Hospital data and testing on Beth Israel Deaconess Medical Center data (AUROC 0.927, 95% CI 0.908-0.944) and vice versa (AUROC 0.968, 95% CI 0.957-0.976).

Conclusions: The proposed EHR-based phenotyping model for CHF achieved excellent performance, external validity, and generalization across two institutions. The model enables multiple downstream uses, paving the way for large-scale studies of CHF treatment effectiveness, comorbidities, outcomes, and mechanisms.

Introduction

Congestive heart failure (CHF) and all types of heart disease are the primary causes of hospital admissions and the leading cause of death in the United States [1-3]. The prevalence of CHF in the United States is estimated to be 7% for men and 4.2% for women [4]. As a result, it is important to diagnose CHF early and accurately, which is difficult given the diversity of CHF and the lack of definitive, universally applicable diagnostic tests [5]. This underscores the need for research on improving diagnosis and predicting patient outcomes. The heterogeneity of CHF makes it hard to design clinical trials that can accurately and uniformly diagnose CHF [6]. In this context, accurate classification is crucial for the reliability of epidemiological and outcomes research. Traditionally, the identification of CHF is a labor-intensive process. Local sites identify potential cases and forward medical records to a Central Clinical Events Committee, comprised of physician experts, who manually review each case against established standards [7-9]. While this method is considered the gold standard, it is impractical for large observational studies, where *International Classification of Diseases* (*ICD*) codes are typically used. However, sole reliance on *ICD* codes is problematic due to their imprecision; it is estimated that approximately 40% of hospitalizations labeled with primary *ICD* codes for CHF do not hold up upon detailed medical record review [9]. Consequently, there is a growing interest in automated methods for adjudicating CHF hospitalizations from medical records that could streamline the process; reduce reliance on physician-based Central Clinical Events Committee reviews; foster the development of large, cost-effective clinical trials; and help gather more accurate data for research [9].

In this context, electronic health records (EHRs) have become invaluable. Encompassing millions of patient profiles, these records are stored across various hospitals and institutions as structured and unstructured data. Much of the data exists as unstructured natural language in physicians' notes, documenting symptoms, conditions, and diagnoses. Natural language processing (NLP) approaches present an opportunity to harness this rich source of data, enabling high-throughput identification and phenotyping of patients directly from hospital databases [10-13]. Some applications of these models in inpatient fall detection [14], emergency triage notes [15], and inpatient fall risk assessment [16] have already achieved a high level of effectiveness using a variety of modeling methods, including large language models such as Bidirectional Encoder Representations from Transformers, showing the need for further development in other medical applications.

Here, we address these gaps by introducing a comprehensive approach to EHR-based phenotyping of CHF within a large multihospital cohort, based on clinical notes, *ICD* codes, and medications, contributing to the growing body of knowledge in automated medical record review and phenotyping of patients with CHF, as well as ensuring reproducible and reliable clinical use [17,18].

Methods

Cohort

We retrospectively obtained EHR data from two sites: Beth Israel Deaconess Medical Center (BIDMC) and Massachusetts General Hospital (MGH), from 2010 to 2023. The EHR data contain clinical notes written by the clinician, *ICD* diagnosis codes (*ICD-9* and *ICD-10*) assigned during encounters, and prescribed medications. To enable initial cohort selection and maximize the chance of including patients with CHF from this large pool of inpatient and outpatient encounters, we divided patients into groups based on the presence of prespecified *ICD* codes ("*ICD*+" or "*ICD*–") related to CHF and prespecified medications ("MED+" or "MED–"), creating four groups: "*ICD*+/MED+," "*ICD*–/MED+," "*ICD*+/MED–," and "*ICD*–/MED–." We then randomly sampled a total of 1400 notes with keywords (such as heart, CHF, etc) from the four groups at each site to undergo manual annotation (described

XSL•FO
RenderX

below) to provide labels for model training. This sample size was selected to enable appropriate training and to not overwhelm the available computing power.

Ethical Considerations

The retrospective data were obtained under Beth Israel Deaconess Medical Center's institutional review board that waived the need for informed consent (BIDMC IRB# 2022P000481).

CHF-Related Keywords, ICD Codes, and Medications for Initial Cohort Selection

ICD codes and medications related to CHF were specified as a part of the model input. *ICD* codes included 428 (*ICD-9*) for "Congestive Heart Failure, unspecified" and I50 (*ICD-10*) for "Heart Failure." The medications are shown in Table 1. We also specified CHF-related keywords to be highlighted during manual note review, to facilitate the annotation of ground-truth CHF status and to include them as classifying features (see below). The keywords were determined using two approaches. The first was the knowledge-driven approach: we obtained as many keywords as possible from medical doctors and by manually reviewing published papers. This was done by simply reading papers and selecting words that appeared frequently and were related to CHF and then presenting them to physicians to check for accuracy (see references for links to papers). The second was the data-driven approach: we listed all unique words (1-gram), consecutive two-word sequences (2-gram), and consecutive three-word sequences (3-gram) in all notes. Then, using the associated, CHF-related *ICD* codes as a rough approximation of ground-truth CHF status, for each n-gram, we conducted a Mann-Whitney *U* test to compare the median number of occurrences in the groups with and without CHF. Words that occurred with significantly different frequencies between groups were included in the keyword list. We further expanded the set of potentially classifying features by augmenting keywords and phrases with their negations.

Table 1. Medications related to congestive heart failure.

Medication generic name	Medication description
Lisinopril	Angiotensin-converting enzyme inhibitor
Furosemide	Diuretic
Bumetanide	Diuretic
Propranolol	Beta-blocker
Amlodipine	Calcium channel blocker
Hydrochlorothiazide	Diuretic
Omeprazole	Proton pump inhibitor
Isosorbide mononitrate	Vasodilator
Enalapril	Angiotensin-converting enzyme inhibitor

Annotation of the Ground-Truth CHF Status

Ground-truth CHF status was based on having human annotators read through clinical notes and make a yes-or-no decision for each note as to whether the note author affirmed a diagnosis of CHF in the note. To ease annotation, we displayed each clinical note with keywords highlighted so that the annotator could more quickly determine CHF status by reading the note. Notes were randomly assigned to 5 independent annotators. We followed a standard operating procedure to ensure consistency between raters. Notes were randomly split between 5 annotators without overlap. Patients who were said to have CHF or a "history of CHF" were labeled as "positive" cases. All others were labeled as "negative" cases. This included patients noted as being "unlikely [to have] CHF," patients with a family history but no personal diagnosis of CHF, and patients with no indication of CHF given in the note.

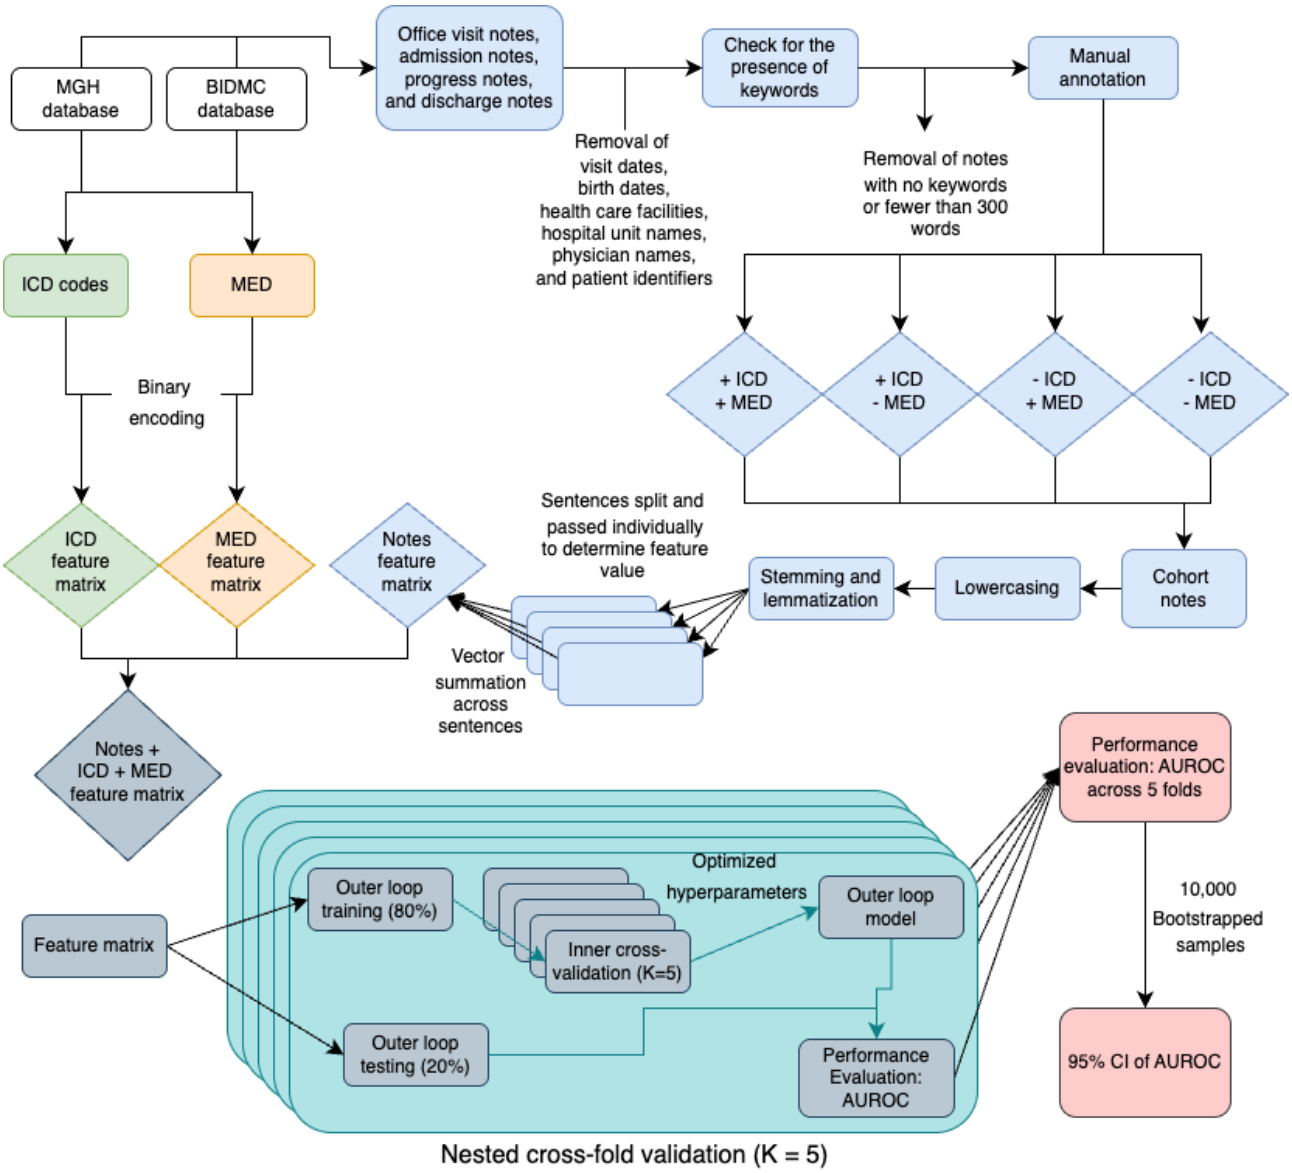
Feature Matrix Construction

Features constructed to train the NLP model included three subsets: features based on keywords and/or phrases in the notes; features based on *ICD* codes; and features based on medications. To construct features based on notes, we applied stemming and lemmatization. The number of occurrences for each keyword or phrase in the note was then defined as the feature value. Features based on *ICD* codes and medications were identified as the number of occurrences in the medical record dated within 18 months before or after the note's date.

Model Development: Logistic Regression, Random Forests, and RoBERTa

We developed models based on different subsets of information and with different model architectures. The first model was a logistic regression model. The training was done using nested, 5-fold cross-validation with an elastic-net penalty, using Bayesian optimization to fine-tune the hyperparameters (penalty strength and L1 ratio) to achieve the maximum average area under the receiver operating characteristic curve (AUROC) across all inner validation sets. For each outer fold, a model was fitted with the best hyperparameters, and a receiver operating characteristic curve was obtained using the outer testing set. Using the Youden index, we determined a probability cutoff value for binary classification in each outer fold. The final performance metric was calculated as the average of the 5 AUROCs from the outer folds. We also trained a random forests classifier using the same approach with nested, 5-fold cross-validation, using Bayesian optimization to fine-tune the hyperparameters (minimum leaves per sample, number of

XSL•FO
RenderX



estimators, maximum depth, and cost-complexity pruning coefficient) to incorporate ensemble methods because of their robustness to reduce bias [19]. We finally trained a deep learning model based on RoBERTa followed by logistic regression. We used the embeddings from RoBERTa as our feature matrix with no additional pretraining, as previous studies have shown that RoBERTa has already been optimized [20]. We did this in three different ways. First, we split the note into sections of up to 512 tokens with each section having a one-sentence overlap. We then took the vector representations of these segments and took the elementwise average to get a feature matrix. Second, we took 250 tokens forward and backward from the keywords "CHF" or "congestive heart failure" and found the embeddings from these sections. Third, if multiple keywords were found, then the elementwise average was taken. If no keywords were found, then all columns were set to zero.

For model type, we tested logistic regression, random forests, and RoBERTa, spanning linear and nonlinear models, as well as simple statistical and deep learning models. While large language models are powerful tools, they are not always necessary, nor are they always the best approach. Simpler approaches often demonstrate that excellent results can be achieved without the additional complexity.

Feature Importance

All models used to derive feature importance were trained using median hyperparameters across the 5 outer cross-validation folds and trained on the entire dataset. For logistic regression, feature importance was given by model coefficients. For random forests, feature importance was measured by the total reduction of the Gini impurity associated with that feature, normalized to sum up to 1 across all features. We did not investigate feature importance from RoBERTa since it did not achieve better performance than logistic regression or random forests (see the *Results* section). Figure 1 summaries the methods into a visual aid.

Figure 1. Flowchart demonstrating the data collection, methods of feature matrix construction, and model usage. Statistical Analysis

Statistical significance was set at $P<.05$. Further, 95% CIs were determined using 10,000 rounds of bootstrapping. All analyses were performed using Python (version 3.10.13; Python Software Foundation).

Results

Cohort Characteristics

The final cohort included 1821 patients with 2800 notes (Table 2). The average age was 66.7 (SD 17.2) years; 978 (54.3%) out of 1821 patients were female. The racial and ethnic composition of the sample was 3.8% (69/1821) Black or African American, 6.3% (115/1821) Hispanic, 1.9% (35/1821) Asian, and 80.7% (1471/1821) White. The three most common medications used were omeprazole, furosemide, and lisinopril. The most common *ICD* code stem was I50. In terms of institutions, of the 2800 notes, 1440 (50%) came from BIDMC and 1400 (50%) came from MGH. CHF prevalence in our cohort was 425 (15.9%) out of 1400 notes in the BIDMC dataset and 445 (15.2%) out of 1400 notes in the MGH dataset. Note length varied from 1907 to 60,870 characters.

Model Performance

Table 3 shows performances from all three models and four input modalities (9 models in total). Models that used *ICD* codes, medications, and notes from both hospitals combined performed the best, followed by models that used notes only. Models that used *ICD* codes or medications only performed substantially worse. Meanwhile, logistic regression models performed the best, followed by random forests models, and then RoBERTa models. The receiver operating characteristic and precision-recall curves for the best-performing model and input modalities are shown in Figure 2.

XSL•FO

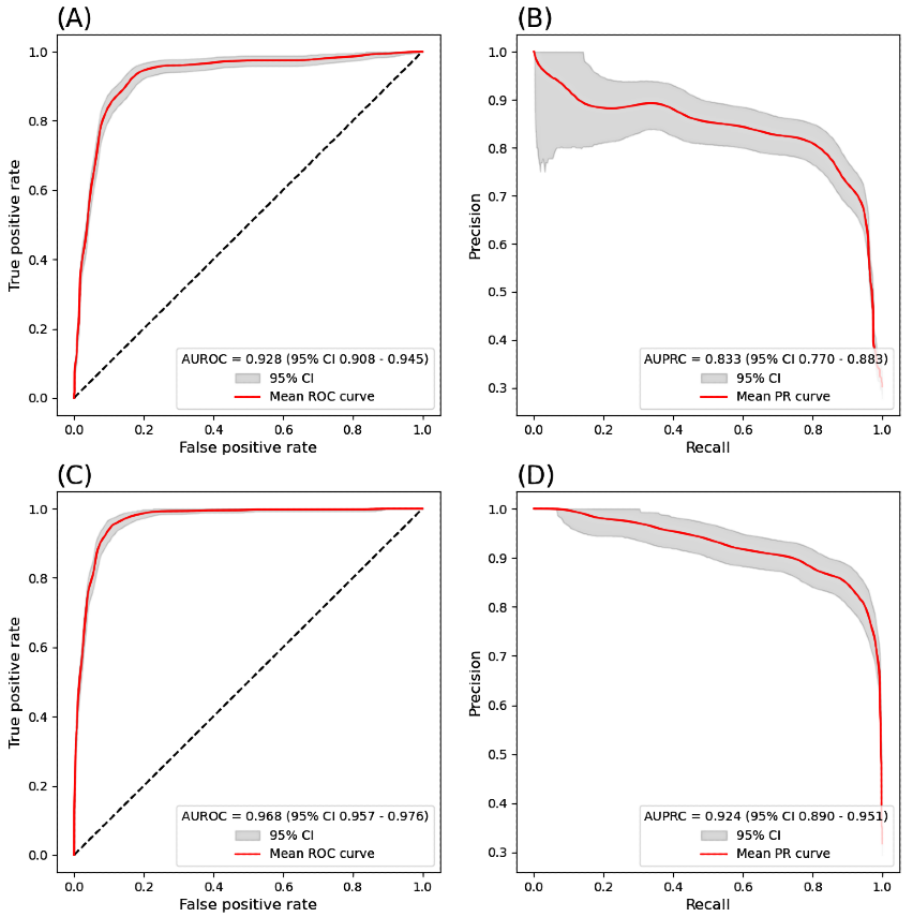
Figure 2. Model performance using the combined MGH and BIDMC test data. (A) Receiver operating characteristic (ROC) curve using logistic regression with notes, ICD codes, and medications as input. The area under the ROC curve (AUROC) was 0.968 (95% CI 0.940-0.982). The optimal cutoff (according to the Youden index) achieved a false positive rate of 11.9% (230/1903; ie, specificity at 88.1%) and a true positive rate of 97.7% (852/870; ie, sensitivity at 97.7%). (B) Precision-recall (PR) curve using logistic regression with notes, ICD codes, and medications as input. The area under the PR curve (AUPRC) was 0.921 (95% CI 0.835-0.969). The optimal cutoff achieved a recall of 96.78% (842/870; ie, sensitivity at 96.78%) and a precision of 80.88% (842/1081). BIDMC: Beth Israel Deaconess Medical Center; ICD: International Classification of Diseases; MGH: Mass General Hospital.



External Validity

To investigate how the model generalizes, we also obtained the performance when training on data from one site and testing on data from the other site (Figure 3 and Table 4). Training on BIDMC data and testing on MGH data showed significantly higher performance than training on MGH data and testing on BIDMC data. The performance of training on BIDMC data and testing on MGH data was similar to the cross-validated performance shown in Figure 2.

The results in Figure 3 show high external validity of the model due to its ability to perform well with training on one hospital dataset and subsequent testing on the other hospital dataset.

() Congestive heart failure	0.52
Diagnosis congestive heart failure	0.49

[a]ICD: International Classification of Diseases.

[b]CHF: congestive heart failure.

[c]Dx: diagnosis.

Feature Importance

Feature importance for the best-performing model (logistic regression) is shown in Table 4. The top-3 positive predictors were the words and phrases "CHF," "congestive heart failure," and "with CHF." The top-3 negative predictors were "CHF father," "CHF mother," and "no CHF."

In Table 4, the negative weights of "CHF father" and "CHF mother" came from clinicians' discussion of family history in the note. Brackets such as those in "[] CHF" or "() CHF" were purposely left in each note as they were often part of a medical questionnaire to obtain the medical history for new patients. Coefficients of "with CHF" and "with congestive heart failure" were given negative and positive weights, respectively, possibly due to the high collinearity between them.

Error Analysis

We investigated reasons for misclassification in cases where the model output disagreed with manual labels. For false positives, reasons included patients with symptoms typical for CHF who had not been given a formal diagnosis of CHF, patients with a family medical history of CHF, cases where negation was expressed unusually (eg, "I do not feel like this is consistent with congestive heart failure"), and notes that had templated preoperative instructions or medication descriptions (eg, "tell your doctor if you have CHF"). For false negatives, reasons included notes explaining a noncardiac medical visit but mentioning a history of CHF, and patients with a diagnosis of CHF no longer experiencing symptoms.

Performance in Unselected or Random EHR Samples

The sample used for training and testing was, by construction, enriched for "positive" cases; that is, there were more "*ICD*+/MED+," "*ICD*–/MED+," and "*ICD*+/MED–" cases and fewer "*ICD*–/MED–" cases than would be present in a random sample. To estimate the expected performance in a general hospital population, we randomly sampled an additional 500 patients from BIDMC and 500 patients from MGH. Using our final fitted model from logistic regression methods (explained in detail above), we classified these 1000 patients as per Table 5. Using the prevalence values (p+/+, p+/–, p–/+, and p–/–) along with the corresponding overall model error rate (P_e+/+, P_e+/–, P_e–/+, and P_e–/–), the estimated performance within the overall hospital population was calculated as follows:

$$P(E) = (P_e+/+ \times p+/+) + (P_e+/- \times p+/-) + (P_e-/+ \times p-/+) + (P_e-/- \times p-/-)$$

$$= (0.074 \times 0.1) + (0.074 \times 0.098) + (0.079 \times 0.0088) + (0.094 \times 0.0021)$$

$$= 0.016$$

$$= 1.6\%$$

Thus, the overall error rate in the general hospital population was estimated to be 1.6%.

XSL•FO

Discussion

Principal Findings

In this work, we present a highly accurate machine learning model that uses NLP to identify patients diagnosed with CHF in EHRs. The simple modeling technique demonstrated excellent discrimination for the presence or absence of CHF. Testing across two hospitals demonstrated the generalization of our model. This model provides a strong foundation for automated, scalable phenotyping of CHF at singular hospitals with big data and enable large-scale, EHR-based, epidemiological outcomes research. This work also provides the groundwork for future clinical applications, with the potential for improving clinical decision-making and patient outcomes by providing classification for diseases overlooked by clinicians. Such models could be incorporated into the current clinical workflow by inputting structured and unstructured data from visit notes by providers and comparing inconsistencies between providers' interpretation of patients' problems and what the model predicts could be an issue. This would ensure greater patient care and better use of technological advancements. The best-performing model was also simplistic, ensuring greater interpretability, computational efficiency, scalability, and cost-effectiveness of implementation of these methods.

In a previous study, EHR-based phenotyping of CHF was performed by comparing a deep learning model's predictions against *ICD* code–based diagnoses using a large cohort from a single hospital [10]. This work, however, did not address the common issues of *ICD* codes being an inaccurate representation of the true diagnosis and the generalizability of the model. Other studies have used inductive logic programming to create helpful rules for phenotyping patients with several diagnoses [8]. These studies, however, did not address how such approaches can be scaled to larger and noisier data as found in clinical databases.

Differences in generalizability between the two hospital cohorts need future research. When comparing training on a single hospital cohort and testing on the other, training on BIDMC data and subsequent testing on MGH data had a slight improvement compared to the reverse. This could be due to different hospitals or clinicians classifying CHF in different ways (such as heart failure with preserved ejection fraction, heart failure with reduced ejection fraction, etc), as well as inconsistencies of information provided in unstructured text (history of present illness, family history, etc) between hospitals.

The performance of the notes-only models was not significantly different from models using notes, *ICD* codes, and medications, suggesting future avenues of research comparing the necessity of obtaining such information for model improvement. Much of the information presented by medication lists and *ICD* codes is already found within clinical notes and could be redundant information.

Our work has important limitations. First, data used for training and testing were collected exclusively from two large hospitals in Boston, Massachusetts. Generalizability to other hospital and health care systems needs to be explored, understanding that these results are biased toward the Massachusetts population and use data from primarily top academic institutions. Second, echocardiography reports were not used. Future models that incorporate echocardiography records may have even better performance for CHF [17]. Third, the lack of racial and ethnic diversity in the saturated sample with CHF may inhibit generalizability.

Conclusion

We developed and validated a highly accurate NLP model for identifying patients with CHF from EHRs. This provides a foundation for large-scale, automated phenotyping of patients with CHF, enabling more efficient and scalable epidemiologic and outcomes research compared to manual chart review.

Abstract

Background: Delirium is common in hospitalized patients and is correlated with increased morbidity and mortality. Despite this, delirium is underdiagnosed, and many institutions do not have sufficient resources to consistently apply effective screening and prevention.

Objective: This study aims to develop a machine learning algorithm to identify patients at the highest risk of delirium in the hospital each day in an automated fashion based on data available in the electronic medical record, reducing the barrier to large-scale delirium screening.

Methods: We developed and compared multiple machine learning models on a retrospective dataset of all hospitalized adult patients with recorded Confusion Assessment Method (CAM) screens at a major academic medical center from April 2, 2016, to January 16, 2019, comprising 23,006 patients. The patient's age, gender, and all available laboratory values, vital signs, prior CAM screens, and medication administrations were used as potential predictors. Four machine learning approaches were investigated: logistic regression with L1-regularization, multilayer perceptrons, random forests, and boosted trees. Model development used 80% of the patients; the remaining 20% was reserved for testing the final models. Laboratory values, vital signs, medications, gender, and age were used to predict a positive CAM screen in the next 24 hours.

Results: The boosted tree model achieved the greatest predictive power, with an area under the receiver operator characteristic curve (AUROC) of 0.92 (95% CI 0.913-9.22), followed by the random forest (AUROC 0.91, 95% CI 0.909-0.918), multilayer perceptron (AUROC 0.86, 95% CI 0.850-0.861), and logistic regression (AUROC 0.85, 95% CI 0.841-0.852). These AUROCs decreased to 0.78-0.82 and 0.74-0.80 when limited to patients who currently do not or never have had delirium, respectively.

Conclusions: A boosted tree machine learning model was able to identify hospitalized patients at elevated risk for delirium in the next 24 hours. This may allow for automated delirium risk screening and more precise targeting of proven and investigational interventions to prevent delirium.

Introduction

Delirium is a common condition in hospitalized patients and has been recognized as an independent risk factor for poor clinical outcomes, including mortality, institutionalization, and cognitive impairment following hospital discharge [1-3]. The US annual national costs attributable to delirium have been estimated to be as high as US $152 billion, rivaling costs attributable to diabetes and falls [4]. As a result, a basic assessment for delirium is recommended for all hospitalized patients aged 65 years or older [5], and formal screening for delirium is recommended for critically ill patients [6].

Despite these recommendations, delirium frequently remains undiagnosed [7]. An automated delirium prediction tool could help address this, by alerting clinicians to at-risk patients so that they could be more carefully assessed for delirium. Such screening tools could also help focus interventions aimed at the prevention of delirium (eg, components of the hospital elder life program [8]) and provide an enriched patient sample for future delirium prevention studies.

In particular, we intend to use an automated tool to identify hospitalized patients at our institution who are at high risk of delirium in the next 24 hours. These patients will then be visited by a member of a delirium service for further evaluation and identification of interventions that may reduce the patient's risk of delirium. For this purpose, near-term risk (24-h risk) is more useful than the risk of delirium at some point during this hospitalization, and any history of prior or current delirium is relevant to identifying the patients at risk of ongoing delirium who should be seen (as reducing the duration of ongoing delirium is still likely to benefit the patient).

Although multiple prior delirium prediction tools have been described [9-12] (for a recent systematic review, see [13]) most have properties that have limited their use as a tool to be applied daily to every patient in the hospital. Most prediction tools are designed to allow a risk score to be easily calculated by a clinician by hand, limiting the model's performance compared to larger models with more features and favoring features that are easy for a human to produce over those easily extracted from the medical record. In addition, most prior models were developed using datasets of only a few hundred to a few thousand patients, limiting the complexity of the models that could be developed without overfitting.

To address these limitations, we have developed a model that can provide automated delirium screening based on data readily available from the electronic health record, emphasizing predictive power over ease of manual computation or ease of interpretation. Because current and prior delirium are known risk factors for future delirium, we also explore the performance of the model in patients without these risk factors. This tool achieves state-of-the-art accuracy for delirium prediction in this automated setting and maintains good performance even when restricted to patients without current or prior delirium.

Methods

Ethical Considerations

This study was reviewed and approved by the Mass General Brigham institutional review board (approval 2013P001024). The institutional review board determined that informed consent was not required for this retrospective study. This study adheres to the applicable TRIPOD (Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis) guidelines.

Study Cohort

Data were obtained for all patients who received any variation of a Confusion Assessment Method (CAM) screen [14] (eg, the CAM-ICU) [15]) in our hospital between April 2, 2016, and January 16, 2019, for a total of 23,006 patients. No specific exclusion criteria were used, as we wished the results to be applicable to the typical population of the hospital. Approximately 20% (n=4511) of patients were randomly selected and set aside for the final evaluation of the model (the "test dataset"); we remained blind to this dataset until after all model choices and parameters had been fixed in preparation for publication. The remaining 80% of patients (the "training dataset") were used for model selection, model training, and hyperparameter tuning.

Model Development Overview

We provide an overview of the model development here; additional details can be found in Multimedia Appendix 1.

For the outcome to be predicted, we used the presence of at least one positive CAM screen within a given day where CAM screens were performed. The CAM screen is a validated and widely used tool for assessing delirium where an observer assesses for a change in cognition with an acute onset and fluctuating course involving inattention and either disorganized thinking or an altered level of consciousness. [14] For each patient, we first identified all 24-hour intervals from 5 AM to 5 AM during which at least one CAM screen or CAM screen variation had been performed. For each such interval, the model was required to predict whether at least one CAM screen variant would be positive during that interval (vs all negative CAM screens).

As model inputs, we used the patient's age, gender, and all prior recorded vital signs, laboratory values, medications, and prior CAM assessments present in the medical record at 5 AM before the 24 hours in which delirium was to be predicted. Categorical values were converted to integers (eg, "1" for "Positive," "0" for "Negative"). These data were reduced to summary statistics for each measurement (eg, minimum, maximum, and mean systolic blood pressure in the past 24 h), which were used to form fixed-length feature vectors for each prediction interval. These feature vectors were then normalized by subtracting the median and dividing by the interquartile interval, with both the median and the quartiles estimated by the P2 algorithm [16]. Because the P2 algorithm provides only an approximation of the quantiles, the resulting values were generally not exact integers even for categorical values (eg, a binary measure that was mostly negative would have an estimated median that was

XSL•FO
RenderX

slightly above 0). Features that were missing in more than 95% of the patients were discarded. The remaining missing values were imputed to be the (P2-estimated) median value for the feature. To provide a consistent basis of comparison, we used these imputed values for all the models, including those (such as boosted trees) that do not strictly require imputation. Because of the sparsity of these features, this implies that most features for a patient will be at the median (imputed) value, especially for the first patient snapshot. Of note, however, because the P2-estimated median is a unique value that is otherwise infrequent in the data, nonlinear models can use this as a marker for missing data (and this missingness itself may have predictive value).

In effect, we are asking the model to produce a single prediction each morning of whether the patient will have delirium later that day using all of the information available that morning (including prior CAM screens). In this study, we do not train or test the performance of the model when used on a rolling basis throughout the day (eg, to generate a new prediction at 4 PM incorporating data from 3 PM that day).

The XGBoost library [17] was used to fit boosted tree models [18] for the cleaned and normalized training datasets. For comparison, random forest models [19] and logistic regression models using L1 regularization [20] were also fit to the data using scikit-learn [21]. In addition, a deep neural network model was developed using TensorFlow (Google) [22]. The final network had a 32-node rectified linear unit [23] input layer, 2 hidden layers of 16 and 8 rectified linear unit nodes, respectively, and an output layer with a single sigmoidal node. All layers were fully connected, and a 50% dropout [24] was used between layers. For the logistic regression and random forest models, Platt scaling was used to improve the calibration of the model. We used 10-fold cross-validation [25] for hyperparameter tuning to minimize overfitting. Hyperparameters (such as lambda for L1 regularization) were tuned using a grid search.

All development was done using the Ubuntu 18.04 distribution of Gnu-Linux. Data processing and analysis were performed using the Python [26] and Julia [27] programming languages. The code used to generate the models and figures is publicly available [28]. The datasets used to develop and test the model contain personally identifiable health information, and thus, are not publicly available; the authors can be contacted for more information.

Statistical Analysis

We provide an overview of the statistical analysis here; additional details can be found in Multimedia Appendix 2. The receiver operator characteristic curve and the area underneath the receiver operating characteristic curve (AUROC) were used to evaluate the performance of each model. To capture the effects of population prevalence on performance, we also used precision-recall curves and the area under the precision-recall curves (AUPRC). Calibration curves were used to qualitatively evaluate model calibration, and the expected calibration error (ECE) and maximum calibration error (MCE) were used to quantify the degree of calibration. CIs were calculated in Python using bootstrapping with 1000 rounds, and resampling by prediction day. To interpret the final behavior of the models, we used Shapley Additive Explanations (SHAP) value estimation methods as described by Lundberg et al [29,30].

The final models were trained on the full training dataset (80% of patients). Once the final models were trained, the test dataset was unblinded and the model performance was measured on the test dataset. The performance of the cross-validated version of the models on the training dataset was similar to the performance of the final models on the test dataset and is not reported here.

Although current and prior delirium are useful predictors for our intended use of the model, these are well-known risk factors for delirium and it is thus useful to explore how the model performs on patients without these risk factors. To test the model performance of these populations with a lower initial probability of delirium, versions of the final models were trained and tested on only snapshots of patients who did not have delirium (ie, no positive CAM screens in the past 24 h) or never had delirium (no prior positive CAM screens). Conceptually, all patients start in the "never delirious" state, and then potentially transition to a "currently delirious" state and then potentially between this state and a "previously but not currently delirious" state. For a summary of the assignment of patient snapshots to these groups, please see Multimedia Appendix 3.

Results

Of the 20,006 patients in the dataset, 4583 (19.9%) patients had at least one positive CAM screen (Table 1). The average age of the patients was 65 (SD 17) years and slightly higher in patients with a positive CAM screen (mean 70, SD 16 years). Approximately, 54% (n=12,502) of patients were male and 46% (n=10,500) of patients were female; no other genders were recorded in this dataset. The fraction of male patients was slightly higher (2614/4582, 57%) in patients with a positive CAM screen. An average of 12.6 (SD 17.9) CAM screens were recorded per patient, with more (mean 24.8, SD 29) recorded for patients with a positive CAM screen than for patients with no positive CAM screens (mean 9.5, SD 12). An average of 8.3% (SD 22%) of CAM screens per patient were positive, which rose to an average of 42% (SD 33%) of CAM screens per patient that were positive in patients who had at least one positive CAM screen. CAM screens were performed on an average of 8.1 (SD 11) days per patient, of which 8.1% (SD 21%) of days with CAM screens had at least one positive CAM screen.

All models provided significant predictive power for delirium (a positive CAM screen in the next 24 h) when applied to all hospitalized patients in the dataset (Figure 1). The boosted tree model had the highest AUROC (0.92, 95% CI 0.913-9.22). This was followed by the random forest model, the multilayer perceptron, and the logistic regression model with L1-regularization (AUROC 0.85, 95% CI 0.841-0.852).

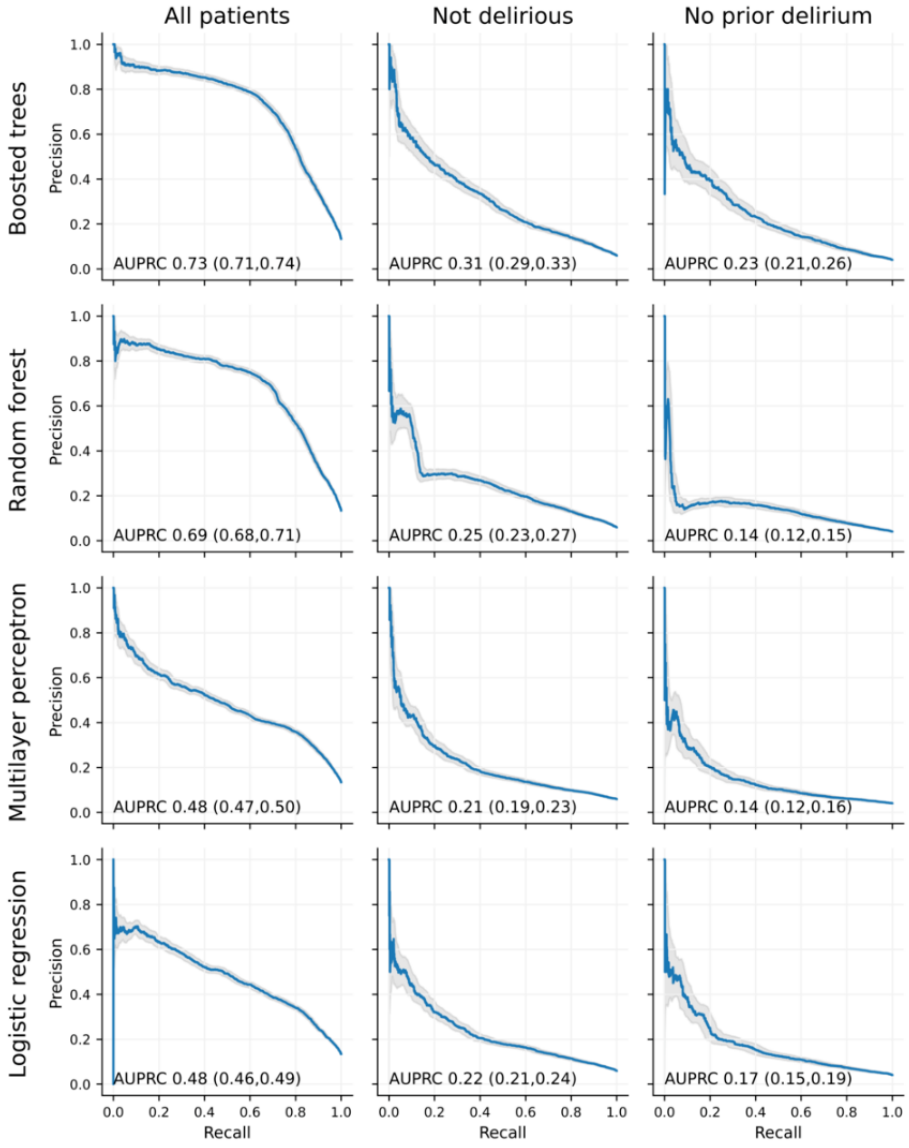
[a]CAM: Confusion Assessment Method.

Figure 1. Receiver operator characteristic curves for different model types (rows) and patient subsets (columns) showing the true positive rate (ie, recall) as a function of the false positive rate. The thin light gray region around the line shows the bootstrap 95% CI. AUROC: area under the receiver operator characteristic curve.

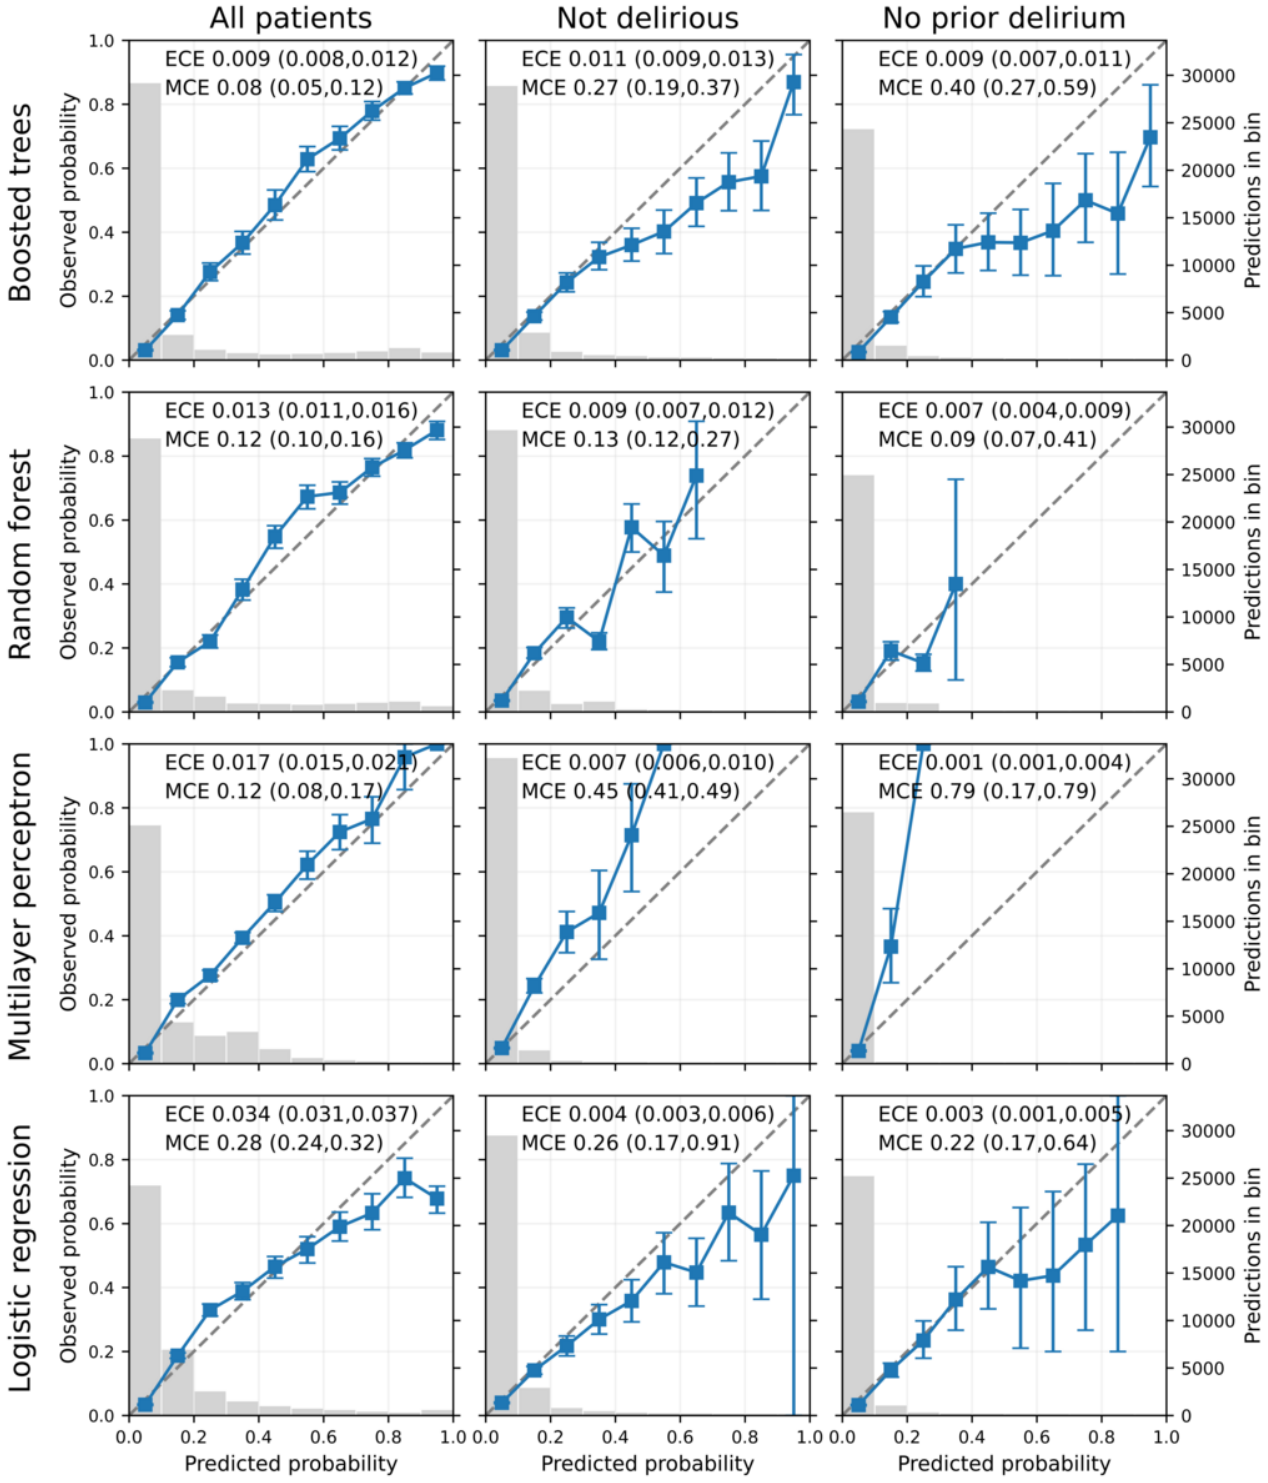


XSL•FO
RenderX

The models were then retrained and evaluated with patients who did not currently have delirium (most recent CAM screen was negative) and with patients who had no history of delirium (no prior positive CAM screens). Although the models did not perform as well on these more difficult subsets, they still provided good predictive power. The boosted tree model declined from an AUROC of 0.92 to an AUROC of 0.82 (95% CI 0.815-0.834) and 0.80 (95% CI 0.79-0.81) when limited to patients who did not currently have delirium and patients with no prior delirium, respectively. The other models showed a similar decrement, with the AUROC decreasing to 0.77-0.81 and 0.74-0.77 when limited to patients who do not currently have delirium and those who never have had delirium, respectively. The boosted tree model outperformed the other models in all three patient groups.

The models significantly varied in their ability to maintain a high positive predictive value as sensitivity was increased (Figure 2). The boosted tree model performed well (AUPRC 0.73, 95% CI 0.72-0.75), its performance declining significantly (AUPRC 0.32, 95% CI 0.30-0.34) for patients who do not currently have delirium and (0.22, 95% CI 0.20-0.25) those with no prior delirium. The incidence of delirium in all patients was 13%, those with no current delirium 6%, and those who never have had delirium 4%; thus, the decrement in AUPRC appears to be largely driven by the decreased incidence in these subgroups. While the random forest model performs relatively (AUPRC 0.70, 95% CI 0.68-0.71), it also experiences significant decrements in performance with patients who do not currently have delirium (AUPRC 0.25) or have no history of delirium (AUPRC 0.14). The multilayer perceptron models perform somewhat worse than the tree-based models, with AUPRCs of 0.50, 0.23, and 0.15 in all patients, those who do not currently have delirium, and those with no prior delirium groups. Logistic regression performed similarly to the multilayer perceptron with AUPRCs of 0.48, 0.22, and 0.17.

Figure 2. Precision-recall curves for different model types (rows) and patient subsets (columns) showing precision (ie, positive predictive value) as a function of recall (ie, true positive rate). The gray region indicates the bootstrap 95% CI.

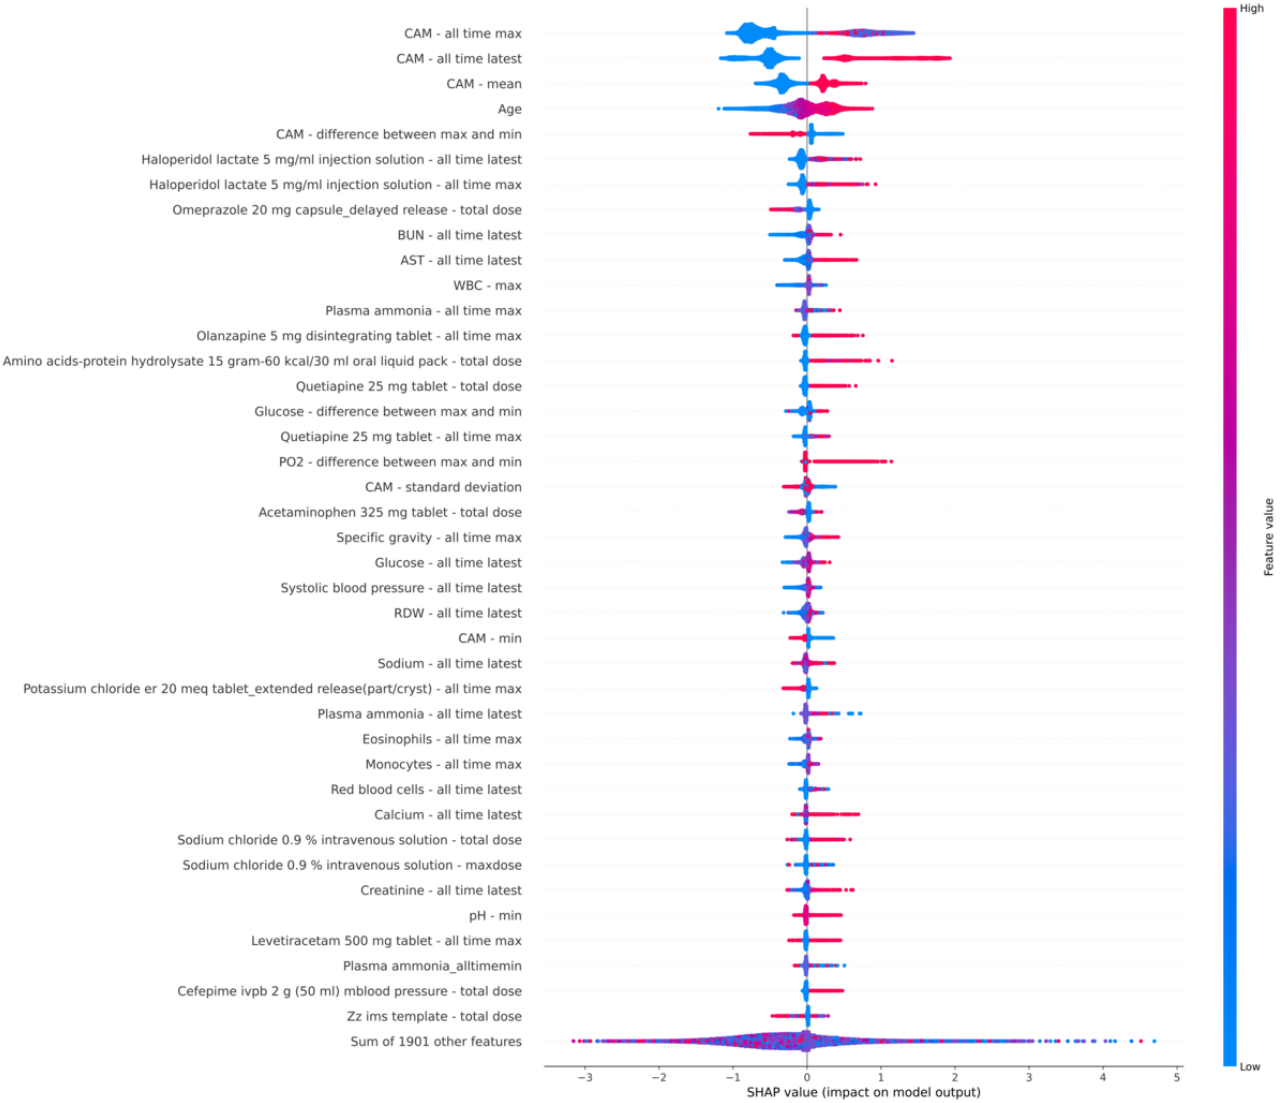


We next investigated the calibration of the prediction models. All the models were well calibrated (ECE≤0.02; MCE≤0.11) when applied to all hospitalized patients (Figure 3), with the exception of the logistic regression model which overestimated

XSL•FO
RenderX

the risk of delirium in the highest-scored group (ECE 0.03; MCE 0.28). The boosted tree model and the random forest model both identified a larger number of high-risk patients while still maintaining good calibration in this higher-risk group. When restricted to patients who do not currently have delirium or to patients with no prior delirium, all models classified very few patients as high risk (consistent with the earlier precision-recall curves), and the random forest did not assign higher probabilities to any patients in these subgroups.

Figure 3. Reliability diagrams for different model types (rows) and patient subsets (columns) showing the actual fraction of patient snapshots with delirium for groups with a given predicted risk of delirium (blue squares, left y-axis). Error bars show the bootstrap 95% CI. The gray bars in the background show the number of patient snapshots in each predicted probability bin (y-axis on the right). ECE and MCE are with a 95% CI. ECE: expected calibration error; MCE: maximum calibration error.

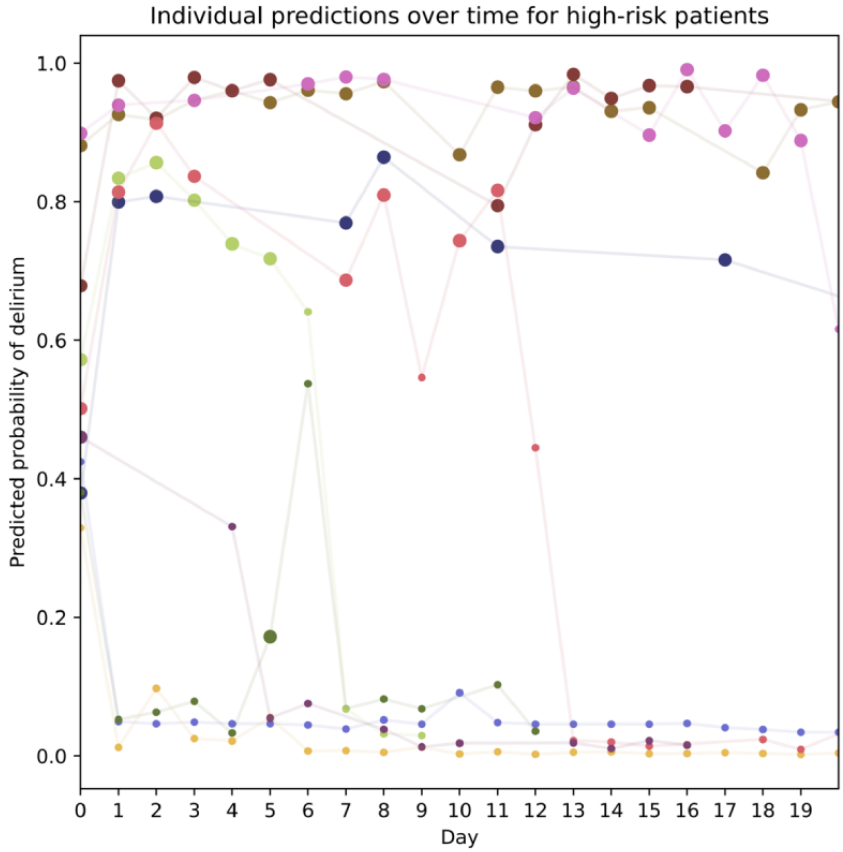


We finally turn to an examination of the features influencing the predictions of the most successful model (the boosted tree model). Ordering the features by average SHAP magnitude (Figure 4 [29,30]), we first note that the range of SHAP values

XSL•FO
RenderX

for any of the top 40 features is smaller than the range of SHAP values for the sum of the remaining 1901 features; thus, the predictions of the model across cannot easily be simplified to a small number of driving features that are the same for all patients. The features with the highest average SHAP magnitude appear to fall into several known risk factors for delirium. Current and prior delirium is a known predictor of future delirium, and 6 of the top 40 features relate to the prior CAM screen (including 4 of the top 5 features). Of note, the model considers a patient with no prior CAM screens to be at higher risk than a patient with prior negative CAM screens, and this feature remains important even for the "no prior delirium" case (not shown). Antipsychotic administration is also as expected a risk-predicting feature, as it is often used to convert hyperactive delirium to hypoactive delirium. The majority of the top 40 risk features fall into other categories, however, which include known risk factors such as age, liver failure (eg, aspartate transferase levels, ammonia levels, and hepatitis C virus levels), infection (eg, white blood cells, monocytes, and cefepime [which is also neurotoxic]), and malnutrition or frailty (amino acid supplementation, albumin levels).

Figure 4. SHAP beeswarm plots [28,29] of the 40 features with the highest SHAP magnitude for patients in the holdout dataset. Each dot shows a single prediction for a patient, the color of the dot indicates how high (red) or low (blue) the feature was for this patient, and the horizontal position of the dot indicates the relative effect of this feature on the predicted risk for the given patient.



Of note, many of the top features had missing values in the majority of patients (Multimedia Appendix 4). These often-included values such as neutrophil counts from cerebrospinal fluid, where the presence of the measurement itself suggests a high risk of delirium. This is again consistent with what is seen with the SHAP plot, where the models are able to use a constellation of low-frequency features of each patient to determine delirium risk (eg, laboratories reflecting concern for meningitis) rather than being limited to a few broad risk factors such as age.

To explore the dynamics of delirium predictions in individual patients over time, we examine the predicted risk and actual occurrence of positive CAM screens over time for a small number of patients with an elevated initial risk of delirium using delirium predictions from the boosted tree model (Figure 5). Of note, the prediction for the next day was strongly correlated with the delirium status of the previous day (as expected), but

XSL•FO
RenderX

the first day without delirium usually had a lower predicted risk of delirium than the last day with delirium, suggesting that the model had identified changes correlated with resolution of the delirium.

Figure 5. Predicted versus actual delirium incidence for ten patients with elevated (>30%) initial risk of delirium using predictions from the boosted tree model. Each patient is plotted in a different color, with a large dot reflecting at least one positive CAM screen that day and a small dot reflecting all negative CAM screens that day. The vertical axis shows the predicted risk for delirium that day (ie, for a perfect predictor, all large dots would be at the top of the plot and all small dots at the bottom). The horizontal axis shows the time (in days) from the first delirium screen, with day 0 being the day of the first delirium screen. CAM: Confusion Assessment Method.

Discussion

Principal Results

We have described the development of a prediction model that can provide automated daily predictions of the risk of delirium for a general population of hospitalized patients. We found that a boosted tree model performed best for this dataset and was able to identify a group of high-risk patients even when limited to patients who did not have delirium or had no prior history of delirium. However, the random forest, multilayer perceptron, and logistic regression models, while less effective, still provided substantial predictive power. All of the models showed good calibration on the full dataset but showed poorer MCE when applied to subsets of the data where delirium was less common—patients who did not currently have delirium and patients with no prior history of delirium.

The relative performance of the various models may reflect the relative match between the flexibility of each of the types of models and the size of the dataset we used. Although the L1 regularization used for the logistic regression model allowed for some tuning of flexibility by adjusting how many features were used, the logistic model can only capture monotonic relationships. Both boosted tree models and random forest models can better capitalize on nonmonotonic relationships which likely underlies their better performance on this dataset. In contrast, it was difficult to prevent overfitting with the multilayer perceptron model; preventing this overfitting would likely require either a larger dataset or additional methods of regularization.

Limitations

All of the models showed a decrement in performance when restricted to patients who did not currently have delirium and a further decrement when restricted without prior delirium. Except for the multilayer perceptron in the no prior delirium case; however, the AUROC of all of the models remained greater than 0.75, which many would consider the threshold for “good” performance of a clinical test [31]. The boosted tree model, in particular, maintained an AUROC of 0.80, which compares very favorably to commonly used diagnostic tests such as D-dimer levels in the setting of a suspected pulmonary embolism (with a reported AUROC of 0.71 [32]). The decrement of performance in these subgroups likely reflects the increased difficulty of the task—those patients with significant risk factors are likely to have had delirium on prior days or hospitalizations and most of those who remain are relatively unlikely to become delirious in the next 24 hours. Even within the patients with no

XSL•FO
RenderX

prior delirium, however, the boosted tree model was able to identify high-risk patients who would likely warrant further evaluation and interventions—for example, from the precision-recall curves (Figure 2), we can see that even if one were to demand a 50% true-positive threshold for an intervention, the model would correctly identify over 10% of the patients who have never had delirium who would become delirious as candidates for that intervention.

An additional limitation is the potential selection bias of the training and evaluation dataset used by this study. During the time period used, CAM screening was used universally on some inpatient units in the study hospital (eg, orthopedics) but not others (eg, general surgery), and thus, the study population is more reflective of these units than of the hospital as a whole. Thus, the generalizability of these results to other institutions will depend on how similar their patient population is to these units, rather than to the patient population of the study hospital. In addition, the results reported reflect this population where serial screens are performed and prior delirium screens are often present, which may not be applicable in many settings. One would expect the model's performance to be worse in this setting (similar to what is seen in the results reported for patients with no prior delirium).

As with many machine learning models, more complex models such as the boosted tree model may trade accuracy for interpretability, for example, for a clinician trying to understand why a particular patient is at risk for delirium. While this can be partially addressed by including the relative contributions of each input to the model to a given patient's risk (eg, using Shapley values [29,30]) as part of the delirium risk report for each patient, this still can hide complex interactions between risk factors that may be important.

We have chosen to leave the predictions of the model in the form of a percentage risk, rather than simplifying the result to a binary prediction as is more familiar for many clinical tests. To the limits of calibration of the model, the predicted percentage of delirium can be interpreted as the positive predictive value of the test for that particular patient (and 100% minus the predicted percentage as the negative predictive value). For given interventions, it may make sense to set a threshold predicted risk based on a cost or benefit analysis of the intervention (thus reducing the prediction to a binary value with a single positive predictive value and negative predictive value for all patients); examinations of specific thresholds for specific interventions may be addressed in future work.

While we have included many potential input features in our prediction model, there are many additional features in the medical record that we have not attempted to use, such as flowsheet data, length of stay, and unstructured data such as clinical notes. In addition, we have not exhaustively explored the types of models available in the literature, including many regularization techniques (such as early stopping and L2 normalization). While future models incorporating these predictors and techniques may perform even better than the models described here, this work provides a lower bound for their performance.

Comparison With Prior Work

Multiple prior prediction models for delirium have been developed for use in intensive care unit patients [11,12,33] and in hospitalized older patients [9]. In general, these models use a small number of predictors (4-11) identified using logistic regression, including such predictors as age, history of cognitive impairment, history of alcohol abuse, respiratory failure, blood urea nitrogen, mean arterial pressure, use of corticosteroids, admission category, admission urgency, and vision impairment. Our prediction goal (predicting a positive CAM screen within the next 24 h) is somewhat different than the existing models we are aware of, as it is aimed at the specific task of helping determine which hospitalized patients should be seen by a delirium service that day. With that caveat, the performance of our model appears to compare well with other models on similar tasks. Chua et al [13] provide a good review of similar models; reported AUROCs in this review range from 0.71 to 0.91 (compared to 0.92 for the boosted tree model we report). As delirium is an infrequent event, however, the AUPRC may provide a better estimate of the model's performance as a screening tool. Comparing our model to the best-performing models in the review by Chua et al [13], only the model described by Corradi et al [34] (one of the two models with an AUROC of 0.91) reported an AUPRC, which was 0.60 (compared to 0.73 for the boosted tree model we report).

One of the challenges machine learning has faced in medicine is translating predictions into improvements in patient outcomes [35]. We plan to use this model to screen all of the patients in a 1000-bed hospital (which would be prohibitively labor-intensive to do by hand) and identify a set of high-risk patients to be visited by a delirium service. The members of this delirium service will then evaluate patients and provide recommendations to the team caring for the patient on how to reduce that patient's risk of delirium. By focusing this additional clinical effort and possible interventions on the patients who would most likely benefit from them, we hope to use this tool to improve care at a lower cost per patient than providing the same interventions to every patient (including those at much lower risk of delirium).

Because of this intended use, we have made trade-offs that may limit the use of this model in other contexts. For example, our focus was on maximizing the ability of the model to identify high-risk hospitalized patients rather than on identifying the causal mechanism for a given patient's delirium. Thus, for example, an arterial blood gas showing mild hyperoxia might be used for prediction by the model because it is correlated with intubation, sedation, and critical illness rather than because it is directly increasing the patient's risk for delirium, and blindly attempting to correct this laboratory value may not decrease the patient's risk of delirium. In addition, some features, such as administering an antipsychotic medication, may happen to treat an agitated delirium that has not been documented in the medical record; while this may still be quite useful for a delirium service, it may be less useful for a responding clinician who is treating the agitation who likely already knows he or she is treating a symptom of delirium. This is an example of a "shortcut feature" as described by Bellamy et al [36], where a causal connection is present in the training data (eg, the use of an antipsychotic

XSL•FO
RenderX

for a patient the clinician has already decided has delirium) may not be present in a desired use-case of the model (eg, a clinician trying to decide whether a patient is at risk of delirium). Thus, while the model works well for finding high-risk patients, interpreting these risk factors and identifying appropriate interventions will still require clinical expertise.

Although our model can be applied in its current form, there are limitations that a user will need to be mindful of. For some machine learning models, such as logistic regression, it can be relatively easy to understand a prediction from the model in terms of the individual features contributing to the prediction. For many others, however, including boosted tree models such as our best-performing model, the nonlinear interaction of many features can make it difficult to understand why a given patient was assigned a high or low-risk score. Providing interpretability for these more complex, nonlinear models is an active area of research in machine learning, and while tools such as SHAP can provide some insight into a model, for some uses, a less accurate but more interpretable model (such as logistic regression) may be preferred.

Another limitation of our model is that many of the risk factors such as sleep disruption may only be documented in clinical notes and not in the structured data we have used, and thus high-risk patients may be missed by the model. We hope to address this in future work by integrating natural language processing techniques into the model.

The dataset used for the development and validation of the model is another potential source of bias in this study. Because the patients from this study are only those patients from a single academic medical center who received delirium screens, they may not be reflective of patients in other settings, and potentially not even representative of patients at the same institution who did not receive delirium screens. Although this could raise concerns that this would bias our dataset toward patients with delirium, this does not appear to have been the case. Only 4583 of the 23,006 patients (Table 1), or about 20%, of the patients in our dataset had one or more positive CAM screens. This is consistent with the 23% (95% CI 19%-26%) incidence of delirium reported in the meta-analysis of estimates of delirium occurrence reported by Gibb et al [37]. Although this is reassuring, future studies will be needed to provide external validation of the model at other institutions and on other patient populations.

Conclusions

In this paper, we have described a method for predicting delirium in hospitalized patients given the information already present in the electronic medical record. A large dataset of over 23,000 patients allowed us to consider a larger number of candidate features while still allowing for rigorous validation with a blinded test dataset. The resulting model provides both good accuracy and good calibration and can be run in an automated fashion on data in the electronic patient record without requiring additional human effort. We believe this model can be of use in guiding clinicians and researchers in focusing on patients at greatest risk of delirium in hopes of mitigating the morbidity and mortality associated with this disease.

Abstract

Background: Consuming high amounts of foods or beverages with high levels of saturated fats, salt, or sugar (HFSS) can be harmful for health. Many snacks fall into this category (HFSS snacks). However, the palatability of these snacks means that people can sometimes struggle to reduce their intake. Machine learning algorithms could help in predicting the likely occurrence of HFSS snacking so that just-in-time adaptive interventions can be deployed. However, HFSS snacking data have certain characteristics, such as sparseness and incompleteness, which make snacking prediction a challenge for machine learning approaches. Previous attempts have employed several potential predictor variables and have achieved considerable success. Nevertheless, collecting information from several dimensions requires several potentially burdensome user questionnaires, and thus, this approach may be less acceptable for the general public.

Objective: Our aim was to consider the capacity of standard (unmodified in any way; to tailor to the specific learning problem) machine learning algorithms to predict HFSS snacking based on the following minimal data that can be collected in a mostly automated way: day of the week, time of the day (divided into time bins), and location (divided into work, home, and other).

Methods: A total of 111 participants in the United Kingdom were asked to record HFSS snacking occurrences and the location category over a period of 28 days, and this was considered the UK dataset. Data collection was facilitated by a purpose-specific app (Snack Tracker). Additionally, a similar dataset from the Netherlands was used (Dutch dataset). Both datasets were analyzed using machine learning methods, including random forest regressor, Extreme Gradient Boosting regressor, feed forward neural network, and long short-term memory. We additionally employed 2 baseline statistical models for prediction. In all cases, the prediction problem was the time to the next HFSS snack from the current one, and the evaluation metric was the mean absolute error.

Results: The ability of machine learning methods to predict the time of the next HFSS snack was assessed. The quality of the prediction depended on the dataset, temporal resolution, and machine learning algorithm employed. In some cases, predictions were accurate to as low as 17 minutes on average. In general, machine learning methods outperformed the baseline models, but no machine learning method was clearly better than the others. Feed forward neural network showed a very marginal advantage.

XSL•FO
RenderX

Conclusions: The prediction of HFSS snacking using sparse data is possible with reasonable accuracy. Our findings offer a foundation for further exploring how machine learning methods can be used in health psychology and provide directions for further research.

high fats, salt, or sugar snacks; machine learning algorithms; internet data collection; just-in-time interventions

Introduction

General Background

Noncommunicable diseases, such as cardiovascular disease, cancer, and chronic respiratory disease, are currently the biggest threats to health [1]. These are greatly influenced by behaviors, such as poor diet, physical inactivity, and smoking (eg, [2,3]). Modification of the obesogenic environment would be most effective at bringing about change on a large scale [4]. However, such an environmental change is unlikely to occur in a short period. Therefore, most related interventions seek to change people's responses to their environments. Approaches to achieve these changes have ranged from mass media campaigns at the population level to group-based and individual healthy lifestyle coaching. Over the last decade, digital technologies for supporting a healthy lifestyle have been on the rise, but there is still room for improvement [5-7].

A potential avenue for improving the effectiveness of technology-assisted interventions is providing just-in-time adaptive interventions (JITAIs). JITAIs are designed to predict the points at which a person is likely to be in most need of and most receptive to reminders or assistance for changing a target behavior [8]. For example, a person engaged in an effort to quit smoking could be reminded of their goal at the point at which they are most likely to lapse [9,10]. This may be effective because motivation for a particular behavior can vary over time [11]. Additionally, health-related behaviors may be elicited by cues in the environment (eg, a certain time of the day or walking past a bakery store) and be largely habitual [12-15]. This can make change difficult unless behaviors elicited by these cues are disrupted. Helping a person identify those cues may reduce the undesired behavior in a number of ways, for example, by helping the person avoid the cues, adjust their behavior, or respond to the cues in a different way [15,16]. JITAIs could help people achieve such goals.

There is increasing research into the use of JITAIs (eg, [17,18]). Their development has been greatly boosted by the widespread adoption of powerful personal smartphones. For example, in 2021, 88% of all adults (aged 16 years or older) possessed a smartphone in the United Kingdom [19], with similar statistics throughout Western Europe and North America. Modern smartphones allow increasingly complex data collection from their owners, including date, time, ambient temperature, and location. Furthermore, owing to the high computational capabilities of modern smartphones, many of the required computations (eg, for prediction) can be carried out locally, without the need for distant servers and an active internet connection.

Snacking on foods and drinks that have high saturated fats, salt, or sugar (HFSS) is the focus of this research. Snacking can be defined as "food and beverage intake between meals, including products, such as potato chips, chocolate, and soft beverages" [20]. HFSS foods contribute to poor health [21], and many snacks fall into this category. Indeed, a previous study found that people who are overweight or obese eat an average of 1.3 snacks per day, with 79% of these snacks being high in either fat or sugar [12]. However, reducing HFSS snacking poses many challenges, particularly because it can be triggered by emotional or environmental factors [22]. It can also occur in an automatized (reflexive) way, making it less amenable to conscious control efforts [12-14]. Additionally, snacks that are high in sugar may make a person crave more sugary foods, because consumption of these snacks can lead to a spike and subsequent dip in blood sugar levels [23,24]. Indeed, feelings of hunger and food preoccupation are key reasons cited for snacking [12].

Several sophisticated approaches to predict aspects of maladaptive eating behavior have already been proposed, using ecological momentary assessments (EMAs). For example, Arend et al [25] studied binge eating episodes in clinical participants. The authors reported excellent predictive accuracy based on an EMA protocol with 36 items, including emotional and environmental variables. Based on initial testing, they were subsequently able to identify a smaller subset (n=5-9) of highly valid individualized predictors (EMA items), thereby reducing the need for an extensive EMA protocol. Forman et al [26] similarly investigated the predictive adequacy of a large number of variables concerning dietary lapses. Some questions, such as those relating to cravings or affect, were answered as many as 4 times a day, and others were answered only once. Kaiser et al [27] used data from 2 weeks of EMAs on stress and emotion, together with sensor data, to predict (reasonable accuracy) food cravings. Finally, Spanakis et al [28] tracked several individual states, such as emotions and cravings, which might predict "unhealthy eating events," including unhealthy snacking and other events, such as consumption of high-calorie food as part of a meal, in people who were overweight or obese. Participants were questioned as many as 10 times a day. Based on the collected data, a bottom-up clustering algorithm was used to arrive at 6 different subgroups of participants characterized by a specific pattern of eating behavior (eg, eating in the evening at home), to enable tailoring the intervention to a specific profile, which was implemented in a randomized controlled trial [29].

Research based on EMAs is valuable because the prediction of a behavior as complex as eating can potentially only be accomplished by considering a multitude of variables, including

XSL•FO
RenderX

environmental, psychological, and physiological variables. Moreover, the assessment of these variables takes place in daily life, contributing to ecological validity. However, health interventions based on EMAs typically require long periods to train the machine learning (ML) algorithms for prediction, as well as considerable commitment and motivation from participants. There is therefore interest in exploring whether the prediction of a particular behavior can proceed based on information that is both minimal and easily available, without much effort from participants.

In the domain of mental health, research on so-called digital phenotyping has recently started to develop. Digital phenotyping uses a smartphone as a tool for objective and ecologically valid measurements. This method includes passively obtained data, without needing input from the user. Digital biomarkers, such as sensor technology, geolocation, characteristics of voice and speech, and human-computer interaction, are obtained [30-33]. Through this method, a pattern might be discovered over several weeks (ie, the user is taking too long to respond to messages, is browsing online until late at night, and is mostly at home). This can lead to suspicion that things are not going particularly well for the user, and the suspicion may be increased by the tone, timing, and content of the user's social media posts. Research has shown that mood states in mood disorders can be predicted using digital biomarkers based on the circadian rhythm [34].

Prediction of HFSS Snacking Using ML

This research project takes a step in the direction of digital phenotyping for the prediction of unhealthy eating behavior. Specifically, to what extent can HFSS snacking be predicted only based on prior HFSS snacking combined with information that can be automatically or easily collected from a smartphone (date, time, and location)? However, this endeavor might fail due to temporal resolution requirements. If high precision is needed, failure will be inevitable owing to the intrinsic stochasticity of the eating behavior. Another problem is the degree of accuracy that can be achieved after a modest training period, because participants may not have the patience for extended training (eg, Tulu et al [35]), and even with mostly passively collected data, participants still need to indicate instances of HFSS snack consumption.

On the positive side, ML has progressed to such an extent that modern algorithms have many characteristics desirable for the present application, including the capacity to deal with sparse data and efficient learning of time series. For example, as an alternative to recurrent neural networks, which are well suited to time series data, ensemble methods have a good ability to deal with sparse data by reducing the impact of noise and outliers [36]. Therefore, our aim was to compare a selection of ML algorithms, with a view to identify a good algorithm for predicting instances of HFSS snacking based on only prior instances, which were coded in terms of time, day, and location (the latter was encoded in terms of broad categories). The algorithms were chosen to reflect complementary characteristics and be representative of the range of good options currently available. Random forest regressor (RFreg), Extreme Gradient Boosting regressor (XGBreg), feed forward neural network (FFNN), and long short-term memory (LSTM) were considered.

RFreg is a tree-based ensemble method that trains many decision trees simultaneously with bootstrapping followed by aggregation, collectively referred to as bagging. Bootstrapping involves the training of several individual decision trees (between 100 and 300 in the present case) on several subsets of the dataset, using various subsets of available features [36]. Aggregation means that the outputs from the distinct decision trees are combined into a single decision. RFreg is considered to generalize well and be resistant to overfitting, as well as produce high prediction accuracy, because of ensemble learning [37].

XGBreg is another tree-based ensemble method, which uses a form of gradient boosting, relying on the idea that correcting the model's earlier errors and learning from them can help to improve performance in the future. This is a sequential ensemble learning method where the model tries to improve performance with each iteration [38]. Both RFreg and XGBreg are ensemble learning techniques, but the former builds multiple trees in parallel and then employs an average for prediction, while the latter constructs 1 tree at a time, in a way that is informed from the errors of the previous tree [39].

FFNN is a relatively simple type of artificial neural network, in which information is processed in 1 direction, from input units to units in one or more hidden layers to output units, such that there are no cycles in the connections between the nodes. Hidden layer units apply nonlinear functions to their input, enabling an FFNN to learn complex associations between input and output [40]. An FFNN is trained using gradient descent methods, specifically error backpropagation [41].

Finally, the LSTM model is a kind of recurrent neural network with an architecture designed for learning long-term dependencies in time series [42]. A recurrent neural network includes cycles that feed network activations from earlier time steps as inputs to determine predictions at the present time step. As a result of these recurrent connections, the model creates an implicit recollection of past occurrences, stored in its hidden layer [43]. Recurrent models can process contexts of arbitrary length; the LSTM model has a specific structure designed to store values for longer compared to standard recurrent neural networks. The LSTM model is the only recurrent model that was employed, with the other models operating on a fixed context.

Summary of the Purpose and Aims

Despite much interest in predicting eating behavior, there has been less work on prediction involving minimal data. Therefore, the feasibility of predicting HFSS snacking using only previous instances of snacking collected across a "practical" length of time (practical in the sense of participant recruitment and engagement) is unclear. Additionally, there is a wide range of ML algorithms. It is of interest to explore the quality of prediction against the assumed characteristics of HFSS snacking behavior, such as sparseness and high noise.

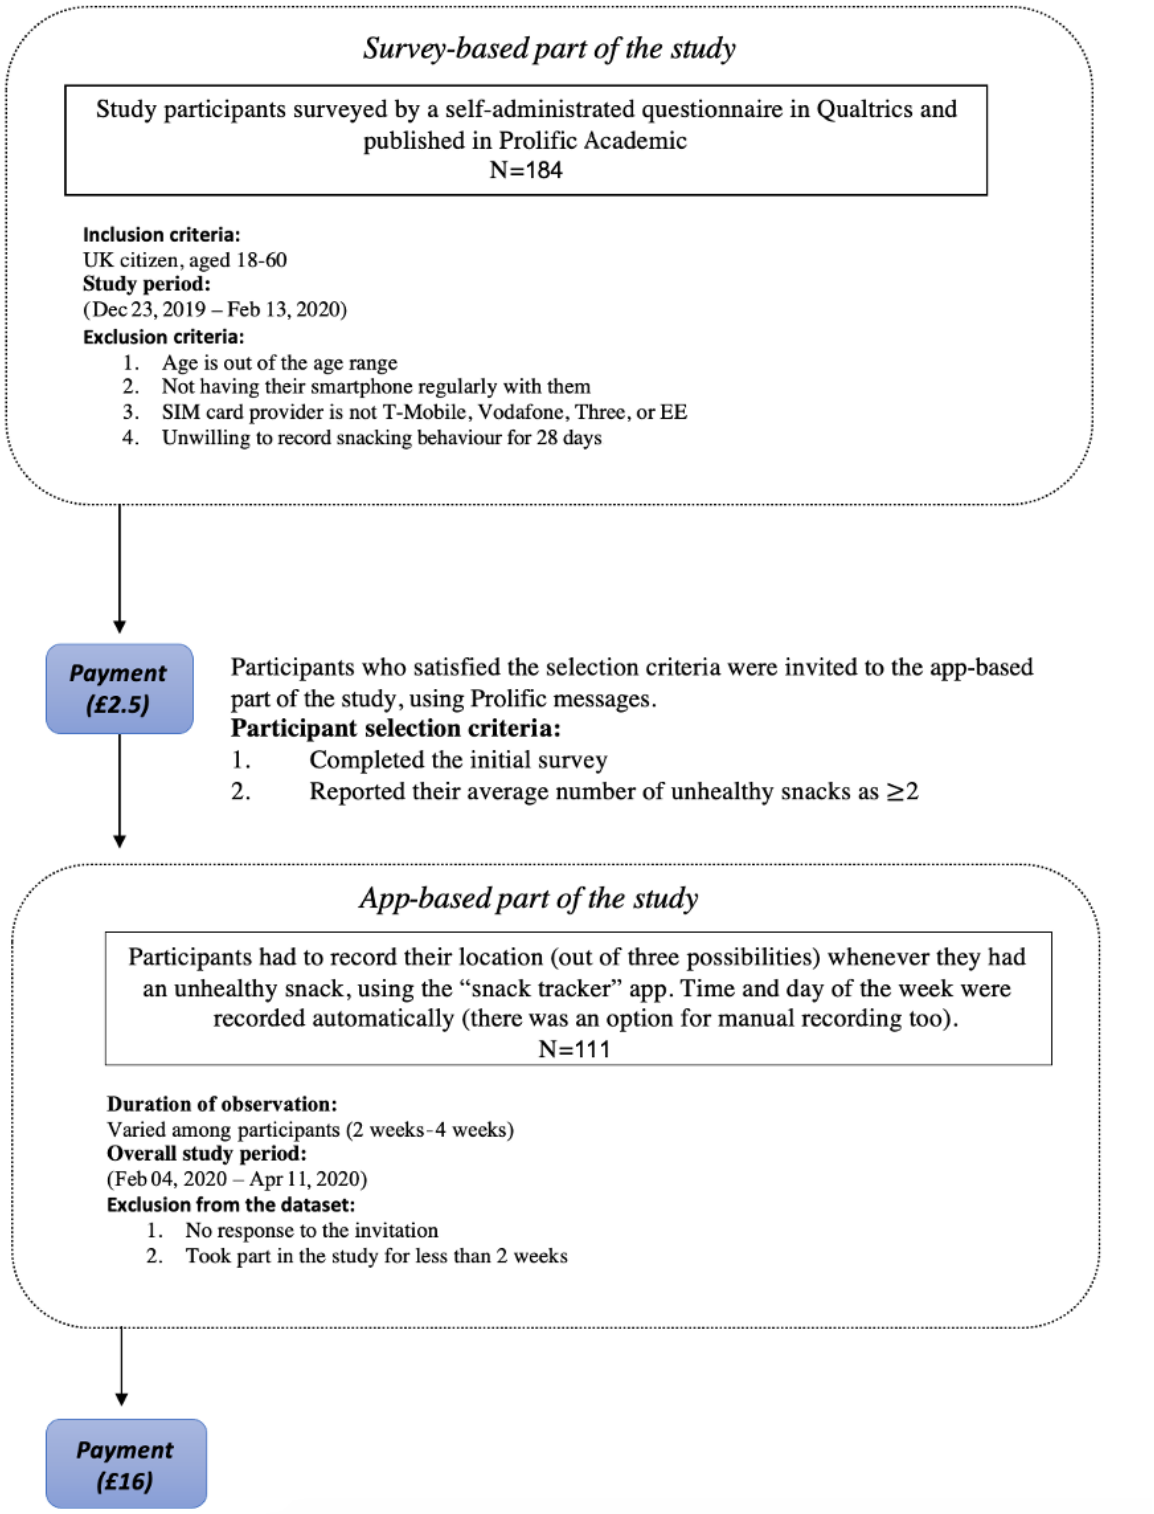
With these considerations in mind, this study aimed to (1) develop an app, which would enable data collection on HFSS

XSL•FO
RenderX

snacking with minimum effort from participants; (2) define a sensible problem for characterizing HFSS snacking behavior (prediction of HFSS snacking using previous instances of snacking and limited information [time, location, and day of the week]); (3) apply a range of standard and unmodified ML algorithms to the problem; (4) compare the performance of these algorithms to each other and to some baseline statistical models; and (5) consider whether the task of predicting HFSS snacking from minimal information is feasible and suggest some directions for future work.

Methods

Outline of Data Collection



Data on HFSS snacking were collected to examine which ML algorithm was best able to predict such behavior based on only previous instances and minimal information (time, location, and day of the week). We first describe the procedures employed to collect the data.

Data were collected in 2 parts. First, a survey was created to explore various assumptions about the target behavior of interest. Second, we implemented an app to obtain data on HFSS snacking. Participants who reported having 2 or more HFFS snacks daily in the first part were invited for the app-based second part of the study. The second part of the study involved monitoring participants' snacking behaviors for 28 days. The 2 parts of the study are outlined in Figure 1. This dataset is referred to as the "UK dataset." To increase the ecological validity of our work, we also employed a cleaned version of a similar dataset collected in the Netherlands, which has been described by Spanakis et al [28]. The dataset in the report by Spanakis et al [28] is referred to as the "Dutch dataset."

The data collection details below concern the UK dataset; corresponding details for the Dutch dataset can be found in the report by Spanakis et al [28].

XSL•FO
RenderX

Figure 1. Screening and data collection processes for the UK dataset. Initially, demographic and lifestyle (weight/diet) surveys were used to determine eligibility for the trial. In part 2 (app-based part of the study), participants were asked to record snacking habits for a target period of 4 weeks.

Ethical Considerations

For the UK dataset, ethics approval was granted by the Psychology Research Ethics Committee at City, University of London (reference: PSYETH (S/L) 17/18 87). The informed consent form for the first study part (survey part) informed participants that the study was about snacks that are high in sugar, salt, and fat and that the study would be conducted in 2 parts (a brief first part concerning some general questions about eating behavior and a 28-day second part, which would involve participants recording occasions of snacking on their smartphones via an app). The informed consent form for the second part (app-based part) explained in detail about HFSS snacks and informed participants that they would have to record their HFSS snack consumption on an app for 28 days. The informed consent form provided some information about the

XSL•FO
RenderX

next steps, if the individual agreed to participate, and the amount of compensation.

All data were collected anonymously. To protect participant anonymity, the Data Protection Office at City, University of London, which is registered with the Information Commissioner's Office (registration number: Z8947127), was engaged to confirm that any personally identifiable information (PII) was securely collected. Data collection involved 3 companies external to City, University of London: Dev Technosys implemented the app, Linode provided virtual private servers, and Twillo provided programmable messaging services. It was ensured that these companies were compliant with the General Data Protection Regulation (GDPR) and used encrypted communication.

Participants were compensated £2.50 (US $3.13) for their time for the survey part of the study and £16 (US $20.00) for the app-based part.

For the Dutch dataset, ethics approval for the study was provided by the Faculty of Psychology and Neuroscience of Maastricht University in 2013. While the data were not open access, the principal investigators of the study stated availability of the data upon reasonable request [28].

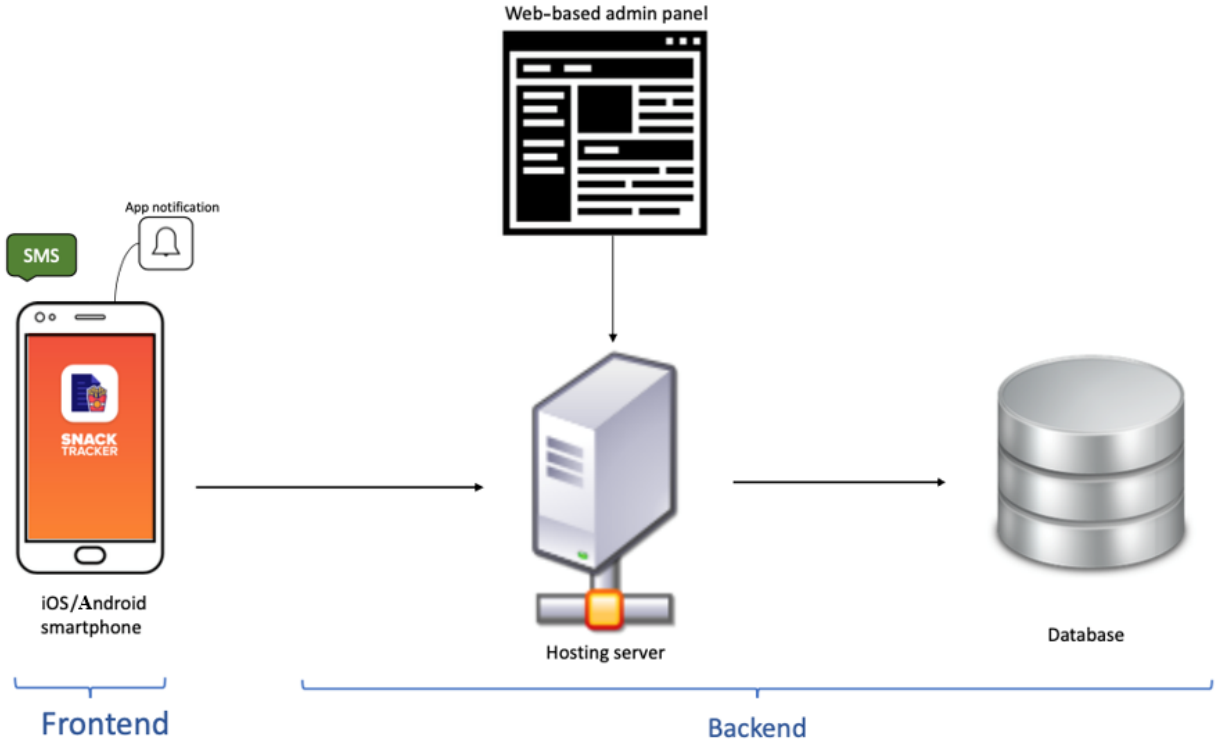
UK Dataset: Survey-Based Part of the Study

Data for the first part of the study were collected using a self-administered survey designed using Qualtrics [44]. The survey was run on the crowdsourcing platform Prolific Academic [45]. The study was made available on Prolific Academic, and prospective participants decided whether to take part. The study had a target sample of 200 participants on December 23, 2019, and recruitment was closed on February 13, 2020, when this participant number had been reached.

There are no established guidelines for the minimum sample size required for an ML assessment, and a particular ML algorithm can work effectively up to a certain error threshold [46] for a promising but still experimental proposal. Based on previous related research (Spanakis et al [28] recruited 100 participants for an ML study broadly similar to our study), the expected time to train all 4 ML models for each participant, and our budget for paying participants to take part for 28 days, we aimed for approximately 100 participants for the ML assessment. The target of 200 participants for the survey part of the study was an estimate of how many participants would be needed to identify enough participants with a reasonably high intake of HFSS snacks, who would be willing to take part in the app-based part of the study across 4 weeks. The survey part had no inferential value.

Only UK citizens between the ages of 18 and 60 years were allowed to participate in the study. Participants were excluded if they did not have a smartphone or stated that they were unwilling to participate in the follow-up study (ie, the app-based part). Additionally, we only recruited participants having a T-Mobile, O2, Vodafone, Three, or EE mobile phone service, since at the time of running the study, these were the only SIM card providers in the United Kingdom providing services compatible with the Twillo messaging service, which we employed in the second part of the study. After these exclusions, there were 184 participants for the first part of the study.

The survey consisted of questions concerning basic demographics and motivation for healthy eating (Tables S1 and S2 in Multimedia Appendix 1). Specifically, there were 10 questions covering gender, ethnicity, employment status, weight, height, HFSS snacking habit, whether the person is trying to lose weight (2 questions), and whether the person is trying to eat in a healthy way. Participants were not allowed to skip questions. The duration of the survey was about 15 minutes.



UK Dataset: App-Based Part of the Study – Snack Tracker App

We developed the Snack Tracker app to record unhealthy snacking for this project. The app was designed by SD, and the coding was undertaken by Dev Technosys [47], a company specializing in app development. We created versions of the app for both Android and iOS devices. However, the app is no longer available for use.

Mobile app development is usually divided into 2 main components: frontend and backend (Figure 2). Regarding the frontend (the user interface), the app was designed to be easy to use, with a simple sequence of screens (Figure 3 and Figure S1 in Multimedia Appendix 1). The current date and day of the week were automatically captured for each recording to minimize user effort. The app worked online, allowing users to log in and record any snacks they had eaten. In the case of connection loss, the app allowed users to save their records, and the app transmitted the data to the server once the mobile device was connected to the internet.

XSL•FO
RenderX

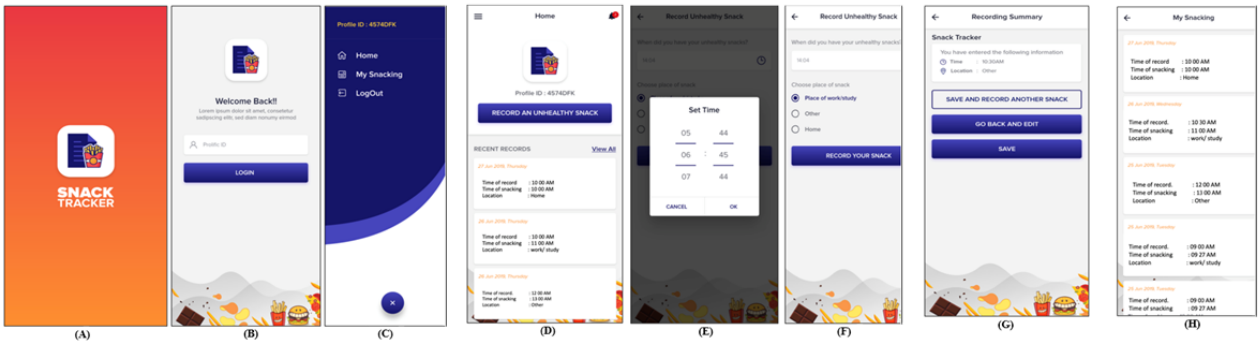


Figure 2. The frontend (user interface) and backend (data storage) of the Snack Tracker app used for participants in the second part of the study to record their intake of snacks with high saturated fats, salt, or sugar over a period of 4 weeks.

The app frontend was coded using React Native, which is an open-source JavaScript framework for writing iOS and Android apps. All operations performed by app users and project admins were handled by Rest Application Programming Interfaces (APIs) created in Node JS, which allows running JavaScript on the server side. Rest APIs were used to communicate with the database of participant data (MongoDB) for store and retrieve operations (ie, these APIs acted as a bridge between the app frontend and the database where participant data were stored). The server used in this project was a cloud-based server (Linode), which controlled all operations and allowed the management of the app environment.

The backend part of the app concerned storing the data and user credentials, as well as offering a web-based admin panel to manage the project. Participants accepting the invitation to the app-based part of the study were registered manually using the admin panel to prevent random users from recording data on the app. The backend also handled initial user login and user requests to save and record another snack, go back and edit, or just save an entry (Figure 3).

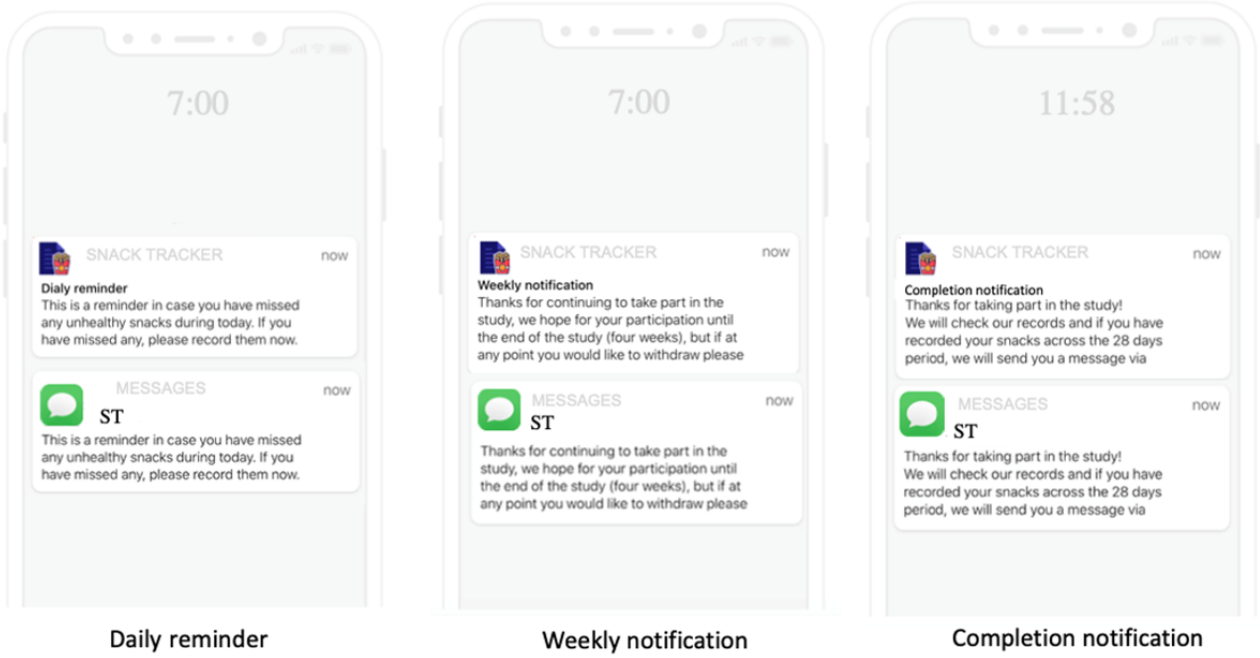

Figure 3. The frontend of the Snack Tracker app: (A) splash screen, (B) login screen, (C) home screen, (D) new snack screen, (E) time recording screen (time picker), (F) location recording screen, (G) recording save screen, and (H) review recording summary.

The app development included designing and delivering messages as SMS text messages and app push notifications to keep users engaged and remind them to record snacks (Figure 4). Push notifications could be offered even if participants had no internet access. For automated SMS text messages, Twilio was used, which is a cloud communication tool. The software could programmatically send SMS text messages using Twillo's web service APIs. For more information, see [48].

RenderX

Figure 4. Examples of reminders sent to participants to "nudge" them to record their intake of snacks with high saturated fats, salt, or sugar during the second part of the study (app-based part).

UK Dataset: App-Based Part of the Study – Data Collection

Among the 184 participants who completed the survey-based part of the study, participants were further excluded if they reported consuming fewer than two HFSS snacks per day, leaving 170 participants. We initially invited 100 of these participants to participate in the app-based part of the study, with the invitations sent in 3 stages between February and March 2020. Initially, only 68 participants accepted the invitation, and in the second and third invitation stages, 45 and 25 participants, respectively, were invited, with 27 and 16, respectively, accepting the invitation, resulting in an overall sample of 111.

Participants were instructed to participate for 28 days. However, exact start and end dates of the study differed between participants, as was expected.

During the study, participants were messaged via Prolific if they made only 1 recording or no recordings on any day and if they had made multiple recordings (two or more) each day for a period but then abruptly made a reduced number of recordings. These messages were sent in part to ensure that there were no technical problems with the Snack Tracker app. Additionally, a few Prolific messages were sent to randomly selected participants to check that the reminders regarding snack recording (Figure 4) were received as intended. Informal feedback from participants throughout the study did not indicate any technical problems.

For the purpose of the study, an HFSS snack was defined as any food eaten between the main meals, which was high in either saturated fat, salt, or sugar. Specifically, participants were informed that we are interested in "snacks high in sugar, salt, or fat, which includes… sugary snacks… salty and fatty snacks." For each of these categories, several examples common in the United Kingdom were provided (eg, biscuits, cake, chocolate, crisps, salted nuts, and salted popcorn). Multimedia Appendix 1 shows exactly how HFSS snacks were explained to the participants. Considering the instructions and several examples of typical items provided, it is likely that participants did not have difficulty with the definition of HFSS snacks. There was no poststudy feedback of any such difficulties. In addition, in keeping with the broad aim of the study (to help people manage their own behavior), there were no strict criteria on what participants should or should not define as an HFSS snack. It was not considered that the app needed to be independently validated, which is in line with similar work, including the study by Spanakis et al [28].

Whenever participants had an HFSS snack, they were asked to record it in the Snack Tracker app. In this mode, they only had to mention the location (coded as home, place of work, and other; although a GPS-based method would aid in this process, this method was not possible in our app) as the time and day of the week were saved automatically. If participants had 2 HFSS snacks at the same time, this would be recorded as a single snacking instance. Throughout the study, participants received 3 kinds of notifications (Figure 4). Daily reminders were sent at 7 PM, asking participants to record any instances of HFSS snacking that they missed. In this mode of the Snack Tracker app, participants had to manually indicate the time and day of the week as well as the location. Additionally, at the end of each week, participants were sent a notification (instead of the daily notification) to keep them engaged and provide information or ask questions (eg, to ask about any technical problems; Multimedia Appendix 1). The final notification was sent at the end of the 28-day period (from the first app recording) to instruct the participants that the study had ended, thank them for their participation, and offer them a completion code for Prolific Academic.

XSL•FO
RenderX

Dutch Dataset: Brief Notes

The Dutch dataset was collected by a research group at the Faculty of Psychology and Neuroscience at Maastricht University (Study I in the report by Spanakis et al [28]). The dataset was collected with an app called Think Slim. The sample consisted of 57 participants who were overweight and 43 participants with a healthy weight in the Netherlands. This study employed EMAs. Data on 15 variables were collected (eg, mood, activity, and location), and the variables were monitored across 8 to 10 measurements per day depending on the participants' waking and sleeping times. Spanakis et al [28] aimed to study eating behavior in general (including main meals and snacks, both unhealthy and otherwise), with a view to identify participant clusters and provide adaptive feedback for improving eating behavior. Accordingly, we extracted measurements corresponding to HFSS snacks from the general eating behavior data [28] to create the Dutch dataset. Only "eating moments" were used from the original dataset [28]. Eating moments were event contingent (ie, they were initiated by users whenever they were about to eat something). Therefore, users were not prompted or reminded to record their eating behavior.

The Dutch dataset was already present when the data collection for the UK dataset was planned, and there is a reasonable question as to why we did not adopt a sampling approach similar to that used for the Dutch dataset. In brief, the purpose of the UK dataset was different from that of the Dutch dataset. For the UK dataset, the priority was to collect snacking information in a way that was as nonintrusive as possible. Moreover, we wanted to focus on individuals with some snacking behavior in the first place, since sparsity of data would complicate the application of ML. On the other hand, the purpose of the Dutch dataset was to explore prediction using a range of variables, with a focus on eating behavior in general and not just snacking, and it aimed to understand differences in daily lifestyle between people with a healthy weight and people who are overweight. Accordingly, the extent of snacking behavior was less relevant.

Data Preprocessing

Regarding the UK dataset, it was decided to exclude participants who did not remain in the study for its intended duration.

Some basic operations were carried out to remove erroneous entries and ensure consistency between the UK and Dutch datasets. In the UK dataset, we removed missing and duplicate entries and ensured that measurement units for height and weight were the same across participants. In the Dutch dataset, we translated data from Dutch to English and manually reclassified 950 locations, originally in free text, into the 3 categories employed in the UK dataset. Finally, HFSS snacks were extracted from the general information about meals or snacks. This involved focusing on data concerning food items, such as burgers, chocolate bars, strawberries, and pasta, and identifying the items considered as snacks. Each snack was manually categorized as healthy or unhealthy (HFSS).

Data were coded in terms of the following 3 features: location (home, place of work, and other), day of the week (Monday to Sunday), and time. A time bin feature was constructed, and there were 4 large and 12 small time bins. A regular day was divided into 4 or 12 time bins. In the former case, the time bins were early morning (midnight to 05:59 AM), morning (6:00 AM to 11:59 AM), afternoon (noon to 4:59 PM), and evening (5:00 PM to 11:59 PM). In the latter case, the first time bin started at midnight and had a 2-hour duration, and every subsequent time bin had a 2-hour duration, resulting in a total of 12 time bins. Models were trained and evaluated for these 2 encodings of the time variable.

As is common in ML, for the 2 nominal variables in the datasets (location and day of the week), one-hot encoding was used, converting each variable to separate variables that take the value 1 or 0 to indicate the presence or absence of different levels of the variable [49]. The time bin variable was kept in its numerical format.

Finally, although additional data were collected from participants in the United Kingdom, including motivation for healthy eating, these additional variables were not considered in this study for practical reasons and for meeting the focus of snacking prediction using minimal information.

Computational Methods

We employed 3 fixed context models (RFreg, XGBreg, and FFNN) and 1 recurrent model (LSTM). Fixed context models require a fixed input size, which can be achieved by windowing a longer sequence. Windowing is a technique used to divide a longer sequence into smaller, fixed-length sequences. Due to the sparseness of our data, we decided to treat each individual data point as a separate window for prediction, rather than grouping them into larger sequences. This approach is often used when the data are not abundant enough to create longer sequences, and it can simplify the modeling process for the algorithms. Recurrent models can process an input sequence of arbitrary length. They function in cycles, during which the activation from the previous time step is used as input (together with other information) for the current time step. For the single recurrent model in the study, we used the observation sequences of 4 time steps. In our study, the day was divided into different time bins, including a case of 4 time bins (early morning, morning, afternoon, and evening). While the 4 time steps in this model do not directly correspond to the day time divisions, they broadly align with it, and this was sufficient for our analysis.

Some models can benefit from standardization, normalization, and dropout regularization more than others, and these techniques were explored accordingly. Feature scaling (such as standardization or normalization) was considered for the FFNN and LSTM models. Neural networks often benefit from having consistent scales across features. This is because neural networks learn complex relationships and patterns among features, which can be influenced by the differing scales of features, if not appropriately managed [50,51]. On the other hand, tree-based models, such as RFreg and XGBreg, operate by splitting nodes based on feature thresholds and thus are less sensitive to feature scaling. For the FFNN model, we standardized features using the formula $z_i = (x_i - \mu) / \sigma$, where μ and σ are the mean and SD values of the variable, respectively; z_i indicates the standardized value; and x_i is the original value. For the LSTM model, we

XSL•FO
RenderX

employed the normalization $y_i = x_i - \min(X) / (\max(X) \cdot \min(X))$.

Dropout was also explored. It is a regularization technique that randomly sets to zero (drops out) a percentage of the features during training [52]. Dropout regularization introduces randomness during training and prevents overspecialization of units, which can improve generalization. This is important for neural networks, as they can overfit the training data. Accordingly, we evaluated and ended up retaining dropout regularization for the FFNN and LSTM models. Tree-based models use other (inherently incorporated) mechanisms, such as feature selection, bootstrapping, and ensemble aggregation, to manage overfitting.

We executed a total of 5 experiments for each model (5-fold cross-validation) to evaluate their performance. In each experiment, the models were evaluated based on their predefined configurations (Table 1). Both random forest and XGBoost are based on decision trees, and Figure 5 illustrates their differences as well as some of the main parameters.

Table 1. Hyperparameters for each of the machine learning algorithms used to analyze the data collected about consumption of snacks with high saturated fats, salt, or sugar during the app-based part of the study.

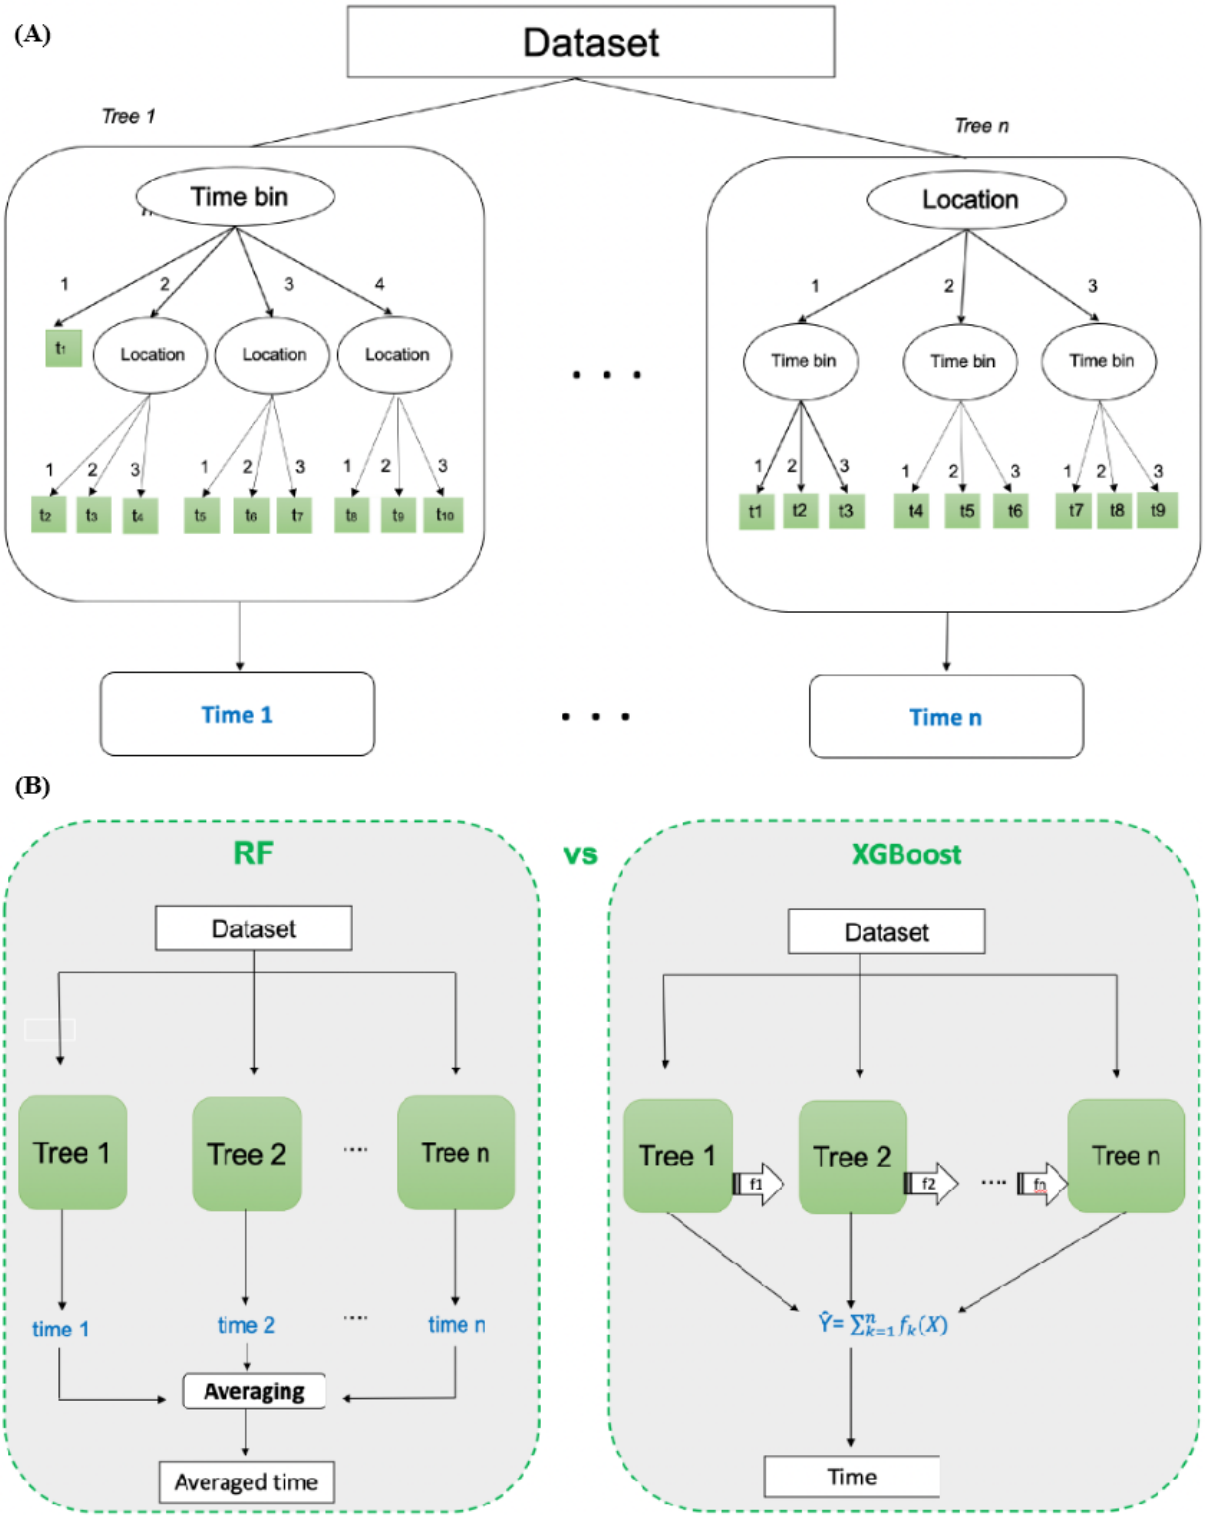
Model and hyperparameter	Value or range
RFreg[a]	
n_E, number of estimators (trees in the forest)	150
Min_{ss}, minimum number of samples an internal node must cover to consider splitting (when a node has fewer samples than this value, it is regarded as final and called a terminal node or leaf)	2
Max_{depth}, maximum number of splits that each tree is permitted to execute	Not user specified (nodes are expanded until leaves are pure or contain less than Min_{ss})
XGBreg[b]	
n_E, number of boosting rounds (estimators)	100
Min_{SS}	2
Max_{depth}	6
LR, learning rate (step size for each boosting iteration)	0.3
Gamma[c] (how much the loss must be decreased by a split in order for that split to occur)	0.05
FFNN[d]	
Number of hidden layers	4
Dropout regularization[e]	0.5, after the 2nd and 4th hidden layers
Number of neurons at the hidden layer (NHL)	1st hidden layer: 32; 2nd hidden layer: 32; 3rd hidden layer: 8; 4th hidden layer: 8
Activation function	ReLU[f], in the dense and output layers
LSTM[g]	
Number of neurons in the LSTM layer (NLL)	128
Number of hidden layers	3
Dropout regularization[e]	0.5, after the 3rd hidden layer
NHL	64
Activation function	ReLU, in the dense and output layers

[a]RFreg: random forest regressor.

[b]XGBreg: Extreme Gradient Boosting regressor.

[c]In relation to gamma, loss is the function minimized during model training. It is based on the difference between the current output of the machine learning model and the target (ie, the true value).

[d]FFNN: feed forward neural network.



[e]Dropout regularization is a technique that randomly switches off neurons in a neural network during training to avoid overfitting. The number given refers to the fraction of neurons switched off.

[f]ReLU: rectified linear unit.

[g]LSTM: long short-term memory.

XSL•FO
RenderX

Figure 5. The 2 panels of the figure illustrate the differences between the 2 random forest machine learning algorithms in the study. (A) Both random forest regressor (RFreg) and Extreme Gradient Boosting regressor (XGBreg) are based on the same building block, a decision tree, which is a set of rules built from the dataset. In our case, the aim is to predict the time until the next snack having high saturated fats, salt, or sugar in minutes. n is the number of trees in the model, selected based on cross-validation performance. Time k is the expected time until the final unhealthy snack is predicted using Tree k. (B) For RFreg (on the left), the model creates several different trees and then averages predictions. For XGRreg (on the right), there is a sequence of trees, which progressively refine the prediction. Splits in a decision tree correspond to the data points associated with a node being divided and the parts assigned to child nodes. RF: random forest; XGBoost: Extreme Gradient Boosting.

All algorithms had the same objective, which was to predict the time until the next HFSS snack (in minutes), given the current time bin, location (work, home, and other), and day of the week. Specifically, given the presence of an HFSS snack in a time bin, the ML algorithms attempted to predict the number of minutes to the next HFSS snack (snack to snack interval). ML algorithms were applied separately to the snacking data from each participant to take into account individual differences in

XSL•FO
RenderX

how the available predictors can be related to snacking behavior. In ML terms, the question is whether there is structure in the data to predict the density of snacking instances, based on the available predictors, location, time bin, and day of the week. To summarize the main approach, we used an input of fixed size, comprising current location, current day of the week, and current time bin, for RFreg, XGBreg, and FFNN. The LSTM model processed data as a sequence of inputs.

To appreciate the capacity of the ML models to extract regularities from the data, 2 baseline models were explored. The first was a simple linear regression model, which attempted to predict snacking instances based on a linear combination of available features, which were suitably weighted. The second was a basic baseline model corresponding to prediction based on the grand mean of snacking (computed separately for each participant) across the time bins.

Five-fold cross-validation was applied on all fixed-context models. In each data split, the datasets were divided into 2 parts (80% for training and 20% for testing). That is, 20% of the data reserved for testing constitutes out-of-sample validation of the models. The error (mean absolute error [MAE]) values were computed on the part of the dataset left for testing (20%). This procedure was repeated 5 times, with each iteration corresponding to a different, randomly determined partition of the data into training and test parts. Reported MAE values were averaged across these 5 iterations. We ensured that data distributions in the training and testing data subsets were similar to those in the whole dataset, using stratified data sampling [53]. Regarding the choice of using 5-fold cross-validation, there is a question of whether it would make sense to have more "folds." However, each different "fold" increases the number of simulations that must be run and leads to more unbalanced training and testing subsets. Five-fold cross-validation is a fairly standard approach.

For the LSTM, a time series cross-validation was employed. Time series cross-validation is more suitable for temporal data modeling, because the training set only includes the observations occurring before those in the testing set. It begins with a small subset of data for training that is successively extended to generate new predictions [54]. Because of the sparseness of the data, it was decided to use time series cross-validation with only 2 splits.

MAE is the main evaluation metric for the models. MAEs were computed as differences in minutes between the time of the current snack and the predicted time for the next snack. This is because our research focus was the time difference between the prediction and the actual time until the next HFSS snack occurrence. Additionally, residuals allow quantification of positive and negative errors, which were employed in a further analysis (related to the creation of hypothetical interventions). Residuals were calculated as true values minus predicted values. Thus, positive residuals indicate that the predicted time is earlier than the observed time, and negative residuals indicate that the predicted time is later than the observed time. It is important to note that the MAE is computed as the average of the absolute values of the residuals. Residuals were examined as standard, and corresponding plots are provided in Multimedia Appendix 2.

Results

Preliminary Notes

Regarding the UK dataset, as expected, some participants did not stay in the study for its intended duration (4 participants). Majority of the participants (107/111) recorded their HFSS snacks for the full 28 days or more. Among these participants, there were 34 female and 73 male participants, with an average age of 32.85 (SD 10.10) years. Some participants continued recording snacking for an additional 6 to 11 days after reaching the 28-day target and after receiving the completion message. These additional data were used in the analyses. Overall, the total number of recordings across all participants was 5391, which reduced to 4978 data points after data cleaning. There were some positive comments about the study in general. For example, participants mentioned that recording their snacks made them aware of the amount consumed daily and helped them reduce food intake.

There were 413 missing and duplicate entries in the UK dataset. Regarding duplicates in the UK dataset, when participants recorded their snacking instances, they might have pressed the submit button twice, which resulted in 2 instances of the same event. However, such duplicate instances were few (approximately 7.7%). In each participant, the total number of recorded snack instances ranged from 7 to 157.

The Dutch dataset included 3705 data points. In each participant, the number of recorded snack instances ranged from 6 to 348. Demographic and other characteristics of the Dutch dataset can be found in the original publication [28].

The sizes of the training and testing sets were 3982 and 996, respectively, in the UK dataset and 2778 and 927, respectively, in the Dutch dataset.

We noted that normalization slightly enhanced the results from the LSTM model but not the FFNN model.

Model Results

Table 2 and Figure 6 show the MAEs for the 4 models using all input features. In brief, the RFreg model performed very poorly with the UK dataset using 4 time bins. In contrast, the XGBreg, FFNN, and LSTM models all demonstrated reasonable performance with the UK dataset using 4 time bins, achieving lower MAE values and indicating better predictive ability compared to the RFreg and baseline (grand mean) models. When using 12 time bins for the UK dataset, all 4 models performed relatively similarly and demonstrated satisfactory performance. It is not possible to compute significance values from MAE differences in such an ML analysis. This is because to compute statistical significance, some knowledge of the sampling distribution of MAE differences is needed if the null hypothesis (there is no structure in the time series) is true, which is not possible. The best guide for the interpretation of MAE values is the MAE of the baseline (grand mean) model.

Figure 6. A graphical illustration of the relative performance of the machine learning algorithms (random forest regressor [RFreg], Extreme Gradient Boosting regressor [XGBreg], feed forward neural network [FFNN], and long short-term memory [LSTM]) for predicting consumption of snacks with high saturated fats, salt, or sugar in the UK and Dutch datasets and using 2 different approaches for partitioning time. Performance is quantified using the average mean absolute error (MAE) values from Table 2 (lower values are better). The error bars indicate the IQR. LR: logistic regression; RF: random forest; XGBoost: Extreme Gradient Boosting.

For the Dutch dataset, errors were high. The FFNN model was the best performing model when using both 4 and 12 time bins. The training MAE for the FFNN model was much higher than the testing MAE, suggesting underfitting of data but good generalization. To assess whether the training MAE can be reduced, regularization and early stopping with the FFNN model were employed for the Dutch dataset.

The results can be explored in 2 ways. First, the scatter plots of residuals can be considered for the best performing version of each model. For most noisy processes, the default expectation is that residuals should be evenly distributed around zero, with the spread of the residuals dependent on the amount of noise and the quality of the model. A narrow spread of residuals around zero is generally indicative of good quality predictions [55]. Model residuals with scatter plots are presented in Multimedia Appendix 2. Overall, nonlinear models, particularly random forest, XGBoost, and FFNN, show the most potential for accurately predicting the time until the next HFSS snack, with the predominance of positive residuals being advantageous for just-in-time interventions (since positive residuals indicate that the prediction is earlier than the actual event).

Second, feature importance can be examined in the prediction task. Although there were only 3 features for prediction (time bin, location, and day of the week) and all of them appeared important, there might be enough information for prediction after eliminating day of the week or location. Feature importance analysis is one way to proceed in this case, but because of the approach used for model fit (individually for each participant), this was deemed impractical. Therefore, instead, we carried out 2 feature ablation analyses, one for location and another for day

XSL•FO
RenderX

of the week. For the UK dataset, both these features appeared essential for the prediction task, since eliminating either one of them reduced model performance quite substantially (without either of the features, model performance became equivalent to that of the grand mean model) (Tables 3 and 4). On the other hand, for the Dutch dataset, the reduction in model performance in the ablation analyses was milder, indicating that prediction could be based on a subset of the available features.

Table 3. Location ablation analysis of the machine learning algorithms for predicting consumption of snacks with high saturated fats, salt, or sugar in the UK and Dutch datasets.

An alternative, exploratory analysis is presented in Multimedia Appendix 3, which illustrates a different way to use the present data. This involved a sensitivity/specificity analysis, and the focus was to predict unhealthy snacks within windows of a certain size. This analysis was arguably better suited to the specific goal of building JITAIs. It was framed as a timing analysis for the delivery of a hypothetical intervention, which involved testing whether predicted snacking times fell within time windows of 120, 60, and 30 minutes before the actual HFSS snack time. This analysis was carried out only for the FFNN model, because FFNN residuals were notably positive and thus indicated early predictions, which is a desirable property for JITAIs. We briefly summarize the results from this analysis on individual behavior. Assuming the delivery of an intervention 45 minutes before a predicted snack, 90% of predictions would occur within a 1-hour window before the actual snack for the UK dataset and the Dutch dataset. If the acceptable window between the intervention and snack is reduced to 30 minutes (and the intervention is delivered 20 minutes before the prediction), the accuracy would be 75% and 74% for the UK dataset and the Dutch dataset, respectively.

Discussion

Principal Findings

Interventions can be made more effective by delivering messages at the right time before the target behavior is performed, as is the case with JITAIs (eg, [17,18]). ML can in principle help. The goal of this study was to design an app to collect data on HFSS snacking behavior in order to explore the capacity of well-known ML methods to capture the underlying statistical structure.

Over a period of 4 weeks, 111 participants provided data on HFSS snacking, using our Snack Tracker app, and this was considered the UK dataset. In addition, we analyzed an analogous dataset from the Netherlands (100 participants with a varying weight status), which was considered the Dutch dataset. In both cases, a number of preprocessing steps were carried out. We considered dividing a regular day into 4 and 12 time bins. We explored 4 established ML models, namely RFreg, XGBreg, FFNN, and LSTM, in the 2 datasets for predicting the number of minutes to the next HFSS snack (given the time bin in which HFSS snacking occurred) in each participant separately. The models were able to predict the time until the next HFSS snack with reasonable accuracy (the MAE was low

XSL•FO
RenderX

at about 17 minutes in the UK dataset and was 130 minutes in the Dutch dataset). Although errors of 130 minutes (more than 2 hours) may appear large, this finding should be evaluated in the context of behaviors that themselves might occur only once every several hours. In many cases, prediction on the basis of the grand mean was inferior, demonstrating that the models were able to extract some regularity from the data. The residual analysis revealed reasonably narrow distributions, with desirable (in most cases) properties, such as positive residuals. Positive residuals mean that the prediction of the next HFSS snack is before the actual event, making them preferable (compared to negative residuals) for JITAIs. It would have been nice to offer a simple summary conclusion regarding which model performed better. Although there was some evidence that the FFNN model was overall superior, this was based mostly on the Dutch dataset. It makes sense to be cautious about overall model adequacy, and more analyses like the present ones are needed.

Strengths

A strength of the study is the use of 2 datasets involving different populations, sampling approaches, and data collection methods. However, there is concern regarding the difference in MAE values between the UK and Dutch datasets. This may be attributed to differences in participant selection criteria between the 2 datasets. In the UK dataset, participants were selected based on their reported frequency of unhealthy snacking, and specifically, those who consumed two or more unhealthy snacks daily were considered. This likely led to a more homogeneous group in terms of snacking behavior, contributing to the lower MAE values. On the other hand, the Dutch dataset had a broader participant base without prior assessment of the snacking habit. The Dutch dataset included both people with a healthy weight and those who were overweight, but the UK dataset did not select participants based on BMI and instead included participants who consumed two or more unhealthy snacks daily. There were also differences in methodology and sampling techniques, which might have led to differences in the variability of snacking behavior and thus the capacity of the ML algorithms to perform well. Another point concerns the difference in the cultural context and how this might impact snacking behavior. For example, people in the United Kingdom (vs those in the Netherlands) eat less fruit (295 g vs 461 g per day; Food and Agriculture Organization of the United Nations, 2023) and are more likely to experience obesity (30% vs 23% of adults) [56].

Overall, there were several potential differences between the Dutch and UK datasets, and examining the performance of the ML algorithms separately for each dataset was an interesting exercise. Conversely, considering the range of differences mentioned above, there was little justification for combining the 2 datasets into a single analysis.

A major difference between the UK and Dutch datasets was related to the dependence on the additional features of location and day of the week over and above the main prediction feature of time bin. While prediction dropped substantially after eliminating either of these 2 additional features in the UK dataset, this was not the case in the Dutch dataset (prediction was equivalent with and without the 2 features). It is possible that location coding in the Dutch dataset was less accurate than that in the UK dataset. In the UK dataset, we specifically asked for location in terms of home, work, or other, which corresponded exactly to the feature coding in the analyses, but in the Dutch dataset, the location variable had to be derived from other data. However, this is a fairly weak reason (there is reasonable confidence in how the location variable was coded in the Dutch dataset), and in any case, this argument does not apply to the day of the week feature. More generally, there might have been more variation in the contextual cues that drive HFSS behavior between the 2 countries. At a preliminary level, it could be argued that the food environments between the 2 countries are broadly similar, but clearly, this is a possibility that cannot be addressed without further work.

From a technical point of view, a feature of the present approach is that the choice of methods represents relevant ML models for this type and size of dataset, without an attempt to develop a customized approach. Our emphasis was on how good prediction can be with standard ML algorithms. It is therefore interesting that the selected models mostly outperformed the baseline grand mean model. Models based on decision trees (XGBoost and random forest) performed competitively in predicting the next HFSS snack, but overall, neural networks (FFNN and LSTM) performed somewhat better. This finding may change with an increase in the number of data points, as neural networks, particularly deep ones, benefit greatly from large datasets. Moreover, there are alternative neural network models that merit examination, such as the Gated Recurrent Unit network, which is fast, requires little memory, and sometimes has better performance than LSTM [57]. One direction for future work is to determine how to use the characteristics of the present modeling challenge (such as sparsity) to fine-tune learning algorithms.

Limitations

There are several technical challenges that need to be mentioned. First, behaviorally, for many users, it is difficult to commit to providing data for a long time, before interesting predictions are made. Even if most information is passively obtained, there would still be a small burden to record snacks. Therefore, it is worth exploring online ML, whereby data streams are used to continuously update a model. Another approach is to entirely obviate the need for user input through the use of sensor data combined with ML (digital phenotyping work mentioned earlier, eg, [30,31]). For example, Bangamuarachchi et al [58] reported some promising results concerning the identification of eating and noneating events, using only passive smartphone data (also see the study by Chen et al [59]). An important future direction would be to compare the quality of prediction from data collected actively versus passively, though the 2 approaches should not necessarily be seen in competition (eg, sensor data could be employed to validate active data entry).

The issue of recording snacks has another facet in terms of the change potential stemming from awareness of a behavior [11]. While this is a desirable effect of data collection (and indeed consistent with other research, eg, research in alcohol abuse; see the study by Pimpini et al [11]), it is a complicating factor regarding the validity of the dataset in that observation of the behavior impacts the behavior itself. However, it is very

XSL•FO
RenderX

difficult, if not impossible, to disentangle such factors from the general variability in behaviors, such as HFSS snacking, which are inherently stochastic and subject to change from random environmental changes (eg, periods of stress or going on holiday). There is a profound challenge here, which goes beyond current standard practice in ML.

Second, a related challenge is that of data sparseness. ML models work better with more data. With a larger sample, it might be possible to examine whether there are natural groupings in HFSS snacking behavior, defined by, for example, demographic characteristics, personality traits, physiological differences, or eating behavior traits (eg, [60-63]). Different groups of this kind might display higher regularity in the HFSS eating behavior. Thus, categorizing a new participant against a pre-existing classification of individuals might inform our confidence of how well one can predict the behavior of that participant (eg, see Study II in the report by Spanakis et al [28]). Currently, the form of such a classification is unclear. Researchers could rely on ML to identify appropriate aspects and then attempt to interpret them against eating behavior characteristics.

Third, there is a question of whether the sample size was adequate. We have already mentioned the lack of established guidelines on sample size to achieve particular levels of sensitivity in ML work [46], as well as noted research similar to ours with similar sample sizes (eg, Spanakis et al [28]). Nonetheless, given the limitations in sampling, it can be questioned whether the present sample is sufficiently representative of the general population. Participants were recruited through Prolific Academic, which is one of the most widely employed crowd-sourcing platforms for behavioral experiments. Their age characteristics and gender balance revealed no peculiarities. The recruited participants were biased toward those who consume more HFSS snacks and those with enough technology familiarity to use our app. Nonetheless, they represent participants who would take part in future interventions, based on the kind of HFSS snacking prediction considered here.

Fourth, in this work, we only employed day of the week, time, and location (coarsely coded). In contrast, the studies by Arend et al [25], Forman et al [26], and Spanakis et al [28] are all sophisticated examples of similar predictive modeling but based on more information. The use of a greater number of features has the potential for more accurate prediction. Regarding HFSS snacks, the times of meals and drinks are particularly pertinent. However, we wanted to explore the predictive potential based on information that would be as straightforward as possible for participants to provide. The motivation for such an approach is that any scheme suitable for roll-out to the general population would benefit from being as unobtrusive as possible in terms of requests for information. In our app, location required participant input, but in future iterations, this feature could be automated through simple look-up tables involving geolocation data and the prerecorded locations of particular users for work, home, etc. Additional information that could be recorded automatically include sensor data from sophisticated smartwatches, such as heart rate, blood pressure, and possibly blood sugar, or whether the individual is alone or with company. There could be a tradeoff here among predictive power, usability, and participant fatigue, which will require more work before clarification.

A related point is whether an autoregressive approach might be more fruitful. Our analyses were based on taking all time bins in which there were snacks and trying to predict the time (minutes) to the next snack (given the time bin, location, and day of the week). What if *all* time bins are considered as input for the models, regardless of whether there is a snack, and the presence of a snack is used as an additional feature? In brief, such an approach does not work with the present data. The likely problem is the sparseness of snacking bins relative to no-snacking bins, and thus, the dataset is skewed toward the latter. This kind of data skew is a recognized problem in ML, leading to poor performance of ML models [64]. Such problems from undersampling of snacking instances might be mitigated in larger datasets.

Fifth, the possibility of using more extensive sensor data goes hand in hand with the intriguing suggestion to individualize the ML approach [65]. There are merits and demerits for both collecting more data per participant (to allow, for example, individualization) and adopting a more general approach with minimal data collection per participant (Spanakis et al [28] provide a discussion of the tradeoff between individualization and generality). It is worth noting, however, that even with the present minimal data collection and a general approach to ML, it was possible to achieve reasonably low prediction errors.

Sixth, HFSS snacking behavior is not necessarily stable and might vary depending on factors such as the time of the year. Accordingly, an ML approach would need to be able to adapt to any changes in behavior. The difficulty then is how to distinguish between routine deviations in baseline behavior and changes in the behavior itself. Online ML might again offer promise in addressing such a challenge [66]. These considerations also challenge a perception that perhaps it would be more appropriate to base predictions on stationary data.

Challenges like those mentioned above are not independent of the goal of the prediction. Arguably, if the purpose of prediction is to carry out an intervention, it may be valuable to know not only the time of an HFSS snacking event, but also additional variables, such as whether particular emotions preceded a snacking event. Currently, for the reasons outlined above, it seems unlikely that a practical method (ie, beyond research) based on multiple variables or EMAs can be developed, but future personal electronic devices may make the collection of the data possible. Participants are likely to engage with intensive data-collection procedures if they are sufficiently motivated to accomplish goals related to dietary change, weight reduction, etc.

Conclusions

The examination of standard ML algorithms produced promising findings concerning the prediction of HFSS snacking based on sparse data involving only previous occasions of such snacking behavior. There are promising behavioral implications given that a reasonable degree of predictive accuracy was possible even with limited data (in terms of both features and the window

XSL•FO
RenderX

for data collection). One direction for application concerns using prediction data to deliver behavior change techniques for HFSS snacking behavior (eg, [16,67]). These behavior change techniques could be delivered in several different ways (eg, by text or audio messages) to increase engagement and could also be selected and personalized for the individual. Additionally, the ML work by itself could be applied to other behaviors targeted for reduction, such as smoking and alcohol consumption.

The present results offer a foundation for further exploring how ML methods can be used in health psychology and provide directions for further research, which can be both more technically oriented and focused on behavioral applications and extensions.

Abstract

Background: Long-term ventilator-dependent patients often face problems such as decreased quality of life, increased mortality, and increased medical costs. Respiratory therapists must perform complex and time-consuming ventilator weaning assessments, which typically take 48-72 hours. Traditional disengagement methods rely on manual evaluation and are susceptible to subjectivity, human errors, and low efficiency.

Objective: This study aims to develop an artificial intelligence–based prediction model to predict whether a patient can successfully pass a spontaneous breathing trial (SBT) using the patient's clinical data collected before SBT initiation. Instead of comparing different SBT strategies or analyzing their impact on extubation success, this study focused on establishing a data-driven approach under a fixed SBT strategy to provide an objective and efficient assessment tool. Through this model, we aim to enhance the accuracy and efficiency of ventilator weaning assessments, reduce unnecessary SBT attempts, optimize intensive care unit resource usage, and ultimately improve the quality of care for ventilator-dependent patients.

Methods: This study used a retrospective cohort study and developed a novel deep learning architecture, hybrid CNN-MLP (convolutional neural network–multilayer perceptron), for analysis. Unlike the traditional CNN-MLP classification method, hybrid CNN-MLP performs feature learning and fusion by interleaving CNN and MLP layers so that data features can be extracted and integrated at different levels, thereby improving the flexibility and prediction accuracy of the model. The study participants were patients aged 20 years or older hospitalized in the intensive care unit of a medical center in central Taiwan between January 1, 2016, and December 31, 2022. A total of 3686 patients were included in the study, and 6536 pre-SBT clinical records were collected before each SBT of these patients, of which 3268 passed the SBT and 3268 failed.

Results: The model performed well in predicting SBT outcomes. The training dataset's precision is 99.3% (2443/2460 records), recall is 93.5% (2443/2614 records), specificity is 99.3% (2597/2614 records), and F_1-score is 0.963. In the test dataset, the model maintains accuracy with a precision of 89.2% (561/629 records), a recall of 85.8% (561/654 records), a specificity of 89.6%

XSL•FO
RenderX

(586/654 records), and an F_1-score of 0.875. These results confirm the reliability of the model and its potential for clinical application.

Conclusions: This study successfully developed a deep learning–based SBT prediction model that can be used as an objective and efficient ventilator weaning assessment tool. The model's performance shows that it can be integrated into clinical workflow, improve the quality of patient care, and reduce ventilator dependence, which is an important step in improving the effectiveness of respiratory therapy.

KEYWORDS

ventilator; ventilator weaning; respiratory therapy; intensive care unit; artificial intelligence; deep learning; neural networks; spontaneous breathing trial

Introduction

According to statistics from the National Health Insurance Administration, Taiwan saw an increase of 175,148 patients dependent on ventilators in 2017, with 70% of intensive care unit (ICU) patients requiring ventilator support. This significant trend in ventilator usage persists in Taiwan, irrespective of its impact on ongoing health crises. The current medical practice requirements involving ventilator use include initiating ventilator support, conducting spontaneous breathing tests, and assessing readiness for ventilator weaning. In practical terms, respiratory therapists must perform a ventilator weaning assessment before a spontaneous breathing trial (SBT). This process is complex, meticulous, time-consuming, and spans a period of 48-72 hours. In other words, successful weaning from a ventilator for patients depends on passing an SBT.

In retrospective studies [1,2], confirming whether all patients receive the same SBT strategy is essential based on the specific study design. SBT strategies typically include fixed pressure support (PS) and positive end-expiratory pressure (PEEP). In this paper, the study's SBT strategy was set at a PS of 10 cm H_2O and a PEEP of 5 cm H_2O, lasting 2 hours. A successful SBT is generally defined as the patient's ability to maintain a stable respiratory state during the trial without mechanical ventilation support and be safely extubated at the end of the trial. An unsuccessful SBT is defined as a patient experiencing respiratory distress, hypoxemia, hypercapnia, or other conditions requiring the reinitiation of mechanical ventilation during the trial.

Conventional weaning criteria often involve manual selection, with therapists assessing patients based on their responses to a ventilator weaning assessment form to determine if they are eligible for an SBT. However, previous studies have explored the use of information systems to automate ventilator weaning assessments, revealing that this approach can reduce ventilator usage time and enhance the efficiency of respiratory therapists [3]. Research also suggests that automated weaning protocols may decrease the weaning period, theoretically surpassing the need for manual weaning [4,5]. Studies have investigated consciousness status, oxygenation, ventilation modes, and airway protection strategies [6]. Reducing ventilator usage time, weaning time, and ICU stay has been discussed [7]. At the same time, certain elements that cannot be automated in the weaning process have been pointed out [8]. Daily screening methods have effectively decreased dependence on ventilators [9].

Recently, numerous studies have investigated the impact of SBT, including assessing the relationship between end-expiratory lung volumes during SBT and successful ventilator weaning [10]. Some studies have suggested considering respiratory rate (RR) and ventilation time in patients intubated in the ICU for more than 72 hours before extubation after passing an SBT [11]. In different populations, research has cautioned against using an SBT to assess the appropriate timing of extubation for premature infants [12]. Additionally, studies have proposed methods for evaluating extubation in neonates through minimal pressure SBTs [13], by measuring diaphragmatic electrical activity in premature infants to predict extubation success [14], and investigating optimal duration and reasons for failure in pediatric SBTs, noting that a 30-minute SBT may be too brief for pediatric acute respiratory distress syndrome patients in the recovery phase [15]. The impact of SBT on extubation success and prognosis in patients diagnosed with acute exacerbation of chronic obstructive pulmonary disease has been evaluated [16]. On another note, some studies have used oxygen saturation as a crucial indicator for predicting SBT success or failure [17].

However, the factors affecting SBTs and ventilator weaning are diverse and include age [18-20], weaning prediction parameters, sputum volume, cough strength, and consciousness status [21-23], as well as ventilator usage time, disease severity (acute physiology and chronic health evaluation II), and patient nutritional status. Patients experiencing difficult or delayed weaning are often presented with a combination of factors, thus requiring careful assessment by health care professionals. Due to the complexity of patient weaning from ventilators, numerous studies have explored various aspects. For instance, the impact of adding different doses of sedatives (ketamine) on spontaneous breathing patients [24], the correlation between microcirculation during SBTs and successful extubation [25], and for patients passing an SBT, a spontaneous awakening trial could serve as a predictive factor for extubation on the same day. It has also been noted that a higher Richmond Agitation Sedation Scale, no sedative administration on the previous day, no infections, and the absence of neurological diseases or hemodynamic instability increase the chances of extubation on the same day [26].

XSL•FO
RenderX

Using varied SBT strategies can affect outcomes in different studies [27,28]. These differences primarily manifest in several aspects, such as the level of PS, PEEP settings, continuous positive airway pressure (CPAP) use, and the T-piece trial. The level of PS directly impacts the patient's ability to breathe spontaneously. Higher PS, such as 10 cm H_2O, reduces the patient's breathing effort, potentially leading to a higher SBT success rate. However, this may not fully reflect the patient's breathing capacity at lower support levels. The setting of PEEP affects alveolar stability and airway pressure. Different PEEP settings, such as 5 cm H_2O, can have varying impacts on a patient's oxygenation and respiratory dynamics, thereby altering the outcomes of the SBT. CPAP provides continuous positive PS, helping to reduce the work of breathing. Conducting an SBT with CPAP at 5 cm H_2O may make it easier for patients to pass the trial. However, compared to PS strategies, this might offer a different assessment of the patient's respiratory muscle function. The T-piece trial provides no PS, relying entirely on the patient's spontaneous breathing ability. This strategy more accurately reflects the patient's autonomous breathing capacity but may result in a lower SBT success rate due to higher demands on the patient.

Given these differences, it is crucial to recognize how varying SBT strategies can influence the interpretation and comparison of study outcomes. The choice of SBT strategy can significantly affect clinical decisions and patient management. Therefore, understanding the potential impacts of different strategies is essential for improving patient care and optimizing treatment protocols.

Different SBT strategies will lead to varying SBT success rates. Higher PS or the use of CPAP might result in higher success rates, while the T-piece trial might lead to lower success rates. Variations in SBT strategy might also affect postextubation outcomes. If an SBT strategy makes it easier for patients to pass the trial, it could increase the risk of postextubation respiratory distress or the need for reintubation. Due to the different SBT strategies used in various studies, caution is needed when directly comparing study results. The potential impacts of strategy differences on outcomes should be considered.

Artificial intelligence (AI) integrated with health care aims to predict disease diagnosis or prevention through medical alerts. In the current trend of AI applications, incorporating physician expertise into the training of predictive models can provide appropriate treatment for high-risk patients [29]. AI applications in health care include medical robots, AI intelligent diagnosis and image recognition, intelligent drug development, and intelligent health management. Intelligent health management applies AI technology to daily health management, focusing on risk identification, virtual nurses, mental health, web-based consultations, and precision medicine-based health management. Certain studies have used deep learning combined with random forest for risk prediction. One study constructed and validated machine learning models to predict unplanned extubation in ICU patients using electronic health record (EHR) data [30]. Another study developed machine learning algorithms to predict the likelihood of successful weaning from mechanical ventilation using clinical and laboratory data obtained before or shortly after intubation [31]. Recent developments have also explored using reinforcement learning to optimize ventilator management. Using real-world ICU data, a reinforcement learning–based model, EZ-Vent, was proposed to dynamically adjust ventilator settings such as PEEP, FiO_2 (fraction of inspired oxygen), and tidal volume [32]. A broader review further emphasized the potential of reinforcement learning as a clinical decision support tool in the ICU, highlighting its application in optimizing mechanical ventilation and predicting outcomes related to SBTs [33]. By way of explanation, the introduction of AI can process more significant amounts of data faster, achieve higher accuracy, and assist in decision-making without medical staff experiencing fatigue, thereby implementing intelligent health care models.

The main objective of this study was to develop an AI-based prediction model to predict the outcome of an SBT under a specific SBT strategy using a pre-SBT clinical record gathered just before a patient's SBT. The proposed model is trained and validated based on pre-SBT clinical records to ensure that the model can predict whether an SBT will succeed under a fixed SBT strategy. The proposed model can provide clinicians with an objective and reliable decision-making aid to reduce the subjectivity and errors of traditional manual judgment. The ultimate goal is to facilitate timely and effective clinical decision-making, optimize the weaning process from the ventilator, and improve ICU management efficiency.

Methods

Data Source

The respiratory information system database of Taichung Veterans General Hospital served as the data source for this study. We covered the research period from January 1, 2016, to December 31, 2022. We conducted a retrospective case review, including patients aged 20 and older admitted to the ICU during this period. The data were accessed on April 7, 2023, for research purposes. The clinical data were collected from 3686 patients, comprising 6536 pre-SBT clinical records gathered just before each SBT of patients. Among these records, 3268 passed the SBT, while the other 3268 did not pass. Each clinical record includes 2 demographic variables, 7 respiratory parameters, and 5 vital signs, as detailed below (Textbox 1).

The pre-SBT clinical records serve as input features for model training and prediction. These input features comprehensively represent the patient's respiratory and physiological status, providing critical information for the model to assess SBT outcomes effectively. In total, 80% (5228/6536 records) were allocated for training, while the remaining 20% (1308/6536 records) were reserved for testing. In addition, the division process of the training and test datasets follows a random split strategy to ensure that the proportions of different categories (those who passed and failed SBT) remain balanced to avoid bias in the model.

RenderX

Textbox 1. Details of clinical record.

- Age—Patient's age
- Gender—Patient's gender
- FiO_2 (%)—Fraction of inspired oxygen, indicating the percentage of oxygen the patient is inhaling
- PaO_2 (mm Hg)—Partial pressure of oxygen in arterial blood
- VTe (exhaled VT) (mL)—Exhaled tidal volume per breath
- Measured respiratory rate (bpm)—Measured respiratory rate, defined as breaths per minute
- Paw (cm H_2O)—Peak airway pressure, the highest pressure reached during inhalation
- MAP (cm H_2O)—Mean airway pressure, representing the average pressure in the airways over the respiratory cycle
- MVe (exhaled MV)—Minute ventilation, the total volume of air exhaled per minute
- Heart rate (bpm)—Number of heart beats per minute
- Systolic blood pressure (mm Hg)—Blood pressure during heart contraction
- Diastolic blood pressure (mm Hg)—Blood pressure during heart relaxation
- SpO_2 (%)—Oxygen saturation, indicating the percentage of oxygenated hemoglobin in the blood
- Body temperature (°C)—Core body temperature of the patient

Ethical Considerations

This study was reviewed and approved by the institutional review board (IRB) of Taichung Veterans General Hospital (IRB number: CE23123A), in accordance with institutional and national ethical standards for human subjects research.

The study involved a retrospective analysis of clinical data. All patient data were fully anonymized prior to access and analysis to ensure privacy and confidentiality.

Given the study's retrospective nature and the anonymization of all data, the IRB waived the requirement for informed consent.

No compensation was provided, as no direct contact with participants occurred, and no new data were collected.

Spontaneous Breathing Test and Ventilator Weaning Assessment

The successful determination of an SBT was defined as a patient undergoing a spontaneous breathing test for 2 hours with the ventilator mode PS level set at 10 cm H_2O and PEEP set at 5 cm H_2O. Additionally, the patient had to meet the Wean Score criteria to be considered a successful SBT. Therefore, this study included model analysis based on the following inclusion criteria (Textbox 2).

Textbox 2. Inclusion and exclusion criteria.

Inclusion criteria

- Pressure support (PS) level set at 10 cm H_2O and positive end-expiratory pressure (PEEP) set at 5 cm H_2O.

Exclusion criteria

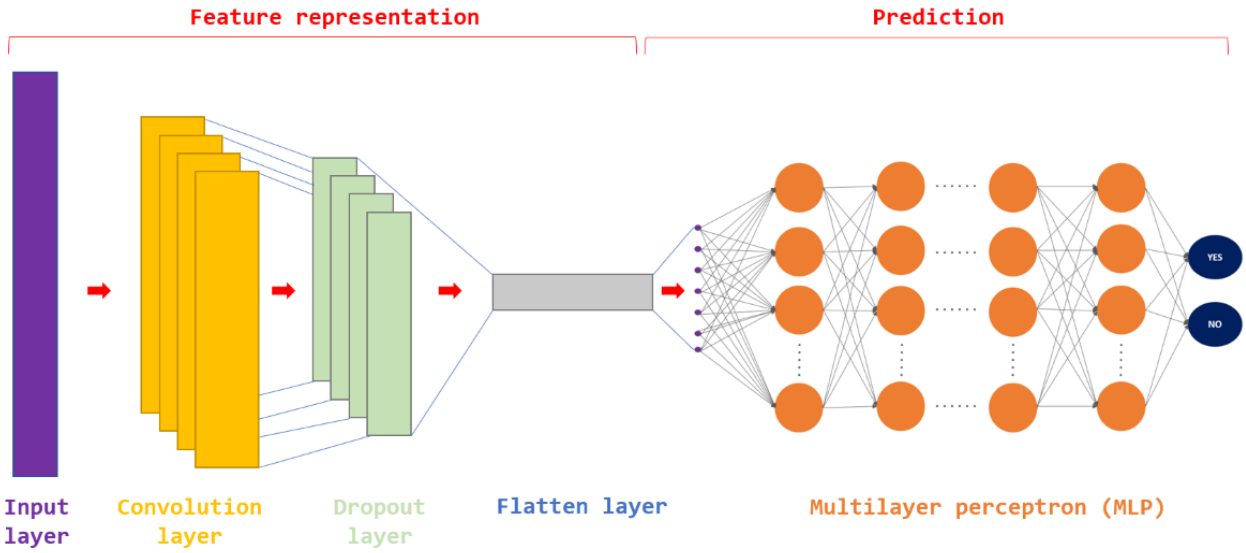
- PS level greater or PS level less than 10 cm H_2O, and PEEP greater or less than 5 cm H_2O.

Model Design

Given the constant advancements in technology, machine learning has now become widely used, primarily due to the effectiveness of information products. As a subset of data science, machine learning is now being further extended through the branch of deep learning. Therefore, we can generate models from extensive data through machine learning and develop predictions for various outcomes using existing data.

Deep learning is an algorithm centered within machine learning that focuses on representation learning from data. Several deep learning architectures exist, including deep belief networks, recurrent neural networks, and convolutional neural networks (CNNs). CNNs, a highly representative data-driven architecture, require large, high-quality datasets for effective model training. Data augmentation, transfer learning from pretrained models, and semi-automatic annotation are often used to address this issue. In the training phase of this study, multiple training datasets were prepared, each including the status feature inputs and corresponding outputs from various investigations of the study cases. CNNs succeed in image recognition and object detection because they can automatically extract spatial hierarchical features from images. Although this study does not include direct visual data, the characteristics of CNNs make it suitable for processing structured nonvisual data [34]. For instance, the convolutional layers of CNNs excel at capturing local patterns and correlations within the data, irrespective of whether these patterns come from spatial features in images,

XSL•FO
RenderX



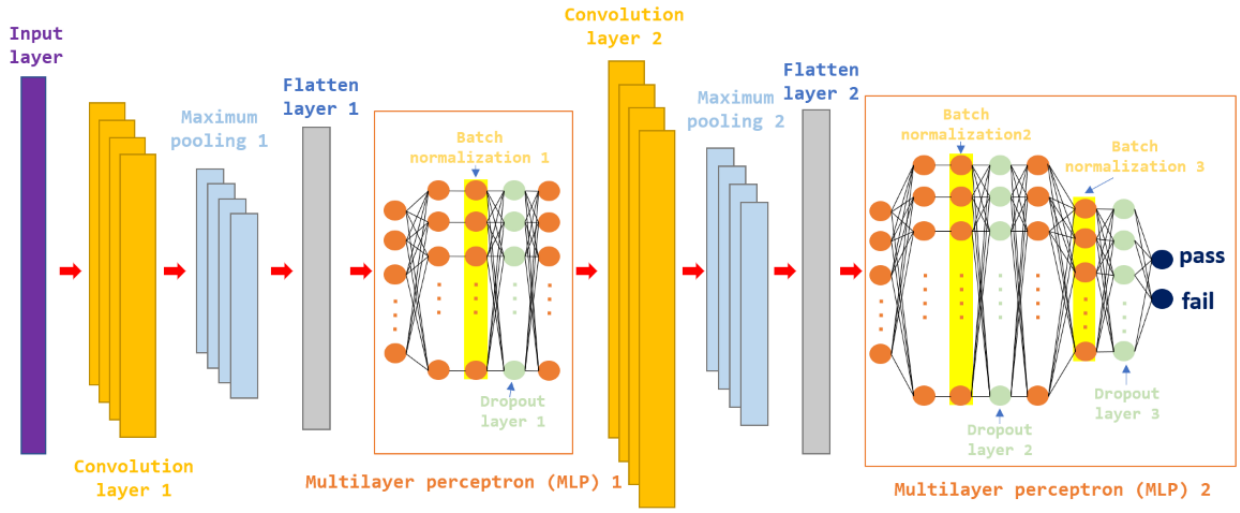
structural features in time-series data, or multidimensional matrices. We used a deep CNN to learn the features of older adults' mental health before storing them in the network. Challenges in this process include preparing training data and designing learning algorithms. Subsequently, we tailor a learning algorithm suitable for the characteristics of the training data [35,36].

At the initial stage, the neural network is assigned random weight values, with its output differing significantly from the standard answer. After multiple learning iterations, the weights gradually adjust in the correct direction, resulting in a better or more accurate prediction. Given the multitude of feature factors influencing the prediction results of ventilator weaning, finding appropriate or correct features amongst the numerous characteristics is highly challenging.

Using the learning characteristics of deep learning, the model can autonomously deduce the characteristics of feature factors from the training data, thereby establishing a highly accurate prediction model. Figure 1 illustrates the architectural layout of the traditional CNN-MLP (convolutional neural network–multilayer perceptron) model. The model design begins with the input layer having the same number of neurons as the dimensions of the dataset. Subsequently, it connects to multiple convolutional layers, with pooling layers interspersed between them. Their primary function is to extract key features from the training data autonomously. Finally, the network concludes with a fully connected multilayer perceptron (MLP), transforming these features into 2 outputs. Selecting appropriate model initialization parameters is crucial for both the stability and convergence of training.

The optimization of the CNN model's ideal architecture is influenced by the task's complexity and the dataset's features. Since deep learning is primarily based on empirical learning methods, the efficiency of CNN models often stems from practical testing and iterative adjustments. The results of preliminary models can also serve as reference points for measuring performance improvements.

Figure 1. Architecture diagram of traditional CNN-MLP model. CNN: convolutional neural network.



In this study, we proposed a novel deep learning architecture, hybrid CNN-MLP, to predict the outcome of an SBT. Figure 2 depicts the proposed hybrid CNN-MLP model architecture in this study. Unlike the traditional CNN-MLP classification method, hybrid CNN-MLP performs feature learning and fusion by interleaving CNN and MLP layers so that data features can be extracted and integrated at different levels, thereby improving the flexibility and prediction accuracy of the model.

This study begins with a simple framework for the hybrid CNN-MLP design, gradually increasing its complexity by adjusting the number of layers and neurons. Starting with a straightforward structure accelerates training and evaluation, streamlining the continuous refinement of the hybrid CNN-MLP model. The hybrid CNN-MLP model architecture is explained as follows (Textbox 3).

XSL•FO
RenderX

Figure 2. Architecture diagram of the hybrid CNN-MLP model. CNN: convolutional neural network.

Textbox 3. Hybrid CNN-MLP (convolutional neural network–multilayer perceptron) model architecture.

The first CNN module

- Convolutional layer (14×64): the input channels are 14, the output channels are 64, and convolutional feature extraction is performed.
- Maximum pooling layer (kernel_size=2, stride=2): dimensionality reduction to retain the main features and reduce the amount of computation.

MLP (fully connected layer)

- Flatten layer: flatten the features extracted by CNN so that they can be input into the fully connected layer.
- Linear layer (64×128): fully connected layer with output dimensions of 128.
- Batch normalization layer (128): Stabilizes the training process.
- Dropout layer (*P*=.50): randomly inactivate 50% of neurons to prevent overfitting.
- Linear layer (128×128): fully connected, keeping the same dimension.

The second CNN module

- Convolutional layer (128×64): performs the convolution operation again.
- Maximum pooling layer (kernel_size=2, stride=2): reduces the dimension again to improve the generalization ability of the model.

The second phase of MLP

- Flatten layer: flatten into a vector for feeding into the MLP layer.
- Linear layer (64×256): fully connected layer with output dimensions of 256.
- Batch normalization layer (256): batch normalization to improve training stability.
- Dropout layer (*P*=.50): prevent overfitting.
- Linear layer (256×64): fully connected layer, reducing the dimension to 64.
- Batch normalization layer (64): batch normalization.
- Dropout layer (*P*=.30): reduce overfitting by inactivating 30% of neurons.
- Linear layer (64×2): output layer, the final output is 2-dimensional (probably representing a binary classification problem).

In the network used in this study, the Xavier Glorot initialization method [1] was used to assign weights. This method mitigates potential issues, particularly gradient vanishing or exploding problems in deep networks, by adjusting weights based on the quantity of input and output units. This ensures a smoother and more effective training process.

To avoid overfitting, we adopt multiple strategies to ensure the stability and generalization ability of the model. First, we use L2 regularization (weight decay) to discourage overly complex models from memorizing too much training data. Second, during the model training process, we applied the dropout technology to randomly deactivate some neurons to reduce the overadaptation (coadaptation) between neurons and improve the model's generalization ability. We also adopt the early

XSL•FO
RenderX

stopping strategy to monitor the loss changes of the validation set during training. When the validation loss fails to decrease within several consecutive training cycles, training is stopped to prevent the model from overfitting to the training data. In addition, to ensure that the model is not too complex, we control the number of layers and neurons in the neural network to balance learning and generalization abilities.

Regarding hyperparameter tuning, we conducted multiple experiments to optimize the model performance. First, in terms of learning rate adjustment, we initially set it to 0.001 and used learning rate decay to gradually reduce the learning rate during training to improve convergence stability. For batch size, we tested different values, such as 32, 64, and 128, and finally chose 64 to balance training efficiency and model stability. Regarding the activation function, the hidden layer uses Rectified Linear Unit to solve the gradient disappearance problem, and the output layer uses Softmax for classification. For the optimizer, we tested Adam and Stochastic Gradient Descent and finally chose Adam because it performed best regarding convergence speed and stability. Finally, in terms of network architecture, we tested different numbers of layers and neuron configurations to ensure that the model can effectively learn data features while avoiding overfitting problems caused by excessive complexity.

During the training of the deep learning network model, this study inputs labeled data into the network, uses backpropagation and the Adam optimization algorithm, and adjusts the network weights based on the loss calculated using the binary cross-entropy function. On the other hand, the batch size used in this study is 64, with the model undergoing training for 6000 iterations. Of the dataset, 80% (5228/6536 records) is used as the training dataset, while the remaining 20% (1308/6536 records) is designated as the testing dataset to evaluate the model's performance on previously unseen data. Regular checkpoints and an early stopping mechanism ensure that the model used in this study does not overfit and retains its optimal performance architecture.

This study aims to develop a neural network model suitable for predicting respiratory outcomes. It aims to serve as an assessment standard and prediction tool for respiratory care, thus helping health care professionals provide higher quality health care. In establishing this study's intelligent respiratory care model, the prediction variable is based on the success or failure of the SBT, with relevant respiratory information incorporated into the model training.

Evaluation Indexes

This study aims to develop an AI-based model to predict whether patients can successfully pass an SBT. Since SBT is a key test for whether mechanically ventilated patients can breathe spontaneously, and its prediction results directly affect clinical decision-making, it is crucial to evaluate the model's accuracy. This study adopted a variety of evaluation indicators to ensure the reliability and stability of the model in clinical applications.

When we try to predict whether a patient will successfully pass the SBT, accuracy alone may not be sufficient to evaluate the model's performance fully. Accuracy represents the proportion of all participants correctly predicted and is applicable when the proportion of SBT passes and fails is equal. However, if the data's ratio of successes to failures is unbalanced, focusing only on accuracy may lead to falsely optimistic estimates. For example, if most patients can successfully pass the SBT, and the model only predicts that “all patients will succeed,” although the accuracy may be high, it cannot effectively assist clinical decision-making. Therefore, we use precision and recall to evaluate the model's effectiveness.

Precision measures the proportion of patients predicted by the model to pass the SBT who did. This is crucial to avoid unnecessary SBTs. If the model's precision is too low, it means that among the successful cases it predicts, many patients actually cannot pass the SBT, which may lead to initiating SBT too early, resulting in respiratory muscle fatigue, hypoxemia, and even acute respiratory failure in patients. Therefore, a higher precision ensures that the model has a higher credibility when recommending the initiation of SBT.

Recall (also known as sensitivity) measures how many of the patients who successfully passed the SBT were correctly identified by the model. This has a critical impact on avoiding erroneous prolongation of mechanical ventilation. If the recall rate is too low, it means that many patients who should be able to be successfully weaned are incorrectly predicted to be unable to pass the SBT, causing them to continue to be maintained on mechanical ventilation, which may increase the risk of lung infection or muscle atrophy. Therefore, the higher recall ensures that no patients who can pass the SBT are missed.

In addition to precision and recall, this study also calculates the F_1-score, which is a comprehensive indicator used to balance the trade-off between precision and recall. In clinical decision-making, we hope to ensure that the SBT is successfully passed (high precision) while not missing patients who should be able to pass the SBT (high recall), so the F_1-score can be used as a measure of the overall effectiveness of the model.

Specificity is also an important evaluation indicator, measuring whether the model can correctly identify patients who cannot pass SBT. High specificity indicates that the model is effective in avoiding erroneous attempts to start SBTs in patients who cannot pass SBT. Finally, we also considered the false positive rate (FPR) and false negative rate (FNR) to analyze the model's error prediction pattern further and help clinicians understand the model's performance in different scenarios.

Based on the predictive results of the proposed model, we can obtain the following parameters: true positive, false positive, false negative, and true negative. Details of the evaluation metric formulas are available in Multimedia Appendix 1. The receiver operating characteristic (ROC) curve is an important tool for evaluating the classification ability of a model. It describes the changes in the true positive rate (TPR; recall rate) and FPR of the model at different decision thresholds. When the threshold is lower, the model is more likely to predict positive cases; TPR will increase, but FPR may also increase. When the threshold is higher, the model becomes more conservative, and FPR decreases, but some true positive cases may be missed. The closer the ROC curve is to the upper left corner, the better the classification ability of the model, while the ROC curve on the

XSL•FO
RenderX

diagonal indicates that the classification effect of the model is no different from random guessing.

Area under the curve (AUC) is the area under the ROC curve, with a value range of 0-1, representing the overall classification ability of the model. The closer the AUC is to 1, the more stable the model is at different thresholds and the more effective it is in distinguishing different categories. In the SBT prediction model, a high AUC value means that the model can more accurately distinguish which patients can successfully pass the SBT and which patients still need mechanical ventilation support.

Results

Table 1 presents the study cases' demographic variables, respiratory parameters, and vital signs. Among the cases, the average age of patients is around 67.5 (SD 16.3) years. In the successful SBT group, the average age is 68.5 (SD 15.3) years, while in the failure group, it is 66.5 (SD 17.2) years. Regarding gender distribution, 4091 out of 6536 (62.6%) patients are male. Among them, 1178 of 3268 (36%) patients were in the successful SBT group, while 2913 of 3268 (89.1%) patients were in the failure group.

Table 1. Characteristics of intubated patients in the intensive care unit.

	Case group		
	Successful SBT[a] (n=3268)	Failure of SBT (n=3268)	Total (N=6536)
Demographic			
Age (years), mean (SD)	68.5 (15.3)	66.5 (17.2)	67.5 (16.3)
Gender, n (%)			
Male	1178 (36.0)	2913 (89.1)	4091 (62.6)
Female	2090 (64.0)	355 (10.9)	2445 (37.4)
Mechanical ventilator settings and respiratory function, mean (SD)			
FiO_2[b] (%)	32.9 (6.2)	37.5 (11.8)	35.2 (9.7)
PaO_2[c] (mm Hg)	107.4 (20.2)	109.6 (27.9)	108.5 (24.4)
VTe[d] (exhaled VT; mL)	0.6 (1.7)	0.9 (2.9)	0.8 (2.4)
Measured RR[e] (bpm)	19 (8)	21 (10)	20 (9)
Paw[f] (cm H_2O)	16.3 (1.9)	22.5 (5.2)	19.4 (5.0)
MAP[g] (cm H_2O)	8.3 (1.2)	11.3 (3.2)	9.8 (2.8)
MVe[h] (exhaled MV; Lpm)	8.0 (3.0)	7.9 (2.4)	7.9 (2.7)
Vital signs, mean (SD)			
Heart rate (bpm)	84.9 (16.7)	87.6 (18.9)	86.2 (17.9)
Systolic blood pressure (mm Hg)	126.5 (20.2)	122.7 (22.5)	124.6 (21.5)
Diastolic blood pressure (mm Hg)	71.7 (14.4)	68.1 (15.4)	69.9 (15.0)
SpO_2[i] (%)	99 (2)	98 (3)	98 (2)
Body temperature (°C)	36.5 (0.5)	36.5 (0.6)	36.5 (0.5)

[a]SBT: spontaneous breathing trial.

[b]FiO_2: fraction of inspired oxygen.

[c]PaO_2: partial pressure of oxygen.

[d]VTe: exhaled tidal volume.

[e]RR: respiratory rate.

[f]Paw: peak airway pressure.

[g]MAP: mean airway pressure.

[h]MVe: minute ventilation.

[i]SpO_2: oxygen saturation.

For respiratory parameters, the average FiO_2 is 35.2%, with the successful group at 32.9% and the failure group at 37.5%. The partial pressure of oxygen levels are similar across all groups, with slight variations. The failure group has a higher exhaled tidal volume and measured RR. The peak airway pressure and mean airway pressure are also higher in the failure group than

XSL•FO
RenderX

in the successful group. Minute ventilation shows minimal difference between the groups.

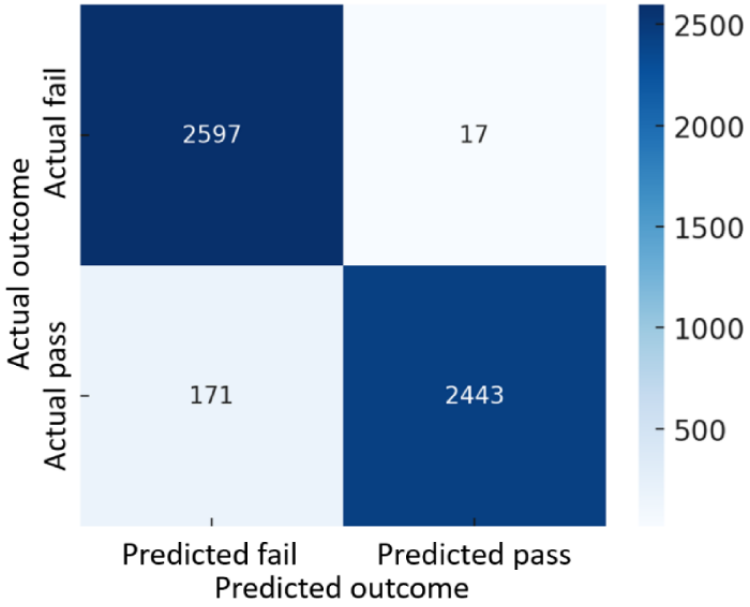
Vital signs indicate that the heart rate is slightly higher in the failure group (87.6 bpm) compared to the successful group (84.9 bpm). Systolic and diastolic blood pressure are lower in the failure group. Oxygen saturation remains high across all groups, with minimal variation. Body temperature is consistent, averaging around 36.5 °C across all groups.

The PyTorch framework in Python is used to construct the proposed model.

In order to present the prediction results of the model more intuitively, this study uses the confusion matrix to show the classification of the model on the training and test datasets. The confusion matrix of the model's prediction results is shown in Figures 3 and 4. The results show that the model performs well on the training data, and the classification ability on the test data remains stable. Although the number of misclassifications increases slightly, it is still within an acceptable range.

Table 2 illustrates the performance metrics of a model for predicting successful and failed SBT across both training and testing datasets.

Figure 3. Confusion matrices for training data.



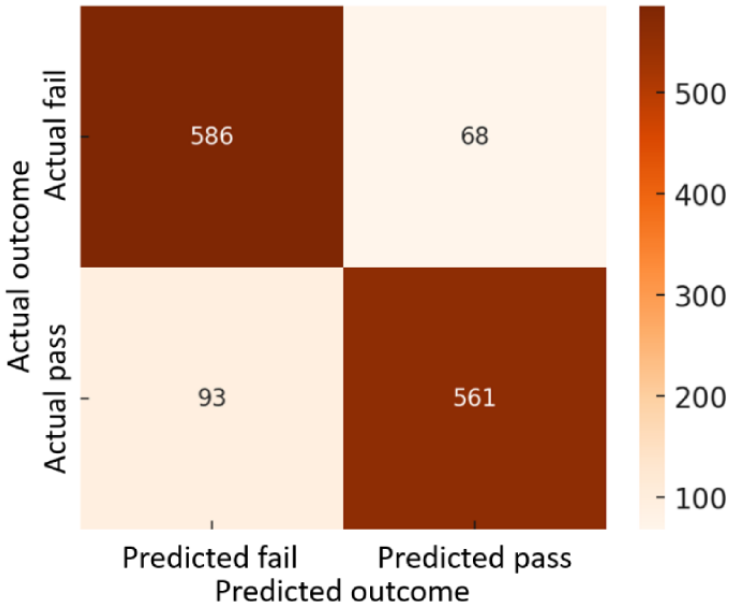


Figure 4. Confusion matrices for testing data.

XSL•FO
RenderX

Table 2. Performance metrics of the spontaneous breathing trial prediction model.

Metric	Training value	Testing value
Accuracy	96.4% (5040/5228)	87.7% (1147/1308)
Precision	99.3% (2443/2460)	89.2% (561/629)
Recall (sensitivity)	93.5% (2443/2614)	85.8% (561/654)
Specificity	99.3% (2597/2614)	89.6% (586/654)
FPR[a]	0.7% (17/2614)	10.4% (68/654)
FNR[b]	6.5% (171/2614)	14.2% (93/654)
F_1-score	0.963	0.875

[a]FPR: false positive rate.

[b]FNR: false negative rate.

Overall, the model's accuracy is 96.4% (5040/5228 records) in the training data and 87.7% (1147/1308 records) in the test data. Although the test results are slightly lower than the training results, they can still maintain a high accuracy, indicating that the model has good generalization ability and no overfitting problem.

Further analysis of the model's performance showed that the precision was 99.3% (2443/2460 records) in the training data and 89.2% (561/629 records) in the test data, indicating that the model had a slightly higher FPR on the test data but was still able to identify patients who could successfully pass an SBT effectively. In other words, in clinical applications, when the model predicts that a patient can pass the SBT, the likelihood of their actual success is still quite high, reducing the risk of unnecessary weaning failure.

However, in terms of recall (sensitivity), the recall rate in the training data was 93.5% (2443/2614 records), while it dropped to 85.8% (561/654 records) in the test data, indicating that some patients who should have passed the SBT in the test data were still not correctly identified. This may result in some patients being wrongly judged as unable to pass the SBT and continuing to receive unnecessary mechanical ventilation, thereby increasing the risk of lung infection or other complications.

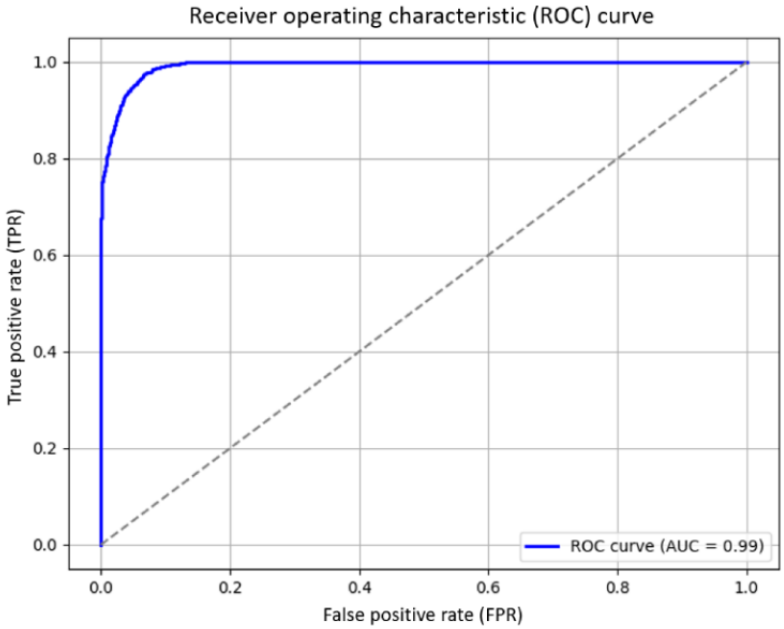
In addition, the specificity was 99.3% (2597/2614 records) in the training data and 89.6% (586/654 records) in the test data, indicating that the model can still maintain good recognition ability for patients who cannot pass the SBT without significant deviation. This means that when the model predicts that a patient will not be able to pass the SBT, its judgment is correct in most cases, reducing the risk of the patient failing the SBT.

The F_1-score, which is a comprehensive measure of precision and recall, is 0.963 in the training data and 0.875 in the test data, indicating that the model has achieved a certain balance between precision and recall and is suitable as a clinical decision-making aid.

Figures 5 and 6 display the ROC curve of the SBT prediction model for both training and test data, with the AUC used to assess the model's classification ability. Figure 5 is the ROC curve of the training data, and Figure 6 is the ROC curve of the test data. Both are used to measure the changes in the TPR and FPR of the model at different decision thresholds, and the AUC value is used to quantify the overall effectiveness of the model in distinguishing between successful and failed patients.

XSL•FO
RenderX

Figure 5. ROC curves for training data. AUC: area under the ROC curve.



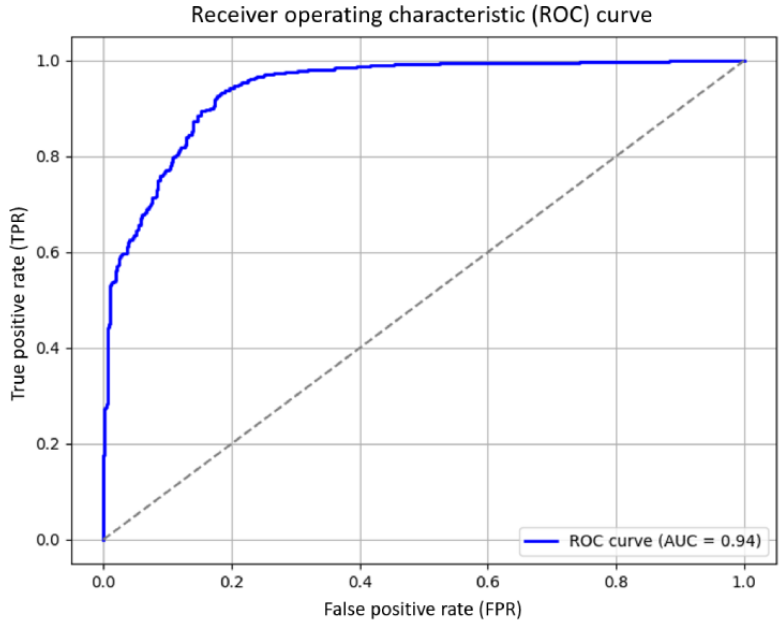


Figure 6. ROC curves for testing data. AUC: area under the ROC curve.

The results showed that the AUC for the training data was 0.99, indicating that the model could almost perfectly distinguish between successful and failed SBT patients during training, showing extremely high predictive ability. However, when the model was applied to the test data, the AUC dropped to 0.94, which is slightly lower than the training data but still within the excellent range, indicating that the model still has a good discrimination ability for unseen data. This means that although the model has a certain degree of generalization ability decline on the test data, it can still effectively distinguish which patients can successfully pass the SBT and which still need mechanical ventilation support.

This study successfully developed an AI-based SBT prediction model that can effectively assist clinicians in determining whether patients can successfully pass the SBT. Through evaluation metric analysis, including accuracy, precision, recall, specificity, F_1-score, FPR, FNR, ROC curve, and AUC, we verified the robust performance of the model on both training and test data. Overall, the accuracy and reliability of the model in clinical applications have reached a high level and can provide strong support for clinical decision-making.

Discussion

Overview

This study demonstrates the potential of deep learning technology in evaluating SBT, which can effectively improve the accuracy and efficiency of managing mechanically ventilated patients. Traditional SBT assessment methods rely on simple threshold settings, which cannot fully reflect the patient's

XSL•FO
RenderX

complex physiological state. The deep learning model developed in this study can integrate multidimensional clinical data to provide more precise prediction results that conform to actual physiological conditions.

A major innovation of this study is the design of the hybrid CNN-MLP architecture. Compared with the traditional deep learning model that only relies on CNN for feature extraction and MLP for classification, this study uses CNN and MLP layers alternately to form a novel feature learning and fusion method. This design helps capture features at different levels, making the model more flexible and efficient when processing data with complex feature structures. The research results show that the model achieves high accuracy in the training phase and maintains stable performance in the testing phase. The final F_1-score on the test dataset is about 0.875, which proves its feasibility and reliability in predicting SBT results. These findings are consistent with previous studies [37,38], showing that AI technology can improve clinical decision-making accuracy and patient outcomes in critically ill patient care.

This study aimed to establish a model to predict whether a patient can successfully pass an SBT. The data division does not necessarily lead to data leakage in our research setting because our model learns the relationship between pre-SBT clinical parameters and SBT outcomes. That means the model does not track a patient's historical SBT trials but makes independent predictions based on the patient's current state before each SBT trial. We treat each SBT trial as an independent sample rather than linking multiple records from the same patient. Even if a patient has undergone multiple SBTs at different time points, each trial is considered a separate instance for training and prediction. Therefore, within-patient clustering does not significantly impact the model's learning process, and even if records of the same patient at different time points appear in the training and test sets, the model still learns the pattern that determines a patient's likelihood of passing the SBT, rather than focusing on individual patient characteristics.

Regarding patients who have undergone multiple SBT attempts with varying outcomes, the model learns to predict each SBT outcome independently based on pre-SBT clinical records of that specific attempt rather than being influenced by previous trials. Therefore, it does not distinguish between patients who succeeded on their first attempt and those who required multiple attempts; instead, it evaluates each instance based on its pre-SBT clinical record.

This study did not specifically adjust the time variables since the time factor has a limited impact on the model based on the following considerations. The SBT implementation standards of the research institutions were consistent with the clinical operation procedures throughout the study period. Therefore, data from different years can be regarded as homogeneous and will not significantly impact the model training and prediction results. In addition, during the data partitioning process, we used random sampling to ensure that the data distribution between the training and test sets was balanced to reduce the possible impact of time variability.

Strengths and Limitations

The innovation of this study is to develop an AI-based prediction model to evaluate the outcome of an SBT under a specific SBT strategy using clinical parameters collected before an SBT begins. Traditionally, clinicians must comprehensively assess multiple physiological parameters to determine whether a patient is suitable for SBT. However, this process is highly subjective, experience-dependent, and has a high risk of misjudgment. This study uses AI technology to develop an objective and efficient prediction model to reduce the error of traditional manual evaluation and improve the accuracy of predicting whether an SBT will be successful.

The model in this study is built on pre-SBT clinical data to identify the relationship between these variables and SBT outcomes and to make predictions under a fixed SBT strategy. Unlike traditional approaches, this study does not compare different SBT strategies or analyze their impact on extubation success rates. Instead, it focuses on developing a data-driven method within a specific SBT strategy's framework to accurately predict whether patients can successfully pass SBT, providing clinicians with an objective and reliable decision-making aid.

Furthermore, the AI prediction model in this study focuses on predicting SBT success and highlights the clinical value of identifying patients who may fail SBT in advance. In current clinical practice, the SBT evaluation process typically takes 48-72 hours, and initiating SBT too early can result in respiratory muscle fatigue, hypoxemia, and even acute respiratory failure in patients. The proposed model can predict whether an SBT will be successful in advance and assist clinicians in identifying patients who may not be ready yet, which would prevent unnecessary testing, reduce the physiological burden on patients, and enhance the efficiency of ICU resource management.

The main advantage of this study lies in its innovative CNN-MLP hybrid architecture, which enables the model to effectively learn and fuse feature information at different levels and improve the prediction ability of SBT results. Compared with traditional deep learning models, the method of this study can not only extract features from image and time series data through CNN but also further enhance the understanding of high-dimensional features through MLP, thereby improving the accuracy and applicability of the model. In addition, by integrating multidimensional physiological data, the model of this study can more comprehensively assess the patient's clinical condition and provide more accurate and personalized extubation decision support compared with traditional threshold-based indicators.

The final F_1-score on the test dataset is about 0.875, which proves its feasibility and reliability in predicting SBT results. The AUC for the test data was 0.94, indicating that the model has a good discrimination ability for unseen data. The study showed that the model maintained stable predictive performance during the testing phase and exhibited an excellent F_1-score, confirming its potential in clinical applications.

The contributions of this study are summarized as follows:

XSL•FO
RenderX

1. Enhancing clinical decision support and prediction accuracy: Traditionally, clinicians assess whether patients are suitable for SBT by comprehensively analyzing multiple physiological parameters. This process relies heavily on experience and is subjective, which can easily lead to errors in judgment. This study uses AI technology to develop a prediction model based on pre-SBT clinical data, providing more accurate prediction results, reducing manual evaluation errors, and enhancing SBT prediction accuracy.
2. Identifying patients who may fail in advance: In current clinical practice, SBT evaluation typically takes 48-72 hours. If SBT is conducted too early, it may lead to respiratory muscle fatigue, hypoxemia, and even acute respiratory failure in patients. The AI prediction model introduced in this study can identify patients who may not successfully pass the SBT beforehand, preventing unnecessary trials, reducing the physiological burden on patients, and effectively managing ICU resources to enhance overall medical efficiency.
3. Innovative hybrid CNN-MLP model design: This study's methodological innovation proposes a hybrid deep learning architecture called hybrid CNN-MLP. This architecture differs from the traditional CNN-MLP classification method since it uses a unique approach to feature learning and fusion through the interlaced combination of CNN and MLP layers, where the data features can be extracted and integrated at various levels, making the model more flexible and efficient in processing complex data structures and enhancing the accuracy and applicability of SBT predictions.

However, this study still has some limitations. First, the data in this study came from a single medical institution, which may affect the model's generalization ability and limit its applicability in different clinical settings. Therefore, its robustness needs to be verified through multicenter data in the future. Second, although the model shows high accuracy at the technical level, in practical application, it is still necessary to consider how to integrate it with the clinical workflow to ensure that medical staff can adopt the technology smoothly. In addition, in the test dataset, the model’s performance decreased slightly compared to the training stage, indicating that there is still room for further optimization. These challenges can be overcome in the future through multicenter data expansion, improved model training strategies, and enhanced AI interpretation capabilities.

Future Perspectives

In order to enhance the influence and application value of this study, the data scope should be further expanded in the future, and model training and verification should be carried out with multicenter data to ensure its applicability in different medical institutions and diverse patient groups. By introducing data from different medical environments, not only can the model's generalization ability be increased, but its adaptability to patients from different groups can also be improved. In addition, prospective clinical trials should be conducted to evaluate the impact of this model in actual clinical decision-making, such as whether it can effectively reduce the duration of mechanical ventilation, improve the success rate of extubation, and further analyze its impact on the clinical prognosis of patients.

In addition to increasing the breadth of data and validating real-world applications, the model in this study can be further optimized to improve its performance and interpretability. Although the deep learning model used in this study has strong predictive capabilities, it is a “black box model” with low interpretability. Hence, to ensure that the model applies to different health care systems, we pay special attention to the availability and variability of the input features. The characteristics used in this study are key indicators in clinical diagnosis and monitoring. These variables were selected primarily based on clinical relevance and availability. However, there may be variations in equipment and data collection methods between different medical systems. For example, the type of ventilator or blood oxygen monitor used in different wards may affect the measurement of certain values. Therefore, when the model is applied to different medical institutions in the future, it is recommended to first conduct a feature distribution analysis to evaluate the input data's adaptability and reduce heterogeneity's impact on model performance through transfer learning or regularization techniques.

By improving the model's training strategy, such as applying transfer learning or reinforcement learning, the model can be helped to learn feature patterns from different environments more effectively, thereby improving its adaptability. In addition, the interpretability of the model is also an important direction for future development. By designing a more transparent AI model architecture, medical staff can understand the decision-making logic of the model, which will help enhance clinical users' trust in AI-assisted decision-making systems and further promote their application in the medical field.

Finally, future attention should be paid to the model's actual deployment and clinical integration and the possibility of embedding it into the EHR system. Through seamless integration with existing medical information systems, the model can be ensured to be immediately available in clinical decision-making and enhance its auxiliary value to medical staff. In addition, when designing the user interface, the user-centered design principles should be considered so that medical staff can operate and understand the system more intuitively, ensuring that it can truly become an effective tool in the clinical decision-making. Through these efforts, deep learning–based SBT assessment technology will be able to be more widely used in clinical fields, improve the efficiency of mechanical ventilation management, and ultimately improve patients' treatment and rehabilitation outcomes.

Conclusions

This study demonstrates the potential of deep learning technology to predict whether a patient can successfully pass an SBT, improving the accuracy and efficiency of mechanically ventilated patient management. Traditional SBT evaluation methods rely on simple threshold settings and are difficult to fully reflect the patient's complex physiological state. This study's AI prediction model integrates multidimensional clinical data to provide more accurate prediction results that meet actual clinical needs.

The main innovation of this study is the proposed hybrid CNN-MLP architecture, which uses CNN and MLP layers

XSL•FO
RenderX

alternately for feature learning and fusion. Compared with traditional deep learning models, this method can more flexibly capture features at different levels and improve the model's ability to handle complex data structures. The results showed that the model achieved an F_1-score of 0.875 on the test dataset, confirming its feasibility and reliability in predicting the success of SBT, which is consistent with previous research results on the application of AI technology in critical care.

In addition, this study highlights the value of AI prediction models in clinical decision support, especially in identifying patients who may not pass the SBT in advance, thereby reducing unnecessary trials, reducing the physiological burden on patients, and improving the management efficiency of ICU resources. However, the study's limitations are that the research data came from a single medical institution and, as a consequence, may affect the generalization ability of the model. In the future, it should be verified through multicenter data. In addition, integrating this technology seamlessly into clinical workflow and increasing the acceptance of medical staff are challenges that need to be addressed in the future.

In the future, this study recommends further expanding the data scope and evaluating the model's applicability in different medical institutions and patient groups through multicenter clinical trials. In addition, the model can be optimized through transfer learning or reinforcement learning to make it more adaptable to data patterns in different environments. Besides, the model's interpretability will be improved to enhance the trust of medical staff, and its integration into the EHR system will be explored to ensure that it can provide real-time support for clinical decision-making.

In summary, the hybrid CNN-MLP proposed in this study can improve the accuracy and efficiency of SBT assessment and provide a more reliable auxiliary tool for clinical decision-making. The ultimate goal is to optimize the mechanical ventilation weaning process, improve patient prognosis, and enhance the quality of ICU care.

Abstract

Background: Acute kidney injury (AKI) frequently occurs in critically ill patients with coronary heart disease (CHD), and its development markedly elevates mortality rates and prolongs hospitalization duration. Early AKI prediction is crucial for timely intervention and amelioration of patient outcomes.

Objective: This study aimed to develop and verify a clinical prediction model for the occurrence of AKI upon admission in the critically ill population with CHD through machine learning (ML).

Methods: Data from the MIMIC-IV (Medical Information Mart for Intensive Care IV) version 2.2 database were gathered and included information about critically ill individuals with CHD in the intensive care unit (ICU). The dataset was randomized into a training set (70%) and a testing set (30%). Least absolute shrinkage and selection operator (LASSO) regression was used for feature variable selection. ML models, including logistic regression (LR), decision tree (DT), naive Bayes (NB), random forest (RF), extreme gradient boosting (XGBoost), and support vector machine (SVM), were constructed using 13 variables in the training set. The 6 models were compared in the testing set to identify the best-performing model. Subsequently, the model was assessed using calibration curve analysis and decision curve analysis (DCA). External validation was conducted using data from the Second Affiliated Hospital of Zhengzhou University. Ultimately, the predictive model was interpreted via Shapley Additive Explanation (SHAP) values.

Results: In total, 2711 patients with CHD admitted to the ICU were selected, with 1809 (66.7%) having AKI. XGBoost exhibited the best performance regarding discrimination (area under the receiver operating characteristic curve [AUROC]=0.765, 95% CI 0.731-0.800), accuracy (0.725), and sensitivity (0.759). External validation using a cohort of 226 patients confirmed the strong generalizability of the XGBoost model (AUROC=0.835, 95% CI 0.782-0.887). Feature importance analyses derived from SHAP values, DT, RF, and XGBoost consistently identified 5 key predictors associated with the development of AKI: mechanical ventilation, use of antiplatelet agents, age, N-terminal pro–B-type natriuretic peptide (NT-proBNP) levels, and acute physiology score III (APSIII).

Conclusions: ML models can serve as reliable tools for forecasting AKI in the critically ill population with CHD. The XGBoost model is highly accurate and may aid doctors in identifying high-risk individuals for early intervention to lower mortality.

Introduction

Acute kidney injury (AKI) is a frequent complication in people admitted to the intensive care unit (ICU), particularly in the coronary care unit (CCU). The incidence of AKI in the CCU is 28.5% [1]. In patients in the ICU, the onset of AKI is linked to significantly longer hospital stays and higher in-hospital death rates in contrast to the population without AKI, resulting in a worse overall prognosis [2]. However, with timely intervention and effective treatment, AKI can be reversed early, thereby reducing mortality related to AKI [3]. Therefore, early AKI identification is essential for critically ill individuals with coronary heart disease (CHD) in the ICU. To better manage critically ill patients with CHD, an accurate predictive model is required to find high-risk individuals, enabling early intervention to ameliorate their prognosis.

In recent years, several cardiac disease–related AKI prediction models have been created. For instance, Ma et al [4] used nomograms to develop a prediction model for contrast-induced AKI in individuals with non–ST elevation acute coronary syndrome (ACS), and Peng et al [5] developed a machine learning (ML)-based predictive model for AKI in patients with congestive heart failure. Existing predictive models are primarily designed for patients with isolated risk factors, such as acute myocardial infarction (AMI) or those undergoing percutaneous coronary intervention (PCI). However, critically ill patients admitted to the ICU often present with complex conditions and multiple comorbidities, rendering current models less applicable to this population. Therefore, it is important to establish a more widely applicable predictive model for AKI in the critically ill cohort with CHD. As statistical theory and computational technologies advance, artificial intelligence (AI) is beginning to play a vital role in medicine. AI can learn to recognize large datasets from databases, enabling precise disease prediction, which helps clinicians develop appropriate treatment plans [6,7]. ML approaches have been extensively used in the construction of predictive models for multiple illnesses, exhibiting higher performance in comparison to conventional models, such as logistic regression (LR) or Cox regression analysis [8,9].

This study endeavored to assess the incidence of AKI following hospital admission in critically ill patients with CHD, as well as to identify potential influencing factors. Using a range of ML algorithms, we aimed to develop a generalizable predictive model for postadmission AKI in this patient population, identify the model with the best predictive performance, evaluate its accuracy and generalizability, and conduct interpretability analyses. Our model is designed to operate within an electronic health record (EHR) system to continuously monitor and analyze patient data in real time, automatically calculate the risk score for AKI, and issue early warnings in high-risk cases. This approach may assist clinicians in implementing timely preventive measures or initiating early interventions.

Methods

Study Design and Population

The Medical Information Mart for Intensive Care IV (MIMIC-IV) database, a single-center ICU dataset of the Laboratory for Computational Physiology at the Massachusetts Institute of Technology (MIT), has gained approval from the Institutional Review Boards (IRBs) of MIT and the Beth Israel Deaconess Medical Center (BIDMC). The patient information within the database is anonymized, obviating the need for informed consent from patients [10,11]. MIMIC-IV version 2.2 includes medical data from 73,181 patients in the ICU from 2008 to 2019 [12]. Our study cohort consisted of patients diagnosed with CHD upon admission. The inclusion criteria were (1) age of 18 years or more; (2) hospitalization duration exceeding 24 hours; (3) patients diagnosed with CHD according to the *International Classification of Diseases, 9th Revision* (ICD-9: 41401, 41402, 41404, 41405, 41407) and *International Classification of Diseases, 10th Revision* (ICD-10: I2101, I2102, I2109, I2111, I2119, I2121, I240, I251). In total, 30,136 patients with CHD were found in the MIMIC-IV database. Patients were excluded if they (1) were not admitted to the ICU (n=13,461); (2) had missing outcome variables (n=1); (3) had missing categorical variables, such as gender, marital status, and ethnicity (n=2420); (4) had missing N-terminal pro–B-type natriuretic peptide (NT-proBNP) or neutrophil count data (n=11,430); (5) had a history of pre-existing renal disease (n=99); or (6) had a lymphocyte count of 0 (n=14).

Additionally, clinical data were collected from 226 critically ill patients with CHD admitted to the Second Affiliated Hospital of Zhengzhou University from January 1, 2021, to August 1, 2024, as an external validation cohort. A retrospective analysis was performed using the hospital's EHR system. The eligibility criteria were consistent with those for the training and internal validation cohorts.

Outcome

Our research team was granted access to the MIMIC-IV database on July 12, 2024, and subsequently extracted data on 2711 critically ill patients with CHD admitted to the ICU. As of March 30, 2025, we had also collected external validation data from 226 patients at the Second Affiliated Hospital of Zhengzhou University. A total of 7 investigators participated in this study.

Data Extraction and Processing

Data extraction was completed via structured query language (SQL) and the PostgreSQL tool (version 16.0). The extracted data consisted of the first recorded vital signs and laboratory parameters following ICU admission, as well as medications administered within the first 7 days of hospitalization. The study extracted the following variables:

- Demographic characteristics: gender, age, race, blood pressure, and BMI
- Comorbidities: AMI, history of previous myocardial infarction (MI), diabetes mellitus, hypertension, heart failure, and atrial fibrillation
- Vital signs: systolic blood pressure, diastolic blood pressure, heart rate, and respiratory rate
- Laboratory parameters: white blood cells (WBCs), red blood cells (RBCs), platelets, albumin, hemoglobin, aspartate aminotransferase (AST), alanine aminotransferase (ALT), lymphocyte percentage, lymphocyte count, neutrophil

XSL•FO
RenderX

percentage, neutrophil count, neutrophil-to-lymphocyte ratio (NLR), anion gap, bicarbonate, total bilirubin, serum potassium, serum sodium, NT-proBNP, blood urea nitrogen (BUN), serum chloride, creatine kinase isoenzymes (CKMB), international normalized ratio (INR), lactate dehydrogenase (LDH), prothrombin time (PT), activated partial thromboplastin time (PTT), RBC distribution width (RDW), and serum creatinine (SCr)
- Medication use and treatment: antiplatelet agents, antihypertensive drugs, statins, vasopressors, heparin, diuretics, coronary angiography (CAG), or PCI
- Simplified acute physiology score III (APSIII) and sequential organ failure assessment (SOFA)

Variables having more than 20% missing values were eliminated from the final cohort in order to reduce bias brought on by missing data. Other variables with missing data were imputed via multiple imputation, a widely used and effective technique to handle missing data [13] estimating multiple plausible values for each missing entry [14]. Additionally, to enhance the accuracy and reliability of data and models, outliers were identified using box plots [15], and extreme values were mitigated through winsorization [16], wherein data points above the 99th percentile were substituted with the value at the 99th percentile and those below the 1st percentile were replaced with the value at the 1st percentile.

Outcome Variables

Our study cohort comprised adult patients diagnosed with AKI following hospital admission. The diagnosis of AKI was based on the guidelines published in 2012 by the organization called Kidney Disease: Improving Global Outcomes (KDIGO) [17]. AKI was defined by the presence of any one of the following criteria: (1) an increase in SCr by ≥26.5 μmol/L (≥0.3 mg/dL) within 48 hours; (2) an increase in SCr to >1.5 times the baseline value, which is known or presumed to have occurred within the prior 7 days; or (3) a urine output of <0.5 mL/kg/hour for more than 6 hours.

Variable Selection

To minimize the potential bias of multicollinearity and model overfitting, we used the least absolute shrinkage and selection operator (LASSO) regression to select and filter variables in the training dataset. LASSO is a regression-based method that reduces model complexity through the construction of a penalty function. The optimal regularization parameter (λ) was determined using tenfold cross-validation, and variables with nonzero coefficients were retained as the final predictors. Following LASSO regression, the variance inflation factor (VIF) was calculated for the included variables to assess multicollinearity. The VIF values for all predictors are presented in Table S1 in Multimedia Appendix 1.

Model Development and Evaluation

The sample was randomized into a training set and a testing set in a 7:3 ratio. Six ML models were established in the training set: LR, decision tree (DT), naive Bayes (NB), random forest(RF), extreme gradient boosting (XGBoost), and support vector machine (SVM). To minimize overfitting and achieve optimal model performance, the hyperparameters of the ML models were tuned using a grid search. In contrast, the LR model was implemented using its conventional parameter settings. Detailed parameter configurations for each model are presented in Table S2 in Multimedia Appendix 1.

The models' predictive performances were evaluated on the testing dataset by comparing the area under the receiver operating characteristic curve (AUROC), accuracy, precision, sensitivity, and specificity. Among these, AUROC was considered the primary performance metric. The model demonstrating the highest predictive performance was selected as the optimal model for this study. A calibration curve was subsequently plotted to assess the agreement between observed outcomes and predicted probabilities. In addition, decision curve analysis (DCA) was conducted to evaluate the clinical utility of the model. Finally, external validation was performed using data from the Second Affiliated Hospital of Zhengzhou University to assess the model's generalizability and applicability in an independent cohort.

Model Interpretation

To interpret the predictive models, feature importance was visualized for 3 tree-based models (DT, RF, and XGBoost) and interpreted using Shapley Additive Explanation (SHAP) values. Feature importance, quantified through each model's intrinsic evaluation mechanism, directly reflects the contribution of individual input variables to the model's predictive output, thereby elucidating the practical relevance of each feature in the decision-making process. SHAP has been widely leveraged to explain the contribution of predictive variables [18,19] to model output by offering consistent, locally accurate attribution values for every characteristic in the model. Higher values would suggest an elevated likelihood of AKI. SHAP dependence plots for the top 5 feature variables were generated to illustrate the relationship between the SHAP values and feature values, as well as to demonstrate feature interactions. In addition, to visually illustrate the decision-making logic of the model, a SHAP force plot for individual samples was generated to demonstrate the contribution of each variable to the model's prediction.

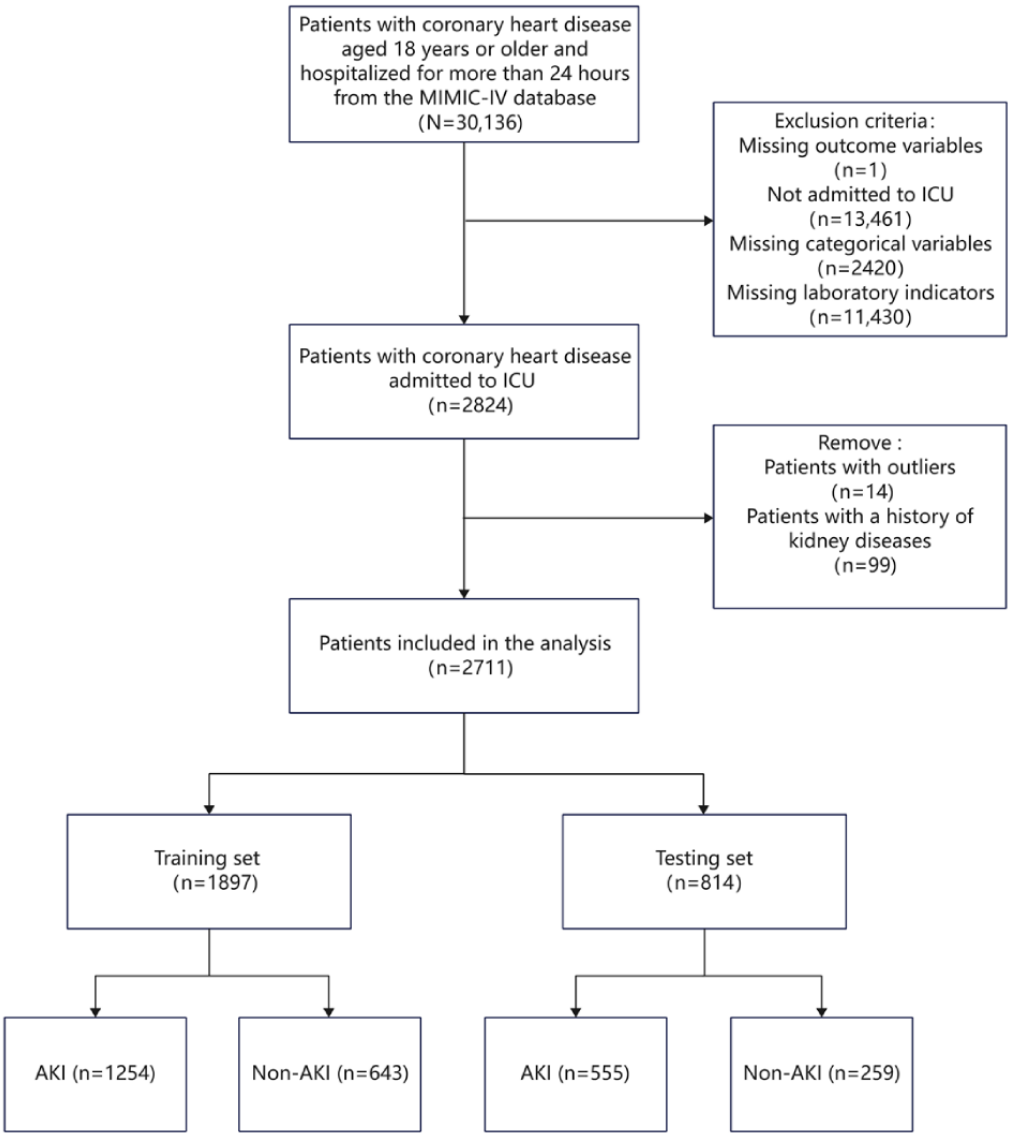
Statistical Analysis

All analyses were conducted in R version 4.3.1 (R Foundation for Statistical Computing). For continuous variables, the Shapiro-Wilk test was performed to evaluate the normality of the data. The mean (SD) was used for expressing variables having a normal distribution, and the independent samples *t* test was performed for comparison. The Wilcoxon rank-sum test was applied to compare non-normally distributed variables, which were displayed as medians (IQRs). The chi-square or the Fisher exact test was carried out to compare categorical variables, which were presented as numbers and percentages. $P<.05$ suggested statistical significance.

Ethical Considerations

The MIMIC-IV database was approved by the IRBs of the MIT(0403000206) and the BIDMC(2011-P-001418). As all patient data contained within the database are deidentified, individual informed consent was not required. This study has obtained access authorization to the MIMIC-IV database through

XSL•FO
RenderX



PhysioNet approval (ID: 13470927). In addition, the study protocol was approved by the Ethics Committee of the Second Affiliated Hospital of Zhengzhou University (approval numer: KY2024215). Informed consent was obtained from all patients enrolled at this institution, and all data were fully deidentified. Given that the study did not involve direct interaction with participants, no compensation was provided.

Results

Patient Characteristics

The inclusion process is illustrated in Figure 1. Of the 2711 patients included whose median age was 71 years, 1629 (60.1%) were males, 1985 (73.2%) White, and 1809 (66.7%) cases of AKI. After randomly splitting the dataset into a 7:3 ratio, the training group had 1897 (70%) patients, with a median age of 71 years, 1139 (60%) males, 1386 (73.1%) White, and 1254 (66.1%) cases of AKI. The testing group comprised 814 (30%) patients, with a median age of 71 years, 490 (60.2%) males, 599 (73.6%) White, and 555 (68.2%) cases of AKI. In the training set, 37 variables, including age, race, mechanical ventilation, albumin, and potassium levels, were statistically significant (P<.05). Table 1 presents the baseline characteristics of the patients in the training set, while the baseline characteristics of the testing set can be found in Table S3 in Multimedia Appendix 2.

Variable Selection

Based on the feature selection results from the LASSO regression (Figure S1 in Multimedia Appendix 3), 13 features were included: age, mechanical ventilation, NT-proBNP, NLR, AMI, history of prior MI, antiplatelet therapy, dual-antiplatelet therapy, heparin, diuretics, norepinephrine, statins, and APSIII.

ML Model Performance

Six ML models were created to forecast AKI occurrence. Figure 2 illustrates the ROC performance of these models in both training and testing cohorts. In the testing cohort, the XGBoost model (AUROC=0.765) demonstrated the best forecasting performance, followed by LR (AUROC=0.758), NB (AUROC=0.754), RF (AUROC=0.759), SVM (AUROC=0.731), and DT (AUROC=0.692). Table 2 presents detailed performance metrics for all 6 models. The XGBoost model demonstrated superior discriminative ability, with accuracy (0.725) and sensitivity (0.759) higher than those of the other 5 models, indicating that XGBoost is the optimal model.

Figure 2. Comparison of AUC values across 6 models: (a) training set and (b) testing set. AUC: area under the curve; KNB: kernel naive Bayes; SVM: support vector machine; XGBoost: extreme gradient boosting.

External validation set	0.835	0.788	0.757	0.772	0.800

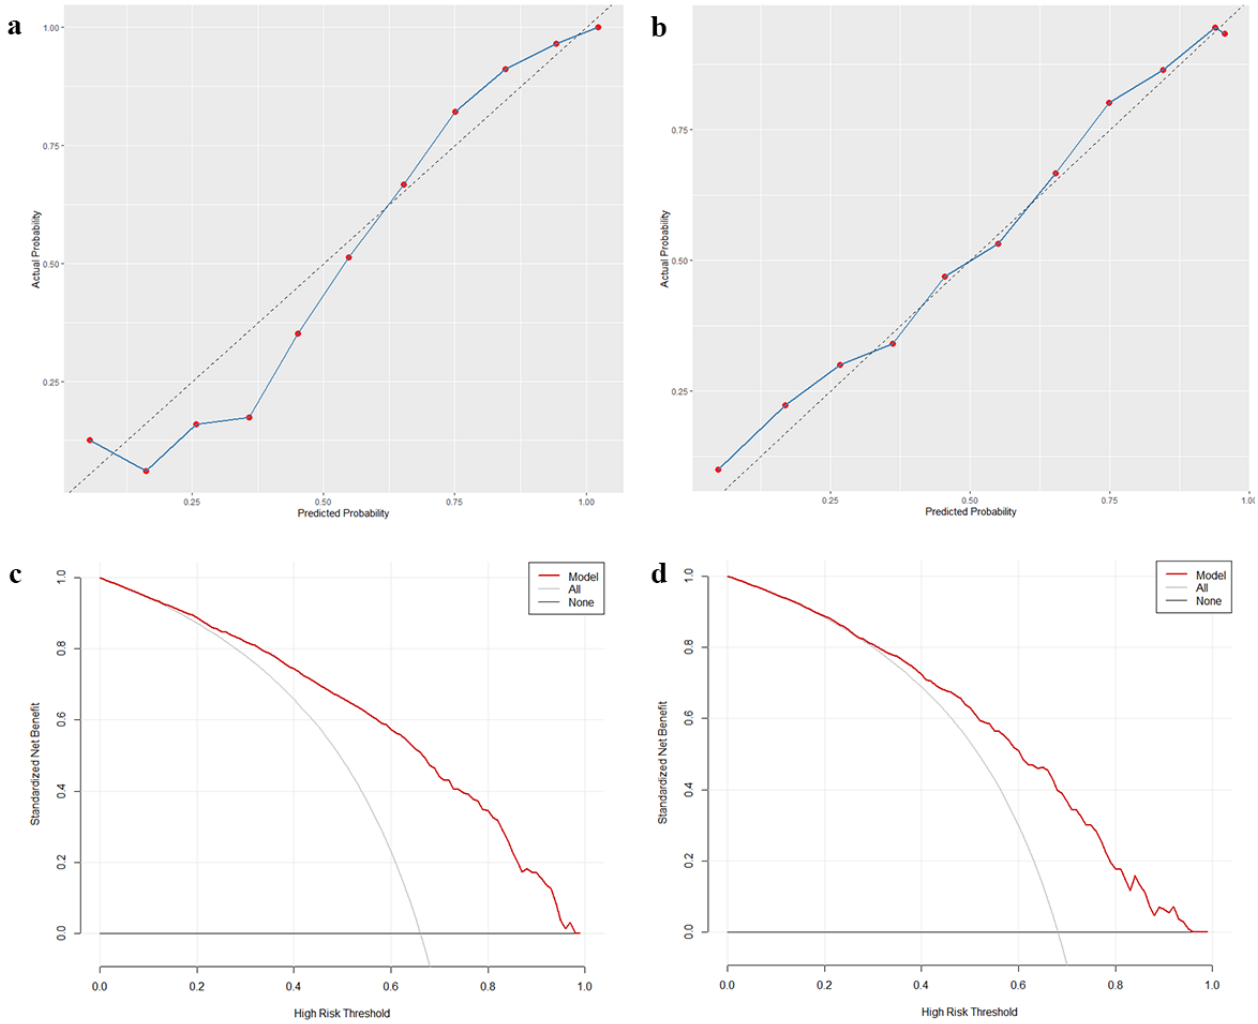
[a]AUROC: area under the receiver operating characteristic curve.

[b]LR: logistic regression.

[c]NB: naive Bayes.

[d]SVM: support vector machine.

[e]DT: decision tree.



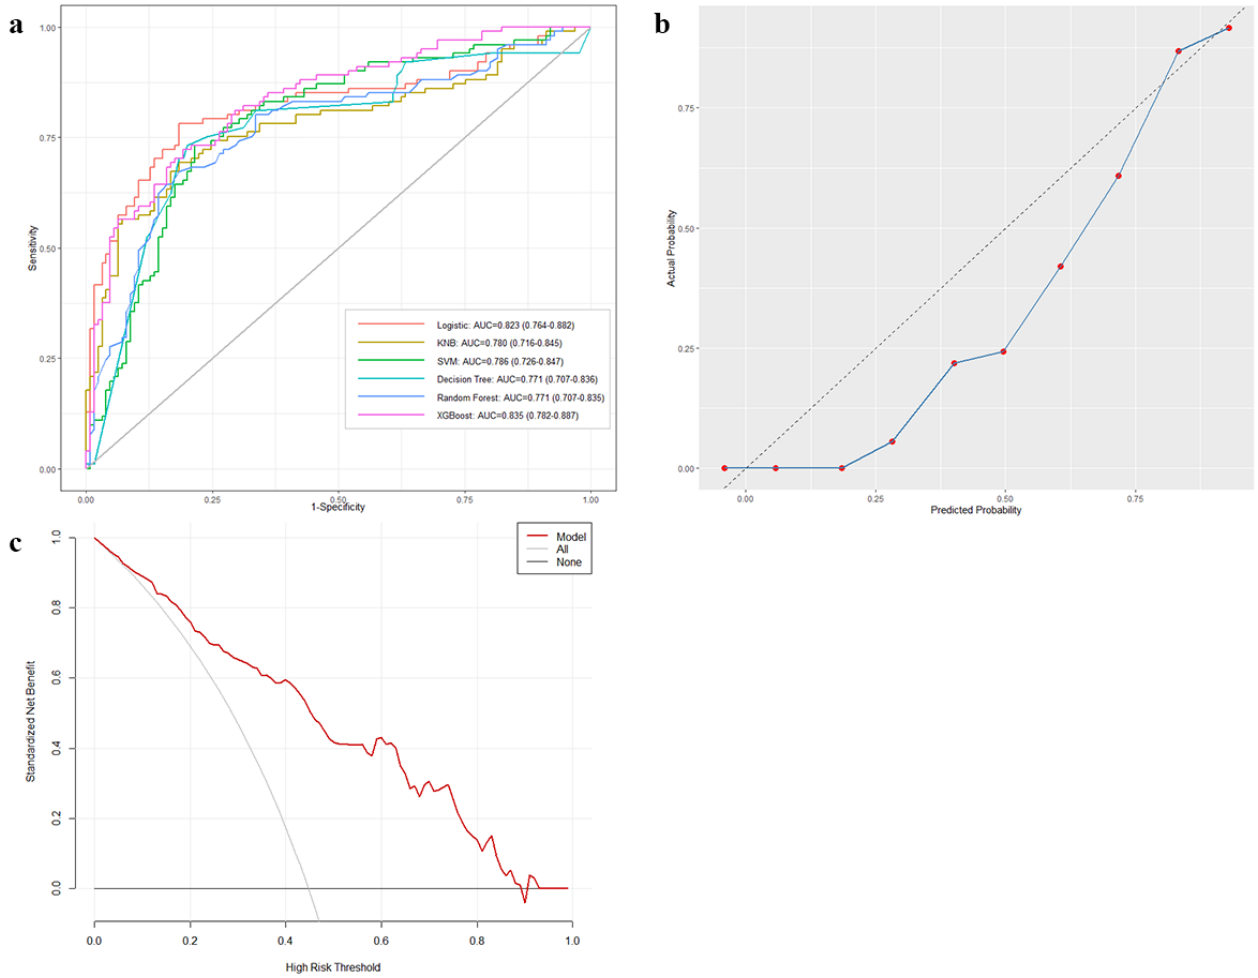
[f]RF: random forest.

[g]XGBoost: extreme gradient boosting.

Calibration curves and DCA were used to further assess the ideal model (Figure 3). The calibration curve is an important tool for assessing the performance of predictive models, as it compares the predicted probabilities with actual observed outcomes to measure accuracy and reliability. Clinical DCA evaluates the practical value of a clinical prediction model by comparing the net benefit of different decision thresholds. Based on the results, the calibration curve of the testing set demonstrated excellent calibration of the model, while DCA indicated that the model provides clinical net benefit across a threshold probability range of 0.20-0.95, suggesting that the model has outstanding clinical applicability.

XSL•FO
RenderX

Figure 3. Calibration curve of the XGBoost model: (a) training set and (b) testing set. DCA of the XGBoost model: (c) training set and (d) testing set. DCA: decision curve analysis; XGBoost: extreme gradient boosting.



External Validation

Clinical data from 226 critically ill individuals with CHD, admitted to the Second Affiliated Hospital of Zhengzhou University between January 1, 2021, and August 1, 2024, were collected and the patients included in the external validation group. Their baseline characteristics are provided in Table S4 in Multimedia Appendix 2. As shown in Figure 4a, the XGBoost model in the external validation set exhibited the highest AUROC of 0.835, similar to its performance in the testing cohort. Furthermore, the calibration curve demonstrated good calibration (Figure 4b), and the DCA curve indicated net benefit at threshold probabilities lower than 0.9 (Figure 4c), indicating that the XGBoost model has superior generalizability and can be reliably applied to external data.

XSL•FO

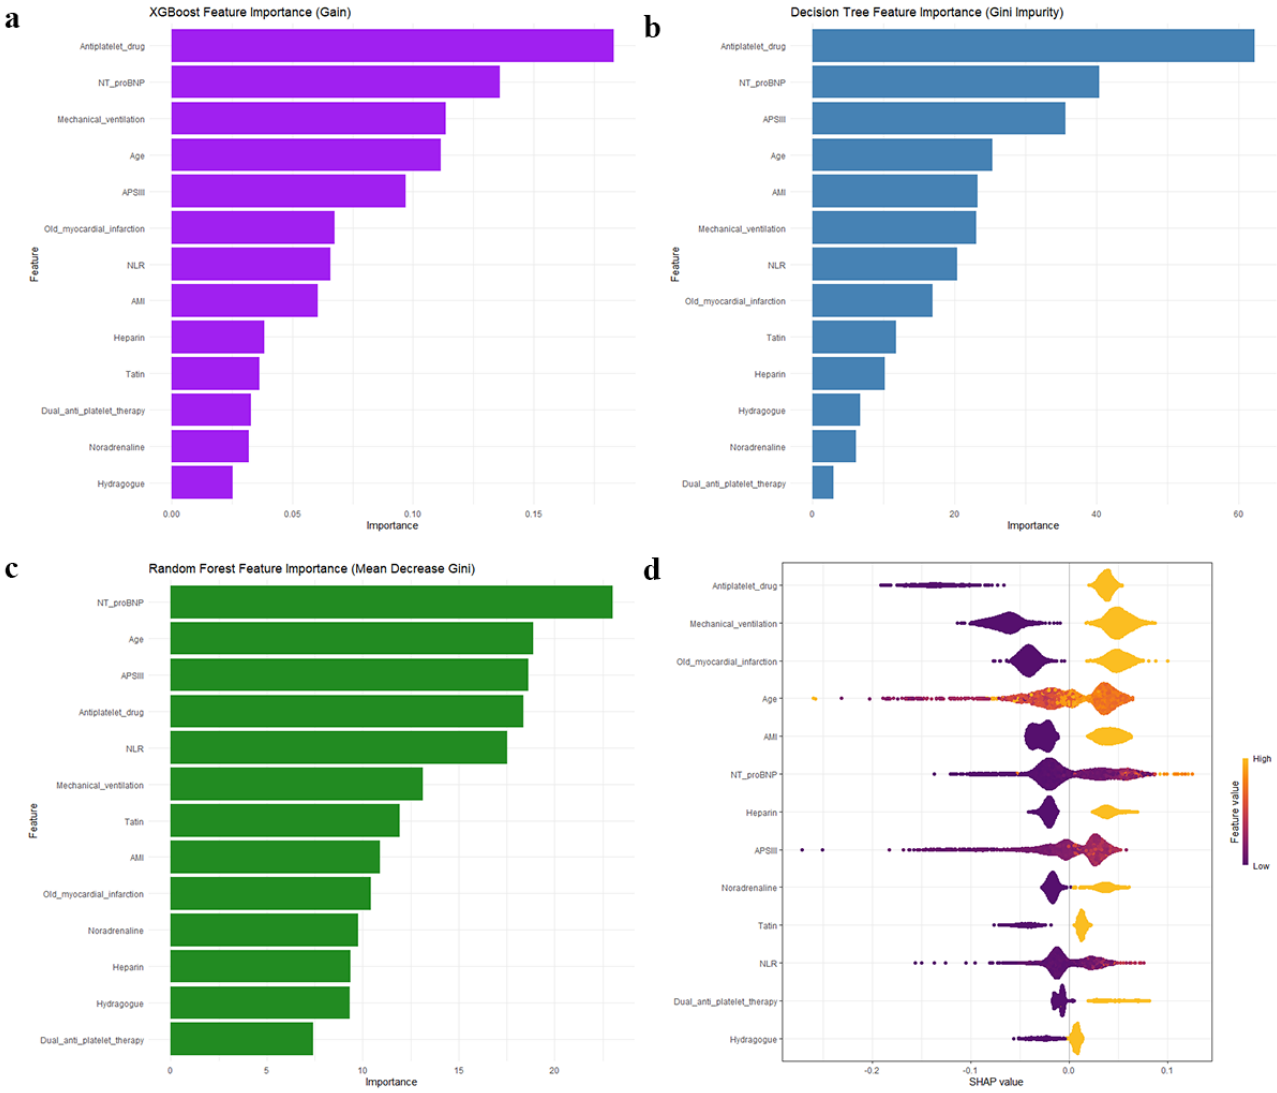
Figure 4. (a) Comparison of AUC values of the 6 models in the external validation set and (b) the calibration curve and (c) the DCA curve of the XGBoost model. AUC: area under the curve; DCA: decision curve analysis; KNB: kernel naive Bayes; SVM: support vector machine; XGBoost: extreme gradient boosting.



Model Interpretation

Our study compared the feature importance rankings of XGBoost (Figure 5a), DT (Figure 5b), and RF (Figure 5c) models, and provided global and local explanations of the predictions using SHAP values (Figure 5d), to comprehensively assess the contribution of each clinical feature to the risk of AKI. NT-proBNP ranked among the top 3 predictors in XGBoost, RF, and DT models, and its global contribution was also significant according to SHAP analysis. The SHAP dependence plot (Figure S2 in Multimedia Appendix 3) shows that as the NT-proBNP value increased, the incidence of AKI also rose, which is highly consistent with the clinical significance of NT-proBNP as a biomarker for heart failure and renal dysfunction, thereby confirming its predictive value for AKI. Age ranked high in XGBoost (fourth in gain importance) and RF models, with SHAP values indicating a positive contribution to the prediction, aligning with the clinical consensus that elderly patients are at a higher risk for AKI. Antiplatelet drugs ranked first in gain importance in the XGBoost model and in Gini impurity in the DT model; the SHAP value for high feature importance was 0.05, the SHAP value for low feature importance reached –0.2. This suggests that the use of antiplatelet drugs has a limited contribution to the promotion of AKI, while patients not using them have a lower risk of AKI. Mechanical ventilation ranked third in the XGBoost model, with its global SHAP contribution indicating a significant positive correlation with AKI risk, which supports the potential mechanisms of iatrogenic renal injury in critically ill patients. APSIII ranked third in both RF and DT models, and its SHAP dependence plot (Multimedia Appendix 3) suggests that when APSIII exceeds 40, the incidence of AKI significantly increases, reflecting the stable predictive value of composite physiological indices in AKI risk prediction.

Figure 5. Feature importance derived from (a) XGBoost, (b) DT, and (c) RF models, along with (d) SHAP analysis summary diagram based on XGBoost. Each row represents a feature; a point represents a sample; yellow represents a high feature value; and purple represents a low feature value. A further distance from a point to the baseline SHAP value of 0 indicates a greater impact on the output. AMI: acute myocardial infarction; APSIII: acute physiology score III; NLR: neutrophil-to-lymphocyte ratio; NT-proBNP: N-terminal pro–B-type natriuretic peptide.

To intuitively demonstrate the consistency between the model's decision logic and clinical-pathological mechanisms, this study selected 2 typical AKI risk prediction cases for SHAP force plot analysis (Figure 6). The SHAP analysis of individual samples reveals how each variable influences the model's decision-making. As shown in Figure 6a, age, NT-proBNP, and mechanical ventilation usage contributed the highest positive predictive values, while the absence of AMI and old MI reduced the risk of AKI. In Figure 6b, the age of 75 years increased the risk of AKI, and the absence of antiplatelet drugs and mechanical ventilation usage significantly reduced the risk of AKI. These variables are all among the top 6 predictive features for AKI in the XGBoost model.

Figure 6. SHAP force plot of (a) a patient with AKI and (b) a patient without AKI. Features contributing to an increase in the predicted value are shown in yellow, whereas those contributing to a decrease are shown in red. The length of the arrows represents the magnitude of each feature's influence on the model output. The scale on the x-axis indicates the extent to which each feature increases or decreases the predicted value. AKI: acute kidney injury; AMI: acute myocardial infarction; NT-proBNP: N-terminal pro–B-type natriuretic peptide; SHAP: Shapley Additive Explanation.

Discussion

Principal Findings

This study, based on data from the MIMIC-IV database and the Second Affiliated Hospital of Zhengzhou University, is the first to develop and externally validate an ML model for predicting AKI in critically ill patients with CHD. By incorporating 13 clinical variables, 6 ML algorithms were systematically compared. The results demonstrated that the XGBoost model exhibited superior predictive performance in both the internal testing set (AUROC=0.765, 95% CI 0.731-0.800) and the external validation cohort (AUROC=0.850, 95% CI 0.731-0.800). Calibration curve analysis and DCA further confirmed the model's excellent calibration and wide range of clinically beneficial threshold probabilities (0.20-0.95). External validation also confirmed the model's net clinical benefit across threshold probabilities below 0.9, underscoring its strong generalizability.

In model development, we used a feature selection strategy that combined LASSO regression with VIF analysis, consistent with methodologies adopted in previous studies [20]. We ultimately included13 variables and applied tree-based feature importance rankings, along with SHAP analysis, to enhance model interpretability. Our findings identified antiplatelet therapy, NT-proBNP, age, mechanical ventilation, and APSIII as the 5 most influential predictors, all of which were clinically plausible. Notably, NT-proBNP ranked among the top 3 variables in importance across the XGBoost, RF, and DT models and contributed significantly to AKI prediction, as indicated by SHAP values—an observation well aligned with its known pathophysiological role. As a sensitive biomarker of cardiorenal syndrome, NT-proBNP is cleared by glomerular filtration and can reflect early declines in the glomerular filtration rate (GFR) during the initial stages of AKI [21,22]. This finding supports the mechanistic evidence reported by Wang et al [23], who observed elevated NT-proBNP levels in patients with postoperative AKI following cardiac surgery. In addition, Liu et al [24] reported that preoperative NT-proBNP levels can more effectively predict postoperative AKI in patients undergoing noncardiac surgery, further corroborating the prognostic utility of NT-proBNP.

Given that our study cohort consisted of patients with CHD, we included relevant pharmacological agents in the predictive model. Results revealed that antiplatelet therapy ranks first in importance in both the XGBoost and DT models. SHAP analysis indicated that the risk of AKI is lowest among patients not receiving antiplatelet agents. Although monotherapy did not significantly increase AKI risk, dual-antiplatelet therapy was associated with a markedly elevated probability of AKI. Concerning how antiplatelet medications affect renal function, a Cochrane systematic review [25] showed that the risk of renal dysfunction in users of antiplatelet drugs is not high. Another systematic review indicated that in patients with chronic kidney disease (CKD), antiplatelet medication did not reduce the eGFR drop rate (−0.15 mL/1.73m²/year, 95% CI −0.89 to 1.20, I^2=40.8%) and affected renal failure events (odds ratio [OR] 0.87, 95% CI 0.32-1.55) [26]. However, retrospective case-control research by Fored et al [27] on the correlation of analgesic use with renal function revealed that in subjects who rarely used acetaminophen, frequent aspirin use was linked to a 2.5-fold increase in the likelihood of chronic renal failure compared to nonusers, with the relative risk increasing as the cumulative lifetime dose increased. Similarly, Bonet-Monné et al [28] noted a decrease in renal function associated with the use of nonsteroidal anti-inflammatory drugs (NSAIDs), analgesics, and antiplatelet drugs, which aligns with our findings.

As a core indicator for assessing disease severity in critically ill patients, APSIII systematically quantifies the extent of systemic pathophysiological derangements by integrating 12 acute physiological parameters, thereby revealing its close association with the risk of AKI. In this study, the SHAP dependence plot demonstrated a marked increase in AKI incidence when the APSIII exceeded 40. This threshold effect may be attributable to the severe hemodynamic instability reflected by high APSIII values [29]. In addition, the SOFA score, a commonly used tool in ICUs, has also been widely applied for predicting AKI in critically ill patients [30]. Although originally developed for sepsis, the SOFA score has been adopted by numerous cardiovascular studies as a quantitative measure of organ dysfunction [31-33]. In our cohort, the median SOFA score was 4.00 (IQR 2.00-6.00), suggesting that a considerable proportion of patients may have been at risk for infection. Notably, although the SOFA score was not selected as a feature variable in the modeling process, NLR, an established inflammatory marker, was selected by LASSO regression and incorporated into the model. This highlights the potential role of infection in the development of AKI among critically ill patients. For example, systemic inflammatory responses may lead to tubular epithelial injury and hemodynamic disturbances that impair renal perfusion, thereby triggering the onset of AKI.

Furthermore, our study revealed that advancing age and the use of mechanical ventilation also contribute to a higher incidence of AKI. Elderly adults represent a particularly vulnerable population for AKI, as the GFR naturally declines with age and the renal functional reserve diminishes, rendering them more susceptible to AKI under stress conditions. According to the SHAP dependence plot, patients between the ages of 70 and 80 years are at the highest risk for developing AKI. Retrospective studies have shown that younger females are less likely to develop postoperative AKI; however, the incidence increases progressively with age [34]. An ML model designed for predicting postoperative AKI similarly identified age as a critical predictor [35]. The use of mechanical ventilation has likewise been associated with an elevated risk of AKI, a finding consistently supported by many studies. Patients who need invasive mechanical ventilation have a threefold higher risk of AKI, according to a high-quality systematic review and meta-analysis, with no decrease in risk despite adjustments in the tidal volume or positive end-expiratory pressure (PEEP) settings [36].

Comparison With Previous Work

Forecasting AKI in individuals in the ICU has long been a focus in intensive care medicine. In recent years, multiple studies have developed ML models for AKI prediction. For example, Yue et al [37] developed a predictive model for AKI in patients with sepsis, Cho et al [38] established an AKI prediction model applicable to patients in general wards, and Zhou et al [39] established a forecasting model for AKI in the cohort with acute respiratory distress syndrome (ARDS) [39], incorporating 12 predictive variables, with XGBoost emerging as the ideal model, which aligns with our findings. Tseng et al [40] used 94 preoperative and intraoperative features to create a prediction model for cardiac surgery–associated AKI (CSA-AKI), where the RF model realized the highest AUROC (0.839, 95% CI 0.772-0.898) and was identified as the best model. They also used SHAP summary and dependence plots to explain the model, a similar approach to ours. Some AKI-forecasting models have been constructed for cardiovascular disease, but these primarily focus on predicting AKI following cardiac surgery. For instance, Kuno et al [41] built one for AKI after PCI [41], and Sun et al [42] predicted contrast-induced kidney injury in patients with AMI. However, patients with severe CHD in the ICU typically receive conservative treatment rather than surgical intervention. Thus, existing predictive models do not apply to these patients. At present, no forecasting models are designed for AKI in the patients with CHD in the ICU. Accordingly, we developed a dedicated predictive model for AKI among patients with CHD in the ICU, using the MIMIC-IV database. To the best of our knowledge, this is the first model specifically designed for the entire population of critically ill patients with CHD. Compared with previously established models limited to single clinical scenarios, our tool offers improved support for clinicians in identifying high-risk patients within complex clinical settings.

Strengths

The strength of ML is in integrating diverse data types and providing personalized treatment recommendations for patients. This study included data from 2 centers: the BIDMC and the Second Affiliated Hospital of Zhengzhou University. The data were rich and multidimensional, providing a meaningful representation of real-world clinical practice. Additionally, new variables not included in previous models, such as NT-proBNP and NLR, along with additional categorical variables, were incorporated with the aim of improving the model's performance. Moreover, the feature variables in our study differ from those in previous research. We used 13 feature variables to construct the model, including 4 continuous variables and 9 categorical variables. Categorical variables predominated in our model; however, in existing AKI prediction models, most selected variables are continuous. This discrepancy may be attributed to the fact that in addition to laboratory indicators, 25 binary categorical variables were incorporated, whereas previous studies have predominantly focused on laboratory indicators and other continuous variables, often lacking detailed data on comorbidities and medication use. Our results suggest that these categorical variables may have higher predictive value, indicating that future predictive models incorporating more categorical variables could potentially enhance predictive performance.

Limitations

First, as a retrospective study based on the MIMIC-IV database, the substantial missing data for several key variables, such as contrast agent dosage, infection markers (eg, procalcitonin and C-reactive protein), and cardiac biomarkers, may have led to the loss of potentially valuable predictive information related to contrast-induced nephropathy, AMI, and sepsis-associated AKI. This feature selection bias could have adversely impacted the model's ability to accurately identify AKI. Second, although hyperparameters were optimized using a grid search approach, the inclusion of 13 feature variables may have contributed to overfitting in certain models, such as the SVM and DT classifiers. Third, the external validation dataset was small, which may impact the external validity of the model. Therefore, further research involving larger sample sizes and multiple centers is necessary. Fourth, multiple imputation was used to estimate variables with less than 20% missing data, which may have introduced deviations from the true values. Additionally, this study aimed to provide a broadly applicable AKI risk assessment model for all critically ill patients with CHD—a clinical context in which the etiology of AKI is often initially unclear. However, due to the limited size of the external validation cohort, we did not perform more refined subgroup analyses to develop prediction models tailored to patients with specific comorbidities, which may have obscured potential heterogeneity across subpopulations with CHD.

Future Work

This study established the first predictive model for AKI encompassing the entire population of critically ill patients with CHD. However, its generalizability requires further confirmation through external validation in multicenter settings. We plan to integrate multicenter data from both CCUs and general ICUs to expand the sample size of the external validation cohort, thereby providing adequate statistical power for subsequent subgroup analyses. In the future, we intend to conduct collaborative multicenter studies and perform more granular stratification of the target population, for instance, critically ill patients with CHD complicated by MI and those undergoing PCI. These efforts aim to develop tailored AKI prediction models specific to different comorbid conditions, further addressing current gaps in our research. Moreover, we will develop an interactive explanatory interface to enable a closed-loop decision support system—from risk alerting to intervention recommendations. In parallel, we will design a user-friendly interface, formulate detailed implementation guidelines, and initiate pilot projects to evaluate the model's practical performance and user experience.

Conclusion

In conclusion, ML models can be a trustworthy tool for forecasting AKI in individuals with severe CHD. Across tested models, the XGBoost model demonstrated the best performance. It can help physicians identify patients with CHD who are at risk of AKI early, allowing for prompt therapies to lower mortality and enhance prognosis.

Abstract

Background: The development of sepsis in the intensive care unit (ICU) is rapid, the golden rescue time is short, and the effective way to reduce mortality is rapid diagnosis and early warning. Therefore, real-time prediction models play a key role in the clinical diagnosis and management of sepsis. However, the existing sepsis prediction models based on artificial intelligence still have limitations, such as poor real-time performance and insufficient interpretation.

Objective: Our objective is to develop a real-time sepsis prediction model that integrates high timeliness and clinical interpretability. The model is designed to dynamically predict the risk of sepsis in ICU patients and establish a practical, tailored sepsis prediction platform.

Methods: Within a retrospective analysis framework, the model comprises a real-time prediction module and an interpretability module. The real-time prediction module leverages 3-hour dynamic temporal features derived from 8 noninvasive, real-time physiological indicators: heart rate, respiratory rate, blood oxygen saturation, mean arterial pressure, systolic blood pressure, diastolic blood pressure, body temperature, and blood glucose. Three linear parameters (mean, SD, and endpoint value) were calculated to construct the prediction model using multiple ML algorithms. The interpretability module uses the TreeSHAP (Tree-Based Shapley Additive Explanations) method to enhance model transparency through both individual prediction and global explanations. Further, it added a link between the output interpretation of the explainable artificial intelligence method and its potential physiological or pathophysiological significance, including the relationship among the output interpretation and the patient's hemodynamics, thermoregulatory response, and the balance between oxygen delivery and oxygen consumption. Finally, a web-based platform was developed to integrate prediction and interpretability functions.

Results: The sepsis prediction model demonstrated robust performance in the test cohort (224 patients), achieving an accuracy of 0.7 (95% CI 0.68-0.71), precision of 0.69 (95% CI 0.68-0.71), F_1-score of 0.69 (95% CI 0.67-0.70), and area under the receiver operating characteristic curve of 0.76 (95% CI 0.74-0.77). The TreeSHAP method effectively visualized feature contributions, enabling clinicians to interpret the model's prediction logic and identify anomalies. The link between the output interpretation of the model and its potential physiological or pathophysiological significance improved the interpretability and credibility of the explainable artificial intelligence method. The web-based platform significantly enhanced clinical utility by providing real-time risk assessment, statistical summaries, trend analysis, and actionable insights.

Conclusions: This platform provides real-time dynamic warnings for sepsis risk in critically ill ICU patients, supporting timely clinical decision-making.

Introduction

Sepsis, a life-threatening clinical syndrome triggered by infection, continues to impose a significant global burden due to its persistently high incidence and mortality rates. In the United States, approximately 750,000 individuals are diagnosed with sepsis annually, with a mortality rate exceeding 30%; Europe reports 150,000 sepsis-related deaths yearly [1,2]. The economic impact is staggering, with annual US health care costs exceeding US $20.3 billion [3]. Patients with sepsis experience hospital stays twice as long as those with other conditions, and the incidence of severe sepsis continues to rise by 13% annually [4]. Early detection is critical to reducing mortality; yet, current diagnostic methods lack accuracy and real-time capability [5]. The multifactorial characteristics of sepsis increase the difficulty of early diagnosis, and the specificity of its diagnostic indicators is relatively low, which is prone to cause misdiagnosis [6]. Timely initiation of protocolized treatment bundles significantly improves survival [7], with evidence suggesting that a 1-hour resuscitation bundle may become the cornerstone of septic shock management [8]. However, sepsis pathophysiology is complex, microbiological confirmation is time-consuming, and existing scoring systems (eg, Mortality in Emergency Department Sepsis or Sequential Organ Failure Assessment) have limitations [9]. Thus, establishing a real-time sepsis prediction system is imperative to reduce clinical mortality.

Current research has leveraged artificial intelligence (AI) to develop sepsis prediction models using dynamic physiological and laboratory data. Machine learning has gained traction in critical care for disease diagnosis [10], outcome prediction [11-13], and clinical decision support [14]. Recent AI models for sepsis prediction outperform traditional methods [15-18], but reliance on non–real-time laboratory data and the "black-box" nature of AI models hinder clinical adoption [19,20]. These models often fall short in real-time performance and interpretability, limiting their clinical utility. Intensive care unit (ICU) clinicians require transparent, medically logical AI tools to preserve decision-making autonomy, aligning with evidence-based principles. Current sepsis prediction models also lack integration into practical platforms, further limiting clinical utility.

This study addresses these gaps by developing ML models based on dynamic features from real-time, noninvasive physiological indicators. We use local and global interpretability methods to enhance clinical trust and establish a web-based sepsis prediction platform.

Methods

Data Source

Data were extracted from the MIMIC-IV (Medical Information Mart for Intensive Care IV) database, developed by the MIT (Massachusetts Institute of Technology) Laboratory for Computational Physiology. This deidentified database includes clinical and waveform data from ICU and emergency department patients at Beth Israel Deaconess Medical Center (2008-2019) [21,22]. The physiological indicators were obtained from patient monitors. Blood oxygen saturation (SpO_2), heart rate (HR), and respiratory rate (RES) were collected 1-10 times per hour. Blood glucose (GLU) and body temperature (TEM) were measured once every 1 to 5 hours, depending on the patient's condition. Other indicators were collected hourly.

Study Cohort and Variable Selection

Patients with sepsis were identified per the 2018 Chinese Guidelines for Sepsis or Septic Shock Management (positive blood culture + antibiotic use + Sequential Organ Failure Assessment score ≥2). A control cohort included ICU patients without sepsis. Among 1118 patients (550 with sepsis and 568 controls), 8 real-time physiological indicators were selected: HR, systolic blood pressure (SP), diastolic blood pressure (DP), mean arterial pressure (MP), RES, TEM, SpO_2, and GLU. Stratified sampling divided the cohort into training (n=894) and test (n=224) groups. Baseline characteristics showed no significant differences (Table 1).

Table 1. *t* test analysis of characteristics between training and test groups[a].

Parameter	Training (n=894), median (IQR)	Test (n=224), median (IQR)	*P* value
Heart rate (bpm)	86.1 (30.5-157)	86.5 (43-137.5)	.81
Systolic BP[b] (mm Hg)	119.6 (48-191)	115.5 (36.8-187)	.08
Diastolic BP (mm Hg)	61.5 (10-116)	61.9 (19-121)	.67
Mean arterial pressure (mm Hg)	77.8 (24.3-149)	75.7 (8-127)	.08
Respiratory rate (bpm)	19.8 (5-44)	19.6 (6-52)	.60
Temperature (°C)	36.8 (31.7-40.4)	36.8 (33.1-39.9)	.74
SpO_2[c] (%)	96 (28.4-100)	95.6 (23-100)	.42
Blood glucose (mg/dL)	140.6 (42-309)	139.3 (63-326)	.75

[a]*P*<.05 indicates statistical significance.

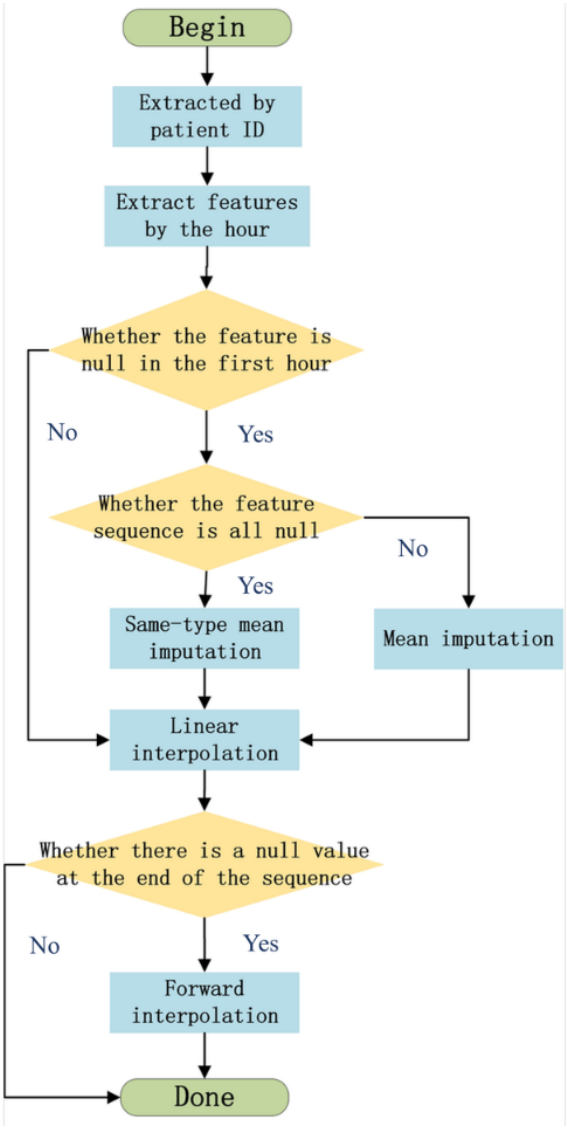
Data Preprocessing

First, the data underwent outlier removal. Since part of the MIMIC-IV data was manually entered by health care providers, potential input errors or anomalies were addressed. Clinical knowledge was applied to define valid physiological ranges and filter absolute outliers (for instance, TEM: 20 °C-50 °C; SpO_2: 21%-100%; HR: 0-300 bpm). Data points outside these ranges were deemed invalid and removed. Next, missing data imputation was performed to address gaps in the cleaned dataset. A hybrid approach combining multiple interpolation methods was applied:

1. Mean imputation: Replacing missing values with the overall mean of the feature.



2. Class-specific mean imputation: Using mean values from subgroups (eg, sepsis vs nonsepsis cohorts).

3. Linear interpolation: Filling gaps using linear trends between adjacent valid data points.

4. Forward-fill imputation: Propagating the last valid observation forward.

The entire preprocessing workflow is illustrated in Figure 1.

Figure 1. The entire preprocessing workflow.

To minimize reliance on long-term temporal dependencies, the prediction model was designed to operate on a 3-hour sliding window of real-time physiological data. This allows the model to initiate sepsis risk prediction immediately after 3 hours of monitoring. A 3-hour window allows sufficient time for sign monitoring and subsequent sepsis prediction, providing doctors with ample time for intervention. From the 3-hour time series of each physiological indicator, 3 linear parameters were computed: mean value over the 3-hour window, fluctuation coefficient (SD within the window), and endpoint value (the last recorded value in the window).

This generated a 24-dimensional feature vector for each patient, structured as follows:

- Endpoint values: HR, SP, DP, MP, RES, TEM, SpO_2, and GLU.
- Mean values: mean-HR, mean-SP, mean-DP, mean-MP, mean-RES, mean-TEM, mean-SpO_2, and mean-GLU.

XSL•FO
RenderX

- Fluctuation coefficients (SDs): var-HR (variation in heart rate), var-SP (variation in systolic blood pressure), var-DP, var-MP (variation in mean arterial pressure), var-RES (variation in respiratory rate), var-TEM (variation in body temperature), var-SpO_2 (variation in blood oxygen saturation), and var-GLU (variation in blood glucose).

All features were standardized (*z* score normalization) to ensure consistent scaling before model training. This preprocessing pipeline ensures robust, clinically meaningful inputs for the subsequent machine learning workflow.

Sepsis Prediction Model

We developed and evaluated the sepsis prediction model for actual ICU sign monitoring to achieve a model with greater generality in a broader clinical setting. Critically ill patients in the ICU have different needs for GLU monitoring frequency. The incidence of glucose metabolism disorders in critically ill patients is high, and the incidence increases in turn in sepsis, severe sepsis and septic shock [23], which not only reflects the abnormal secretion of hormones and the severity of the disease, but is also closely related to the increase of mortality and complications [24]. High or low GLU is one of the causes of organ dysfunction. Therefore, it is necessary to increase the frequency of GLU monitoring in the face of the clinical background of insufficient energy intake, high catabolism, impaired GLU regulation mechanism, or the implementation of insulin treatment. At the same time, it is also necessary to increase the frequency of GLU monitoring in critically ill patients with diabetes or hypoglycemia. Whereas in most other ICU patients, GLU is usually measured only once or twice a day.

Therefore, to improve the generalization of sepsis prediction models, we developed and evaluated 2 sepsis prediction models, one based on high-frequency glucose monitoring and the other based on routine vital signs monitoring without glucose. By combining the 2 models, a model with greater generality in a wider range of clinical settings was achieved.

This study used 6 machine learning algorithms—support vector machine, random forest, ExtraTrees, XGBoost (Extreme Gradient Boosting), AdaBoost, and Logistic—to construct real-time sepsis prediction models. Model performance was evaluated and compared using metrics including accuracy, precision, recall, F_1-score, and area under the receiver operating characteristic curve (AUROC).

Model Interpretation

The TreeSHAP (Tree-Based Shapley Additive Explanations) method was used to provide both local (individual prediction) and global explanations for the sepsis prediction model. TreeSHAP, grounded in cooperative game theory, constructs an additive explanation model that treats all features as “contributors” to the prediction outcome. For each sample, TreeSHAP generates a Shapley value for each feature, quantifying its marginal contribution to the model’s decision. For the sepsis prediction model with 24 features, let the original model be f, trained using AdaBoost. The explanation model g in SHAP (Shapley Additive Explanations) is defined as:

$x=(x_1,x_2\ldots x_{24})$ represents the feature vector of a single patient. f(x) is the prediction from the original model. g(x) is the prediction from the explanation model. $ø_i$ is the Shapley value for the ith feature.

S is a subset of {1,2,3…24}, with 2^{24-1} possible combinations. |S| is the number of features in subset S. f_x (S ∪ i) and f_x(S) are model predictions with and without feature i, respectively. Global interpretation aggregates local explanations by averaging the absolute Shapley values across all samples.

Ethical Considerations

Our study was conducted in accordance with the guidelines of the Helsinki Declaration. The Review Committee of the Massachusetts Institute of Technology and Beth Israel Deaconess Medical Center approved access to the MIMIC-IV database. Authors fulfilled the database access request. All these data were deidentified; therefore, the study was exempt from ethical approval and informed consent requirements.

Results

Model Prediction Performance

The performances of the sepsis prediction models based on high-frequency glucose monitoring are summarized in Figure 2 and Table 2. Among all models, AdaBoost achieved the highest accuracy of 0.70 (95% CI 0.68-0.71), precision of 0.69 (95% CI 0.68-0.71), F_1-score of 0.69 (95% CI 0.67-0.70), and AUROC of 0.76 (95% CI 0.74-0.77), demonstrating superior real-time prediction capability. The performances of the sepsis prediction models based on routine vital signs monitoring without glucose are summarized in Figure 3 and Table 3. Among all models, AdaBoost achieved the highest accuracy of 0.67 (95% CI 0.66-0.69), precision of 0.67 (95% CI 0.65-0.68), and AUROC of 0.75 (95% CI 0.74-0.77). The experimental results show that the sepsis prediction model based on high-frequency monitoring of GLU has better prediction performance, and the sepsis prediction model based on routine vital signs monitoring has a wider application scenario.

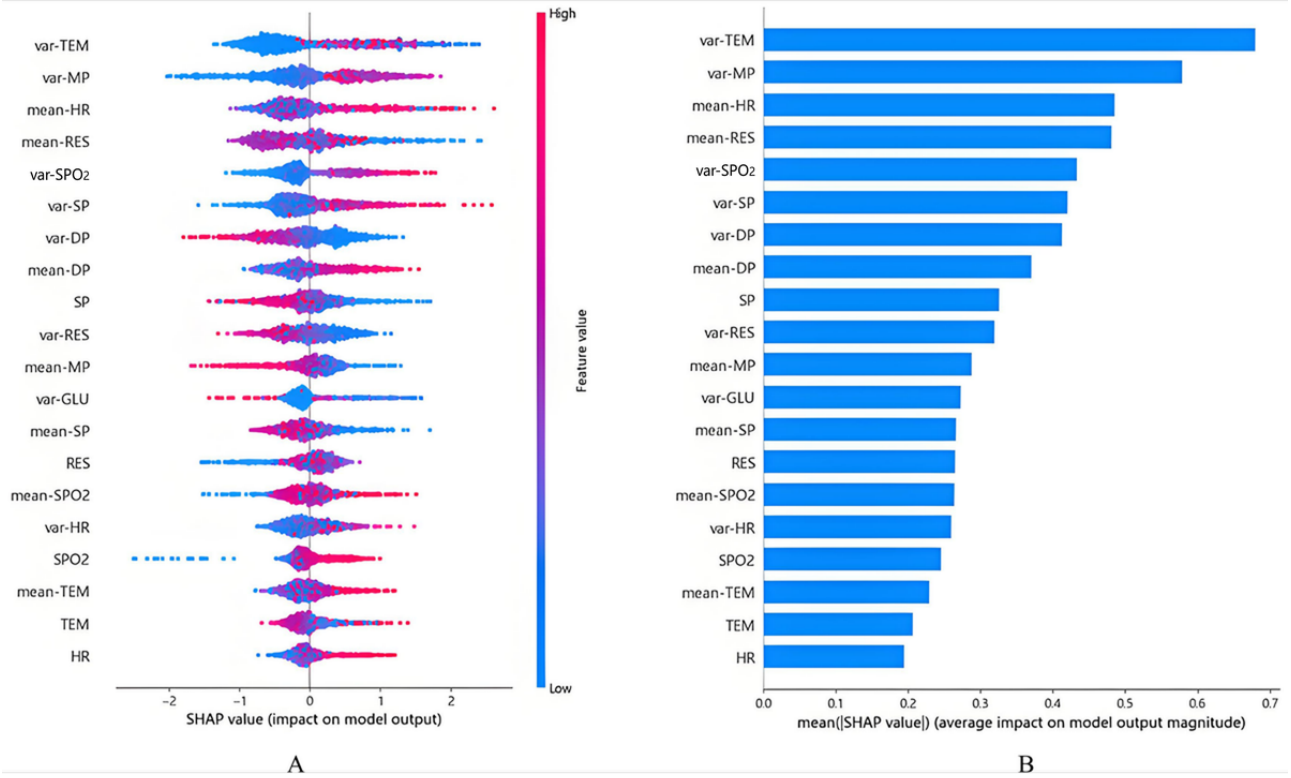
Interpretability Analysis Using TreeSHAP

Individual Prediction Explanation

The TreeSHAP method was used to generate local explanations for individual cases to elucidate the contribution of dynamic features to model predictions. Figure 4 illustrates the interpretability analysis for a patient predicted as having sepsis, where features are color-coded to reflect their impact: red denotes a positive contribution (increasing sepsis risk) and blue indicates a negative contribution (reducing sepsis risk). The baseline value E[f(x)], representing the model's average prediction across the dataset, serves as the reference point. Key findings include: SP fluctuation coefficient (var-SP=12.257) exerted the strongest positive influence (+1.18), followed by SpO_2 fluctuation (var-SpO_2=2.867), mean RES (mean-RES=3.667), mean DP (mean-DP=68.667), TEM (TEM=35.833), and MP fluctuation (var-MP=6.164). Negative contributors included SP (SP=15), RES (RES=11), and DP (DP=75). These results basically align with clinical intuition, where elevated variability in hemodynamic parameters (eg, var-SP or var-MP), hypothermia, and reduced RES correlate with sepsis pathophysiology. The interpretability framework enables clinicians to validate model logic against established diagnostic criteria and identify anomalous predictions.

Figure 4. Individual prediction explanation. DP: diastolic blood pressure; MP: mean arterial pressure; RES: respiratory rate; SP: systolic blood pressure; SpO_2: blood oxygen saturation; TEM: body temperature.



Global Interpretation

Global interpretability analysis aggregated Shapley values across all samples to reveal the model's overarching decision logic and feature importance rankings (Figure 5). As illustrated in Figure 5A, the model demonstrated associations between decreased SP and elevated sepsis risk (row 9), increased SP fluctuation (var-SP) and elevated sepsis risk (row 6), and increased MP fluctuation (var-MP) with elevated sepsis risk (row 2). These interpretations align closely with existing clinical evidence and provide clinically meaningful insights that are of particular interest to clinicians. For instance, increased var-SP is more likely to elevate the probability of sepsis compared to increased var-MP. The Surviving Sepsis Campaign 2021

XSL•FO
RenderX

guidelines emphasize the importance of SP in the diagnostic criteria for sepsis and recommend using SP<90 mm Hg after adequate fluid resuscitation as one of the indicators for evaluating septic shock [25]. Additionally, studies have shown that blood pressure variability in sepsis patients correlates with disease severity [26].

Figure 5. Global interpretation of the model and feature importance based on mean Shapley values. DP: diastolic blood pressure; GLU: blood glucose; HR: heart rate; MP: mean arterial pressure; RES: respiratory rate; SHAP: Shapley Additive Explanations; SP: systolic blood pressure; SpO_2: blood oxygen saturation; TEM: body temperature.

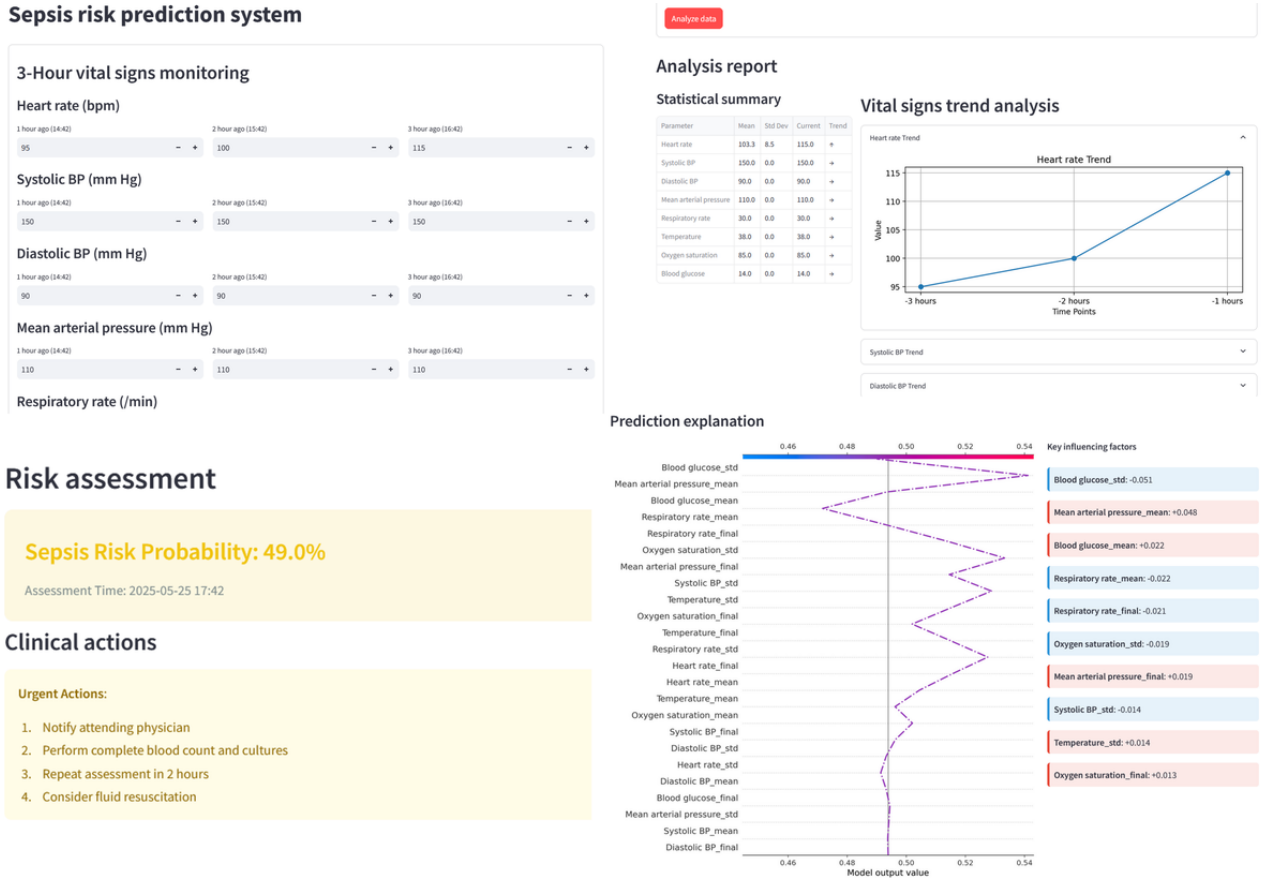
The connection between the parasympathetic nervous system and inflammation suggests interdependence between autonomic nervous system function and inflammatory responses [27]. Furthermore, physiological systems exhibit nonlinear patterns of complexity, including fractal self-similarity across time scales [28]. Previous research has documented an association between the complexity of autonomic nervous system control and hemodynamic instability, indicating that such complexity may serve as a potential window into understanding hemodynamic confusion. However, the relevance of these measures of complexity in sepsis remains unclear [26].

High temperature fluctuations (var-TEM) were strongly associated with increased sepsis probability, while stable temperatures reduced the risk (row 1). Notably, extreme TEMs, whether hyperthermia or hypothermia, were linked to elevated risks, whereas normal-range temperatures exhibited protective effects (row next-to-last). This interpretation of the model aligns with the clinical presentation of sepsis.

Both hypothermia and hyperthermia are generally associated with elevated lactate levels, and patients with severe sepsis often develop either hypothermia or, more commonly, a febrile response. Hypothermia in some patients with sepsis is well-documented and forms part of the definition of systemic inflammatory response syndrome [29]. There is variable thermoregulatory response in sepsis, and the definition of systemic inflammatory response syndrome in sepsis-1 includes both fever and hypothermia. The impact of thermoregulatory response on sepsis prognosis remains controversial. Studies have shown that hypothermia or fever can have either protective or detrimental effects in animal models of severe infection or inflammation [30]. Fever is a physiological response to infection that inhibits bacterial growth, prevents fungal proliferation, and enhances immune cell activity against pathogens [31]. Pathogens detected in blood cultures and elevated procalcitonin levels, both associated with high fever, indicate robust immune resistance to pathogen challenges [32].

The model revealed an association between increased variability in oxygen saturation (var-SpO_2) and elevated sepsis risk (row 5). This finding underscores the necessity of maintaining SpO_2 levels within a reasonable range for ICU patients during hospitalization, which is consistent with existing clinical evidence. Studies have demonstrated a U-shaped relationship between SpO_2 levels and in-hospital all-cause mortality in patients with sepsis, where both hyperoxia and hypoxia are associated with increased mortality risk. The optimal SpO_2 range is determined to be 0.96-0.98 [33]. Under normal physiological conditions, oxygen supply and consumption remain relatively stable, with SpO_2 fluctuating within a normal range without extreme variation. During shock, however, the imbalance between oxygen supply and consumption leads to deviations in SpO_2 values, resulting in increased var-SpO_2. A multicenter observational study involving over 600 patients with sepsis confirmed that abnormal SpO_2 levels (either

XSL•FO
RenderX



abnormally high or low) were associated with increased mortality [34].

Figure 5B ranks feature mean absolute Shapley values, identifying the top 6 determinants of sepsis risk: temperature fluctuation (var-TEM), MP fluctuation (var-MP), mean HR (mean-HR), mean RES (mean-RES), SpO_2 fluctuation (var-SpO_2), and SP fluctuation (var-SP). These findings underscore the critical role of hemodynamic and thermoregulatory instability in sepsis onset, consistent with clinical biomarkers. The global analysis also highlights potential outliers, guiding model refinement and clinical vigilance.

Implementation of the Practical and Efficient Sepsis Risk Prediction Platform

We developed a practical and intelligent sepsis risk prediction platform using a web-based tool [35] (Figure 6). By monitoring 3-hour dynamic temporal features of ICU patients—including HR, SP, DP, MP, RES, TEM, SpO_2, and GLU—the platform automatically generates a graphical analysis report comprising:

Figure 6. Practical and efficient sepsis risk prediction platform. BP: blood pressure.

Statistical summary: quantitative analysis of dynamic temporal features (mean, SD, and endpoint values).

Vital signs trend analysis: visualization of physiological trends via time-series curves.

- Risk assessment: sepsis risk prediction using the trained model, based on calculated linear parameters.
- Clinical actions: automated recommendations (for reference only) tailored to risk stratification.
- Prediction explanation: visual display of key influencing factors using Shapley values to interpret model decisions.

This platform, built on real-time dynamic temporal features, enables personalized sepsis risk prediction for ICU patients, enhances clinical utility by integrating interpretable AI insights, and streamlines decision-making through intuitive data visualization and actionable outputs.

Discussion

Principal Findings

Our study developed a real-time sepsis prediction model that integrates high timeliness and clinical interpretability based on 3-hour dynamic temporal sequences of 8 rapidly accessible physiological indicators. The real-time sepsis prediction model demonstrated robust performance. The output interpretation of explainable artificial intelligence (XAI) enhanced model transparency through both individual prediction and global explanations, and it linked the potential physiological or pathophysiological significance, including the patient's hemodynamics, thermoregulatory response, and the balance between oxygen delivery and oxygen consumption. Although current consensus emphasizes early intervention for sepsis management, the optimal predictors guiding intervention and markers of early sepsis severity remain unclear. In this study, we further elucidated the model's output results, explored the potential relationships between relevant sign parameters and

XSL•FO
RenderX

sepsis, and discussed their potential physiological or pathophysiological significance. This enhances the interpretability and credibility of the XAI method, supporting the model's applicability in real-world clinical practice. Finally, the web-based platform significantly enhanced clinical utility by providing real-time risk assessment, statistical summaries, trend analysis, and actionable insights.

Limitations

However, as a retrospective study, potential biases may exist in this study. Future efforts should prioritize multicenter validation and large-scale prospective studies to strengthen the robustness of these results. XAI holds immense promise in sepsis diagnosis and treatment, yet its development and clinical application face significant challenges [36]. Data quality remains a critical bottleneck. Heterogeneous hospital databases, inconsistent data collection and storage standards, and poor interoperability between health care information systems have led to fragmented "data silos," hindering the application of large-scale clinical feature datasets. Additionally, the reliance on limited public or institution-specific databases in research settings restricts generalizability. In clinical practice, clinicians must integrate XAI predictions with laboratory findings (eg, lactate or procalcitonin), imaging results, and patient-specific symptoms to ensure accurate diagnosis and treatment planning.

Conclusions

In ICU settings, real-time physiological indicators—such as HR, RES, and SpO_2—are typically used to monitor symptom fluctuations rather than generate objective diagnostic reports. This limitation stems from the significant variability in individual physiological data, the complexity of multiparameter interactions, and the diverse clinical implications of these metrics. This study demonstrates that XAI can bridge this gap by synthesizing real-time physiological data into actionable insights. By analyzing dynamic trends and providing interpretable explanations, XAI uncovers the diagnostic potential of these data. Our model, focused on sepsis risk prediction, leverages real-time physiological features to generate predictions while emphasizing the interpretability of results. In the future, XAI systems could deliver intelligent diagnostic reports integrating disease prediction, anomaly detection, and causal analysis of abnormal indicators, empowering clinicians to navigate complex physiological data with precision.

Data Availability

The data used in this study are publicly available from the Medical Information Mart for Intensive Care IV (MIMIC-IV) database. As a result of patient privacy concerns, the raw EHR (electronic health records) text data cannot be shared publicly but can be accessed through a compliant application to MIMIC-IV.

Authors' Contributions

M Zhang conceptualized the study and carried out the formal analysis, investigation, and writing and editing of the original draft. M Zhong conceptualized the study and carried out the formal analysis, investigation, and validation. YC carried out the formal analysis, investigation, and validation. TZ assisted with the conceptualization, investigation, analysis, project administration, and paper review and editing.

Abstract

Background: The growing availability of electronic health records (EHRs) presents an opportunity to enhance patient care by uncovering hidden health risks and improving informed decisions through advanced deep learning methods. However, modeling EHR sequential data, that is, patient trajectories, is challenging due to the evolving relationships between diagnoses and treatments over time. Significant progress has been achieved using transformers and self-supervised learning. While BERT-inspired models using masked language modeling (MLM) capture EHR context, they often struggle with the complex temporal dynamics of disease progression and interventions.

Objective: This study aims to improve the modeling of EHR sequences by addressing the limitations of traditional transformer-based approaches in capturing complex temporal dependencies.

Methods: We introduce Trajectory Order Objective BERT (Bidirectional Encoder Representations from Transformers; TOO-BERT), a transformer-based model that advances the MLM pretraining approach by integrating a novel TOO to better learn the complex sequential dependencies between medical events. TOO-Bert enhanced the learned context by MLM by pretraining the model to distinguish ordered sequences of medical codes from permuted ones in a patient trajectory. The TOO is enhanced by a conditional selection process that focus on medical codes or visits that frequently occur together, to further improve contextual understanding and strengthen temporal awareness. We evaluate TOO-BERT on 2 extensive EHR datasets, MIMIC-IV hospitalization records and the Malmo Diet and Cancer Cohort (MDC)—comprising approximately 10 and 8 million medical codes, respectively. TOO-BERT is compared against conventional machine learning methods, a transformer trained from scratch, and a transformer pretrained on MLM in predicting heart failure (HF), Alzheimer disease (AD), and prolonged length of stay (PLS).

Results: TOO-BERT outperformed conventional machine learning methods and transformer-based approaches in HF, AD, and PLS prediction across both datasets. In the MDC dataset, TOO-BERT improved HF and AD prediction, increasing area under the receiver operating characteristic curve (AUC) scores from 67.7 and 69.5 with the MLM-pretrained Transformer to 73.9 and 71.9, respectively. In the MIMIC-IV dataset, TOO-BERT enhanced HF and PLS prediction, raising AUC scores from 86.2 and 60.2 with the MLM-pretrained Transformer to 89.8 and 60.4, respectively. Notably, TOO-BERT demonstrated strong performance in HF prediction even with limited fine-tuning data, achieving AUC scores of 0.877 and 0.823, compared to 0.839 and 0.799 for the MLM-pretrained Transformer, when fine-tuned on only 50% (442/884) and 20% (176/884) of the training data, respectively.

XSL•FO
RenderX

Conclusions: These findings demonstrate the effectiveness of integrating temporal ordering objectives into MLM-pretrained models, enabling deeper insights into the complex temporal relationships inherent in EHR data. Attention analysis further highlights TOO-BERT's capability to capture and represent sophisticated structural patterns within patient trajectories, offering a more nuanced understanding of disease progression.

Introduction

In modern health care, electronic health records (EHRs) are crucial as comprehensive repositories encompassing a wide range of patient data, including diagnoses, medications, treatments, laboratory data, and demographic information. The accumulation of EHR data longitudinally builds EHR trajectories, sometimes called patient trajectories. This information serves as an important resource for assessing a patient's current health status and predicting potential health risks. Using advanced deep learning (DL) models with this extensive data opens the possibility of making predictions, such as disease risks, treatment outcomes, and patient prognoses. This possibility equips health care providers with the tools to make informed decisions, ultimately improving patient care, optimizing interventions, and reducing health care costs.

However, developing DL methods for modeling EHR data is full of challenges. Effectively addressing the complexity of the heterogeneous data extracted from patients' EHR [1-4], capturing short- and long-term relationships between medical codes across various visits, contending with the scarcity of publicly available EHR sources, and navigating the vast diversity of diseases pose significant hurdles. In addition, ensuring transparency and explainability in the predictions made by DL techniques demands substantial effort [5-7].

Current state-of-the-art models for EHR trajectory data are based on transformer architecture [8], in particular, models inspired by the Bidirectional Encoder Representations from Transformers (BERT) [9] architecture [10-14]. Such models aim to capture short- and long-term relationships through a task-agnostic representation learning (RL) approach, where the masked language model (MLM) pretraining objective is very common.

The BERT-inspired models for EHR trajectory data can be examined from various perspectives: data and model size, used data modalities, architecture, and pretraining objectives. Within this context, we focus on the primary and auxiliary pretraining objective functions designed to enhance the capabilities of the learned representation.

The primary objective typically takes the form of a generative task, benefiting from its enhanced ability to grasp intricate relationships. MLM objectives have found widespread application in EHR trajectory prediction tasks, largely owing to the capabilities of BERT models to learn the context (both past and future simultaneously) [10,11,15-22]. The autoregressive pretraining objective [23,24] serves as the other approach for RL of EHR trajectory data. It accomplishes this by predicting upcoming medical events, such as the codes for the next day or the subsequent visit, leveraging the patient's historical data [25-27].

A range of auxiliary pretraining objectives has been proposed to enhance the RL performance, incorporating either external knowledge or using contrastive learning. Examples of the former include Shang et al [15] and Amirahmadi et al [28] that predicted medications based on diagnoses and diagnoses based on medication to induce relationships within the diagnoses and interventions in the learned representation. Med-BERT [11] introduced a length of stay auxiliary prediction task to enrich contextual information about the severity of patients' health conditions. CEHRT-BERT [16] and Claim-PT [27] incorporated visit type predictions (eg, inpatient and outpatient visits) to represent external domain knowledge into the model, mitigating the effect of sparse codes based on the observation that different medical concepts are associated with different visit types.

RareBERT [19] introduced a 1-class classification objective to improve model performance for rare disease prediction. Similarly, AdaDiag [18] added a domain classifier to distinguish data from different institutes and enhance the generalizability and robustness of the learned representation against dataset shifts.

From the contrastive learning category, we find Hierarchical BEHRT (Hi-BEHRT) [17] that used bootstrap your own latent (BYOL) [29] similarity learning, operating under the assumption that varying augmentations of the same input yield similar representations, thereby enhancing the latent representation of the network. Rapt [21] trained the transformer to differentiate between different patient trajectories, relying on the Euclidean distance between their last visits to enrich the RL's understanding of their health condition. In addition, Rapt used another auxiliary objective, like the next sentence prediction, to discern whether a trajectory belongs to a specific patient or constitutes a fusion of various patient trajectories, facilitating the learning of trends within health trajectories. Generative Adversarial Networks Enhanced Pretraining (GRACE) [22], addressing the EHR data insufficiency challenge, incorporated a real or fake contrastive learning objective to distinguish authentic EHR data from generative adversarial network (GAN)–generated EHR data within the MLM framework.

Instances of medical events can influence the likelihood of other medical events, shaping the trajectory of patients toward more or less severe health conditions. Moreover, numerous medical events exhibit semicausal relationships through chains of probability paths that have not been extensively studied [30-33].

XSL•FO
RenderX

The relative intervals between medical events play a pivotal role in adjusting a patient's trajectory and are a key factor for the RL model. In pretrained language models, similar concepts are applied to comprehend the global coherence of data. BERT [9] used a next-sentence prediction (NSP) to capture the global relations between sentences. However, Liu et al [34] showed that NSP does not generate a positive impact, and Lan et al [35] speculate that the reason lies in the simplicity of NSP and its overlap with the MLM loss. Consequently, they replaced NSP with sentence order prediction, prioritizing coherence prediction over topic prediction [36,37]. Before the mentioned studies, researchers improved their machine translation, constituency parsing models, and object detection by altering the order of input [38-40]. Vinyals et al [41] delved into the problem that, while in theory incorporating the order of sequences should not have a significant impact when using complex encoders due to their nature as universal approximators, in practice, it does matter due to underlying nonconvex optimization and more fitting priors.

Furthermore, EHR trajectories encompass a history of abnormal health conditions, including diseases, laboratory data, and prescribed interventions like medications and procedures. The occurrence of certain diseases can alter a person's health trajectory and increase the probability of other illnesses. Similarly, interventions often mitigate the severity of conditions at the cost of raising other health risks. Thus, every medical event, whether it involves diseases or medications, can serve as a cause, complication, or early symptom of the recorded codes [42]. This study will demonstrate that order objectives, besides the context, enhance the model performance by learning more structural information. In summary, the contributions are mentioned in Textbox 1.

Textbox 1. Overview of the study's main contributions.

- We have examined the ability of Bidirectional Encoder Representations from Transformers–inspired models to capture the representation of sequential information of medical codes. Our findings indicate that although transformers and language models excel at identifying global dependencies based on contextual information, learning the order of diseases and medications can be challenging, especially for patients with long trajectories.
- We introduced a novel "trajectory order objective" self-supervised auxiliary task to the masked language model (MLM). This new objective was applied at both the single code and visit levels, and we demonstrated its efficacy in enhancing the original MLM by evaluating it on heart failure, Alzheimer disease, and prolonged length of stay downstream prediction tasks on 2 distinct datasets.
- We introduced the conditional code swapping and conditional visit swapping functions built on the "conditional-based order of medical codes." This function allows swapping more frequent consecutive repetitions, enabling the model to systematically learn the patterns of transitions at both the single code and visit levels.
- We demonstrated how adding the new objective reshapes the attention behavior of the transformer model and encourages the model to attend to relations between 2 sets rather than 2 individual codes, enabling the learning of more complex structural relationships.

Methods

Data

In this study, we extracted medical diagnoses and medication histories from 2 distinct (EHR) trajectory datasets, namely the Medical Information Mart for Intensive Care IV (MIMIC-IV) hosp module [43] and the Malmo Diet and Cancer Cohort (MDC) [44]. These 2 datasets have unique characteristics that suit our research objectives.

The MIMIC-IV hosp module encompasses a rich, detailed collection of inpatient EHR trajectories, comprising a total of approximately 173,000 patient records recorded during 407,000 visits. The data spans from 2008 to 2019, offering a comprehensive view of patient journeys within the hospital setting. MIMIC-IV hosp module contains approximately 10.6 million medical codes associated with a large volume of patients. The MDC data is a prospective cohort from Sweden. It consists of approximately 30,000 individuals residing in the municipality of Malmo (southern Sweden) between 1991 and 1996. The cohort was recruited from a total population of about 74,000 individuals, encompassing all men born between 1923 and 1945 and all women born between 1923 and 1950. All inpatient and outpatient visits between 1992 and 2020 have been recorded, resulting in a total of 531,000 visits. Although the MDC dataset has fewer overall samples, it excels in providing a more extensive patient history, averaging 257 codes per patient compared to MIMIC-IV's 61 (for more details, refer to Multimedia Appendix 1).

Diseases and medications in both datasets are classified using the *ICD* (*International Classification of Diseases and Related Health Problems*) and Anatomical Therapeutic Chemical Code (ATC), respectively. These coding systems follow a hierarchical format, providing granular details about diseases or medications based on code length.

To facilitate our self-supervised pre-training, supervised fine-tuning, and final testing, we randomly partitioned the extracted cohort into 3 subsets: 70%, 20%, and 10%, respectively. For further details on the specifications of the MIMIC-IV and MDC datasets, refer to Tables 1 and 2.

Ethical Considerations

The use of the MDC dataset for this study was approved by the Ethics Review Board of Sweden (Dnr 2023-00503-01). Regarding the MIMIC-IV dataset, all protected health information (PHI) is officially deidentified. It means that the deletion of PHI from structured data sources (eg, database fields that provide age, genotypic information, and past and current diagnosis and treatment categories) is performed in compliance with the HIPAA (Health Insurance Portability and Accountability Act) standards in order to facilitate public access to the datasets.

Data Processing and Problem Formulation

Each dataset D comprises a set of patients P, $D = \{P^1, P^2, ..., P^{|D|}\}$. In our study, we considered a total of |D|= 172,980 patients for MIMIC-IV and |D|= 29,664 patients for the MDC cohort. We represent each patient's longitudinal medical trajectory through a structured set of visit encounters. Given the continuous recording of medical codes in the MDC cohort, we define a visit entity V for each code and all previous subsequent codes occurring within a 6-month time window. For the MIMIC-IV, we used the predefined visits. This representation is denoted as P, $P^i = \{V^i_1, V^i_2, \ldots, V^i_O\}$, where O represents the total number of visit encounters for patient I. For each visit, $V^i_j = I_j \cup M_j$ is the union of all diagnoses codes $I_j \subset I$ and prescribed medications $M_j \subset M$ that are recorded for the P^i at visit V^i_j. To reduce the sparsity, we excluded less frequently occurring medical codes and retained only the initial 4 digits of *ICD* and ATC codes (refer to Multimedia Appendix 1). This process resulted in 2195 *ICD-9* (*International Classification of Diseases, Ninth Revision*) and 137 ATC-5 unique codes for the MIMIC-IV dataset and 1558 *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) and 111 ATC-5 unique codes for the MDC dataset. In addition, for the MIMIC-IV, we converted medication data from National Drug Code (NDC format to ATC format to benefit from its hierarchical structure and improve comparability.

To guide the model in understanding changes in encounter times and the structure of each patient's trajectory, like BERT, we used special tokens. A CLS token is placed at the beginning of each patient's trajectory, while a SEP token is inserted between visits. Consequently, each patient trajectory is represented as $P^i = \{CLS, V_1^i, SEP, V_2^i, SEP, \ldots, V_0^i, SEP\}$, providing the model with valuable context for analysis and prediction.

Heart Failure Prediction

The primary downstream task is heart failure (HF) prediction, where the model predicts the incidence of the first HF *ICD* codes $I_{N=HF}$ on the Nth visit, given the patient's previous history of diagnosis and medication intervention:

For each patient's trajectory, if there were no occurrences of the target disease, it is considered a negative case; otherwise, we excluded the first visit with target codes and all subsequent visits and considered it a positive case. Furthermore, all ATC codes related to HF treatment are excluded. To mitigate trajectory length bias, trajectories with fewer than 10 and 30 visits are excluded from MIMIC IV and the MDC dataset, respectively, ensuring an equal average number of visits within positive and negative cases. Following these preprocessing steps, we obtained Cohorts with a history of 5 visits for

XSL•FO
RenderX

MIMIC-IV and 20 visits for the MDC dataset on average. As a remark, in the MDC Cohort, this task is equivalent to predicting HF in the next 6 months, as per the preprocessing design.

Alzheimer Disease Prediction

The next downstream task is Alzheimer disease (AD) prediction. Similar to the HF prediction downstream task, the model predicts the occurrence of the first AD *ICD* codes $I_{N=AD}$ on the Nth visit, considering the patient's previous history of diagnoses and medication interventions:

We followed the HF prediction preprocessing steps. The AD downstream prediction task was tested on the MDC dataset.

Prolonged Length of Stay Prediction

To explore the adaptability of pretrained models to a distinct task from the one they were initially trained on (code prediction), we used the prediction of prolonged length of stay (PLS) as a binary classification downstream task. In this task, the model is assigned the objective of predicting the PLS in the Nth visit based on a patient's diagnoses and medications in previous visits in the MIMIC-IV dataset:

Consistent with [45], patients with a stay longer than 5 days were considered positive cases for PLS. To maintain consistency with the HF prediction task, trajectories with fewer than 3 visits were excluded, and the average number of visits was equalized between positive and negative cases. Following these steps, we obtained a Cohort with an average history of 5 visits (refer to Multimedia Appendix 1).

Methods

Recent studies have underscored the effectiveness of using multihead transformer architecture and MLM self-supervised learning in the domain of EHR trajectory modeling. While these methods have exhibited superior performance in various contexts, we focus on investigating their limitations related to sequential order learning and propose enhancements to address this issue.

A fundamental aspect of EHR trajectory modeling is the critical role of the sequential order of medical events in guiding patients' trajectories. For instance, the timely administration of appropriate medical interventions can significantly alter a patient's trajectory, either improving the severity of their condition or, conversely, leading to unintended side effects.

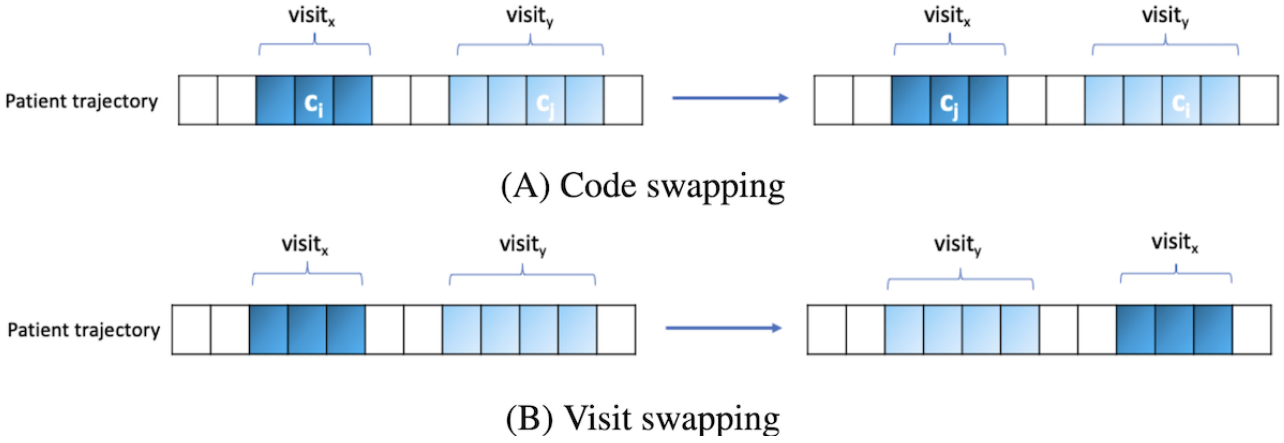
Models Objective

Our approach involves pretraining a transformer model on 2 distinct generative and contrastive self-supervised learning objectives: MLM and Trajectory-Order Objective (TOO). The MLM is crafted to learn the context, while TOO is designed to capture relations between local contexts. By simultaneously training the model on both of these objectives, we aim to leverage the entire set of patient trajectories and acquire a more comprehensive data representation.

MLM

The MLM generative task is used to learn the contextual dependencies among medical codes. In this paper, we corrupt the input by randomly masking the medical codes in each patient's trajectory, denoted as $P^i_{corrupted}$, and train the model to maximize the likelihood of the masked codes, denoted as x^k:

where is the conditional probability modeled by a deep neural network with parameter . We used a sliding window approach across patients' trajectories to generate additional samples for the MLM objective (refer to Multimedia Appendix 1).



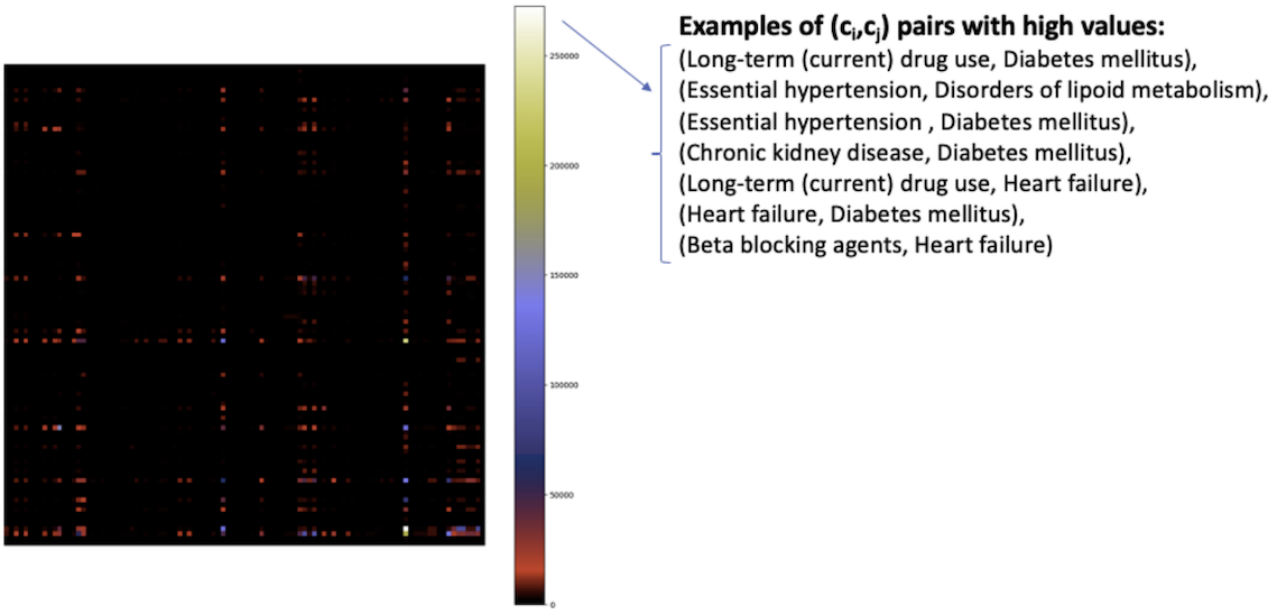
In the trajectory order objective, we train the transformer model to learn the relative positions of local features across 2 hierarchical levels, visits and medical codes. The TOO task helps the model gain insights into both causal and noncausal relationships within medical codes and visits. We achieved this by permuting each patient's trajectory, using them as negative samples, while the unpermuted sequences served as positive examples for the TOO self-supervised contrastive learning task.

In this equation, state ∈ {permutated, ordered} denotes whether the trajectory P^i is ordered or permutated, and $y_{state} \in \{0,1\}$ is the corresponding label. We implemented the TOO task at the code level and visit level, by code swapping and visit swapping, respectively (refer to Figure 1).

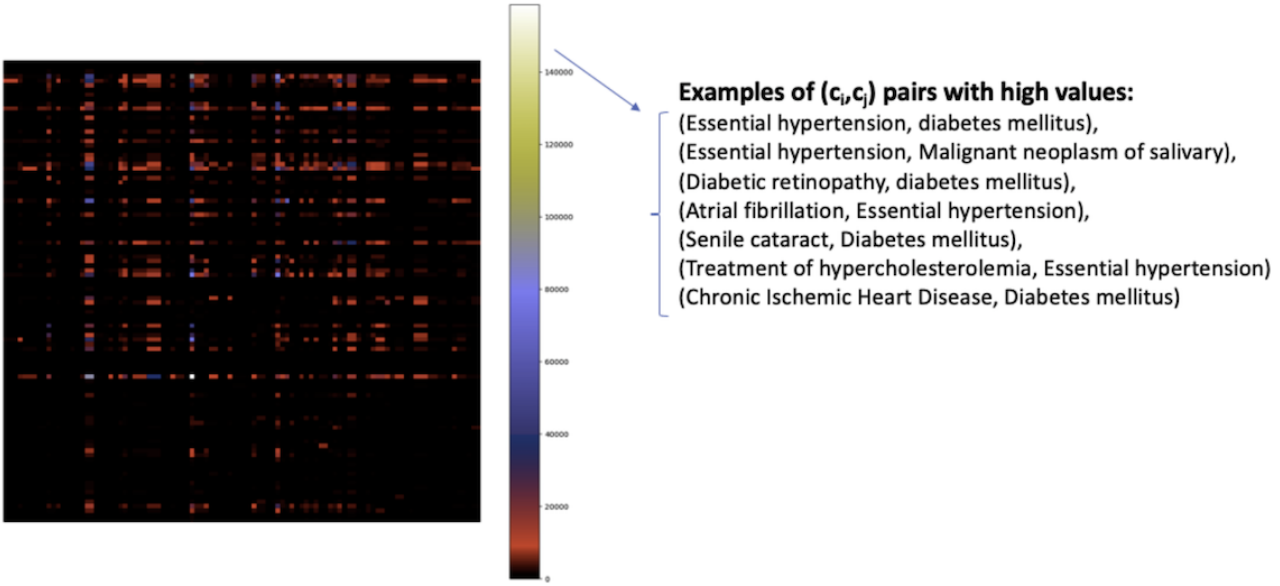
XSL•FO
RenderX

Figure 1. Code versus visits swapping. (A) Code swapping does not alter the visit structures of patient trajectories and only substitutes one medical code with another medical code in a different visit. (B) Visits swapping substitutes one visit, along with all its contents, with another visit, further disrupting the relative-time-wise dependencies between diagnoses and medications.

Code swapping: We initiated code swapping by swapping codes between different visits of a patient's trajectory. Given the complexity, especially for long trajectories, we designed and implemented 2 distinct methods. First, we randomly selected and swapped a subset of code pairs c_i and c_j with uniform probability, called random code swapping (RCS).



Second, to further facilitate the learning process for the transformer model and guide it toward more meaningful patterns, we introduced a conditional code swapping function (CCS; c_i, c_j). The idea is to prioritize code pairs that show a temporal dependency. The CCS function will provide a numerical estimate for such temporal relations, and in practice, code pairs (c_i, c_j) with large CCS (c_i, c_j) values are sampled more often than pairs with smaller values. We defined the CCS function as follows:



Here, CCnt(c_i, c_j) is the count of all occurrences of code pairs (c_i, c_j) with the condition that code c_i appears after code c_j and that they are located in different visits. The count is performed over all patient trajectories in the pretraining dataset. The max operator in the nominator forces the CCS function to only consider the simple temporal dependencies that code c_i follows code c_j. In other words, the maximum operator transforms the bidirectional transition graph between 2 medical codes into a unidirectional graph based on observations in the pretraining dataset. To account for a possible difference in the number of diagnoses and the number of medications, the CCS function was adjusted with a scaling factor $S_{i,j}$ (refer to Multimedia Appendix 1, for more details). Finally, ε is a small number added to allow for a nonzero probability of selecting code pairs regardless of the relation between CCnt(c_i, c_j) and CCnt(c_j, c_i). Figure 2 show the CCS values, as a heatmap, for a selection of code pairs (c_i, c_j) for both datasets used in this study.

Visits Swapping

Visit swapping aims to teach the model the coherence between different levels of local features in the global context. Instead of swapping positions of individual c_i and c_j codes, this method involves swapping the positions of all medical codes in visit x with those in visit y. Similar to code swapping, we implemented 2 methods for swapping visits. In the first method, we randomly sampled 2 visits x and y, with a uniform probability, and swapped them, denoted random visit swapping (RVS).

Second, we introduced the conditional visit swapping (CVS) function to prioritize among the visits to swap. This prioritization is based on the presence of codes within the visits that exhibited the simple temporal relation from the CCS approach as expressed by the CCS function above. To that end, the CVS function is calculated as the sum of CCS scores for all medical codes within visits x and y:

Similar to the way the CCS function was used for code swapping, pairs of visits with large $CVS(v_x,v_y)$ values are sampled more often than visit pairs with lower values.

Figure 2 shows the CCS matrix heat map for a subset of medical codes in the MIMIC-IV and MDC datasets. Each row and column represents a medical code, and the heat map indicates the CCS score for all combinations of medical codes. Pairs with higher scores (indicated by lighter colors here) are more likely to be swapped with each other. Due to the long-tail distribution of medical codes and the predominance of less frequent codes, only a subset of the more frequent codes is displayed here. Examples of medical code pairs with the highest CCS scores are printed on the right side. For instance, in the MIMIC-IV dataset, “chronic kidney disease” and “diabetes mellitus” exhibit one of the highest CCS scores, suggesting that kidney disease frequently follows diabetes (but not vice versa). Similarly, in the MDC dataset, “atrial fibrillation” and “essential hypertension” have a high CCS score, indicating that atrial fibrillation often appears after hypertension. Training the model explicitly on such relationships allows it to learn more relevant connections between diseases and medications.

Model Architecture

In this study, we used a multihead attention transformer encoder, drawing inspiration from BERT [8,9]. The model architecture, illustrated in Figure 3, includes an embedding module, a multihead attention transformer encoder, a feed-forward layer, and 2 classifier heads. The embedding module integrates medical codes with their associated temporal information. To capture the temporal dynamics, each medical code is paired with a visit sequence number, represented by 2 types of embeddings: a trainable visit number embedding and a nontrainable sinusoidal embedding, added together. These embeddings are summed with the medical code embeddings to form the input tensor X_0, which is then passed through a standard transformer encoder to obtain the transformed representation X_1:

XSL•FO
RenderX

The learned representation is then passed to both the MLM and TOO classifier heads. The MLM classifier is a large softmax applied along the vocabulary dimension, used for predicting masked tokens. The TOO classifier is a binary classifier responsible for predicting the correct temporal order of the medical codes.

Pretraining TOO-BERT

In the pretraining phase, we adopted a multitask learning approach to train the transformer network on both the MLM and TOO tasks simultaneously. For each batch, we alternated between these 2 objectives and performed gradient descent-based optimization on the weighted sum of their respective losses. This strategy allowed the model to learn both tasks cohesively, mitigating the risk of catastrophic forgetting that could occur if the objectives were trained sequentially [46,47] (ie, training on MLM first and then on TOO).

The total loss function for pretraining was defined as follows.

Each patient trajectory consists of a sequence of diagnoses, medications, and their associated visit sequence numbers, which are processed as input to TOO-BERT. The model includes an embedding layer, a multihead transformer encoder, and 2 classifier heads. First, all medical codes and their temporal information are embedded in the embedding layer. The combined embeddings are then passed through the multihead transformer encoder, followed by the MLM and TOO classifiers.

where W_{MLM} and W_{TOO} represent the weights assigned to each loss.

For the MLM objective, we randomly masked 15% [9] of the medical codes (equation 4). Similar to BERT and Med-BERT, during the masking process, each code had an 80% (n/N) chance of being replaced by [Mask], 10% (n/N) by a random code, and 10% (n/N) remained unchanged.

In the TOO task, we trained the model to classify the permuted trajectories using RCS, CCS, RVS, and CVS methods. We initially evaluated the model's capability on the TOO task across various permutations.

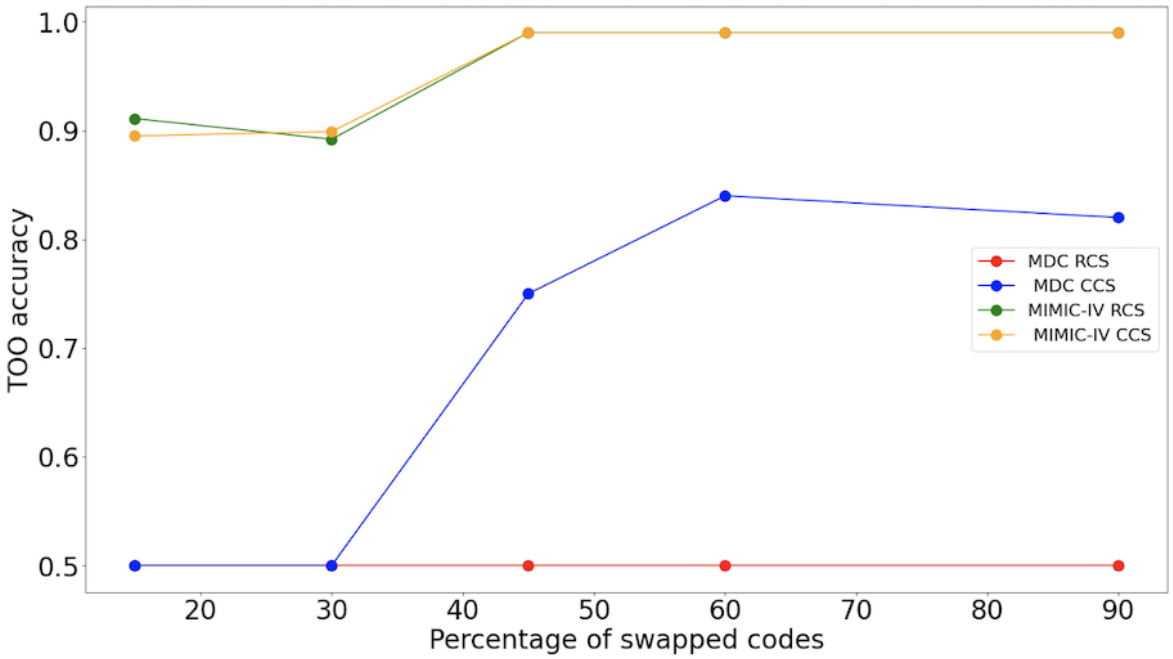
Fine-Tuning for Downstream Task

Following the pretraining phases for trajectory representation learning, we added a Bidirectional Gated Recurrent Unit (Bi-GRU) classifier head on top of the pretrained network, similar to Med-BERT, and finetuned it using the fine-tuning split for each specific downstream task. To enhance the fine-tuning process, we incorporated a layer-wise learning rate decay strategy [48,49] with gradient descent to decrease the weight changes in the initial layers compared with the later layers, thereby retaining the basic knowledge acquired during pretraining. In the final step, we compared the performance of our models against Logistic Regression, Random Forest, MLP, Bi-GRU, and a pretrained transformer with only the MLM objective.

Implementation Details

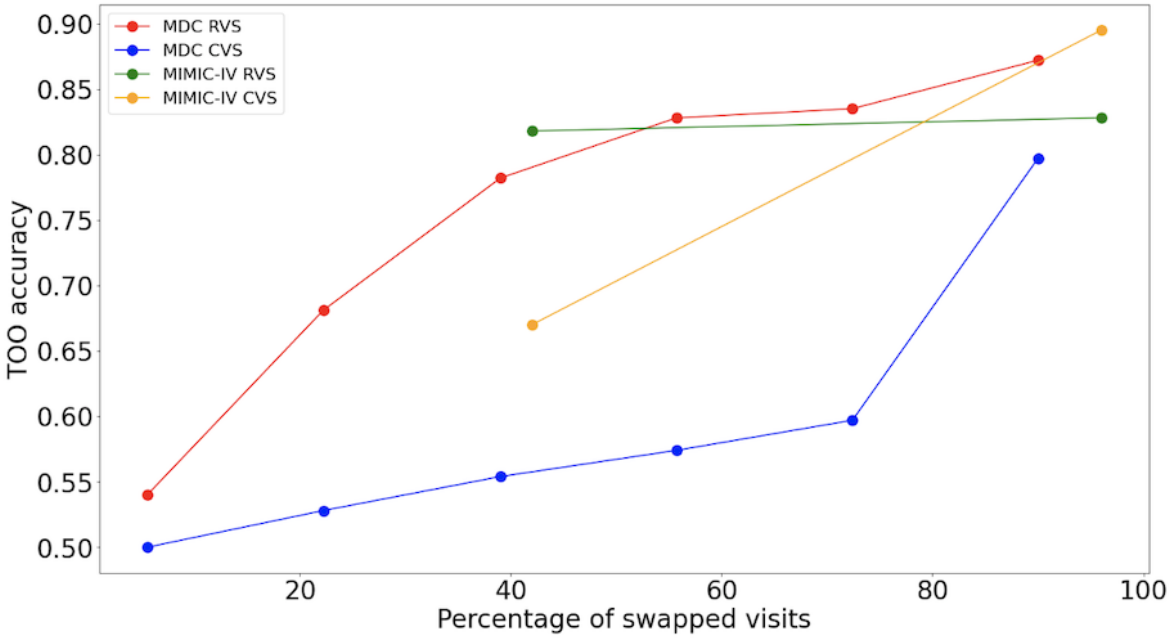
We set aside 10% (12000/121000 in the MIMIC-IV and 2000/21000 in the MDC dataset) of the pretraining dataset for monitoring the transformer's performance on the MLM and TOO pretraining objectives. The fine-tuning dataset was divided into 5 splits. For each iteration, we fine-tuned the pretrained models and trained the baseline models on 4 splits, using the remaining portion for early stopping. The reported results represent the average and SD of the performance across the 5 trained models on the isolated test dataset.

For the pretraining phase, we used a neural network featuring 5 self-attention heads and one transformer encoder with a $d_k = d_v = d_x = 36$ (refer to Multimedia Appendix 1), comprising approximately 300,000 learnable parameters. In each dataset, we computed the length of the trajectory for all patients and considered the 0.7 quantiles of the trajectory lengths as the maximum sequence length. For trajectories exceeding this length, we applied a moving window to generate additional augmented pretraining samples. We used the Adam optimizer with a learning rate of 7e-5, a weight decay of 0.015, and a dropout rate of 0.1, and trained the model until the loss curve stabilized. The MLP network comprises 2 hidden layers with 250 and 100 nodes, and the Bi-GRU network features one bidirectional GRU layer with 64 hidden nodes.



Results

Evaluation of Pretraining on the TOO Auxiliary Task



We assessed the effectiveness of the transformer models in learning the proposed TOO auxiliary objectives through a series of experiments conducted on the MDC and MIMIC-IV datasets. The four proposed swapping methods (RCS, CCS, RVS, and CVS) were applied with different amounts of swapped code or visit pairs, and the models' performance in detecting whether a trajectory contained swapped codes or visits was evaluated under varying amounts of swapping. Figure 4 illustrates the impact of increasing the percentage of swaps on classification performance for each dataset and swapping method.

XSL•FO
RenderX

Figure 4. The accuracy of the transformer model in classifying various types of swapping during the pretraining phase on the 10% unseen data from the pretraining split is shown for MDC and MIMIC-IV datasets. (A) The pretrained model can classify permuted samples with even a very low percentage of swapping on the MIMIC-IV dataset. On the other hand, classifying the permuted samples on the MDC was quite challenging. (B) The classification accuracy of the visits-swapped samples increases by raising the number of swapped visits for both methods and both datasets. MDC: Malmo Diet and Cancer Cohort; MIMIC-IV: Medical Information Mart for Intensive Care IV.

(A) The pretraining accuracy of the transformer models for different percentages of medical code swapping.

(B) The pretraining accuracy of the transformer models for different percentages of visit swapping.

As shown in Figure 4A, for the MIMIC-IV dataset, the transformer model could easily detect swapped trajectories using RCS and CCS methods for swap percentages above 40% (25/62). In contrast, the MDC dataset presented a different challenge. MDC trajectories are, on average, approximately 8 times longer (in terms of visits per patient) than those in MIMIC-IV. Here, the model struggled with the RCS, failing to find solutions effectively across any percentage of swapped pairs. In the CCS task, the model began to classify swapped trajectories more accurately only when the percentage of swaps exceeded 45% (102/254).

XSL•FO
RenderX

The results for the visit-swapping tasks (RVS and CVS) are presented in Figure 4B. These tasks proved more challenging for the models, especially at lower percentages of swaps. For the CVS task in the MDC dataset, the model required over 80% (14/18) of visits to be swapped before achieving satisfactory classification performance. Conversely, in the RVS task, the model achieved 0.8 accuracy with just 40% (7/18) of swapped visits.

For the MIMIC-IV dataset, the CVS task remained difficult for the transformer models, with only a single visit swap (1/2, 42%). However, in the RVS task, the model successfully classified trajectories with only one visit swap, demonstrating greater ease in learning visit-level temporal disruptions in this dataset.

To improve the pretraining performance on the MDC cohort with the RCS swapping method, we used a transfer learning approach. Initial weights from the transformer using the CCS method were used for the RCS task with 45% (102/254) code swapping, and this resulted in an accuracy of 0.684. This approach was also applied during the fine-tuning step for MLM+TOO$_{RCS}$ on the MDC dataset.

Evaluation of Downstream Tasks

We evaluated the prediction performance of HF and PLS for the MIMIC-IV dataset, while for the MDC dataset, we evaluated the HF and AD prediction performance. The datasets' specifications and the downstream tasks definitions are described in the section data. The percentages of swapping used for RCS, CCS, RVS, and CVS during pretraining are shown in Multimedia Appendix 1, Table S2 in Multimedia Appendix 1, and the selection was based on the performance on the validation performance within the fine-tuning dataset.

Table 3 shows the performance of Logistic Regression, Random Forest, MLP, Bi-GRU, the transformer pretrained with the MLM auxiliary task, and the 4 variations of the MLM+TOO auxiliary tasks. Consistent with the results of the Med-BERT model [11], the transformer pretrained with only MLM outperformed almost all other conventional methods in all downstream tasks for both datasets.

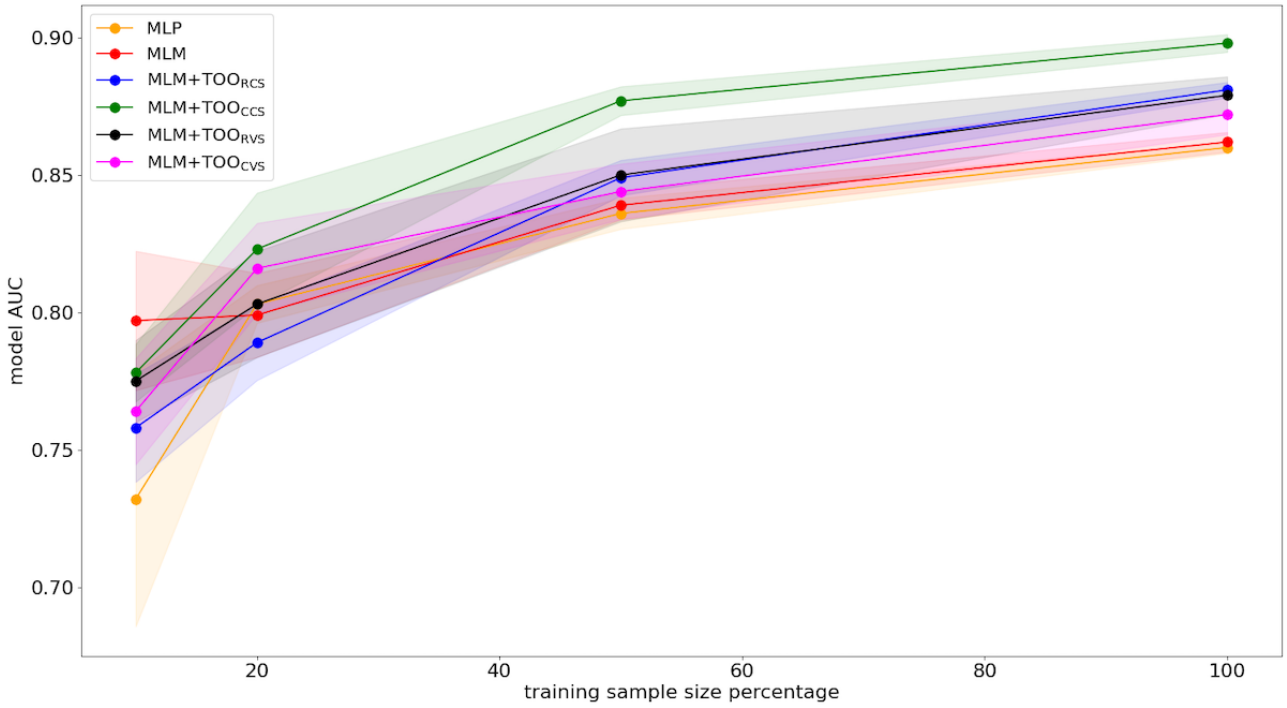
Table 3. Average AUC[a] values (%) and SD for different methods for the HF[b] prediction, AD[c] prediction, and PLS[d] prediction downstream tasks on the test datasets.

Model or dataset	HF prediction (MDC[e])	AD prediction (MDC)	HF prediction (MIMIC-IV[f])	PLS prediction (MIMIC-IV)
Logistic regression	62.4 (1.1)	56.4 (1.1)	83.8 (1.1)	54.2 (0.4)
Random forest	60.7 (0.5)	51.8 (0.3)	78.6 (1.6)	51.1 (0.3)
MLP	67.9 (3.0)	68.0 (1.5)	86.0 (0.5)	59.3 (1.9)
Bi-GRU	62.3 (1.2)	60.4 (1.1)	85.0 (1.3)	55.9 (1.0)
MLM[g]	67.7 (2.6)	69.5 (1.6)	86.2 (0.9)	60.2 (1.2)
MLM+TOO[h]$_{RCS}$[i]	65.1 (1.2)	65.6 (0.7)	88.1 (0.7)	58.4 (0.9)
MLM+TOO$_{CCS}$[j]	64.6 (2.7)	67.2 (1.3)	89.8 (0.8)	60.4 (1.2)
MLM+TOO$_{RVS}$[k]	72.8 (3.1)	70.4 (0.2)	87.9 (1.7)	57.3 (0.8)
MLM+TOO$_{CVS}$[l]	73.9 (1.9)	71.9 (1.6)	87.2 (1.8)	58.8 (1.6)

[a]AUC: area under the receiver operating characteristic curve.
[b]HF: heart failure.
[c]AD: Alzheimer disease.
[d]PLS: prolonged length of stay.
[e]MDC: Malmo Diet and Cancer Cohort.
[f]MIMIC-IV: Medical Information Mart for Intensive Care IV.
[f]gLM: masked language modelling.
[h]TOO: trajectory-order objective.
[i]RCS: random code swapping.
[j]CCS: code swapping function.
[j]RVS: random visit swapping.
[l]CVS: conditional visit swapping.

The visit-level TOO objective methods yielded the best HF and AD prediction performance on the MDC dataset, which features much longer patient trajectories. Using the CVS for the TOO objective achieved the highest area under the receiver operating characteristic curve (AUC) of 0.739 and 0.719 for HF and AD prediction, respectively. Moreover, since the model pretrained with random code swapping exhibited weak performance on the MDC dataset (Figure 4A), we initialized the model with the weights of the CCS pretrained model. We achieved approximately 0.74 accuracy on the TOO objective and subsequently fine-tuned this model for HF prediction, increasing

XSL•FO
RenderX



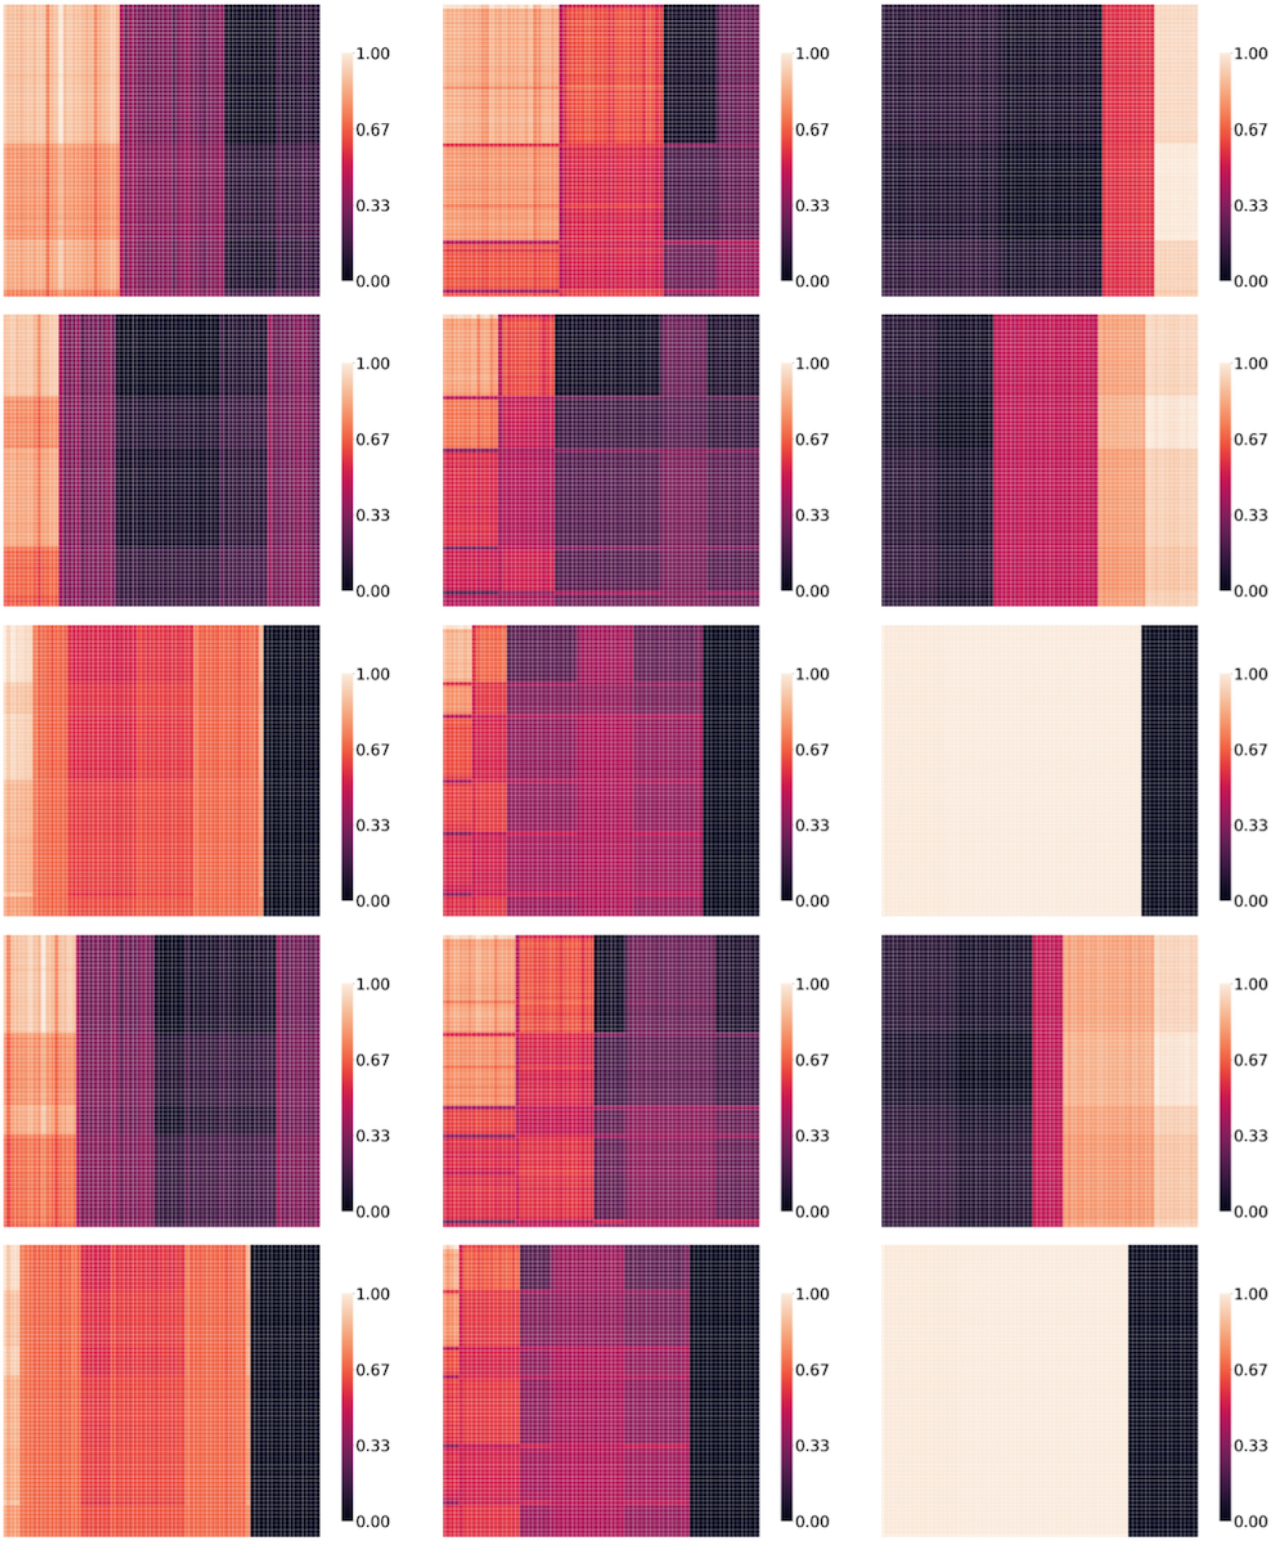
the AUC to 0.65.9. However, this result remained lower than that of the transformer pretrained solely on MLM.

For HF prediction on the MIMIC-IV dataset, the TOO auxiliary task with code swapping improved performance more than other methods. Applying the CCS over the TOO objective achieved the best AUC of 0.89.8. Although predicting the PLS on the next visit is challenging for all models, adding the CCS objective led to the best AUC.

Performance Boost on Data Insufficiency

We further evaluated the impact of combining the proposed TOO with the MLM, using varying fine-tuning sample sizes for predicting HF on the MIMIC-IV test dataset, and compared its performance to the transformer pretrained on MLM and MLP, the most successful conventional method. Fine-tuning sample sizes was reduced to 50% (442/884), 20% (176/884), and 10% (88/884). Figure 5 presents the performance of the MLP (orange line), the transformer pretrained with only MLM (red line), and transformers pretrained with MLM combined with RCS (blue line), CCS (green line), RVS (black line), and CVS (pink line). As the sample size decreased, the transformer pretrained with MLM+TOO_{CCS} achieved higher AUC scores, highlighting its effectiveness in handling data insufficiency.

Figure 5. Comparison of HF prediction AUC values for the test sets by fine-tuning on different data sizes on the MIMIC-IV dataset. The shadows represent the 90% CI. AUC: area under the receiver operating characteristic curve; HF: heart failure; MIMIC-IV: Medical Information Mart for Intensive Care IV. MLM: masked language modeling; MLP: multilayer perceptron; TOO: trajectory-order objective.



The Effect of TOO on Attention Weights

Visualizing the attention scores, A_h, of the transformer provides valuable insights into the model's decision-making process and its representation learning capabilities. More capable models can learn and attend to more complex patterns. Figure 6 shows attention scores for the fine-tuned models based on only MLM, MLM+TOO_{RVS}, and MLM+TOO_{CCS} pretraining. The attention scores come from a single patient trajectory for the HF prediction task on the MIMIC-IV dataset. Attention scores for all TOO-BERT variants can be found in Multimedia Appendix 1. In the rightmost column, the attention scores of the model pretrained solely with MLM show a primary focus on the latest codes in the trajectory. In contrast, models pretrained with the TOO objective (shown in the first and second columns) exhibit more diverse attention patterns, capturing more complex and structured relationships across the trajectory. In addition, models pretrained with the visit-level TOO objective (RVS) demonstrated an increased focus on the interactions between sets of consecutive codes (ie, segment-level attention). In contrast, the model pretrained with the CCS objective tended to exhibit attention at the individual code level.

XSL•FO
RenderX

Figure 6. The attention scores (5 heads) for 3 fine-tuned models on HF prediction for the MIMIC-IV dataset, shown for a specific sample from the test set. HF: heart failure; MIMIC-IV: Medical Information Mart for Intensive Care IV.

In Figure 6, lighter colors in the heatmap indicate higher attention weights, while darker colors represent lower attention weights. The variations within each model's attention heads are meaningful, reflecting how the model allocates attention to specific medical codes within the trajectory. The attention scores of the model pretrained on MLM+CCS demonstrate a greater ability to learn complex patterns. For better interpretability, the attention scores for each head are normalized between 0 and 1, though the original values range from 0 to 0.033, with slight variations across different models.

Discussion

Principal Findings

The sequential order of the medical codes and their interactions within a patient's EHR trajectory is crucial for understanding

XSL•FO
RenderX

and modeling their health status. While BERT-inspired methods have shown good results in this domain, the challenge lies in capturing the intricate relationships between diseases and prescribed interventions. TOO-BERT enhances the performance of BERT-inspired models by simultaneously learning the order of medical codes and the context of the EHR trajectory. Our approach involves pretraining these models explicitly on the sequential information within a patient's EHR trajectory, aiming to enhance their learning capability by using the temporal structure. In addition, the introduction of 2 novel weighting methods, CCS and CVS, within the TOO objective enables the models to learn more relevant and frequent causal and correlation dependencies with a data-driven approach.

The pretraining results highlight the differences in learning sequential information between the MIMIC-IV and MDC datasets. The MDC dataset, characterized by an average of approximately 18 visits per patient, presented more challenges in learning single code level sequential information compared to the MIMIC-IV dataset, which has an average of about 2.5 visits per patient (Figure 4A). This discrepancy could stem from the tendencies of transformers to learn the global dependencies and might require additional strategies to capture local patterns as well [50-53]. In addition, the performance of the model initialized with weights from the CCS task in the MDC dataset on the RCS task demonstrated that the proposed conditional probability approach can effectively help the model converge (section Evaluation of pretraining on the TOO auxiliary task).

Combining the proposed TOO with the MLM improved estimated AUC values for all downstream tasks on both datasets. Interestingly, in longer trajectories, visit-level swapping seemed more informative than code-level swapping, suggesting that the TOO auxiliary pretraining objective may improve the efficacy of the transformer in modeling long EHR trajectory data, in addition to suggested architectural improvements [54,55]. Moreover, code-level TOO-BERT reduced the performance of MLM in the MDC dataset, possibly due to the increase in MLM loss associated with adding the TOO auxiliary task during pretraining. Transformers trained solely on MLM demonstrated similar performance to MLP, indicating the complexity of EHR trajectories and data insufficiency in pretraining these models. The addition of the TOO task leveraged the MLM, potentially compensating for data insufficiency in complex models.

Predicting PLS from previous visits based on diagnoses and medications proved to be a particularly challenging task for all models. In addition, while previous research has indicated that BERT-inspired models are excellent few-shot learners [11,24,56], the addition of the TOO auxiliary task showed superior performance with reduced fine-tuning sample sizes for HF prediction in the MIMIC-IV dataset.

The CCS and CVS weighting function enhances the learning process by prioritizing more frequent transitional patterns. This prioritization helps the model focus on meaningful dependencies, such as transitions where the occurrence of one event strongly predicts the occurrence of another. By emphasizing these strong correlations, the model can converge more efficiently and avoid learning from rare or noisy transitions that may not represent meaningful relationships.

This approach is particularly beneficial in the context of small datasets. CCS and CVS ensure the model concentrates on the most informative patterns early in training, which not only facilitates convergence but also helps reduce overfitting to spurious relationships. While larger datasets and highly expressive models may eventually learn such relationships without CCS, the function remains valuable for guiding the model toward robustness in more resource-constrained settings. The other way to conceptualize CCS and CVS is the resemblance to first-order and higher-order Markov chains. CCS amplifies the probability weight of swapping a code pair based on the observation that the occurrence of one code increases the probability of observing the other in future visits. Similarly, CVS approximates a higher-order Markov chain by considering a set of conditions [57].

An interesting finding in our study was that training transformers on sequential information enables them to learn more intricate structures. The variability in the size and number of tiles in the attention weights (Figure 6) suggests that the TOO-objective enabled the transformers to learn a wide range of patterns. However, a quantitative analysis approach would be more suitable for gaining a more concrete understanding of the attention behaviors.

Limitations

This study has several limitations. The TOO task only considers the order of the medical codes and skips the time irregularity of visits in the EHR [58-60]. Extending the investigation of the new TOO-BERT variant to other datasets with larger sample sizes and longer visit trajectories would enhance our understanding of the differences between code and visit-level swapping pretraining objectives. Furthermore, the inclusion of additional EHR data sources with various modalities, such as test result values and demographic information, with continuous and categorical data types, in TOO-BERT requires further exploration.

Future Directions

Future research directions may involve a more comprehensive investigation of the challenges associated with the lack of locality in transformers and the exploration of more sample-efficient techniques to enhance the performance of TOO-BERT methods in data-limited scenarios. Enhanced positional encoding techniques and transformer architectures could prove beneficial. The impact of history length, influenced by code and visit level swapping, could be examined by pretraining TOO-BERT on larger datasets with longer visit histories. Furthermore, assessing the performance of pretrained TOO-BERT on other types of downstream tasks or tasks subject to dataset shifts would be valuable.

Conclusion

In this study, we explored the potential of incorporating the relative positions of medical codes to improve the learned representation of intricate disease-intervention dependencies, especially in scenarios involving lengthy sequences and limited data. Our introduction of TOO-BERT extends the capabilities of the MLM by focusing on the sequential information within patients' trajectories at both the single code and visit levels. In

XSL•FO
RenderX

addition, to enhance the TOO objective, we introduced condition-based code and swapped self-supervised tasks. The outcomes highlight TOO-BERT's superior performance in predicting PLS, AD, and HF across different sample sizes. Our analysis of attention weights reveals that the TOO task equips transformers to grasp more intricate structural patterns. Future research might involve exploring more sample-efficient pretraining methods and refining transformer architecture and positional encoding to enhance TOO-BERT's representation learning capabilities further.

Acknowledgments

This study was conducted as part of the AIR Lund (Artificially Intelligent use of Registers at Lund University) research environment and was funded by the Swedish Research Council (VR, grant 2019-00198). Additional support was provided by CAISR Health, funded by the Knowledge Foundation (KK-stiftelsen) in Sweden (grant 20200208 01 H).

We shared the Trajectory Order Objective Bidirectional Encoder Representations from Transformers (TOO-BERT) source code on TOO-BERT [61]. The pre-trained models are available from the authors upon request and with permission from the Medical Information Mart for Intensive Care IV (MIMIC-IV) and the Malmo Population-Based Cohorts Joint Database.

Data Availability

The MIMIC-IV dataset is publicly available from the PhysioNet repository [62]. The Malmo Diet and Cancer Cohort data that support the findings of this study are not publicly available due to data access restrictions imposed by the Malmo Population-Based Cohorts Joint Database. However, the data are available from the corresponding author upon reasonable request and with permission from the Malmo Population-Based Cohorts Joint Database [63].

Authors' Contributions

All persons who meet authorship criteria are listed as authors, and all authors certify that they have participated sufficiently in the work to take public responsibility for the content, including participation in the concept, design, analysis, writing, or revision of the manuscript. AA managed conceptualization, methodology, data curation, validation, formal analysis, writing-original draft, writing-review, editing, and visualization.

FE contributed to the investigation, conceptualization, methodology, validation, supervision, and writing—review and editing. JB was involved in validation, supervision, and writing—review and editing. OM contributed to validation, supervision, and writing—review and editing. MO contributed to the investigation, conceptualization, methodology, validation, supervision, writing—review and editing, as well as project administration.

Conflicts of Interest

None declared.

Abstract

Background: Sarcopenia is a common muscle disorder in older adults, and its early identification and management in middle-aged populations are essential for ensuring a healthier later life. Detecting sarcopenia at an earlier stage may reduce the future burden on health care systems and enhance the quality of life in older adults. Machine learning (ML) models can evaluate large datasets, identify essential variables, and find complicated correlations between input variables. However, using ML models to detect sarcopenia remains an unsatisfied need.

Objective: This study aimed to develop and externally validate an ML model to predict sarcopenia risk among middle-aged adults using a nationally representative dataset.

Methods: We analyzed data from 1926 participants aged 40 to 64 years and enrolled in the 2022 Korea National Health and Nutrition Examination Survey (KNHANES). Sarcopenia was diagnosed and defined based on the 2019 Asian Working Group for Sarcopenia criteria, which incorporate both low muscle mass and reduced muscle strength. Muscle mass was assessed using bioelectrical impedance analysis with cutoffs of <7.0 kg/m² for men and <5.7 kg/m² for women. Muscle strength was measured via handgrip strength using a digital dynamometer with thresholds of <28 kg for men and <18 kg for women. Participants meeting both criteria were classified as those with sarcopenia. Four ML algorithms, random forest, support vector machine, extreme gradient boosting, and logistic regression, were used to identify risk factors of sarcopenia and predict its likelihood. The top-performing model was subsequently validated in an external cohort of 2247 middle-aged adults from the 2023 KNHANES. Model performance was assessed using the F_2-score, area under the curve of a receiver operating characteristic curve, and sensitivity. All analyses were conducted using Python 3.13.2 (Python Software Foundation).

Results: Among the 4 models, the logistic regression model demonstrated the strongest performance, yielding an area under the curve of 0.85, a sensitivity of 0.92, and an F_2-score of 0.66. External validation using the 2023 KNHANES dataset confirmed the model's robust performance, indicating its potential for widespread applications.

Conclusions: This study developed and externally validated an ML model that accurately identified sarcopenia in middle-aged adults. Leveraging data from a comprehensive national survey, our findings underscore the significance of early detection and customized interventions in midlife to mitigate sarcopenia risk and optimize long-term health outcomes.

Introduction

Sarcopenia is increasingly recognized as a significant muscle disease characterized by progressive and generalized loss of skeletal muscle mass and function, resulting in an elevated susceptibility to falls, fractures, infections, cardiovascular diseases, disability, and mortality [1].

In 2019, both the European Working Group on Sarcopenia in Older People [2] and the Asian Working Group for Sarcopenia (AWGS) [1] updated their definitions to emphasize the clinical importance of low muscle strength and function and reduced muscle mass.

Various causes for early-life sarcopenia have been identified, and the gap between sarcopenia progression and normal processes starts early in life [3-5]. The loss of muscle mass occurs as early as age 55 years in men and 45 years in women [6]. Midlife is also a period commonly associated with the emergence or escalation of chronic diseases and metabolic syndrome, which can further exacerbate muscle loss and functional decline. Skeletal muscle mass declines by about 6% every decade beyond middle age. Sarcopenia has a prevalence of up to 29% in middle-aged adults depending on the diagnostic criteria used [7]. Increased hospitalization expenditures due to sarcopenia are considerably greater in patients younger than 65 years than in those older than 65 years [8]. In addition, sarcopenia develops gradually and without obvious signs until a substantial decrease in muscle function occurs. Therefore, it is critical to detect risk factors for early sarcopenia in middle-aged adults. Nevertheless, the majority of risk prediction models for sarcopenia have been created to work for older adults because sarcopenia is a severe form of senescence that only affects older people [3,7]. Thus, these prediction models have restricted use in midlife populations. This gap emphasizes the importance of developing and validating new, data-driven models for early detection and intervention, promoting healthier trajectories into retirement and beyond.

Machine learning (ML) models can evaluate large datasets, identify essential variables, and find complicated correlations between input variables, making them practical tools for predicting health outcomes [9]. Clinical prediction models that use ML allow for integrating many elements to predict individual outcomes, providing deeper insights into disease risk determinants and enhancing prognosis precision [10]. Leveraging data from a population-based Korea National Health and Nutrition Examination Survey (KNHANES), this study aimed to provide a reliable, generalizable ML-based tool that can be integrated into clinical or public health settings for early detection and intervention in sarcopenia for middle-aged adults. The findings of this study could help develop approaches for improving the management and treatment of sarcopenia.

This direction is substantiated by growing evidence indicating that the risk factors for sarcopenia vary meaningfully across different age groups [4,11]. Specifically, our findings suggest that low body weight and insufficient protein intake are more influential in middle-aged adults, whereas sarcopenic obesity patterns are more frequently reported in older adults [12,13]. These distinctions highlight the need for age-specific prediction models throughout the course of life.

Methods

Datasets

The data for this study were obtained from the KNHANES, a nationwide dataset compiled by the Korea Ministry of Health and Welfare to investigate the nutritional and overall health status of the general public since 1998. Since 2007, cross-sectional datasets of around 10,000 people have been produced annually by stratified multilevel cluster sampling to ensure the representativeness of samples and allow the findings of research to be combined [14]. In this study, we categorized all selected variables into four domains to improve clarity and interpretability: (1) demographic variables (eg, age, gender, education level, marital status, and residence), (2) clinical variables (eg, BMI category, hypertension, diabetes mellitus, hypercholesterolemia, high-sensitivity C-reactive protein (hs-CRP), number of comorbid conditions, and subjective health perception), (3) health behavioral variables (eg, current smoking, current alcohol use, average sitting time per day, protein intake, and weekly aerobic and strength exercise participation), and (4) psychological variables (eg, perceived stress and generalized anxiety) based on the Generalized Anxiety Disorder-7 (GAD-7) score. A complete list of these variables and their distributions is provided in Table 1. Feature selection was guided by a combination of theory-driven rationale and data-driven evaluation. Initially, variables were selected based on their clinical relevance to sarcopenia as supported by existing literature. Subsequently, model-based methods, including L1-regularized logistic regression (LR) and recursive feature elimination, were used to refine the feature set based on contribution to model performance. To refine variable selection beyond theoretical rationale, we applied L1-regularized LR and recursive feature elimination as supplementary strategies. These approaches helped identify variables that consistently contributed to model performance while maintaining interpretability. Because KNHANES measurement items differ slightly from year to year, we only used datasets from years that included measurements of all relevant features (2022: test and training set; 2023: external validation set). We examined data of middle-aged adults (aged 19-64 years) from 1926 participants in 2022 and 2247 in 2023 in this study. After excluding participants who were missing variables, 1119 participants in 2022 and 1359 in 2023 were included in the final analysis (Multimedia Appendix 1).

[a]hs-CRP: high-sensitivity C-reactive protein.

[b]Ranked on a 5-point scale from 1 (very good) to 5 (very bad).

Variables

For the diagnosis of sarcopenia, AWGS 2019 maintained the original cutoffs in a sarcopenia diagnosis as a bioelectrical impedance analysis <7.0 kg/m^2 in men and <5.7 kg/m^2 in women [15]. Predictable variables included the following 4 categories: demographic variables, clinical variables, health behavioral variables, and psychological variables. Demographic variables included age, gender, level of education, marital status, and residence. Clinical variables included hypertension, diabetes mellitus, hypercholesterolemia, hypertriglyceridemia, anemia by diagnosis or medication, hs-CRP, number of comorbid conditions, BMI categories, and subjective health perception. For clinical variables, BMI was included as an important predictor of sarcopenia. BMI categories were classified according to the World Health Organization Asia-Pacific criteria adopted by the KNHANES as underweight (<18.5 kg/m²), normal (18.5-22.9 kg/m²), overweight (23-24.9 kg/m²), and obese (≥25 kg/m²). Subjective health perception, often measured via a single self-rated health question, is a key indicator in KNHANES and internationally. This variable was recorded as 1 (very good) to 5 (very bad). Health behavioral variables included current smoking, rate of alcohol drinking per month (under 1 cup, 0; over 1 cup, 1), sitting time per day, amount of protein intake, aerobic exercise participation, and strength exercise participation. Psychological variables included perceived stress and generalized anxiety disorder evaluated using the GAD-7 scale. Perceived stress assessed how strongly respondents feel stress in daily life from 1 (very high) to 4 (none). For reporting purposes, when analyzing the data, KNHANES typically collapses 1 and 2 together as a high-stress group and 3 and 4 as a low-stress group, deriving the variable high perceived stress (yes or no) for analysis. The GAD-7 is a self-report questionnaire with 7 items. Each item is scored on a 4-point Likert scale from 0 (not at all) to 3 (nearly every day), yielding a total possible score from 0 to 21. Researchers commonly create a binary variable for anxiety disorder (yes or no) by using a cutoff of ≥10 on the total GAD-7 scale [16].

Model Development

We sought to predict sarcopenia by first randomly partitioning our dataset into training (75%) and test (25%) subsets using the

XSL•FO
RenderX

2022 dataset and a stratified method to preserve the original class distribution of sarcopenia. To enhance generalizability and minimize overfitting, we applied 5-fold stratified cross-validation during model training. This approach preserved class distribution in each fold and ensured robust performance evaluation across splits. Furthermore, to counteract class imbalance in the training data, we applied the synthetic minority over-sampling technique (SMOTE). Unlike simple random oversampling, which merely duplicates existing minority-class instances, SMOTE generates synthetic data points by interpolating between similar minority samples, resulting in a more generalized representation of the positive class. Following SMOTE, the number of sarcopenia-positive cases in the training set achieved a balanced 1:1 ratio between positive and negative classes. To prevent data leakage and ensure fair evaluation, SMOTE was applied exclusively to the training dataset. The test and external validation sets were left unaltered to reflect real-world class distribution during evaluation.

Model Evaluation and External Validation

We independently evaluated the predictive performance of 4 models using area under the curve (AUC), accuracy, precision, recall, specificity, F_1-score, and F_2-score as the primary metrics. For external validation, the same 4 models were subsequently tested on the 2023 dataset, and their predictive performances were assessed and compared using the same evaluation criteria. This approach facilitated a robust comparison of model effectiveness across the original and external validation datasets. Then, we conducted an original variable importance analysis to evaluate each predictor's contribution to the model's performance because assessing the significance of input features is critical in ML models [17]. In addition, a confusion matrix–based comparison was conducted for the test set and the external validation set. This method offers a detailed view of each model's classification performance by explicitly displaying true positives, false positives, true negatives, and false negatives. By applying it to both data partitions, we could directly assess the consistency of model predictions and identify misclassification patterns. This approach complements standard summary metrics (eg, accuracy and precision) by illuminating where errors occur, thereby enhancing the overall interpretability and validating the generalizability of the models [18].

Data Analysis

All statistical analyses were performed with Python 3.9.13 (Python Software Foundation). All continuous variables were standardized using z-score normalization, and categorical variables were 1-hot encoded. To address extreme values, particularly in hs-CRP, which exhibited high skewness, we applied percentile-based trimming by capping values at the 99th percentile. This preprocessing strategy ensured comparability across variables, mitigated the impact of outliers, and enhanced model stability. All continuous variables were normalized via z-score standardization, and categorical variables were coded as dummy features. A *t* test was performed to compare the characteristics of the sarcopenia and nonsarcopenia groups. Variables with *P* values of <.05 were defined as statistically significant.

To achieve our research objective of developing a fast and accurate predictive model for sarcopenia diagnosis in middle-aged adults, we conducted analyses as follows. Several different ML models were selected and applied to determine the model with the best accuracy and speed. We implemented LR, a traditional statistical model, to compare its performance with the relatively recently introduced ML models. Hyperparameter tuning was performed using GridSearchCV for LR and RandomizedSearchCV for tree-based models, namely, random forest (RF) and extreme gradient boosting (XGBoost). The tuning process aimed to optimize parameters such as regularization strength, tree depth, and learning rate based on validation performance. Moreover, we used several ML algorithms, including support vector machine (SVM), RF, and XGBoost. To support reproducibility, all data preprocessing and modeling steps have been documented in Multimedia Appendix 1. A deidentified version of the analysis code will be made publicly available via GitHub upon manuscript acceptance.

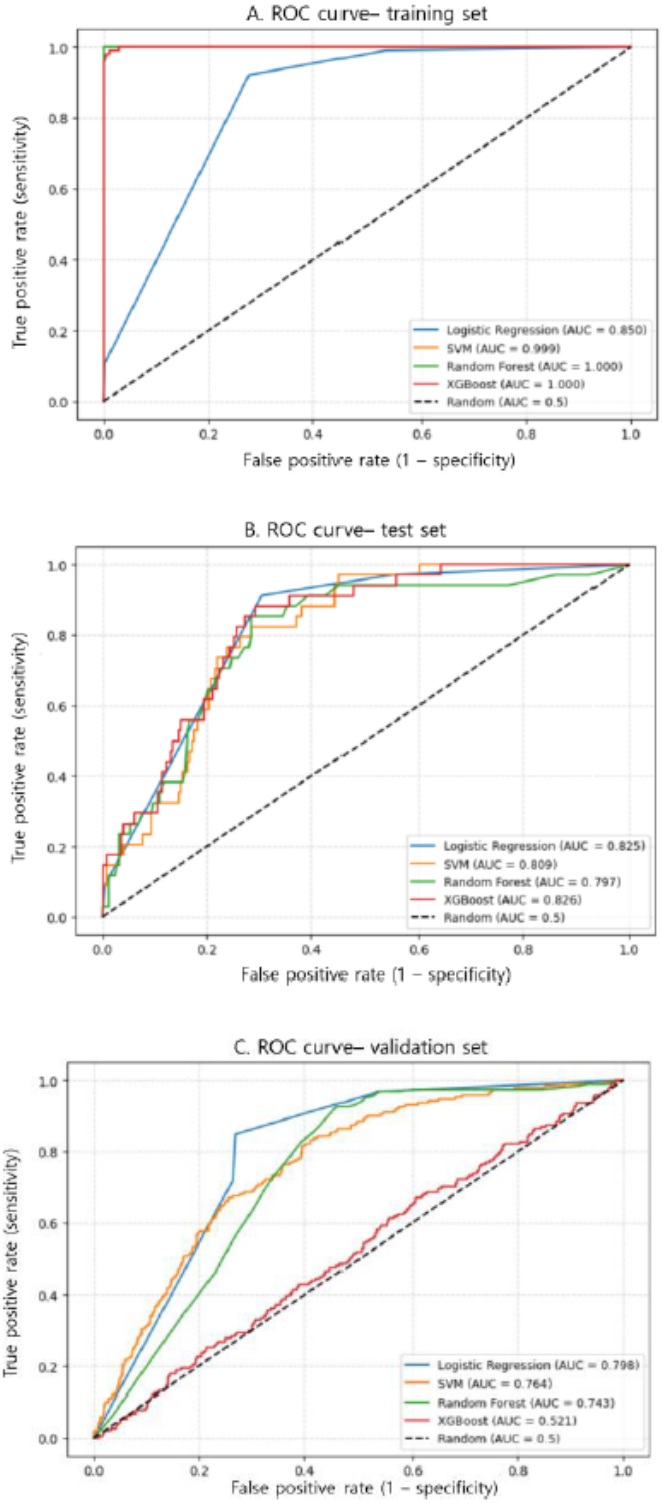
Ethical Considerations

This study was approved by the Ethics Committee of Sunchon National University (1040173-202503-HR-010-02).

Results

Population Characteristics

The study analyzed 1119 middle‐aged adults, comprising 984 (88%) individuals in the group without sarcopenia (nonsarcopenia group) and 135 (12%) in the group with sarcopenia (sarcopenia group). As shown in Table 1, the mean age was significantly higher in the sarcopenia group (mean 56.61, SD 5.46 years) than in the nonsarcopenia group (mean 54.85, SD 5.70 years; *P*<.001); protein levels differed significantly between the groups (sarcopenia group: mean 61.76, SD 27.12 g/day; nonsarcopenia group: mean 69.94, SD 32.54 g/day; *P*=.002). Obesity was more prevalent in the nonsarcopenia group (n=457, 46.4%) than in the sarcopenia group (n=2, 1.5%; *P*<.001). Conversely, the proportion of low weight individuals was much higher in the sarcopenia group (n=14, 10.4%) than in the nonsarcopenia group (n=3, 0.3%). Health behavioral and psychosocial factors, such as current smoking (*P*=.68) and stress (*P*=.50) did not differ significantly between the 2 groups; however, drinking status did (*P*=.007). Gender showed a notable association (*P*=.001), with individuals with sarcopenia more likely to be female (n=97, 71.9%) than male (n=38, 28.1%). Hypertension (*P*<.001) and diabetes status (*P*=.011) also differed significantly between the 2 groups. Other variables, including hs‐CRP, sitting time, anxiety, hypercholesterolemia, and hypertriglyceridemia, were not significantly different between the 2 groups. Marriage status (*P*=.80), residence (*P*=.55), aerobic exercise participation (*P*=.27), and strength exercise participation (*P*=.11) similarly showed no statistical differences between the sarcopenia and nonsarcopenia groups.



Model Evaluation and External Validation

Figure 1 and Table 2 show that in comparing 4 ML models for predicting sarcopenia, LR demonstrated the most stable performance in the test set, with an AUC of 0.82, an F_2-score

XSL•FO
RenderX

of 0.64, and a sensitivity of 91%. Notably, its high sensitivity and F_2-score for the minority class (patients with sarcopenia) suggest a strong potential for clinical application. In contrast, SVM, RF, and XGBoost exhibited extremely high performance on the training set but significant drops in F_2-score in the test set, indicating a risk of overfitting. Their sensitivities ranged from 24% to 29% in the test set, reflecting limited practical utility in detecting sarcopenia. Given its consistent performance across the training and test sets, along with advantages in identifying the minority class, LR was selected as the final predictive model in this study.

Specificity	0.722	1.0	0.995	0.996	0.695	0.947	0.923	0.898	0.731	0.000	0.944	0.0000

[a]SVM: support vector machine.

[b]XGBoost: extreme gradient boosting.

[c]AUC: area under the curve.

In external validation, LR exhibited stable and consistent results across the training, test, and external validation sets. Notably, it achieved an AUC of 0.80, sensitivity of 0.85, and F_2-score of 0.65 in the validation dataset, indicating the most balanced capability for detecting the clinically significant minority class. In contrast, RF and XGBoost showed extremely high performance in the training set (AUC 1.00), yet demonstrated severe overfitting during validation, with a sensitivity of 1.00 but a specificity of 0.00, predicting all cases as patients. Although SVM achieved a high specificity of 0.94, its sensitivity was only 0.20 in the validation set, revealing limited utility for actual patient detection. These observations support that LR should be selected as the final predictive model in this study.

Model Interpretation

Table 3 shows the top ten important variables. Using the LR coefficients, we evaluated each predictor's importance by aggregating dummy-coded levels into the original variable units and calculating the mean absolute coefficient values. Obesity emerged as the most critical predictor, indicating the strongest association with sarcopenia risk in this model. Age and protein intake were also identified as influential factors.

Table 3. Top10 important variables based on the mean of absolute logistic regression coefficients across dummy-coded variables. This table represents the relative contribution of predictors to the model.

Variable	|Coefficient|, mean (SD)
Obesity	0.84, 0.41 (0.50)
Age	0.44, 55.06 (5.70)
Protein	0.39, 68.95 (32.04)
Drinking	0.14, 0.52 (0.50)
Hypercholesterolemia	0.14, 0.37 (0.48)
Gender	0.12, 0.42 (0.49)
Subjective health perspective	0.12, 2.85 (0.79)
Comorbidity	0.08, 0.58 (0.49)
Anxiety	0.08, 0.04 (0.19)
Hypertension	0.08, 0.33 (0.47)

Figure 2 presents the confusion matrices for the LR model in the test set (left panel) and external validation set (right panel). In the test set, a sensitivity (recall) of 91.2% (true positives=31, false negatives=3) and a specificity of 69.5% (true negatives=171, false positives=75) were achieved, suggesting that the model correctly identifies a high proportion of sarcopenia cases and maintains reasonable accuracy in classifying nonsarcopenia instances. A similar pattern was observed in the validation set, with a sensitivity of 84.8% (true positives=162, false negatives=29) and a specificity of 73.1% (true negatives=854, false positives=314). These results indicate that the model generalizes well, maintaining stable classification performance when applied to external data. Although SMOTE was applied only to the training set, we acknowledge that class imbalance remained in the test and validation datasets. Nonetheless, the LR model maintained high sensitivity and a

XSL•FO
RenderX

stable AUC, suggesting good generalizability even under imbalanced evaluation conditions.

Table 4 provides a critical comparison of sarcopenia incidence across predicted risk categories (low, medium, high) in the test set and the external validation set, visually demonstrating the consistent classification performance and clinical applicability of the LR model. In the high-risk group, sarcopenia incidence was 29.2% in the test set and 30.8% in the validation set, reflecting a high degree of consistency and underscoring that the risk stratification threshold effectively functions in a clinically meaningful way.

Figure 2. Confusion matrix for the logistic regression model.

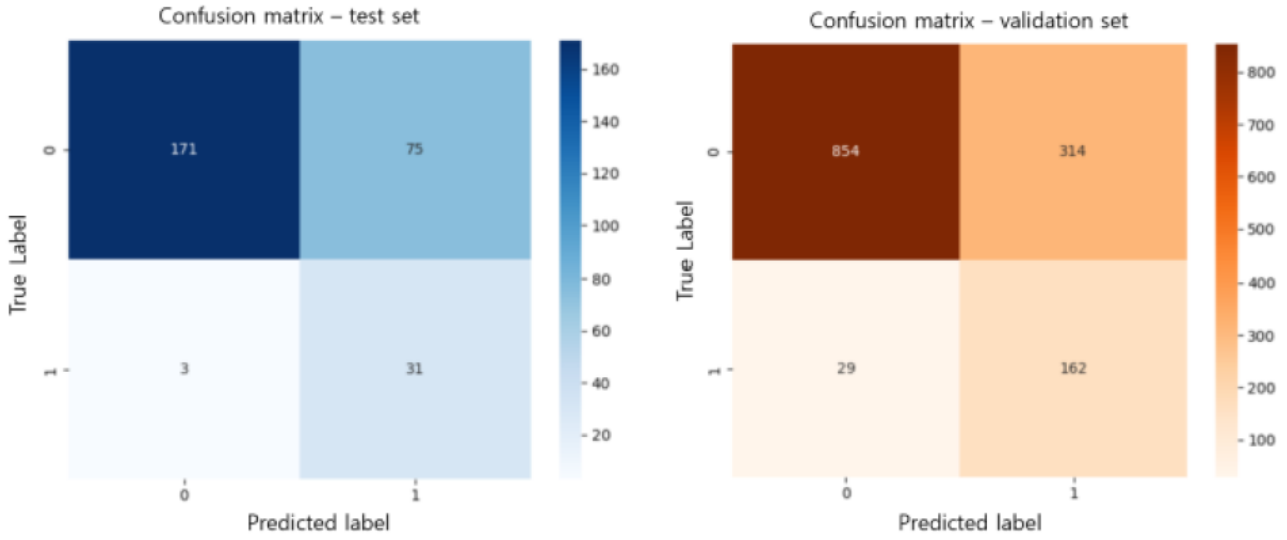

Table 4. Observed sarcopenia incidence rate by risk group in the logistic regression model.

Predicted risk group	Test set	Validation set
Low	1.7	0.0
Medium	0.0	5.9
High	29.2	30.8

Discussion

Principal Findings

The primary objective of this study was to develop an ML-based model for predicting sarcopenia in middle-aged adults and to identify the optimal model among various algorithms. As a result, our study demonstrated that an ML-based risk prediction model, particularly using LR, can reliably identify sarcopenia in middle-aged adults. The LR model showed strong and consistent performance in internal testing and external validation (AUC range 0.80-0.85), underscoring its clinical applicability for early detection. One notable strength of this model is that its coefficients allow us to discern both the direction (positive or negative) and the relative magnitude of each variable's impact, thereby providing more than just strong predictive capabilities. While interpretation tools, such as Shapley additive explanations and local interpretable model agnostic explanation, are valuable for complex models, they were not applied in this study because LR, our final model, is inherently interpretable. The model coefficients provide both direction and magnitude of each predictor's impact, making additional posthoc interpretability tools unnecessary. This preserves clarity and enhances clinical applicability.

By elucidating how individual variables contribute to sarcopenia risk, the model offers enhanced explanatory power and actionable insights into clinical and public health interventions. Moreover, the high generalizability and strong clinical applicability of the model are evident in its consistently superior performance relative to a random classifier (AUC=0.5) across the training, test, and external validation sets. This robust and stable performance, maintained regardless of the dataset used, underscores the model's potential for broad clinical implementation. Although direct comparisons are challenging due to a lack of research on predicting models for middle-aged adults, we were successful in developing a sarcopenia prediction model for middle-aged adults that might serve as a valuable diagnostic tool in clinical settings.

Our findings that obesity, age, and protein intake are key predictors highlight the importance of addressing modifiable risk factors before substantial muscle function decline sets in. By leveraging a large, population-based dataset, our work provides robust evidence that targeted interventions and screening in midlife can potentially mitigate the burden of sarcopenia in later life. Our findings indicate that, among middle-aged adults, lower body mass, rather than obesity, was associated with an increased risk of sarcopenia. This observation contrasts with several prior studies conducted in older populations where obesity, particularly sarcopenic obesity, has been frequently cited as a contributing factor for poor muscle function and outcomes [12,13]. However, our findings,

XSL•FO
RenderX

comprising individuals in midlife, may reflect a different trajectory of muscle decline, wherein low body weight, often indicative of inadequate nutritional reserves or underlying muscle wasting, emerges as a more salient predictor [19]. Previous evidence suggests that body composition plays a distinct role depending on life stage: in older adults, excess fat mass may exacerbate functional limitations, while in younger or middle-aged adults, insufficient muscle and fat mass (as seen in underweight individuals) may indicate early sarcopenic changes [20]. Our findings thus support a life course perspective on sarcopenia, emphasizing that underweight status in midlife is not benign and may serve as a precursor to more severe muscle dysfunction in later life. This underscores the need for early lifestyle interventions aiming at maintaining healthy muscle mass and adequate protein intake before the onset of significant age-related musculoskeletal decline [21]. On the other hand, age and protein intake emerged as key predictive factors, aligning with a robust body of evidence, indicating that advancing age is a primary risk factor for sarcopenia due to age-related muscle mass decline and that insufficient protein intake significantly contributes to muscle loss and functional impairment [19,22]. Conversely, factors such as strength training, urban versus rural residence, and anemia demonstrated comparatively lower variable importance in the model, which further highlights the central role of obesity, age, and nutritional intake in sarcopenia pathogenesis and prediction [21-24].

When contextualized within prior research, our study offers several distinct advancements in the domain of sarcopenia prediction. First, while much of the existing literature has predominantly focused on older adults and has frequently relied on conventional analytical techniques, such as LR, without incorporating robust sampling strategies, our research addresses a gap by targeting middle-aged populations and using state-of-the-art ML algorithms in conjunction with SMOTE to mitigate class imbalance, an approach shown to enhance classification performance in imbalanced biomedical datasets [25,26]. Prior studies have recognized the significance of age and nutritional status in sarcopenia etiology [3], but they have often lacked external validation. In contrast, our 2-step validation strategy comprising internal cross-validation and external dataset testing strengthens the model's generalizability and clinical utility, in line with recent calls for more rigorous validation frameworks in predictive modeling [27]. Second, conventional sarcopenia prediction tools often rely on limited indicators, such as grip strength alone. Our model adheres to the updated AWGS 2019 guidelines, integrating both handgrip strength and bioelectrical impedance analysis to provide a more comprehensive diagnostic foundation [28]. This alignment with contemporary clinical standards enhances the translational potential of our findings. Third, although muscle deterioration is known to begin in midlife, especially from the mid-40s onward [11], few studies have systematically investigated the interplay of obesity, protein intake, and age within this demographic. Our findings identify obesity and low protein intake as significant risk factors for sarcopenia in middle-aged adults, thereby extending earlier work on modifiable lifestyle components in muscle preservation [21,23]. Lastly, we demonstrate the utility of ML-based variable importance analyses, offering refined insights into the predictive strength of individual risk factors. This granularity supports the development of personalized interventions, such as tailored dietary strategies and exercise programs, for an often-overlooked age group [29].

Limitations and Future Directions

This study has several limitations and offers opportunities for future research. First, although the large national dataset strengthens generalizability, the cross-sectional design precludes establishing causal relationships among variables. A longitudinal cohort study would be beneficial to determine temporal patterns and causation in sarcopenia onset. Second, certain lifestyle and dietary variables relied on self-reported data, which may introduce recall bias. Due to limitations in the KNHANES dataset, which lacked harmonized continuous measures of physical activity across the 2022 and 2023 waves, we adopted a categorical representation to ensure consistency and comparability across cohorts. This methodological choice is acknowledged as a limitation. Future research should integrate more objective measures, such as wearable device data, to improve accuracy. Third, while our model performed robustly overall, additional tuning or integration with newer ML techniques could further enhance prediction metrics. Larger, multicountry cohorts and diverse populations are recommended for validating and extending the applicability of our findings.

Conclusions

Our ML-based prediction model offers a valuable framework for the early identification of sarcopenia risk in middle-aged adults, addressing a gap left by previous studies that have predominantly focused on older populations. These findings underscore the significance of proactive, personalized interventions targeting key modifiable risk factors, particularly obesity and nutrition, to mitigate muscle decline and related morbidities. By advocating for earlier detection and tailored preventive strategies, this study paves the way for improved midlife health care protocols, contributing to healthier aging trajectories globally.

Data Availability

All data supporting the findings of this study are available from the Korea National Health and Nutrition Examination Survey

Abstract

Background: Untreated dental caries is the most common health condition worldwide. Therefore, new strategies need to be developed to reduce the manifestations of dental caries.

Objective: This study aimed to develop and test a machine learning (ML) algorithm for detecting present and predicting future carious lesions in the adolescent population using a set of easy-to-collect predictive variables. In addition, this study aimed to deal with an imbalanced and small dataset using an oversampling method.

Methods: This population-based study was conducted among secondary schoolchildren, aged between 13 and 17 years, from the northern parts of Finland in 2022. After meeting the inclusion criteria, a total of 218 participants were included in this study. The inclusion criteria consisted of participants having completed a web-based risk assessment questionnaire and having undergone a clinical examination at public health care services. Dental caries (International Caries Detection and Assessment System [ICDAS] scores of 4, 5, and 6; ie, ICDAS 4-6) and active initial caries (ICDAS 2+, 3+) were considered as outcomes. Several predictors, such as behavioral and dietary habits, were included. An extreme gradient boosting model was developed, tested, and assessed for its predictive performance. A 4-fold cross-validation was performed using the nested resampling technique. The random oversampling examples method and the k-nearest neighbors classifiers were used for all 4 folds. The mean (SD) performance of all the folds was computed.

Results: Dental caries (ICDAS 2+,3+,4-6) were prevalent in 65.6% (143/218) of the participants. The mean area under the curve was 0.77 (SD 0.04) and the mean F_1-score was 0.82 (SD 0.06) for the extreme gradient boosting model. Similarly, the mean area under the curve and mean F_1-scores after oversampling were 0.74 (SD 0.05) and 0.79 (SD 0.04), respectively. The Shapley additive explanation values were calculated for all 4 folds to assess feature importance, revealing that previous dental fillings were the feature most strongly associated with the need for restorative treatment.

Conclusions: On the basis of the performance metrics, the ML algorithm developed and tested in this study can be considered good. The ML algorithm could serve as a cost-effective screening tool for dental professionals to identify the risk of future restorative treatment needs. However, future studies with longitudinal cohorts and longitudinal data, along with external validation for generalizability, are needed to validate our model.

KEYWORDS

oral health; machine learning; dentistry; dental caries; caries management

Introduction

Background

Dental caries is the most common dietary-microbial disease, requiring regular exposure to fermentable carbohydrates. Enrichment of acid-producing and acid-tolerating microorganisms in dental plaque leads to a demineralized tooth structure, which, in turn, can lead to loss of tooth structure, ultimately resulting in cavities [1]. The risks of dental caries include physical, biological, environmental, behavioral, and lifestyle-related factors [2]. The balance between pathological and protective factors, such as insufficient exposure to fluoride or irregular brushing of teeth, influences the initiation and progression of dental caries [3].

Individual-level risk recognition is of utmost importance, since recent dental caries management protocol prioritizes early prevention and minimal intervention at an individual level [4]. The availability of caries risk assessment tools (CRATs) has assisted clinicians in risk identification, as well as in risk minimization. However, most existing CRATs require either dental visits or measurements of salivary parameters at dental clinics (face-to-face methods). A systematic review [5] considered the possibility of using a reduced Cariogram (without saliva parameters), one of the CRATs, due to its better performance when compared to a full Cariogram. The use of artificial intelligence (AI) and machine learning (ML) in the medical field is gaining attention worldwide. The possibility of an automated dental caries risk prediction method using ML algorithms needs to be explored. A recent study by Xiong et al [6] highlighted the possibility of using ML algorithms and easy-to-collect predictors in screening active dental caries and urgent treatment needs in school-age children. However, the questionnaire mainly consisted of predictors covering physical, mental, and social aspects, missing important predictors, such as dietary habits and oral health-related behaviors. As the development and progression of carious lesions are multifactorial, such information is important to consider.

AI can be defined as the nonbiological ability of a computer to try to imitate human intelligence to accomplish complex tasks, such as problem-solving and decision-making [7]. ML is a subset of AI designed to identify patterns or make predictions based on the data used. ML algorithms can model nonlinear and high-dimensional characteristics, such as health data [8]. In addition to being the latest and often the most popular technology, ML algorithms have the ability to learn themselves and improve over time when exposed to more data [9]. The use of ML models can improve patient care by providing individualized outcome predictions and by reducing standardized processes, allowing clinicians to spend more time with patients [10]. In dentistry, the literature showed that various ML algorithms, such as logistic regression, decision trees, random forest, and extreme gradient boosting (XGBoost), are used in predicting dental caries. However, these studies are in their early stages, and more research needs to be conducted to validate these methods [11]. Furthermore, the ground truth in the above-mentioned studies is based only on clinical examinations (visual-tactile), even though it is recommended to perform both clinical and radiographic examinations to minimize the risk of misdiagnosis in caries evaluation [12]. In this regard, the severity and activity of carious lesions are crucial when deciding on the treatment path [13,14]. It is important to include real-life clinical environment observations when training and testing ML algorithms.

However, there are some challenges, such as high costs, data security, and legal restrictions in dentistry, making the acquisition of individual-level comprehensive data more difficult [15,16]. Studies have used electronic health records and national registries for training ML algorithms [17]. However, in dentistry, the availability of extensive electronic health record data or national registries is scarce [18]. Therefore, to overcome the challenges associated with small datasets, oversampling techniques can be explored. Oversampling is a data augmentation technique that aims to rebalance the training data distribution by amplifying the volume of instances that belong to the underrepresented class, helping to correct the imbalance between minority and majority examples [19,20]. Another challenge in dentistry is also related to class imbalance. When the number of patients with a target disease differs from the healthy population, the situation is referred to as the imbalanced data problem. The accuracy of ML models can be affected by these imbalances.

Objectives

Therefore, this study aimed to (1) develop and test an ML algorithm in detecting present and predicting future carious lesions among adolescents using a set of easy-to-collect predictive variables; and (2) deal with challenges due to the imbalanced and small dataset in cariology with the use of the oversampling method.

Methods

Study Population and Data Sources

This cross-sectional study used data collected for the Digileap project, conducted among secondary school children aged 13 to 17 years from the northern parts of Finland in 2022. Before the study, the sample size (N=246) was calculated based on the prevalence of dental caries from a previous study by Suominen-Taipale et al [21] with 95% CIs and a precision set at 0.05, assuming that the total population of children aged 13 to 15 years is 100,000 [22]. Participants completed a web-based risk assessment questionnaire within their school premises, and their oral health records were registered at public health care services from 2022 to 2023, from where they were later requested through Findata services [23]. Findata is the Finnish Social and Health Data Permit authority, which grants permits for the secondary use of social and health care data, improving

XSL•FO
RenderX

data protection for individuals. The inclusion criteria for this study included the following: (1) aged 13 to 17 years with signed informed consent, (2) completion of a web-based risk assessment questionnaire, and (3) completion of a dental examination performed at public dental clinics during 2022 to 2023. After meeting the inclusion criteria, a total of 218 participants were included in this study.

Ethical Considerations

The study was conducted in full accordance with the World Medical Association Declaration of Helsinki. The ethical committee of Northern Ostrobothnia Hospital District approved the study protocol (EETTMK 62/2021), and the Finnish Medicines Agency [24] also issued the Medical Device Permit (2022/007715). In addition, study permissions were also obtained from the public health care services in Kuusamo, Ylivieska, Oulu, and Liminka. Oral health records (dental caries registered at the public dental services) were obtained from the Finnish Social and Health Data Permit Authority, Findata [25], with a data permit (THL/6268/14.02.00/2021). All the schools were contacted before the study via an official email requesting the participation of schoolchildren and their parents. Participants aged ≥15 years signed the informed consent, and informed consent was obtained from the parents of participants aged <15 years. Participation was completely voluntary, privacy and confidentiality were secured, and the participants had the right to withdraw their participation at any given phase of the study.

Study Variables

Outcome Variables

Initial active carious lesions (enamel and dentin caries) and all cavitated lesions were considered as the main outcome variable for this study. The carious lesions were diagnosed using the International Caries Detection and Assessment System (ICDAS) criteria with the aim to differentiate between different stages of dental caries. ICDAS stands for the assessment of the caries process by stage (noncavitated or cavitated) and activity (active or arrested or inactive). The "+" symbol indicates a caries lesion that is active and progressing. The "–" symbol indicates an inactive lesion with no active progression, and the tooth surface is considered sound [26].

To describe the transition of caries lesions in this study, the ICDAS score of 0 or ICDAS scores of 2− and 3− were considered as sound in contrast to the ICDAS scores of 2+, 3+, 4, 5, and 6 being considered as diseased. The ICDAS 2+ and 3+ codes were merged into 1 category (ICDAS 2+, 3+) to represent noncavitated lesions or microcavitated active lesions, and the ICDAS 4, 5, and 6 codes were used as 1 category (ICDAS 4-6) to represent cavitated lesions. A study by Abdalla et al [27] concluded that the active caries lesions were more likely to progress to more severe conditions than inactive lesions; active noncavitated (ICDAS 2+) and active microcavitated or shadow lesions (ICDAS 3+) had a 2-fold progression rate compared to noncavitated inactive lesions. In a nutshell, any initial active carious lesion (enamel and dentin caries) and all cavitated lesions were considered as the main outcome variable for this study (ICDAS 2+,3+,4-6) [13]. ICDAS 1 was not found in our study population due to challenges in diagnostics; these lesions were characterized by the first visual changes in enamel, often appearing as white spots or lines that were only visible when the tooth was carefully air-dried for 5 seconds.

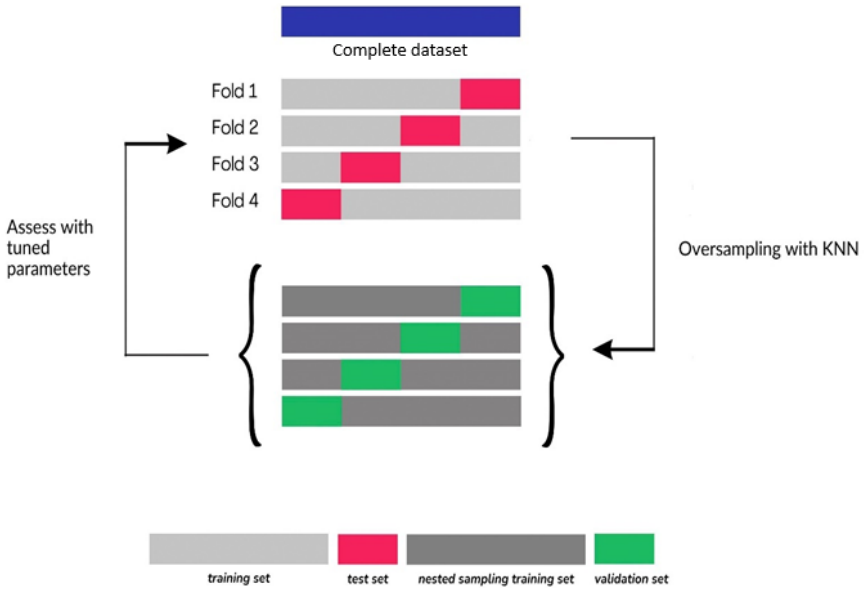
Caries assessment with surface-by-surface evaluation was conducted by a licensed dentist following the Finnish Current Care Guidelines [28]. All teeth of the participants were examined with halogen light with a surface reflecting mirror and explorer and a fiberoptic transilluminator, followed by radiographic examination, if needed. A radiographic examination was suggested if (1) one localized enamel breakdown lesion was found, (2) the patient had several initial caries lesions, (3) the patient had dental caries risk factors or suspicion that the patient might have hidden dental caries lesions, or (4) radiographs had not been taken in the past few years [29]. Previously, data collected from the Finnish public health care records were shown not to be inferior to the calibrated examiners [30].

Predictors

For this study, age, sex, and oral health-related behaviors (such as frequency of toothbrushing, toothbrush type, toothpaste type, frequency of fluoride toothpaste use, interdental cleaning frequency, frequency of xylitol use, additive sugar consumption, and smoking habits) were considered as independent variables. The questionnaire consisted of information about the food and drink consumption of the participants. Participants were asked to report the amounts and frequencies. The average daily consumption was calculated for each product and multiplied by the quantity consumed. The additive sugar consumption was calculated using the Fineli database, a Finnish national food consumption database maintained by the Finnish Institute for Health and Welfare [31]. Using the Fineli database, total sugar content was matched to the food items, and the amount of sugar (g) in each item was calculated. Finally, the total daily sugar intake was calculated for each food item consumed per day (daily added sugar intake). Similarly, local factors, such as recent restorations, extracted teeth, bleeding when brushing, and the dry mouth index, were considered as predictors. To complement the self-reported survey, clinical data on missing teeth and dental fillings were also included as predictors. The dry mouth index included questions, such as "Does your mouth feel dry when you eat?" "Do you have difficulties swallowing some food?" and "Do you have to drink in order to make it easier to swallow dry food?" Participants responded yes or no, and answers were combined as one continuous variable, achieving values from 0 to 3.

Model Development and Training

In this study, the XGBoost algorithm was applied to predict the outcome variable. The model was trained using the R software (version 4.3.1; R Foundation for Statistical Computing) [32].



Model Fitting (Training and Testing)

The training and testing of the ML models were performed using the nested resampling technique with 4-fold cross-validation. In a typical k-fold cross-validation, the dataset is randomly and evenly split into k parts. The model is built using k−1 parts of the dataset, called the training set, and

XSL•FO
RenderX

evaluated based on the remaining part, known as the test set. This process is repeated k times so that each part is used as a test set once [33]. Four folds were created, each containing 75% of the data as a training set and 25% of the unseen data as a test set. These 4 folds are seen in Figure 1.

Figure 1. The model training protocol: The training and testing of machine learning algorithms were performed using 4-fold cross-validation, the nested resampling technique, and hyperparameter tuning. The tuned model was evaluated by a separate validation set, which was distinct from the nested sampling testing set. The oversampling technique was applied to all 4 folds. The oversampling fold included both the original training set and the nested sampling training set. Finally, the performance of the optimized model was assessed on each fold's test set. This entire training protocol was repeated for all 4 folds. KNN: k-nearest neighbor.

Model Training Protocol

For each 4 folds, the ML models were built by using the mlr package [34]. During the training, hyperparameter tuning was conducted separately for all 4 folds. The grid search method was used for hyperparameter tuning, allowing the model to identify the optimal combination from a predefined set of hyperparameters. Detailed information on these predefined hyperparameters is provided in the Multimedia Appendix 1. The tuned model was evaluated based on a validation set, which was independent of the nested sampling testing set. Finally, the optimized model's performances were evaluated on each fold's completely unseen test set. For all 4 folds, the model training protocol was then repeated using the new oversampled training dataset. The model training protocol is shown in Figure 1.

Oversampling

As the total sample was 218, the oversampling technique was used as suggested by previous studies [35,36]. The oversampling technique was applied exclusively to each training dataset, while the respective test sets remained untouched to ensure the absence of data leakage. The random oversampling examples (ROSE) method and the k-nearest neighbors classifier were used for all folds [37]. Oversampling simulated 2000 new synthetic participants to the training dataset (P=.05). In the context of oversampling techniques, "P" refers to the proportion or percentage of the minority class instances that are to be oversampled. In the complete dataset, the number of participants with carious lesions was 143. The training sets consisted of 75% of the data, and the average number of participants with carious lesions in the training set was 0.75×143=107. Using the oversampling method, 2000×0.95=1900 new participants with carious lesions were created. As a result, the total number of participants with carious lesions increased on average to 107+1900=2007. Likewise, in the complete dataset, the number of participants with sound teeth was 75. The training set included 75% of the complete data, and the average number of participants with sound teeth in the training set was 0.75×75=56. Using the oversampling method, a total of 100 (2000×0.05=100) new synthetic participants with sound teeth were created. This resulted in an average total of 156 participants with sound teeth.

Model Evaluation

To assess the predictive performance of the ML models, the area under the curve (AUC), accuracy, sensitivity, specificity, positive predictive value, negative predictive value, no information rate, precision, recall, and F_1-score for each predictive model were calculated. The mean (SD) performance of all folds was computed.

Shapley additive explanations (SHAP) values were computed for all folds and also after oversampling. The SHAP values were computed to determine the importance of each variable in predicting the dental caries outcomes of this study. The SHAP values are an additive feature importance measure that represents the responsibility of each feature in pushing the model output away from its base value [38]. This study was reported in accordance with the TRIPOD+AI (Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis–Artificial Intelligence) statement for developing or evaluating the performance of prediction models [39].

Results

The demographic characteristics and descriptive analysis of the categorical independent variables are shown in Table 1. In this study group, 143 out of 218 (65.6%) participants had carious lesions (enamel and dental caries, ICDAS 2+, 3+, 4-6). More than half of the study participants were female (118/218, 54.1%), and more than half (124/218, 56.9%) had a habit of toothbrushing twice daily. Most of the participants (158/218, 72.5%) reported using fluoride toothpaste, while less than half of the participants (106/218, 48.6%) reported using an electronic toothbrush. Most of the participants (198/218, 90.8%) did not smoke, and the mean daily added sugar intake was 50.6 (SD 81.3) g. In addition, more than half of the participants (122/218, 56%) had dental restorations as seen in Table 1.

The performance metrics of all folds of the XGBoost model before and after oversampling are shown in Table 2. In addition, the mean performance across all folds is presented. The mean AUC value, which evaluates the model's ability to discriminate between carious and sound teeth, was good after oversampling (before oversampling: 0.77, SD 0.04; after oversampling: 0.74, SD 0.05). The mean accuracy, which evaluates the performance of the models, was also high (before oversampling: 0.75, SD 0.06; after oversampling: 0.73, SD 0.03). The AUC and accuracy values were complemented by the F_1-scores. The F_1-score is the harmonic mean of precision and recall, and it provides a comprehensive evaluation of a model with an imbalanced dataset. The mean F_1-score was 0.82 (SD 0.06) before oversampling and 0.79 (SD 0.04) after oversampling. The ability of the model to predict carious lesions (true positive cases), expressed as a mean sensitivity, was 0.85 (SD 0.12) before oversampling and 0.78 (SD 0.09) after oversampling. These values were considered high. The ability to predict sound teeth (true negative cases), expressed as mean specificity, was 0.56 (SD 0.13) before oversampling, and it slightly increased to 0.61 (SD 0.15) after oversampling. These values, in turn, were considered low, as seen in Table 2.

[e]XGBoost: extreme gradient boosting.

[f]The performance across all folds is presented as mean (SD).

After evaluating the performance of each model, the SHAP values were computed for all 4 folds and after oversampling. The SHAP values for each of the 4 folds of the XGBoost model before and after oversampling are shown in Figures 2 and 3. The feature that most strongly predicted the need for present and future restorative treatment was previous fillings in all folds, followed by the total added sugar intake, frequency of smoking, toothpaste type, and frequency of toothbrushing, varying between 4 folds, as seen in Figures 2 and 3. Interestingly, the importance of minor predictors slightly increased after the oversampling method was applied in all folds. Fillings and total added sugar intake were in the top 4 most important features in every fold before oversampling. There was more variation in the folds after oversampling, but clearly, fillings remained the most important feature.

Figure 3. Shapley additive explanation (SHAP) values from folds 3 and 4, before and after oversampling. The absolute SHAP value shows how much a single feature affected the prediction of dental caries. The higher the SHAP value of a feature, the more likely it is to influence the prediction.

Discussion

Principal Findings

The main aim of this study was to develop and test an ML algorithm for predicting carious lesions among the adolescent population using a set of easy-to-collect predictors and to evaluate the importance of each predictor. Another aim was to use a novel oversampling approach in cariology research to deal with and improve the imbalance of a small dataset. The ML models developed and tested in this study performed well in predicting present and future restorative treatment needs among adolescents. Despite the drop in performance metrics after oversampling, the parameters were within the acceptable range, supporting the positive performance of the ML algorithm in this study. The XGBoost algorithm used in this study performed well. This is comparable with previous studies by Toledo et al [40] and Bomfim [41] from Brazil. In both studies, the XGBoost model outperformed other ML algorithms, such as logistic regression and decision tree. Both studies used socioeconomic variables, such as income and parents' employment, as predictors for carious lesions. However, these variables were not considered in this study, because in Finland, all individuals aged ≤18 years are entitled to free dental care. This study aimed to use easy-to-collect predictors. A recent study by Xiong et al [6] also used ML algorithms and easy-to-collect information when screening active dental caries and urgent treatment needs in adolescents and concluded that the naïve Bayes model outperformed other models. However, that study particularly considered physical, mental, and social factors rather than behavioral factors. Furthermore, both clinical and radiographic examinations were performed in this study to minimize the risk of over- or underdiagnosis. In a real-life clinical environment, the use of radiographic methods is considered advantageous when deciding the need for operative care, especially when a patient was presented with an ICDAS score of 3 [29]. The drop in performance after oversampling in this study is comparable to a previous study [6] from the United States. Xiong et al [6] considered the synthetic minority oversampling technique for oversampling in their studies. However, the ROSE was used in this study for oversampling. The ROSE technique created synthetic examples by drawing from a smoothed bootstrap distribution in the feature space around the minority class, thus producing more balanced datasets with better generalization properties [42]. This method is particularly suitable for datasets containing categorical or binary variables, which were prominent in our study. In contrast, the synthetic minority oversampling technique was primarily designed for a continuous feature space and might not perform optimally with categorical or binary variables. In addition, the k-nearest neighbors classifier cleaning method was used in this study to further enhance the data quality after oversampling. In this study, the ability of the model to predict carious lesions (sensitivity) was high before and after oversampling. For dental caries screening, high sensitivity is vital to ensure that diseased individuals are correctly identified with the disease. However, the ability to predict sound teeth

XSL•FO
RenderX

(specificity) was lower, which might be subject to overdiagnosis; therefore, cautious explanation is necessary. Therefore, oral health care professionals are encouraged to carefully examine those with high dental caries risk.

Dental caries is a multifactorial disease influenced by individual, biological, behavioral, and environmental factors [43]. In the literature, past caries experience was found to be the most powerful caries predictor [44]. High consumption of carbohydrates increased the chance of developing dental caries [45], and xylitol-containing products significantly prevented caries when compared with other nonxylitol products [46]. These findings from previous literature are in line with the results of this study, as delivered by the feature importance SHAP values. The past caries experience, nonuse of fluoridated toothpaste, socioeconomic level, and a higher frequency of sugar consumption were predictors that influenced caries progression the most in a previous longitudinal study that aimed to predict dental caries in primary and permanent teeth among children aged 1 to 5 years [40]. Similarly, the use of dental floss, unhealthy food consumption, self-declared race, and exposure to fluoridated water were the most predictive variables in another study by Bomfim [41]. The previous fillings (explaining past caries experience) and total added sugar intake (explaining high consumption of carbohydrates) were the most predictive variables in this study.

The application of SHAP values in this study enhanced the interpretability of the ML model, providing a transparent understanding of how each feature contributed to the predictions. Interpretability was a key element of explainable AI, which played a critical role in ensuring that the ML models were not only accurate but also transparent and reliable for real-world applications. In contrast to black-box models, explainable AI makes the model's decisions more comprehensible and trustworthy. Understanding the rationale behind predictions helps in validating the model's clinical relevance.

Strengths and Limitations

One of the strengths of this study is that the outcome variable, carious lesions, was recorded by a licensed dentist based on both clinical and radiographic evaluations, following the Finnish Current Care Guidelines [29]. Another strength is the absence of missing values, which was ensured by the strict inclusion criteria of this study. Selection bias due to voluntary participation in this study can be considered a limitation. Another limitation is the potential for response bias due to the use of a self-reported questionnaire; self-reported data can be biased due to respondents' subjective perceptions, memory recall issues, or intentional misreporting. However, the aim was to keep the questionnaire short and simple to minimize response bias. Finally, the generalizability of the ML algorithm might be questionable, as the model did not undergo external validation. Future studies with longitudinal cohorts are needed both to validate our models and to perform external validation in socioeconomically diverse or racially varied populations. In ML, validation provides evidence that a model is reliable and performs sufficiently with new data. External validation also requires testing the model on independent populations to assess its applicability [47]. Before clinical use, external validation is necessary [48]. However, this was beyond the scope of this study. For the external validation to be successful, dental caries categorization needs to be synchronized using ICDAS in both study populations.

Clinical Implications

Rising health care costs associated with restorative treatment require justification in early prevention and control of dental caries. New strategies need to be developed to reduce social impacts, such as aesthetic and functional disturbances, on both the individual and societal levels. A potential application of ML algorithms in dental caries prognostic studies enables evidence - based personalized dental care that could assist in decreasing dental caries prevalence globally. The ML model developed and tested in this study has the potential to identify possible risk factors of dental caries before the onset of actual dental caries lesions. In this study, each SHAP indicated the importance of each feature in dental caries progression, and the information gained can be transformed into a deeper dental caries risk assessment. Algorithm-based risk assessment tools can be integrated into electronic health records and used in electronic preassessment forms. Information about dental caries risk is valuable for both patients and dental professionals, influencing treatment and prevention plans, follow-up, and patient education [49]. Linking ML algorithms to intraoral images using deep learning algorithms is expected to increase dental screening potential. Individuals encounter unique challenges in adhering to behavioral changes. To overcome these obstacles, behavioral change interventions need to be both multifaceted and personalized. Health behavior factors, such as unhealthy food consumption, can be modified by health promotion policies and strategies. This study is unique and innovative because it is the first study to use ML models in dental caries prediction in adolescents using easy-to-collect predictors. In the future, after further development and external validation, this ML model could be used as a risk assessment tool and even be integrated into health record systems, which would be beneficial for the patient and the health care professionals in saving time and resources [50]. For the CRAT to be successful, it needs to be inexpensive, user-friendly, and open for everyone, even in low-income countries. SHAP values include participants' dental caries risk profile and can be used for personalized behavioral change interventions in which patients themselves can alter their overall risk.

Conclusions

Despite the small and imbalanced dataset, XGBoost performed well in predicting restorative treatment among adolescents with and without the oversampling method in this study. The results from this study suggest the potential feasibility of the ML models in caries risk assessment, enabling easier, cost-effective, less time-consuming, and more effective decision-making. However, future studies with longitudinal data and external validation are needed to validate our models.

Abstract

Background: Emergency department (ED) overcrowding remains a critical challenge, leading to delays in patient care and increased operational strain. Current hospital management strategies often rely on reactive decision-making, addressing congestion only after it occurs. However, effective patient flow management requires early identification of overcrowding risks to allow timely interventions. Machine learning (ML)–based predictive modeling offers a solution by forecasting key patient flow measures, such as waiting count, enabling proactive resource allocation and improved hospital efficiency.

Objective: The aim of this study is to develop ML models that predict ED waiting room occupancy (waiting count) at 2 temporal resolutions. The first approach is the hourly prediction model, which estimates the waiting count exactly 6 hours ahead at each prediction time (eg, a 1 PM prediction forecasts 7 PM). The second approach is the daily prediction model, which forecasts the average waiting count for the next 24-hour period (eg, a 5 PM prediction estimates the following day's average). These predictive tools support resource allocation and help mitigate overcrowding by enabling proactive interventions before congestion occurs.

Methods: Data from a partner hospital's ED in the southeastern United States were used, integrating internal and external sources. Eleven different ML algorithms, ranging from traditional approaches to deep learning architectures, were systematically trained and evaluated on both hourly and daily predictions to determine the models that achieved the lowest prediction error. Experiments optimized feature combinations, and the best models were tested under high patient volume and across different hours to assess temporal accuracy.

Results: The best hourly prediction performance was achieved by time series vision transformer plus (TSiTPlus) with a mean absolute error (MAE) of 4.19 and a mean squared error (MSE) of 29.36. The overall hourly waiting count had a mean of 18.11 and a SD (σ) of 9.77. Prediction accuracy varied by time of day, with the lowest MAE at 11 PM (2.45) and the highest at 8 PM (5.45). Extreme case analysis at (mean + 1σ), (mean + 2σ), and (mean + 3σ) resulted in MAEs of 6.16, 10.16, and 15.59, respectively. For daily predictions, an explainable convolutional neural network plus (XCMPlus) achieved the best results with an MAE of 2.00 and a MSE of 6.64. The daily waiting count had a mean of 18.11 and a SD of 4.51. Both models outperformed traditional forecasting approaches across multiple evaluation metrics.

XSL•FO
RenderX

Conclusions: The proposed prediction models effectively forecast ED waiting count at both hourly and daily intervals. The results demonstrate the value of integrating diverse data sources and applying advanced modeling techniques to support proactive resource allocation decisions. The implementation of these forecasting tools within hospital management systems has the potential to improve patient flow and reduce overcrowding in emergency care settings. The code is available in our GitHub repository.

emergency overcrowding; time series prediction; patient flow forecasting; hospital resource management; reactive and proactive full capacity protocol

Introduction

Background

Emergency departments (EDs) are the primary source of hospital admissions, even though most individuals seen in the ED are ultimately discharged [1]. In 2021, there were more than 140 million visits to American EDs [2], of which 14.5 million (10.4%) led to hospital inpatient admissions, and 2 million (1.4%) led to admission to critical care units [3]. Several factors lead to ED overcrowding, including complexity of complaints and injuries [4,5], resource limitations [6], large patient volumes [7], and inefficient flow of patients [8]. ED overcrowding is associated with poor health care outcomes. It can lead to delays in diagnosis and treatment, which can result in poorer patient outcomes, higher comorbidities, and increased patient illness [9,10]. For instance, it was found that patients with acute coronary syndrome who presented to overcrowded EDs had a significantly higher rate of serious complications compared with those who presented to noncrowded EDs (6% vs 3%). The complications include death, late myocardial infarction, cardiac arrest, arrhythmias, heart failure, stroke, and hypotension [11]. Treatment delays also lead to serious complications, including death [12]. Sprivulis et al [13] observed a significant linear relationship between ED overcrowding and patient mortality based on 3 years of data from 3 large hospital systems.

The Emergency Medicine Practice Committee of the American College of Emergency Physicians reported that ED overcrowding is a hospital-wide patient flow problem rather than an isolated ED problem [1,2]. The full capacity protocol (FCP), a key approach recommended by the American College of Emergency Physicians to improve patient flow across the entire hospital, is an internationally recognized communication tool between the ED and inpatient units [8]. It contains a set of interventions that can be tailored to the severity levels of ED overcrowding [14]. A set of criteria triggers each intervention level. The criteria are based on different patient flow measures (PFMs), such as the number of patients waiting to be admitted to an inpatient unit (boarded patients) [14,15].

In the current FCP practice, the unit responsible for managing patient flow relies on near real-time PFM values to activate different FCP levels, which is a reactive approach. Specifically, at our partner hospital—an urban, university-affiliated academic medical center in the southeastern United States—this unit is referred to as the patient flow coordination team (PFCT). Implementing FCP interventions (eg, creating hallway treatment spaces or activating on-call personnel) requires preparation time, forcing PFCT to prepare and act simultaneously when the ED is already overcrowded, significantly increasing their stress. Therefore, accessing the predicted PFM values before overcrowding can provide the PFCT enough time to prepare before they implement FCP interventions. Given the critical role of timely and accurate information in driving FCP interventions, it is essential to develop prediction models to forecast PFMs used by the FCP criteria, transforming FCP from reactive to proactive. Proactive FCP can help in planning and implementing interventions at different crowding severity levels proactively before the ED is already overcrowded. Predicted PFMs built into a proactive FCP can help the PFCT anticipate future FCP level escalation and prepare for interventions, such as coordinating staffing needs and creating additional hallway treatment spaces.

There are many PFMs that can be used to determine the FCP level, such as ED hourly waiting count, ED boarding count, ED arrival count, and the number of patients by Emergency Severity Index (ESI), among others. For this study, the advisory board of the project recommended that we start with building a prediction model for the ED waiting count, as it is one of the most important PFMs. The ED waiting count represents the number of patients who have arrived at the ED but have not yet been moved to a treatment room or started their clinical care. The advisory board members represent different ED units at the partner hospital. The members include the chair of Emergency Medicine, the chief medical information officer, the associate principals of the Office of Clinical Practice Transformation, the associate vice president of clinical operations at the center of patient flow, the senior director of Emergency Services, and the nurse director for Emergency Services. Based on the feedback from the advisory board, the goal of this paper is to build deep learning models to predict the ED waiting count at two time points: (1) In the hourly basis, in which the prediction models forecast the waiting count in the next 6 hours; (2) In daily basis where the models predict the average waiting count for next working day. The prediction information allows PFCT to prepare ED resources to improve patient flow and consequently mitigate ED overcrowding. This study is part of a larger funded ED improvement project, and the models presented in this study will be integrated into a decision support system to be used by our partner hospital.

As part of a broader effort to build a data-driven decision support system for ED operations, this paper focuses on the critical metric of ED waiting room count. This predictive model represents a foundational component of the broader effort to operationalize proactive FCP. Using real-world operational and contextual data, we assess the utility of multiple time-series

XSL•FO
RenderX

algorithms and dataset variations to inform timely, data-driven predictions in ED management. The contributions of this study are as follows:

- We proposed an improvement for the current reactive FCP to make it proactive based on prediction models.
- This study was based on a real-world dataset and was conducted in collaboration with key decision makers from the ED.
- We developed predictive models that integrate multiple predictors from various sources to provide a comprehensive understanding of patient flow dynamics and improve forecasting performance.
- We introduced 2 complementary prediction approaches—hourly and daily—that provide actionable insights at different time scales.

Prior Work

Numerous studies in the literature have focused on predicting different ED PFMs or outcomes. Traditional models have been developed to predict hospital admissions at ED triage, often relying on a limited set of demographic, administrative, and clinical variables [16-18]. For example, Parker et al [17] used variables such as age group, race, postal code, day of the week, time of day, triage category, mode of arrival, and fever status in a logistic regression model to predict hospital admissions with an area under the curve of 0.825. Similarly, Sun et al [18] developed a model to predict immediate hospital admission at the time of ED triage using routine administrative data, including age, patient acuity category, arrival mode, and coexisting chronic diseases like diabetes, hypertension, and dyslipidemia, achieving an area under the curve of 0.849. However, because these models focus on only individual patient-level triage outcome predictions, they offer limited utility for administrative management in addressing ED crowding, as they do not provide a comprehensive view of overall patient flow or resource utilization.

In one of the earlier studies that focused on predicting ED PFMs at the aggregate patient level, Schweigler et al [19] developed a baseline model to predict ED overcrowding using historical averages and compared its performance to more advanced time series models, including seasonal autoregressive integrated moving average (ARIMA) and a sinusoidal model with an autoregressive error term. However, these models relied solely on historical averages to predict ED crowding based on bed occupancy, without considering any other predictors, limiting their utility for comprehensive ED crowding management. A subsequent time series modeling study by Kadri et al [20] also developed an ARIMA model to predict daily pediatric ED attendances using only historical attendance data, without external predictors.

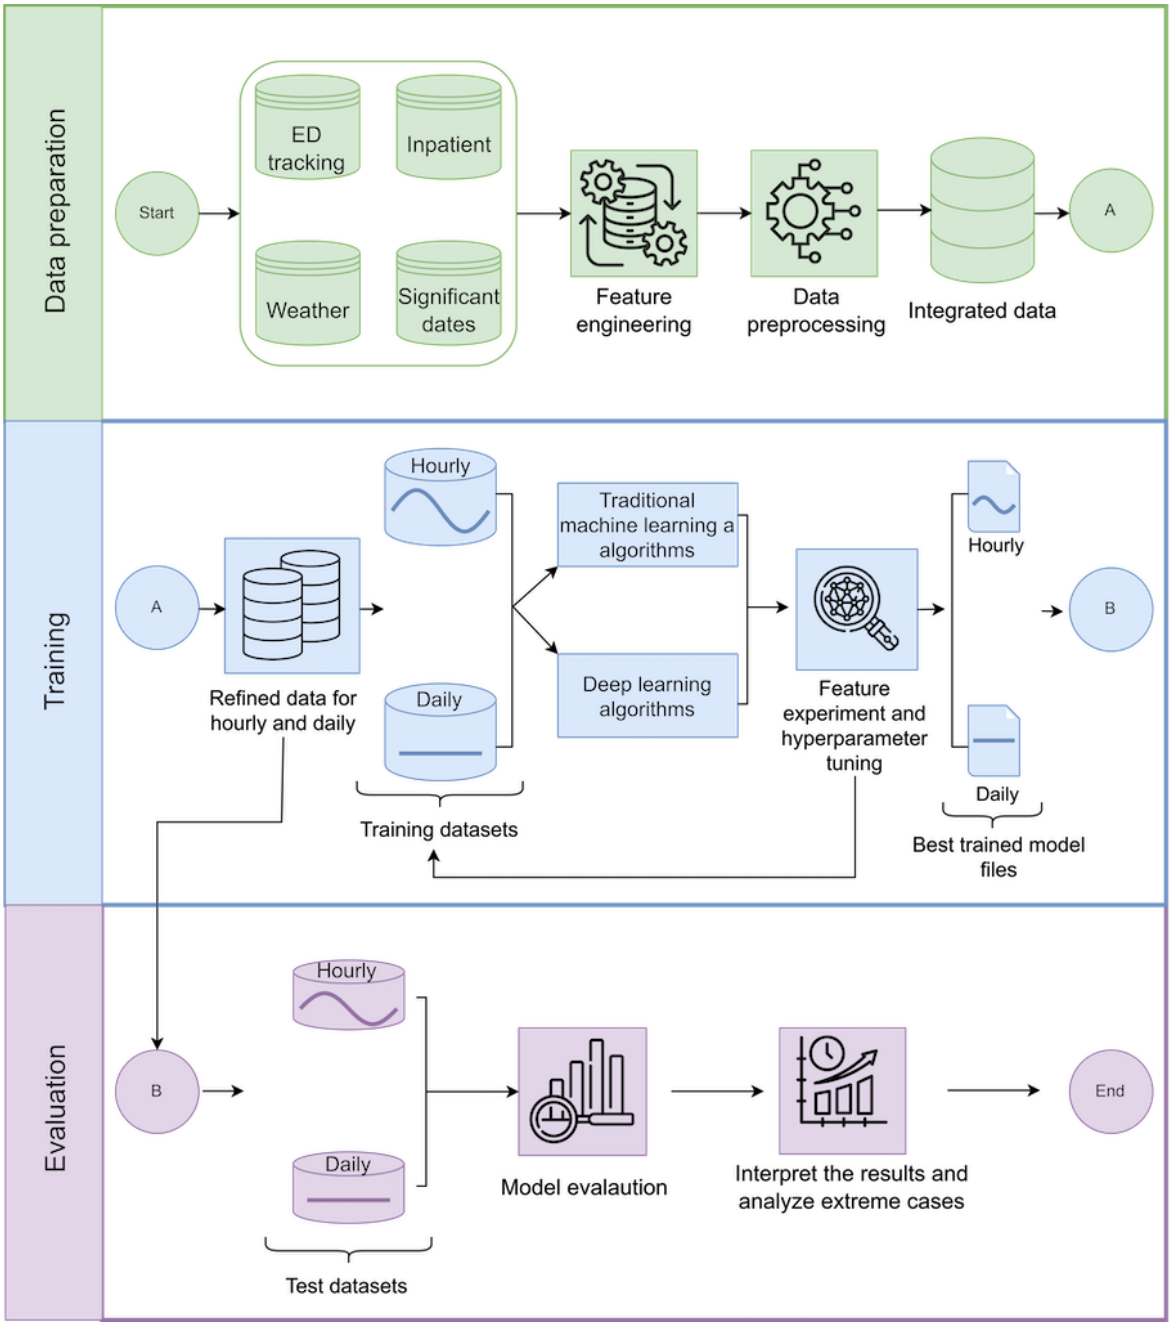
Recent studies have leveraged advanced machine learning (ML) models to predict ED PFMs, which are generally the number of patients arriving [21-23] or waiting time [24,25], across different prediction horizons. Our study targets waiting count prediction, which measures the number of patients present in the ED waiting room during each time interval by cumulatively adding patients for every hour they remain. Arrival count and waiting count are fundamentally different PFMs: arrival count records each patient once, at the moment they enter the ED, whereas waiting count tracks each patient for every hour they remain in the waiting area. For example, if a patient arrives at 1:05 PM and leaves at 3:35 PM, they are counted for 1-2 PM in the arrival count but are included in the waiting count for 1-2 PM, 2-3 PM, and 3-4 PM. To the best of our knowledge, no published studies have focused on predicting waiting count in US EDs using deep learning models. Since the literature on waiting count prediction is lacking, we summarize key studies on arrival count prediction, which most closely align with our research objective. For example, Harrou et al [6] developed deep learning models to predict hourly and daily ED arrival counts, comparing the performance of a variational autoencoder with 7 others: recurrent neural networks (RNNs), long short-term memory (LSTM), bidirectional long short-term memory (BiLSTM), convolutional LSTM, restricted Boltzmann machine, gated recurrent units, and convolutional neural networks (CNN). Tuominen et al [26] used advanced ML models, including probabilistic forecasting with autoregressive recurrent networks (DeepAR) [27], neural basis expansion analysis for interpretable time series forecasting (N-BEATS) [28], temporal fusion transformer, and light gradient boosting machine (LightGBM) [29], with multivariable inputs such as bed availability in catchment area hospitals, traffic data, and weather variables to predict daily ED occupancy. Similarly, Giunta et al [30] developed a multivariable predictive model based on the National Emergency Department Overcrowding Study score to predict sustained critical ED overcrowding lasting 8 or more hours, incorporating weather, patient flow, and bed occupancy variables. However, despite their advanced methodologies and multivariable approaches, none of these studies examined their predictions within the context of a proactive FCP.

Although these studies advance ED overcrowding prediction, each has limitations that reduce practical use in high-volume EDs. Many models have relied on a narrow set of inputs, such as patient arrivals or historical bed occupancy, without incorporating a broader range of operational, staffing, or environmental variables. In our study, we focus on forecasting the ED waiting count rather than the arrival count, as the arrival count only captures new patient entries and does not reflect ongoing congestion in the waiting area. In contrast, waiting count directly measures the number of patients present at any given time, providing a more accurate assessment of real-time crowding. Additionally, most studies have focused exclusively on daily metrics, failing to capture both hourly and daily fluctuations needed for real-time resource planning. To address these gaps, this study integrates hourly and daily predictions for more granular, actionable forecasting.

Methods

Ethical Considerations

This study was reviewed and approved by the Institutional Review Board (IRB) at the University of Alabama at Birmingham, with IRB# IRB-300011584.



Research Framework

Figure 1 shows our proposed framework, which has 3 main phases: data preparation, training, and evaluation. The

XSL•FO
RenderX

framework includes 2 prediction approaches. The first provides hourly predictions, estimating the number of patients in the waiting room 6 hours ahead to support intraday resource management. The second provides daily predictions, estimating the average waiting count for the next 24 hours to help anticipate ED conditions for the following day. In this paper, patient counts in the waiting room are referred to as "waiting counts," and their 24-hour average as "average waiting count."

Figure 1. Proposed research framework. ED: emergency department.

The data preparation phase involves processing data from 4 sources: the ED tracking system, inpatient records, weather information, and significant dates. After obtaining data from different sources, feature engineering and data preprocessing are applied separately to each source before creating the integrated final data. Following this, data preprocessing focuses on cleaning, scaling, and recategorizing certain categorical variables to prepare datasets for use in predictive modeling. After completing feature engineering and data preprocessing for each data source, all sources are integrated on an hourly basis into a single comprehensive dataset. The mathematical calculation of all features, including the target variable waiting count, along with all preprocessing and feature engineering steps, is described in detail in Multimedia Appendix 1 [31-56]. Table 1 includes descriptive statistics: numerical features show mean (SD), min, and max; categorical features indicate dataset percentages; and temporal features specify the time range used.

[a]Data from January 1, 2020, to May 1, 2021, was excluded due to COVID-19.

[b]ESI: Emergency Severity Index.

[c]28.77% of rows have nonzero values, indicating days that experienced extreme patient volumes during at least some portion of the day.

During the training phase, the integrated data from the data preparation stage is used to generate 2 refined datasets: one for the hourly prediction approach and another for the daily prediction approach. Subsequently, 16 different dataset variations are created to be used by both approaches, each with distinct feature combinations, as detailed in Table S2 in Multimedia Appendix 2. A total of 11 ML algorithms, in Table S1 in Multimedia Appendix 1 [31-56], are used to train and evaluate models on both hourly and daily datasets to identify the best-performing models. These algorithms are categorized into four groups: (1) traditional machine learning (random forest [RF] [31] and extreme gradient boosting [XGBoost] [32]); (2) RNN-based models (LSTM) [33], BiLSTM [34], and sequence to sequence learning with neural networks [Seq2Seq] [35]; (3) CNN-based architectures (fully convolutional network plus [FCNPlus] [36], residual network plus [ResNetPlus] [37], XceptionTimePlus [38], and explainable convolutional neural network plus [XCMPlus] [39]); and (4) transformer-based models (time series transformer plus [TSTPlus] [40] and time series vision transformer plus [TSiTPlus] [41]). The architectures of all algorithms are explained in detail in Multimedia Appendix 1 [31-56]. Each combination of an algorithm and a dataset is considered a separate model in this study. To improve performance, different hyperparameter configurations are tested across the 16 dataset variations.

In the evaluation phase, performances of the trained models are evaluated. The best-performing models, selected for both hourly and daily prediction tasks, are tested using evaluation metrics detailed in the Model Evaluation section of Multimedia Appendix 1 [31-56]. The evaluation is primarily based on 4 different metrics: mean absolute error (MAE), mean squared error (MSE), root mean squared error (RMSE), and the coefficient of determination (R^2). To further assess model effectiveness, the best-performing hourly prediction model is evaluated under extreme case scenarios, representing periods of exceptionally high patient volumes, with the results presented in Table 2. Additionally, the performance of the best hourly model is analyzed across the hour-of-day, capturing variations and trends in predictive accuracy at different times, as illustrated in Figure S3 in Multimedia Appendix 3.

[b]σ: SD.

[c]Lowest MAE.

Data Sources

The data sources in this study cover the period from January 2019 to July 2023 and are categorized into hospital data, including ED tracking system and inpatient records, and external data, consisting of weather information and significant dates for football games and federal holidays.

The ED tracking data provides detailed records of patient arrivals and departures within the ED waiting and treatment rooms of our partner hospital. This data also includes ESI levels indicating acuity, patient classifications, room types, event status (eg, complete, request, and cancel), and other ED-related information. Both waiting room and treatment room identifiers are recorded, enabling comprehensive tracking of patient movements from arrival to discharge or inpatient admission through unique patient and visit identifiers. The data contains 161,477 unique patients and 308,196 unique visits.

The inpatient data contains time-stamped records of patient admissions to and discharges from inpatient units. These records enable the hourly calculation of the hospital-wide patient census feature, as shown in Table 1. The dataset comprises 293,716 unique inpatient visits for 180,589 unique patients, representing hospital-wide admissions encompassing the study period.

The external data includes weather data and significant events, which are federal holidays and local football game event data. The weather data provides hourly weather information collected from a nearby weather station located close to the partner hospital. This data is sourced from the historical data archive of the OpenWeatherMap History Bulk [57] and includes numerical variables such as temperature, humidity, and wind speed, as well as a categorical variable indicating categories of clear skies, clouds, rain, mist, thunderstorm, snow, drizzle, haze, fog, and smoke. The significant dates consist of 2 external datasets: federal holidays and football game dates for a major team near the hospital. On average, there are 13 football games and 10 federal holidays each year. Federal holidays were obtained from the United States Office of Personnel Management Government website [58], and football game dates were sourced from the team's official website [59].

Problem Modeling

To predict waiting counts in the ED waiting room at a time point h steps into the future (eg, predicting 6 hours from now, or any other chosen future time point), we model this problem as a time series ML problem. We set up the problem as a direct single-step forecast targeting y_{t+h} from the current time t. Let:

- y_t represent the waiting count at the current time t.
- h be the prediction horizon (ie, the number of time steps ahead for the forecast (eg, h=6 for 6 hours ahead).
- k denote the number of past observations (lags) included in the model.
- $(l_1, l_2,\ldots, l_N)$ represent variables that do not require lagging (eg, weather conditions, holidays).
- $x_t, x_{t-1},\ldots, x_{t-k+1}$ represent any feature other than the waiting count that has a lag.

XSL•FO
RenderX

- $g(.)$ be the function learned by the ML model, trained using historical data.

The model can be expressed as follows:

Where:

- y_{t+h} is the predicted waiting count at time $t+h$.
- y_t, y_{t-1},…, $y_{t-k+1}$are waiting count lag features to capture temporal dependencies.
- M is the total number of observations and the training dataset size is $M-k-h+1$.

Model Design

Model design involves selecting the relevant feature combinations for prediction. With a total of 34 main features, excluding lag and rolling mean features, determining the optimal feature set is an essential step in improving model performance. Therefore, numerous experiments were conducted initially to refine feature combinations, scaling methods, COVID-19 date exclusion ranges, weather categorizations, and hyperparameter ranges. Based on the outcomes of these experiments, a total of 16 datasets were generated, as shown in Table S2 in Multimedia Appendix 2, each containing different combinations of features. These combinations were selected through a manual but systematic approach guided by domain knowledge and performance feedback. Specifically, we varied key dimensions such as lag lengths, rolling window sizes, weather encodings, temporal coverage, and the inclusion of engineered variables like the extreme case indicator. Each dataset was crafted to test how individual or grouped feature categories (eg, ED tracking, inpatient census, weather, significant dates) influence model generalization and forecasting accuracy. To evaluate these combinations, 11 different algorithms, as detailed in Table S1 in Multimedia Appendix 1 [31-56], were applied to train models on each dataset. The primary objective was to identify the most effective combination of features and algorithms for achieving optimal performance. For both hourly and daily prediction models, a total of 8800 experiments (11 algorithms × 16 datasets × 50 trials) were conducted separately to evaluate these combinations and determine the best-performing model and feature set.

Hourly and Daily Time Horizons

To address the varying forecasting needs in ED, this study uses 2 types of predictive models: hourly and daily, as illustrated in Figure S4 in Multimedia Appendix 3. These models were developed to handle different prediction horizons, allowing for more comprehensive management of patient flow in the ED.

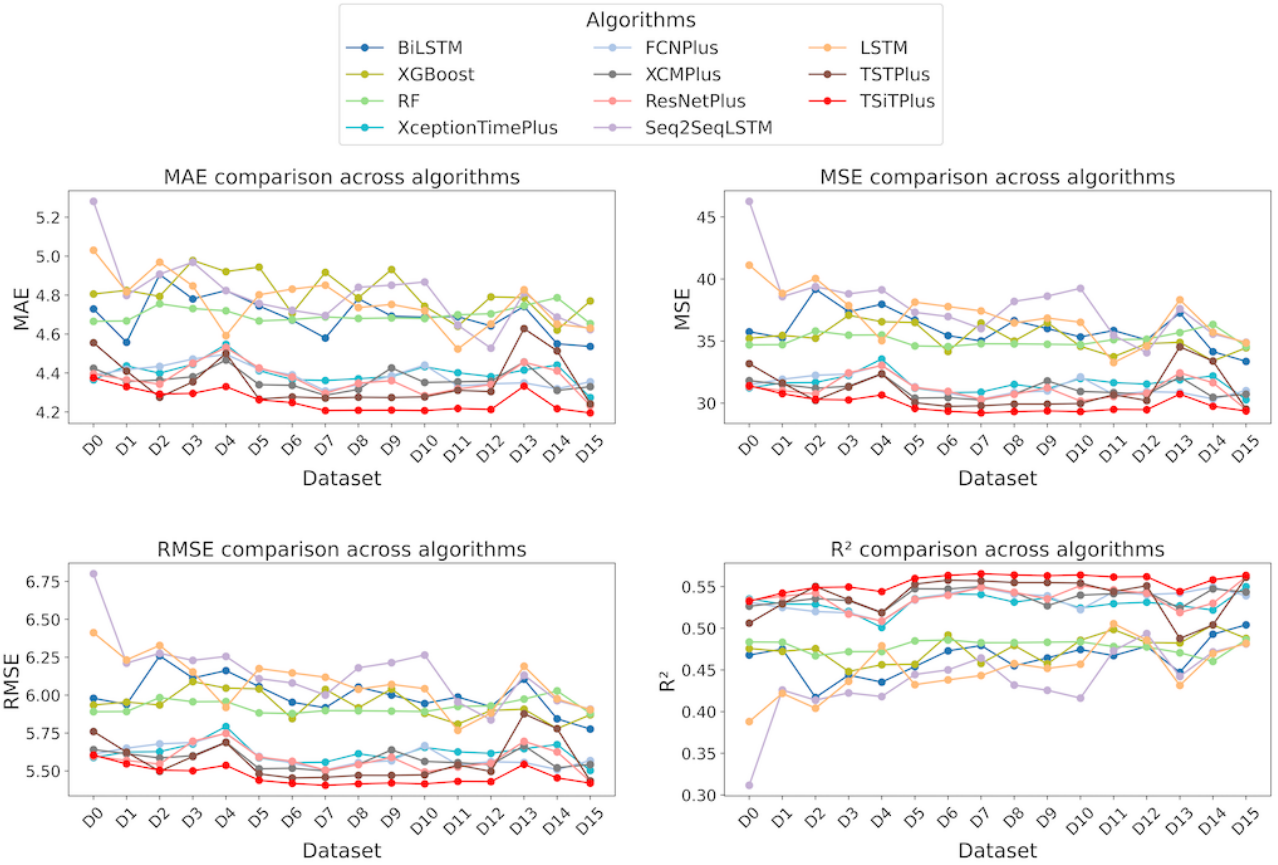
The hourly model predicts the waiting count 6 hours ahead. As shown by the red arcs in Figure S4 in Multimedia Appendix 3, this model provides flexibility by not being restricted to specific times of the day. Instead, it generates forecasts for 6 hours into the future whenever it runs, enabling it to be applied at any time when updated predictions are needed.

The daily model predicts the average waiting count for the next 24-hour period, running each day at 5 PM and using data from the previous 24 hours (5 PM the previous day to 5 PM today). At each run, it provides a single estimate for the upcoming 24-hour window (5 PM today to 5 PM tomorrow), offering insights that aid in planning for the next day. Figure S4 in Multimedia Appendix 3 shows the daily model's prediction timeline, represented by the orange elements, where forecasts are generated once per day to estimate the average waiting count in the waiting room for the next 24-hour period.

The selection of the 2 prediction horizons—6 hours ahead and daily—was informed by consultations with hospital operational leadership and the clinical advisory board to align with real-world decision-making workflows. The 6-hour-ahead forecast supports intrashift planning by enabling proactive resource allocation for anticipated short-term crowding. The daily forecast facilitates long-range planning, including staffing, bed coordination, and potential FCP activation based on projected 24-hour patient volumes. Together, these models address both immediate and next-day operational needs.

Results

Overview



We present and analyze the evaluation results of 11 ML algorithms (listed in Table S1 in Multimedia Appendix 1 [31-56]) applied to 16 different datasets (described in Table S2 in Multimedia Appendix 2). The results cover 2 separate prediction approaches: one focuses on forecasting the waiting count 6 hours ahead, and the other estimates the average waiting count over the next 24-hour period.

Performances of Hourly Prediction Models

The target variable waiting count, which represents the number of patients in the waiting room during a given hourly interval, has a mean value of 18.11 and a SD of 9.77, as shown in Table 1. Figure 2 presents the performance analysis of ML models in predicting waiting counts 6 hours ahead across 16 different datasets (DS0 to DS15). In Figure 2, the x-axis in all subplots represents the datasets, while the y-axis corresponds to each evaluation metric. Among the evaluated models, the TSiTPlus algorithm demonstrated the best overall performance, achieving an MAE of 4.19, an MSE of 29.36, an RMSE of 5.42, and an R^2 of 0.56 on dataset DS15.

XSL•FO
RenderX

Figure 2. Comparison of hourly model performances across 16 datasets and 11 algorithms based on different evaluation metrics. BiLSTM: bidirectional long short-term memory; FCNPlus: fully convolutional network plus; LSTM: long short-term memory; MAE: mean absolute error; MSE: mean squared error; ResNetPlus: residual network plus; RF: random forest; RMSE: root mean squared error; Seq2Seq: sequence to sequence learning with neural networks; TSiTPlus: time series vision transformer plus; TSTPlus: time series transformer plus; XCMPlus: explainable convolutional neural network plus.

As shown in Figure 2, traditional ML algorithms, RF and XGB, displayed similar performance patterns, with RF achieving its best results on dataset DS15 and XGB on dataset DS14. Specifically, RF's performance on DS15 yielded an MAE of 4.65, an MSE of 34.56, an RMSE of 5.87, and an R^2 of 0.48, using 100 estimators, a maximum depth of 30, and 4 samples per leaf, with bootstrapping enabled. Across all datasets, RF's MAE varied between 4.65, its best performance, and 4.78, its worst performance. On the other hand, XGB achieved slightly better values on dataset DS14, with an MAE of 4.62, an MSE of 33.40, an RMSE of 5.78, and an R^2 of 0.50, with a maximum depth of 15, a learning rate of 0.02, a subsample ratio of 0.8, and a column sampling rate of 0.3. These results highlight the limitations of traditional algorithms, which treat each observation independently and lack the ability to capture the long-term dependencies and complex sequential patterns inherent in time-series data.

RNN-based models, including Seq2Seq, LSTM, and BiLSTM, delivered better results than traditional ML algorithms for predicting waiting counts 6 hours ahead. Among these, Seq2Seq achieved its best performance on dataset DS12, with an MAE of 4.52, an MSE of 34.06, an RMSE of 5.83, and an R^2 of 0.49. This result was obtained using a batch size of 32, a learning rate of 0.01, a weight decay of 0.2, a dropout rate of 0.1, and Adam as the optimization function. The Seq2Seq model's performance, based on MAE, ranged from its worst result of 5.28 on dataset DS0 to its best result of 4.52 on dataset DS12. LSTM demonstrated consistent results across datasets, delivering its best performance on dataset DS11, with an MAE of 4.52, an MSE of 33.26, an RMSE of 5.76, and an R^2 score of 0.505. This result was achieved using a batch size of 32, a learning rate of 0.01, a dropout rate of 0.2, a weight decay of 0.1, and stochastic gradient descent as the optimization algorithm [60]. The LSTM model's performance, based on MAE, ranged from its worst result of 5.03 on dataset DS0 to its best result of 4.52 on dataset DS11. BiLSTM, which leverages its bidirectional architecture, achieved its best results on dataset DS15, with an MAE of 4.54, an MSE of 34.67, an RMSE of 5.89, and an R^2 score of 0.48. However, it encountered higher errors on datasets such as DS2, where the MAE was 4.91.

The CNN-based algorithms, including ResNetPlus, XceptionTimePlus, FCNPlus, and XCMPlus, demonstrated better performance than both traditional ML and RNN-based algorithms across multiple datasets in this study. Among these, ResNetPlus achieved the best overall performance, particularly on dataset DS15, with an MAE of 4.23, an MSE of 29.93, an RMSE of 5.47, and an R^2 of 0.555. XceptionTimePlus achieved its best results on dataset DS15 as well, with an MAE of 4.274, an MSE of 30.279, an RMSE of 5.503, and an R^2 of 0.55. FCNPlus performed best on dataset DS7, with an MAE of 4.3081, an MSE of 30.3208, an RMSE of 5.5064, and an R^2 of 0.5491. Finally, XCMPlus delivered its best results on dataset

XSL•FO
RenderX

DS7, with an MAE of 4.285, an MSE of 30.254, an RMSE of 5.5, and an R^2 of 0.55. These results suggest that CNN-based models generally provided more accurate predictions than traditional and RNN-based algorithms.

The transformer-based models, TSiTPlus and TSTPlus, delivered better results compared with other algorithm categories in this study, with TSiTPlus being the best-performing model based on MAE. TSiTPlus achieved its best performance on dataset DS15, with an MAE of 4.19, an MSE of 29.36, an RMSE of 5.41, and an R^2 of 0.56. In comparison, TSTPlus showed good performance but had slightly higher errors. Its best results were on dataset DS15, with an MAE of 4.24, an MSE of 29.52, an RMSE of 5.43, and an R^2 of 0.561. DS15 incorporated a range of features, including waiting count lags, rolling averages, patient flow indicators, weather conditions, hospital census data, and significant event markers. Across other datasets, TSTPlus achieved MAE values such as 4.27 on DS7 and 4.27 on DS8. The performance of TSiTPlus indicates that it was the most accurate model in this study for predicting waiting counts. To examine the impact of including the COVID-19 period, TSiTPlus was evaluated on DS15, the best-performing model and dataset combination. The results indicated noticeably higher prediction errors (MAE: 4.82 vs 4.19; MSE: 40.22 vs 29.32), suggesting that patient flow anomalies during the pandemic adversely affected model performance.

TSiTPlus demonstrated superior performance over all other models in hourly predictions. Specifically, it achieved a 9.8% reduction in mean MAE compared with RF (MAE=4.65), a 7.3% reduction compared with the best-performing RNN-based model, Seq2Seq (MAE=4.52), and a 0.9% improvement over the best CNN-based model, ResNetPlus (MAE=4.23). Although the performance gap between TSiTPlus (MAE=4.19) and the best traditional ML model, XGBoost (MAE=4.62), may initially appear modest, its operational significance becomes clear when scaled to the continuous nature of ED operations. Given that predictions are generated hourly—24 times each day—this 0.43 improvement in MAE results in approximately 10.3 (0.43 × 24 hours), more accurate waiting count forecasts per day. When extended over an entire year, this translates to 3767 waiting counts (10.3 × 365 days), more accurate predictions, each representing a more informed decision point for hospital staff.

To estimate uncertainty around our model's point estimates, we applied a bootstrap resampling approach [61], which repeatedly samples from the original test data to approximate the sampling distribution of evaluation metrics. Specifically, we used block bootstrapping with our best-performing model, TSiTPlus, on DS15. A block size of 24 was chosen to match the 24-hour lag window, preserving local temporal dependencies inherent in hourly hospital data. For each iteration, blocks of 24 consecutive hours were resampled with replacement from the test dataset to form a new evaluation set, and performance metrics were computed. This method yielded robust IQRs for each metric. As shown in Table 3, MAE reaches 4.19 with an IQR of 4.16-4.25, varying by only 0.09 across samples—indicating highly consistent model performance. MSE reaches 29.36 (IQR 28.65-30.20), RMSE reaches 5.42 (IQR 5.35-5.49), and R^2 reaches 0.56 (IQR 0.55-0.57); all similarly demonstrate narrow IQRs, further supporting the stability and reliability of the model's predictions. These narrow IQRs suggest that the model is not only accurate but also reliable under different test-time conditions.

Table 3. Bootstrap-based uncertainty estimates for model performance metrics using Time Series Vision Transformer Plus (TSiTPlus) on dataset DS15.

Model and metric	Median (IQR)
TSiTPlus	
MAE[a]	4.19 (4.16-4.25)
MSE[b]	29.36 (28.65-30.20)
RMSE[c]	5.42 (5.35-5.49)
R^2	0.56 (0.55-0.57)

[a]MAE: mean absolute error.

[b]MSE: mean squared error.

[c]RMSE: root mean squared error.

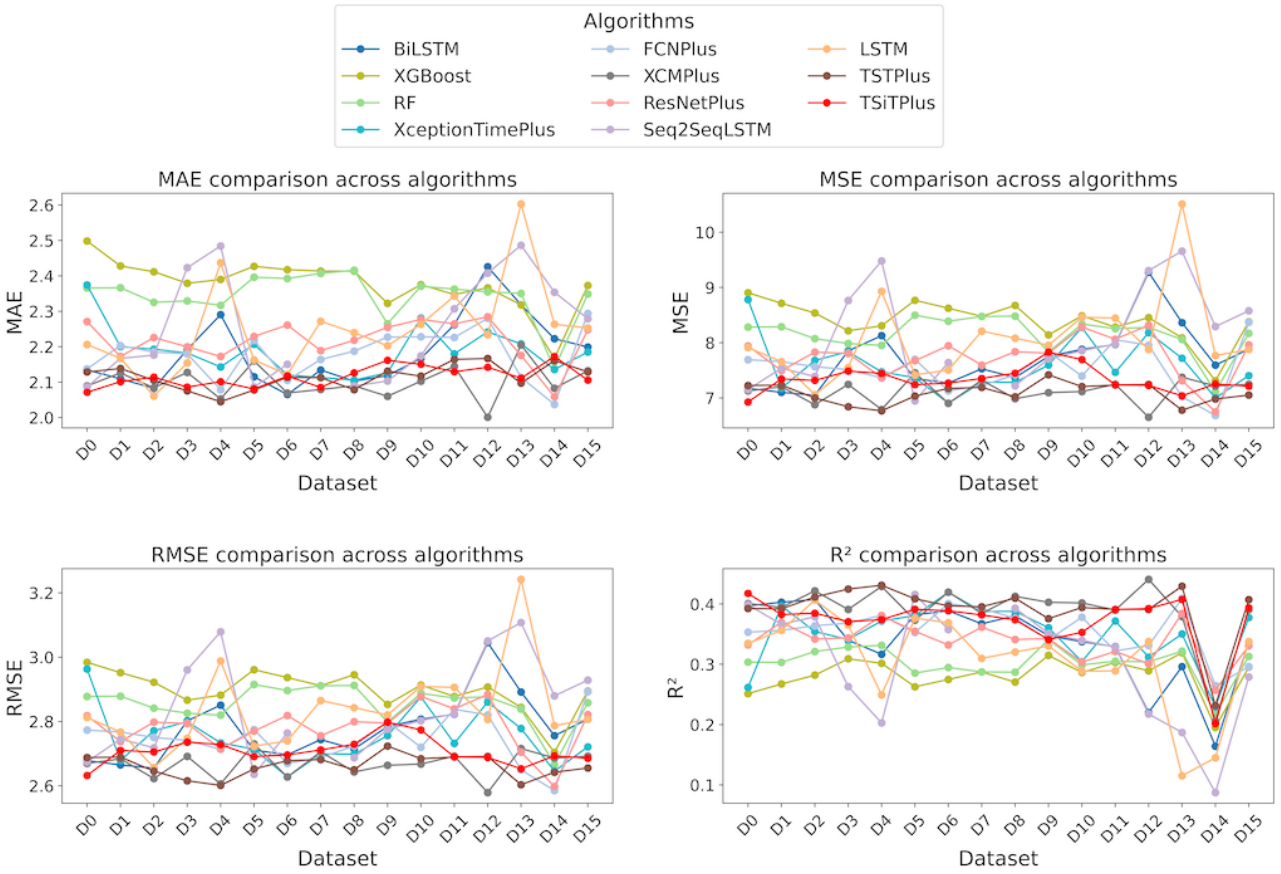
The strong performance of TSiTPlus in this study can be attributed to its ability to capture complex patterns in multivariate time series data. As a transformer-based model, it is well-suited for recognizing relationships and trends over time. TSiTPlus divides the time series into smaller segments, treating them as input tokens—similar to words in a sentence—which allows the model to capture both short- and long-term patterns. This design enables it to learn from multiple timeframes, making it particularly effective for datasets with complex temporal dynamics.

Analysis of Extreme Case and Hour-of-Day

Table 2 presents the performance of TSiTPlus, the best-performing algorithm, in predicting extreme cases across various datasets. For "Extreme Cases" (mean + 1σ), MAE ranged from 6.16 on DS14 to 7.08 on DS2. In "Very Extreme Cases" (mean + 2σ), MAE ranged from 10.16 on DS14 to 12.13 on DS1. For "Highly Extreme Cases" (mean + 3σ), TSiTPlus achieved its best result on DS14 with an MAE of 15.59. When averaging errors across all 3 categories, DS14 performed best, followed by DS15, demonstrating strong predictive capabilities under high patient volume. DS14's superior performance is

XSL•FO
RenderX

likely due to its 48-hour lag features, which incorporate data from the past 2 days (Table S2 in Multimedia Appendix 2).



Our best-performing model not only predicts typical waiting counts accurately but also performs well under extreme crowding. Compared with traditional models, such as RF (MAE: 14.0 for Very Extreme, 20.0 for Highly Extreme) and XGBoost (MAE: 13.9 for Very Extreme, 19.6 for Highly Extreme), TSiTPlus consistently shows lower error rates during critical situations. This reduction in prediction error during peak periods allows for earlier, more accurate interventions, improving ED responsiveness and resource coordination. When evaluating the cumulative effect of prediction performance over time, the difference becomes even more meaningful. For example, in very extreme scenarios, TSiTPlus achieves an MAE of 10.16 compared with XGBoost's 13.9—an improvement of 3.74. This translates to approximately 90 (3.74 × 24 hours) more accurate waiting count predictions per day. When applied year-round, this provides a clear operational advantage for anticipating and managing ED overcrowding.

Figure S3 in Multimedia Appendix 3 shows the TSiTPlus model's performance by hour of day. It performs best between 10 PM and 6 AM, with MAE under 4 and RMSE between 3 and 5.25, reflecting more stable patient volumes. Error metrics increase between 6 PM and 8 PM, where MAE nears 5 and RMSE exceeds 6, likely due to higher variability in waiting counts during this time.

Performance of Daily Prediction Models

As shown in Figure S4 in Multimedia Appendix 3, daily prediction is conducted at 5 PM each day to estimate the next day's average waiting count. The target variable has a mean of 18.11 and an SD of 4.51 (Table 1). Daily prediction errors are lower than hourly due to smoother target values and a smaller dataset. Using the same 11 ML algorithms (Table S1 in Multimedia Appendix 1 [31-56]) across 16 datasets (Multimedia Appendix 2), the best performance was achieved by XCMPlus with an MAE of 2.00, MSE of 6.64, RMSE of 2.57, and R^2 of 0.44, as shown in Figure 3.

Figure 3. Comparison of daily model performance across 16 datasets based on different evaluation metrics. BiLSTM: bidirectional long short-term memory; FCNPlus: fully convolutional network plus; LSTM: long short-term memory; MAE: mean absolute error; MSE: mean squared error; ResNetPlus: residual network plus; RF: random forest; RMSE: root mean squared error; Seq2Seq: sequence to sequence learning with neural networks; TSiTPlus: time series vision transformer plus; TSTPlus: time series transformer plus; XCMPlus: explainable convolutional neural network plus.

Traditional ML algorithms, RF and XGBoost, demonstrated similar performance across all 16 dataset configurations for daily predictions, as illustrated in Figure 3. Both algorithms achieved their best results on dataset DS14, with RF slightly outperforming XGBoost. Specifically, RF recorded the lowest MAE of 2.13, MSE of 7.10, RMSE of 2.66, and an R^2 of 0.217, while XGBoost followed closely with an MAE of 2.16, MSE of 7.31, RMSE of 2.70, and an R^2 of 0.195. The performance gap between the best and worst configurations for both algorithms, with RF ranging from 2.13 to 2.41 MAE and XGBoost from 2.16 to 2.49 MAE, indicates consistent behavior across different feature combinations. RF achieved its optimal performance with 200 estimators, a maximum depth of 40, a minimum sample split of 10, and 8 samples per leaf with

XSL•FO
RenderX

bootstrapping enabled. Similarly, XGBoost's best configuration used a dart booster with a maximum depth of 12, learning rate of 0.02, subsample ratio of 0.8, column sampling rate of 0.4, and weighted sampling with a rate drop of 0.2.

The analysis of the RNN-based models, including LSTM, BiLSTM, and Seq2Seq, shows varying performance across datasets. The LSTM model performs consistently, with MAE values between 2.06 and 2.60 and RMSE between 2.65 and 3.24, achieving the lowest MAE on dataset DS2 and the highest on dataset DS13. BiLSTM performs slightly better, with MAE ranging from 2.06 to 2.42 and RMSE from 2.65 to 3.07, showing the best performance on dataset DS6 and the highest error on dataset DS12. Seq2Seq provides competitive results, with MAE between 2.08 and 2.48 and RMSE from 2.63 to 3.10, performing best on dataset DS5 and worst on dataset DS13. The R^2 values indicate that all models exhibit moderate predictive power, with the highest values around 0.41 and the lowest around 0.11. Among the 3 models, BiLSTM offers the best balance between low MAE and stable R^2 values, while Seq2Seq shows more consistent performance across datasets.

The analysis of CNN-based models, including FCNPlus, ResNetPlus, XceptionTimePlus, and XCMPlus, shows varying performance across datasets. FCNPlus has MAE values from 2.03 to 2.44 and RMSE between 2.58 and 3.01, performing best on dataset DS14 and worst on dataset DS11, with R^2 values ranging from 0.26 to 0.23. ResNetPlus shows slightly better performance, with MAE values between 2.05 and 2.40, RMSE from 2.59 to 3.02, and R^2 values between 0.25 and 0.22. XceptionTimePlus provides competitive performance, with MAE between 2.10 and 2.33 and RMSE from 2.71 to 2.88, achieving its best results on dataset DS8 and the highest error on dataset DS11. XCMPlus outperforms the other models, with the lowest MAE (2.00 to 2.28) and RMSE (2.57 to 2.92), showing the best performance on dataset DS12 and the highest error on dataset DS0. DS12 incorporated waiting count by ESI levels, treatment and boarding counts, and weather conditions, with rolling means and lag features enhancing trend detection. These features contributed to its strong predictive performance, especially for XCMPlus. It also has the highest R^2 values, ranging from 0.44 to 0.28, indicating better predictive accuracy. Overall, XCMPlus demonstrates the best performance among all algorithms, not just CNN-based models, achieving the lowest MAE and highest R^2 values, making it the most effective model for predicting daily waiting counts across datasets.

The analysis of the transformer-based models, TSiTPlus and TSTPlus, highlights differences in their performance across datasets. TSiTPlus demonstrates MAE values ranging from 2.08 to 2.17 and RMSE values between 2.63 and 2.80, with the best performance observed on dataset DS5 and the highest error on dataset DS14. The R^2 values for TSiTPlus vary from 0.41 to 0.20, indicating moderate predictive accuracy. TSTPlus achieves slightly lower MAE values compared with TSiTPlus, ranging from 2.04 to 2.18, and RMSE values between 2.57 and 2.70. The best results

are observed for dataset DS4, while the highest error occurs on dataset DS11. The R^2 values range from 0.42 to 0.27, showing slightly better predictive power compared with TSiTPlus. Overall, TSTPlus shows slightly better performance than TSiTPlus in terms of lower MAE and higher R^2 values across datasets, making it the more effective transformer-based model for predicting waiting counts.

Discussion

Principal Findings

This study developed time series ML models to forecast ED waiting room counts using real-world operational and contextual data. TSiTPlus achieved the best 6-hour-ahead prediction performance (MAE: 4.19, RMSE: 5.42, R^2: 0.56 on DS15), while XCMPlus performed best for daily forecasts (MAE: 2.00, RMSE: 2.57, R^2: 0.44 on DS12). MAE differences across datasets for TSiTPlus and XCMPlus were minimal in hourly predictions; however, the extreme case analysis revealed greater variation, underscoring the importance of feature engineering. For the hourly prediction models, comparing datasets highlights the incremental impact of added features. For example, the MAE for TSiTPlus decreased from 4.29 in DS2 to 4.26 in DS5 with the inclusion of weather status and ESI-based waiting counts. Incorporating significant dates such as football games and federal holidays further improved performance, reducing the MAE to 4.24 in DS6. Additional operational features—like treatment count, boarding count, and related time metrics—lowered the MAE to 4.21 in DS8. Further adjustments, such as different lagged features and rolling means, resulted in only minor MAE changes across DS8 to DS14. Ultimately, the best performance was achieved with DS15, where TSiTPlus reached an MAE of 4.19 after integrating all available features. For the daily prediction models, the best accuracy was achieved using DS14, which shares the same feature combination as the best hourly dataset, DS15, except that DS14 does not include temperature, humidity, wind speed, or football match variables. This suggests these variables do not significantly impact long-term average waiting count predictions. These results demonstrate the potential of deep learning–based time series models to support proactive FCP implementation through accurate, time-sensitive predictions. Additionally, we evaluated the impact of including COVID-19 period data for TSiTPlus on DS15. Contrary to some findings in the literature [62], which reported improved results for arrival count prediction when COVID-19 data was included, our results showed that adding the pandemic period to our training data negatively affected model performance for waiting count prediction (MAE increased from 4.19 to 4.82; MSE increased from 29.32 to 40.22). This suggests that the atypical patient flow patterns during the COVID-19 pandemic introduced additional variability, making it harder for the model to accurately capture or reflect standard ED operations.

Managerial Impact

EDs often face overcrowding due to challenges such as limited resources [6], high patient volumes [7], and inefficient patient flow management [8]. This represents an initiative to transform reactive FCP to be proactive by developing predictive models that forecast a key PFM, which is ED waiting counts. The prediction is done at two distinct time scales—6 hours ahead and 24 hours in advance—allowing for both hourly operational

XSL•FO
RenderX

adjustments and daily planning. The selection of these prediction horizons was based on input from the hospital's PFCT and the project advisory board. The 6-hour window was identified as a critical lead time for initiating immediate operational responses such as surge staffing, bed reassignments, and overflow room activation. In contrast, the 24-hour forecast was designed to inform daily planning activities, including staff scheduling, diversion decisions, and intensive care unit (ICU) bed coordination. Predictions with longer windows can provide a greater margin for operational adjustments, making it easier for hospitals to mobilize resources and take proactive action when surges are anticipated. However, evidence is still lacking as to which prediction window offers the most sustainable and actionable foundation for managing real-world ED surges, since practical constraints and response capabilities can vary significantly between institutions.

The hourly prediction model, which predicts the total waiting count in the next 6 hours, enables real-time resource allocation by giving hospital managers enough time (eg, 6 hours) to proactively implement FCP interventions and resources that help mitigate ED crowding, such as adjusting staffing, mobilizing overflow spaces, and ensuring the availability of critical equipment before surges occur. For example, if the model predicts a peak in patient volume during the evening shift, managers can activate a surge plan, offering voluntary short-term shifts to nurses or physicians who opt in to alleviate crowding. Additionally, they can offer overtime to extend staff hours, call in additional clinical staff, or reassign staff to the ED ahead of anticipated crowding. These proactive measures help prevent bottlenecks, ensuring adequate coverage during peak times while minimizing unnecessary overtime costs. This capability minimizes understaffing during peak times while reducing unnecessary overtime costs. Additionally, FCP interventions—such as coordinating with inpatient units to expedite bed turnover or opening additional inpatient surge capacity, such as unstaffed beds or hallways, to absorb some of the ED boarding patients and relieve crowding—can be activated before crowding worsens, improving compliance with key performance indicators such as Centers for Medicare & Medicaid Services door-to-provider times and reducing "left without being seen" rates, which impact hospital revenue and reputation. These FCP interventions are not reserved for rare or exceptional circumstances but are routinely needed in everyday ED operations due to the persistent and dynamic nature of crowding.

The daily prediction model, which estimates the average patient waiting count over the next 24 hours (ie, from 5 PM on the current day to 5 PM the following day), supports broader decision-making processes. By forecasting average daily patient volumes, managers can optimize next-day staffing schedules and implement strategic interventions such as placing the hospital on diversion to temporarily halt nonessential incoming transfers, thereby preserving ED and inpatient capacity for critical cases. These predictions also enhance cross-departmental collaboration by facilitating proactive ICU bed reservations for anticipated ED admissions or diverting nonurgent cases to alternative care settings, such as urgent care clinics, to alleviate ED congestion. Over time, insights from daily predictions inform long-term capacity planning, such as adjusting seasonal budgets for flu surges or expanding ED infrastructure to accommodate growth trends.

The ability to act in advance is supported by the model's predictive accuracy, particularly under extreme crowding scenarios. This is critical because the most impactful decisions—such as activating surge capacity, reallocating staff, or adjusting admissions—are typically required when the ED is under the most pressure. Having reliable forecasts during these peak periods ensures that hospital managers can make timely, confident decisions that reduce overcrowding and maintain the quality of patient care.

The practical implications of this study go beyond forecasting accuracy, offering direct support for real-world hospital operations. By leveraging both internal operational features—such as patient flow metrics, boarding counts, treatment activity, and hospital census—and external contextual features—including weather conditions, federal holidays, and major local events—the models provide actionable insights tailored to each facility's environment. For example, if the 6-hour-ahead model forecasts a surge in ED waiting counts during an upcoming evening shift, hospital managers can proactively deploy surge nurses, call in backup physicians, prepare overflow treatment areas, or expedite inpatient bed turnover hours in advance. In parallel, daily forecasts indicating above-average volumes can be used during morning planning meetings to revise staffing levels, reserve ICU beds, or activate diversion protocols for nonurgent cases. In cases of anticipated extreme crowding, hospitals may also delay elective admissions, accelerate discharge rounds, or mobilize unstaffed bed capacity. Embedding these forecasts into hospital dashboards or integrating them with electronic health record systems enables timely alerts and streamlined workflows. By incorporating both operational and external drivers of demand, the system supports proactive, risk-informed decision-making that improves patient throughput, reduces waiting times, and enhances overall ED efficiency.

Limitations and Future Work

A key limitation of this study is that we did not evaluate how the predictions directly support proactive FCP implementation. While our models can anticipate patient surges, their real-world impact on operational decision-making remains untested. In a future study, we will address this by using discrete event simulation to compare reactive versus proactive FCP strategies, assessing how prediction-driven interventions influence resource allocation, patient flow, and ED performance metrics.

Short-notice staffing adjustments can be challenging in ED settings, and a 6-hour notice may be insufficient for several reasons. Many clinical staff may be unable to respond to requests for additional coverage with such limited advance notice, particularly during nights or weekends. Longer-term forecasting horizons—such as 24-hour, weekly, or monthly predictions—may provide a more practical foundation for surge planning. While many studies have adopted daily or multiday horizons [21,22,26,63,64], the literature does not provide clear evidence about which prediction window is most effective in real-world practice. Given these constraints, future work will

XSL•FO
RenderX

include a systematic evaluation of prediction windows across both short and long horizons to identify the most practical and operationally relevant timeframes for ED staffing.

Refinement of model adaptability and incorporation of more external data sources could further enhance predictive performance and real-world applicability. Another important consideration is the potential for data drift, including both covariate drift [65] and concept drift [66] over time. As clinical workflows, hospital policies, and external conditions evolve, model performance may degrade. To mitigate this risk, future deployments should incorporate drift detection mechanisms and model monitoring systems to ensure consistent forecast accuracy and trigger retraining when necessary.

The proposed system is designed for real-time operation, and a key direction for future work is its pilot deployment in a live clinical environment. This will be accompanied by a simulation-based evaluation to assess how the system integrates into operational workflows and influences decision-making. This study represents one component of a larger project, specifically focusing on the development of a predictive model for one of the PFMs—the waiting count. The broader project includes additional modules to predict other PFMs, such as boarding count and average waiting time, which will collectively support a comprehensive decision-support system for ED operations. Building on this, our future work will extend beyond standard ML workflows by implementing a real-time deployment architecture tailored for hospital operations. The planned deployment pipeline will run within the partner hospital's internal supercomputing infrastructure, ingesting hourly data streams from the ED tracking system, inpatient units, weather application programming interfaces, and event calendars. We will consider technologies such as columnar storage formats (eg, Apache Parquet [67]) and embedded analytical engines (eg, DuckDB [68]) to enable low-latency access to recent data. A containerized preprocessing pipeline using Docker [69] is envisioned to ensure consistent and reproducible real-time data cleaning and feature engineering. Model lifecycle management, including data versioning and experiment tracking, will be managed by tools such as MLflow [70], enabling continuous preprocessing, inference, and updates as new data arrives. Predictions will ultimately feed into a decision support module to provide early warnings for crowding, with results visualized on an internal dashboard to enhance operational planning. Additionally, future efforts will address key implementation steps such as ensuring data privacy, developing user-facing interfaces aligned with clinical workflows, and conducting usability testing. The goal is to build a fully automated infrastructure for continuous monitoring, model retraining, and maintenance, supporting long-term reliability and clinical utility.

Conclusions

The results of this study show that advanced ML approaches are effective in predicting ED waiting counts based on real-world data from our collaborating hospital. By integrating multiple datasets—ED tracking, inpatient data, weather, and significant dates—the research developed hourly and daily prediction models. The hourly model provides real-time, 6-hour-ahead forecasts, enhancing decision-making and resource allocation. The daily models offer insights into patient volumes at daily averages, aiding in operational planning.

A comprehensive evaluation was conducted by testing 11 different ML algorithms on 16 distinct datasets, each generated through careful feature engineering and hyperparameter optimization to explore optimal feature combinations. The results revealed that for the hourly prediction approach (6-hour-ahead prediction), the TSiTPlus algorithm consistently delivered the best performance, with DS15 emerging as the most effective dataset. DS15 incorporated a diverse range of features, including waiting count lags, rolling averages, patient flow indicators, weather conditions, hospital census data, and significant event markers. This combination enabled the model to achieve an MAE of 4.19, MSE of 29.36, RMSE of 5.42, and R^2 of 0.56, outperforming all other datasets. For the daily prediction approach (predicting the next 24-hour average waiting count), the best performance was achieved by the XCMPlus model using DS12, with an MAE of 2.00, MSE of 6.64, RMSE of 2.57, and an R^2 of 0.44. Through the creation and analysis of multiple feature sets, we identified the most effective feature combinations for improving prediction accuracy, demonstrating the critical role of feature engineering in model optimization.

This study also incorporated detailed extreme case and hour-of-the-day analyses to better understand prediction performance under various conditions. Extreme case analysis specifically evaluated how well the model predicts waiting counts during periods of severe overcrowding, defined as values exceeding the mean by 1, 2, or 3 SDs. The hour-of-the-day analysis further highlighted performance variations throughout the day, providing actionable insights into periods of higher prediction uncertainty and variability. This research paper represents one component of a larger decision support system initiative; in the future, hourly and daily prediction models—alongside additional PFMs such as boarding count and treatment count—will be integrated and operated together as part of a comprehensive, real-world decision-support system for ED management. Such a system can improve resource allocation, optimize staffing, and enhance overall operational efficiency. By leveraging the hourly model's real-time forecasts and the daily model's planning insights, ED administrators can make data-driven decisions to better handle patient flow, reduce overcrowding, and ensure timely care delivery.

Data Availability

The data used in this study were obtained through a formal collaboration with our partner hospital and are subject to strict confidentiality agreements, institutional review board regulations, and institutional data protection policies. Access is limited to authorized personnel for research purposes under the approved ethical framework. As such, we are unable to share the dataset outside the terms of this agreement to ensure compliance with privacy and institutional standards. However, deidentified data may be shared under a data-use agreement upon reasonable request and institutional approval. The source code and model implementation are available in our GitHub repository [71].

Abstract

Background: Data scarcity and dispersion pose significant obstacles in biomedical research, particularly when addressing rare diseases. In such scenarios, synthetic data generation (SDG) has emerged as a promising path to mitigate the first issue. Concurrently, federated learning is a machine learning paradigm where multiple nodes collaborate to create a centralized model with knowledge that is distilled from the data in different nodes, but without the need for sharing it. This research explores the combination of SDG and federated learning technologies in the context of acute myeloid leukemia, a rare hematological disorder, evaluating their combined impact and the quality of the generated artificial datasets.

Objective: This study aims to evaluate the privacy- and fidelity-related impact of horizontally federating SDG models in different data distribution scenarios and with different numbers of nodes, comparing them with centralized baseline SDG models.

Methods: Two state-of-the-art generative models, conditional tabular generative adversarial network and FedTabDiff, were trained considering four different scenarios: (1) a nonfederated baseline with all the data available, (2) a federated scenario where the data were evenly distributed among different nodes, (3) a federated scenario where the data were unevenly and randomly distributed (imbalanced data), and (4) a federated scenario with nonindependent and identically distributed data distributions. For each of the federated scenarios, a fixed set of node quantities (3, 5, 7, 10) was considered to assess its impact, and the generated data were evaluated, attending to a fidelity-privacy trade-off.

Results: The computed fidelity metrics exhibited statistically significant deteriorations (P<.001) up to 21% in the conditional tabular generative adversarial network and up to 62% in the FedTabDiff model due to the federation process. When comparing federated experiments trained with diverse numbers of nodes, no strong tendencies were observed, even if specific comparisons resulted in significative differences. Privacy metrics were mainly maintained while obtaining maximum improvements of 55% and maximum deteriorations of 26% between both models, although they were not statistically significant.

Conclusions: Within the scope of the use case scenario in this paper, the act of horizontally federating SDG algorithms results in a loss of data fidelity compared to the nonfederated baseline while maintaining privacy levels. However, this deterioration does not significantly increase as the number of nodes used to train the models grows, even though significative differences were found in specific comparisons. The different data partition distribution configurations had no significant effect on the metrics, as similar tendencies were found for all scenarios.

Introduction

Overview

Acute myeloid leukemia (AML) is a group of bone marrow stem cell cancers that causes an extreme proliferation of clonal hematopoietic cells. This abnormal growth is caused by multiple cytogenetic and genetic malformations, resulting in a poorly differentiated myeloid cell accumulation in the bone marrow and the consequent spread to the blood [1].

Despite the latest scientific advances and at least 10 recently approved therapies, it is still causing 250,000 deaths yearly worldwide [2]. Moreover, even if AML accounts for about 80% of all diagnosed leukemias in adults, there are just 4.2 new cases per 100,000 people in the United States yearly, which makes it classifiable as a rare hematological disease [3]. On top of that, the proportion of AML cases among all the diagnosed leukemias worldwide increased from 18% in 1990 to 23.1% in 2017, augmenting their incidence and suggesting a potential upcoming major global public health concern [4].

According to the World Health Organization (WHO), AML can be classified into several categories: those that are derived from (1) genetic abnormalities, (2) myelodysplasia-related changes, those that are related to (3) previous chemotherapy or radiation therapies, (4) myeloid sarcomas, (5) myeloid proliferations related to Down syndrome, (6) undifferentiated and biphenotypic leukemias, and those that (7) are not otherwise specified [5,6]. In them, symptoms include bleeding, bruising, infections, fatigue, and bone pain.

The rarity of AML as a prevalent form of leukemia brings with it inherent limitations with regard to the data exploitation and consequent improvement in terms of artificial intelligence (AI) models and their application in real-world environments. First, the necessity of data is leading to the emergence of various repositories that encompass information of the disease [7], but it is important to highlight that these are often limited in size [8,9], revealing an underlying problem of data scarcity. Besides, the data protection legislation, such as the General Data Protection Regulation in Europe or the Health Insurance Portability and Accountability Act in the United States, adds a layer of complexity to the process of data sharing due to the sensitive nature of health data, as it typically consists of electronic health records (EHRs) that may contain extensive clinical or even genomic data. As a consequence, even if AML data records exist, they are unevenly distributed across different institutions, hindering any intention to make use of large amounts of data. This uneven distribution not only refers to the amount of data points available in each data silo but also to biases in them, such as racial and ethnic disparities in AML prevalence statistics [10], especially in pediatric patients [11]. This makes it even more difficult to access quality data that can be used to infer knowledge using AI.

Synthetic data (SD) is defined as artificial information that is generated from original data and a model that is trained to reproduce its characteristics and structure [12]. Thus, SD generation (SDG) is a widely used tool for creating data that mimics real-world datasets, which has been found to be helpful for augmentation tasks, as a class balancing tool, and as a privacy-enhancing technology [13]. Therefore, SD is often evaluated in terms of its fidelity with respect to the real data, its utility for downstream applications, and the privacy that it offers, the last one being one of the main topics of research in literature. In light of the current situation regarding the AML use case, SD can be considered a suitable approach for improving the current paradigm by increasing the quantity of data institution-wise. However, while SD aims to replicate real-world distributions by capturing the same range and structure as the input data, its primary focus is on addressing data scarcity rather than mitigating the problem of scattering. In this regard, SDG would be able to learn based on the local distributions and attending to the data variability found within an institution, possibly limiting the learning process and not being able to sufficiently represent a global population [14].

To mitigate the challenges related to data fragmentation and governance in distributed environments, federated learning (FL) offers a decentralized machine learning (ML) framework that enables collaborative model training across multiple institutions, ensuring that raw patient data remains local and is never transferred or shared externally. [15]. In a canonical FL environment, a model is trained in a central server using the weights each client shares after training local models on local real data [16]. Even if that local real data does not leave the node, the learned information is shared, and a global model is created, covering all the local distributions among the federated nodes and better adapting to a theoretical global distribution. That said, the type of data distributions found within a federated network directly impacts models' behaviors, affecting communication efficiency, model convergence, and FL accuracy. Nonindependent and identically distributed (non-IID) data are currently being widely explored, as they may pose performance and privacy-related difficulties in FL contexts [17,18]. When data are distributed such that clients share the same feature space but contain distinct sets of records, the FL setting is referred to as horizontal federated learning (HFL). Conversely, when clients hold different feature subsets corresponding to the same set of records, the setting is known as vertical FL. The results presented in this work belong to HFL and may not generalize to other FL settings, like vertical FL. Hereafter, the term FL will be used analogously to HFL for the sake of clarity.

However, the adoption of technologies that combine both elements and the posterior validation of those should go hand in hand with thorough prior analyses. To do that, the contributions of this paper are:

- An evaluation of the impact of federating SDG algorithms with respect to having a model trained on all data available on the same site (centralized).

XSL•FO
RenderX

- An evaluation of the impact of the number of federated nodes on the performance of SDG models.
- An evaluation of the impact of having a randomly sampled imbalanced quantity of data in each federated node.
- An evaluation of the impact of having an imbalanced quantity of data that constitutes non-IID distributions in each federated node.

The remainder of this paper is organized as follows: the Methods section provides information about the materials used and the methodology, describing the dataset that was used, the generative model, the evaluation metrics that were implemented, and the FL setup. The next section presents the Results, while the Discussion section shows the principal results, the limitations of this work, a comparison with prior existing work, and final conclusions.

Background

Over the last few years, the use of SD has gained momentum in several contexts. In health care, simulations and prediction research, educational and training content creation, and investigation, including the release of data, have benefited from SD use [19]. In this sense, SDG must be understood as a spectrum of possibilities regarding model selection, parameter tuning, and use case-specific contextualization. However, generating data inevitably involves sophisticated techniques, which may include generative adversarial networks (GANs), variational autoencoders (VAEs), or diffusion models, among other AI approaches.

One of the most promising uses of SD, as was mentioned previously, is the generation of artificial information that does not compromise patient privacy while maintaining its fidelity to the original counterpart. Therefore, the assessment and analyses of SD are expanding to such an extent that the expectations are surpassing those of traditional anonymization techniques, which are algorithms that typically reduce the quality of the data in terms of fidelity and utility, even attempting to combine them. In this sense, it is important to mention differential privacy (DP), which is a technique that ensures the privacy of individuals by adding random noise to the data, making it nearly impossible to determine whether any individual's data is included in a dataset or not. DP is the most widely used privacy-enhancing technology that is being implemented in generative models to enhance data privacy, and its implementation in them depends on the intended use for the resulting SD [20-22], aligning it with the fidelity of the data. Privacy preservation of real data trades directly off with the fidelity and the utility of the generated SD, which must be maintained to ensure its suitability for downstream applications.

Regarding AI models, a GAN is composed of two networks, a generator and a discriminator, working in an adversarial manner. While the former one is supposed to minimize the loss function by generating samples that are as similar as possible to the training set, the latter is tasked with differentiating original samples from synthetic ones, trying to maximize the loss. GANs were first presented by Goodfellow et al [23] in 2014, and since then, several modifications have been proposed in order to cover a wide range of use cases. The work developed by Zhao et al [24], for example, represents the latest generation of GAN architectures, named CTAB-GAN+, which includes state-of-the-art features such as conditional generation of samples, improved loss functions, the possibility to handle both categorical and continuous data simultaneously, and DP. Narrowing down to tabular data generation for health care–related use cases, GANs were identified to be the most widely used architectures [25]. Additionally, several recent publications have addressed various unresolved questions within the field. For instance, Ramachandranpillai et al [26] introduced the bias-transforming GAN, which addresses the challenge of biased data generation in the health care domain by incorporating several information constraints inside the generation process. Moreover, various GANs are currently being experimentally tested for several use cases, as demonstrated by Akiya et al [27] in oncological clinical trials, Khan et al [28] in cardiovascular disease mortality predictions, or Dhawan and Nijhawan [29] in brain magnetic resonance imaging and chest x-ray data.

As for VAEs in the context of SDG, they are also composed of two fundamental components: the encoder and the decoder. In this context, the encoder is responsible for mapping the input training data into a latent space with a lower dimensionality, while the decoder samples new values from this latent space to reconstruct data that imitates the original inputs. Starting from the original architecture, VAEs have also undergone several modifications that help cover diverse use cases [30]. As for the latest research, Biswas and Talukdar [31] researched the enhancement of clinical documentation using both GAN and VAE-generated SD with the aim of improving patient care. Li et al [32] implemented the causal recurrent VAE, aiming to generate medical time series data. Other applications that are being investigated and include VAEs are drug dosing determinants, such as in Titar and Ramanathan [33].

Finally, diffusion models create SD by gradually transforming simple, noise-like data into complex data structures that were used during the training process. Even if this type of generative model has mostly been focused on image generation, currently, they are able to support different data types, too [34,35]. For example, Naseer et al [36] presented ScoEHR, a continuous-time diffusion model able to generate artificial EHRs. Digital pathology data was also generated with diffusion models by Pozzi et al [37].

As for generative modeling applied to rare hematological diseases, recently, D'Amico et al [38] trained a conditional tabular generative adversarial network (CTGAN) with the aim of generating myelodysplastic syndromes and AML data. Additionally, Eckardt et al [39] made their synthetic AML dataset publicly available after having considered both utility and privacy thresholds. The published synthetic dataset comprises 1606 patients generated using a CTAB-GAN+ [24]. Licandro et al [40] used a Wasserstein GAN for two distinct scenarios where differently sized datasets were used. In their research, the primary objective was to discern the embeddings of the data, enabling subsequent differentiation between blast and nonblast cells. The results show that using the generator model to learn embeddings outperforms the results obtained with baseline models, improving the area under the curve (AUC) for both dataset sizes. The study carried out by Rupapara et al

XSL•FO
RenderX

[41] made use of the ADASYN [42] SD generator to balance the dataset and enhance prediction outcomes. The dataset encompassed data from various blood-related cancers, including AML. By using the ADASYN resampler, the classification models demonstrated improved accuracy.

Regarding FL-related studies, several experiments have been conducted to overcome the data scattering issue. For example, the study carried out by Linardos et al [43] simulates a federated environment consisting of four nodes. The study aimed to help diagnose hypertrophic cardiomyopathy diseases, the results supporting the effectiveness of FL by achieving better AUC results than with a collaborative data-sharing framework. The work presented by Liu et al [44] focused on using FL to achieve a deep learning model that makes use of EHRs to predict patient mortality, which they called FADL. The work presented by Azizi et al [45] also used EHR information scattered among 50 nodes, each of which contained 560 patients, to predict mortality. However, in this case, they used a clustering method and used community-based FL, surpassing the performance of the canonical FL environment across various scenarios.

Both techniques, SDG and FL, have demonstrated their effectiveness in various sectors and use cases. The combination of both is being investigated to such an extent that inherently federated generative models are being published in the literature, such as the private FL-GAN model [46]. Focusing on health care–related topics, in Azizi et al [45], a framework for cardiovascular data based on an FL architecture of two nodes and a generative model using sequential trees is shown. The study presented by Behera et al [47] demonstrates the implementation of a GAN within a federated environment, called FedSyn. In addition to applying DP, thereby enhancing data protection, the researchers used the CIFAR10 and Modified National Institute of Standards and Technology datasets for their analyses. The research outlined by Xin et al [48] uses a federated GAN augmented with DP, trained on both Modified National Institute of Standards and Technology and CelebA datasets. The authors analyzed the privacy of the generated data offered against the original one, concluding an improved privacy against membership inference attacks (MIA). However, despite the combination of both SDG and FL explored in different studies, many aspects of this mixture still require evaluation.

Methods

AML Dataset

The AML dataset used to perform the research of this paper was accessed from the work developed by Tazi et al [49] and its associated GitHub repository [50].

Among the available datasets in the repository, the paper_full_data_validation dataset was chosen for this research. All the genetic mutation-related variables were discarded, preserving clinical, demographic, and disease-related information. Multimedia Appendix 1 includes a description of the variables used in the experiments. The variable selection was carried out to maintain acceptable sample-to-feature ratios across various federated configurations regarding node quantities, as the original dataset comprised 130 features. Having a low number of samples and too many variables would have limited the experiments in this regard, as highly overfitted models would appear. The resulting dataset consisted of 1540 samples and 12 features, from which the categorical ones were label encoded in the preprocessing stage. All these preprocessing steps were applied before the data were split into different client nodes for the sake of simplicity. Applying these specific preprocessing steps to our federated experiments would entail just an additional preliminary step in the training process, which was omitted by manually preprocessing the data.

Ethical Considerations

That study was conducted following the completion of informed consent forms by all the included participants. In addition, all the relevant ethical guidelines were followed, and necessary Institutional Review Board and ethics committee approvals were obtained. The trial was conducted in accordance with the tenets of the Helsinki Declaration, and it was sponsored by Cardiff University and approved by the Wales research ethics committee (protocol 08/MRE09/29). The analysis of the data in the original study was approved by the Memorial Sloan Kettering Cancer Center Institutional Review Board (protocol x20-064). All the raw data were deposited in the European Genome Phenome Archive (reference EGAS00001000570). In this paper, all the information that allows the identification of any of the participants was omitted in accordance with privacy and confidentiality standards. The authors in Tazi et al [49] and Tazi [50], who performed the original analysis on the data, do not bear any responsibility for the further research reported in this work.

Generative Models

The first generative model that was selected for this experiment is the CTGAN [51], as it was recently reported to have one of the most appropriate generators among different GAN and VAE architectures [52]. Additionally, it is implemented in a way that models the relationships between imbalanced variable distributions [53]. The Synthetic Data Vault [54] CTGAN implementation was used in this work, even if some modifications had to be implemented for the correct use of the model in a federated environment.

Regarding the model parameters used on the CTGAN, the default parameters presented in the Synthetic Data Vault (v0.18.0) implementation were used. The same architecture was set for both the discriminator and the generator with a two-layer hidden structure, both containing 256 units each. The learning rates of both objects were set to 2×10^{-4}, with the decay fixed to 1×10^{-6}. A batch size of 500 samples was defined along with an embedding dimension of 128 samples. The discriminator was updated along with the generator at every training step, and a 10-sample group (pac parameter) was introduced into the discriminator each time it was applied.

On the other hand, a diffusion model was also included. Diffusion models [55] are a newer class of generative models that have demonstrated superior performance compared to other tabular generative models [56,57]. The implementation used in this work is the one presented by Sattarov et al [58], where the

XSL•FO
RenderX

authors claim high fidelity and privacy metrics were obtained in their experiments.

As for the FedTabDiff model parameters, default values were also chosen. Specifically, the number of diffusion steps was set to 500, and the multilayer perceptron layers were configured as {512,512}. To ensure comparability across models, a consistent batch size of 500 was used, and the learning rate for the deep learning models was fixed to 1×10^{-4}, with a linear scheduler. Additionally, the diffusion beta start was set to 1×10^{-4}, and the beta end was set to 0.02. It is worth mentioning that the model was slightly modified in order for it to interact multiple times with similar data, with the idea of the results being comparable among experiments.

As mentioned previously, in order for each participant node to transform the data in the same manner and to avoid averaging mismatches, one-hot encoding for discrete columns and Gaussian mixture transformations for continuous variables were fit using the whole dataset, also being able to avoid unseen classes in federated nodes. The objects were then included in each client with the aim of transforming each data partition in situ and using the same mapping.

Regarding the number of epochs to be performed during the training process of the models, different experiments were empirically conducted on the baseline model with 500, 1000, 1500, 2000, and 3000 epochs. The optimal configuration was proven to be 500 epochs, as increasing the iterations did not show any significant improvement in the generated synthetic sample quality. All the federated models were trained for 500 epochs for the experiments to be comparable. In addition, the number of federation rounds was set to 500.

Evaluation Metrics

The generated SD was analyzed to gauge its fidelity and privacy with respect to the real data. In the scope of this work, fidelity is defined as the degree to which the generated SD replicates the characteristics, patterns, correlations, and distributions of the real data. While a high fidelity means the SD resembles the real data well, a low fidelity would indicate poor learning by the model generators. On the other hand, privacy is defined as the extent to which the generated data protects sensitive information from being disclosed in the original dataset. In this section, the methods and metrics to evaluate the SD are described.

Considering a simulated FL scenario, the comparison was performed against the whole real data, thus being able to compare the performance of each setup against the nonfederated scenario as a baseline. Inspired by usual ML cross-validation, 10 different synthetic datasets were generated with each model, allowing a separate evaluation for each of them. The results were then averaged to provide a more robust perspective on their generalizability. The set of metrics calculated in each fold also enabled the execution of statistical tests for significance.

In order to assess intervariable correlations, the φ_k coefficient [59] and the Vendi Score (VS) [60] metrics were implemented. On the one hand, the φ_k coefficient is based on the refinement of Pearson hypothesis tests. However, unlike Pearson hypothesis, φ_k can calculate correlations with both numerical and categorical variables, the higher the values, suggesting better intervariable relations. Moreover, φ_k can capture nonlinear relationships. Correlation matrices were generated for both real and synthetic versions of the datasets using the φ_k coefficient, and the cosine similarity (CS) metric was used to obtain a quantitative measure that compares them, which is defined as $1-d_{cos}$:

Where x_i is a real sample and x_i' is a synthetic counterpart. A low CS metric suggests the two matrices do not look alike, while higher values imply higher similarities between them.

On the other hand, the VS is a novel metric that computes the diversity of a given dataset without the need to compare it against another set of data. This score requires defining a positive semidefinite similarity function, which was set to be the CS in this case [61]. Accordingly, the VS of just the numerical attributes was computed due to the CS only being applicable to numerical features. In the following equation, the mathematical expression for the VS can be observed.

Where k is a given similarity function and λ_n are the eigenvalues of K/n, and K is the kernel matrix.

Furthermore, a data labeling analysis (DLA) was performed. In this procedure, an ML classifier is trained to ascertain its ability to differentiate between synthetic and real samples, mimicking the functionality of a GAN discriminator. Due to the characteristics of the analysis, the classification process was evaluated using the F_1-score metric since it is sensitive to the class distributions, making it a reliable metric when labels are imbalanced, and the recall score, as it returns the number of correctly identified synthetic samples. On top of that, the AUC curve was calculated. Regarding the trained ML models for the DLA, the LazyPredict classifier [62] object was used to train various models per iteration. The best classifier was chosen for each fold to account for the most restrictive case, while the mean and standard deviation were calculated in the process.

On top of those, the Hellinger distance was chosen to quantify the similarity between two probability distributions, offering a bounded metric that is interpretable and less sensitive to outliers than other distance calculations, such as the Wasserstein one [63]. Finally, the depth versus depth plot (DD-plot) was used, which is a nonparametric method that can evaluate the multivariate distributional similarity between two distributions (real and synthetic, in this case). While the DD-plot aims to represent the depth of a real distribution with respect to the associated synthetic depth in a graphical way, the coefficient of determination (R^2) is proposed in the literature to obtain an analytical value from it. Both the real and SD depths are more similar when R^2 is higher, meaning that the DD-plot better fits a theoretical optimal function $x=y$.

XSL•FO
RenderX

With respect to privacy metrics, four types of attacks were conducted: MIAs, attribute inference attacks (AIAs), linkability attacks, and singling out attacks. MIA and AIA assessments were conducted using the Anonymeter tool [64]. In MIAs, an adversary is simulated to assess whether a specific data point was part of the training dataset used to train a generative model, thereby posing potential privacy risks. The attack methodology involves computing distance measures between pairs of records and applying a threshold to distinguish between high-risk matches and those considered safe. In the context of this experiment and following the work of Hernandez et al [63], a Gower distance of 0.05 was defined, which is a similarity measure that may be used to handle multitype data within the same dataset.

In contrast, AIAs occur when an adversary attempts to infer sensitive information that was not originally disclosed with the dataset. AIAs seek to extract additional private information about individuals, even if their membership is already known or assumed. In this case, risks are calculated variable-wise as each one may pose differently ranked sensitivities. For numerical variables, an AIA is considered successful if the predicted value falls within a predefined confidence interval of the true value, which is defined to 0.05 in the scope of this work. For categorical variables, a correct prediction requires an exact match. This evaluation is conducted across all variables individually, and the average success rate is used to compute the overall attribute inference risk.

Regarding linkability attacks, their goal is to associate attributes from two or more records with the same individual or group, either using a single dataset or multiple ones. If the known attributes and a synthetic dataset allow the linkage to the real dataset, revealing sensitive information, the attack is considered successful. Singling out attacks, on the other hand, occurs when unique data records can be identified based on a distinct combination of attributes within the real data. In the scope of this work, the most stringent approach was adopted, using the conjunction of all attributes to perform the attacks (multivariate singling out).

Experimental Setup

In this experiment, a comparison between nonfederated and federated generative models was performed for three different federated scenarios. In the first one, the data quantity was assumed to be evenly distributed across the participant nodes (from now on, B scenario, for balanced), while for the second, the data points were randomly split, creating partitions with uneven sample quantities (from now on, IB scenario). In the third federated scenario, non-IID distributions (Figure 1) were built depending on the age variable (from now on, $IB_{non\text{-}iid}$ scenario).

For the three scenarios, the data were partitioned prior to the model training phase, allowing for traceability and higher result reproducibility. The partitions for the B scenario were created by randomly selecting n/N samples for each of the nodes, being the total number of samples in the original dataset and being the number of nodes that participate in a specific federated experiment. On the other hand, the IB scenario partitions were created so that for a specific N, N–1 nodes were trained on 5% of the data that was chosen randomly, and the th node was trained on the remaining samples. The $IB_{non\text{-}iid}$ scenario was created by sampling age-dependent data points from Dirichlet (α=10) distributions [65]. The distribution of categorical variable labels across the partitions, as well as the exact number of samples per scenario, can be consulted in Multimedia Appendix 2, showing bias among scenarios. In this analysis, the federation was evaluated for a set of $N \in \{3,5,7,10\}$.

Regarding the aggregation method selection, a preliminary study was performed using the federated average (FedAvg), the adaptive federation optimization (FedOpt), and the federated optimization for heterogeneous networks (FedProx) algorithms. The most challenging experiment scenarios (10 nodes and non-IID scenarios) were tested with the three algorithms, evaluating the models using the metrics that were presented in the previous section. The results either demonstrated that FedAvg was the best-performing algorithm or showed no statistically significant improvement when comparing to FedOpt or FedProx algorithms. Therefore, the experiments intended to evaluate the contributions defined in the introduction section of this paper were trained by averaging the model weights coming from each node and attending to the number of samples each one contained (FedAvg). The results of the preliminary analysis can be found in Multimedia Appendix 3.

The Flower 1.7.0 Framework [66] was used in order to federate the models using the simulation module. The experiments were performed in a high-performance computing cluster, and they were allocated for 10 central processing unit and 2 graphics processing unit jobs, having initiated a Ray actor cluster prior to executing federation rounds. Figure 2 represents the workflow that was carried out during the experiment execution, where data partition, model training, and evaluation phases are shown.

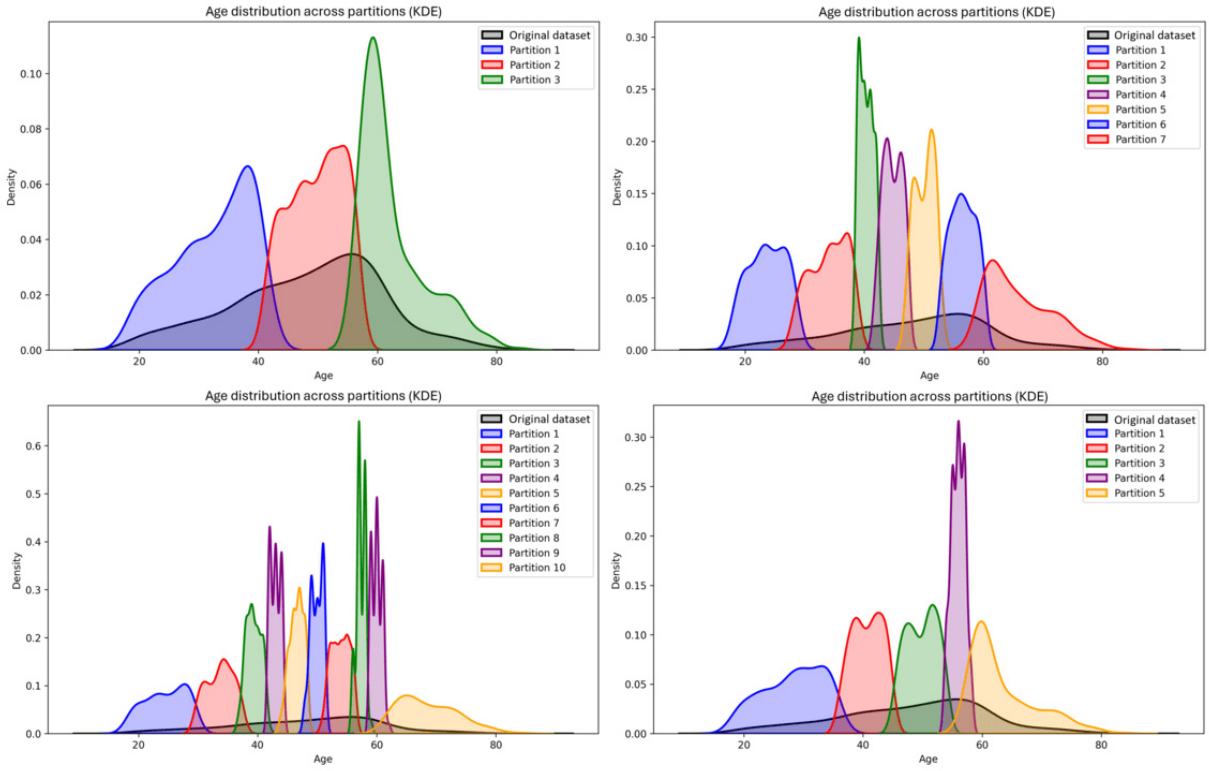
Figure 1. Generated non-IID age-dependent distribution plots. The top left shows the scenario with 3 nodes, the top right shows the 7-node scenario, the bottom left shows the 10-node scenario, and the bottom right shows the 5-node one. KDE: kernel density estimate; non-IID: nonindependent and identically distributed.



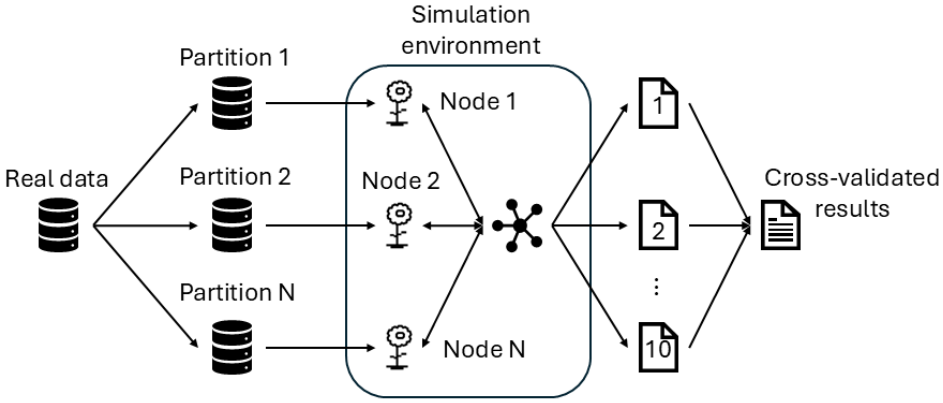


Figure 2. Experiment execution framework, including data partitioning, model training, and synthetic data evaluation processes.

Results

Overview

The results of the study are presented in this section, comparing the three presented federated scenarios with the baseline model, both for the CTGAN and the FedTabDiff. All statistical tests were performed for a significance level of .05 using the averaged results, while some variable-specific metrics can be checked in Multimedia Appendices 4 and 5.

CTGAN

Starting with the baseline nonfederated CTGAN model fidelity evaluation, the coefficient results showed a mean CS of 0.930 (standard deviation 0.002). Regarding the DLA execution, the obtained AUC was 0.796 (standard deviation 0.026), the F_1-score was 0.872 (standard deviation 0.015), and the recall metric was 0.958 (standard deviation 0.009). The VS resulted in a mean value of 1.405 (standard deviation 0.004) in the SD, compared to the VS obtained in the real dataset of 1.406. To finish, the average Hellinger distance was 0.223 (standard deviation 0.002). Regarding the privacy evaluation, the MIA demonstrated no significant membership inference risk, while the averaged AIA resulted in a 5% risk for attribute information to be inferred.

Regarding the federated models that were trained with balanced datasets (the B scenario), most of the performed experiments showed statistically significant differences in fidelity metrics with respect to the baseline scenario (P<.001), even with variations in the number of nodes (Table 1). Statistical significance was found in singling out attack metrics, while the rest of the privacy measures did not significantly vary from the baseline.

[a]CTGAN: conditional tabular generative adversarial network.

[b]*t* tests were performed between the baseline and each federated experiment. Significance level is .05 for all statistical tests.

[c]CS: cosine similarity.

[d]Not applicable.

[e]DLA: data labeling analysis.

[f]AUC: area under the curve.

[g]VS: Vendi Score.

[h]MIA: membership inference attack.

[i]*t* tests were not performed for these due to the standard deviation being zero.

[j]AIA: attribute inference attack.

[k]*t* tests were not performed for these due to the results being the same as the ones found in the baseline metrics.

Specifically, intervariable correlations were shown to be more distorted than the ones presented by the baseline model, and the DLA suggested that the synthetic samples that were generated by federated models are prone to being detected more easily than the ones generated by the baseline model, although variable-wise metrics such as the Hellinger distance did not demonstrate too different results.

In the IB scenario, most of the performed experiments showed high statistical significances ($P<.001$) with respect to the baseline, too (Table 2). Intervariable correlations, DLA metrics, and VS values were shown to be quite different from the baseline model, attending the statistical tests, while the Hellinger distances did not show too big a difference. In this case, the 10N experiment showed statistically significant differences with the AIA metric obtained in the baseline, suggesting an improvement in privacy while deteriorating the fidelity values. All the experiments in this scenario supported the privacy improvement suggestion, as all the multivariate singling out attacks proved to perform better in federated setups. However, no specific tendency can be observed while increasing the number of nodes in this sense.

The $IB_{non\text{-}iid}$ scenario followed the same overall patterns found in the previous two scenarios, showing statistically significant differences in fidelity metrics but with no difference in the performed privacy metrics other than those found for multivariate singling out attacks (Table 3).

Gathering all the results in a single figure, similar tendencies can be observed in the three scenarios, where lower correlation values and higher DLA-related metrics can be found among the federated models with respect to the baseline model. The VS metric fluctuated most among the scenarios along with the DD-plot R^2, offering insight regarding the variability of each generated SD. Hellinger distances were found not to fluctuate even when comparing centralized and federated models, while a difference in privacy protection measures is observable in singling out attacks (Figure 3).

Now, considering federated experiment pairs (ie, comparing 3N experiments with 5N, 5N with 7N, and 7N with 10N) to evaluate if additional federated nodes impact the SD quality in terms of fidelity and privacy, no clear tendencies can be observed in either scenario (Table 4). Privacy metrics did not show statistical significance; therefore, assuming no improvement was achieved in terms of privacy, even though the baseline centralized model offered good results already. Among the fidelity metrics, the CS of the was found to differ between pairs of experiments in some cases, but no specific trend was detected. The same occurred for the DLA-related metrics, where some pairs pointed out significant differences. All the VS metrics were found to be different, even if no improvement or deterioration trend was found, and the Hellinger distance metric varied depending on the scenario, just as the DD-plot R^2.

[a]CTGAN: conditional tabular generative adversarial network.

[b]Significance level is .05 for all statistical tests.

[c]CS: cosine similarity.

[d]DLA: data labeling analysis.

[e]AUC: area under the curve.

[f]VS: Vendi Score.

[g]DD-plot: depth versus depth plot.

[h]MIA: membership inference attack.

[i]*t* tests were not performed for these due to the standard deviation being zero.

[j]Not applicable.

[k]AIA: attribute inference attack.

[l]*t* tests were not performed for these due to the results being the same as the ones found in the baseline metrics.

FedTabDiff

Regarding the baseline FedTabDiff model, a CS φ_k value of 0.866 was obtained, while results above 0.990 were obtained for all DLA-related metrics. The VS was 1.417, while the Hellinger distance was 0.339, and the DD-plot R^2 was 0.971. The privacy analyses demonstrated there was no membership inference risk, while the linkability risk was minimal. Values of 0.031 for the AIA and 0.156 for the singling out were obtained.

The FedTabDiff models that were trained with balanced datasets (the B scenario) showed statistical significance in most of the fidelity metrics when compared to the baseline scenario ($P<.001$), while the tests carried out with the privacy metrics were found to be nonsignificant. Therefore, fidelity metrics worsened while the number of nodes augmented, but privacy seemed not to be affected (Table 5).

[j]AIA: attribute inference attack.

[k]*t* tests were not performed for these due to the results being the same as the ones found in the baseline metrics.

In this scenario, the intervariable correlation metric, φ_k, was the measure that most varied among the fidelity metrics, while the DLA metrics showed a similar tendency to the one found within the CTGAN results. The DD-plot R^2 value, the VS, and the Hellinger distance, although statistically significant, did not show any relevant tendency linked to the number of nodes.

Regarding privacy measures, no membership inference risk was found among the generated SD in scenario B, while calculated linkability risks were minimal. Privacy risks did not significantly vary linked to the number of nodes.

In the IB scenario, the results were found to be similar to the ones found in scenario B, most of the fidelity metrics showing statistically significant differences between experiments with different numbers of nodes (P<.001), and no significance in privacy-related metrics (Table 6). In this scenario, the DLA metrics varied slightly more, even if no clear tendency is observable. In addition, the intervariable correlations seemed to be better maintained within this experiment, even if no tendency was found either.

[j]AIA: attribute inference attack.

Regarding the privacy metrics, no statistical significance was detected among the results. No membership inference risk was found in any of the experiments, while the linkability risk was minimal, as it was in scenario B.

The $IB_{non\text{-}iid}$ scenario followed the same pattern as those of the B and IB scenarios, with the difference of some singling out risk differences were statistically significant in this case. No membership inference risk was found in this scenario, and the linkability risks were also found to be minimal (Table 7).

[a]*t* tests were performed between the baseline and each federated experiment. Significance level is .05 for all statistical tests.

[b]CS: cosine similarity.

[c]Not applicable.

[d]DLA: data labeling analysis.

[e]AUC: area under the curve.

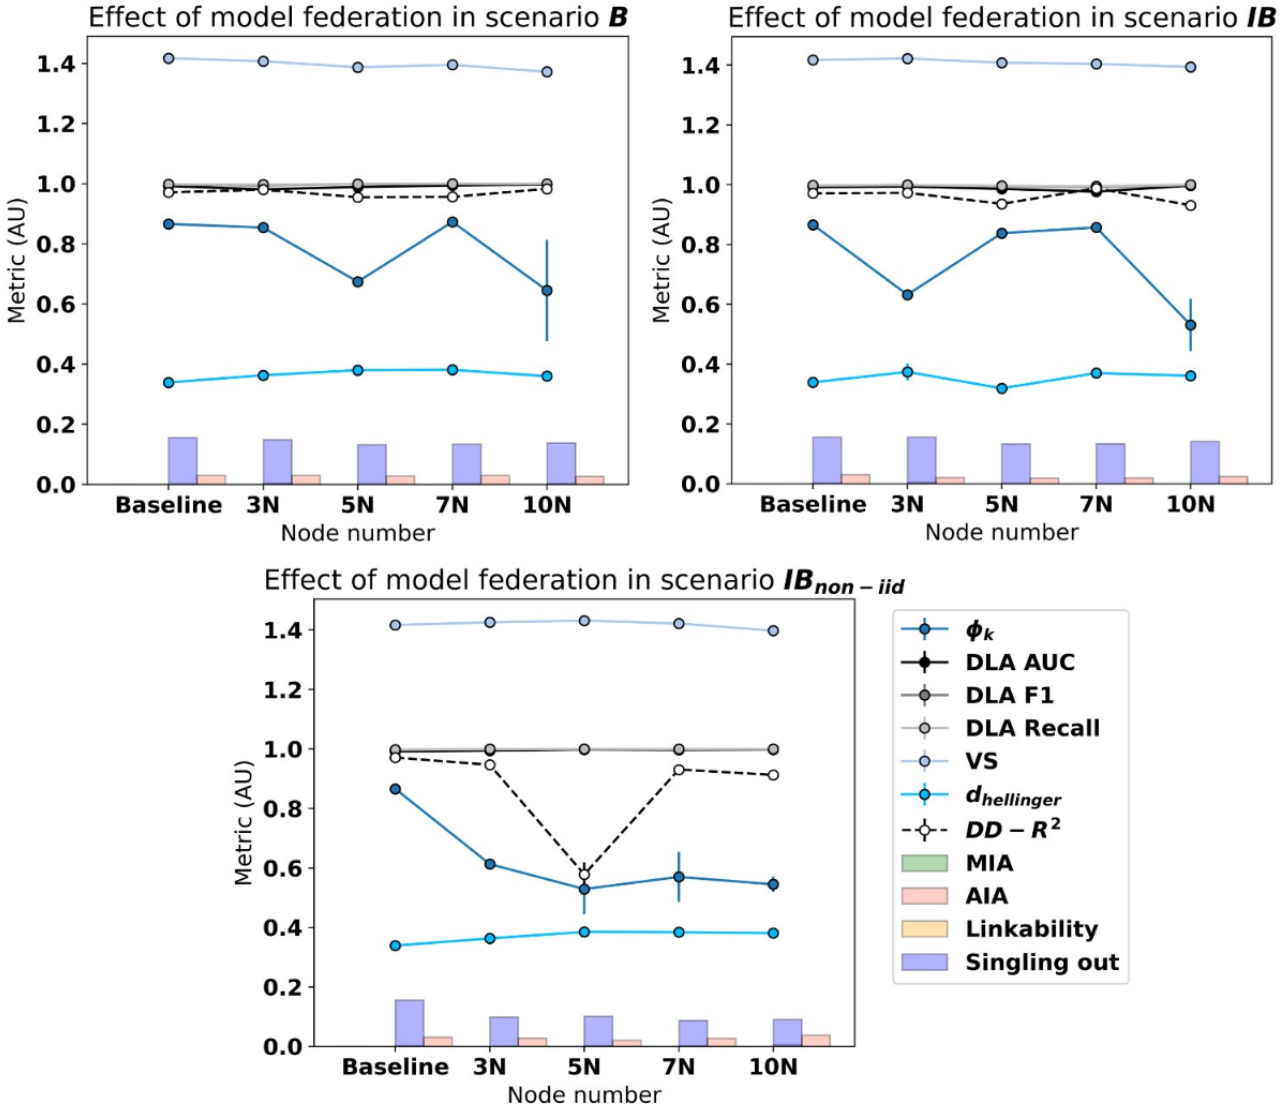
[f]*t* tests were not performed for these due to the standard deviation being zero.

[g]VS: Vendi Score.

[h]DD-plot: depth versus depth plot.

[i]MIA: membership inference attack.

[j]AIA: attribute inference attack.



[k]*t* tests were not performed for these due to the results being the same as the ones found in the baseline metrics.

Fidelity metrics specifically showed a kind of worsening tendency in terms of the CS φ_k metric along with the increase in the number of nodes. In addition, the Hellinger distance seemed to increase accordingly. The DLA did not show any significant change, nor did the DD-plot R^2.

Now, gathering all the results in a single figure (Figure 4) to find all the information in a graphical manner, it can be observed that the singling out and attribute inference risks prevail over the membership and the linkability ones. Saying that, either a neutral tendency to maintain the privacy levels on the federated experiments, or an improvement of it (mostly in scenario $IB_{non\text{-}iid}$), is observable with respect to the centralized baseline metrics.

XSL•FO
RenderX

Figure 4. Graphical comparison of federated scenarios regarding fidelity and privacy metrics using the FedTabDiff model. AIA: attribute inference attack; AUC: area under the curve; DD: depth versus depth; DLA: data labeling analysis; MIA: membership inference attack; non-IID: nonindependent and identically distributed; VS: Vendi Score.

As it was pointed out in the CTGAN results, the fidelity metric tendency can be found to kind of worsen once the FedTabDiff model is federated, but the effect seems to be mostly maintained across experimentation with different numbers of nodes.

Now, to finish with the result explanation and considering federated experiment pairs as previously (ie, comparing 3N experiments with 5N, 5N with 7N, and 7N with 10N), no statistically significant differences were observed in terms of the privacy metrics in any of the scenarios. Statistical significance was found in some of the comparisons across fidelity metrics and different scenarios (Table 8).

[a]Significance level is .05 for all statistical tests.

[b]CS: cosine similarity.

[c]DLA: data labeling analysis.

[d]AUC: area under the curve.

[e]*t* tests were not performed for these due to the results being the same as the ones found in the baseline metrics.

[f]Not applicable.

[g]*t* tests were not performed for these due to the standard deviation being zero.

[h]VS: Vendi Score.

[i]DD-plot: depth versus depth plot.

[j]MIA: membership inference attack.

[k]AIA: attribute inference attack.

Discussion

Principal Results

In these experiments, a comparison between centralized SDG models and federated implementations of them was performed using AML data with the aim of evaluating the SD fidelity and privacy in each of the scenarios, assessing the SD generation techniques over an FL approach to address the data scattering issue while addressing data scarcity. Three different scenarios were considered for the federated models: the one in which the number of samples in each node was evenly distributed (B), the one where the node-wise data quantity was randomly and unevenly distributed (IB), and the one where non-IID data distributions were created ($IB_{non\text{-}iid}$).

In the case of the CTGAN model, in the B scenario, the φ_k metric deteriorated to a maximum of 9% with respect to the baseline, while the DLA showed an average difference of 17% in the AUC, a difference of 9% for the F_1-score, and a difference of 0.21% for the recall metric. The VS showed a difference between 2% and 12% showing that the diversity of the generated samples varied among experiments. For this scenario, the Hellinger distance varied to a maximum of 3%, and the DD-plot R^2 to a maximum of 35%. The most privacy-preserving experiments in terms of the AIA were 3N and 7N, with a risk reduction of 18% with respect to the baseline, while the worst one (5N) performed 18% below, although not statistically significant. Privacy against singling out attacks improved between 46% and 61%, while no difference was found for MIAs and linkability attacks.

In the IB scenario, the maximum deterioration of the φ_k metric was 11%, and the DLA showed average values of 17% in the case of the AUC, 10% for the F_1-score, and 1% for the recall metric. The VS showed that numerical variables are diversely generated, achieving differences between 1% and 3%, while the Hellinger distances varied to a maximum of 3%. DD-plot R^2 values varied by about 22%. AIA analyses showed a maximum improvement of 55% on data privacy, while the maximum deterioration was 26%, although not statistically significant. Singling out attacks showed differences between 51% and 80%, while the linkability ones varied minimally.

Finally, the $IB_{non\text{-}iid}$ scenario showed a maximum deterioration of 11% in the φ_k metric, while DLA AUC scores showed average differences of 21%, the F_1-score varied 10%, and the recall varied minimally. The VS showed maximum variations of 17%, and the Hellinger distance varied to 5%. Regarding privacy metrics, the AIA showed a maximum improvement of 2% and a maximum deterioration of 21%, although neither was statistically significant in this case either. In this case, singling out attack risk differences varied between 73% and 83% with respect to the baseline, and the linkability measure differences were again minimal.

Now talking about the principal results of the FedTabDiff model in scenario B, the metric varied between 26% and 81%, the VS between 1% and 3%, and the Hellinger distance between 6% and 12%. In the DLA, the AUC value varied to a maximum of 1% while both the recall and the F_1-score matched the baseline results. To finish with the fidelity metrics, the DD-plot R^2 results varied between 1% and 2% with respect to the baseline. In terms of privacy, no membership inference risk was detected, while the linkability risk difference was minimal. The AIA results varied between 10% and 13%, while the singling out ones varied between 4% and 15%.

Talking about scenario IB, the φ_k metric varied between 1% and 27%, and the DLA-related AUC metric varied by 2% at most, matching the baseline results for both the recall and the F_1-score, just as in the B scenario. The VS variation was neither high, reaching 2% differences at most. While the Hellinger

XSL•FO
RenderX

distance oscillated between 6% and 10%, the DD-plot R^2 varied to a maximum of 4%. Regarding the privacy metrics, no membership inference risk was found, and the linkability varied minimally with respect to the baseline results. While the attribute inference risk difference oscillated between 23% and 39%, the singling out risk difference varied to a maximum of 15%.

To finish, the $IB_{non\text{-}iid}$ scenario showed an oscillation between 29% and 39% for the φ_k metric, while all the DLA AUC changes were minimal and the recall- and F_1-score-related results matched those of the baseline. For the VS, the variation reached 22% at maximum, and the Hellinger distance varied between 7% and 62%. The DD-plot R^2 varied between 2% and 40%. To finish, the privacy metrics in this scenario followed the previous tendencies by showing no membership inference risk and minimal linkability risks. Attribute inference risk differences oscillated between 10% and 35%, while the singling out ones varied between 35% and 44%.

Limitations

As it was pointed out in the beginning, this work aims to provide insight into a specific use case of federated SDG for an AML dataset, both with a GAN-type model and a diffusion-type model. However, extending the analysis by using upcoming SDG models and more extensive aggregation functions for the FL framework may result in more generalizable conclusions, which will be prioritized in future work. Linked with that, models incorporating more novel tools like DP and the implementation of advanced FL security frameworks should be covered in future extensions of this research. Parameter tuning for model optimization remains a considerable path for analyzing the combination of both SDG and FL.

Furthermore, the three scenarios resulted in similar overall tendencies for all the calculated metrics and both models, suggesting the scenario proposals in this work may not have that much of an impact on the results. Further research may uncover differences for various data dispersion schemas and non-IID distribution types, which may have a much greater impact on the calculated metrics and the methodology to be followed. In addition, extremely imbalanced approaches may show different tendencies in the analyses.

Finally, the generative aspect of this research should be taken into account for future research, as expanding the calculations to a higher number of datasets may result in more robust and scalable optimizations on federated SDG. Related to the issue, a more extensive set of metrics could also be considered in the future, as literature is rapidly evolving and novel metrics could be introduced in upcoming publications. Our metric selection, however, is intended to be comparable to other state-of-the-art works.

Comparison With Prior Work

While there are a few studies that analyze the combination of both FL and SDG, this is, to the best of the authors' knowledge, the first research work that tries to quantify the impact of generative model federation over fidelity and privacy metrics, using different numbers of nodes, and considering different real-world data distribution scenarios in AML.

Expanding the literature search, incorporating DP to federated SDG models has been widely investigated, as well as successfully integrated into several use cases, improving privacy metrics under those conditions [46-48]. Our research, however, has shown reasonable privacy guarantees both for centralized and federated scopes without the need for using DP, suggesting the incorporation of it may depend on the final use case, as it deteriorates SD fidelity, even though more extensive evaluations should be performed. In addition, the latest research shows DP may not have statistically significant differences in terms of privacy, suggesting that applications with no need to implement it exist [63].

Furthermore, in the scope of FL, previous works on classification and regression models have hardly shown any deterioration due to the federation process with regard to a centralized model [67]. Instead, when SDG models were compared to centralized results in this AML use case, statistically significant differences appeared, suggesting that SDG models may be more sensible to the federation step than usual ML cases, such as classification or regression.

To finish, the data distribution scenarios considered for this research demonstrated robustness against non-IID distributions, which is in line with other experiments performed in the literature [68].

Conclusions

The results for both models and the three scenarios showed considerable data fidelity losses after the model federation process, while no significant deterioration or improvement tendency was found in the respective privacy metrics. The number of federated nodes did not show any significant trend, even though specific comparisons resulted in statistically relevant differences in some cases.

Abstract

Background: Machine learning (ML) has shown great potential in recognizing complex disease patterns and supporting clinical decision-making. Diabetic foot ulcers (DFUs) represent a significant multifactorial medical problem with high incidence and severe outcomes, providing an ideal example for a comprehensive framework that encompasses all essential steps for implementing ML in a clinically relevant fashion.

Objective: This paper aims to provide a framework for the proper use of ML algorithms to predict clinical outcomes of multifactorial diseases and their treatments.

Methods: The comparison of ML models was performed on a DFU dataset. The selection of patient characteristics associated with wound healing was based on outcomes of statistical tests, that is, ANOVA and chi-square test, and validated on expert recommendations. Imputation and balancing of patient records were performed with MIDAS (Multiple Imputation with Denoising Autoencoders) Touch and adaptive synthetic sampling, respectively. Logistic regression, support vector machine (SVM), k-nearest neighbors, random forest (RF), extreme gradient boosting (XGBoost), Bayesian additive regression trees, and artificial neural network were trained, cross-validated, and optimized using random sampling on the patient dataset. To evaluate model calibration and clinical utility, calibration curves, Brier scores, and decision curve analysis (DCA) were performed.

Results: The exploratory dataset consisted of 700 patient records with 199 variables. After dataset cleaning, the variables used for model training included age, smoking status, toe systolic pressure, blood pressure, oxygen saturation, hemoglobin, hemoglobin A_{1c}, estimated glomerular filtration rate, wound location, diabetes type, Texas wound classification, neuropathy, and wound area measurement. The SVM obtained a stable accuracy of 0.853 (95% CI 0.810-0.896) with an area under the receiver operating characteristic curve of 0.922 (95% CI 0.889-0.955). The RF and XGBoost acquired an accuracy of 0.838 (95% CI 0.793-0.883) and 0.815 (95% CI 0.768-0.862), respectively, with areas under the receiver operating characteristic curve of 0.917 (95% CI 0.883-0.951) for RF and 0.889 (95% CI 0.849-0.929) for XGBoost. SVM, RF, and XGBoost were well-calibrated, with average

XSL•FO
RenderX

Brier scores around 0.127 (SD 0.013). DCA showed that the SVM provided the highest net clinical benefit across relevant risk thresholds.

Conclusions: Handling missing values, feature selection, and addressing class imbalance are critical components of the key steps in developing ML applications for clinical research. Seven models were selected for comparing their predictive power regarding complete wound healing, and each model representing a different branch in ML. In this initial DFU dataset used as an example, the SVM achieved the best performance in predicting clinical outcomes, followed by RF and XGBoost. The model's calibration and clinical utility were determined through calibration curves, Brier scores, and DCA, demonstrating its potential relevance in clinical decision-making.

Introduction

Machine learning (ML) has demonstrated remarkable efficacy in recognizing complex disease patterns and informing clinical decision-making, where conventional methods do not provide sufficient insights [1-4]. ML algorithms have been applied in various medical conditions, including cardiovascular diseases and diabetic foot ulcer (DFU) research. Previous papers have either provided an overview of potential ML models through a review or applied ML in data analyses [5]. However, there seems to be no prior medical study that has created a clear and detailed overview including examples of all the key steps generally involved in applying ML to datasets: data preprocessing, model selection, hyperparameter optimization, evaluation and comparison of model performance, and interpretation of results. Certain critical aspects of data analysis, such as addressing missing values and class imbalance, are frequently left out of the literature [6-11]. While a wide range of models can be used and compared, heavily imbalanced classes can still result in low area under the receiver operating characteristic curve (AUC) scores and accuracy [12]. Furthermore, previous studies compare at most 6 ML models, and no paper was found that explores the full spectrum of common ML models [6].

DFUs represent a complex and significant multifactorial medical problem, making these highly suitable for the application of ML. According to estimates from the International Diabetes Federation, in 2021, 537 million adults worldwide (10.5%) were living with diabetes mellitus, a number projected to escalate to 642 million by 2030. On average, 1 in 4 diabetics will experience a DFU in their lifetime, of which 22.3% (95% CI 15.3-29.2) eventually undergo a lower extremity amputation [13,14]. The personal and societal costs of DFUs and amputations are enormous, and as such, it is of utmost importance to correctly identify predictors of treatment response to optimize targeted interventions and prevent unnecessary treatments [15-18].

This study evaluates the use of 7 distinct ML models: logistic regression (LR), support vector machine (SVM), k-nearest neighbors (KNN), random forest (RF), extreme gradient boosting (XGBoost), Bayesian additive regression trees (BART), and artificial neural network (ANN). These models accommodate a wide range of regression, tree-based, probabilistic, and neural network methods, addressing higher complexity data. Moreover, LR, tree-based models, and BART provide a level of transparency that offers clear insights into the decision-making process.

Despite notable progress and research in ML, challenges persist in fully implementing all necessary steps. The multifactorial nature of DFU makes it a demanding and challenging case for evaluating the performance of ML models. By elucidating these methodologies, this paper aims to provide a framework for the proper use of ML algorithms to predict clinical outcomes of multifactorial diseases and their treatments, thereby assisting decision-making for clinicians.

Methods

Data Acquisition and Contextual Analysis

This study made use of a dataset containing records from 700 patients with a DFU due to neuropathy, ischemia, or both, who were treated at the Haaglanden Medical Center in The Hague, The Netherlands, between October 1, 2013, and October 1, 2021. Patients with a wound resulting from trauma, a surgical procedure, venous insufficiency, unguis incarnatus, or a wound located proximal to the malleoli were excluded. Structured into 71 unique categories, the dataset encapsulated 199 features per patient, reflecting a detailed record of each patient's medical journey. These features spanned from generally available information to data acquired through medical examinations and posttreatment outcomes, all extracted from the electronic patient record, Healthcare Information Exchange. General demographic information was obtained from the cover page of the record, while medical history was retrieved from referral letters, outpatient reports, hospitalization records, and discharge summaries. Substance use was assessed through records from the departments of surgery, internal medicine, pulmonology, cardiology, and anesthesiology. Vital sign measurements and laboratory results were extracted from designated Healthcare Information Exchange sections, with averages calculated for the period in which the DFU was present. Medication use was determined based on prescription records, pharmacy verifications conducted during hospital admissions, and data from the National Exchange Point (ie, LSP). Information regarding the DFU was extracted from wound care center reports and hospitalization records.

XSL•FO
RenderX

A subset of the collected features was selected for analysis (see Feature Selection section). The patient's age at the onset of the DFU was recorded in the database. Smoking encompassed the use of cigarettes, cigars, or other tobacco products. Wound location was categorized according to the angiosome concept [19]. Diabetes type was classified as type 1, noninsulin-dependent, and insulin-dependent diabetes. Neuropathy was defined as peripheral impairment of gnostic sensory function. Wound area was calculated by multiplying the average length by the average width of the DFU. Complete wound healing was defined as full closure of the DFU, with an intact epithelium and no signs of infection, necrosis, or fluid.

A key criterion for the inclusion of patient data in this retrospective cohort study was the completeness of the feature set. Patient data were included for analysis if it was entirely complete or if any missing values could be reliably imputed (see Handling Missing Values section). A significant proportion of patients did not undergo any form of treatment (ie, other than wound care or offloading), resulting in systematic presence of missing values in treatment-related features. To accommodate this and enhance the model's predictive power, the selection of features for model training and application was intentionally restricted to those that are obtainable early in the patient's care pathway (see Feature Selection section). In preparing the dataset for analysis, meticulous cleaning processes were used, which involved the exclusion of features based on redundancy in information, insufficiency in example frequency (eg, features related to rare treatments), and duplication of information through inverse representation.

Handling Missing Values

Addressing missing values was paramount for the effective use of patient data in ML models. Imputation of missing values was used to mitigate substantial information loss (Table 1) [20,21]. Numerical variables necessitating imputation, such as average systolic and diastolic blood pressure, O_2 saturation level, serum hemoglobin A_{1c} (HbA_{1c}), hemoglobin (Hb), and estimated glomerular filtration rate (eGFR), were predominantly missing due to unmeasured instances rather than systemic bias. As such, to ensure statistical validity, a multiple imputation technique was applied to preserve the integrity of the data distribution. The technique used was matching imputation, specifically the MIDAS (Multiple Imputation with Denoising Autoencoders) Touch algorithm, due to its effectiveness in handling both numerical and categorical data gaps [22-24]. This algorithm identified data patterns to infer missing values through a linear regression model, with coefficients randomly selected from the feature distribution, and the process was iteratively refined to enhance imputation accuracy. Additionally, a weighted mean imputation strategy was incorporated that adopted 50 repetitions to ensure realistic and generalized imputation. Weight determination was based on the absolute difference between the median of the imputation and its vector value, followed by calculating the reciprocal of this difference. Weight values were capped at 2.0 to prevent excessive weighting.

Table 1. Features selected and transformed for model training and testing.

Feature name	Missing amount prior to imputation, n (%)	Data type	Transformation
Age	0 (0)	Numerical	$x \rightarrow \sqrt{\max(x)-x}$
Smoking	0 (0)	Categorical	N/A[a]
Systolic blood pressure	113 (16.1)	Numerical	N/A
Diastolic blood pressure	113 (16.1)	Numerical	N/A
Oxygen saturation level	154 (22)	Numerical	$x \rightarrow \sqrt{\max(x)-x}$
HbA_{1c}[b]	82 (11.7)	Numerical	$x \rightarrow \log(x)$
Hemoglobin	0 (0)	Numerical	N/A
eGFR[c]	21 (3)	Numerical	$x \rightarrow \sqrt{x}$
Wound location	0 (0)	Categorical	N/A
Toe systolic blood pressure	264 (37.7)	Numerical	N/A
Diabetes type	0 (0)	Categorical	N/A
Texas wound classification	0 (0)	Categorical	N/A
Neuropathy	0 (0)	Categorical	N/A
Wound area	80 (11.3)	Numerical	$x \rightarrow \log(x)$
Complete wound healing	0 (0)	Categorical	N/A

[a]N/A: not applicable.

[b]HbA_{1c}: hemoglobin A_{1c}.

[c]eGFR: estimated glomerular filtration rate.

Feature Selection

In the preprocessing phase, feature selection played a crucial role in managing model complexity and ensuring adequate patient representation across different scenarios. This process relied on both statistical analysis and validation through literature to identify influential features, thus streamlining the model while preserving its predictive capability. Normalization of numerical values to approximate normal distributions was performed as a preliminary step to enhance statistical validity and facilitate effective feature selection. Normalization proved beneficial, where the normal distribution's statistical properties were leveraged for analysis. Transformations were applied to nonnormally distributed variables, such as age, HbA_{1c}, wound area, and eGFR, to align them with normal distribution characteristics. This helps the model recognize possible nonlinear correlations. To prevent imposing normality on the data, only common transformations such as lognormal, Box-Cox, and inverse transformations were applied. The selection of transformation depended on the form of skewness. Log and inverse transformations were applied to right-skewed data, while the Box-Cox transformation was used to address left-skewed data. Each transformation was based on visual inspection of the distribution and skewness prior to transformation. To check whether the distribution aids the transformation to normality, the Shapiro-Wilk test was performed after transformation with a threshold of 0.05. Feature selection was carried out using a 2-fold approach. First, relevant features were identified statistically. For each numeric feature, the group means were compared using ANOVA for normally distributed variables and Kruskal-Wallis for nonnormally distributed data. Chi-square tests were used for categorical variables. For both approaches, the 5% threshold was used to evaluate whether the feature should be included in the model. To prevent multicollinearity, only variables with a variance inflation factor below 5 were included. In the second time, expert recommendations (TJS, DE, WJJJ, JCSW, and KEAB) contributed to a second round of selection in the feature set, to include the role of clinical judgment in the final selection for context, and to resolve conflicting results, supported by literature on known predictors of DFU outcomes [25-32]. Age, smoking history, toe systolic pressure, blood pressure, oxygen saturation, Hb, HbA_{1c}, eGFR, wound location, diabetes type, Texas wound classification, neuropathy, and wound area measurement were ultimately the features used to train the models.

Addressing Class Imbalance

The balance of datasets is crucial for ML models, especially in medical diagnostics, where accurate identification of rare instances such as hemodialysis is significant despite their lower incidence in patient populations. Imbalanced datasets, with predominance of one class over another, can lead to bias in ML models by undervaluing the minority class, adversely affecting the model's predictive performance on critical, less common outcomes [33,34]. A balanced dataset ensures equitable representation of all classes, mitigating bias and enhancing the model's ability to capture the nuances of each category. To address class imbalance, sampling methods were used to adjust the class distribution within the dataset. The adaptive synthetic (ADASYN) oversampling method, a weighted variant of a synthetic minority oversampling technique, was used to balance the dataset between patients exhibiting full healing and those not, thereby correcting the initial skewness [35]. ADASYN focuses on oversampling in regions where the minority class is sparse, essentially making the algorithm focus on harder cases to predict. Furthermore, it improves on usual oversampling methods, as it uses a combination of KNN and linear interpolation, which helps preserve the statistical properties of the dataset. It was shown that ADASYN can improve the accuracy of a classifier in clinical trials [36]. Oversampling is a common practice in handling imbalanced classification problems. In numerous cases, it helps improve the accuracy of the model. However, in some studies, oversampling has shown no significant improvement in the performance of the classifier [37]. In oversampling, it is crucial that the original data are accurate, as any existing bias can be amplified through the oversampling process. Moreover, the smaller the number of minority class examples, the greater the risk of overfitting to synthetic patterns. Oversampling may also lead to the generation of illogical cases, which is why it is important to carefully inspect the synthetic data for such issues. To ensure the validity of synthetic patients with a nonhealing ulcer, logical tests were applied to detect any illogical oversampling instances. For example, when synthetic patient data fell outside of their respective prior distribution, this patient was deemed illogical and was then resampled. Validations included the ratio of systolic to diastolic blood pressure, the limitation to a single wound location, and the correct use of the Texas wound classification.

Model Selection

This study evaluated 7 widely adopted, distinct ML models, LR, KNN, SVM, RF, XGBoost, BART, and ANN, for their efficacy in predicting DFU healing outcomes within 1 year. With these 7 models, an attempt was made to apply ML across the broadest range of possibilities. Specifically, the following range represents all ML models for the prediction of a (binary) classification.

LR, the baseline model, is widely recognized for its simplicity and effectiveness in medical binary classification tasks, although it may struggle with capturing nonlinear data relationships. LR is most appropriate when the relationship between features and the outcome is linear and when model interpretability and simplicity are prioritized. It performs effectively with smaller datasets and under conditions of minimal multicollinearity.

SVM excels in handling high-dimensional spaces through its capability to perform both linear and nonlinear classification; yet, it faces challenges with large datasets. Its capacity to handle nonlinear relationships via kernel functions makes it a robust choice for small- to medium-sized datasets where interpretability is less critical than accuracy.

KNN introduces flexibility by predicting outcomes based on the majority outcome of the most similar patients, adapting well to complex datasets at the cost of sensitivity to the number of patients and the distance metric. The KNN algorithm is well-suited for applications where no strong assumptions about the data distribution can be made. It is particularly effective for nonlinear decision boundaries and is most efficient on small-

XSL•FO
RenderX

to medium-sized datasets due to its computational overhead during inference.

RF, an ensemble method, is praised for its ability to manage nonlinear data and variable interactions, offering insights into feature importance despite its comparatively lower interpretability. RF is a preferred method when dealing with datasets containing a large number of features or where overfitting is a concern. It effectively reduces variance and is versatile for both classification and regression tasks while also handling missing values well.

XGBoost stands out for its speed, performance, and robustness against overfitting through gradient boosted decision trees, although it demands meticulous hyperparameter tuning. XGBoost is highly effective for large-scale datasets with complex interactions and structured noise, particularly when computational efficiency and predictive performance are paramount. Its built-in handling of missing data and regularization makes it especially suitable for imbalanced datasets and high-stakes prediction tasks.

BART leverages probabilistic relationships to model dependencies between variables, making them useful for interpretative insights in complex datasets. Although BART can handle uncertainty effectively, it may require extensive domain knowledge and computational resources for accurate structure learning in large datasets. BART is recommended for problems requiring flexible nonparametric modeling with integrated uncertainty quantification and automatic variable selection.

ANN is powerful for capturing complex, nonlinear patterns in high-dimensional data, often outperforming other models in prediction accuracy for intricate tasks. However, their "black-box" nature limits transparency, making it difficult to interpret specific decision pathways, and they typically require substantial, highly varied data and computational power for optimal performance.

Hyperparameter Optimization

The configuration of the hyperparameters affects the performance of the model, as the structure of the model and its capacity to generalize from the training data are significantly altered. These hyperparameters are configured independently of the data on which the model is trained, but the inherent meaning of the data does affect the predictive power of the configuration. Therefore, identifying the optimal configuration is crucial. A grid search was used to identify the best hyperparameter combination based on model accuracy. The grid search method iterated 1000 times over the model training and testing, recording the results of each iteration along with its hyperparameter setup and the prediction accuracy. In the event of missing values, class imbalance, or lack of data, it is essential to measure all performance metrics (see Evaluation and Comparison of Model Performance section). Only accuracy was ultimately used, as other metrics did not yield additional insight, and the other factors have been addressed. In cases where the hyperparameter range is large or computational time is a concern, heuristic search methods offer a more efficient alternative. For grid search specifically, each possibility of the configuration is included at least once. Visual confirmation was used to determine whether convergence toward the best hyperparameter combination was incidental or deterministic.

For LR, only the model weights were adjusted to reflect feature importance. For KNN, the k-number of neighbors was optimized to balance flexibility and overfitting. In SVM, cost and γ controlled the margin and kernel function, while degree and kernel type shaped the function itself.

In tree-based models like RF and XGBoost, hyperparameters such as the number of trees, maximum tree depth, and features per split regulated complexity and diversity of the ensemble trees. XGBoost further required learning rate η for convergence, split thresholds γ to prune weak splits, and regularization terms λ and α to reduce overfitting. BART retained default prior distributions for simplicity, although they can be adjusted when data-specific insights deem them unfit. For ANN, the number of hidden layers and neurons per layer was prioritized for their impact on model capacity and complexity.

Evaluation and Comparison of Model Performance

As random variation in dataset partitioning can influence model outcomes, steps were taken to ensure that the results reflected both robustness and representativeness rather than chance. To address this challenge, repeated random split cross-validation was used by iteratively splitting the dataset and training the hyperparameter-optimized model 1000 times, ensuring that each possible configuration was included at least once in the grid search. In each iteration, the dataset was randomly divided into a unique training (70%) and testing (30%) set, which were kept separate to prevent data leakage. This iterative process allowed the model to be evaluated on different combinations of training and testing data, enhancing the reliability of its predictions. For each split, the model, configured with optimal hyperparameters, was then trained on the training set and evaluated on the testing set, both using patient characteristics. Following the prediction, the results were compared to the true values and fitted into a confusion matrix, with performance further quantified by average accuracy, specificity, precision, recall, and AUC. Finally, the iterative process provided not only a look into the average performance but also the variance. Low variance indicates the model's ability to generalize well for patients outside of the training and testing data. Noteworthy indicators of model performance included accuracy for average performance, specificity for predictive power on patients with a nonhealing ulcer, and the considered balance between specificity and recall.

For the BART model, uncertainty quantification was enhanced through a density plot, providing greater transparency in the decision-making process. The density plot visualizes the probability distribution of wound healing. The peak of the plot indicates where the model is most confident in its classification. A red line marks the threshold, the probability level used to distinguish between healing and nonhealing outcomes. Predicted probabilities exceeding this threshold are classified as healing, while those falling below it are classified as nonhealing.

A calibration curve was used to ensure that the predicted probabilities reflect true outcome likelihoods. This curve

XSL•FO
RenderX

compares predicted probabilities to observed outcomes to detect systematic over- or underestimation. To quantitatively evaluate calibration, Brier scores were calculated. The Brier score, ranging from 0 to 1, reflects the model's ability to estimate true outcome probabilities with high certainty, with lower values indicating better calibration.

Decision curve analysis (DCA) was used to evaluate the clinical use of the ML models (see Model Selection section) [38]. DCA measures the net benefit of a model dependent on risk threshold probability. It displays the most beneficial decision-making strategy corresponding to a patient risk probability. For instance, in a patient with a DFU who receives a predicted 85% risk of nonhealing, a clinical decision rule that recommends amputation for any risk exceeding 80% would lead to an amputation. If, in reality, the DFU would have healed without surgical intervention, this decision would constitute overtreatment. DCA allows such trade-offs to be visualized and quantified across a range of thresholds, thereby supporting the selection of a decision threshold that yields the highest overall clinical benefit.

Dataset Size

A common challenge in ML training is the need for a sufficiently large dataset to effectively train a classification model. In practical applications, obtaining such data is difficult and time-consuming. Hence, the improvement in model performance relative to dataset size was measured. The selected ML models were trained with randomly sampled, evenly classified train and test datasets. The performance results were visualized together with a learning curve illustrating the dataset size expansion required to achieve the anticipated performance level. Learning curves are a practical tool for evaluating the relationship between model performance and dataset size. These curves help determine the extent to which additional training data might enhance model performance.

Ethical Considerations

The study was conducted in accordance with the principles of the World Medical Association Declaration of Helsinki. The independent Medical Ethics Review Committee Southwest Holland reviewed the study and determined that it does not fall within the scope of the Medical Research Involving Human Subjects Act (approval number 18-038), as it does not constitute scientific research as defined in article 1, paragraph 1, subsection b of the Medical Research Involving Human Subjects Act. The study consists of a retrospective chart review rather than research in which individuals are subjected to interventions or imposed behavioral regulations. Additionally, the scientific and general board of directors of the Haaglanden Medical Center approved the execution of the study and granted an exemption from obtaining informed consent due to the retrospective nature of data collection and the exclusive use of anonymized data. This decision was based on the minimal risk to patients, the impracticality of contacting patients, and the strict safeguards implemented to protect privacy. The data were derived from electronic patient records and documented anonymously within the Castor medical web application. All data handling was conducted in compliance with the General Data Protection Regulation. Access to the dataset was restricted to authorized members of the research team, which was stored on a protected hospital server with controlled access. No identifiable information was used in the analyses or presented in the results. As the study relied exclusively on retrospective and anonymized data, no patients were contacted, and no financial or other compensation was provided.

Results

The final dataset used for prediction and analysis contained information from 900 patients. After applying imputation and oversampling techniques for incomplete patient records, 308 (44%) patients were recovered for model training (Table 2). The original dataset comprised 700 patients, with 427 (61%) representing cases of complete wound healing. Through ADASYN, approximately 200 synthetic patient records with a nonhealing ulcer were generated, equalizing the representation of both classes to 450 (50%) patients.

Table 2. Statistical validity before and after imputation of empty values.

Feature	Before imputation, mean (SD)	After imputation, mean (SD)
Diastolic blood pressure (mm Hg)	69 (12)	70 (12)
O_2 saturation (%)	97 (2)	97 (2)
Serum eGFR[a] (mL/min/1.73 m^2)	66 (33)	66 (33)
Serum hemoglobin (mmol/L)	7.8 (1.2)	7.8 (1.1)
Serum HbA_{1c}[b] (mmol/mol)	69 (19)	69 (18)
Systolic blood pressure (mm Hg)	137 (18)	137 (16)
Toe systolic blood pressure (mm Hg)	77 (46)	76 (39)
Wound area measurement (cm^2)	4.1 (11.6)	3.8 (11.0)

[a]eGFR: estimated glomerular filtration rate.

[b]HbA_{1c}: hemoglobin A_{1c}.

Feature selection of the dataset yielded the features that are linearly correlated with wound healing (α=.05) and used in the prediction of DFU healing (see Feature Selection section). Only wound location contained variance inflation factor values greater than 5 due to the wide variety of locations. Seven models, LR, KNN, SVM, RF, XGBoost, BART, and ANN, were optimized

XSL•FO
RenderX

with a grid search set within the most commonly used boundaries (see Table 3 for hyperparameters) [39]. These models were trained and tested, resulting in the following outcomes. The validation of model training demonstrated a high predictive power with an average accuracy of 0.794 (SD 0.023). However, notable performance differences existed when comparing models against their respective baselines. Feature importance measured by both the RF and XGBoost models revealed critical predictors for DFU healing outcomes. These predictors were determined by their use in decision-making. Key predictors highlighted by both models included toe systolic pressure on the affected side, Hb, wound area, age, systolic blood pressure, and diastolic blood pressure. Furthermore, BART offered enhanced insights into uncertainty quantification through a density plot, contributing to greater transparency in the decision-making process. The density plot represents the probability of wound healing for a randomly selected patient, with a 69% likelihood that healing will occur (Figure 1). Table 4 shows the model performance averaged over 1000 iterations in terms of accuracy, specificity, precision, recall, and AUC metrics. SVM achieved the highest performance with an accuracy of 0.853, followed by RF (accuracy=0.838) and XGBoost (accuracy=0.815). KNN (accuracy=0.789) and ANN (accuracy=0.789) scored lower, followed by BART (accuracy=0.748), with LR (accuracy=0.725) scoring the least in overall performance. The reliability of the predicted probabilities was assessed using calibration curves (Figure 2). The ideal calibration is represented by the diagonal dotted black line, indicating perfect alignment between predicted and actual probabilities. Deviations from this line indicate miscalibration. Curves below the diagonal suggest overconfidence (ie, predicted probabilities are too high), while curves above the diagonal indicate underconfidence (ie, predicted probabilities are too low). The Brier scores indicate that SVM, RF, and XGBoost are better at class discrimination, whereas LR, KNN, and ANN exhibit less reliable probability estimates (Table 4).

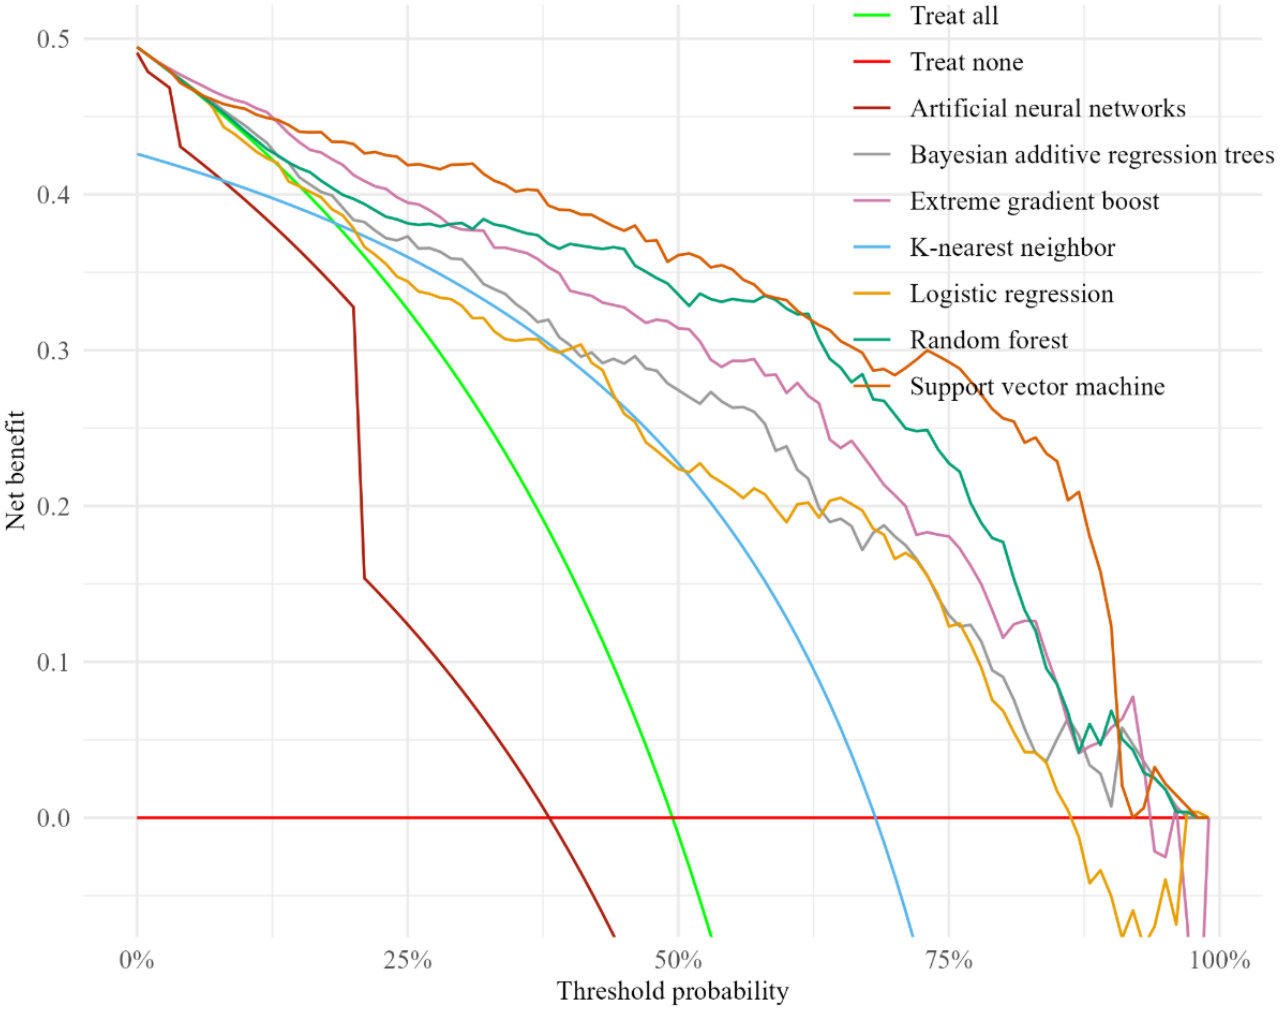

Figure 2. Calibration curves: calibration performance of the machine learning models compared to the ideal calibration represented by the diagonal dotted black line.

The DCA showed the benefit of each ML model in the application of complete wound healing within 1 year (Figure 3). To facilitate interpretation, the threshold probability was modeled to the estimated risk of patients not achieving complete wound healing within 1 year. Overall, the SVM consistently outperformed both the treat all and treat none strategies, as well as the other ML models evaluated. This advantage was particularly evident at the 75% risk threshold, where the SVM demonstrated the highest net benefit. With the exception of the ANN, the curves remained distant from the extremes of treating all or no patients, demonstrating clear clinical benefit. The ANN curve remained close to the treat all baseline, indicating limited net benefit compared to the other models. The analysis highlighted the potential of ML to support and enhance clinical decision-making in DFU care, especially between the higher risk threshold values (0.2-1.0).

XSL•FO
RenderX

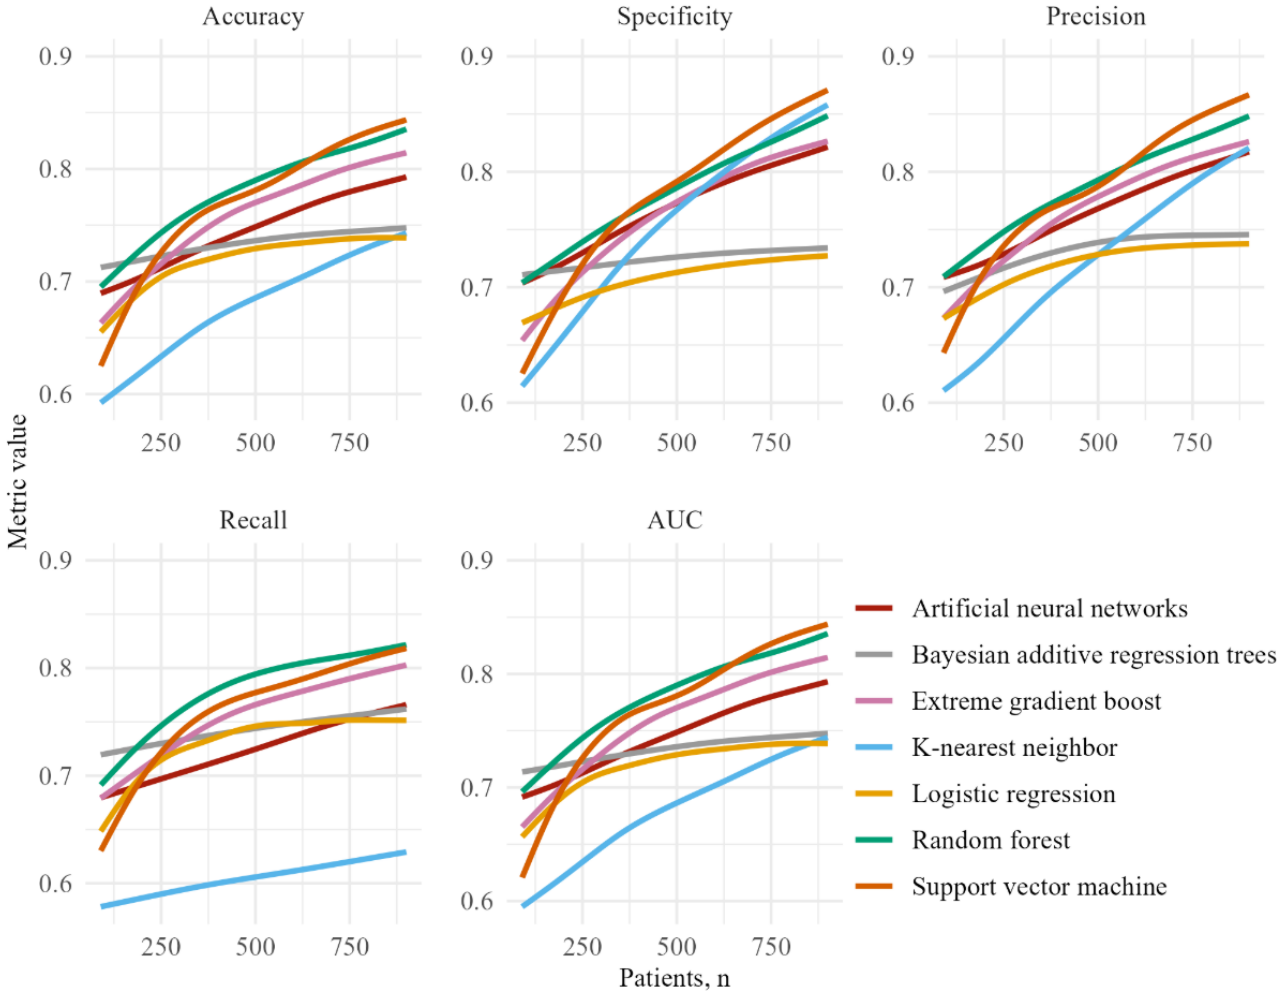

Figure 3. Decision curve analysis: correlation between net benefit and patient risk threshold probability of model predictions.

Finally, the model's performance in relation to the dataset size provided valuable insights into potential improvements in average performance (Figure 4). While the baseline LR reached its peak accuracy at approximately 73%, the SVM, RF, XGBoost, and ANN exhibited promising signs of improvement with increasing dataset size.

Discussion

Principal Findings

This paper offered a structured framework for applying ML models in clinical research. Using ML in a dataset necessitated several fundamental steps: data acquisition, contextual analysis, handling missing values, feature selection, addressing class imbalance, model selection, hyperparameter optimization, evaluation and comparison of model performance, and interpretation of results. As ML models become more accurate with more examples in a database, developing a good model requires significant computational power. The choice of different statistical methods was related to the number of available variables, the size of the studied population, and the outcomes of interest. This study demonstrated that SVM, RF, and XGBoost achieved the best performance in predicting outcomes from a dataset related to a multifactorial disease.

Imputation with low variance in feature distribution ensured statistical coherence, which is essential in medical research. This coherence supports the accuracy of patient representation and validates the reliability of the results, providing a statistically coherent foundation for model training.

Preprocessing and feature selection resulted in a clean dataset with features that were linearly correlated with complete wound healing within a year. These features included age, smoking status, toe systolic pressure, blood pressure, oxygen saturation, Hb, HbA_{1c}, eGFR, wound location, diabetes type, Texas wound classification, neuropathy, and wound area measurement. These features aligned with findings reported in prior literature [40,41]. Seven models were selected for comparing their predictive power regarding complete wound healing, and each model representing a different branch in ML [42,43]. Each model provided distinct characteristics and unique insights, suggesting that combining multiple models could be a valuable approach to enhance predictive accuracy and interpretability. This study's comparative approach sought not only to discern the optimal models for predicting DFU healing but also endeavored to deepen the understanding of the underlying factors influencing these outcomes. Feature importance therefore played a pivotal role in understanding the relative significance of features within each algorithm. To achieve this, the influence of features on model predictions was explored. Specifically, the feature importance of the RF and XGBoost models was taken into account due to their ability to measure nonlinear correlations. Upon comparing overall predictive scores, SVM performed best. While the baseline LR model and BART plateaued at 0.75

XSL•FO
RenderX

accuracy, KNN, RF, XGBoost, ANN, and even SVM itself continued to show signs of improvement when trained on an increasing dataset size. Although BART did not achieve high accuracy, it demonstrated value by providing predictive certainty, which is essential for supporting informed decision-making, assessing risk, and enhancing transparency in complex scenarios, where achieving complete accuracy is not feasible. The Brier scores, which quantify overall model calibration quality, supported the results observed in model performance. SVM achieved the lowest Brier score, indicating that the predicted probabilities were also well-calibrated and were able to discriminate between classes. These findings are further reinforced by the DCA, which demonstrated that ML models, especially SVM, consistently yielded the highest net benefit across the full range of threshold probabilities, validating clinical usability. The limited performance of the ANN likely stems from its inclination to predict predominantly a single class, reflecting both insufficient training data and difficulty in capturing complex patterns within the dataset. To realize improved model performances for KNN, RF, XGBoost, ANN, and SVM, we aim to include more patients before moving toward clinical applicability.

Imperative Steps in Clinical ML

The fundamental steps necessary for applying ML to a dataset are elaborated on in the Methods section. Each step serves a distinct purpose, and omitting any of them may lead to detrimental consequences. For instance, handling missing values is imperative, as ignoring them can result in an inaccurate representation of the patient population, distorting the model's output and leading to incorrect predictions that fail to reflect the true clinical situation. Similarly, neglecting class imbalance can cause the model to perform poorly in predicting the rarer class, which may lead to incorrect treatment decisions in clinical practice. Additionally, choosing the wrong model or failing to optimize hyperparameters can prevent the model from generalizing well to new data, ultimately undermining its clinical applicability.

Comparison with Prior Work

In other DFU-related studies, 1 or a combination of up to 6 different ML models were used to predict disease outcomes [6,11,25,44-49]. In addition to the 7 models selected for this paper, various papers proposed the use of specialized model variants, ensembles, or hybrids. Some examples are stacking C, bagging, Adaboost, and light gradient boosting machine [42,45,50]. We chose to exclude these models to uphold the simplicity and clarity of our application.

Transferability Across Clinical Domains

The methodological framework outlined in this paper is intended to be broadly applicable across a wide range of clinical domains and is particularly well-suited for multifactorial diseases, such as cardiovascular diseases, oncology, autoimmune disorders, neurodegenerative diseases, and psychiatric conditions. These disorders are often characterized by complex, nonlinear interactions between numerous variables. ML models offer a distinct advantage over conventional analytical approaches by effectively identifying and prioritizing relevant features. Moreover, there is growing recognition that environmental and geographical factors significantly influence disease outcomes, contributing to an increasing number of relevant variables in datasets. To ensure optimal model performance and enhance clinical applicability, it is crucial to ensure that a database comprises a sufficiently large cohort with an adequate number of variables. Potential challenges in applying the framework to other clinical conditions include the presence of variables with many distinct classes or free-text fields, rare outcomes occurring in only a small subset of the population, a dataset with a large proportion of imaging data, and structurally missing or incomplete data. In certain domains, temporal dynamics play a critical role, which may necessitate the use of more advanced modeling techniques to appropriately capture and analyze time-dependent patterns.

Strengths and Limitations

For this paper, a near-complete dataset was compiled, encompassing all consecutive patients from one of the largest hospitals in the Netherlands regarding DFU management, comprising 199 variables. Substantial effort was dedicated to collecting and curating the data to ensure its completeness and quality. Additionally, 7 different ML models were applied, making this paper a strong representation of the current capabilities of ML in this domain.

Leveraging this extensive dataset and the application of multiple ML models, this study highlights the advantages of ML over conventional statistical methods in DFU management. Besides their ability to process large amounts of data, these ML models offer several key benefits. First, the models can identify complex, nonlinear relationships between variables that may be overlooked by conventional methods. In complex datasets such as the one used in this paper, interactions between different factors can be subtle. Second, the ML models used provided alternative methods to extract relevant features from data, helping researchers identify important predictive factors that might have otherwise been overlooked. Certain variables may unexpectedly prove important, as manually identifying the most relevant features in high-dimensional datasets can be challenging. Unlike traditional approaches, which rely on human intuition and domain knowledge, both of which can introduce bias, ML models use data-driven techniques to determine feature importance objectively. Third, the models effectively handled missing data through imputation, enhancing data usability and improving predictive accuracy. It is important to note, however, that imputation should only be applied when a small proportion of data is missing. Applying imputation to a large number of missing values can significantly distort the dataset, introduce bias, and compromise the validity and reliability of the resulting predictive models. ML models can adapt and improve, as more data become available, continuously refining and optimizing predictions. Integrating ML models into clinical decision support systems can offer objective, data-driven insights for health care providers and patients, allowing informed personalized decisions, such as the option to wait longer for wound healing or to pursue a different path in DFU treatment such as amputation and early revalidation when muscle mass is not yet decreased because of prolonged immobilization.

XSL•FO
RenderX

The retrospective nature of this database presents a limitation for this study, as some data were not recorded for a portion of the patient cohort. In this regard, it would have been ideal to analyze a prospective dataset. Furthermore, clinical applicability would be more profound with a larger database. This could not have been anticipated prior to the analysis, as the learning curves demonstrate an increase in performance up to at least 900 patients (Figure 4). Learning curves provide valuable insights into how much the model's performance might improve with additional training data, helping to determine whether collecting more data is beneficial or if the model has reached its performance plateau. When there is still room for improvement, one must be cautious of overfitting, where models overly adapt to training data, performing well on training data but poorly generalizing to new, unseen data. This can result in inaccurate predictions and decision-making in practice. This limitation may be overcome by providing sufficient training data, reducing the likelihood that unseen data will yield a different outcome. In addition, implementing cross-validation helps assess generalizable performance, while avoiding data leakage, ensuring balanced class distributions, and minimizing the number of features further contribute to reducing overfitting. Moreover, there was limited availability of specific variables, such as having a rare condition. These variables could not be included in the feature selection, as their absence can lead to biases in the models and inaccurate predictions. Therefore, clinical applicability needs to be validated in an extended database.

To ensure the added value of ML models in clinical practice, it is an important role of computer data scientists to formulate quality standards for clinical decision models. In addition, a careful collaboration between the computer scientists, statisticians, and clinicians is necessary to identify suitable outcomes in clinical, imaging, and biochemical parameters. For example, one would be most interested in factors that can be clinically modified or that strongly predict good or absolutely worst outcomes. Moreover, clinical interpretation of findings from ML models is clearly needed. For example, Hb levels showed a strong relationship with wound healing outcomes in this study. However, while poor wound healing could be a direct result of anemia, anemia may also be a consequence of a generally ill patient because of a chronic wound.

Future Research

The next step will focus on obtaining more than 1000 complete patient records in the DFU dataset to provide clinically relevant features and develop a combined ML prediction model with an accuracy exceeding 90%.

Conclusions

This study aimed to provide a framework for using ML models to investigate factors influencing a multifactorial disease. Taken together, the steps involved in the process include data acquisition, contextual analysis, handling missing values, feature selection, addressing class imbalance, model selection, hyperparameter optimization, evaluation and comparison of model performance, and interpretation of results. By using 7 different ML models, we have shown quality control for each method. In the pilot DFU dataset used as an example, the SVM performed the best, followed by RF and XGBoost. By incorporating our framework, explanations to model behavior can be structurally approached, providing better insights compared to metric values alone.

Acknowledgments

The authors are grateful to Dr Mathis JF Mourey for his assistance with the editing phase. Funding for VYV and HLB was provided by Stichting Researchfonds Bronovo. This study was supported by the Haaglanden Medical Center Scientific Fund and RULER (real time multimodal and multidisciplinary perfusion imaging) project.

Data Availability

The dataset generated and analyzed during this study is not publicly available due to the protection of patient privacy but are available from the corresponding author on reasonable request. All analyses were performed on the Windows 11 operating system using RStudio (version 4.4.1; Posit PBC) and open-source packages. The complete code and workflow are available on GitHub, ensuring full reproducibility [51].

Abstract

Background: Venous thromboembolism (VTE) remains a critical cause of mortality among patients who are hospitalized. Patients with traumatic brain injury (TBI) are particularly susceptible to VTE due to coagulation abnormalities and immobilization. Despite this elevated risk, no validated predictive model currently exists for postoperative VTE in populations with TBI.

Objective: This study aims to develop machine learning (ML)–based predictive models for VTE in patients with TBI undergoing surgical procedures, with a focus on clinical translatability.

Methods: Data were collected from patients with TBI who underwent surgical treatment at Chongqing University Central Hospital (from October 2016 to December 2024). The dataset was randomly partitioned into a training set and an internal test set in a 7:3 ratio. The recursive feature elimination algorithm was applied for feature selection, followed by the synthetic minority oversampling technique to address class imbalance. Six ML models, including logistic regression (LR), random forest, gradient boosting decision tree, extreme gradient boosting, support vector machine, and categorical boosting, were trained and validated. Model performance was evaluated using receiver operating characteristic analysis, calibration curves (assessing probability-observation alignment), and decision curve analysis to quantify clinical net benefit. For the LR model, clinical utility was enhanced through nomogram construction, with Shapley additive explanation values providing interpretability.

Results: A total of 1806 participants were enrolled in this study, and 257 (14.2%) experienced VTE events. All ML models demonstrated strong predictive performance, with area under the receiver operating characteristic curve values ranging from 0.79 to 0.83. The LR model exhibited the highest discriminatory power (area under the receiver operating characteristic curve 0.83; accuracy 0.80; specificity 0.83). Calibration curves confirmed that the LR model provided well-calibrated probability estimates. Shapley additive explanations analysis identified key contributors to VTE risk and transformed model outputs into individualized risk predictions. A user-friendly postoperative VTE risk prediction nomogram was developed for patients with TBI.

Conclusions: This study successfully developed and validated multiple ML models for postoperative VTE prediction in patients with TBI. The LR-based nomogram, supported by calibration and decision curve validation, offers a clinically actionable tool to guide thromboprophylaxis strategies. Future external validation across diverse populations is warranted to confirm generalizability.

Introduction

Venous thromboembolism (VTE), encompassing deep vein thrombosis (DVT) and pulmonary embolism (PE), is a critical clinical syndrome associated with high morbidity and mortality among hospitalized patients [1]. Globally, an estimated 10 million individuals experience VTE annually. In the United States, PE ranks among the leading causes of cardiovascular death, accounting for up to 300,000 fatalities per year [2]. Patients with VTE experience severe complications, including adverse effects of long-term anticoagulation (eg, hemorrhage risk), prolonged hospitalization, elevated 30-day readmission rates, and delayed adjuvant therapies (eg, chemotherapy or radiotherapy) [3]. VTE significantly contributes to extended hospital stays and increased mortality [4,5]. Notably, patients with traumatic brain injury (TBI) who develop VTE exhibit prolonged intensive care unit stays and extended mechanical ventilation duration [6].

TBI affects approximately 50 million individuals globally each year, with epidemiological models suggesting that nearly half of the global population may sustain at least 1 TBI during their lifetime [7]. TBI is an independent risk factor for VTE, elevating the risk through multifactorial pathophysiological mechanisms [6]. Studies indicate that patients with multitrauma and TBI face significantly higher VTE risk than those without TBI, attributable to disease complexity and delayed early interventions [8]. Coagulopathy is prevalent in this population; 67% of the patients with severe TBI exhibit coagulation abnormalities upon emergency presentation, which often progress during hospitalization [9,10]. In addition, cohorts of patients who underwent surgical procedures demonstrate elevated VTE incidence due to venous stasis from general anesthesia and intraoperative immobilization, postoperative mobility restrictions, and tissue injury–induced inflammation and coagulation pathway activation [11].

Severe TBI is strongly associated with coagulopathy, substantially elevating the risk of VTE, particularly in cohorts of patients who underwent surgical procedures. Identifying patients at high risk for postoperative VTE is thus critically imperative. Despite this established clinical need, current literature lacks dedicated studies developing VTE predictive models tailored to patients with surgical TBI. Machine learning (ML) has demonstrated significant efficacy in perioperative risk prediction across diverse surgical contexts [12]. Therefore, the objective of our study is to develop an ML-based risk assessment model for VTE in patients with TBI undergoing surgical procedures.

Methods

Recruitment

This retrospective study consecutively enrolled patients hospitalized with TBI who underwent surgical intervention at Chongqing University Central Hospital between October 2016 and December 2024.

Ethical Considerations

This study was approved by the Institutional Review Board of Chongqing University Central Hospital (2024-66). The requirement of obtaining written informed consent was waived owing to the retrospective study design. All visual representations in this manuscript, including feature importance diagrams, contain only aggregated or anonymized data. No personally identifiable information of research participants is displayed in any figures or supplementary materials.

Data Collection

Overview

This study collected comprehensive clinical data from patients with TBI who underwent surgery, encompassing 6 core domains.

Demographics

Demographic data included age, sex, weight, height, American Society of Anesthesiologists (ASA) physical status classification, and history of smoking and alcohol use.

Preoperative Comorbidities

Preoperative comorbidities included hypertension, coronary heart disease, diabetes mellitus, atrial fibrillation, chronic renal insufficiency, myocardial infarction, pulmonary infection, and malignant tumors.

Injury Characteristics

The following variables were recorded: Glasgow Coma Scale (GCS) score, Rotterdam computed tomography score, injury mechanism (falls, traffic accidents, or assaults), Injury Severity Score, Abbreviated Injury Scale (AIS), head injury types (eg, concussion, cerebral contusion, diffuse axonal injury, subdural or epidural hematoma, subarachnoid hemorrhage, or skull fracture), and injury-to-admission interval.

Biochemical Parameters

Biochemical parameters included complete blood count, liver function tests, comprehensive metabolic panel, and coagulation profiles.

Preoperative Interventions

Information on medications and supportive measures included the following: anticoagulants and antiplatelets (eg, rivaroxaban, clopidogrel, and aspirin), hemostatic agents (eg, tranexamic acid, vitamin K, and etamsylate), and supportive therapies (eg, pneumatic compression therapy, mechanical ventilation, blood transfusion, endotracheal intubation or tracheostomy, and mannitol administration).

Surgical and Anesthesia Details

Data included surgical site (intracranial or extracranial), emergency status, multiple surgeries (≥2 procedures), anesthesia method (general or regional), surgery duration, intraoperative fluid balance, blood loss volume, vasopressor use, invasive monitoring (central venous), and intraoperative hypotension (systolic blood pressure <90 mm Hg).

Missing data were imputed using the K-nearest neighbors algorithm for continuous variables and the mode for categorical variables.

RenderX

Outcome

The diagnosis of VTE, encompassing DVT and PE, relies on confirmatory imaging studies integrated with clinical presentation. The first-line imaging modality for DVT is Doppler ultrasonography, which identifies noncompressible veins with hypoechoic thrombi and abnormal blood flow patterns. Symptoms of PE typically present acutely and include respiratory and cardiovascular manifestations. The diagnosis of PE is commonly established using computed tomography pulmonary angiography. Clinical signs suggestive of DVT in the lower limbs include edema, discomfort, tenderness, the presence of a palpable cord, and erythema or cyanosis.

Inclusion and Exclusion Criteria

The inclusion and exclusion criteria are presented in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion Criteria

- Patients with traumatic brain injury (including concussion, cerebral contusion, diffuse axonal injury, subarachnoid hemorrhage, and epidural or subdural hemorrhage of traumatic origin)
- Patients undergoing surgical management during the current hospitalization
- Patients aged 18 years or older at the time of enrollment

Exclusion Criteria

- Patients aged younger than 18 years
- No surgical intervention performed during the study period, surgery performed before admission to the study institution, or surgery conducted during previous hospitalizations
- Missing more than 20% of essential study variables
- Length of hospital stay shorter than 72 hours after admission
- Venous thromboembolism diagnosed before surgery

Model Development and Explanation

The comprehensive dataset was stratified randomly and partitioned into a training set (1264/1806, 70%) and an internal validation set (542/1806, 30%) while preserving class distribution. Feature selection was performed using the recursive feature elimination algorithm followed by application of the synthetic minority oversampling technique to mitigate class imbalance [13,14]. A total of 6 ML algorithms were evaluated for predictive performance: logistic regression (LR), support vector machine (SVM), random forest (RF), gradient boosting decision tree (GBDT), extreme gradient boosting (XGBoost), and categorical boosting (CatBoost).

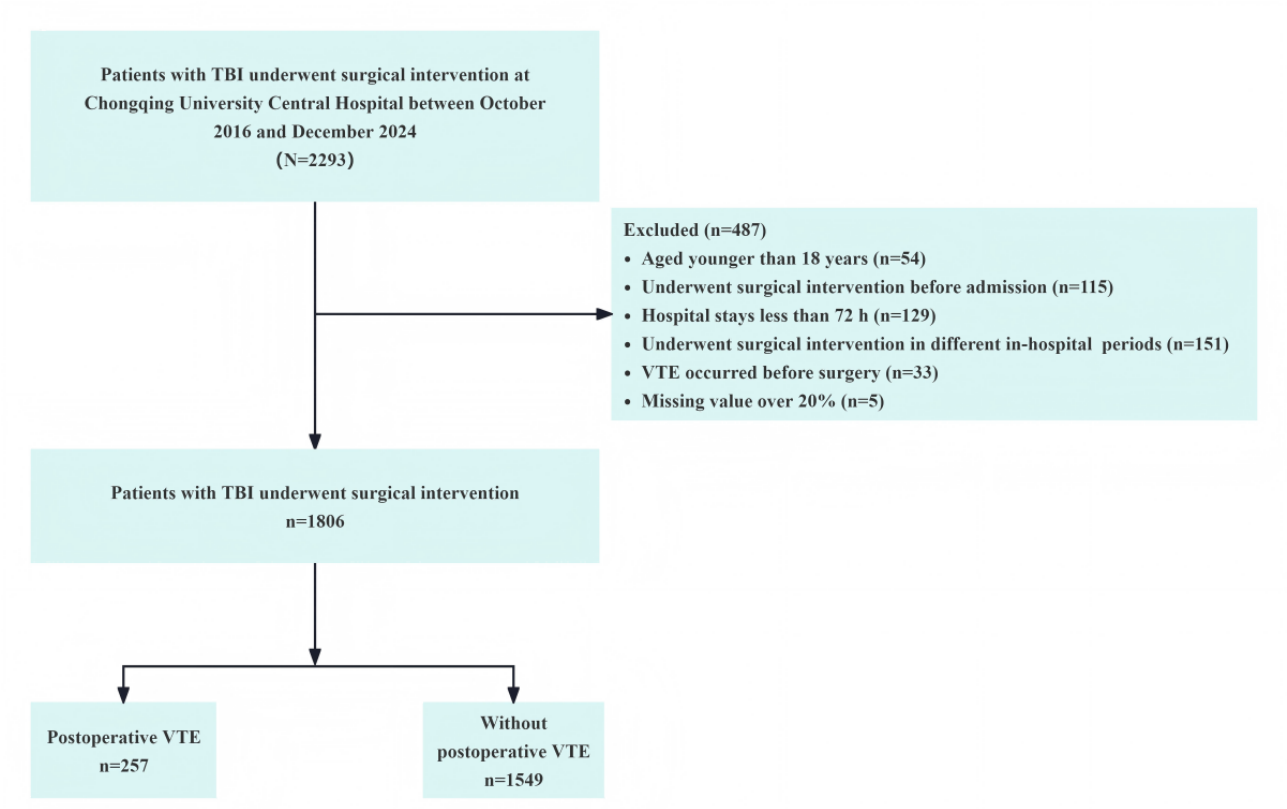
Model performance was comprehensively evaluated through a suite of discriminative, calibrated, and clinically interpretable metrics. For discriminative capacity, we assessed receiver operating characteristic analysis with area under the curve, alongside precision-recall metrics (including F_1-score—the harmonic mean of precision and recall), sensitivity, specificity, positive predictive values (PPVs), and negative predictive values (NPVs). Calibration was quantified using the Brier score and visualized via calibration curves that compared predicted probabilities against observed outcomes across risk deciles to ensure reliable probability estimates. In terms of clinical interpretability, Shapley additive explanations (SHAP) were applied to quantify feature contributions to individual predictions, elucidating both global feature importance and local decision logic, while a nomogram was developed based on LR coefficients to translate model outputs into clinically actionable risk stratification categories. Advanced validation further strengthened the robustness of findings. Decision curve analysis was performed to evaluate net clinical benefit across threshold probabilities (0%-100%), comparing model-guided interventions against “treat-all” or baseline strategies.

Statistical Analysis

Continuous variables were presented as medians (IQRs), and categorical variables were presented as numbers and percentages. All analyses were performed using PyCharm (version 2023.3.4; JetBrains), SPSS (version 26.0; IBM Corp), and R (version 4.2.1; R Foundation for Statistical Computing).

Results

Overview



From October 2016 to December 2024, a total of 1806 patients with TBI who underwent surgical intervention were enrolled in this study (Figure 1). Among these patients, 257 (14.2%) experienced VTE, including 254 (14.1%) cases of DVT and 3 (0.2%) cases of PE (Figure S1 in Multimedia Appendix 1). Table 1 presents the demographic and clinical characteristics of the study population. The median age of the patients was 51 (IQR 37-62) years. A total of 1324 (73.4%) patients were male. The most common cause of injury was traffic accidents, affecting 1033 (57.2%) patients. Cerebral contusion was diagnosed in 1017 (56.3%) patients, subdural or epidural hematoma in 967 (53.5%) patients, and subarachnoid hemorrhage in 910 (50.4%) patients (Figures S2 and S3 in Multimedia Appendix 1). Regarding the severity of head injury based on the GCS scores, 1022 (56.6%) patients had mild head injury (GCS score 13-15), 226 (12.5%) had moderate head injury (GCS score 9-12), and 558 (30.9%) had severe head injury (GCS score 3-8; Table 1 and Figure S4 in Multimedia

Appendix 1). For the modeling dataset, 1806 cases were included, with 1264 (70%) assigned to the training set and 541 (30%) to the internal validation set (Table 1).

The top 7 variables selected for inclusion in the models based on the recursive feature elimination were as follows: age, Barthel index (BI), ASA class, multiple surgeries, anesthesia types, serum magnesium (Mg^{2+}) levels, and limb AIS score (Figure 2).

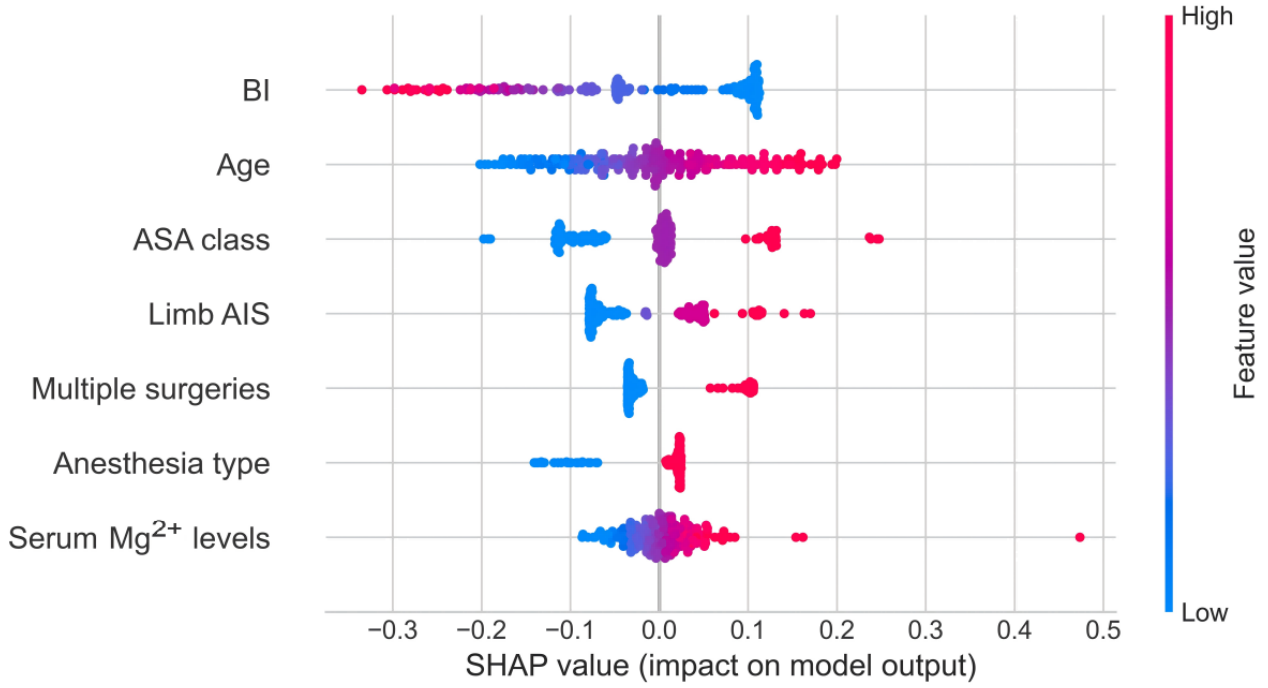
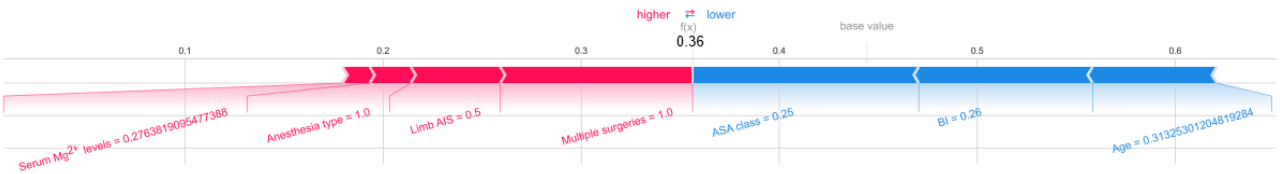
Among the evaluated models, LR demonstrated superior performance in the internal validation set, achieving the highest AUC-ROC of 0.83, with an accuracy of 0.80 and specificity of 0.83, consistently generating reliable predictions and accurately identifying true negative cases. Although other models showed merit, they fell short in key performance domains. RF had an AUC-ROC of 0.78 (lower than LR), accuracy of 0.72, and specificity of 0.82, but its sensitivity of 0.69 (relatively low)



XSL•FO
RenderX

led to more false negatives. SVM had an AUC-ROC of 0.81 (close to LR) but underperformed in sensitivity (0.74) and PPV (0.36). GBDT and XGBoost both achieved an AUC-ROC of 0.80 (respectable but trailing LR), with GBDT's sensitivity (0.65) slightly better than LR and XGBoost, despite the highest accuracy (0.80) among non-LR models, suffering from suboptimal PPV (0.38) and lower sensitivity (0.58). CatBoost, with an AUC-ROC of 0.81, had a low sensitivity (0.57) despite a high NPV (0.92; still lower than LR's NPV of 0.93). These results underscore LR's balanced performance across discriminative, calibration, and clinical utility metrics, making it the most robust choice for VTE prediction in this cohort of patients with TBI undergoing surgical procedures.

Model Explanation Results and Nomogram



The SHAP algorithm enabled interpretable insights at both global and instance-specific levels. Figure 4 visualizes the relative importance and directional impact of 7 key features on the LR model's predictions, as derived from SHAP's interpretation of the model's output. These features were identified as critical predictors: BI, age, limb AIS, ASA Class, multiple surgeries, serum magnesium (Mg^{2+}) levels, and anesthesia type.

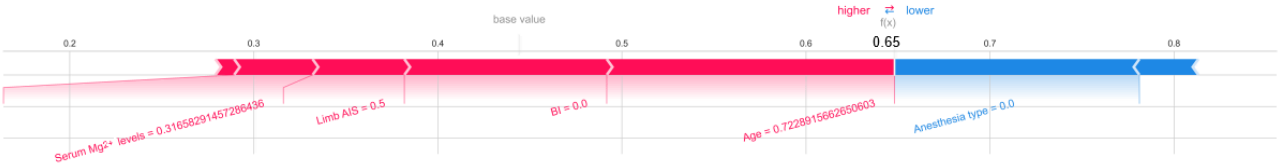
Figure 4. Global feature importance on the logistic regression model. AIS: Abbreviated Injury Scale; ASA: American Society of Anesthesiologists; BI: Barthel Index; Mg: magnesium; SHAP: Shapley additive explanations.

Subsequently, we linked SHAP values to their directional impact on VTE risk (ie, the probability of a feature increasing or decreasing the likelihood of VTE) and visualized these relationships using data from 1 patient with VTE and 1 patient without VTE in the internal validation dataset (Figure 5). Figure 6 specifically illustrates a case of a patient with VTE, where red segments denote features with positive SHAP values (indicating they contributed to an increased predicted VTE risk) and blue segments represent features with negative SHAP values (indicating they reduced the predicted VTE risk). This visualization clarified how individual features collectively modulate the model's risk stratification for VTE.

Figure 5. Local explanation for a non–venous thromboembolism sample. AIS: Abbreviated Injury Scale; ASA: American Society of Anesthesiologists; BI: Barthel index; Mg: magnesium.

XSL•FO
RenderX

Figure 6. Local explanation for a venous thromboembolism sample. AIS: Abbreviated Injury Scale; ASA: American Society of Anesthesiologists; BI: Barthel index; Mg: magnesium.



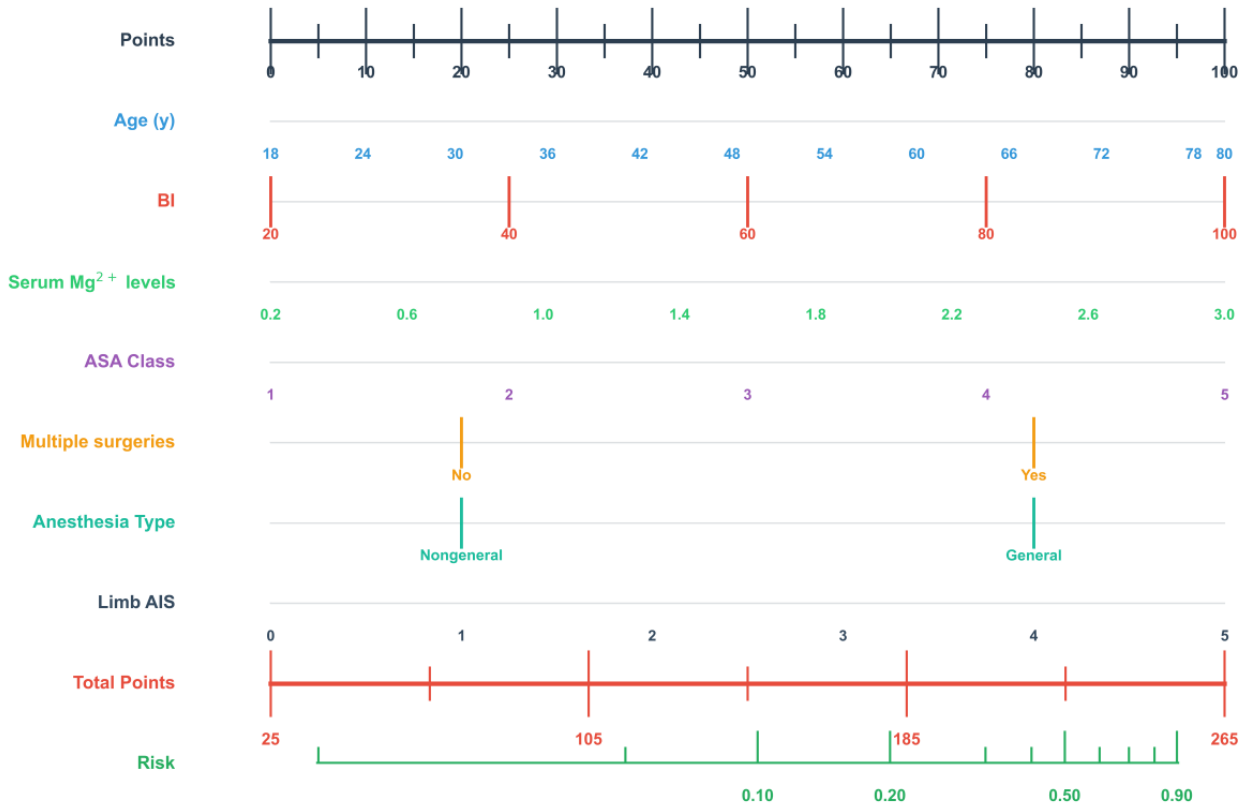


Figure 7 presents a user-friendly nomogram for rapid risk quantification, where feature scores are weighted by regression coefficients, allowing clinicians to sum points and visualize risk thresholds. This aligned with SHAP-derived feature importance, bridging statistical rigor with clinical decision-making. The calibration curve illustrated the calibration performance of the LR model in the internal validation set, with the x-axis representing predicted probabilities (0-1) and the y-axis depicting observed risks (0-1). Key curves included the bias-corrected curve (derived from 1000 bootstrap resamples), which aligned closely with the ideal reference line in the moderate-risk range (0.2-0.7), indicating strong predictive accuracy and the apparent curve, reflecting raw data fit with minor deviations at extreme probabilities (<0.2 and >0.8; Figure S6 in Multimedia Appendix 1). Further evaluation of clinical utility using the decision curve analysis demonstrated that the nomogram provided superior net benefits on the validation set (Figure S7 in Multimedia Appendix 1).

Collectively, the LR model's balanced performance (AUC-ROC=0.83; NPV=0.93), robust calibration, and actionable interpretability—coupled with the nomogram's clinical utility—establish it as a reliable tool for VTE prediction in TBI surgical cohorts.

Figure 7. Postoperative venous thromboembolism risk prediction nomogram for patients with traumatic brain injury. AIS: Abbreviated Injury Scale; ASA: American Society of Anesthesiologists; BI: Barthel index; Mg: magnesium.

Discussion

Principal Findings

The prevention of VTE remains a cornerstone in the management of patients with TBI, particularly those undergoing surgical intervention, due to their heightened thrombotic risk driven by prolonged immobilization, hypercoagulability, and endothelial injury. Although pharmacological thromboprophylaxis (eg, low-molecular-weight heparin) and mechanical methods (eg, sequential compression devices) are widely implemented, balancing efficacy with safety remains challenging due to the risk of intracranial hemorrhage associated with these agents [15]. Current guidelines lack consensus on optimal dosing protocols, timing of initiation, and patient selection criteria, further complicating clinical decision-making [16].

XSL•FO
RenderX

In this study, we documented a postoperative VTE incidence of 14.2% among patients with TBI, markedly exceeding the 3.9% reported in a 2019 national registry study [17]. This disparity underscores the urgent need for improved risk assessment tools to identify high-risk patients and guide targeted thromboprophylactic interventions.

Previous studies have used various risk-scoring systems to assess PE risk in patients who were hospitalized, including the Caprini and Padua scores [18-20]. The Caprini score, while simple and widely adopted, has significant limitations, such as its overreliance on subjective historical data (eg, previous VTE and obesity), omission of objective biomarkers (eg, D-dimer dynamics), and failure to account for anatomical factors (eg, craniotomy type) or anticoagulation therapy risks. For instance, in Asian cohorts, where patients with TBI frequently undergo prolonged surgeries (>45 min) and present with comorbid conditions (eg, hypertension), the Caprini score often overestimates VTE risk by classifying excessive numbers of patients as high risk. This has led to unnecessary anticoagulation therapy, increasing bleeding risks and health care costs [21,22].

To address these challenges and more accurately identify patients with TBI at high risk of postoperative VTE, we used 6 ML algorithms (including LR, RF, SVM, XGBoost, GBDT, and CatBoost) to develop predictive models and created a postoperative VTE risk prediction nomogram specifically for patients with TBI. These models aim to enhance risk assessment precision, enabling more targeted and effective thromboprophylactic interventions. ML has demonstrated efficacy in VTE prediction across various patient populations. Wang et al [23] and Liu et al [24] validated the RF model for VTE risk assessment in Chinese inpatients and patients who have experienced stroke, respectively.

Comparison With Prior Work

The morphology and influence of most features on the predictions are consistent with clinical practice and previous evidence. LR-based global feature importance analysis identified several critical VTE risk factors. BI scores, a validated measure of activities of daily living, emerged as the strongest predictor, with poorer functional status (lower BI scores) substantially increasing VTE risk—likely due to immobility and venous stasis—with moderate-certainty evidence supporting this association [25,26]. Advanced age was another key determinant of VTE risk, as older patients exhibited heightened susceptibility to VTE, attributed to age-related coagulation changes, increased comorbidity burden, and potential immobilization—all well-documented VTE risk factors consistent with previous epidemiological studies. Severe limb injuries (eg, pelvic fractures) were significantly associated with elevated VTE risk, aligning with findings by Hereford et al [27]. Higher ASA scores, reflecting greater comorbidity burden and poorer physiological reserve, strongly correlated with increased VTE risk, consistent with the American College of Chest Physicians' guidelines, which emphasize ASA status in VTE risk assessment for patients undergoing major surgeries [28].

Our study further demonstrated that lower serum magnesium (Mg^{2+}) levels are associated with higher VTE risk, potentially mediated by endothelial dysfunction (eg, slowed endothelial cell proliferation, stimulated monocyte adhesion, and impaired synthesis of vasoregulatory molecules) and myocardial instability (eg, altered intracellular calcium handling, prolonged QT intervals, and increased arrhythmia risk) [29-31]. However, a prospective cohort study conducted by Kunutsor and Laukkanen [32] among middle-aged Caucasian men (n=2361) reported no significant association between serum magnesium (Mg^{2+}) levels and VTE risk (adjusted hazard ratio 1.38, 95% CI 0.48-3.96), with discrepancies potentially attributed to population heterogeneity (eg, age, sex, and comorbidities). Therefore, future studies are warranted to validate the association between serum magnesium levels and VTE risk in more diverse populations encompassing varying age groups, sexes, and comorbid conditions. Although other factors (eg, multiple surgeries and anesthesia type) also influenced VTE risk to a lesser extent, these findings collectively provide critical insights for developing targeted preventive strategies and enhancing patient-specific risk assessment in clinical practice. This study investigated potential VTE predictors in patients with TBI after undergoing surgery and compared the performance of multiple machine learning algorithms. Nonetheless, the model's reliance solely on preoperative and intraoperative variables, excluding postoperative data such as laboratory tests and therapeutic interventions, potentially constrained its predictive power. Abbasi et al [33] successfully predicted postoperative bleeding events, VTE, and stroke risk in cardiac surgery by integrating preoperative, intraoperative, and postoperative variables, achieving high performance (AUC-ROC=0.92-0.97). Their study demonstrated that including postoperative variables significantly enhanced model performance, with prediction accuracy critically dependent on these data. Thus, future studies should integrate postoperative laboratory tests and therapeutic interventions as key variables to enhance the predictive capability of VTE risk models in populations with TBI.

Limitations

Several limitations of this study warrant acknowledgment. First, the dataset was derived from a single medical center for an 8-year period, which may have introduced data heterogeneity and unavoidable selection bias. Second, although this study included 1806 cases with a notably high VTE incidence, the number of VTE-positive events remained relatively small. Therefore, larger sample sizes are critical for future studies to enable more precise analyses and the development of robust predictive models. Third, postoperative laboratory tests and treatment regimens were not integrated into the analysis, which may have affected the study outcomes. Finally, given that all data originated from a single center, external validation of the developed model across multiple centers over time is necessary to confirm its generalizability.

Conclusions

This study successfully developed and validated ML models for VTE risk prediction in patients with TBI undergoing surgery, with a specific focus on clinical translatability. Leveraging the LR model's robust performance, we constructed a practical nomogram that enables bedside VTE risk assessment using

XSL•FO
RenderX

routinely collected preoperative and intraoperative data. This user-friendly tool empowers clinicians to rapidly quantify individualized VTE risk and guide targeted thromboprophylactic decisions at the point of care. Future external validation across diverse clinical settings and patient populations is warranted to confirm the model's generalizability and ensure its broader applicability in real-world practice.

Abstract

Background: Patients with acute coronary syndrome (ACS) who undergo percutaneous coronary intervention (PCI) remain at high risk for major adverse cardiovascular events (MACE). Conventional risk scores may not capture dynamic or nonlinear changes in postdischarge MACE risk, whereas machine learning (ML) approaches can improve predictive performance. However, few ML models have incorporated time-to-event analysis to reflect changes in MACE risk over time.

Objective: This study aimed to develop a time-to-event ML model for predicting MACE after PCI in patients with ACS and to identify the risk factors with time-varying contributions.

Methods: We analyzed electronic health records of 3159 patients with ACS who underwent PCI at a tertiary hospital in South Korea between 2008 and 2020. Six time-to-event ML models were developed using 54 variables. Model performance was evaluated using the time-dependent concordance index and Brier score. Variable importance was assessed using permutation importance and visualized with partial dependence plots to identify variables contributing to MACE risk over time.

Results: During a median follow-up of 3.8 years, 626 (19.8%) patients experienced MACE. The best-performing model achieved a time-dependent concordance index of 0.743 at day 30 and 0.616 at 1 year. Time-dependent Brier scores increased and remained stable across all ML models. Key predictors included contrast volume, age, medication adherence, coronary artery disease severity, and glomerular filtration rate. Contrast volume ≥300 mL, age ≥60 years, and medication adherence score ≥30 were associated with early postdischarge risk, whereas coronary artery disease severity and glomerular filtration rate became more influential beyond 60 days.

Conclusions: The proposed time-to-event ML model effectively captured dynamic risk patterns after PCI and identified key predictors with time-varying effects. These findings may support individualized postdischarge management and early intervention strategies to prevent MACE in high-risk patients.

Introduction

Acute coronary syndrome (ACS) is a critical and sudden presentation of underlying coronary artery disease (CAD); it requires timely intervention to reduce the risk of adverse outcomes and mortality [1-5]. The primary method of revascularization used in the management of ACS is percutaneous coronary intervention (PCI) because it promptly improves coronary blood flow and minimizes myocardial damage [4,6]. Although timely PCI enhances acute survival, patients often face challenges such as poor medication adherence, insufficient lifestyle modification, and residual psychosocial stress following discharge [7,8]. They also remain at substantial risk for major adverse cardiovascular events (MACE), particularly within the first year after PCI [9-12]. MACE are typically defined as the composite outcome of cardiovascular death, nonfatal myocardial infarction, stroke, or unplanned revascularization [4,13]. Approximately 14.8% to 34.4% of patients who have ACS and undergo PCI experience MACE within the first year [14,15]. The MACE risk arises from the combined influence of multiple contributing factors, including demographic characteristics, lifestyle-related factors, comorbidities, and medication-related factors such as polypharmacy and medication use patterns [2,11].

Several risk stratification tools have been developed to estimate the MACE risk in patients with ACS; among them, the Thrombolysis in Myocardial Infarction Risk Score and the Global Registry of Acute Coronary Events Risk Score are the most widely used [16]. Although these tools provide valuable support for initial triage and decision-making, they have several critical limitations. First, they are based on a limited set of clinical variables; as such, they fail to capture the multifactorial nature of the MACE risk [7,16]. Second, they do not reflect temporal variations in MACE risk after discharge; instead, they rely on static, single timepoint assessments [1,16]. Additionally, these traditional models are built on simplified linear statistical assumptions, which may inadequately reflect the complex, nonlinear relationships between risk factors [1,16]. Moreover, when risk stratification scores are used, manual data entry is required, thereby reducing practicality and limiting routine use in real-world clinical settings; it also lacks adaptability to incorporate emerging clinical guidelines [17,18].

Some of these limitations have been addressed by recent advances in machine learning (ML). For instance, ML models have improved the ability to capture complex nonlinear relationships, automate risk prediction without manual data entry, and facilitate faster updates consistent with evolving clinical knowledge [19,20]. Despite these improvements, most ML models developed for predicting MACE in patients with ACS who undergo PCI continue to rely on a limited set of clinical variables and fail to incorporate time-to-event information [21-23]. As a result, they overlook the dynamic nature of MACE risk over time. Particularly, most existing ML studies have framed MACE prediction as a binary classification problem [21-23] and focused solely on whether an event will occur within a fixed time frame. With this approach, right-censored patients are often excluded, thereby introducing a potential risk of bias in the prediction model because of the underlying covariate shift [24]. Moreover, such models have a limited ability to estimate the probability of event occurrence across clinically relevant time intervals [25]. Consequently, their applications are limited in guiding temporally informed clinical interventions.

Time-to-event ML models that combine the strengths of survival analysis and ML offer a compelling solution to overcome the limitations of traditional methods. They can be used to estimate event occurrence probabilities over time without requiring the proportional hazards assumption of traditional Cox models; consequently, they provide greater flexibility for modeling complex real-world scenarios [24,25]. Accordingly, we aimed to develop a time-to-event ML model for predicting MACE in patients who had ACS and underwent PCI. Our model incorporated clinical, demographic, and medication-related variables and used time-to-event information to enable dynamic risk estimation. Furthermore, we aimed to identify how key risk factors contributed to MACE at different time intervals by evaluating the time-varying importance of predictive variables, thereby supporting personalized and time-sensitive clinical decision-making.

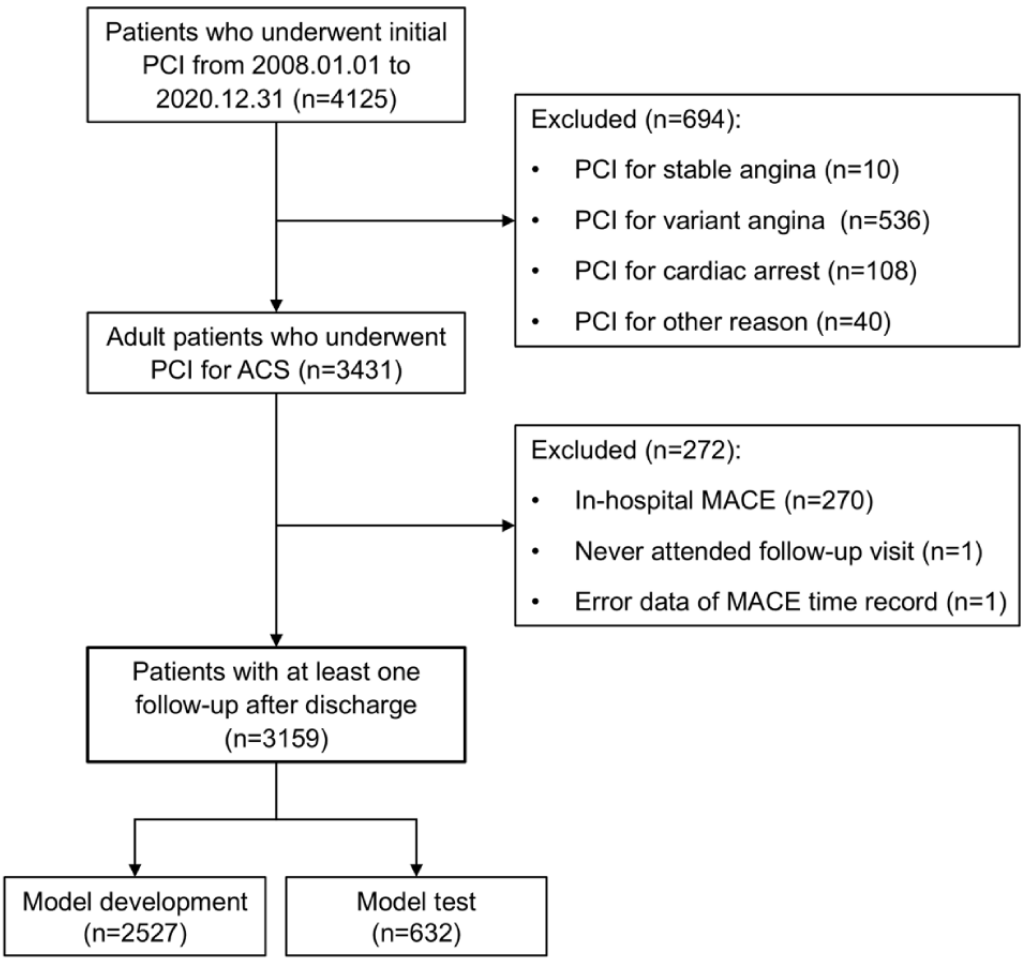
Methods

Study Design

This retrospective cohort study followed the Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis + Artificial Intelligence (TRIPOD+AI) checklist to uphold methodological rigor and ensure transparent reporting of the ML–based predictive model [26]. In addition, we adhered to the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) checklist [27]. Details of the TRIPOD+AI checklist are provided in Multimedia Appendix 1, and the STROBE reporting items are presented in Multimedia Appendix 2.

Data Sources and Patients

This study was conducted using electronic medical record (EMR) data from a single tertiary hospital in Seoul, South Korea. Patients diagnosed with ACS and subjected to PCI between January 1, 2008, and December 31, 2020, were identified. The EMR data included demographic, lifestyle, clinical, and medication-related information. The extracted data were fully anonymized to protect patient privacy. PCI procedures were performed in accordance with current guideline recommendations [4,6,27].



The patients were eligible for inclusion if they met the following criteria (1) aged 19 years or older and (2) underwent PCI for the first time. The exclusion criteria were as follows (1) patients who experienced MACE during the index hospitalization, (2) patients without follow-up records after discharge, and (3) patients with missing or erroneous outcome records for MACE after discharge.

The required sample size was determined on the basis of the number of predictors and the incidence of 1-year MACE, following the established recommendations for prediction model development [28]. An estimated 1-year MACE incidence ranging from 14.8% to 34.4% was considered [14,15]. The

XSL•FO
RenderX

minimum required sample size calculated using the lowest event rate (14.8%) to ensure adequate statistical power was 3006 patients. The final analytical cohort was composed of 3159 patients who satisfied all eligibility criteria (Figure 1).

Figure 1. Flowchart of the study population. ACS: acute coronary syndrome; MACE: major adverse cardiovascular events; PCI: percutaneous coronary intervention.

Data Collection

Based on an extensive review of the literature and the clinical expertise of the cardiology and cardiovascular nursing team participating in the study, 54 variables were selected as potential predictors of MACE. These variables covered a broad range of patient characteristics, including demographic variables, lifestyle-related variables, comorbidities, PCI-related variables, laboratory tests, medication status, and medication adherence. The predictor variables and measurement methods are described in detail in Multimedia Appendix 3.

Predictors

The final set of predictors included 54 variables classified into 7 categories: demographic variables (eg, age, sex, and insurance type), lifestyle-related variables (eg, smoking status and alcohol consumption), comorbidities (eg, presence of hypertension, renal impairment, or diabetes mellitus), PCI-related variables (eg, contrast volume, catheterization status, and left ventricular ejection fraction), laboratory tests (eg, troponin I and glomerular filtration rate [GFR]), medication status (eg, use of antiplatelets, statins, and beta blockers), and medication adherence indicators (eg, medication regimen complexity index [MRCI]).

The nutrition risk index was used to assess nutritional status, where low values indicate a high nutritional risk [29]. The catheterization status was categorized as elective, urgent, emergent, or salvage procedures based on the clinical context [30]. The MRCI was used to quantify the complexity of each patient's medication regimen; high scores reflected increased regimen complexity and potentially poor medication adherence [31,32]. Changes in the MRCI between admission and discharge (MRCI changed) were evaluated as a dynamic indicator of medication adjustment during hospitalization. Laboratory test values were collected on the basis of the most unfavorable results on the day of admission, reflecting the worst clinical status likely to influence outcomes. A complete list of all predictors and their detailed definitions is available in Multimedia Appendix 3.

Outcome Variable: MACE

The primary outcome of this study was the time to the first occurrence of MACE after hospital discharge as identified through EMRs. MACE was defined as a composite outcome comprising cardiovascular death, myocardial infarction, stroke, or revascularization according to standardized definitions from prior consensus guidelines [4,33]. The final date for data

XSL•FO
RenderX

collection was December 31, 2021, and survival time was calculated from the date of hospital discharge.

Statistical Analysis

Means and SDs were used to summarize continuous data; categorical data were reported as counts and percentages. Groups were statistically compared using 2-tailed *t* tests and chi-square tests.

For the time-to-event analysis, patients who did not experience MACE during follow-up were treated as censored cases, and MACE occurrence was coded as a binary outcome (1=event, 0=no event). Statistical analyses were performed using SPSS (version 25.0; IBM Corp), and the time-to-event ML model was developed in Python (version 3.9.13; Python Software Foundation). All tests were 2-tailed, and the significance level was set at $P<.05$.

Model Development

The valid ranges of all variables were reviewed and confirmed by the cardiology and cardiovascular nursing team involved in this study. Missing values were assumed to follow a missing-at-random pattern and handled using standard imputation techniques; specifically, the mode was used for binary and categorical variables, and the mean was used for continuous variables. Continuous variables were normalized using minimum–maximum scaling, and categorical variables were processed using one-hot encoding.

The dataset was stratified by MACE occurrence and randomly split into a training set (80%) and a test set (20%) to preserve the event-to-censoring ratio across sets. Five-fold cross-validation within the training set was applied to evaluate model discrimination and calibration and to minimize the risk of overfitting. Among the time-to-event ML models evaluated, Survival Quilts served as the primary algorithm. Survival Quilts is an open-source AutoML framework (implemented from Survival Quilts GitHub [34]) that constructs an ensemble of baseline time-to-event models and adaptively adjusts their weights across time horizons to optimize discriminative performance while maintaining calibration constraints [24].

In total, six time-to-event ML models were developed and compared: Survival Quilts, ensemble-based survival models including Random Survival Forest and CoxBoost (implemented with *scikit-survival* v0.23.0); parametric accelerated failure time models including LogNormal and Weibull (implemented with *lifelines* v0.30.0), and the Cox proportional hazards model (implemented with *scikit-survival* v0.23.0).

Model development was conducted using the training set, with 20% of this training data reserved as a validation subset for hyperparameter optimization. Hyperparameters were tuned through an exhaustive grid search. For ensemble models (Random Survival Forest and CoxBoost), the number of estimators was varied across (50, 100, 200, 300, 400, 500). For accelerated failure time models (LogNormal and Weibull) and the Cox model, 10 regularization coefficients logarithmically spaced between 10e-3 and 1 were tested. For Survival Quilts, time horizons were defined as (30, 60, 90, 180, 270, 365), while all other parameters were set to default values. Random seeds were fixed (seed=1234) across all analyses to ensure reproducibility.

Model Performance

The performance of the time-to-event ML models was evaluated on the basis of discrimination and calibration, which are essential factors for assessing the clinical use of time-to-event ML models [24]. Model performance was examined using the metrics tailored for right-censored data: the time-dependent concordance index (C-index) for discrimination and the time-dependent Brier score for overall prediction accuracy. The time-dependent C-index measures the effectiveness of the model in distinguishing individual risks at different time points, particularly in the presence of censored observations [35]. The time-dependent Brier score assesses the accuracy of predicted survival probabilities by comparing them with the actual distribution of observed events across multiple time points [36].

Permutation-based variable importance scores were calculated to assess the contribution of individual predictors to model performance. Through this method, the decrease in model performance is quantified when the values of a specific variable are randomly permuted, thereby disrupting its relationship with the outcome [37]. The greater the reduction in model performance, the greater the importance of that variable. The time-dependent C-index was used as the reference metric for assessing the effect of each permutation; a large drop indicated a strong influence on the model's discriminative power.

Partial dependence plots were used to show the effect of changes in each predictor on the model's predicted risk. For continuous variables, predictor values varied from minimum to maximum, and the corresponding changes in the predicted risk were plotted [25]. For binary variables, predictions were compared between 0 and 1. For categorical variables, predictions were calculated for each category.

Ethical Considerations

The study was conducted in accordance with the ethical principles outlined in the Declaration of Helsinki. This study was approved by the institutional review board of Seoul Metropolitan Government-Seoul National University Boramae Medical Center, Seoul, Korea (IRB No 30-2024-31).

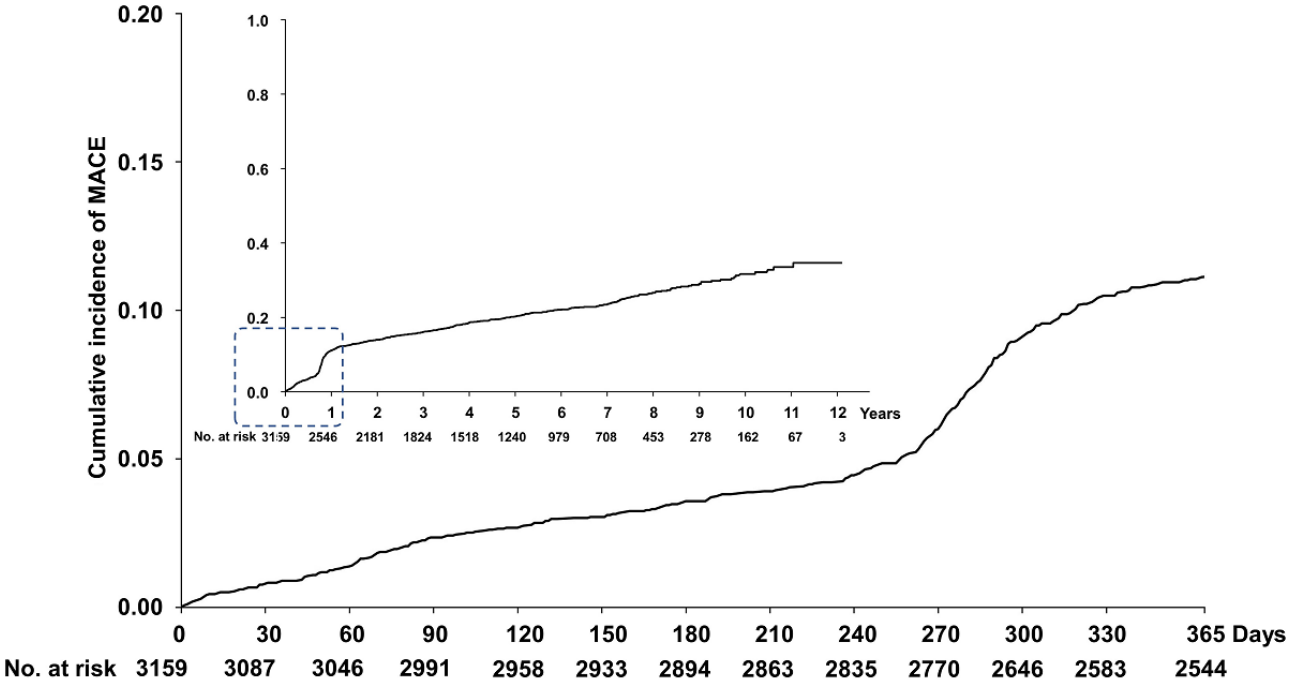
Results

Baseline Characteristics

The baseline characteristics of the study participants are summarized in Multimedia Appendix 4. The median follow-up duration for the total cohort (N=3159) was 3.8 (IQR 1.6-6.7) years; during follow-up, 626 (19.8%) patients experienced MACE. The mean age of the total patient population was 66.8 years, and 2084 (66%) patients were male. The MACE group was significantly older than the censored group (68.33, SD 11.29 vs 66.42, SD 11.77 years; $P<.001$).

Comorbidities were more common in the MACE group than in the censored group. The prevalence of hypertension was significantly higher in the MACE group (420/626, 67.1%) than in the censored group (1573/2533, 62.1%; $P=.02$). Similarly, higher proportions were observed for peripheral artery disease

XSL•FO
RenderX



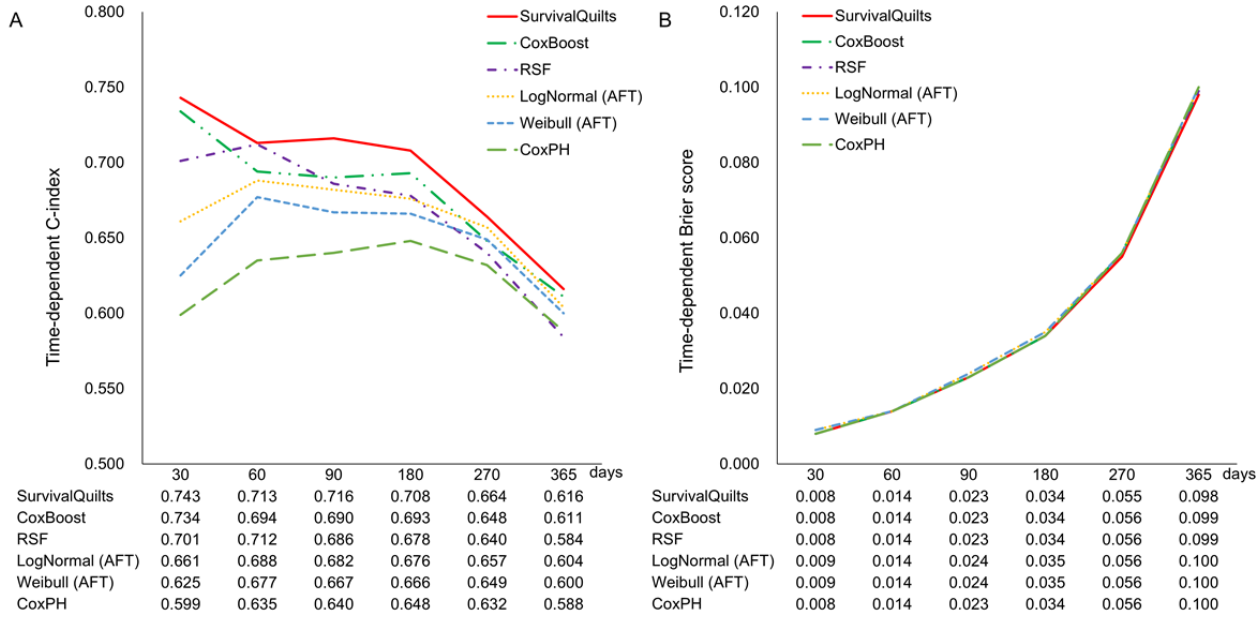
(23/626, 3.7% vs 41/2533, 1.6%; *P*=.002), atrial fibrillation (39/626, 6.2% vs 90/2533, 3.6%; *P*=.004), heart failure (50/626, 8% vs 81/2533, 3.2%; *P*<.001), chronic kidney disease (63/626, 10.1% vs 126/2533 5.0%; *P*<.001), and dialysis-dependent renal failure (32/626, 5.1% vs 49/2533, 1.9%; *P*<.001). The prevalence of diabetes mellitus differed significantly between the MACE and censored groups (χ^2_3=39.7, *P*<.001). Patients without diabetes were less common in the MACE group (361/626, 57.7%) than in the censored group (1718/2533, 67.8%).

Unstable angina was the most frequent ACS subtype (1703/3159, 53.9%) among patients who underwent PCI, and 50.4% (1592/3159) were admitted via the emergency department. Overall, 40.5% (1281/3159) of patients had three-vessel disease, and 7.3% (230/3159) had left main disease. The MACE group received a significantly larger contrast volume during PCI than the censored group (300.66, SD 140.38 mL vs 256.10, SD 125.98 mL; *P*<.001). The severity of CAD was also greater in the MACE group, with three-vessel disease observed in 53.7% (336/626) patients compared with 37.3% (945/2533) patients in the censored group (*P*<.001).

In general, patients who experienced MACE had lower lipid profiles and higher C-reactive protein levels than those without MACE. GFR was also lower in the MACE group (70.68, SD 28.73 mL/min/1.73 m² vs 77.25, SD 26.26 mL/min/1.73 m²; *P*<.001). Among baseline medications, the most frequently prescribed were antiplatelets (2932/3159, 92.8%), followed by nitrates (1992/3159, 63.1%) and statins (1706/3159, 54%). MRCI at discharge was significantly higher in the MACE group (26.14, SD 12.68 vs 24.91, SD 11.20; *P*=.03).

Figure 2 shows the Kaplan–Meier curve of the cumulative MACE rate after hospital discharge. The main graph presents the 1-year survival curve. Within 1 year, the incidence of MACE increased gradually over time; after approximately 270 days, it increased more sharply. The cumulative MACE rates were 0.8%, 3.6%, and 11.1% after 30 days, 180 days, and 1 year, respectively. Our analysis primarily focused on the first year following discharge because most MACE occur, and early intervention is likely to be the most effective during this period.

Figure 2. Incidence of major adverse cardiac events (MACE) after percutaneous coronary intervention (PCI) in patients with acute coronary syndrome ACS.



Model Performance

We evaluated the predictive performance of the models for MACE by using the time-dependent C-index and the time-dependent Brier score (Figure 3). Figure 3A presents the time-dependent C-index of multiple models, including Survival Quilts, CoxBoost, Random Survival Forest, LogNormal, Weibull, and Cox proportional hazards model. We compared the model performance on days 30, 60, 90, 180, 270, and 365. Although the time-dependent C-index values decreased over time across all models, the Survival Quilts model consistently demonstrated the highest discriminative performance at each time point. It also showed the highest C-index of 0.743 on day 30, but this index gradually declined to 0.616 on day 365. Figure 3B displays the time-dependent Brier scores for the same models. Overall, the Brier scores increased over time. All models demonstrated comparable and stable Brier scores in the observed time points.

XSL•FO
RenderX

Among the 6 time-to-event ML models compared, Survival Quilts exhibited the best overall performance based on the time-dependent C-index and Brier score. Therefore, Survival Quilts was defined as the best model in this study, and subsequent analyses, including predictor importance and time-varying risk contribution, were conducted using this model. A web-based demonstrator of the best-performing model is available at Streamlit [38], where individualized MACE risk predictions based on the Survival Quilts algorithm can be interactively explored.

Variable Importance in the Best Model

Table 1 presents the permutation-based variable importance of the best model at different time points. At 30 days post discharge, contrast volume emerged as the strongest predictor, followed by age and the MRCI at discharge. On day 60, the most important predictor was CAD severity, followed by GFR. Conversely, the importance of age and MRCI at discharge decreased. After day 60, CAD severity and GFR remained the most important predictors throughout the follow-up.

Table 1. Top 10 predictor variables for major adverse cardiovascular events (MACE) over time in the best machine learning model.

Rank	30 days	60 days	90 days	180 days	270 days	365 days

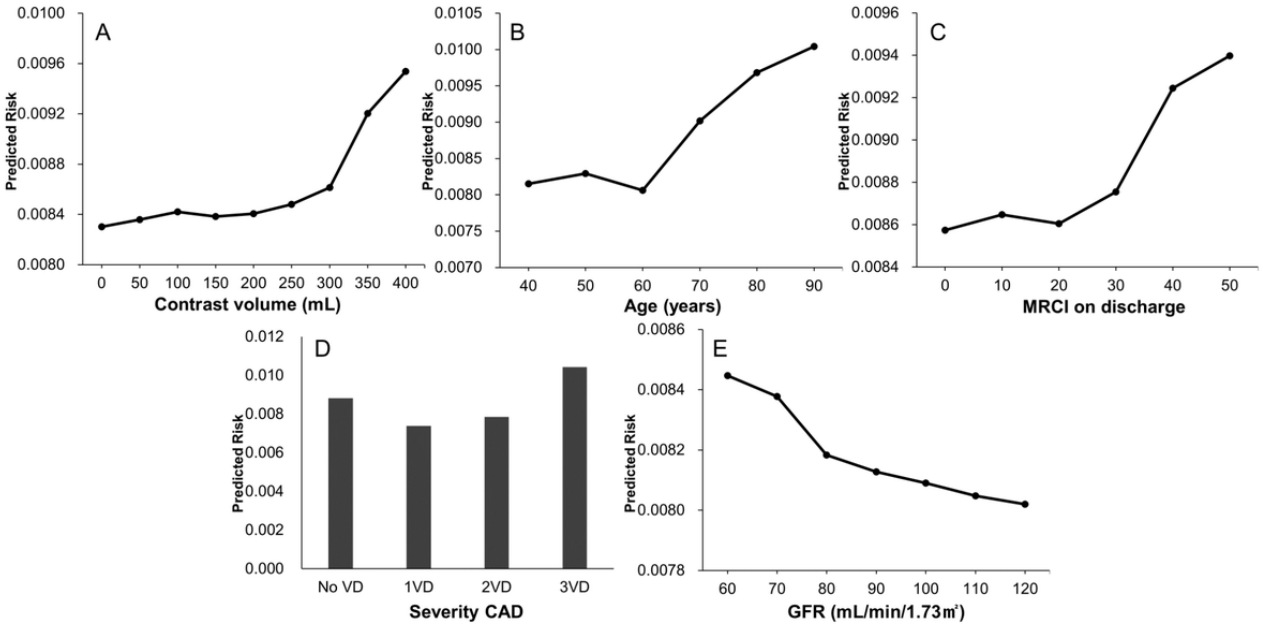
Figure 4 shows the partial dependence plots of the top predictors in the best model: contrast volume, age, MRCI at discharge, CAD severity, and GFR. An increase in contrast volume was associated with a high risk of MACE occurrence, particularly when the contrast volume exceeded 300 mL (Figure 4A). Age showed similar predicted risks of MACE occurrence among patients aged 40-49 years and 60-69 years; however, the risk increased sharply in patients aged >60 years (Figure 4B). The MRCI at discharge minimally influenced the MACE occurrence risk up to a score of 20, but the risk progressively increased above this threshold; it showed a steep rise beyond 30 points (Figure 4C). The MACE occurrence risk of patients with three-vessel disease was higher than that of patients with single- or two-vessel disease (Figure 4D). A high GFR was associated with a low MACE occurrence risk, while the risk increased sharply in patients with GFR below 80 mL/min/1.73 m^2 (Figure 4E).

Figure 4. Partial dependence plots of key predictors of major adverse cardiovascular events (MACE) based on the best machine learning (ML) model. (A) Contrast volume and predicted risk of MACE. (B) Age and predicted risk of MACE. (C) The medication regimen complexity index (MRCI) at discharge and predicted risk of MACE. (D) Severity of coronary artery disease (CAD) and predicted MACE. (E) The glomerular filtration rate (GFR) and predicted risk of MACE. VD: vessel disease.



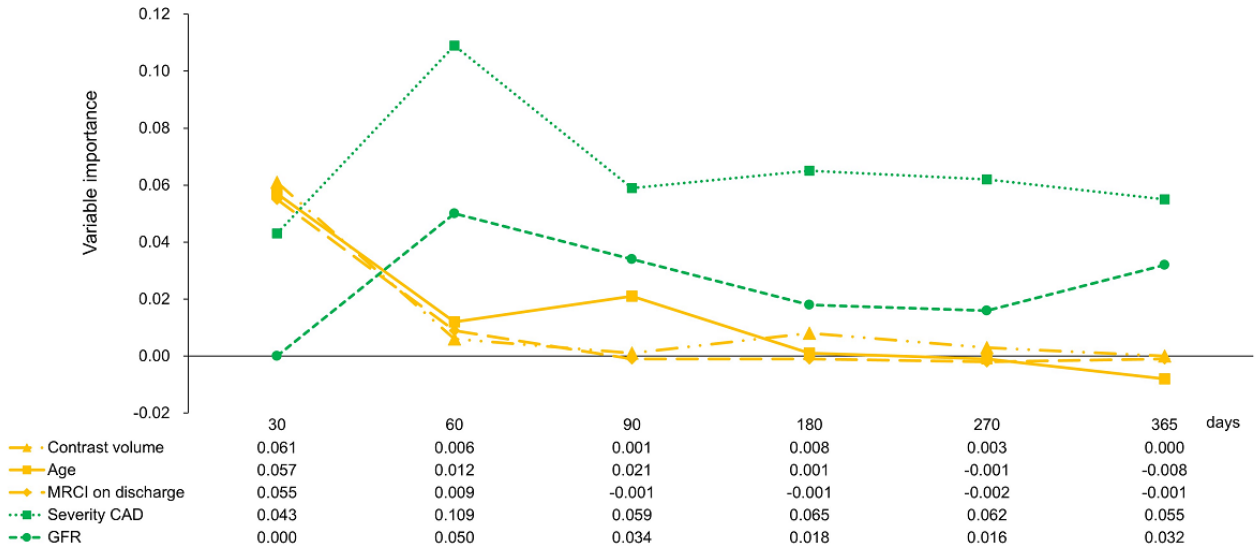


Figure 5 illustrates the time-varying patterns of variable importance for the key predictors based on permutation analysis. Contrast volume, age, and MRCI at discharge showed the highest importance on day 30, but they gradually declined over time. Conversely, CAD severity and GFR became more important after day 60 and maintained high importance throughout the follow-up.

Figure 5. Temporal variation in the importance of key variables in the best machine learning (ML) model. CAD: coronary artery disease; GFR: glomerular filtration rate; MRCI: medication regimen complexity index.

Discussion

Overview

We identified 5 key predictors, namely, contrast volume, age, medication adherence (measured by MRCI at discharge), severity of CAD, and GFR, which showed time-varying importance in predicting MACE after PCI in patients with ACS. The risk of MACE occurrence exhibited nonlinear patterns; specifically, abrupt changes were observed at specific thresholds rather than a steady increase or decrease. Furthermore, the temporal patterns of predictor importance revealed 2 distinct trends. First, contrast volume, age, and medication adherence were the most influential predictors within the first 30 days after hospital discharge; however, their importance diminished over time. Our findings highlighted the importance of optimizing care during the early postdischarge period to prevent early adverse events. Second, CAD severity and renal function emerged as the dominant predictors after 60 days and remained consistently important throughout the follow-up. These insights were obtained through the application of a time-to-event ML framework. This framework could be used to identify nonlinear risk patterns and temporal changes in predictor importance, which are difficult to achieve using traditional statistical methods. By focusing on the first year after discharge, the period of the highest clinical vulnerability could be determined. Thus, actionable insights into timely intervention could be provided.

Early Hospital Discharge Period: Within 30 Days

In this study, the risk of MACE increased sharply when the contrast volume exceeded 300 mL. Contrast volume was identified as the most important variable in the early hospital discharge period, particularly within the first 30 days. The sharp increase in MACE risk above the 300 mL threshold suggests a nonlinear relationship; thus, contrast volume was an important early determinant of MACE after PCI. This finding highlighted the relevance of minimizing contrast exposure during the procedure to reduce MACE early after hospital discharge.

Our results were consistent with previous studies reporting the association between a higher contrast volume and the increased risk of contrast-induced nephropathy and MACE [39,40]. Saito and Kobayashi [41] examined patients with ACS who received PCI and found that those treated for multivessel disease received a higher average contrast volume (295 mL) than those with single-vessel disease (180 mL); they also exhibited a significantly increased MACE incidence. Similarly, Yao et al [40] reported that contrast volumes exceeding 300 mL are a strong independent risk factor for kidney injury, which in turn increases MACE incidence. Notably, Ng et al [39] showed that contrast-induced nephropathy is associated with an approximately 82% increase in MACE risk within the first 30 days after discharge; however, they also demonstrated that this risk decreased to 13% between 30 days and 1 year and was no longer statistically significant beyond 12 months.

This time-varying importance of contrast volume may be explained by the transient effect of contrast-induced renal injury occurring in the early post-PCI period. The early increase in MACE risk is attributed to the occurrence of acute kidney injury shortly after PCI; however, its effect decreases as renal function stabilizes over time [42]. Therefore, targeted efforts to minimize contrast use are crucial, particularly in the periprocedural and early period after hospital discharge.

From a clinical perspective, the health care team should work collaboratively to reduce contrast use during PCI. After PCI, information regarding contrast volume should be clearly communicated to the ward team to facilitate ongoing monitoring of renal function, particularly in patients who receive more than 300 mL of contrast and may require closer follow-up. Previous quality improvement initiatives established that interdisciplinary collaboration could reduce the incidence of contrast-induced renal impairment by up to 21% [43]. In patients who had ACS treated with PCI and received a large contrast volume, outcome improvement may depend on effective interdisciplinary communication and coordinated care efforts. In addition, emerging technologies such as the dynamic coronary roadmap, which provides real-time vascular guidance without the need for repeated contrast injections, show potential for applications in further reducing contrast volume during PCI [44]. The adoption of such innovations in clinical practice may help prevent contrast-related complications and reduce the incidence of MACE following PCI.

In this study, age was identified as an important predictor of MACE, particularly in the early period after hospital discharge. The risk of MACE remained relatively stable among patients aged 40-60 years but increased sharply in those older than 60 years. The importance of age as a predictor was highest at 30 days after discharge and decreased over time. This finding suggested that older patients are at a greater risk of early MACE following PCI and may benefit from closer monitoring during this period. These results were consistent with prior evidence suggesting that age is a recognized contributor to an increased MACE risk [45-47]. The increased vulnerability associated with advancing age may be explained by the cumulative effects of vascular degeneration, increased prevalence of comorbidities, and reduced medication adherence [45,47]. Helber et al [48] reported that patients aged 75 years and older who underwent PCI for ST-elevation myocardial infarction (STEMI) have higher risks of in-hospital complications, including bleeding, cardiogenic shock, and mortality, than younger patients. However, Chen et al [49] found that MACE incidence does not significantly differ between older and younger groups at 6 months post-PCI. This result supports the interpretation that the influence of age on MACE risk diminishes over time as the effect of acute complications decreases. These findings indicate that management immediately after the hospital discharge of older patients with ACS subjected to PCI may help reduce the risk of early MACE through enhanced surveillance and tailored interventions.

A key finding of this study is that lower medication adherence, as reflected by higher MRCI at discharge, was notably related to a higher likelihood of MACE occurrence, particularly during the early period after hospital discharge. In our cohort, the mean MRCI score at discharge was approximately 25, which typically indicated that patients were prescribed 2 or more additional medications beyond standard PCI-related medications because of comorbid conditions.

XSL•FO
RenderX

Further subgroup analysis based on MRCI component scores, namely, dosage forms, dosing frequency, and additional user instructions, revealed that the patients with MRCI scores of 20, 25, and 30 exhibited a progressively higher MACE risk (Multimedia Appendix 5). Differences in dosage forms were significant only between the lowest (20) and highest (30) score groups; conversely, dosing frequency and additional user instructions significantly differed across all 3 groups. These findings indicated that all components of medication adherence—namely, dosage forms, dosing frequency, and additional user instructions—play a meaningful role in influencing MACE risk; therefore, comprehensive strategies should be developed to simplify medication regimens. This finding is consistent with earlier research, which indicated that the increased regimen complexity reduces medication adherence and consequently raises MACE risk [50,51]. In this study, the predictive importance of medication adherence was also the highest within the first 30 days during the early period after hospital discharge and declined thereafter. Therefore, early intervention strategies should be developed to simplify medication regimens and improve adherence, particularly during the early period after hospital discharge, to reduce the risk of MACE.

Later Hospital Discharge Period: From 60 Days to 1 Year

In this study, CAD severity and renal function, measured by GFR, emerged as the most important predictors of MACE during the later period after hospital discharge, particularly beyond 60 days. Patients with more severe CAD, especially those with three-vessel disease, showed a consistently higher risk of MACE over time. Similarly, reduced GFR was related to an increased risk of MACE, independent of acute kidney injury related to contrast exposure.

These findings were consistent with prior research, which demonstrated that the extent of CAD reflects the burden of atherosclerosis, which increases the likelihood of new lesion development or restenosis over time [52]. Three-vessel disease has been well established as a predictor of long-term MACE because of factors such as persistent myocardial ischemia, plaque instability, and progression of atherosclerosis [4,45,47]. Regarding renal function, our findings highlight that lower GFR remained a significant independent risk factor for MACE even beyond the early period of PCI. This finding was consistent with previous studies showing that reduced GFR, reflecting chronic kidney dysfunction, independently contributes to increased MACE regardless of contrast-induced acute kidney injury [53]. Decreased GFR reflects the progression of chronic kidney disease, which is closely associated with the increased long-term MACE incidence [54].

Time-to-Event ML for Risk Prediction

The application of a time-to-event ML framework enabled the identification of time-varying predictor importance and nonlinear risk patterns for MACE following PCI in patients with ACS. Through this approach, risk estimation can be performed to reflect the changes over time at different hospital discharge periods, which is difficult to achieve using traditional statistical models, such as the Cox proportional hazards model. These findings were consistent with previous studies that demonstrated the utility of time-to-event ML models in various clinical contexts. For example, Choi et al [25] applied a time-to-event ML approach to patients who experienced cardiac arrest and showed that temporal changes in predictor importance can guide the optimal timing of reperfusion therapies. Similarly, Lee et al [24] highlighted that incorporating time-to-event ML improves prediction accuracy and supports more informed clinical decision-making.

The ability of time-to-event ML models to determine changes in risk over time and nonlinear relationships provides meaningful advantages in long-term risk prediction. In patients with ACS undergoing PCI, this approach offers the potential to inform the timing of tailored interventions based on changes in risk over time. Future studies are warranted to validate these methods in larger and more diverse patient populations and to explore their integration into real-time clinical decision support systems.

Strengths and Implications

This study has several key strengths. First, we developed a ML model specifically for patients with ACS undergoing PCI; thus, MACE could be more accurately predicted by incorporating time-to-event information. Second, we identified nonlinear risk patterns and specific thresholds for key predictors using permutation-based variable importance and partial dependence plots, providing deeper insights into risk dynamics. Third, our approach could estimate how risk changes over time, which can support the planning of tailored interventions at different time points after hospital discharge.

Limitations

This study is subject to several limitations. First, because the model was developed and internally validated using data from a single center, there remains a potential risk of overfitting and optimistic performance estimates despite the use of 5-fold cross-validation. External validation using multicenter data is required to confirm generalizability. Second, missing values were handled under a missing-at-random assumption using simple imputation. However, this approach may underestimate variability and does not fully capture the uncertainty associated with missing data. More advanced strategies, such as multiple imputation or the k-fold cross validation, could be explored in future work to reduce potential bias. Third, as this study relied on EMR data, the available predictors were limited; some potential risk factors, such as psychosocial variables including stress, were also not considered. Fourth, all patient data were collected prior to PCI, and laboratory values were represented using either maximum values or averaged results from multiple measurements. Thus, temporal changes in patient condition after PCI were not reflected in the model. Fifth, medication adherence was indirectly assessed using the MRCI, which measures regimen complexity rather than actual adherence behavior. Although MRCI demonstrated good reliability in this population, future studies should incorporate the direct measures of medication adherence to improve predictive accuracy. Sixth, although the study identified a nonlinear relationship between contrast volume and MACE risk, particularly beyond 300 mL, factors such as body weight and renal function ratio were not

XSL•FO
RenderX

considered; results should be carefully interpreted, and further investigation should be performed. Finally, because of the nature of secondary data analysis, there may have been data entry errors or missing values, which could have influenced the results. Despite these limitations, this study provides meaningful contributions by demonstrating the utility of time-to-event ML in predicting MACE in patients with ACS undergoing PCI and by identifying key risk factors that may inform clinical practice.

Conclusions

We developed a time-to-event ML model to predict MACE in patients with ACS undergoing PCI. This model incorporated time-dependent risk estimation during the entire follow-up; thus, nonlinear risk patterns and temporal changes in predictor importance could be identified, thereby enhancing interpretability and clinical applicability. Notably, contrast volume, age, and medication adherence exhibited the greatest influence within the first 30 days after hospital discharge; conversely, the severity of CAD and GFR became more influential in the later period, particularly beyond 60 days. Although the model was trained using full follow-up data, our findings highlighted that the first year after discharge was a critical window for intervention. During this period, targeted strategies, such as minimizing contrast use, closely monitoring renal function, and improving medication adherence, might provide the most clinical benefit. These insights might help health care providers implement time-informed, personalized strategies to improve patient outcomes.

Abstract

Background: Prolonged hospital stays can lead to inefficiencies in health care delivery and unnecessary consumption of medical resources.

Objective: This study aimed to identify key clinical variances associated with prolonged length of stay (PLOS) in clinical pathways using a machine learning model trained on real-world data from the ePath system.

Methods: We analyzed data from 480 patients with lung cancer (age: mean 68.3, SD 11.2 years; n=263, 54.8% men) who underwent video-assisted thoracoscopic surgery at a university hospital between 2019 and 2023. PLOS was defined as a hospital stay exceeding 9 days after video-assisted thoracoscopic surgery. The variables collected between admission and 4 days after surgery were examined, and those that showed a significant association with PLOS in univariate analyses (P<.01) were selected as predictors. Predictive models were developed using sparse linear regression methods (Lasso, ridge, and elastic net) and decision tree ensembles (random forest and extreme gradient boosting). The data were divided into derivation (earlier study period) and testing (later period) cohorts for temporal validation. The model performance was assessed using the area under the receiver operating characteristic curve, Brier score, and calibration plots. Counterfactual analysis was used to identify key clinical factors influencing PLOS.

Results: A 3D heatmap illustrated the temporal relationships between clinical factors and PLOS based on patient demographics, comorbidities, functional status, surgical details, care processes, medications, and variances recorded from admission to 4 days after surgery. Among the 5 algorithms evaluated, the ridge regression model demonstrated the best performance in terms of both discrimination and calibration. Specifically, it achieved area under the receiver operating characteristic curve values of 0.84 and 0.82 and Brier scores of 0.16 and 0.17 in the derivation and test cohorts, respectively. In the final model, a range of variables, including blood tests, care, patient background, procedures, and clinical variances, were associated with PLOS. Among these, particular emphasis was placed on clinical variances. Counterfactual analysis using the ridge regression model identified 6 key

XSL•FO
RenderX

variables strongly linked to PLOS. In order of impact, these were abnormal respiratory sounds, postoperative fever, arrhythmia, impaired ambulation, complications after drain removal, and pulmonary air leaks.

Conclusions: A machine learning–based model using ePath data effectively identified critical variances in the clinical pathways associated with PLOS. This automated tool may enhance clinical decision-making and improve patient management.

Introduction

Prolonged length of stay (PLOS) remains a persistent challenge in modern health care, contributing to inefficient resource use, increased health care costs, and delayed recovery [1]. To address these concerns, hospitals have adopted strategies such as standardized clinical pathways designed to streamline care and promote timely discharge [2,3]. Despite these efforts, PLOS remains common, particularly among surgical patients, due to factors such as postoperative complications, functional decline, and comorbidities.

Identifying patients at high risk of PLOS is crucial for enabling timely and targeted interventions. However, predicting PLOS in routine clinical settings remains challenging due to the complex and dynamic nature of patient conditions and the multidimensional nature of clinical data. Recent advancements in electronic clinical pathways have enabled systematic, real-time recording of deviations from expected recovery trajectories—referred to as “variances” [2]. These variances may reflect meaningful clinical events and could provide valuable insights for predicting outcomes such as PLOS. Nevertheless, predictive systems that fully leverage variance data remain underdeveloped.

To address this gap, we developed a novel electronic clinical pathway system called “ePath,” which records outcomes, outcome assessments, and associated tasks in a structured format known as the outcomes-assessments-tasks (OAT) unit. ePath integrates seamlessly with electronic medical records via a custom data conversion interface and provides a standardized data model for pathway-based care [4-6].

In this study, we applied machine learning algorithms to real-world ePath data from patients undergoing video-assisted thoracoscopic surgery (VATS) for lung cancer, aiming to develop a robust model to predict PLOS risk. VATS has become widely adopted as a minimally invasive alternative to traditional open thoracotomy and is associated with shorter hospital stays and lower health care costs [7-14]. These cost savings are largely attributed to a reduction in PLOS [11,14]. However, a considerable proportion of patients still experience prolonged hospitalization, highlighting the need for more advanced predictive tools.

The objective of this study was to develop an accurate and clinically actionable PLOS prediction model using machine learning applied to variance data captured by ePath. Establishing such a system could enable timely interventions and support clinical decision-making to reduce PLOS.

Methods

Ethical Considerations

The study design was approved by the Certified Review Board of the Clinical Research Network Fukuoka (M23082-00). The requirement for informed consent was waived, as this was a retrospective study using anonymized records. No compensation or incentives were provided to participants because this retrospective study used anonymized data and did not involve direct contact with individuals.

Study Design

This study included patients with lung cancer hospitalized at Kyushu University Hospital in Fukuoka, Japan, who received treatment via the VATS electronic clinical pathway. The ePath system implemented at Kyushu University Hospital in 2018 has been described in previous publications [4-6]. Inpatient clinical data were electronically collected through ePath and compiled into a dataset for outcome prediction using machine learning models.

Clinical Outcomes

The clinical outcome of interest, PLOS, was defined as a postoperative hospital stay exceeding 9 days based on the target length of stay outlined in the clinical pathway at Kyushu University Hospital.

Clinical Variables

Data collected during routine inpatient care were comprehensively recorded in the ePath system and used as variables. ePath is an electronic clinical pathway platform developed to standardize and share clinical pathways across multiple electronic medical record systems [4-6]. It facilitates the systematic collection and analysis of related clinical data, thereby supporting the application of artificial intelligence in routine clinical practice. The variables included baseline patient characteristics, functional status, pharmacotherapy, surgical procedures, care processes, variance, and laboratory results.

Baseline patient characteristics, functional status, care procedures, and pharmacotherapy were obtained from the Diagnosis Procedure Combination database, Japan’s medical billing data system, which comprises forms 1, H, and EF files. Form 1 contains demographic information, diagnoses, and disease severity. The H file provides daily records of physical condition, patient care, and activities of daily living. The EF file details daily pharmacotherapy, surgeries, and other clinical activities.

XSL•FO
RenderX

Care processes, outcomes, and variances were embedded in the electronic clinical pathway and collected using the ePath system. The clinical pathway data comprised OAT and variances for each care process during hospitalization; these were collectively referred to as OAT units [4-6]. The OAT units included expected outcomes, assessments of outcomes, and tasks required for assessments, all of which are interlinked. Deviations from predefined care processes were recorded as variances in the OAT units.

Laboratory results were obtained from the laboratory database using the Standardized Structured Medical Information eXchange, a standardized clinical data export system.

The number of discharges began to increase on postoperative day 5. To minimize the impact of missing values due to discharge and to reduce the risk of reverse causality, we limited the candidate explanatory variables to those available by postoperative day 4. From these, we first excluded variables with high overall missingness or outcome-related missingness, as these could introduce substantial bias. Although regularization methods are designed to mitigate overfitting, our previous research showed that including a large number of variables improved apparent prediction accuracy in the derivation cohort but reduced performance in the validation cohort, likely because of high-dimensional noise. To optimize model performance while maintaining generalizability, we used a 2-step variable selection process that combined the exclusion of variables with high missingness and univariate screening. This hybrid approach enabled us to retain clinically important predictors, reduce noise, and enhance the robustness of the final model [15].

Study Participants

Between July 2019 and May 2023, a total of 577 patients with lung cancer at Kyushu University Hospital underwent VATS treatment. Daily patient data were collected using the ePath system, resulting in 1562 variables. To reduce potential bias, the selection of both the explanatory variables and patients was based on the method described above. We excluded 18 variables with significant differences in PLOS status and 106 with a missing rate of >10%. Of the remaining variables, from those with a univariate significance level of $P<.01$ between the PLOS groups, 63 variables from the day with the lowest P values (from admission to postoperative day 4) were chosen as explanatory variables. Patients with missing data for any of these 63 key variables were excluded, resulting in a final cohort of 480 patients for complete case analysis. Figure S1 in Multimedia Appendix 1 shows the flowchart detailing the variables and patient selection process.

Machine Learning–Based Model

The PLOS prediction model was developed using machine learning algorithms, including sparse linear regression models (Lasso [16], ridge [17], and elastic net [18]) and decision tree ensemble models (random forest [19] and extreme gradient boosting [XGBoost] [20]), following previous research [15]. These algorithms include L1, L2, and mixed regularization techniques for linear models; random forest as a bagging-based decision tree ensemble model using parallel trees; and XGBoost as a boosting-based decision tree model using sequential trees.

The algorithms used in this study were selected considering their complementary strengths. Real-world clinical datasets often contain variables with multicollinearity. To address this issue, we used regularized regression models (ie, Lasso, ridge, and elastic net), which incorporate penalty terms (based on the absolute values, squares, or both) into their loss functions to suppress variance inflation caused by multicollinearity. We also used tree-based ensemble models (ie, random forest and XGBoost), which are inherently robust to multicollinearity because they do not rely on regression coefficients or the inversion of a design matrix. Additionally, sparse regression models offer interpretable, coefficient-based outputs and perform well with high-dimensional clinical data, whereas tree-based models are capable of capturing nonlinear interactions and assessing variable importance.

For each algorithm, hyperparameters were optimized using grid search with 5-fold cross-validation within the derivation cohort (refer to Multimedia Appendix 2 for details). This process was designed to maximize predictive performance while minimizing the risk of overfitting.

The study period was divided into early and late phases, with April 2022 constituting the boundary due to reimbursement revisions and staff turnover in Japan. To assess the generalizability of the predictive model, we used a temporal validation approach. For temporal validation, patients admitted during the early phase (July 2019 to March 2022) were included in the derivation cohort, whereas those admitted during the late phase (April 2022 to May 2023) were included in the test cohort. The model was developed using data from July 2019 to March 2022 and validated with data from April 2022 to May 2023.

To evaluate model performance, we used the area under the receiver operating characteristic curve (AUROC) to assess discrimination and both calibration plots and Brier scores to evaluate calibration (ie, the agreement between predicted probabilities and observed outcomes). AUROC provides a threshold-independent measure of a model's ability to distinguish between positive and negative cases. The Brier score quantifies the accuracy of probabilistic predictions, while calibration plots visually assess the alignment between predicted and observed probabilities. These metrics are widely used in clinical prediction research and offer complementary perspectives on model performance.

For internal validation, the derivation data underwent 5-fold cross-validation, and the AUROC was calculated. For external validation, the model developed using the derivation data was applied to the test data to calculate the AUROC. Calibration plots were created by dividing the predicted PLOS probabilities into 10 groups and plotting the average predicted PLOS probability against the observed PLOS rate for each group.

Variable importance was assessed using standardized regression coefficients in sparse regression models, MeanDecreaseAccuracy in a random forest, and Gain in XGBoost. All the variables in each predictive model were ranked by importance, with percentages calculated relative to the highest value. These percentages were then averaged across all machine learning algorithms to determine the top-ranking variables, and the values across the models were compared.

XSL•FO
RenderX

The algorithm and variables with the best predictive performance were selected as the final models. Using this final model, differences in PLOS probabilities were estimated for the test cohort based on the presence or absence of variance within OAT units. Variance variables were selected from the highest-ranking variables in the final model based on their importance. This estimation involved comparing PLOS probabilities, assuming that all patients had variances, with actual variance values.

Statistical Analysis

Differences in frequency based on PLOS presence were tested using the χ^2 test or Fisher exact test, while continuous variables were used for the Mann-Whitney *U* test. Differences in the predicted PLOS probabilities (assuming all variances vs actual variances) were evaluated using the Wilcoxon signed-rank test. Machine learning model development and statistical analyses were performed using the R statistical package (version 4.0.5; R Foundation for Statistical Computing). Statistical significance was defined as a 2-sided $P<.05$. The detailed R code is provided in Multimedia Appendix 2.

Results

Baseline Characteristics of the Patients

The study included 480 patients with lung cancer, with a mean age of 68.3 (SD 11.2) years, of whom 263 (54.8%) were men. Of the 480 patients, 141 (29.4%) had PLOS (Figure S2 in Multimedia Appendix 1). The baseline characteristics were compared according to the PLOS status (Table 1). The patients with PLOS were older, included a higher proportion of men, and had a higher smoking index. In addition, a lower proportion of patients underwent wedge resection in the PLOS group.

Table 1. Baseline characteristics of patients with and without prolonged length of stay (PLOS; n=480).

	Without PLOS (n=339)	With PLOS (n=141)	*P* value
Age (y), mean (SD)	67.0 (11.4)	71.5 (9.8)	<.001
Male, n (%)	173 (51)	90 (63.8)	.01
BMI (kg/m^2), median (IQR)	23.3 (21.0-25.2)	22.6 (20.9-25.8)	.45
Diabetes mellitus, n (%)	43 (12.7)	22 (15.6)	.48
Smoking index, median (IQR)	0 (0-600)	400 (0-900)	<.001
Type of surgery, n (%)			.005
Lobectomy	134 (39.5)	77 (54.6)	
Segmentectomy	45 (13.3)	19 (13.5)	
Wedge resection	160 (47.2)	45 (31.9)	

Time Course Changes in Variables Related to PLOS

A heatmap was created to visualize the relationship between daily clinical variables and PLOS, highlighting specific variables associated with an increased risk of PLOS. The heatmap provided temporal information on the timing since admission, measurement frequency of each variable, and their association with PLOS. Various factors, including the occurrence of variances (Figure S3 in Multimedia Appendix 1), activities of daily living (Figure S4 in Multimedia Appendix 1), treatments (Figure S5 in Multimedia Appendix 1), medications (Figure S6 in Multimedia Appendix 1), and laboratory results (Figure S7 in Multimedia Appendix 1), were significantly associated with PLOS at different time points.

Machine Learning–Based Prediction Models for PLOS

Five machine learning algorithms were used to develop prediction models in the derivation cohort. The ridge, elastic net, and random forest models showed high discrimination (Figure 1; Multimedia Appendix 3), with calibration plots indicating a good fit (Figure 2) and low Brier scores (Multimedia Appendix 3). These models were validated in the test cohort. Among the models, ridge regression demonstrated the best performance with high discrimination (Figure 3; Multimedia Appendix 4), good calibration (Figure 4), and a low Brier score (Multimedia Appendix 4). Consequently, it was selected as the final model, and the importance of the individual variables was assessed.

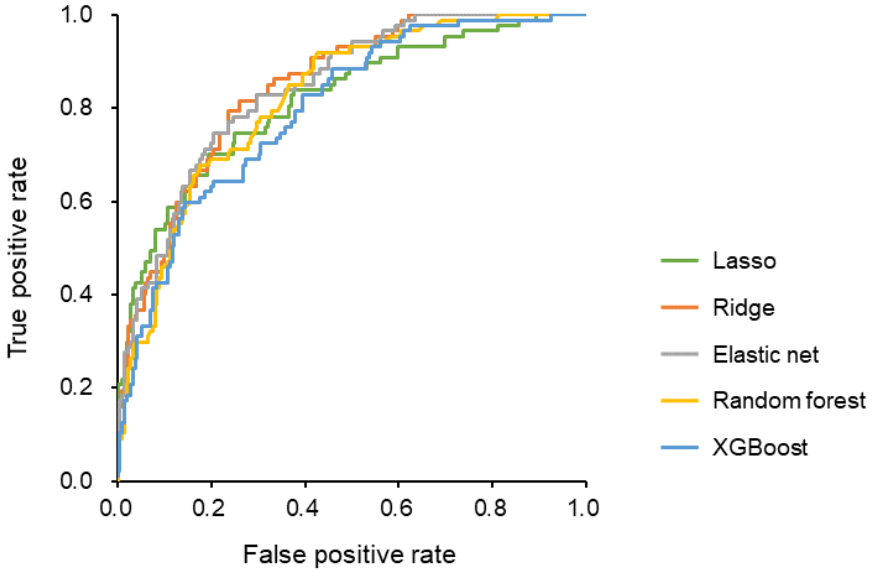
Figure 1. Discriminative performance of the prolonged length of stay (PLOS) prediction model in the derivation cohort. This figure demonstrates the predictive performance of the PLOS prediction model for the derivation cohort of patients admitted in the earlier phase. Variables were selected as predictors from each day between 2 days before VATS and 4 days after surgery based on the lowest *P* value in univariate analysis for each day by PLOS status. The model was developed with 5 machine learning algorithms: Lasso (green), ridge (orange), elastic net (gray), random forest (yellow), and extreme gradient boosting (XGBoost; blue). A 5-fold cross-validation was conducted, and the receiver operating characteristic curve is shown.



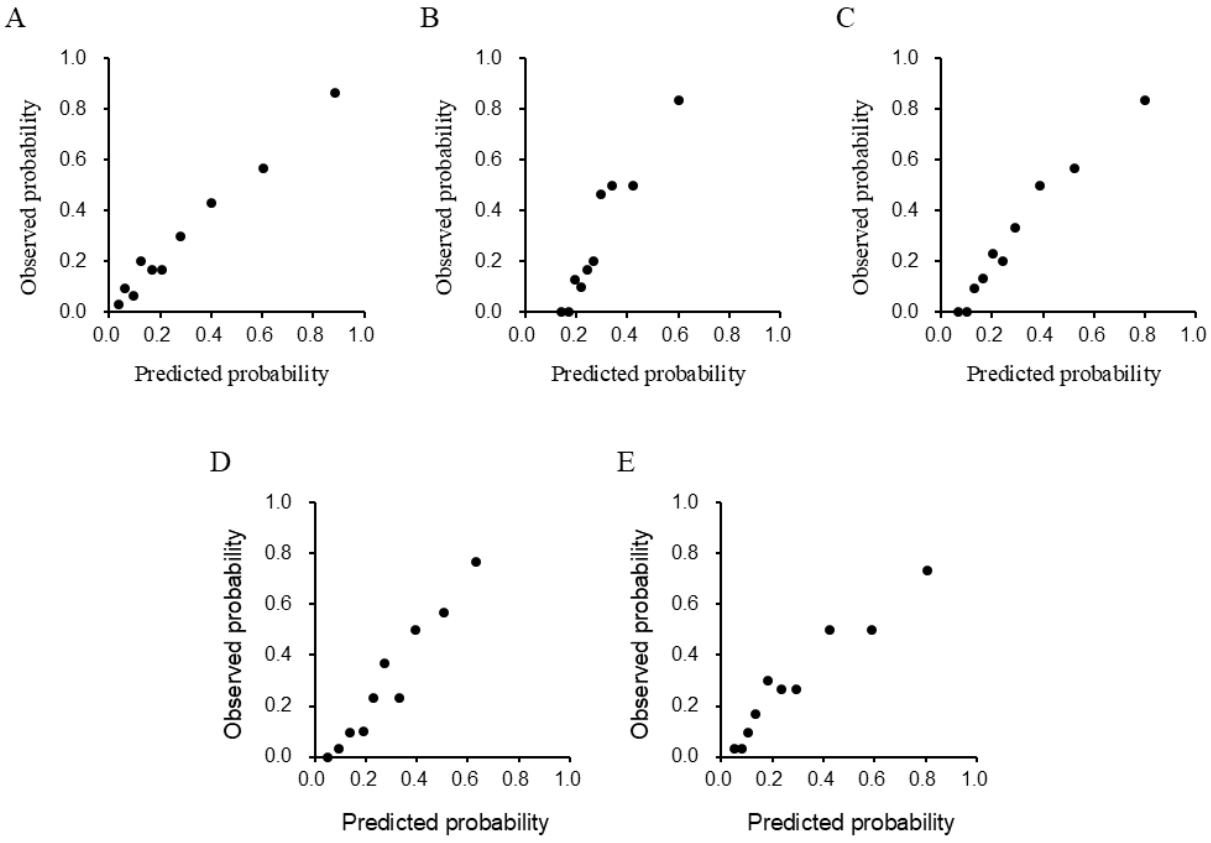


Figure 2. Calibration of the prolonged length of stay (PLOS) prediction model in the derivation cohort. This figure shows the calibration performance of the PLOS prediction model for the derivation cohort of patients admitted in the earlier phase. The model, constructed using 5 machine learning algorithms, namely, Lasso (A), ridge (B), elastic net (C), random forest (D), and extreme gradient boosting (XGBoost; E). The calibration plot divided patients into 10 groups based on predicted PLOS probabilities, with the mean predicted probability on the x-axis and the observed probability on the y-axis.

RenderX

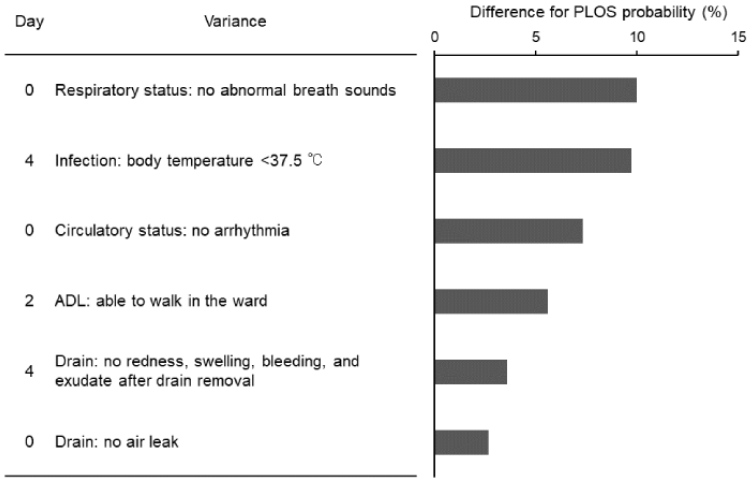
Variable Importance in Machine Learning–Based Prediction Models

We comprehensively analyzed the variable importance identified by the final ridge regression model (Figures S8 and S9 in Multimedia Appendix 1). The ridge regression analysis highlighted several key predictors, such as drain management, respiratory care, use of fibrin sealants, wedge resection, smoking index, age, and levels of C-reactive protein and albumin. Multimedia Appendix 5 shows the importance of the predictors identified by the final model.

Key Variances Influencing PLOS



The frequency of clinical variance differed between patients with and without PLOS (Multimedia Appendix 6). Using the final ridge model, we calculated the predicted probability of PLOS for each patient by comparing scenarios assuming a specific variance to be present in all patients with its actual occurrence in individual patients (Figure 5). This analysis identified 6 key postoperative variables whose presence significantly increased the predicted probability of PLOS: abnormal respiratory sounds (P<.001), fever (P<.001), arrhythmia (P<.001), inability to ambulate (P<.001), abnormal drain characteristics (P<.001), and air leak (P=.005; Figure 6). These were identified as critical variances associated with a higher risk of PLOS in this patient population.

Figure 5. Variance presence and changes in prolonged length of stay (PLOS) probability. This figure shows predicted PLOS probability distributions under different variance conditions: (a) assuming all patients exhibit specific variances ([A] respiratory status: no abnormal breathing sounds; [B] infection: body temperature <37.5 ˚C; [C] circulatory status: no arrhythmia; [D] activities of daily living (ADL): able to walk in the ward; [E] drain: no redness, swelling, bleeding, and exudate after drain removal; and [F] drain: no air leak), (b) under actual variance values, and (c) assuming each patient has variances. Box plots show PLOS probabilities for each condition per patient.

XSL•FO
RenderX

Figure 6. Change in prolonged length of stay (PLOS) probability based on the presence or absence of variances. This figure shows the percentage difference in predicted PLOS probabilities when the PLOS prediction model, developed in the derivation cohort, was applied to the temporally validated test cohort under 2 scenarios: assuming all patients had variances or using the actual presence or absence of variances. The final model was constructed using ridge regression, and the figure illustrates the estimated change in PLOS probability for each variance, assuming all patients exhibit them compared to actual values.

Discussion

Principal Findings

In this study, we successfully collected comprehensive real-world data using the ePath system from routine clinical practice. A heatmap was used to visualize the timing and emergence of factors potentially associated with PLOS. The importance of the variables, except the top-ranked ones, varied across machine learning algorithms. Temporal validation in the test cohort demonstrated that the ridge regression model performed well in both cohorts. Using this data-driven ridge model, we identified 6 key variances in the clinical pathway that significantly influenced the PLOS risk. Applying machine learning to real-world data allowed us to identify the variances contributing to PLOS, providing a foundation for potential mitigation strategies. This system is promising as a data-driven support tool that leverages electronic information to improve patient care in clinical practice.

Factors Related to PLOS

Compared with open surgery, VATS is associated with fewer postoperative complications and thus preferred for early-stage lung cancer [7-10,12,13,21]. However, postoperative complications can still arise, leading to potential PLOS [22-24]. Previous studies have identified various factors contributing to PLOS in patients undergoing VATS [25-37]. Many of these factors, such as age [25,27,31,32,34,36,37], male sex [25], BMI [25,31], functional status [25,31], smoking history [25,36], pulmonary function [25,28,31-34], comorbidities [25,26,30-32], tumor status [29,36], and the American Society of Anesthesiologists score [25,32,36], are challenging to modify after admission. Additionally, surgical factors [27-29,31,37], postoperative complications [28,29,37], and chest tube duration [29,30,32] are contributing factors that require further optimization from a surgical perspective.

In real-world settings, addressing modifiable factors before and after VATS is critical for effectively predicting and reducing PLOS. In this study, a heatmap was used to visualize the timing of the relevant factors and their associations with PLOS in the patient cohort. We assessed variable importance in machine learning–based models to identify the key contributors to PLOS risk. The identified factors are consistent with previously reported ones, such as age, smoking history, and surgical techniques (lobectomy and wedge resection), as well as laboratory results indicative of inflammation and malnutrition. Furthermore, we identified additional daily fluctuating factors, described as variances in clinical pathways, that may be associated with postoperative complications. These factors underscore the importance of close monitoring and targeted intervention to enable early and accurate prediction of PLOS and mitigate its impact.

Key Variances Influencing PLOS

Previous studies on PLOS-related factors have primarily focused on patient characteristics that are not easily modifiable during hospitalization, leading to a lack of clarity regarding specific in-hospital conditions associated with an increased PLOS risk. Moreover, many factors are interrelated, highlighting the need for a comprehensive assessment of how in-hospital conditions affect PLOS risk while adjusting for baseline patient characteristics. Clinical pathways capture variances or deviations from the expected course, enabling the identification of atypical patient trajectories. Recognizing the variances linked to higher PLOS risk can help identify at-risk patients early, optimizing patient care.

Although numerous factors influencing PLOS have been reported in previous studies, their impacts may vary across populations [25-37]. In our cohort, several variables significantly altered the PLOS risk, including postoperative abnormal respiratory sounds, arrhythmia, air leaks, fever, reduced mobility, and abnormal drain characteristics. These variances reflect underlying issues such as pulmonary air leaks, arrhythmias (eg, atrial fibrillation), postoperative infections, and functional impairments.

The emergence of variances may contribute to PLOS through these underlying causes. For instance, a prolonged air leak may

XSL•FO
RenderX

delay drain removal, arrhythmias and related complications may necessitate prolonged treatment, infections may require extended use of antibiotics and additional testing, and decreased activities of daily living may slow rehabilitation progress. Although these variances may also be interrelated, identifying and addressing the underlying causes of the 6 key variances may help reduce the risk of PLOS.

Once a variance occurs, prompt clinical intervention is essential. Evaluation of potential causes may include chest x-rays, blood tests (eg, arterial blood gas analysis, inflammatory markers, and electrolyte panels), and inspection of the drainage system. Interventions may include oxygen therapy, postural adjustments, enforced rest, infection control (eg, wound irrigation, disinfection, and dressing changes), administration of antiarrhythmic medications, early mobilization, antibiotic therapy for infections, or pleurodesis for persistent air leaks. Implementing a structured, variance-specific response protocol that integrates timely assessment and targeted intervention may be critical in minimizing PLOS.

Nonmodifiable factors during hospitalization, such as age and comorbidities, are beyond the scope of immediate interventions. However, by understanding how deviations from typical recovery (ie, variance) impact PLOS risk, we can target these specific variances for early intervention. By quantifying changes in the predicted PLOS probability under hypothetical scenarios of variance, we can objectively assess their impact on patient outcomes. Counterfactual analyses simulating changes in outcome probabilities may help estimate population-level effects, paving the way for clinical improvements using the ePath system.

When key variances associated with PLOS are identified, feedback should be provided to the medical team, followed by discussions and consideration of potential improvements. Wherever possible, the underlying causes of each variance should be addressed to prevent recurrence. For variances with significant clinical impact or those amenable to effective intervention, specific management strategies should be developed. Strengthening interprofessional collaboration, providing staff education on early response protocols, and evaluating outcomes can all contribute to continuous improvement. In this context, ePath can facilitate a sustainable plan-do-check-act or plan-do-study-act cycle.

In real-world clinical practice, the variances identified through our approach may help reduce PLOS if managed with appropriate clinical responses. For example, a variance response bundle or an actionable protocol triggered by the model could provide a formal structure for these interventions. Assessing whether such structured approaches reduce PLOS is an important next step.

Clinical Implications

Machine learning and deep learning are being increasingly applied in health care to uncover hidden patterns in complex datasets and generate predictive insights [38-40]. One of their most promising clinical applications is the automated prediction and visualization of outcomes such as PLOS, which can support clinical decision-making and enhance operational efficiency. However, predicting outcomes using real-world clinical data remains challenging due to its unstructured and heterogeneous nature [41].

To address these challenges, we developed the ePath system—an electronic clinical pathway system designed to systematically collect patient-level and care process data through an integrated workflow. In this study, we adopted a data-driven approach to explore potential causes of PLOS. As a result, we were able to confirm several clinical risk factors. Moreover, we provide novel insights by visualizing when and how specific changes in patient status contribute to the risk of PLOS. This was achieved by integrating a prediction model into the ePath system, enabling real-time, patient-specific visualization of PLOS risk. The structured nature of ePath facilitates robust, data-driven analysis and model development. Recently, tools using clustering techniques on real-world clinical data have been developed to support the design of clinical pathways for patients with lung cancer [42]. The integration of real-world data with pathway analysis via electronic health information systems may mark a new era in data-driven health care.

The novelty of our study lies in leveraging the ePath to capture real-time postoperative clinical variances and applying machine learning techniques to identify key factors associated with PLOS. By embedding the predictive models into a dashboard system, clinicians can visualize each patient's risk and corresponding clinical variances. When high-risk patterns are detected, the system can generate alerts that prompt timely interventions. Early and appropriate responses may help reduce unnecessary hospitalization and improve patient outcomes. In this way, the system has the potential to serve as an effective clinical decision support tool.

Beyond its clinical utility, ePath also offers managerial value. Hospitals can monitor the occurrence of variances and predicted PLOS risks across patient populations in real time. This enables data-driven decision-making for care delivery and supports the implementation of quality improvement initiatives. By tracking length of stay metrics before and after protocol modifications, institutions can assess the effectiveness of interventions and refine care pathways accordingly. Once validated, such interventions can be standardized and scaled across the organization.

It is important to note that factors contributing to PLOS can vary by institution and patient population [25,31] and may include not only clinical indicators but also social and operational factors [34]. Therefore, models developed using an institution's data—as enabled by ePath—may be particularly valuable for generating context-specific insights and designing tailored interventions.

Nonetheless, several barriers must be addressed to implement such a system effectively. First, a structured data collection infrastructure, such as ePath, must be established and integrated into clinical workflows. Second, model transparency is essential for clinicians' trust. While many machine learning models are often perceived as "black boxes," we selected ridge regression (L2 regularization) as our final model due to its strong performance and interpretability. This model effectively handles multicollinearity and provides coefficients with clear direction

XSL•FO
RenderX

and magnitude, which are easily interpretable in clinical contexts.

To further enhance interpretability, we used visualization techniques such as standardized coefficients and variable importance heatmaps. These tools can assist clinicians in understanding model outputs and recognizing the clinical relevance of key variances. Ultimately, the integration of predictive outputs into actionable clinical workflows—through protocols linked to specific alerts—will be essential for translating data insights into meaningful improvements in patient care.

Limitations

This study has several limitations. Because it used real-world data, issues such as missing values persisted even after dataset preprocessing. In this study, 97 patients were excluded from the complete case analysis (Multimedia Appendix 7), which may have introduced potential selection bias. Additionally, the misclassification of variables cannot be ruled out, which may introduce bias. Given the use of machine learning models, caution is required to address potential overfitting, which may reduce the generalizability of the results. Although we used methods such as 5-fold cross-validation to enhance generalizability and conducted temporal validation, the developed model may not be fully applicable to other patient populations. Moreover, to minimize overfitting from excessive noise, we performed initial variable selection by excluding potentially noncontributory variables. However, this approach may have excluded predictors that were not significant in univariate analyses but could become significant in a multivariate context, potentially reducing predictive accuracy. Further research is warranted to refine variable selection methods that address this methodological trade-off. Differences in health care systems, especially with Japan's universal health insurance system leading to longer hospital stays than international standards, could also affect the defined outcomes. The postoperative length of stay following VATS varies across countries. Numerous studies have reported a median hospital stay of 4 to 6 days after VATS [25-37]. Although the definition of PLOS differs in the literature—ranging from 2 to 14 days after surgery—it is most commonly set at 4 to 7 days. In this study, the median length of stay was 8 (IQR 7-10) days, and we defined PLOS as 9 days or more based on our institutional clinical pathway target. This threshold may be longer than those used in other countries, and therefore, cross-national comparisons should be interpreted with caution. Hospital length of stay is influenced by a wide range of factors that vary across hospitals, regions, and countries. In addition to patient-level clinical characteristics, institutional and systemic factors can significantly impact length of stay. These include health care financing and reimbursement systems, the availability of regional health care resources, hospital size and function, clinical staff expertise, adherence to clinical guidelines, the robustness of discharge planning infrastructure, access to postacute care services, and the presence of family support systems. This study was based on data from one university hospital, which may not be representative of the general hospital population. To enhance the generalizability of our findings, future research should include model retraining and validation using multicenter datasets, the incorporation of health care system–related variables into the models, and the development of customizable models that can be adapted to specific institutional or regional contexts.

Conclusions

Using the ePath system, we systematically collected real-world data and developed machine learning models to predict PLOS in a data-driven manner. Successful implementation of data-driven PLOS prediction for specific patient populations could serve as a valuable tool for evidence-based quality improvement in health care. However, additional validation is necessary to implement and operationalize these prediction systems in real-world clinical environments.

Abstract

Background: Reusing long-term data from electronic health records is essential for training reliable and effective health artificial intelligence (AI). However, intrinsic changes in health data distributions over time—known as dataset shifts, which include concept, covariate, and prior shifts—can compromise model performance, leading to model obsolescence and inaccurate decisions.

Objective: In this study, we investigate whether unsupervised, model-agnostic characterization of temporal dataset shifts using data distribution analyses through Information Geometric Temporal (IGT) projections is an early indicator of potential AI performance variations before model development.

Methods: Using the real-world Medical Information Mart for Intensive Care-IV (MIMIC-IV) electronic health record database, encompassing data from over 40,000 patients from 2008 to 2019, we characterized its inherent dataset shift patterns through an unsupervised approach using IGT projections and data temporal heatmaps. We trained and evaluated annually a set of random forests and gradient boosting models to predict in-hospital mortality. To assess the impact of shifts on model performance, we checked the association between the temporal clusters found in both IGT projections and the intertime embedding of model performances using the Fisher exact test.

Results: Our results demonstrate a significant relationship between the unsupervised temporal shift patterns, specifically covariate and concept shifts, identified using the IGT projection method and the performance of the random forest and gradient boosting models (P<.05). We identified 2 primary temporal clusters that correspond to the periods before and after *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) implementation. The transition from *ICD-9* (*International Classification of Diseases, Ninth Revision*) to *ICD-10* was a major source of dataset shift, associated with a performance degradation.

Conclusions: Unsupervised, model-agnostic characterization of temporal shifts via IGT projections can serve as a proactive monitoring tool to anticipate performance shifts in clinical AI models. By incorporating early shift detection into the development pipeline, we can enhance decision-making during the training and maintenance of these models. This approach paves the way for more robust, trustworthy, and self-adapting AI systems in health care.

Introduction

Leveraging trustworthy artificial intelligence (AI) and machine learning (ML) in health critically depends on reusing data from diverse sources collected over extended periods. However, the inherent variability in medical data and their acquisition processes often results in significant shifts in data distributions [1-3]. At the population level, data-generating processes are generally nonstationary, leading to shifting statistical patterns over time. These shifts can arise from changes in clinical protocols, environmental or seasonal variations, inherent biological and social behaviors, or unexpected biases caused by systematic or random errors [4,5]. Such variability between training and test datasets, whether temporal or site-specific, can severely undermine the development and performance of ML models in health [6-10]. These variations in data distributions are classified as dataset shifts [11,12] and are especially relevant in a nonstationary environment, such as real-world health data [2,13]. Addressing dataset shifts proactively is crucial to ensure the reliability and effectiveness of the training and prospective continual use of health AI.

In classification problems involving input (x) and output (y) variables, a dataset shift occurs when the joint probability distribution of the data differs between training and test datasets. This can happen, for instance, when translating a model to a different site or during the AI's use or adaptation over time (equation 1).

In this work, we considered 3 primary sources of dataset shift: covariate shift, prior probability shift, and concept shift [11], as described next.

Covariate shifts refer to changes in the marginal features distribution over time, such as changes in the distribution of the population (equation 2) [14].

Prior probability shifts refer to changes in the distribution of each class p(y) over time (equation 3) [15].

Concept shifts refer to changes in the posterior distribution p(y|x) [11] over time (equation 4).

Approaches to identifying dataset shifts can be broadly classified into supervised and unsupervised methods. Supervised methods, such as progressive error and external holdout [16], require evaluation of the target model to detect shifts. Progressive error involves tracking the performance of the model over time to identify deviations, while external retention evaluates the model's performance on a held-out dataset collected over different periods [11]. Additionally, domain adaptation methods like transfer component analysis and domain-adversarial neural networks help in adapting models to new domains by aligning feature representations across different distributions [17,18]. These techniques can be effective but are often model-dependent and require labeled data, limiting their applicability and flexibility.

On the other hand, unsupervised methods do not rely on model performance and can be applied directly to the data. Techniques such as computing statistical distances (eg, Kullback-Leibler divergence, Wasserstein distance) between distributions, novelty detectors, and discriminative distance measures are commonly used [4,16,19]. Change detection algorithms, such as the Page-Hinkley test and the cumulative sum algorithm, detect changes in the statistical properties of data streams in real time, making them particularly useful for online monitoring of data shifts [20]. Reconstruction-based methods, such as autoencoders, detect shifts by measuring reconstruction error on new data, where high reconstruction error can indicate a distribution shift [21].

Among these unsupervised methods, the Information Geometric Temporal (IGT) projection proposed by Sáez et al [4] provides an unsupervised approach to characterization and exploratory visualization of distributional changes over time. The IGT methodology estimates the statistical distributions of data over time and projects their temporal evolution through nonparametric statistical manifolds. This method presents a robust, straightforward, and model-agnostic way to characterize dataset shifts. It excels in its ability to capture the dynamic nature of data distributions, making it highly sensitive to subtle changes that other techniques might miss. Furthermore, its nonparametric nature ensures flexibility and applicability across various datasets and AI models, enhancing its utility in diverse health settings.

In this study, we investigate how temporal changes in the Medical Information Mart for Intensive Care-IV (MIMIC-IV) health record repository [22] influence the performance of AI models, aiming to develop more reliable and robust health AI applications. Through early, unsupervised characterization of dataset shifts, we seek to identify early indicators that can predict performance variations before they impact clinical outcomes. To detect these shifts, we used the IGT projection method implemented in the *EHRTemporalVariability* package using R software (version 1.2.1; R Foundation for Statistical Computing) [3,4], previously validated in health care data studies [3,23,24]. The combination of temporal heatmaps and IGT projections provided actionable insights into the underlying dynamics of the data. By training AI models in annual data batches, we were able to link these temporal shifts with changes in performance metrics. Our findings demonstrate the potential of early characterization of temporal dataset shifts as a proactive monitoring tool to anticipate performance shifts over time. This proactive identification of dataset shifts paves the way for the development of reliable AI systems, leading to improved health outcomes and increased reliability in clinical settings.

Methods

Overview

Our study comprised 4 phases, including the MIMIC-IV data preparation, the characterization of temporal dataset shifts, the characterization of changes in predictive models' performance metrics, and the test for association between the dataset shifts and model performance metrics (Figure 1). Next, we describe each of the phases of the methodology.

Figure 1. Workflow of the study phases to assess the relationship between the temporal dataset shift characterization of the Medical Information Mart for Intensive Care-IV (MIMIC-IV) database and the machine learning models developed to predict the mortality of the patients. (A) Data preprocessing steps. (B) Dataset shift characterization. (C) Predictive model's development and evaluation. (D) Association of dataset shifts characterization with predictive models outcome process. ICD: International Classification of Diseases; PR-AUC: precision recall area under the curve; ROC-AUC: receiver operating characteristic area under the curve.

MIMIC-IV Dataset

The MIMIC-IV dataset contains electronic health records (EHRs) of more than 40,000 patients from the Beth Israel Deaconess Medical Center (BIDMC) [22]. The MIMIC-IV dataset contains information sourced from the intensive care unit, which is known for its abundance of data and its use in other AI-related works [9]. This modern EHR dataset spans a decade of admissions from 2008 to 2019 and includes precise digital records, such as the electronic medicine administration record. The data are organized modularly, allowing for easy linking to external departments.

For our aim of in-hospital mortality prediction, we included adult patients (age ≥18 years) with at least one hospital admission in the MIMIC-IV dataset. The input features include, on one hand, characteristics of each patient, such as the gender, age, or ethnic group, and on the other hand, the *ICD* (*International Classification of Diseases*) codes of the diagnoses and procedures of each admission in the versions 9 (*ICD-9* [*International Classification of Diseases, Ninth Revision*], from 2008 to 2015) and 10 (*ICD-10* [*International Statistical Classification of Diseases, Tenth Revision*], from 2016 to 2019). Each admission can be linked with multiple *ICD* codes for procedures and diagnoses.

Data Preprocessing

Since we aim to evaluate dataset shifts and model performance over time, the temporal identifier of data is of utmost importance. In MIMIC-IV, admission dates are anonymized and grouped into 3-year cohorts spanning 2008-2019. To approximate the admission year for each record, we applied the date preprocessing method developed by Yao et al [9], which assigns each admission to a specific year within its cohort (see Section 1.1 in Multimedia Appendix 1 for details). This process allows for yearly analysis but introduces a possible deviation of up to ±1 year for any given admission. Consequently, some admissions from, for example, 2015 or 2016 may be labeled as 2014.

To reduce the dimensionality of the dataset and the effect that updating the codes could have on temporal variability, all the *ICD-9* and *ICD-10* codes have been grouped and mapped into common chapters [25] using information from the Chronic Condition Indicator from the Healthcare Cost and Utilization Group [26]. Despite the increased number of codes between *ICD-9* (13,000 codes) and *ICD-10* (68,000 codes), both keep a hierarchical structure that allows the aggregation of the codes at higher levels. In both systems, codes are organized into chapters or categories, representing a broader group of diseases. Regarding diagnosis codes, the *ICD-9* codes are aggregated into 19 chapters (Table S1 in Multimedia Appendix 1), while the *ICD-10* codes are aggregated into 21 (Table S2 in Multimedia Appendix 1) [27]. Furthermore, we created some final chapters by merging the corresponding chapters from both *ICD-9* and *ICD-10* versions (Table S3 in Multimedia Appendix 1). Regarding procedure codes, we aggregated them into 18 chapters for the *ICD-9* version (Table S4 in Multimedia Appendix 1) and 17 for the *ICD-10* version (Table S5 in Multimedia Appendix 1). Then, these chapters were merged into 17 final chapters (Table S6 in Multimedia Appendix 1). Most of the *ICD-9* procedure chapters were merged into a single final chapter, Medical and Surgical, linked to only 1 *ICD-10* chapter based on the merging method used. This could reduce the degree of detail in our study. We decided to expand this final chapter into 13 different subchapters to provide a more detailed mapping of the *ICD-9* chapters into the *ICD-10* ones. (Table S7 in Multimedia Appendix 1). Lastly, given the multiplicity in the number of *ICD* codes per patient, the final groups were coded

XSL•FO
RenderX

using one-hot encoding to allow a richer, unordered input for the predictive models regarding the *ICD* codes.

Dataset Shift Characterization

To characterize dataset shifts, we used the unsupervised approach by Sáez et al [3,4]. This method enables an exploratory characterization and quantification of temporal changes using data temporal heatmaps (DTHs) and IGT projections [5]. The DTHs allow users to dynamically explore changes in absolute and relative frequencies of the variables over time and simultaneously at multiple variable values. The IGT projections embed time batches as a series of points in a latent information space, namely a geometric statistical manifold of nonparametric information from the temporal batches. The IGT projection is obtained, first, by calculating the dissimilarity matrix of the probability distribution functions in temporal batches and, second, by embedding the batches through their dissimilarity matrix with multidimensional scaling in a reduced dimensional space of 2 or 3 dimensions. Consequently, the data batches are represented as temporally indexed points in a latent information space where distances between them correspond to the dissimilarity of their statistical distributions. The IGT projection allows for delineating trends as continuously flowing time batches, abrupt changes as gaps between groups of batches, temporal subgroups as clusters of batches, and seasonality as temporal cycles [3]. Additionally, the IGT projection enables the empirical characterization of conceptually related temporal subgroups using unsupervised machine-learning techniques on the projected temporal points.

We characterized covariate and prior probability shifts using the DTHs and IGT projections provided by the *EHRTemporalVariability* package. To capture concept shifts, we extended the library to compute both class-conditional feature distributions p(x|y) and posterior probabilities p(y|x) and then visualized their temporal evolution with corresponding DTHs and IGT plots.

To explore temporal relationships and patterns in both categorical (eg, *ICD* codes) and numerical variables (eg, age), we conducted a multivariate analysis. This approach allowed us to examine how variables evolve collectively over time, revealing trends, cycles, or structural shifts in the data. We applied factorial analysis of mixed data (FAMD) [28], a dimensionality reduction technique suitable for datasets with mixed data types. Unlike t-distributed Stochastic Neighbor Embedding or Uniform Manifold Approximation and Projection (UMAP), FAMD is a linear technique that preserves the global relationships and variance, which aids with the interpretability [29]. We retained the first 3 FAMD dimensions, which together explained 15.16% of the total variance, striking a balance between meaningful representation for our exploratory analysis and computational efficiency. This reduced space enabled clearer visualization of latent patterns while minimizing the computational load, especially for resource-intensive steps like kernel density estimation (KDE), which scales poorly with higher dimensionality. Finally, to determine whether the low variance retained by the first 3 components of the FAMD was adequate for capturing temporal variability, we conducted the same unsupervised characterization analysis using UMAP as the dimensionality reduction method.

Then, we separated the FAMD coordinates into 2 datasets, one for deceased patients and one for nondeceased patients. This allowed us to study how concepts might change over time using conditional probability p(x|y). We derived probability distributions from the FAMD dimensions to obtain the DTHs, which helped us spot shifts in probabilities linked to covariate or concept shifts. Next, we applied a KDE by year on the first 3 FAMD dimensions for the full and conditioned datasets. Then, for the conditioned datasets, we combined their KDE probability maps into a single map. This map was renormalized to calculate the IGT projection for conditional probabilities, using the *EHRTemporalVariability* package [3]. This step helped us identify shifts in concepts and temporal trends. Finally, we calculated the IGT for the entire FAMD dataset to examine covariate shifts and broader temporal trends.

Next, we conducted a univariate analysis to pinpoint which features drive temporal variability. We began by estimating each feature's marginal distribution in the overall dataset, p(x), to detect covariate shifts, and the class prior, p(y), to detect prior probability shifts. We then estimated the class-conditional feature distributions, p(x|y), for each outcome. Applying Bayes' theorem (equation 5),

we derived the posterior probability p(y|x) for each feature, thereby isolating concept shifts. Finally, we embedded each of these univariate distributions into an IGT projection. This IGT projection for each distribution allowed us to visualize each feature's temporal trajectory and systematically identify covariate, prior, and concept shifts over time.

Predictive Models' Development and Evaluation

The models developed to predict the in-hospital mortality of the patients in the dataset were based on ensemble learning methods, including random forest and gradient boosting. These methods are at the state of the art for the classification of tabular data [30,31]. Random forest is an ensemble learning method that builds multiple decision trees during training and then combines their predictions to improve overall accuracy and reduce overfitting. Gradient boosting is an ensemble learning technique that iteratively combines weak predictive models, typically decision trees, to create a robust predictive model. Through sequential optimization of an objective function, this method progressively reduces errors, demonstrating significant efficacy in diverse classification and regression tasks within high-dimensional data spaces.

To analyze the performance of the models over time, the initial dataset was batched on a yearly basis from 2008 to 2019. Thus, we used 12 subsets to train and validate the yearly models. We divided each subset following a criterion of 80% for training and 20% for testing. Of the 80% of the training data, 70% was for pure training, and the remaining 30% was used for validation.

We trained each model on the training set and tuned hyperparameters using grid search on the validation set. For

XSL•FO
RenderX

random forest and gradient boosting, we predefined values for the number of trees and maximum depth. To reduce computation time, we ran a grid search in parallel. We validated models on data from the same year as training, using the receiver operating characteristic area under the curve (ROC-AUC) as the metric for its robustness to class imbalance and threshold independence [32]. Finally, we averaged ROC-AUC scores across 12 models for each hyperparameter set and selected the configuration with the highest mean score.

Once the hyperparameters were defined, we studied each model's performance over time, evaluating them on the test sets from all 12 temporal batches. The metrics used to evaluate a more detailed performance of the models, in this case, included the ROC-AUC, precision recall area under the curve, recall (or sensitivity) of the positive class, precision, accuracy, and macro F_1-score. However, due to the high class imbalance (Figure S2 in Multimedia Appendix 1), we used a prediction threshold other than the default 0.5. To determine this threshold, we ranked possible values using the Youden index (equation 6) and selected the one with the highest score using the validation data from the most recent temporal batch. We then applied this optimal threshold to binarize the test data predictions.

Association of Dataset Shift Characterization With Predictive Model Outcomes

To prove our objective of determining whether an early unsupervised exploratory characterization of dataset shifts can explain prospective changes in the performance of predictive models, we compared the patterns from the dataset shift characterization, those in the IGT projections, with equivalent embeddings from the interbatch evaluation of AI performance metrics over time. These embeddings, leading to a characterization of the patterns in AI performance metrics, were calculated by applying multidimensional scaling to the interbatch evaluation matrices evaluated year by year and representing the batches in a 3-dimensional space. This procedure is equivalent to the obtention of the IGT for the predictive models' metrics.

We applied agglomerative hierarchical clustering to identify temporal clusters in both the IGT projection and interbatch model evaluation embeddings. We aimed to delineate temporal subgroups, thus elucidating patterns of similarity in the data and the behavior of the models over time [5]. This allowed us to identify groups of conceptually related time periods in which probability distributions are similar within a group but dissimilar between groups. We used a complete linkage and the Manhattan distance, which, according to Strauss and Maltitz [33], is less sensitive to outliers. To justify the number of clusters to be performed on each case, we applied the elbow method [34] and the analysis of the dendrogram distances, joined to the results extracted from the exploratory unsupervised characterization.

Additionally, we implemented a k-means clustering process to reinforce the results obtained in the hierarchical clustering process. To do so, we initialized the k-means with 2 centroids in the data of the first and last years to follow the natural temporal trend, as it was the optimal number of clusters obtained in the hierarchical clustering.

Finally, to statistically determine the existence of a significant association between the clusters from the dataset shift characterization and the interbatch model evaluation embeddings, we applied the Fisher exact test with a significance level of .05.

Ethical Considerations

This study used the MIMIC-IV dataset, which is a publicly available deidentified dataset of EHRs from the BIDMC. The dataset was obtained in accordance with the guidelines set forth by the Massachusetts Institute of Technology and the BIDMC Institutional Review Board. Access to the dataset was granted upon completion of the required Collaborative Institutional Training Initiative program course on data use and privacy for researchers, ensuring compliance with ethical standards for using health data. To ensure patient privacy, all data collected at BIDMC as part of routine clinical care are deidentified and transformed before being made available to researchers who have completed human research training and signed a data use agreement [22]. As the data are fully deidentified and publicly accessible, patient consent was not required.

Results

Data Preprocessing Results

The final dataset comprised 61 features and 239,246 admissions, of which 232,276 belonged to nondeceased patients and the remaining 6970 (2.91%) to deceased ones. After batching data on a yearly basis, the average number of patients per year was 35,781, with a standard deviation of 27,610 (Figure S1 in Multimedia Appendix 1 shows the amount of data per year).

Dataset Shifts Characterization

As an overall representation of the data changes over time, Figure 2A shows the first 2 components of the FAMD divided by class and 2 time periods, previous and after 2014, the year the update of *ICD-9* to *ICD-10* took place. These results show that both survivors' and nonsurvivors' positions and class-conditional layouts change over time. The nondeceased patients show a wider variance over the first dimension. The magnitude and impact of these changes on AI are further explored.

Figure 2. Results of the multivariate dataset shift characterization. (A) Scatter plot of the first 2 dimensions of the studied Medical Information Mart for Intensive Care-IV (MIMIC-IV) dataset's factorial analysis of mixed data (FAMD). Dim 1 is the largest variance dimension, and Dim 2 is the second largest variance dimension. The data are divided by classes (green and red) and time (darker and lighter colors). (B) Information Geometric Temporal (IGT) projection of the entire dataset after applying the FAMD and the kernel density estimation to the first 3 dimensions. Temporal subgroups are highlighted by red circles. (C) Heatmap of the probability distribution of the first 2 dimensions of the FAMD over time. (D) Heatmap of the conditional probability distribution of each class in the second dimension of the FAMD.

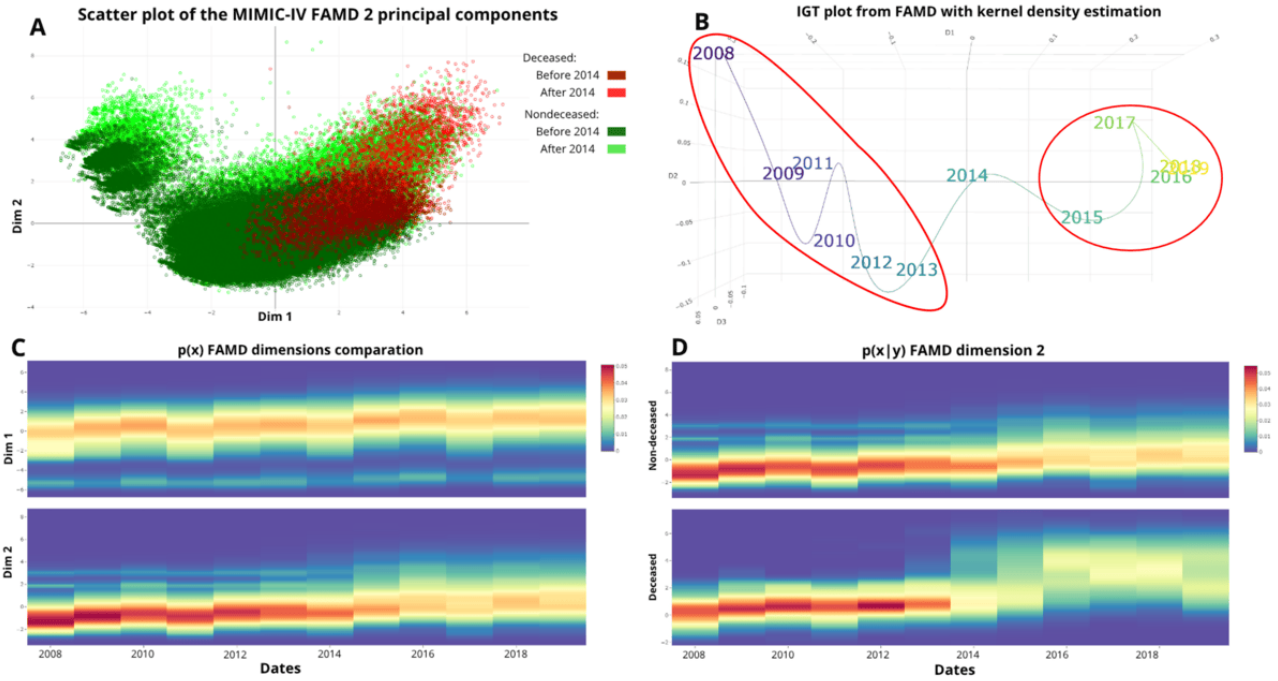

Figure 2B shows the IGT of the data after applying the FAMD and the KDE to the principal 3 dimensions. The colors in the IGT projection plot represent a gradient that distinguishes different yearly temporal batches. Subsequently, Figures 2C and 2D present temporal heatmaps depicting the temporal variability derived from the first 2 dimensions of the FAMD applied to the entire dataset and the second dimension when segmented by class, respectively. In Figure 2D, we chose the second dimension of the FAMD over the first one because it better represents the presence of the temporal discriminative variability of the classes. The contribution of the variables to the principal components of the FAMD can be examined in Figure S16 in Multimedia Appendix 1. Figure S17 in Multimedia Appendix 1 displays the results of the unsupervised characterization of temporal variability based on the UMAP-reduced data. It is evident that the IGT projection reflects the same trend previously observed with FAMD. Specifically, there are 2 distinct temporal groups, one comprising data from 2008 to 2013 and the other from 2015 to 2019, along with a transition year in between. The rest of the results are obtained for the FAMD dimensionality-reduced data.

A notable increase in the variability of the data's probability distribution occurs after 2014, coinciding with the adoption of the *ICD-10* coding system, leading to enhanced dispersion across the temporal spectrum. Specifically, 2014, 2015, and 2016 exhibited pronounced shifts in the conditional probability distribution, characterized by significant variations in distribution trends and increased dispersion, which is indicative of concept shifts. Additionally, a distinct covariate shift was detected in 2015, marked by a notable dispersion in data and an ascending trend. The IGT analysis, as depicted in Figure 2, corroborated these phenomena, affirming the initial observations. In the IGT plot, we identified 2 distinguished groups, one from 2009 to 2013 and the other from 2016 to 2019. In the middle, there are some transition years. Thus, the presence of covariate shift and concept shift is justified.

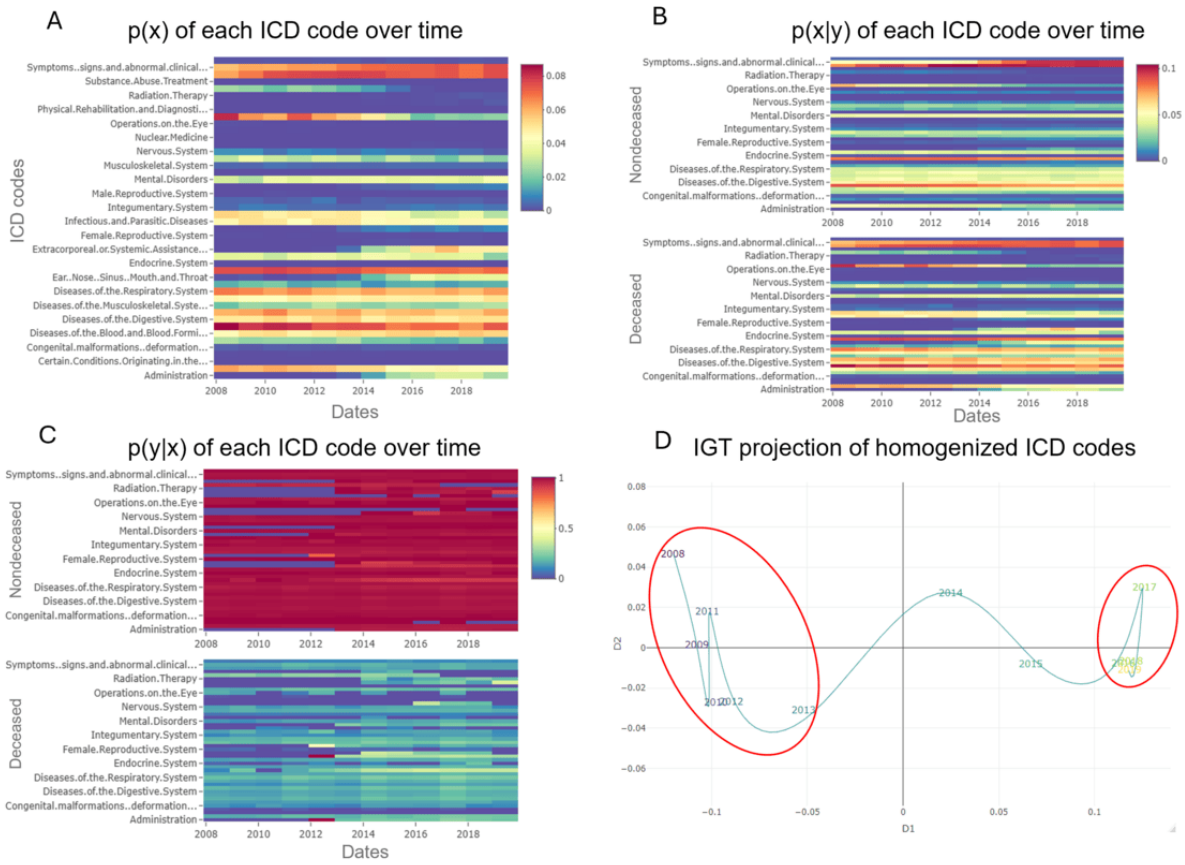

Figure 3 shows the results of the univariate analysis regarding the homogenized *ICD* codes. Figure 3A shows each chapter's overall prevalence from 2008 to 2019. Notably, "Other procedures" code diminishes its distribution over time, as it is much more present between 2008 and 2015 than in the following years. It happened similarly in the "Cardiovascular system" code. These are 2 of the most frequent chapters, both exceeding 70,000 entries. This means that variations in their distributions have a high relevance in the total variability of the dataset. The diagnosis chapters "Diseases of the circulatory system" and "Endocrine nutritional and metabolic diseases and immunity disorders" also show a diminution in the probability distribution over time. As before, these are very frequent chapters. The common fact between these chapters is that their probability distribution is higher when only *ICD-9* codes were used. This means that some of the procedures and diagnosis codes related to these chapters have been redistributed into others with the implementation of the *ICD-10*. This may have happened with the diagnoses chapter "Symptoms signs and abnormal clinical and laboratory findings not elsewhere classified" and the procedures chapters "Imaging" and "Extracorporeal or systemic assistance and performance administration," which increased their probability distribution over time. Again, these variations are clear evidence of a covariate shift. Both the DTHs for p(x|y)

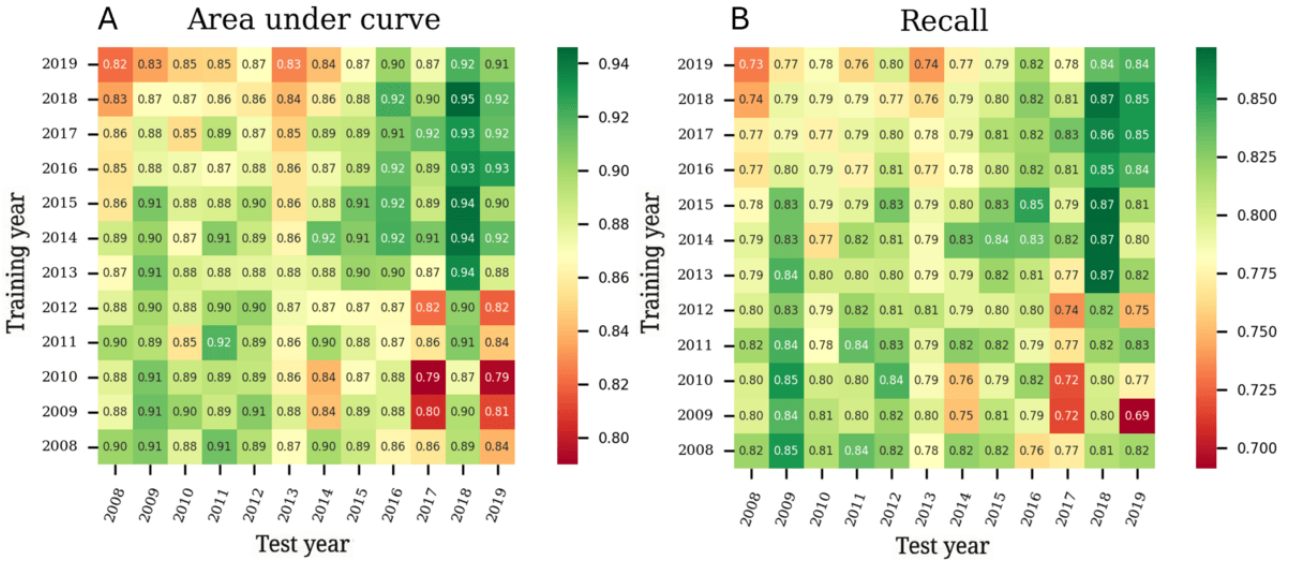
XSL•FO
RenderX

and p(y|x), shown in Figures 3B and 3C, reveal synchronous changes in key chapters, such as "Administration" or "Extracorporeal or systemic assistance." These parallel shifts in feature prevalence and their link to mortality confirm a genuine concept shift, where the relationship between certain codes and the outcome evolves over time. Figure 3D shows the IGT projection of the features' marginal distribution, yielding 2 clear temporal subgroups (2008-2013 and 2015-2019), with a transition year.

Finally, Figure S2 in Multimedia Appendix 1 shows a stable probability for the mortality class over time, indicating no prior probability shift.

Figure 3. Results of the dataset shift characterization of each International Classification of Diseases (*ICD*) code, homogenized between *ICD-9* (*International Classification of Diseases, Ninth Revision*) and *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) versions (Tables S1-S7 in Multimedia Appendix 1). (A) Heatmap of the probability distribution p(x) of each homogenized ICD code over time, sorted alphabetically. (B) Heatmap of the conditional probability distribution p(x|y) of each class for each homogenized ICD code sorted alphabetically. (C) Heatmap of the posterior probability distribution p(y|x) for each class of homogenized ICD codes, sorted alphabetically, with a square root transformation for improved visualization. (D) Information Geometric Temporal (IGT) projection of the p(x) of ICD codes. Temporal subgroups are highlighted by red circles.



Assessment of Models' Performance Over Time

After applying grid search for the hyperparameter tuning, the number of trees selected for the random forest models was 500 with a maximum depth of 9. In the case of gradient boosting models, the number of estimators was 100 with a maximum depth of 2. Figure 4 shows the matrices of resulting metrics from training, representing how the trained models perform when validated with data from different years. This provides insight into their behavior across temporal variations for random forest. Almost every metric described the same trend. The best results were in the lower left and upper right quadrants. These areas belonged to the models trained and tested with data batches preinstauration of *ICD-10* codes and post instauration, respectively. The remaining metrics for random forest are in Figure S3 in Multimedia Appendix 1.

As with the random forest, for gradient boosting models, every metric except precision showed better results when the models were trained and tested with pre–*ICD-10* and post–*ICD-10* data (Figure S4 in Multimedia Appendix 1). The precision metric showed very similar results in every temporal batch. Both techniques performed similarly, with slightly better results in the random forest.

XSL•FO
RenderX

Figure 4. Interyear evaluation of the random forest (RF) machine learning models using the test datasets for (A) area under the receiver operating characteristic curve and (B) recall of the positive class metrics. The selected hyperparameters for the RF model were 500 trees and a maximum depth of 9.

Relationship Between Temporal Variability and ML Models' Performance

Figure 5 presents the exploratory results of hierarchical clustering applied to the IGT of both the dataset shift (covariate shift) characterization of the FAMD data and the recall metric from the random forest models. The remaining metrics are detailed in Figures S5-S15 in Multimedia Appendix 1. For the covariate shift (Figures 5B and 5C), the clustering results reveal 2 distinct groups (one covering 2008-2014 and the other 2015-2019), indicating similar probability distributions within these periods. These clusters suggest periods with consistent covariate characteristics, while also highlighting the presence of shifts between them. Figure 5D shows the IGT for the recall metric over time, reflecting fluctuations in model performance. The clustering results (Figures 5E and 5F) reveal 2 distinct clusters as well, with one corresponding to 2008-2013 and the other to 2014-2019. These findings illustrate how both dataset shifts and model performance evolve over time, identifying similar temporal patterns in both the data and the model behavior.

Table 1 shows the results of the Fisher exact tests comparing groups formed by hierarchical and k-means clustering of temporal variability against the metrics of random forest models for 2 clusters. All metrics registered *P* values of <.05 for both clustering methods, indicating statistically significant differences between the clusters. Specifically, these *P* values suggest that the likelihood of observing such differences by chance is less than 5%, allowing us to confidently reject the null hypothesis of independence between clusters and model performance metrics.

Similarly, Table 2 presents the results of the Fisher exact tests comparing groups formed by hierarchical and k-means clustering of temporal variability with the performance metrics of gradient boosting models across 2 clusters. In the hierarchical clustering scenario, all performance metrics except for recall exhibited *P* values <.05, indicating statistically significant differences between the clusters. This allows us to reject the null hypothesis of independence, suggesting a significant association between temporal variability and the performance metrics of gradient boosting models. For the k-means clustering, every metric recorded a *P* value of <.05. To minimize the type 1 error rate after conducting multiple statistical tests and to ensure the robustness of our results, we adjusted the *P* values using the false discovery rate method (Tables S8 and S9 in Multimedia Appendix 1). The adjusted *P* values yielded the same statistically significant results. Furthermore, the findings from the gradient boosting analysis reinforce the association between temporal variability and model performance, which aligns with the patterns observed in the random forest results. The significant *P* values for key metrics in both hierarchical and k-means clustering reinforce the conclusion that temporal variability is an important factor influencing AI model performance outcomes. These results highlight the necessity of monitoring temporal shifts in datasets to maintain and enhance the reliability and accuracy of AI models in clinical settings.

Discussion

Overview

Our study reveals a strong link between temporal dataset shifts in the MIMIC-IV dataset and the observed variations in ML performance. By using an unsupervised exploratory method to detect these shifts before model training, we can offer actionable insights regarding data curation or learning strategies (eg, domain adaptation or continual learning techniques). This early characterization not only enhances the robustness and reliability of AI models but also sets the stage for future work on online dataset shift detection. Such real-time monitoring could dynamically adjust training processes, ensuring optimal performance without frequent retraining.

When considering approaches for detecting dataset shift, there are important trade-offs between unsupervised and supervised methods. Unsupervised methods, like the one used in our study, since they are based only on data, do not require any model training nor, in the case of covariate shift analyses, labeled data. This makes them scalable and relatively cost-effective for large and dynamic clinical datasets. In contrast, supervised methods such as progressive error tracking or evaluation on external holdout sets provide direct insights into performance changes but require training particular models and computational resources. This may limit their feasibility for continuous or real-time monitoring when no labeled data are still available, as well as the inherent limitations of the selected model. Ultimately, combining both approaches may offer the most comprehensive strategy for maintaining robust AI performance in the face of evolving health data.

Our analysis of the MIMIC-IV dataset provides crucial information for understanding its characteristics and potential applications in AI. We have observed both gradual and abrupt changes in the dataset's probability distribution over time, primarily due to variations in *ICD* codes. The transition from *ICD-9* to *ICD-10* has been the main factor contributing to this temporal variability. Even after standardizing the values, we found that this transition can significantly impact data analysis. Although mapping *ICD-9* codes to *ICD-10* codes helps reduce dimensionality and facilitates longitudinal analysis, it may not fully account for changes in coding practices or semantic shifts between the 2 versions. This issue is particularly important for chapters that have undergone significant restructuring. It has opened up new avenues for investigation, such as a thorough fidelity assessment for all chapters. Although this assessment is currently beyond the scope of this work, it may lay the groundwork for future research.

We have also discovered that the optimal number of clusters aligns with the number of *ICD* code versions. The data years are typically grouped based on the *ICD* versions used during the clustering process. Although the transition year from *ICD-9* to *ICD-10* was 2015, this study's cutoff point was 2014. This is because the data deidentification process is not entirely precise, which is the biggest limitation in this paper, and the obtained year falls within a 3-year group. Therefore, data from 2015 may be labeled as from 2014. For this reason, we have established 2014 as the cutoff point for our association analysis (more information about the deidentification process in Section 1.1 in Multimedia Appendix 1).

It is important to note that small differences between years may arise from variations in available data, deidentification procedures, and the approximate date assignment. By following the annual extraction approach of Yao et al [9], we achieve better temporal granularity, but we must recognize that the assigned admission year may be offset by up to 1 year due to the 3-year cohort structure. As a result, the timing of observed transitions, such as the shift to *ICD-10*, should be interpreted as occurring within a 3-year window rather than as a precise annual event. This limitation may artificially sharpen the observed temporal break and exaggerate the separation between clusters in our analysis. Therefore, some of the distinct clustering observed around the *ICD* system transition could reflect this methodological artifact rather than a purely organic change in the underlying data distribution. To assess the impact of this limitation, we repeated our analysis using the original 3-year cohort groups instead of annual assignments and observed that our main conclusions regarding dataset shifts and their effects on model performance remained unchanged. This suggests that our findings are robust to the temporal aggregation method.

Importantly, we showed that both linear (FAMD) and nonlinear (UMAP) dimensionality reduction techniques produce consistent

XSL•FO
RenderX

temporal clusters, supporting the robustness of our findings despite FAMD capturing only 15.16% of total variance. This robustness underscores the value of unsupervised characterization for understanding temporal variability. It suggests that, despite the relatively low explained variance of the FAMD approach, our main conclusions regarding temporal dataset shifts remain stable across both linear and nonlinear dimensionality reduction techniques.

Recent studies have further emphasized the importance of considering temporal shifts in health AI. Peracchio et al [35] and Nicora et al [36] focused on performing an online detection of temporal changes in clinical settings during the deployment phase of AI models, highlighting how these shifts impact AI model performance, which aligns with our findings. Saurav et al [37] contributed to this field by performing an anomaly detection methodology using recurrent neural networks to make multistep time series predictions and using the prediction errors to detect shifts and rapidly adapt the model to changes. Furthermore, Koch et al [38] have shown that detecting dataset shifts is crucial for monitoring AI-based medical products during postmarket surveillance, implementing 3 different methods to do it. While Guo et al [39] also used an unsupervised approach to investigate dataset shifts in the MIMIC-IV dataset, our study differs by focusing on a model-agnostic and exploratory characterization of these shifts. Our approach is computationally simpler and offers enhanced flexibility and scalability. Additionally, our study explores how unsupervised methods can interact with supervised approaches, offering complementary insights into the identification of temporal variability.

Overall, our work builds upon existing literature on the impact of temporal variability and dataset shifts on ML models. By adopting an unsupervised, model-agnostic approach based on information geometry, we contribute to a growing body of research seeking to address the challenges posed by temporal shifts in clinical AI. Our findings enhance the understanding of how these shifts influence model robustness and performance.

This approach not only optimizes decision-making in clinical practice but also enhances the adaptability of AI systems. By enabling early characterization of dataset shifts, our work can guide clinicians and developers in identifying emerging trends and anticipating potential risks. Ultimately, this work lays the groundwork for the development of continuously learning, self-adaptive AI models that are better equipped to handle the dynamic nature of health data.

Conclusions

This work demonstrates that early identification of changes in data statistical distributions through unsupervised dataset shift characterization is a potential indicator of performance variations in prospective ML models. The association between variations in data distributions and the model's performance has been statistically demonstrated in the MIMIC-IV dataset as a significant benchmark. Noteworthy, the implementation of *ICD-10* coding resulted in significant temporal variability in covariates and outcome-conditional distributions. This translates into the presence of covariate and concept shift, but not prior probability shift in the dataset.

Our findings underscore the importance of characterizing and adjusting for dataset shifts when developing AI models in health. By integrating temporal variability analysis, such as IGT projection data, with the development of AI models, we pave the way to the creation of trustworthy and self-adaptive AI systems. Our research sets the stage for building more resilient and adaptable AI solutions, which will help enhance patient safety and increase the applicability of AI in the ever-evolving health industry.

Funding

This study was funded by the project PID2022-138636OA-I00 (KINEMAI) by Agencia Estatal de Investigación-Proyectos de Generación de Conocimiento 2022.

Authors' Contributions

DFN, PF, and CS conceived and designed the work. DFN performed data collection, processing, and analysis. CS, PF, AGS, JMGG, and DFN reviewed and interpreted the results. DFN drafted the study. CS, PF, AGS, and JMGG provided critical revision of the study. All authors approved the final version to be published.

Conflicts of Interest

None declared.

Abstract

Background: Depressive episodes in bipolar disorder are frequent, prolonged, and contribute substantially to functional impairment and reduced quality of life. Therefore, early and objective detection of bipolar depression is critical for timely intervention and improved outcomes. Multimodal speech analyses hold promise for capturing psychomotor, cognitive, and affective changes associated with bipolar depression.

Objective: This study aims to develop between- and within-person classifiers to screen for bipolar depression and monitor longitudinal changes to detect depressive recurrence in patients with bipolar disorder. A secondary objective was to compare the predictive performance across speech modalities.

Methods: We collected 304 voice audio recordings obtained during semistructured interviews with 92 patients diagnosed with bipolar disorder over a 1-year period. Depression severity was assessed using the Hamilton Depression Rating Scale. Acoustic features were extracted using the openSMILE toolkit, and linguistic features were extracted using the Linguistic Inquiry and Word Count frameworks following automatic speech recognition and machine translation. Mixed-effects multivariate linear regression evaluated the associations between speech markers and Hamilton Depression Rating Scale scores adjusting for demographic variables, diagnosis, and feature-specific covariates. Extreme gradient boosting and light gradient boosting were used as base learners. We developed a between-person classifier to detect moderate to severe depression and a within-person classifier to detect recurrence. Hyperparameter tuning and 95% CI estimation were performed using a bootstrap bias-corrected cross-validation (k=5) approach combined with a grid search. Feature contributions were interpreted using Shapley additive explanations.

Results: Patients with depression showed reduced energy modulation, prolonged monotony, and more frequent use of words related to death and negative emotions. The between-person classifier combining acoustic and linguistic features detected moderate to severe depression with an area under the curve of 0.76 compared to 0.54 for the demographic model. The within-person classifier based on speech features detected depression recurrence with an area under the curve of 0.70 compared to 0.55 for the demographic model.

Conclusions: Between- and within-person comparisons of speech markers can be leveraged in detecting and monitoring bipolar depression. We demonstrate the feasibility of applying Linguistic Inquiry and Word Count–based psycholinguistic analysis to

XSL•FO
RenderX

machine–transcribed and translated speech, supporting the replicability of this approach across languages. Automated multimodal voice analysis can be integrated into digital health platforms, providing a scalable and effective approach for accessing mental health monitoring and care.

Introduction

Depression affects more than 280 million individuals worldwide and is a leading contributor to the global burden of disease [1,2]. As diagnosis relies entirely on symptomatology without the support of laboratory tests or imaging, clinicians must depend on subjective evaluations of patients' reported experiences and observable behaviors [3], which poses challenges for accurate and timely diagnosis.

Clinicians have long observed speech changes in depression, such as reduced pitch variation, slower speech rate, and diminished output [4,5]. Speech has acoustic features (eg, lower pitch and narrower pitch range) [5,6], which may reflect psychomotor or autonomic alterations, and linguistic features (eg, increased use of first-person singular pronouns and negative-sentiment words) [7], which may reflect cognitive and affective disturbances. Voice data offer several advantages: they are noninvasive, low cost, and suitable for repeated assessments even in remote or resource-limited settings. Furthermore, voice is also sensitive to within-person mood fluctuations, making it well suited for longitudinal monitoring [8]. Recent advances have increased sophistication in voice-based depression detection, with growing adoption of multimodal approaches [9-11] and application of deep learning–based models [12].

A recent systematic review highlighted the promising potential of voice markers in the detection of depression [13], reporting classification performance with an area under the receiver operating characteristic curve (AUC) ranging from 0.71 to 0.93. However, substantial methodological heterogeneity was identified across the studies, including patient selection and diagnosis based on clinician- or self-rated symptom scales. Many studies have not validated models using cross-validation or an independent test set. Some studies have explored changes in speech patterns associated with changes in depression severity [14] or clinical outcomes after treatment [15-17], but they are limited in modality—primarily acoustic—and duration, typically involving 4 to 6 weeks of follow-up. To the best of our knowledge, no previous study has systematically compared the cross-sectional and longitudinal performance of acoustic and linguistic speech markers in a clinically diagnosed sample and assessed their utility for ongoing symptom monitoring in real-world practice.

While much of this research has focused on major depressive disorder (MDD), depressive episodes are also the predominant and most debilitating feature of bipolar disorder. Although bipolar disorder is defined by the presence of manic or hypomanic episodes, longitudinal studies have consistently shown that patients spend most of their illness course in depressive states rather than manic or hypomanic phases [18-20]. These depressive episodes are frequent and prolonged and contribute disproportionately to functional impairment, suicide risk, and reduced quality of life. Accordingly, developing objective methods for detecting and monitoring bipolar depression is of high clinical importance.

In this prospective study, we collected voice recordings from 92 individuals with a psychiatrist-confirmed diagnosis of bipolar disorder over a 1-year period. The main objective of this study was to develop machine learning–based classification models for detecting and monitoring bipolar depression using voice recordings. A between-person classifier that compared the severity of depression between individual recordings and a within-person classifier that compared changes in severity within the same individual were developed. The secondary objective was to compare the acoustic, linguistic, and combined speech features to detect and monitor depressive symptoms.

Methods

Study Participants and Clinical Assessments

Adult patients (aged ≥19 years) diagnosed with bipolar disorder (type 1, type 2, and not otherwise specified) attending the Mood and Anxiety Clinic at Seoul National University Hospital were recruited through convenience sampling. Board-certified psychiatrists confirmed the psychiatric diagnoses. The exclusion criteria included major psychiatric disorders other than bipolar disorder, laryngeal conditions or surgeries that could impair voice production, and psychiatric symptoms attributable to organic brain diseases or previous intracranial surgery.

Clinical evaluations were conducted at baseline and repeated at 2, 4, 8, and 12 months. Demographic and clinical data, including age, sex, height, weight, comorbidities, and prescribed medications, were collected at baseline, and changes were tracked at each follow-up visit. Cumulative antipsychotic dosages were standardized to the equivalent dose of aripiprazole [21,22], which was the predominant antipsychotic prescribed in the study sample. Depressive symptom severity was assessed using the Korean adaptation of the 17-item Hamilton Depression Rating Scale (HAM-D) [23,24], administered by trained raters. Each HAM-D item is scored from 0 (not present) to 4 (severe), yielding total scores ranging from 0 to 68. Standard clinical cutoffs classify scores of ≤7 as minimal depression, scores of 8 to 16 as mild depression, scores of 17 to 23 as moderate depression, and scores of ≥24 as severe depression [25]. The patients also self-rated suicidality, depression, and anxiety symptoms using the Korean version of the Beck Scale for Suicide Ideation, Patient Health Questionnaire-9 items, and

XSL•FO
RenderX

Beck Anxiety Inventory. A more detailed study protocol has been published previously [22].

Preprocessing of Voice Data and Speech Feature Extraction

Study participants' voices were recorded during semistructured psychiatric interviews conducted by 1 of the 2 research nurses using a Sony ICD-SX813 voice recorder in a standardized interview room setting [22]. While interview structure ensured consistency across participants, interviewers were encouraged to use open-ended prompts. Segments with the interviewer's voice, overlapping speech or background noise, and utterances shorter than 3 seconds were excluded. Audio files were transcribed using the Daglo application programming interface (ActionPower Corp), a conformer-based automatic speech recognition engine [26-28] recognized for its superior accuracy in Korean speech recognition tasks. We manually reviewed 2% of the automatically generated transcripts and compared them to their corresponding audio recordings to verify transcription accuracy and calculate the character error rate (CER). CER quantifies transcription errors as the percentage of incorrectly transcribed characters (including substitutions, deletions, and insertions) normalized by the total character count [29].

The acoustic features were extracted using the INTERSPEECH 2016 Computational Paralinguistics Challenge (ComParE 2016) feature set, the largest available set in the openSMILE toolkit (audEERING GmbH) [30-32], which is widely used for depression detection because of its well-documented and standardized feature extraction process [31,33-35]. A total of 6373 features were extracted per recording, covering functionals derived from low-level descriptors such as pitch (F0), loudness, mel-frequency cepstral coefficients, jitter, shimmer, and spectral features.

Linguistic features were extracted using a Linguistic Inquiry and Word Count (LIWC) framework (Pennebaker Conglomerates, Inc). The LIWC framework calculates the frequency of words within psychologically relevant categories serving as proxies for various social, cognitive, and affective processes. It is one of the most widely used psycholinguistic dictionaries in natural language processing tasks [36,37]. For this analysis, we used the LIWC and the LIWC Extension framework (Receptiviti) [38]. As the Korean LIWC library was unavailable at the time of our study, we machine translated texts using the DeepL application programming interface (DeepL SE) from Korean to English and then assigned words to categories using the LIWC frameworks in English [39,40]. LIWC scores range between 0 and 1 and denote the proportion of words in a specific category relative to the total word count in the text.

Statistical Analyses and Development of Machine Learning Classifiers

Given the repeated-measurement structure, we applied mixed-effects multivariate linear regression models to identify the speech features associated with the HAM-D score after applying an inverse normal transformation. Features that were constant across all recordings (such as the "parentheses" LIWC category) were excluded from analysis. Covariates included age, sex, BMI, diagnosis, and antipsychotic dosage for acoustic feature analysis and age, sex, years of education, and diagnosis for linguistic analysis. The significance level was set at $P<.05$, and the Benjamini-Hochberg test was conducted to correct for multiple hypotheses. All statistical analyses were conducted using R (version 4.1.0; R Foundation for Statistical Computing).

All acoustic and linguistic features were used for classifier development. Decision tree classifiers were selected for their robustness and established performance in previous studies [22,41,42]. We used extreme gradient boosting (XGB) and light gradient boosting (LGB) as the base learner algorithms. XGB and LGB are both gradient boosting frameworks. LGB is noted for its computational efficiency, whereas XGB is renowned for its fast convergence speed.

To address class imbalance at both the data and algorithmic levels, we combined the synthetic minority oversampling technique (SMOTE) with the focal loss function. SMOTE was applied exclusively to the training set within each cross-validation fold to generate synthetic samples of the minority class while preventing data leakage. In parallel, focal loss was implemented in both the LGB and XGB models to further mitigate imbalance during model optimization. The α parameter of focal loss was automatically calculated based on class ratios to balance positive and negative samples, and the γ parameter was fixed at 2.0 to emphasize harder-to-classify samples.

Hyperparameter tuning and 95% CIs were estimated using a bootstrap bias-corrected cross-validation (BBCV; k=5) approach. BBCV involves nonparametric bootstrapping with 1000 iterations on the out-of-sample predictions from the validation folds combined with a grid search for hyperparameter optimization [43]. BBCV provides unbiased and conservative estimates of model performance, particularly in studies with small sample sizes, and it may outperform alternatives such as nested cross-validation. The model performance was evaluated using the AUC. The accuracy, sensitivity, specificity, and positive predictive value at the optimal threshold defined by the Youden index (sensitivity + specificity − 1) were also reported.

The participants were categorized as having moderate to severe depression if their HAM-D score was ≥17 [25]. The HAM-D is the gold-standard instrument for evaluating antidepressant treatment efficacy, with a ≥50% reduction in score considered a conventional criterion for treatment response [44]. Although there is no established consensus regarding the operational definition of relapse or recurrence in depression, we defined recurrence as a transition from minimal or mild depression (HAM-D<17) to moderate or severe depression (HAM-D≥17) between consecutive visits. In this paper, we use the term *recurrence* to refer to such worsening without formally distinguishing it from *recurrence* as defined in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* [3]. The following two models were developed: (1) a between-person model to classify patients with moderate to severe depression and (2) a within-person model to detect recurrence since the last visit. All recordings were treated as individual data points with the goal of cross-sectional screening for severe depression.

XSL•FO
RenderX

Within-person models used changes in voice features between time intervals to predict recurrence. Five-fold GroupKFold cross-validation was used to perform cross-validation at the participant level and prevent data leakage. To evaluate multimodal integration, we tested the following five feature sets: (1) age and sex variables only (referred to as "demographic"); (2) acoustic features only (referred to as "acoustic"); (3) linguistic features only (referred to as "linguistic"); (4) acoustic and linguistic features combined (referred to as "speech"); and (5) age, sex, and speech features (referred to as "speech+demographic"). Shapley additive explanation (SHAP) analysis was conducted to interpret feature contributions for each prediction task [45].

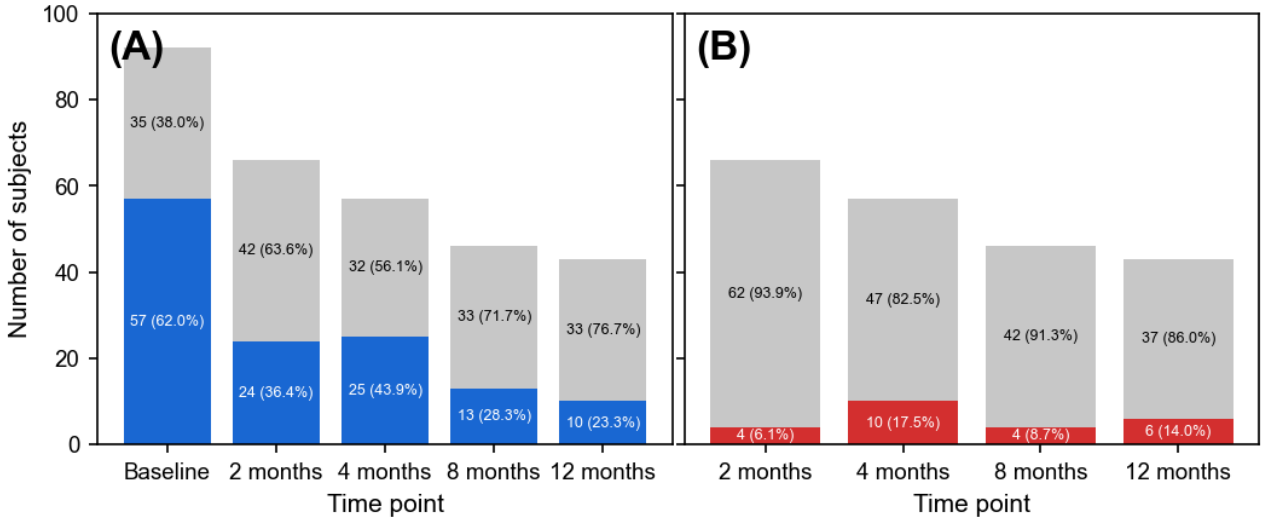
Machine learning experiments were conducted on a computing cluster with Intel Xeon Gold 6138 central processing units, NVIDIA RTX A6000 graphics processing units (48-GB video RAM), and 128-GB RAM. Analyses used Python (version 3.9.6; Python Software Foundation) with the scikit-learn (version 1.6.1; Google Summer of Code project), *lightgbm* (version 4.6.0), and *xgboost* (version 3.0.2) packages.

Ethical Considerations

This study was approved by the institutional review board of Seoul National University Hospital (1812-081-995) and conducted in accordance with the ethical standards of the 1964 Declaration of Helsinki and its later amendments. Written informed consent was obtained from all participants during their initial visit, which included information about the study purpose, data use, and the right to withdraw at any time. All audio files were anonymized and securely stored and are not to be used for any purpose beyond the scope of consent. No identifiable information appears in the manuscript or supplementary materials, and participants are not recognizable in any shared data or figures. Participants received approximately US $20 per visit as reimbursement for transportation and time in line with standard research practices.

All participants in our study were receiving ongoing care at our outpatient psychiatric clinic throughout the study period, ensuring continuous clinical monitoring and appropriate treatment independent of the research protocol. Given that bipolar disorder is associated with high suicide risk [46], the research nurses were instructed to immediately notify the attending psychiatrist if a participant appeared to be at high risk during the interview.

Results



Study Participants and Speech Recordings

Participants (N=92; 70/92, 76% female) were outpatients visiting the Mood and Anxiety Clinic at Seoul National University Hospital for mild to severe depressive symptoms. After the baseline interview, 72% (66/92) of the participants attended the 2-month follow-up, 62% (57/92) attended at 4 months, 50% (46/92) attended 8 months, and 47% (43/92) attended at 12 months. In total, we collected 304 recordings, and the study participants collectively spoke for approximately 55 hours (197,081 seconds) and said 323,280 words. The average length of the concatenated patients' voice segments at each interview session was 648.69 (SD 486.4) seconds and included 1063 (SD 833.5) words. The average sentence was 15.91 (SD 5.9) words. When manually reviewing 2% of the randomly selected machine-generated transcripts against their corresponding audio recordings, we identified a CER below 1% (range 0.02%-1.08%). There was no significant correlation between CER and HAM-D scores (r=0.10; P=.83). In total, 6373 acoustic features and 105 linguistic features were extracted.

At baseline, 62% (57/92) of the participants had moderate to severe depression. A total of 36% (24/66) at 2 months, 44% (25/57) at 4 months, 28% (13/46) at 8 months, and 23% (10/43) at 12 months were moderately to severely depressed (Figure 1A). At baseline, there were no statistically significant differences in sex (P=.54), BMI (P=.84), psychiatric diagnosis (P=.54), socioeconomic status (P=.64), years of education (P=.61), antipsychotic dosage (P=.40), and medical comorbidities (P=.20) between patients with bipolar disorder with moderate to severe depression and their counterparts with minimal to mild depression (Table 1). Patients with more severe depressive symptoms had greater self-reported depressive, anxiety, and suicidal symptoms (P<.001 in all cases). At baseline, 89% (82/92) of the participants were prescribed antipsychotics; 94% (86/92) were prescribed mood stabilizers; 30% (28/92) were prescribed antidepressants; 67% (62/92) were prescribed benzodiazepines; and 46% (42/92) were prescribed other medications, such as propranolol and benztropine. The type and dosage of medications were modified by the attending psychiatrist at each visit. Of the 92 participants, 14 (15%) completed only 1 visit, 13 (14%) completed 2 visits, 22 (24%) completed 3 visits, 17 (19%) completed 4 visits, and 26 (28%) completed all 5 visits. In 11.3% (24/212) of cases, participants had recurrence at follow-up (Figure 1B).

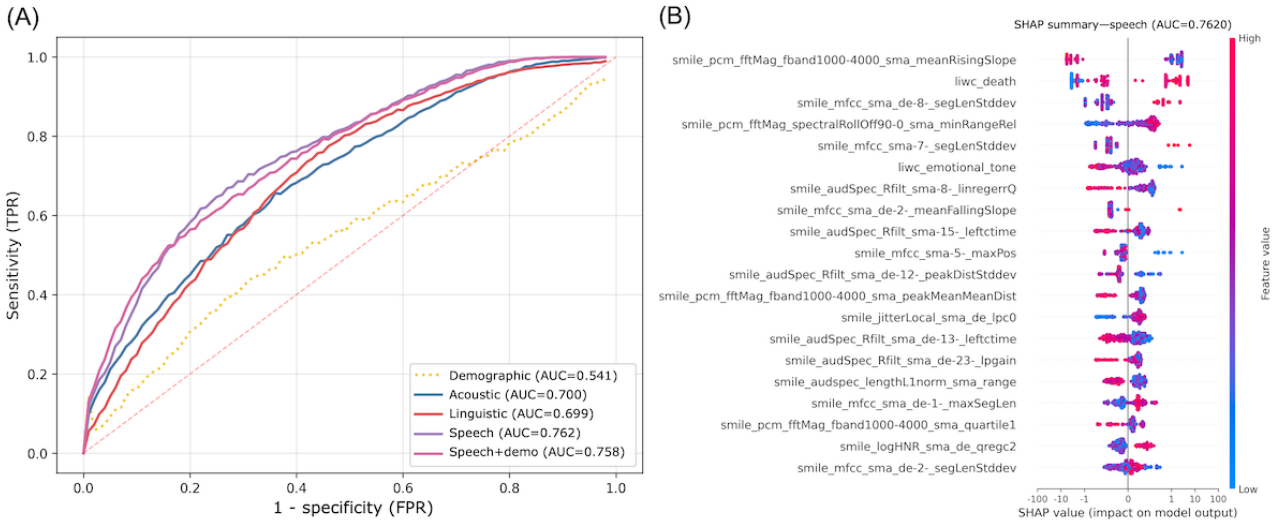
Acoustic and Linguistic Features Associated With Depression Severity

After adjusting for age, sex, BMI, and antipsychotic dosage and correcting for multiple testing, 1709 acoustic features were significantly associated with depression severity. The 5 most strongly associated acoustic features were audSpec_Rfilt_sma_de(8)_lpgain (linear prediction gain computed from the delta (first derivative) of the smoothed 8th RASTA-filtered auditory spectral band; β=−1.89; SE 0.31; Benjamini-Hochberg adjusted $P<.001$), pcm_fftMag_spectralCentroid_sma_de_meanSegLen (mean segment length of the time-derivative (delta) of the smoothed spectral centroid computed from the FFT-magnitude spectrum of the PCM signal; β=1.89, SE 0.31; adjusted $P<.001$), pcm_fftMag_psySharpness_sma_de_meanSegLen (mean segment length of the time-derivative (delta) of the smoothed psychoacoustic sharpness computed from the FFT-magnitude spectrum of the PCM signal; β=1.819, SE 0.31; adjusted $P<.001$), mfcc_sma_de(1)_maxSegLen (maximum segment length of the time-derivative (delta) of the smoothed first MFCC coefficient; β=1.765, SE 0.31; adjusted $P<.001$), and pcm_fftMag_spectralRollOff50.0_sma_de_meanSegLen (mean segment length of the time-derivative (delta) of the smoothed 50% spectral roll-off computed from the FFT-magnitude spectrum of the PCM signal; β=1.77, SE 0.30; adjusted $P<.001$; Multimedia Appendix 1). Participants with greater depression severity exhibited a reduced gain in relative spectral transform–filtered bands, which is related to speech clarity. The spectral centroid reflects the brightness of sound, whereas spectral roll-off measures the frequency below which 50% of the spectral energy is concentrated. Psychoacoustic sharpness captures the perceived clarity or harshness of the sound. Increased segment lengths in their temporal derivatives suggest prolonged periods of relatively unchanging frequency distribution, energy concentration, and perceptual sharpness (Figure 2A) [31].

XSL•FO
RenderX

Figure 2. Forest plots displaying the results (β estimate) of mixed-effects multivariate linear regression between depression severity and (A) acoustic and (B) linguistic features. Only 30 acoustic features with the lowest *P* values are depicted for brevity. Red represents a positive association, whereas blue represents a negative association.

After adjusting for age, sex, and years of education, 14 linguistic features were significantly associated with depression severity. The top 5 psycholinguistic categories associated with depression severity were "death" (β=2.307; SE 0.31; adjusted *P*<.001), "avoidance" (β=1.641; SE 0.30; adjusted *P*<.001), "emotional tone" (β=−1.50; SE 0.29; adjusted *P*<.001), "positive emotion" (β=−1.356; SE 0.30; adjusted *P*<.001), and "family" (β=1.32; SE 0.32; adjusted *P*<.001; Multimedia Appendix 2). Participants with depression more frequently used words related to death, avoidance, family, health, religion, negative emotions, and discrepancies and less frequently used words related to positive emotions and reward than their counterparts with minimal to mild depression (Figure 2B).



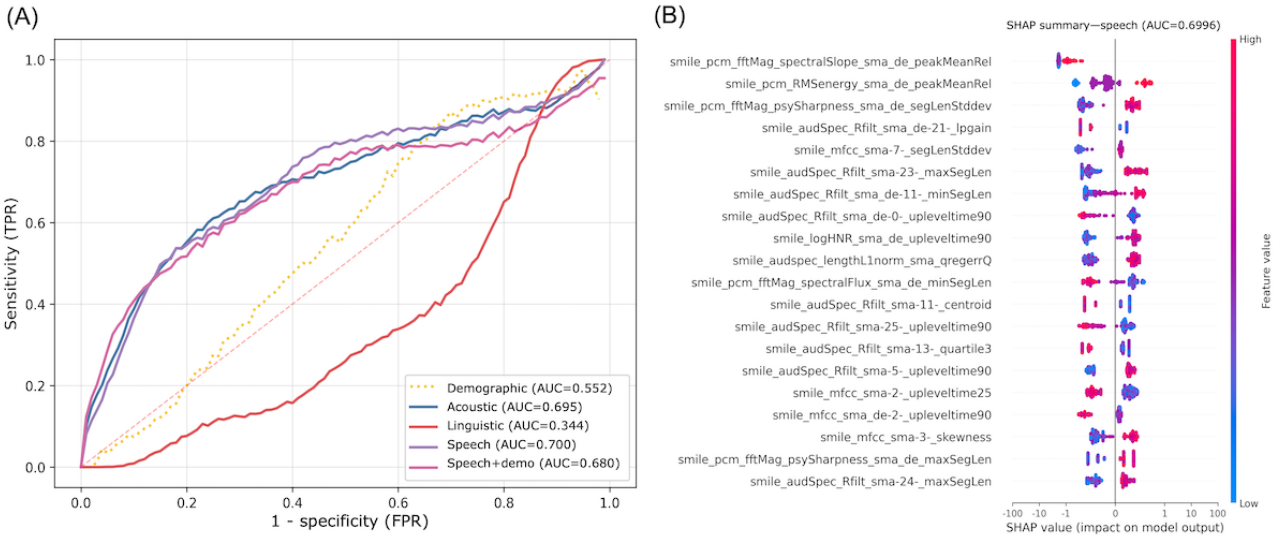
Machine Learning Classification

Between-Person Classifier

Of 304 audio recordings, 129 (42.4%) were from patients with moderate to severe depression. Overall, LGB outperformed XGB. The best-performing classifier was the speech model (mean AUC 0.762, SD 0.002), followed by the speech+demographic model (mean AUC 0.758, SD 0.002). At the cutoff determined by the Youden index (0.30), the speech model achieved 72.5% sensitivity, 67.4% specificity, 69.6% accuracy, and a positive predictive value of 62%. Both acoustic and linguistic models outperformed the demographic model (AUC=0.700 and 0.699, respectively, vs AUC=0.541; Figure 3A).

XSL•FO
RenderX

Figure 3. Between-person classification models for detecting moderate to severe depression: (A) receiver operating characteristic curves for light gradient boosting models (yellow line: demographic model [age and sex]; blue line: acoustic model; green line: linguistic model; purple line: speech model [acoustic+linguistic]; pink line: speech+demographic model) and (B) Shapley additive explanation (SHAP) summary plot for feature contributions for the best-performing model. AUC: area under the receiver operating characteristic curve; FPR: false positive rate; TPR: true positive rate.



SHAP analysis indicated that both acoustic and linguistic features contributed meaningfully to the inference of bipolar depression. Among linguistic features, a higher frequency of words related to death and lower emotional tone were associated with an increased likelihood of a positive (depressive) prediction. Acoustic predictors such as reduced variation in spectral slope and temporal instability increased the likelihood of a positive prediction (Figure 3B). To verify that the predictive importance of the LIWC "death" category was not driven by a small number of extreme cases, we examined its distribution (mean 0.00238, SD 0.00282). After excluding the recordings that exceeded the 3 SD cutoff (>0.01084; z=+3.04 to +5.55), the between-person model performance remained comparable or slightly improved (linguistic AUC=0.678 vs 0.699 before exclusion; acoustic AUC=0.781 vs 0.700; speech AUC=0.800 vs 0.762). These results confirm that the association between the "death" category and depression severity was not driven by outlier effects.

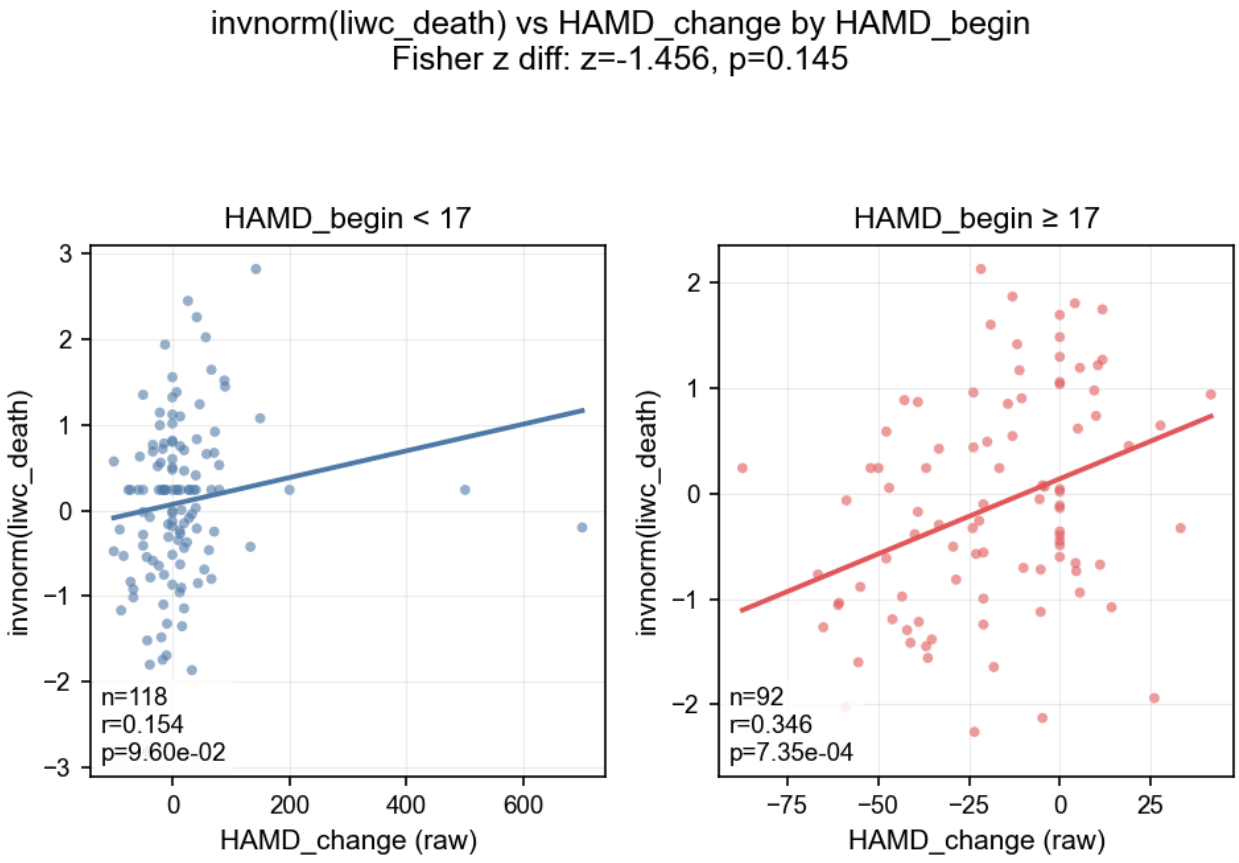
Within-Person Classifier for Predicting Recurrence

The change in features from 212 paired audio recordings from consecutive visits was used, among which 24 (11.3%) follow-ups corresponded to recurrence events. XGB outperformed LGB. The best performance was achieved by the speech model, with a mean AUC of 0.700 (SD 0.003), accuracy of 80.6%, sensitivity of 49.3%, and specificity of 84.6% at the optimal cutoff of 0.10. The acoustic model achieved a comparable performance, with an AUC of 0.695 and accuracy of 0.835 (Figure 4). All performance metrics can be found in Multimedia Appendix 3.

Figure 4. Within-person classification models for detecting recurrence: (A) receiver operating characteristic curves for extreme gradient boosting models (yellow line: demographic model [age and sex]; blue line: acoustic model; green line: linguistic model; purple line: speech model [acoustic+linguistic]; pink line: speech+demographic model) and (B) Shapley additive explanation (SHAP) summary plot for feature contributions for the best-performing model. AUC: area under the receiver operating characteristic curve; FPR: false positive rate; TPR: true positive rate.

XSL•FO
RenderX

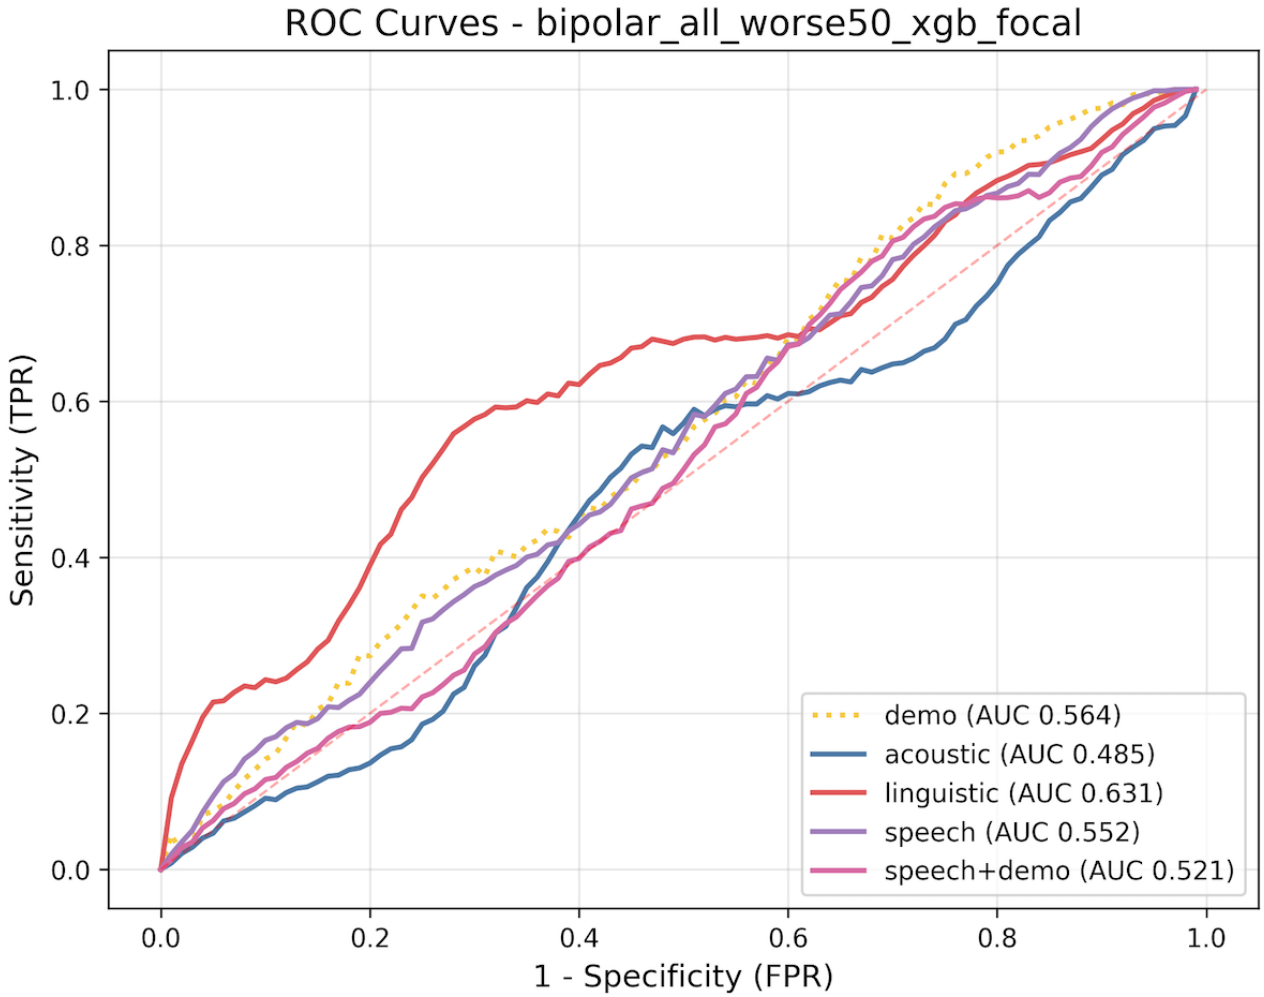
SHAP analysis of the speech model suggests that the model relied primarily on acoustic features of reduced vocal energy, prosodic flattening, and articulatory slowing to infer depressive recurrence in bipolar disorder.



Discussion

Principal Findings

In this prospective longitudinal study of individuals with bipolar disorder, we demonstrated that both the acoustic and linguistic features of voice are strongly associated with depression severity and can be leveraged to accurately detect and monitor depressive states. In both between- and within-person analyses, models combining acoustic and linguistic speech features achieved the highest performance for identifying moderate to severe depression and predicting recurrence. In the between-person analysis, single-modality models using either acoustic or linguistic features outperformed the demographic-only (null) model, whereas in the within-person analysis, only the acoustic model showed superior performance over the null model. Incorporating demographic variables did not improve model performance in either task.



The within-person models did not outperform the between-person models. A major challenge was the substantial class imbalance, with recurrence occurring in only 11.3% (24/212) of follow-up visits. We addressed this by applying SMOTE to the training set within each cross-validation fold. Because participants who completed more visits contributed more paired samples to model training, these individuals may have exerted a greater influence on model learning. If attrition was nonrandom—if participants with sudden worsening were more likely to drop out—the within-person models may have been biased toward patterns characteristic of participants with better clinical course. We further examined the unexpected negative finding of the linguistic-only model. Changes in linguistic content were more pronounced among participants already in a severe depressive state where suicidal ideation and negative appraisals were more likely. For instance, the correlation between changes in death-related word use and HAM-D score change was stronger in those with a baseline HAM-D score of ≥17 than in those below the threshold (r=0.346 vs 0.154; Figure 5). Therefore, in many cases, the model would have predicted that greater increases in HAM-D scores were associated with worsening mood, yet these instances were labeled as negative because recurrence was defined as crossing the threshold from HAM-D<17 to ≥17. When recurrence was defined as a ≥50% increase in HAM-D score, thereby including the cases showing further worsening within the range of HAM-D≥17, the linguistic model's performance improved (AUC=0.631; Figure 6), supporting our hypothesis.

Figure 5. Correlation between changes in the Linguistic Inquiry and Word Count "death" category and changes in depression severity (Hamilton Depression Rating Scale) stratified by baseline severity. HAM-D: Hamilton Depression Rating Scale.

XSL•FO
RenderX

Figure 6. Receiver operating characteristic curves for the within-person classification models predicting recurrence defined as a ≥50% increase in Hamilton Depression Rating Scale score. The yellow line represents the demographic model (age and sex), the blue line represents the acoustic model, the green line represents the linguistic model, the purple line represents the speech model (acoustic+linguistic features), and the pink line represents the speech+demographic model. AUC: area under the receiver operating characteristic curve; FPR: false positive rate; ROC: receiver operating characteristic curve; TPR: true positive rate.

Among the most important acoustic markers distinguishing depressed speech, we identified a reduced gain in the relative spectral transform–filtered spectral bands and longer continuous segments exhibiting changes in the spectral centroid, roll-off, and sharpness. These findings suggest that individuals with more severe depression display greater temporal monotony in the key spectral properties of their speech, which is consistent with the clinical observation of monotonous or less modulated vocal output in depression [5,8]. Numerous studies and meta-analyses have highlighted pitch-related features as one of the most robust acoustic markers of depression [5,6,8,15]. Changes in the fundamental frequency (F0), including reductions in mean pitch, pitch range, and pitch variability, have consistently been reported as characteristics of depressed speech. In our analysis, various pitch-related features were significantly associated with depression severity (Multimedia Appendix 1). Several metrics reflecting the temporal variability, range, and distributional characteristics of pitch change (ΔF0) were strongly associated with higher HAM-D scores.

Linguistically, individuals with depression used words related to death, avoidance, family, health, religion, negative emotions, and discrepancies more frequently, whereas positive emotions and reward-related words were less common. These linguistic features reflect the cognitive and affective themes of depressive states. Our findings closely align with meta-analytic results showing that depression is associated with increased use of negative emotion words and decreased use of positive emotion words [7]. Notably, although previous studies have highlighted increased first-person singular pronoun use as a linguistic marker of depression, no significant association between the use of first-person singular pronouns and depression severity was observed in our analysis. One explanation is that our study sample consisted of patients already diagnosed with bipolar disorder, which may have attenuated the discriminatory power of this marker. Additionally, the Korean language is known as one of the “pro-drop languages,” where pronouns are often omitted within sentences, especially when the subject, such as “I,” remains unchanged throughout the discourse [47]. Increased use of words related to death and health may reflect suicidal and somatic symptoms in patients with depression, whereas increased use of words related to avoidance and discrepancies and decreased use of reward-related words may reflect cognitive changes.

Comparisons to Prior Work

While similar designs have demonstrated the potential for applying LIWC to automatically transcribed speech, this study implemented LIWC-based psycholinguistic analysis on automatically transcribed and machine-translated speech derived from psychiatric patient interviews. Previous research has applied LIWC to manually transcribed psychiatric interviews [36,48] or examined its use in artificial intelligence–generated transcripts in nonclinical populations [49]. However, none have used a fully automated pipeline combining both automatic speech recognition and machine translation in psychiatric populations. By advancing this methodology, our findings highlight the feasibility of scalable, cross-linguistic, multimodal speech-based digital biomarkers for depression.

Our study also included age, sex, antipsychotic dosage, and years of education as covariates in speech analysis. Previously, we have reported how antipsychotic medication can act as a confounder when analyzing changes in voice features associated with psychiatric symptoms, especially when drug-naïve individuals were used as controls [22,50]. Clinicians commonly prescribe or increase the dosage of antipsychotics when psychiatric symptoms worsen. Studies have reported that atypical antipsychotics affect vocal pitch and spectral features in a dose-dependent manner [50,51]. Years of education and speech content are also strongly associated with each other; individuals with fewer years of education produce less lexical and semantic content than those with higher levels of education [52]. Our covariate adjustments strengthened the robustness of our findings regarding the speech characteristics of patients with depression.

We implemented several strategies to mitigate overfitting, including BBCV with patient-level 5-fold cross-validation and 1000 iterations [43]. For linguistic analysis, we used the LIWC framework to quantify changes in the use of different psycholinguistic classes instead of counting the lexicons themselves. We considered the risk of overfitting by using a purely lexical approach, particularly when multiple recordings were collected from each participant. Previous studies have illustrated this limitation: Cohen et al [53] reported “yeah,” “very,” and “at” as top text model features, and Shin et al [54] reported “admission” as the single most important feature for detecting current depression, which is a finding unlikely to be replicated outside the tertiary hospital setting. To further assess the stability of our linguistic predictors, sensitivity analyses excluding recordings with extreme “death”-related word frequencies (>+3 SD) showed that between-person model performance remained comparable or slightly improved. This indicates that, rather than reflecting isolated outliers, the predictive contribution of death-related language represents a consistent and generalizable linguistic marker of depressive severity across participants.

Limitations

This study has several limitations. First, all participants were diagnosed with bipolar disorder, which may limit the generalizability of our findings to other mood disorders. To assess the impact of diagnostic composition, we repeated all analyses after including patients with MDD. Including participants with MDD (44 recordings) did not substantially affect the between-person model performance (speech model AUC=0.751) but reduced the performance of the within-person model (speech model AUC=0.505; Multimedia Appendix 3). This finding suggests that consistent with the clinical distinction between bipolar and unipolar depression, their acoustic and linguistic patterns may diverge more prominently in the context of longitudinal recurrence prediction. The increased class imbalance introduced by including patients with MDD (from 7.83:1 to 8.38:1) may have also hindered classifier learning.

Second, because there is no established consensus on defining recurrence based on HAM-D scores, we adopted an operational definition of recurrence as a change from HAM-D<17 to 17 across 2 consecutive visits. This definition may have missed clinically meaningful fluctuations within the same severity range (eg, from 1 to 16 or from 17 to 24). We also tested an alternative definition of recurrence as a ≥50% increase in HAM-D scores; however, this approach did not improve classification performance (speech model AUC=0.552). Interestingly, the linguistic model was better trained at predicting 50% increase (AUC=0.631) than at predicting recurrence based on threshold crossing (AUC=0.344). This suggests that linguistic changes may be more sensitive to relative shifts in symptom severity than to categorical transitions in depression status.

Third, all interviews were conducted in a controlled environment, which may not reflect the variability in speech quality, background noise, or recording conditions encountered in real-world settings such as telemedicine or mobile apps.

Fourth, although participants were regularly followed up on in outpatient clinics and received appropriate care, we did not collect objective measures of hypomanic or manic symptoms, which may have influenced speech patterns.

Fifth, although antipsychotic dosage was included as a covariate in acoustic analyses, other psychotropic medications were not. Benzodiazepines can theoretically affect voice due to their muscle relaxation properties [55], and an early study reported that they can influence the modulation of the fundamental frequency of speech [56]. We found no empirical evidence that mood stabilizers affect voice acoustics. Although these medications were not included as covariates due to the limited evidence base, they may nonetheless represent potential confounding factors that warrant consideration in future work.

Sixth, the sample size was relatively small compared with the large number of features used in the classifiers. Nonetheless, a post hoc DeLong test incorporating the observed sample size, label distribution, and AUCs indicated statistical power exceeding 0.95 for feature comparisons against the demographic (null) model. We also applied BBCV to reduce overfitting. However, no independent external validation set was available at the time of our study.

Seventh, the sample was restricted to Korean-speaking individuals, which may constrain cross-cultural and cross-linguistic applicability. Given that acoustic and linguistic markers of depression may vary across languages and cultures, model performance may differ in more diverse populations.

XSL•FO
RenderX

Finally, we did not perform a manual validation of the translation accuracy. Therefore, potential translation bias may have influenced the distribution of specific LIWC categories, and this limitation should be considered when interpreting the linguistic results.

Future Work

Replication in larger, independent samples—including different demographic groups, languages, and clinical settings—will be essential before widespread clinical implementation. While our study demonstrated the feasibility of applying LIWC-based analysis to machine–transcribed and translated speech, the impact of linguistic and cultural nuances on model accuracy can be further explored. Cross-cultural validation studies or fine-tuning of large language models on domain-specific corpora—such as annotated clinical interview transcripts—could enhance the accuracy and contextual relevance of linguistic feature extraction. Future studies should also compare speech-based biomarkers with other digital biomarkers and traditional clinical assessments to establish their relative utility and optimal integration strategies for comprehensive mental health monitoring platforms. Moreover, privacy and data security concerns are paramount when implementing such monitoring platforms in the real world based on biomarkers such as speech as voice can contain sensitive biometric information. With secure data pipelines, ethical governance frameworks, and clear clinical decision support protocols, speech-based mood monitoring can be effectively deployed across a spectrum of digital mental health tools, from virtual care services to AI-driven therapeutic platforms.

Conclusions

Our findings provide evidence that both acoustic and linguistic features of speech serve as digital biomarkers of depression. By leveraging multimodal voice analysis and longitudinal modeling, we demonstrated the feasibility of scalable, automated, and noninvasive monitoring of depressive symptoms in real-world clinical practice. These results provide the groundwork for the future integration of speech-based tools into digital health platforms, offering new opportunities for personalized and continuous mental health care.

Acknowledgments

This study was supported by the Basic Science Research Program of the National Research Foundation of Korea funded by the Ministry of Education (grant NRF-2018R1D1A1A02086027), the Seoul Business Agency (CY140170), and Seoul National University Hospital (032022230). The funders played no role in the study design; data collection, analysis, or interpretation; or writing of the manuscript. The authors would like to thank Editage for editing and reviewing this manuscript for the English language.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to the consent that did not cover public sharing of data, but the processed data are available from the corresponding author on reasonable request. Raw audio recordings could not be made available because of their sensitivity. Both the principal investigator (YMA) and first authors (SM and TY) had complete access to the data and took responsibility for their integrity.

Authors' Contributions

SM and TY conducted the data analysis, prepared the figures and tables, and drafted the manuscript. SP and JL contributed to machine learning. SM, DS, HL, HSL, SJR, and YMA contributed to the conceptualization and design of the study, including data collection. YMA supervised this study. All authors have reviewed and approved the final manuscript.

Conflicts of Interest

SP was an employee and JL is the chief technology officer of ActionPower Corp, which commercializes the automatic speech recognition tool used in this study. Unrelated to this work, YMA has received research support from or served as a speaker for Janssen Korea Ltd and Korea Otsuka Pharmaceutical. All other authors declare no other conflicts of interest.

Abstract

Background: Accurately predicting the survival outcomes of patients with lung cancer receiving chemotherapy remains challenging.

Objective: To improve clinical management of this population, this study developed a multivariate machine learning (ML) model to assess all-cause mortality risk in chemotherapy-treated patients with lung cancer.

Methods: This study retrospectively recruited 1278 postchemotherapy patients with lung cancer from Guangzhou Chest Hospital between 2017 and 2019. Candidate features such as demographic characteristics, environmental exposures, clinical information, and patient-reported symptoms were collected via questionnaires and the electronic medical record system. The survival status and the deceased date were investigated twice a year. A total of 84 predictive models were constructed on the training set using 5 ML algorithms either individually or in pairwise combinations. The concordance index was used to identify the optimal model on the testing set, with performance validated via receiver operating characteristic curves, calibration curves, and decision curve analysis. Additionally, Shapley Additive Explanations and restricted cubic splines were applied for feature attribution analysis.

Results: The optimal model ultimately retained 21 prognosis-association features, including age, sex, BMI, smoking status, environmental smoke, the MD Anderson Symptom Inventory for Lung Cancer total score trajectories, cluster of differentiation

XSL•FO
RenderX

56, TNM stage, histology, and prechemotherapy blood biomarkers. On the testing set, the model acquired a concordance index of 0.702 (95% CI 0.652-0.753). The decision curves demonstrated positive clinical benefit when the risk thresholds were 0.40-0.69, 0.62-0.99, and 0.72-0.99 for 1-, 3-, and 5-year mortality predictions, respectively. The calibration curves showed that the predicted mortality probabilities fluctuated around the observed probabilities, and the Brier scores for 1-, 3-, and 5-year predictions were 0.20, 0.18, and 0.11, respectively. The area under the curve of the model was 0.740, 0.777, and 0.915 for 1-, 3-, and 5-year mortality predictions, respectively. Interpretability feature attribution analysis revealed that the significant features could predict all-cause mortality risk in chemotherapy-treated patients with lung cancer.

Conclusions: Our ML models exhibited acceptable discrimination, calibration, and clinical benefit in predicting the mortality risk of chemotherapy-treated patients with lung cancer, which could help clinicians in personalized prognostic management.

KEYWORDS

lung cancer; chemotherapy; mortality; machine learning; prediction model

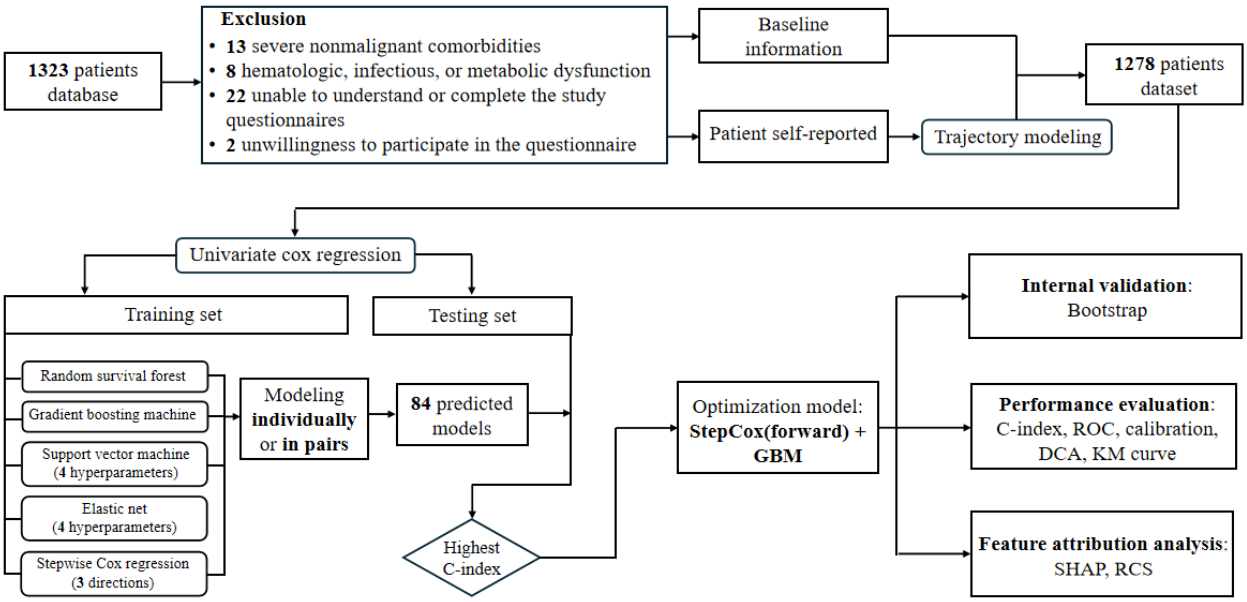
Introduction

Lung cancer is the leading cause of cancer-related deaths globally. Lung cancer claimed approximately 1.8 million lives in 2022 alone, accounting for 18.7% of global cancer deaths [1]. With the advancements in medicine, the emergence of targeted and immune drugs introduces new options for lung cancer treatment. Personalized treatment strategies combining surgery, radiotherapy, chemotherapy, targeted therapy, and immunotherapy demonstrate significant efficacy in improving the living quality and long-term survival rates of patients with lung cancer. However, for some advanced lung cancers lacking driver mutations and with negative immune checkpoint expression, chemotherapy remains the primary treatment modality [2,3]. Thus, accurately predicting the mortality risk of chemotherapy-treated lung cancers to optimize treatment planning and patient care is of significant public health importance.

Machine learning (ML) models have become increasingly important tools for predicting the mortality risk of patients with lung cancer treated with chemotherapy, offering new insights and improved accuracy over traditional methods. While demographic and clinical characteristics are important, recent research has highlighted the potential benefits of incorporating additional data sources to enhance model performance [4-6]. For example, although the TNM stage is a recognized factor associated with the prognosis, it explains just less than 30% of the prognostic differences [7,8]. It is noted that genomic biomarkers present a means of refining prognosis assessment models, but the expensive genetic testing restricts the clinical application [9-11]. The above situation underscores the requirement for a more effective and interpretable mortality risk stratification model for postchemotherapy patients with lung cancer.

The biopsychosocial framework advocates dissecting disease from diverse angles, including symptom burden. The MD Anderson Symptom Inventory for Lung Cancer (MDASI-LC), a patient-reported outcome (PRO) tool, offers key perspectives into the self-reported symptom experience of patients receiving chemotherapy [12]. Integrating longitudinal PRO information into prognostic models has notable value in refining the prediction of patient outcomes [13-16].

This study adheres to the transparent reporting of a multivariable prediction model for individual prognosis or diagnosis guidelines as much as possible to ensure the transparent and accurate reporting of our predictive model development and validation [17]. This study developed a multivariable ML model that integrated demographic characteristics, clinical features, environmental factor exposure, immunohistochemical indicators, and total PRO score to predict the mortality risk of chemotherapy-treated patients with lung cancer. The model aims to provide clinicians with an effective tool for predicting the risk of death in patients with lung cancer after chemotherapy, assisting clinicians in customizing treatment plans, optimizing patient care plans, and improving patient prognosis.



Methods

Overview

An overview of the entire study design and ML framework is provided in Figure 1.

Figure 1. The flowchart of this study. This study provided a comprehensive framework for building machine learning models to predict mortality risk for patients with lung cancer after chemotherapy. C-index: concordance index; DCA: decision curve analysis; GBM: gradient boosting machine; KM: Kaplan-Meier; RCS: restricted cubic spline; ROC: receiver operating characteristic curve; SHAP: Shapley Additive Explanations.

Study Population

This retrospective and semilongitudinal investigation included 1278 patients with lung cancer who received platinum-based chemotherapy at Guangzhou Chest Hospital between November 2017 and 2019. Demographic characteristics, environmental exposures, clinical information, and patient-reported symptoms were collected using questionnaires and the electronic medical record system. Patients' TNM stage was identified by the seventh edition of the classification system.

Patients who met the following inclusion criteria were included (1) histologically confirmed diagnosis of primary lung cancer, (2) absence of prior chemotherapy for lung carcinoma, and (3) demonstrated ability to comprehend and complete study questionnaires with clear consciousness.

Patients with the following presentations that would bias their symptom reporting or outcome were excluded: (1) severe nonmalignant comorbidities; (2) hematopoietic, infectious, or metabolic dysfunction; and (3) preexisting psychological disorders. The specific number of excluded participants is presented in the flowchart of Figure 1.

Patient-Reported Symptom

Patients completed self-report questionnaires at admission and the first 4 chemotherapy cycles. The professional questionnaires included (1) the MDASI-LC: this is a validated PRO tool specifically designed to assess symptom severity in patients with lung cancer. It consists of 22 items divided into 3 parts: core symptoms, lung cancer-specific symptoms, and additional symptoms. Each item is scored on a scale from 0 to 10, with higher scores indicating more severe symptoms [18]. (2) The Karnofsky Performance Status (KPS): this is a widely used tool for assessing the overall health status and functional state of patients. The KPS score ranges from 0 to 100, with higher scores indicating better functional status. It is commonly used in clinical practice to evaluate patient prognosis and treatment response, and it has been validated in various studies [19]. (3) The Zubrod Performance Score (ZPS): this tool assesses the physical condition of patients, with scores ranging from 0 to 5. Higher scores indicate worse physical status. ZPS is another widely used tool in clinical practice, providing valuable insights into patients' daily living abilities and overall health [20].

The Primary End Point

All-cause mortality served as the primary end point in this study. The professionals monitored the patients biannually by telephone. The death date was recorded if the patients had died; otherwise, they would be followed until death. The time horizon for this outcome is defined as 1-, 3-, and 5-year posttreatment initiation. The follow-up period in this research ranged from 1 month to 11 years.

Statistical Analysis Methods

The normality of continuous variables was assessed using the Shapiro-Wilk test, and the group comparisons were made using the 2-tailed *t* test or the Mann-Whitney *U* test. Categorical variables were analyzed using the chi-square or the Fisher exact test. Survival curves were generated using Kaplan-Meier and compared using the log-rank test. Hazard ratio and 95% CI were estimated using Cox regression. Statistical significance was defined when $P<.05$ (2-tailed). Missing data imputation was performed using the missForest algorithm, which accommodated mixed data types and handled nonlinearities and outliers.

The reliability of the scales was assessed using Cronbach α to measure internal consistency. Pearson correlation coefficients were calculated to examine the correlations between the 3 scales, assessing their validity. Longitudinal symptom burden trajectories were identified using group-based trajectory modeling (GBTM), with data from the 3 scales assessed across 5 separate time points [21]. GBTM criteria were odds of correct

XSL•FO
RenderX

classification >5, average posterior probability (Avepp) >0.7, posterior probability of group membership (P_j) >5%, correspondence between P_j and probability of group membership (π_j), relative entropy (E_k) >0.7, and a minimized Bayesian information criterion value.

ML Methods

Random survival forest (RSF), gradient boosting machine (GBM), survival support vector machine (survival-SVM), elastic net (Enet), and stepwise Cox regression were used to develop a prognostic model [22-25]. For the RSF and GBM models, the best hyperparameters for these 2 models were determined by constructing separate base models on the training set and performing preliminary cross-validation and performance evaluation. For the hyperparameter γ of the survival-SVM model, the hyperparameter α of the Enet model, and the 3 directions of the stepwise Cox regression model, a grid search method was used. The specific parameters of the five algorithms are as follows: (1) RSF: ntree=1000, nodesize=32, mtry=10; (2) GBM: ntrees=3750, interaction.depth=2, n.minobsinnode=20; (3) survival-SVM: γ in 0.25, 0.5, 1, 2, 4; (4) Enet: α in 0.1, 0.2, 0.3, 0.4; and (5) stepwise Cox regression: direction in both, backward, forward. Five separate ML models with a total of 13 models (different hyperparameter models of the same algorithm are considered as different models) were first constructed: RSF (1 model), GBM (1 model), survival-SVM (4 hyperparameters and 4 models), Enet (4 hyperparameters and 4 models), and stepwise Cox regression (3 directions and 3 models). Second, two-by-two combinations of the above 13 models in sequential order totaled 71 models, for a total of 84 models being constructed.

Continuous features were not binarized or split-boxed during the modeling process in order to maximize the amount of information retained in the data, and for categorical features, such as sex, smoking status, and tumor staging, the modeling process used discrete values.

Model discrimination, accuracy, and clinical benefit were evaluated using the concordance index (C-index), decision curve analysis, calibration curves, and the area under the curve (AUC). Internal validation of the models was performed using the bootstrap method. Feature attribution analysis was conducted using Shapley Additive Explanations and restricted cubic splines (RCSs).

Ethical Considerations

The protocol for this study was approved by the ethics review board of Guangzhou Medical University. All patients were informed of the data collection methods and privacy protection measures. All patient identifiers were removed after data collection and replaced with unique nonidentifiable serial numbers, and deidentified data were stored in a password-protected electronic database, with access restricted to the core research team. The deidentified data were only used for this study without sharing with third parties without additional approval.

Results

Baseline Characteristics of the Patients

This study enrolled 1278 eligible patients, with a median age of 61 (IQR 54-68) years, comprising 946 (74%) male and 332 (26%) female patients. Among 1278 enrolled patients with lung cancer undergoing chemotherapy, 408, 94, and 19 cases were alive at the 1-, 3-, and 5-year follow-ups, yielding overall survival rates of 31.9% (95% CI 29.4%-34.6%), 7.4% (95% CI 6%-9%), and 1.5% (95% CI 0.9%-2.4%), respectively. The specific distribution of histological types in our study population is as follows: adenocarcinoma (876/1274, 68.8%), squamous cell carcinoma (247/1274, 19.4%), small cell lung cancer (SCLC; 125/1274, 9.8%), and other types (26/1274, 2%). Some of the more important characteristics can be found in Table 1, and the complete Table 1 can be found in Multimedia Appendix 1.

Patient Report Outcomes Trajectory Modeling

GBTM was applied to characterize PRO trajectories. Table 2 presents detailed information on the GBTM evaluation indicators and trajectory groups. A comprehensive evaluation process is described in Tables S1-S6 in Multimedia Appendix 2. In particular, following a rigorous evaluation of model fit indices and clinical interpretability, 3 distinct trajectory groups were identified for the MDASI-LC total score (group A: high burden, group B: medium burden, and group C: low burden), 3 for the KPS score (group A: high burden, group B: medium burden, and group C: low burden), and 2 for the ZPS score (group A: high burden and group B: low burden). All equation coefficients showed significant differences (P<.001; Figure S1 in Multimedia Appendix 2).

Table 2. The number of each scale trajectory groups, classification counts, and results of various evaluation indicators for the scale[a].

Scales	Group number	OCC[b]	Avepp[c] (%)	P_j[d] (%)	π_j[e] (%)	E_k[f]	BIC[g]
MDASI-LC[h]	3 (3 0 3)	33.2/33.4/81.1	98.24/90.83/93.18	62.82/22.89/14.29	62.71/22.87/14.42	0.91	–9140.61

ZPS[j]	2 (0 2)	5.60/538.10	93.74/98.94	90.84/9.16	85.26/14.74	0.77	–376.79

[a]Optimization model criteria: The odds of correct classification should surpass a value of 5, reflecting a high likelihood of accurate classification. Each group should exhibit an Avepp exceeding the threshold of 0.7, indicating a high degree of confidence in the classification. The P_j should be greater than 5%, signifying that the probability of an entity belonging to a particular group is statistically significant. There should be a close alignment between P_j and the π_j, ensuring that the posterior probabilities are congruent with the a priori probabilities. The E_k should be greater than 0.7, indicating a substantial degree of differentiation between the groups in terms of information content.

[b]OCC: odds of correct classification.

[c]Avepp: average posterior probability.

[d]P_j: posterior probability of group membership.

[e]π_j: probability of group membership.

[f]E_k: relative entropy.

[g]BIC: Bayesian information criterion.

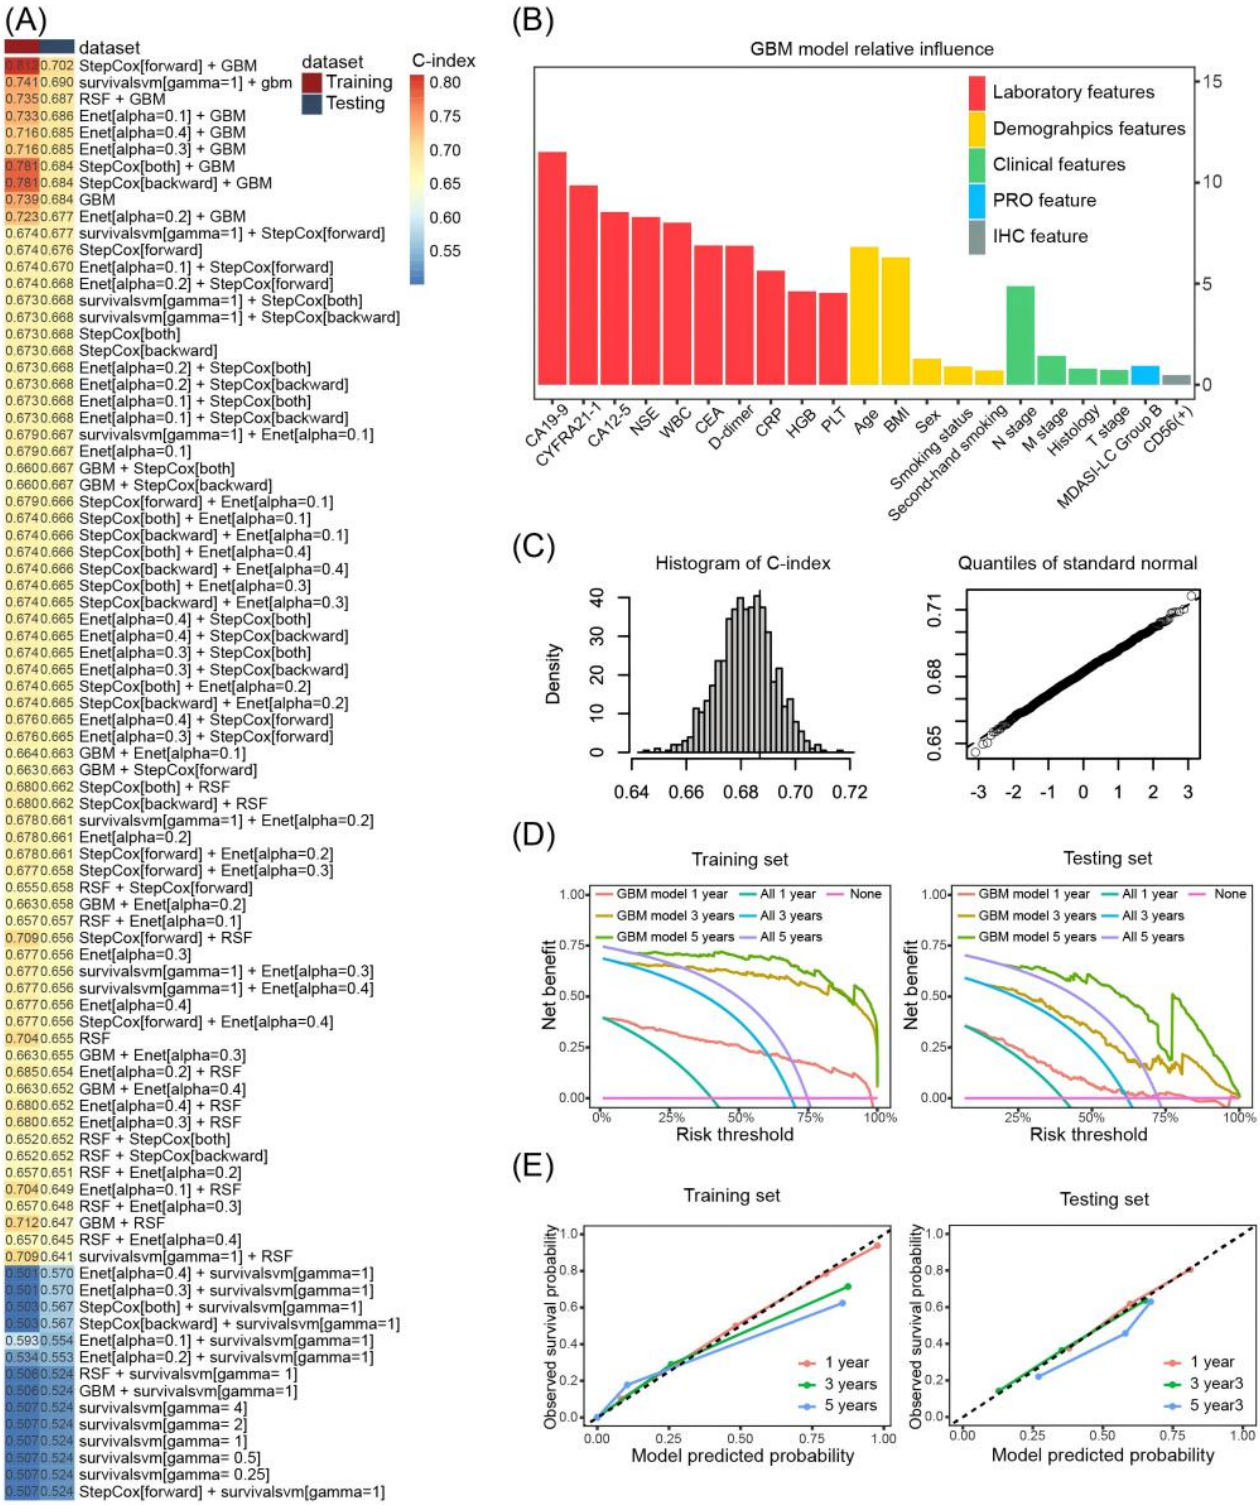
[i]KPS: Karnofsky Performance Status.

[j]ZPS: Zubrod Performance Score.

Univariate Cox Regression Analysis of Feature Selection

The missForest algorithm did not induce statistically significant changes in the data distribution after baseline imputation. A detailed comparison of the baseline data distribution before and after imputation is reported in Table S7 in Multimedia Appendix 2.



Univariate Cox regression analysis (P value of <.05 is statistically significant) identified 27 features significantly associated with prognosis in patients with lung cancer receiving chemotherapy, which served as an initial feature selection step. A comprehensive summary of the univariate analysis is available in Table S8 in Multimedia Appendix 2. Beyond statistically significant findings, an additional 10 features with perceived prognostic relevance, such as a family history of respiratory disease, were included in feature selection despite their lack of statistical significance in the univariate analysis. These features were retained to ensure a comprehensive evaluation of potential prognostic factors and to allow the ML models to capture complex interactions between features. Finally, 37 features were retained for the ML model development.

Models Development and Internal Validation

The dataset of 1278 observations was randomly split into a training dataset (n=895) and a testing dataset (n=383) at a 7:3 ratio. Table S9 in Multimedia Appendix 2 shows that there is no difference between the distributions of the main baseline features of the patients in the training and testing sets. On the training set, a total of 84 predicted models were built with 5 ML algorithms individually or binately 5 ML models were trained and then tested both individually and in all possible combinations of pairs, yielding a total of 84 predictive models (Figure 2A).

XSL•FO
RenderX

Figure 2. Illustration of the machine learning procedure for prediction model development and validation. (A) displays a ranking of 84 predictive models from highest to lowest based on their C-index calculated on the testing set. These models resulted from all possible 2-way combinations of 5 machine learning models. (B) presents the ranked feature importance identified by the GBM model, with the y-axis indicating the relative importance. (C) displays the C-index distribution along with results of a Shapiro-Wilk normality test, obtained during an internal validation using bootstrap resampling. (D) and (E) display DCA curves and calibration plots, respectively, for predicting 1-, 3-, and 5-year mortality risk using the optimal model on both the training and the testing set. CA12-5: carbohydrate antigen 12-5; CA19-9: carbohydrate antigen 19-9; CD56: cluster of differentiation 56; CEA: carcinoembryonic antigen; C-index: concordance index; CRP: C-reactive protein; CYFRA21-1: recombinant cytokeratin fragment antigen 21-1; DCA: decision curve analysis; Enet: elastic net; GBM: gradient boosting machine; HGB: hemoglobin; IHC: immunohistochemistry; MDASI-LC: MD Anderson Symptom Inventory for Lung Cancer; NSE: neuron-specific enolase; PLT: platelet count; PRO: patient-reported outcome; RSF: random survival forest; WBC: white blood cell.

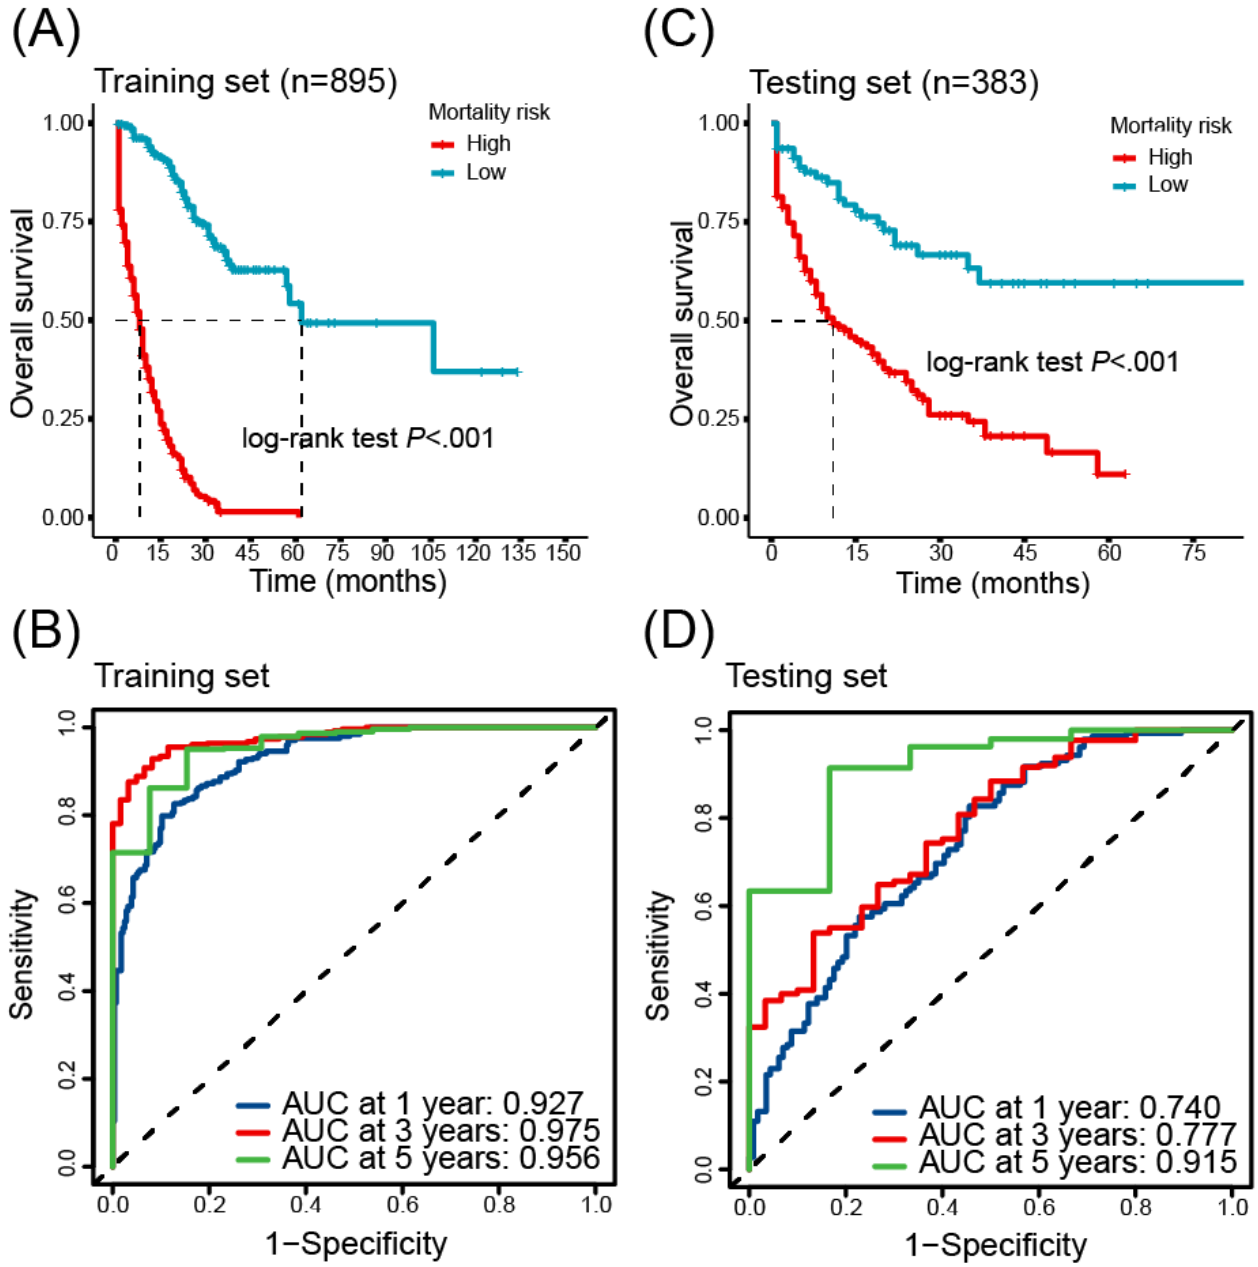
On the testing set, we calculated the C-index of the 84 predicted models to identify the optimal predictive model. We found that the optimal predictive model was a combination of forward stepwise Cox regression and GBM and demonstrated the highest

XSL•FO
RenderX

C-index of 0.702 (95% CI 0.652-0.753; Figure 2A). The final feature set of the optimal predictive model comprised 5 demographic features, 10 prechemotherapy laboratory features, 1 PRO feature, 4 clinical features, and 1 immunohistochemical feature (Figure 2B).

In total, 1000 bootstrap resamplings were performed and yielded an average C-index of 0.682 (95% CI 0.676-0.689) on the testing dataset. Shapiro-Wilk test indicated that the distribution of the C-index was normal (P=.86; Figure 2C). The evidence suggested a reasonable robustness of the optimal predictive model.

Performance Evaluation of the Model



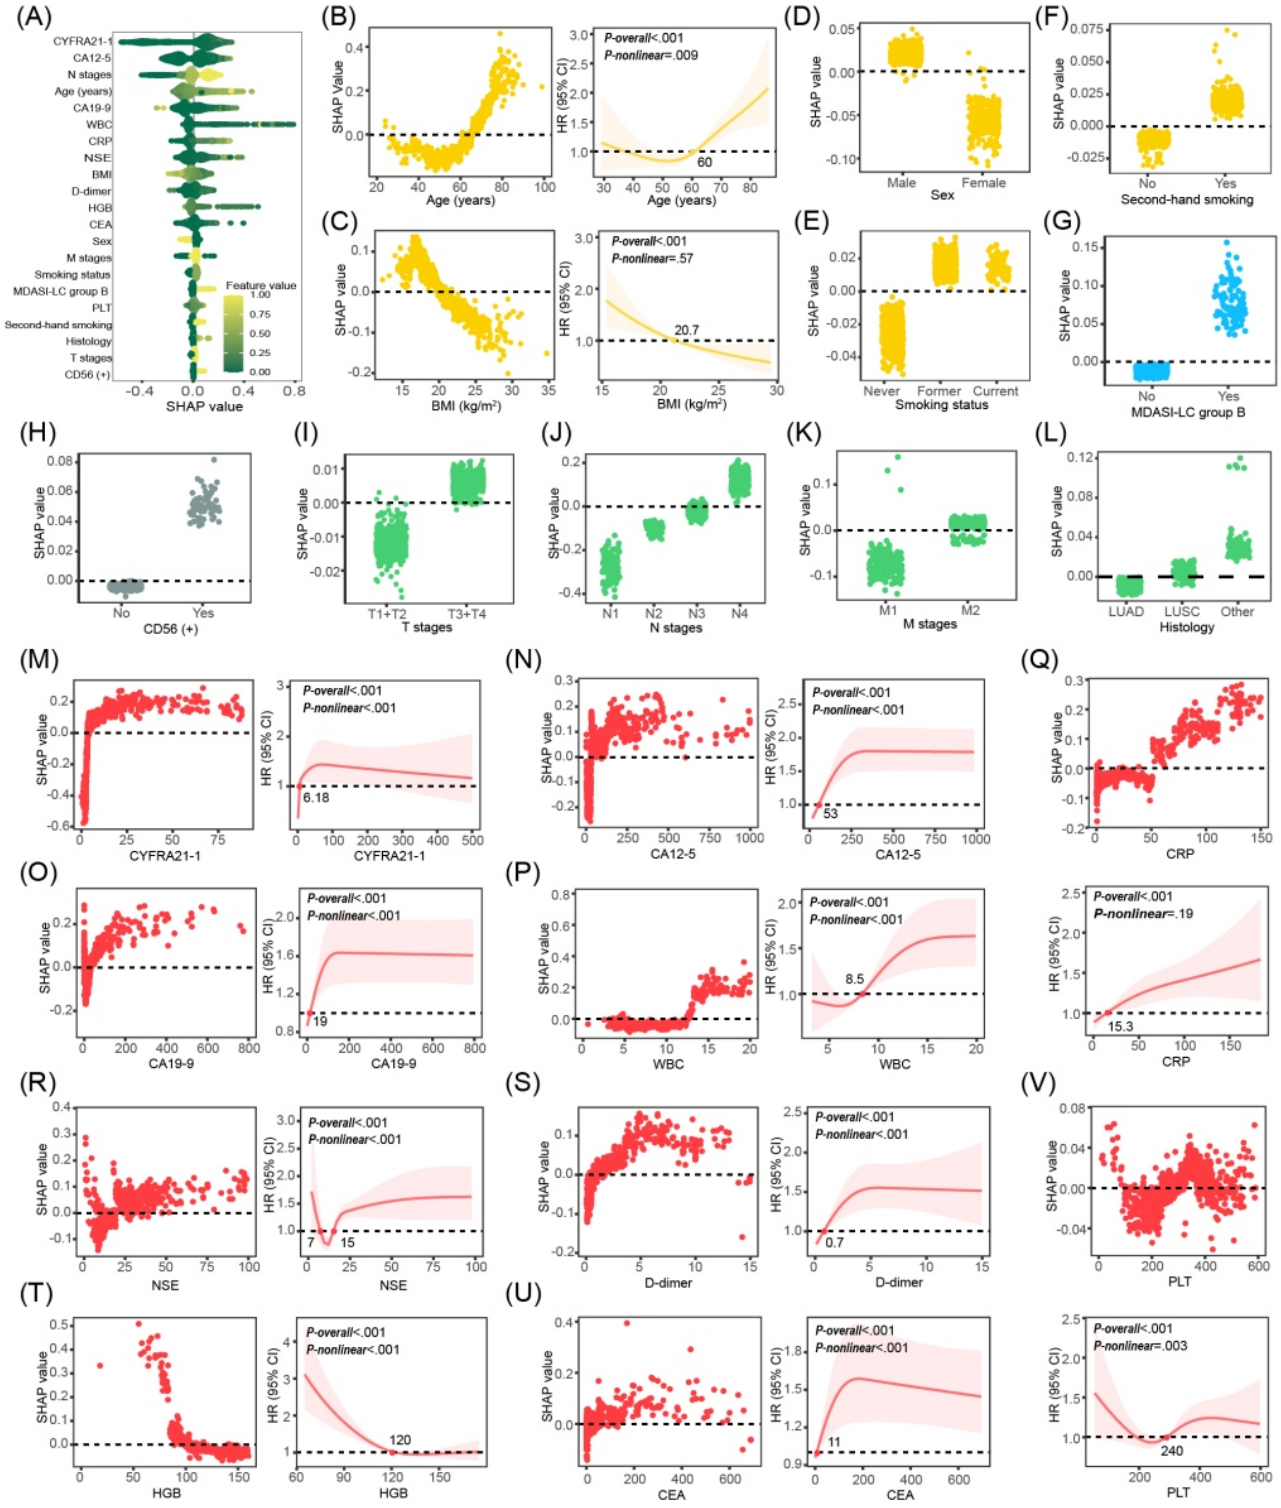
Performance evaluation of the model was implemented on both the training and testing sets. The decision curve analysis demonstrated that the predicted model had a net benefit over the strategies of predicting all deaths or all survivals when the risk thresholds were 0.40-0.97, 0.68-0.99, and 0.75-0.99 for 1-, 3-, and 5-year mortality predictions, respectively, on the training set, while 0.40-0.69, 0.62-0.99, and 0.72-0.99 on the testing set (Figure 2D).

In addition, the calibration curves displayed strong agreement between model predictions and observed outcomes (Figure 2E). The Brier scores for 1-, 3-, and 5-year mortality predictions were 0.11, 0.07, and 0.08, respectively, on the training set, while 0.20, 0.18, and 0.11 on the testing set.

Furthermore, we determined an optimal risk score cutoff point by the *survminer* package to stratify patients into high-risk and low-risk groups. Kaplan-Meier survival analysis showed a significant difference in survival curves between the 2 groups, indicating that the model could well stratify patients when predicting 1-, 3-, or 5-year survival (P<.01; Figures 3A and C). The time-dependent receiver operating characteristic curve analysis found that the model demonstrated AUC values of 0.927, 0.975, and 0.956 for 1-, 3-, and 5-year mortality predictions, respectively, on the training set, while 0.740, 0.777, and 0.915 on the testing set, which exhibited robust predictive accuracy for both short-term and long-term mortality risk (Figures 3B and D).

XSL•FO
RenderX

Figure 3. Evaluation of the mortality risk prediction model's prognostic performance. (A) and (C) show the Kaplan-Meier curve for high- and low-risk patients, generated from the training and testing set, respectively, illustrating significant differences in survival. (B) and (D) present the time-dependent receiver operating characteristic curves assessing 1-, 3-, and 5-year mortality prediction in the training and testing data, respectively. AUC: area under the curve.



Feature Attribution Analysis

Figure 4A provides insights into the most significant features influencing the model's prediction of mortality risk in this study. These insights facilitate an improved understanding of the biological basis of risk and the identification of potential targets to optimize clinical care. The visualization of these influential features highlights their importance in guiding clinical decisions and the development of personalized treatment approaches grounded in individual patient risk profiles.

XSL•FO
RenderX

Figure 4. Visualization of feature importance and variable relationships influencing mortality risk. (A) displays the global feature importance. (B-F) illustrate partial dependence plots for demographic characteristics and RCS analyses for continuous variables. (G and H) and (I-L) show partial dependence plots for symptom burden PRO trajectories, immunohistochemical indicators, and tumor biological indicators, respectively. (M-V) provide partial dependence plots and RCS analysis results for prechemotherapy blood biomarkers. All partial dependence plots are annotated with the zero-SHAP value position, while the RCS plots show the points where changes in mortality risk occur. CA12-5: carbohydrate antigen 12-5; CA19-9: carbohydrate antigen 19-9; CD56: cluster of differentiation 56; CEA: carcinoembryonic antigen; CRP: C-reactive protein; CYFRA21-1: recombinant cytokeratin fragment antigen 21-1; HGB: hemoglobin; HR: hazard ratio; LUAD: lung adenocarcinoma; LUSC: lung squamous cell carcinoma; MDASI-LC: MD Anderson Symptom Inventory for Lung Cancer; NSE: neuron-specific enolase; PLT: platelet count; RCS: restricted cubic spline; SHAP: Shapley Additive Explanations; WBC: white blood cell.

The use of RCS in this study facilitated the detection of key inflection points within continuous variables, thereby providing valuable insights into the intricate relationships among factors that contribute to mortality risk in patients with lung cancer. This refined understanding can support clinical decision-making and provide personalized approaches to patient management.

XSL•FO
RenderX

Age emerged as a significant predictor of mortality risk, with a key threshold at 60 years. Individuals younger than 60 years of age presented with a lower and less prominent mortality risk, while the risk accelerated beyond this age (Figure 4B). BMI demonstrated an inverse relationship with mortality, with a critical value of 20.7 kg/m^2, below which mortality risk was diminished (Figure 4C). Furthermore, male sex, smoking history (inclusive of both former and current smoking), and passive smoke exposure were all linked to an increased mortality risk (Figures 4D and F).

Patients in the MDASI-LC relatively high-symptom burden group exhibited a higher mortality risk, with a median symptom score of 45.4 (IQR 36.2-51.4), while the other group had a score of 8.2 (IQR 5.2-19.8; Figure 4G). A higher chemotherapy symptom burden was associated with reduced survival.

Key clinical features, including the presence of cluster of differentiation 56 (CD56) positivity, T3 or T4 stage, N2, N3, and N4 stages, and M2 stage, were associated with a significantly higher relative risk of mortality. No significant difference in mortality risk was observed between patients with lung squamous cell carcinoma and lung adenocarcinoma, while patients with SCLC or other less frequently occurring lung cancers demonstrated decreased survival times (Figures 4H-L).

Prechemotherapy levels of laboratory markers recombinant cytokeratin fragment antigen 21-1, carbohydrate antigen 12-5, carbohydrate antigen 19-9, white blood cell count, D-dimer, and carcinoembryonic antigen showed a nonlinear increase in mortality risk, with respective critical values identified at 6.18 ng/mL, 53 U/mL, 19 U/mL, 8.5×10^9/L, 0.7 mg/L, and 11 ng/mL, respectively. Mortality risk was significantly higher beyond these thresholds. Hemoglobin exhibited a distinct pattern, with mortality risk increasing significantly at levels below 120 g/L. In contrast, C-reactive protein was associated with a linear increase in mortality risk, with a risk inflection point at 15.3 mg/L. Prechemotherapy neuron-specific enolase levels exhibited a nonlinear relationship with mortality, where risk increased both below 7 ng/mL and above 15 ng/mL. Platelet counts also had a nonlinear relationship with mortality risk, displaying an initial decrease followed by an increase, with a turning point at 240×10^9 per liter (Figures 4M-V).

The observed relationships are visually depicted in Shapley Additive Explanations partial dependence plots and through RCS analyses (Figures 4B-V). Subgroup analyses further confirmed these observations, demonstrating statistically significant differences in mortality risk associated with the described characteristics (P<.05), except for prechemotherapy platelet levels (Figure S2 in Multimedia Appendix 2 illustrating subgroup analysis validation performed after determining key values via feature attribution analysis).

Discussion

Principal Findings

This study developed a combined ML prediction model by integrating multisource data to assess the all-cause mortality risk of patients with lung cancer receiving chemotherapy. It identified key prognosis-related factors, including demographic characteristics, prechemotherapy laboratory indicators, longitudinal symptom burden, and clinical features, and analyzed the correlation patterns between each factor and mortality risk. The model exhibited favorable performance in discriminative ability, predictive accuracy, and clinical utility, with overall satisfactory effectiveness.

Demographic and Lifestyle Impacts on Lung Cancer Prognosis

Age is a core factor influencing the chemotherapy outcomes of patients with lung cancer. Aging is accompanied by decreased genomic and transcriptomic stability, leading to the accumulation of mutations and abnormal gene expression, which promotes the development of malignant tumor phenotypes and reduces treatment sensitivity. Meanwhile, aging-induced metabolic disorders (such as abnormal glucose metabolism and insulin resistance) provide a favorable environment for tumor growth; the decline in immune function weakens the body's antitumor capacity; and the reduction in tissue repair ability increases the risk of chemotherapy side effects, ultimately affecting survival [26-28]. The impact of sex on prognosis may be related to the regulation of tumor progression and chemotherapy response by sex hormones (especially estrogen), but the specific mechanism requires further research [29-31]. BMI showed a negative correlation with mortality risk, with a critical value of 20.7 kg/m^2, and the risk increased when BMI was below this value. This finding is consistent with the "obesity paradox"—individuals with mild overweight may gain survival advantages due to the secretion of cardioprotective adipokines by adipose tissue [32-34]. In addition, smoking history (including former and current smoking) and second-hand smoke exposure significantly increased mortality risk, emphasizing the importance of smoking cessation and reducing second-hand smoke exposure for improving treatment efficacy and survival [34]. These results suggest that chemotherapy regimens should be formulated based on individual patient characteristics; nutritional status should be closely monitored during treatment with targeted support provided; and research on sex-specific treatment differences needs to be strengthened.

The Prognostic Significance of Tumor Biological Characteristics

SCLC is often diagnosed at an advanced stage and is typically more aggressive. Tumors at T3/T4 stages (locally advanced or invasive tumors) are closely associated with increased tumor burden and local invasion, which may lead to chemotherapy resistance and elevated all-cause mortality risk [35]. The N stage reflects the spread of cancer cells to lymph nodes, leading to increased drug resistance. Patients with advanced metastatic stages (M2) frequently lose the opportunity for curative surgery, making platinum-based chemotherapy the main palliative treatment modality. However, metastatic disease, especially distant organ metastasis, is associated with inherent chemotherapy resistance, resulting in an unfavorable prognosis [36].

RenderX

Potential Prognostic Value of CD56

The association between CD56 positivity and lung cancer prognosis remains controversial. Some studies have found a correlation with poor prognosis [37,38], while others have not observed a significant association [39]. This discrepancy may be related to sample size and patient population heterogeneity, and larger-scale multicenter studies are needed to clarify the relationship between the two.

Prognostic Value of PRO

This study suggested that the symptom burden reflected by the MDASI-LC score is related to survival time, with patients in the high-symptom burden group having a significantly increased mortality risk. This is consistent with previous research conclusions on the prognostic value of health-related quality of life [40]; incorporating MDASI-LC into routine follow-up can timely capture symptom changes and provide a basis for individualized prognostic management.

Clinical Application Value of Biomarkers

Blood biomarkers directly reflect tumor burden and biological characteristics. Elevated prechemotherapy biomarker levels have been associated with unfavorable chemotherapy outcomes in patients with lung cancer [41-44]. For patients with abnormal biomarkers, early interventions, such as anti-inflammatory and anti-infective treatments, can improve prognosis.

Limitations

This study has several limitations, which need to be taken into account when interpreting the results. The study used retrospective single-center data, which might limit the external validity and universality of the constructed model. Although the sample size of 1278 patients is relatively large for a single-center study, the complexity of the ML framework increases the risk of overfitting. We did not adjust the performance estimates using optimistic correction or penalty methods, which might overestimate the model's predictive ability. The robustness of the feature attribution results was not verified under different model parameter settings, so the stability of these key prognostic thresholds still needs to be further confirmed.

Among the 1278 enrolled patients with lung cancer undergoing chemotherapy, the survival rates at 1-, 3-, and 5-year follow-ups were 31.9% (95% CI 29.4%-34.6%), 7.4% (95% CI 6.0%-9.0%), and 1.5% (95% CI 0.9%-2.4%), respectively. A smaller sample size may increase the variability of the AUC statistic. This might be part of the reason why the 5-year AUC (0.915) is higher than the 1-year (0.740) and 3-year (0.777) AUC, which needs to be taken into account when interpreting the long-term predictive performance of the model.

In this study, 84 models were constructed on the training set, and then, the C-index was used on the test set to determine the best model. This process may violate the principle that the test set should only be used once to evaluate the performance of the final, prespecified model, which may lead to an overestimation of the model's C-index. In future research, model selection and hyperparameter tuning can be attempted to be accomplished solely through cross-validation of the training set, with the test set reserved only for evaluating the prespecified final model performance.

Conclusions

This study developed an innovative ML model to predict all-cause mortality risk in patients with lung cancer receiving chemotherapy. The model demonstrates acceptable discrimination, accuracy, and clinical efficacy, offering clinicians an interpretable tool for mortality risk assessment. By enabling personalized risk stratification, this model can guide targeted postchemotherapy care for patients with high risk, ultimately supporting the development of individualized treatment plans.

Acknowledgments

The authors are sincerely grateful to Professor Charles S Cleeland and Professor Shelley X Wang of The University of Texas MD Anderson Cancer Center and Professor Qiuling Shi from Chongqing Medical University, who provided the MD Anderson Symptom Inventory for Lung Cancer questionnaire and other assistance for this study.

Abstract

Background: The development of immunotherapy has provided new hope for patients with advanced gastric cancer (AGC). However, due to the high heterogeneity of the disease, the efficacy of first-line immunochemotherapy varies among patients. There is still a lack of simple and effective models to predict the efficacy of immunochemotherapy in this setting.

Objective: This study aimed to identify critical factors and develop predictive models to evaluate the efficacy of first-line immunochemotherapy in patients with AGC using clinically available data. The goal was to offer evidence-based guidance for clinical practice and enable personalized treatment strategies.

Methods: To evaluate the effectiveness of first-line immunochemotherapy in AGC, we retrospectively collected clinical data from The First Affiliated Hospital of Nanjing Medical University between January 2018 and October 2023. The data collected were divided into a training set (168/240, 70%) and an internal validation set (72/240, 30%). Additionally, a temporal validation cohort of 76 patients recruited from November 2023 to September 2024 was assembled to further evaluate the predictive performance of the models. We used univariate and multivariate Cox regression analyses, along with the least absolute shrinkage and selection operator (LASSO) regression, and integrated clinical expertise to identify key predictors of treatment efficacy and to construct the LASSO-Cox model. We developed 4 models (LASSO-Cox, random survival forest [RSF], extreme gradient boosting, and survival support vector machine) and evaluated their performance using the C-index, area under the curve (AUC), calibration curves, and decision curve analysis. The optimal model was interpreted using Shapley additive explanations, and its risk scores were used to stratify patients for Kaplan-Meier survival analysis.

Results: Among the 4 prognostic models developed in this study, the RSF model demonstrated superior predictive accuracy and discrimination for progression-free survival, as evidenced by its higher AUC, concordance index, continuous AUC curves, and calibration curves compared with the other 3 models. Additionally, decision curve analysis showed that the RSF model offered greater net clinical benefit. The Shapley additive explanations results identified that age, histological subtype, the proportion of $CD19^+$ B cells, $CD16^+CD56^+$ natural killer cells, and the presence of liver metastasis were key prognostic factors influencing patient outcomes. Patients in the low-risk group, as determined by the RSF model's risk score, exhibited a significantly higher progression-free survival rate than those in the high-risk group, further validating the value of the RSF model for risk stratification.

Conclusions: This study is the first to use machine learning algorithms to develop a predictive model for the efficacy of first-line immunochemotherapy in AGC, and to identify key predictors of treatment outcome. The results indicate that the RSF model not only enables precise stratification of patients likely to benefit but, more importantly, provides quantifiable decision support for individualized clinical strategies, underscoring its potential value in clinical decision-making.

KEYWORDS

advanced gastric cancer; immunochemotherapy; machine learning; random survival forest; prognostic models

Introduction

Gastric cancer (GC) ranks as the fifth most common malignancy worldwide and is the fourth leading cause of cancer-related mortality [1]. In 2022, there were over 968,000 new cases of GC, resulting in nearly 660,000 deaths [2]. Due to the delayed onset of clinical symptoms and the absence of effective diagnostic methods for early-stage GC, 40% of patients are diagnosed at an advanced stage, where surgical intervention is typically not feasible [3]. Among patients undergoing radical resection, over two-thirds experience recurrence or metastasis [4,5]. Consequently, chemotherapy remains the cornerstone of treatment for advanced gastric cancer (AGC), yet the prognosis for advanced or metastatic cases remains dismal, with an overall survival (OS) of only 9-14 months [6]. Therefore, a comprehensive upfront assessment of prognosis is essential for guiding clinical decisions in multidisciplinary treatment approaches [7].

The advent of immune checkpoint inhibitors (ICIs), particularly those targeting programmed cell death protein 1 (PD-1) and programmed death-ligand 1 (PD-L1), has revolutionized cancer therapy, yielding robust and durable responses in GC. Clinical trials, such as CheckMate-649 and KEYNOTE-062, have demonstrated that combining immunochemotherapy significantly improves OS and progression-free survival (PFS) in patients with PD-L1–positive tumors [8,9]. However, the high heterogeneity of GC leads to variations in the efficacy of immunochemotherapy among different patients [10]. Identifying individuals who are likely to respond to immunochemotherapy is therefore critical for providing personalized treatment.

Nowadays, numerous biomarkers, including tumor mutation burden (TMB), PD-L1 expression, microsatellite instability (MSI), and Epstein-Barr virus infection status, have been proposed to predict responsiveness to PD-1 and PD-L1 inhibitors [11,12]. Additionally, circulating tumor DNA positivity has been associated with relapse and poorer prognosis [13]. However, given the highly heterogeneous nature of GC, relying on a single factor for prognostic prediction is often insufficient [14]. For instance, only 45% of patients with high TMB (≥20 mutations per megabase [mut/Mb]) respond to immunotherapy, while approximately 5% of patients with low TMB exhibit significant therapeutic responses to ICIs [15,16]. Furthermore, the predictive utility of single biomarkers is undermined by the dynamic alteration of the tumor microenvironment following therapeutic interventions (eg, chemotherapy or radiotherapy), as well as inconsistencies in detection methodologies and threshold definitions—such as the varying PD-L1 scoring systems (tumor proportion score, combined positive score, immune cell score, and H-score) and platform-dependent criteria for MSI and TMB. While recent studies have developed prognostic models based on transcriptomics or targeted metabolomics [17-19], the clinical translation of these omics-based signatures is severely constrained by their high costs, complex data processing, and reliance on specialized laboratory infrastructure [20,21]. This creates a clear and unmet need for prognostic tools built on more accessible, cost-effective, and routinely collected data. Although recent studies have made progress in applying machine learning (ML) algorithms to clinical data for postoperative patients with GC or to predict immunotherapy-related adverse events in AGC [22,23], a critical gap remains, as robust predictive models for the efficacy of first-line immunochemotherapy in the advanced setting are notably lacking. Therefore, this study was designed to address this specific gap. We aimed to develop and validate a robust prognostic model based only on readily available baseline clinical parameters. The objective of this tool is to effectively predict first-line immunochemotherapy outcomes, identify patients most likely to benefit, and thereby advance personalized therapy for AGC. Furthermore, understanding the key risk factors derived from such a model is crucial for devising appropriate follow-up strategies.

The Cox proportional hazards model has long been the standard for quantifying the impact of clinical indicators on survival outcomes [24,25]. However, its reliance on linear assumptions often fails to capture the intricate, nonlinear patterns characteristic of heterogeneous diseases like GC. Consequently, there is a need for more adaptive modeling strategies to maximize predictive performance. To this end, we used a comprehensive ML framework comprising random survival forest (RSF), extreme gradient boosting (XGBoost), and survival support vector machine (SVM). These algorithms were selected for their specific strengths in handling complex survival data: RSF is robust in ranking variable importance [26,27]; XGBoost offers superior efficiency and the ability to model complex feature interactions; and survival-SVM excels in distinguishing risk stratifications in high-dimensional spaces [28,29]. Our primary objective was not merely to compare these methodologies, but to leverage their combined strengths to select the best-performing model. This approach ensures the development of a clinically practical and highly accurate prognostic instrument for first-line immunochemotherapy [30-32].

Given the poor prognosis and high recurrence rate of AGC, as well as the urgent need for individualized treatment strategies, the ability to predict risk factors associated with prognosis and survival rates before treatment could enable more targeted therapeutic adjustments, ultimately improving patient outcomes and quality of life. This study aims to retrospectively analyze the clinical and pathological data of patients with AGC who received first-line immunochemotherapy. By identifying key prognostic factors that predict the efficacy of immunochemotherapy, 4 prognostic models will be developed and compared in terms of discrimination, calibration, stability, and clinical net benefit. The optimal model will be selected for clinical application, providing a reference for personalized treatment strategies and ultimately improving the prognosis of patients with AGC.

Methods

Data Source and Study Population

Clinical data of patients for the model development cohort were collected retrospectively from January 1, 2018, to October 31, 2023, at The First Affiliated Hospital of Nanjing Medical University, China. Additionally, a temporal validation cohort between November 1, 2023, and September 13, 2024, was included from the same hospital. Patients were enrolled in this study based on the following inclusion criteria: (1) aged 18 years or older, (2) histologically or cytologically confirmed gastric adenocarcinoma, (3) received ICIs as first-line treatment for advanced disease, (4) presence of at least 1 measurable lesion according to the Response Evaluation Criteria in Solid Tumors (RECIST) version 1.1. (lesions in hollow viscera, such as the esophagus and stomach, were not considered measurable; lesions situated in a previously irradiated area were considered measurable only if progression had been demonstrated), and (5) Eastern Cooperative Oncology Group performance status of 0 or 1. The exclusion criteria were (1) discontinuation of treatment due to intolerance to immunotherapy or combination agents, (2) receiving fewer than 2 treatment cycles, precluding efficacy assessment, (3) presence of concurrent malignancies of other origins, and (4) incomplete baseline clinical data or lost to follow-up.

Data Collection and Outcomes

Baseline characteristics were assessed, including age, sex, BMI, presence of underlying comorbidities, Eastern Cooperative Oncology Group performance status, smoking history, drinking history, tumor location (including cardia and esophagogastric junction, fundus, body, antrum, and pylorus of the stomach), Lauren classification (including intestinal type, mixed type, diffuse type, and unknown), tumor differentiation (including G3, G2, G2-G3, and unknown), histopathological type (including gastric adenocarcinoma and signet ring cell carcinoma), intraperitoneal chemotherapy (with or without), type of PD-1 or PD-L1 inhibitor (including sintilimab, nivolumab, tislelizumab, camrelizumab, and others), radiotherapy (with or without), targeted therapy (with or without), use of antiangiogenic drugs (including anlotinib, apatinib, others, and none), pretreatment levels of alpha-fetoprotein (AFP; <1.9 or ≥1.9 ng/μL), the pretreatment percentage of $CD16^+CD56^+$ natural killer (NK) cell (<27.41 or ≥27.41), the pretreatment percentage of the ratio of $CD4^+$ to $CD8^+$ T cell (<2.66 or ≥2.66), the pretreatment percentage of $CD19^+$ B cell (<12.04 or ≥12.04), human epidermal growth factor receptor 2 (HER2) expression status (including positive, negative, and unknown), PD-L1 expression status (including positive, negative, and unknown), microsatellite stability (including microsatellite stability, high MSI, and unknown), TMB status (including low, high, and unknown), presence of liver metastasis (with or without), peritoneal metastasis (with or without), bone metastasis (with or without), and distant organ metastasis (with or without).

To ensure data consistency and reliability, all data collection adhered to strict standards. Tumor location, differentiation grade, Lauren classification, and histopathological type were categorized based on the 2024 guidelines of the Chinese Society of Clinical Oncology. BMI was classified according to the World Health Organization criteria, with a BMI ≥25 considered overweight. Continuous numerical variables, including age, pretreatment levels of AFP, and pretreatment lymphocyte subset percentages, were subsequently categorized into discrete groups by determining optimal cutoff values in order to enhance analytical convenience and effectiveness. HER2 expression status was determined through immunohistochemistry or fluorescence in situ hybridization: 0 to 1+ was classified as negative; 2+ was considered equivocal, requiring confirmation via fluorescence in situ hybridization; and 3+ was classified as positive. PD-L1 expression status was assessed following the standards of the US Food and Drug Administration: PD-L1 combined positive score <1 was classified as negative; PD-L1 combined positive score ≥1 was classified as positive. Microsatellite stability status was defined as follows: microsatellite stability indicated no significant difference in microsatellite length between tumor and normal tissue; high MSI was defined as the presence of insertion or deletion mutations in at least 2 microsatellite loci. TMB≥10 mut/Mb was classified as high expression; TMB<10 mut/Mb was categorized as low expression. AFP and lymphocyte subset data were obtained from peripheral blood samples collected before first-line immunochemotherapy in patients with AGC. Distant metastasis and disease progression were evaluated through contrast-enhanced computed tomography scans of the chest and entire abdomen. Progressive disease was determined based on the RECIST version 1.1. The primary end points of this study were the predictive capability, validity, and clinical utility of the developed prognostic model. The primary time-to-event outcome was PFS, defined as the interval from the initiation of first-line immunochemotherapy to the date of radiologically confirmed disease progression. The model development cohort was followed up until March 13, 2024, while the temporal validation cohort was followed up until September 13, 2024. Progressive disease was assessed via imaging evaluations conducted every 2 treatment cycles, ensuring that all outcome assessments were supported by radiographic evidence. This methodology ensures the robustness and clinical applicability of the prognostic models developed in this study.

Statistical Analysis

The dataset for the model development cohort was split into a training cohort (168/240, 70%) and a validation cohort (72/240, 30%). The training cohort was used for model construction, while the training cohort and the internal validation cohort were used for model assessment. Additionally, a temporal validation cohort was used to further assess model performance over time as an external validation set. Categorical variables are presented as frequencies and percentages, with group comparisons made using the chi-square test or Fisher exact test. Normally distributed continuous variables are expressed as the mean and SD, and between-group comparisons are performed using the 2-tailed *t*-test. Nonnormally distributed continuous variables are reported as the median and IQR, with between-group comparisons conducted using the Wilcoxon rank-sum test. Statistical significance is defined as $P<.05$.

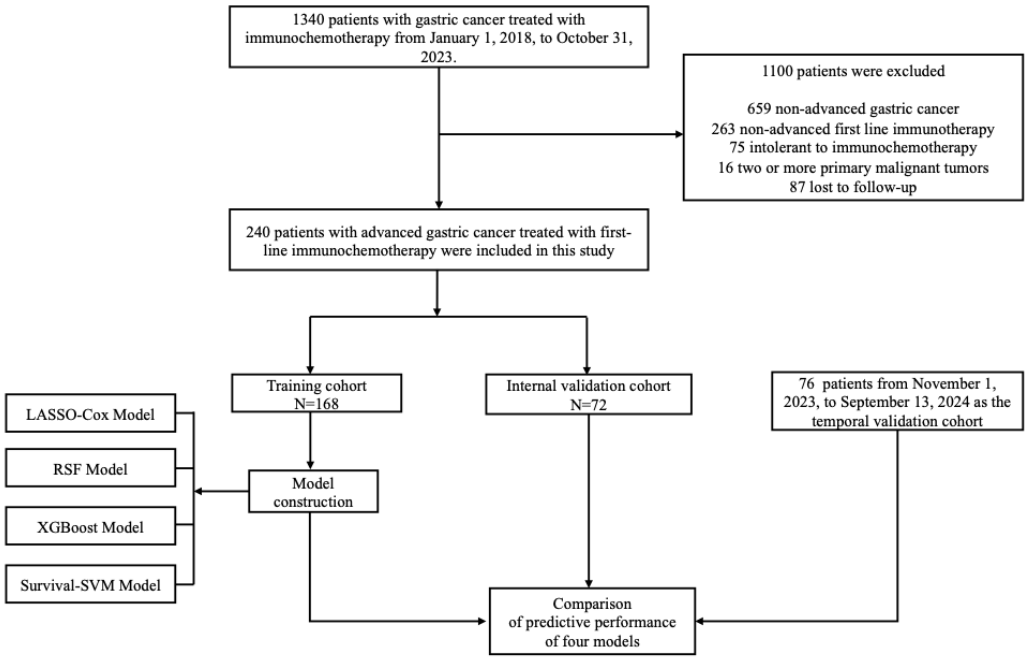
XSL•FO
RenderX

All baseline clinical characteristics were incorporated into the construction of the prognostic model. Patients with missing data rates ≥10% for baseline characteristics were excluded from the analysis. For cases with missing values <10%, we used multiple imputation by chained equations, implemented with the "mice" R package. The multiple imputation by chained equations procedure was configured to generate five imputed datasets (m=5), with a fixed random seed to ensure reproducibility. The imputation model included predictor variables (the pretreatment proportions of $CD16^+CD56^+$ NK cells, $CD19^+$ B cells, and $CD4^+/CD8^+$ T cells) and the outcome variable (PFS and event status) to preserve prognostic correlations. For continuous variables, the default predictive mean matching method was used, which is robust to nonnormality. This advanced approach iteratively generates multiple imputed datasets through observed data patterns while appropriately accounting for the uncertainty inherent in the imputation process. After imputation, we generate diagnostic plots to examine the distribution of the imputed data (Multimedia Appendix 1). The results indicated that, for most variables, the imputed values aligned well with the original data distribution. Because missing data patterns may influence study outcomes, we conducted 2-tailed *t*-tests and Kolmogorov-Smirnov (KS) tests on both the imputed and original complete datasets to assess any significant differences. The pretreatment proportion of $CD16^+CD56^+$ NK cells had 2-tailed *t*-test and KS test *P* values of .73 and .98, respectively, before and after imputation; the pretreatment proportion of $CD19^+$ B cells showed 2-tailed *t*-test and KS test *P* values of .51 and .99, respectively; and the pretreatment proportion of $CD4^+/CD8^+$ T cells had 2-tailed *t*-test and KS test *P* values of .60 and .99, respectively. None of these variables demonstrated a statistically significant difference ($P>.05$), suggesting that the chosen imputation method had minimal impact on the overall analysis. Furthermore, to assess the robustness of our results and rule out potential bias introduced by the imputation of missing values, a sensitivity analysis was performed. We reconstructed and re-evaluated all 4 models using a complete-case cohort (excluding all patients with missing data). The results from this analysis were consistent with those derived from the imputed dataset, indicating that the imputation procedure introduced negligible bias to the model performance (Multimedia Appendix 2).

In this study, important predictive features were identified through a combination of univariate analysis, least absolute shrinkage and selection operator (LASSO) regression, multivariate analysis, and the clinical expertise of 2 experienced clinicians, which served as the foundation for constructing a LASSO-Cox model. In parallel, ML was used to develop RSF, XGBoost, and survival-SVM models, with parameter tuning carried out for each. The performance of these 4 models was systematically evaluated and compared using metrics such as area under the curve (AUC), concordance index (C-index), receiver operating characteristic (ROC) curves, continuous AUC curves, calibration curves, and decision curve analysis (DCA) to identify the optimal predictive model. Patients were then stratified into high- and low-risk groups based on the risk scores derived from this optimal model, and Kaplan-Meier (KM) analysis was performed to assess survival differences. Finally, Shapley additive explanations (SHAP) analysis was conducted to interpret the optimal model and to pinpoint the key predictive variables. All statistical analyses were performed using R version 4.4.1 (R Foundation for Statistical Computing).

Ethical Considerations

This study was approved by the Ethics Committee of The First Affiliated Hospital of Nanjing Medical University (approval 2024-SR-453). No personally identifiable information was involved in this study. Due to the retrospective nature of the research, the requirement for informed consent was waived.



Results

The Clinical Characteristics of Patients With AGC

The workflow of the study is illustrated in Figure 1. Ultimately, 316 eligible patients were included in the study. Among them, 240 patients were enrolled between January 1, 2018 and October 31, 2023, forming the model development cohort, while the remaining 76 patients, recruited between November 1, 2023 and September 13, 2024, comprised the temporal validation cohort for further assessment of the model's predictive performance. The median follow-up duration for the model development cohort was 16 (95% CI 13.1-18.9) months, with a median progression-free survival (mPFS) of 8.97 (95% CI 7.9-11.1) months. In the temporal validation cohort, the median follow-up time was 10.3 (95% CI 9.5-upper limit not reached) months. Patients in the model development cohort were randomly divided into a training set (n=168, 70%) and an internal validation set (n=72, 30%). Baseline clinical characteristics of all patients are summarized in Multimedia Appendix 3. The mPFS was 8.83 (95% CI 7.43-11.4) months in the training cohort and 10 (95% CI 7.77-15.6) months in the internal validation cohort. In the temporal validation cohort, the mPFS was 6.8 (95% CI 6.4-8.03) months. The 6-month, 12-month, and 18-month PFS rates in the training set were 61%, 25%, and 11%, respectively, while in the internal validation set, they were 57%, 26%, and 13%, respectively. In the temporal validation cohort, the 6-month, 9-month, and 12-month PFS rates were 53%, 17%, and 8%, respectively. Due to the limited follow-up period in the temporal validation cohort, the 18-month PFS rate was not determined.

Construction of the LASSO-Cox Model and Nomogram

The prognostic value of various factors for predicting PFS was assessed using the training cohort. In univariate analysis, age, histological subtype, pretreatment levels of AFP, pretreatment proportion of $CD19^+$ B cell, $CD16^+CD56^+$ NK cell, $CD4^+/CD8^+$ T cell, TMB expression, and the presence of liver metastases were all found to be statistically significant ($P<.05$) (Multimedia Appendix 4). Recognizing that reliance solely on univariate analysis might introduce bias, 2 experienced clinicians reviewed these results and manually incorporated additional clinically relevant variables that, although not significant in the univariate analysis, have been linked to treatment efficacy, for example, PD-L1 expression, HER2 status, and MSI. This approach ensured that the model encompassed variables that are both clinically relevant and biologically meaningful. Subsequently, the significant factors from the univariate analysis were combined with clinically pertinent variables to form a LASSO regression. The LASSO algorithm was applied to identify the variables most strongly associated with PFS (Figure 2A). Through cross-validation, the optimal regularization parameter (λ) was determined to be 0.043, corresponding to the minimum partial likelihood deviance. Ultimately, 7 variables with nonzero coefficients were retained, that is, age, histological subtype, pretreatment levels of AFP, pretreatment proportion of $CD19^+$ B cell, $CD16^+CD56^+$ NK cell, $CD4^+/CD8^+$ T cell, and the presence of liver metastases (Figure 2B).

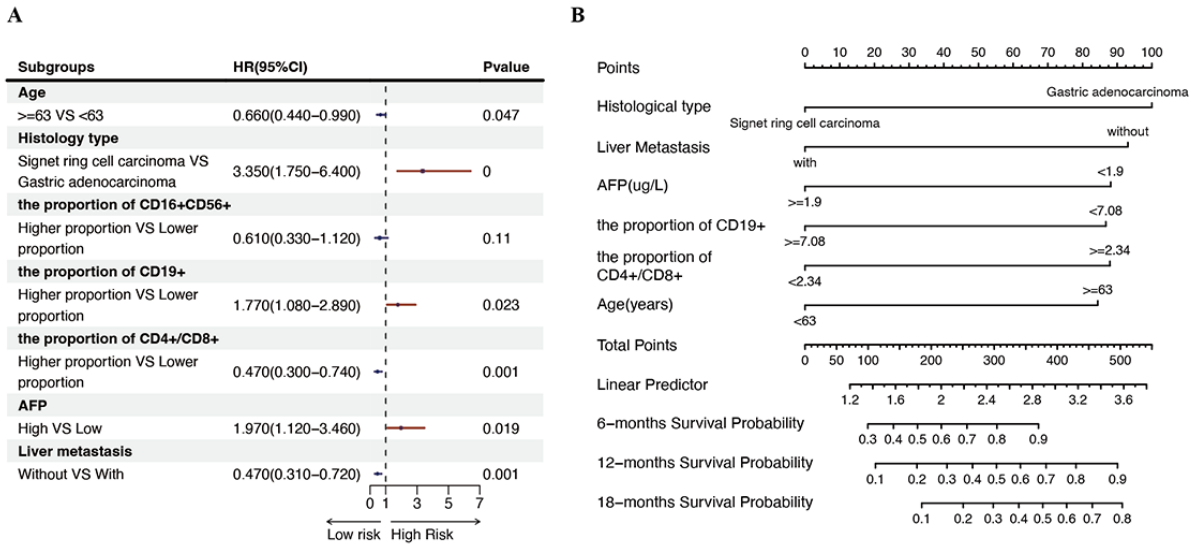
Figure 2. Feature selection using the least absolute shrinkage and selection operator regression. (A) The variation characteristics of the coefficient of variables; and (B) the selection process of the optimum value of the parameter λ in the least absolute shrinkage and selection operator regression model by cross-validation method.



To further evaluate the independent impact of the selected variables on the prognosis of AGC, a multivariate Cox regression analysis was performed based on the 7 variables identified through LASSO regression. Among these, age (*P*=.047), histological subtype (*P*<.001), pretreatment levels of AFP (*P*=.02), pretreatment proportion of $CD19^+$ B cells (*P*=.02), $CD4^+/CD8^+$ T cells (*P*=.001), and liver metastasis (*P*=.001) were identified as independent predictors of PFS in patients with AGC (Table 1). The forest plot of the multivariate Cox regression analysis is illustrated in Figure 3A. Subsequently, the 6 independent predictors determined by the multivariate analysis were incorporated into a nomogram model for visual representation. In the nomogram, each variable is assigned a specific weight, and scores for individual predictors are projected onto a total points axis. The cumulative score is then used to estimate the 6-, 12-, and 18-month PFS rates by drawing a vertical line from the total points to the outcome axis (Figure 3B).

Table 1. Results of multivariate Cox proportional hazards regression analysis for progression-free survival in the training set.

Characteristics	Multivariable Cox regression, hazard ratio (95% CI)	*P* value
Age (years)		
≥63 vs <63	0.660 (0.44-0.99)	.047
Histological type		
Signet ring cell carcinoma vs gastric adenocarcinoma	3.35 (1.75-6.40)	<0.001
AFP (ng/μL)		
≥1.9 vs <1.9	1.97 (1.12-3.46)	.02
The proportion of $CD16^+CD56^+$T cell		
≥27.41 vs <27.41	0.61 (0.33-1.12)	.110
The proportion of $CD19^+$B cell		
≥12.04 vs <12.04	1.77 (1.08-2.89)	.02
The proportion of $CD4^+/CD8^+$T cell		
≥2.66 vs <2.66	0.47 (0.30-0.74)	.001
Liver metastasis		
Without vs with	0.47 (0.31-0.72)	.001

Construction of Prognostic Models Based on ML

To establish a robust predictive model, PFS was categorized into short-PFS and long-PFS groups based on the cut point value determined in the training cohort. A decision tree (DT) model was first developed using the training cohort and validated on the internal validation cohort. However, the DT model demonstrated suboptimal performance (accuracy=0.5278). Given the limitations of the DT model described above, we turned to a more robust ML method—the RSF model. In the training cohort, we used 5-fold cross-validation and grid search to optimize the model's hyperparameters. The grid search spanned a range of values for "mtry" (1 to 30) and "nodesize" (1 to 50), and the number of trees ("ntree") was ultimately fixed at 1000. When "mtry" (the number of variables considered at each split) was set to 9 and "nodesize" (the minimum sample size in terminal nodes) was set to 6, the model achieved an out-of-bag error rate of 37%. At this configuration, the model reached its maximum AUC, while the error rate remained low and stable (Multimedia Appendix 5). The RSF model presents the relationship between the trees and error rate, and the variable importance rankings and grid search process. The top 9 variables significantly influencing the model were age, pretreatment proportion of $CD19^+$ B cells, liver metastasis, pretreatment proportion of $CD16^+CD56^+$ NK cells, histological subtype, pretreatment proportion of $CD4^+/CD8^+$ T cells, pretreatment levels of AFP, sex, and PD-L1 expression (Multimedia Appendix 6).

In addition, we developed XGBoost and survival-SVM models based on ML methods to comprehensively evaluate the performance of different algorithms for predicting prognosis in patients with AGC. For the XGBoost model, grid search and cross-validation were used to determine the optimal hyperparameters, and the model was constructed and fine-tuned on the training cohort. In contrast, the survival-SVM model leveraged the strengths of SVMs in handling survival data by optimizing kernel parameters to capture nonlinear relationships among samples. Subsequently, the predictive performance of these 4 models was compared to assess their robustness and practical applicability.

Comparison of Predictive Performance of 4 Models

To evaluate the predictive performance of the models, we assessed their discrimination, calibration, and robustness at different time points (Table 2). The RSF and XGBoost models exhibit higher C-index values, suggesting stronger predictive capabilities. In both the internal validation cohort and the temporal validation cohort, the RSF model demonstrated significantly superior AUC values compared with the other 3 models, indicating its superior discriminatory power.

XSL•FO
RenderX

Table 2. The concordance index and area under the curve values for the 4 models in both the internal validation cohort and the temporal validation cohort.

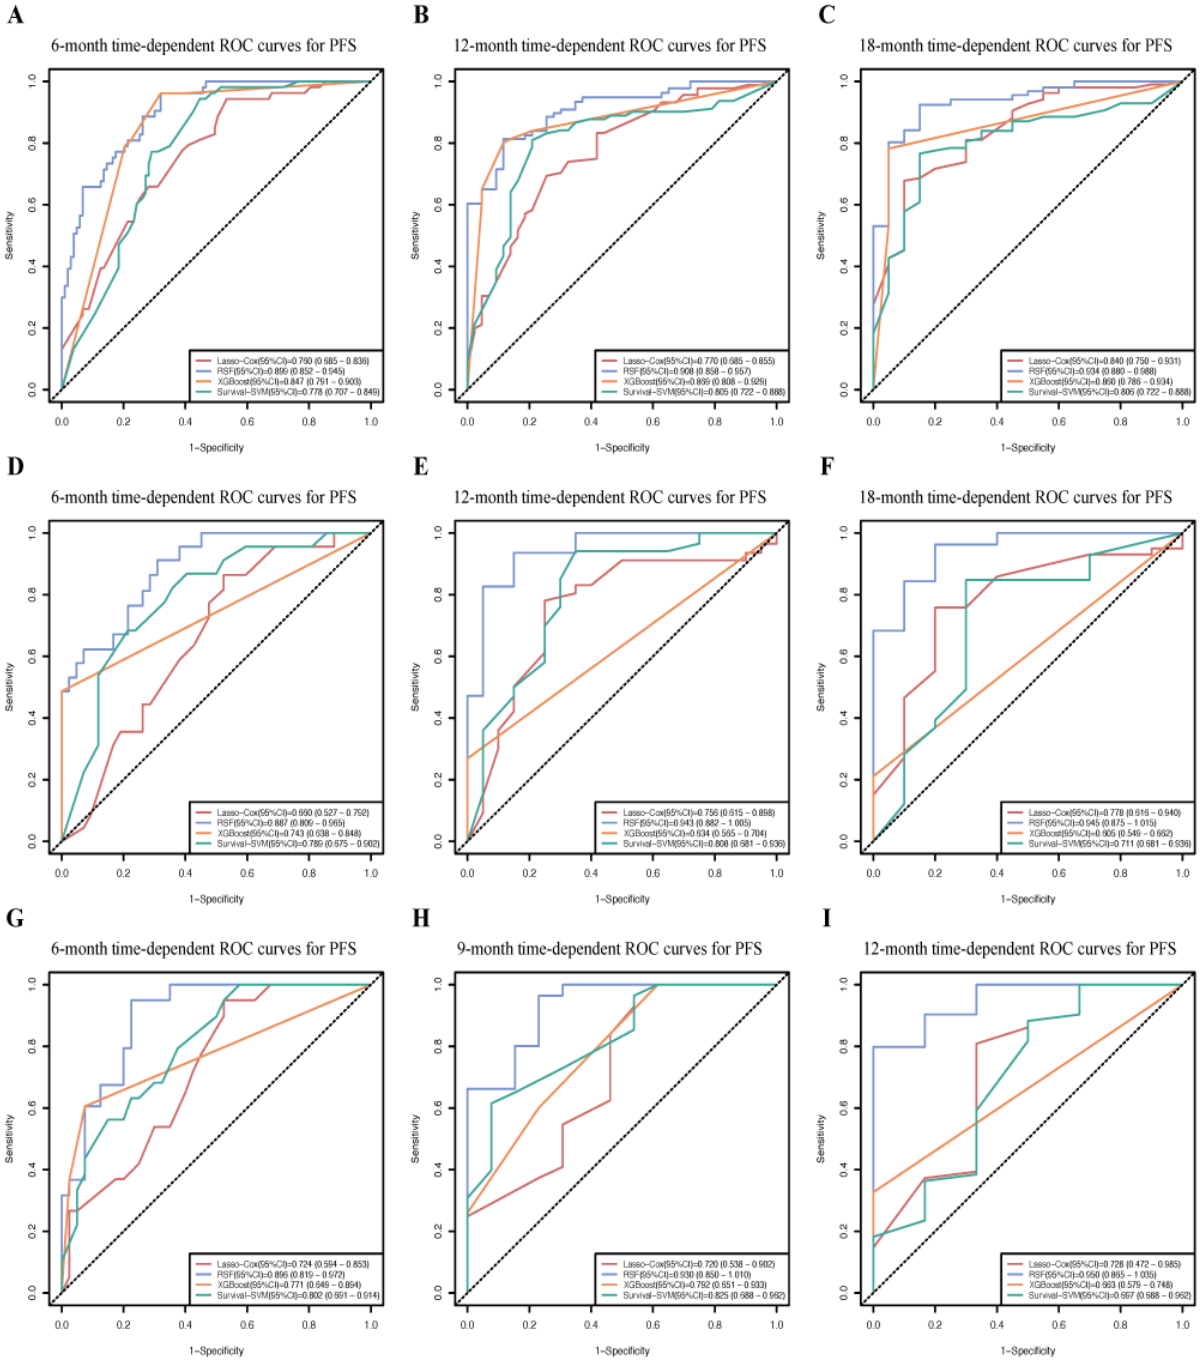
Model	C-index[a]	AUC[b]					
		Internal validation cohort (n=72)			Temporal validation cohort (n=76)		
		6 months	12 months	18 months	6 months	9 months	12 months
RSF[c]	0.828	0.887	0.943	0.945	0.896	0.930	0.950
LASSO[d]-Cox	0.719	0.660	0.756	0.778	0.724	0.720	0.728
XGBoost[e]	0.836	0.743	0.634	0.605	0.771	0.792	0.663
Survival-SVM[f]	0.740	0.789	0.808	0.711	0.802	0.825	0.697

[a]C-index: concordance index.

[b]AUC: area under the curve.

[c]RSF: random survival forest.

[d]LASSO: least absolute shrinkage and selection operator.



[e]XGBoost: extreme gradient boosting.

[f]SVM: support vector machine.

Figures 4A-4F illustrate the ROC curves for predicting 6-, 12-, and 18-month PFS rates using 4 models in both the training and internal validation cohorts, while Figures 4G-4I display the ROC curves for predicting 6-, 9-, and 12-month PFS rates in the temporal validation cohort. To compare the performance of these models, we analyzed the differences in AUC values using the DeLong test. The results confirmed that the RSF model significantly outperformed the other 3 models at all time points (P<.05). Notably, the RSF model exhibited higher AUC values for 12- and 18-month PFS predictions across all cohorts, suggesting its strong potential in long-term survival prediction.

XSL•FO
RenderX

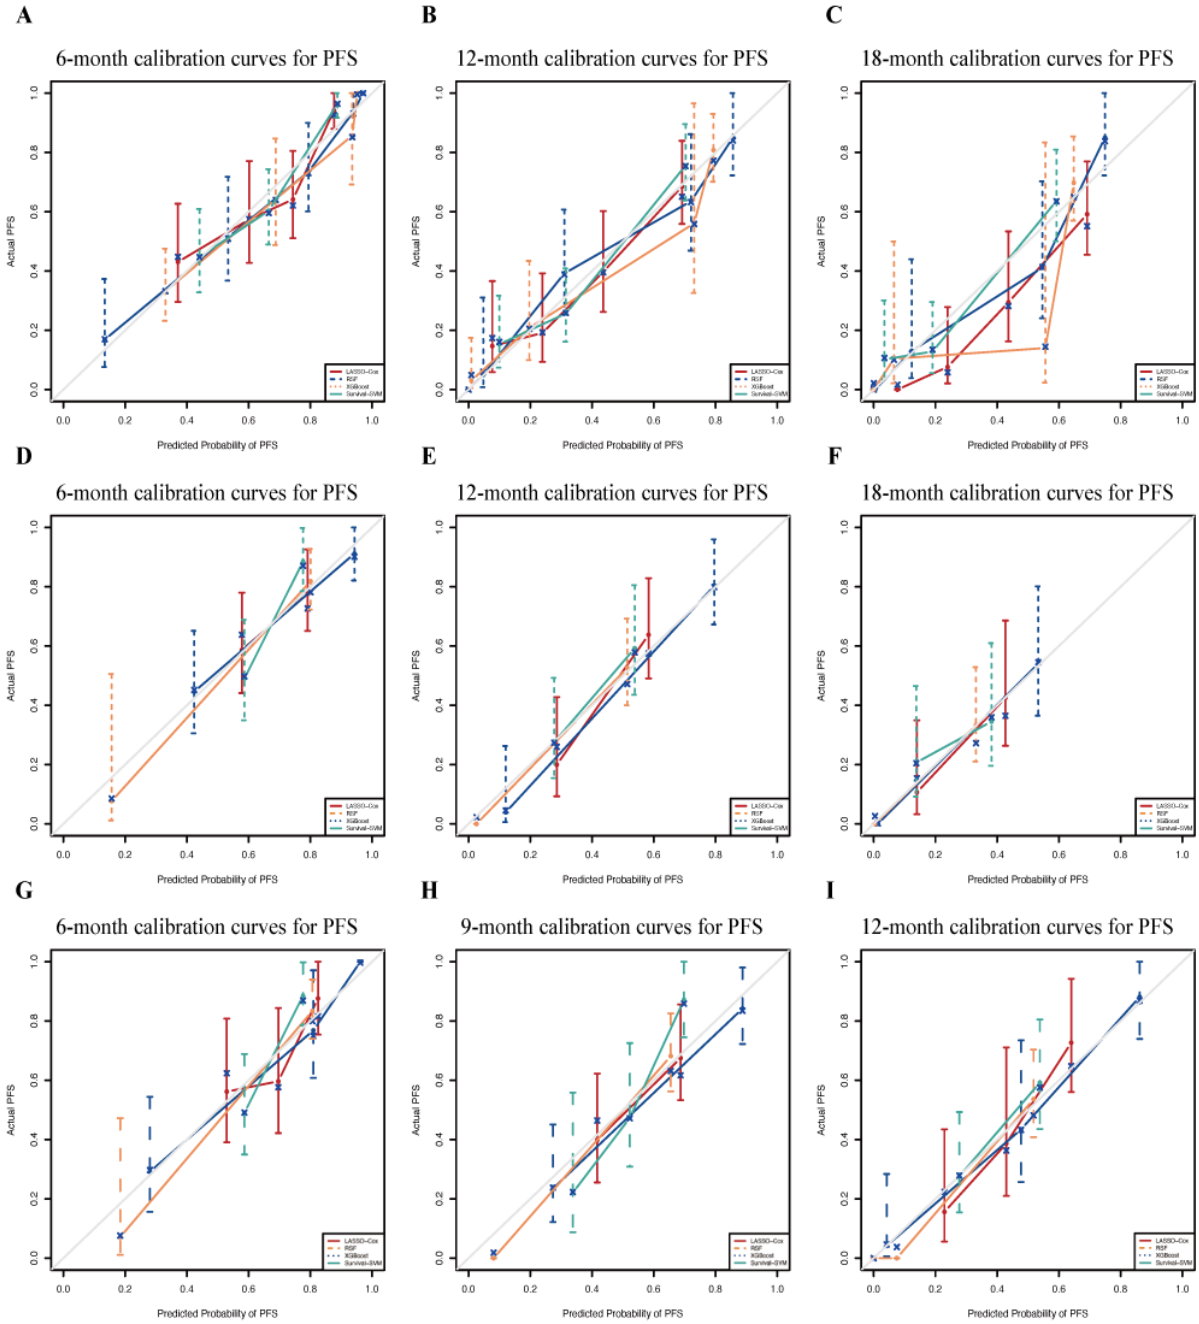


Figure 4. Comparison of time-dependent receiver operating characteristic curves of 4 models for predicting progression-free survival. (A-C) Receiver operating characteristic curves in the training cohort; (D-F) receiver operating characteristic curve in the internal validation cohort; and (G-I) receiver operating characteristic curves in the temporal validation cohort. Lasso: least absolute shrinkage and selection operator; PFS: progression-free survival; RFS: random survival forest; ROC: receiver operating characteristic; SVM: support vector machine; XGBoost: extreme gradient boosting.

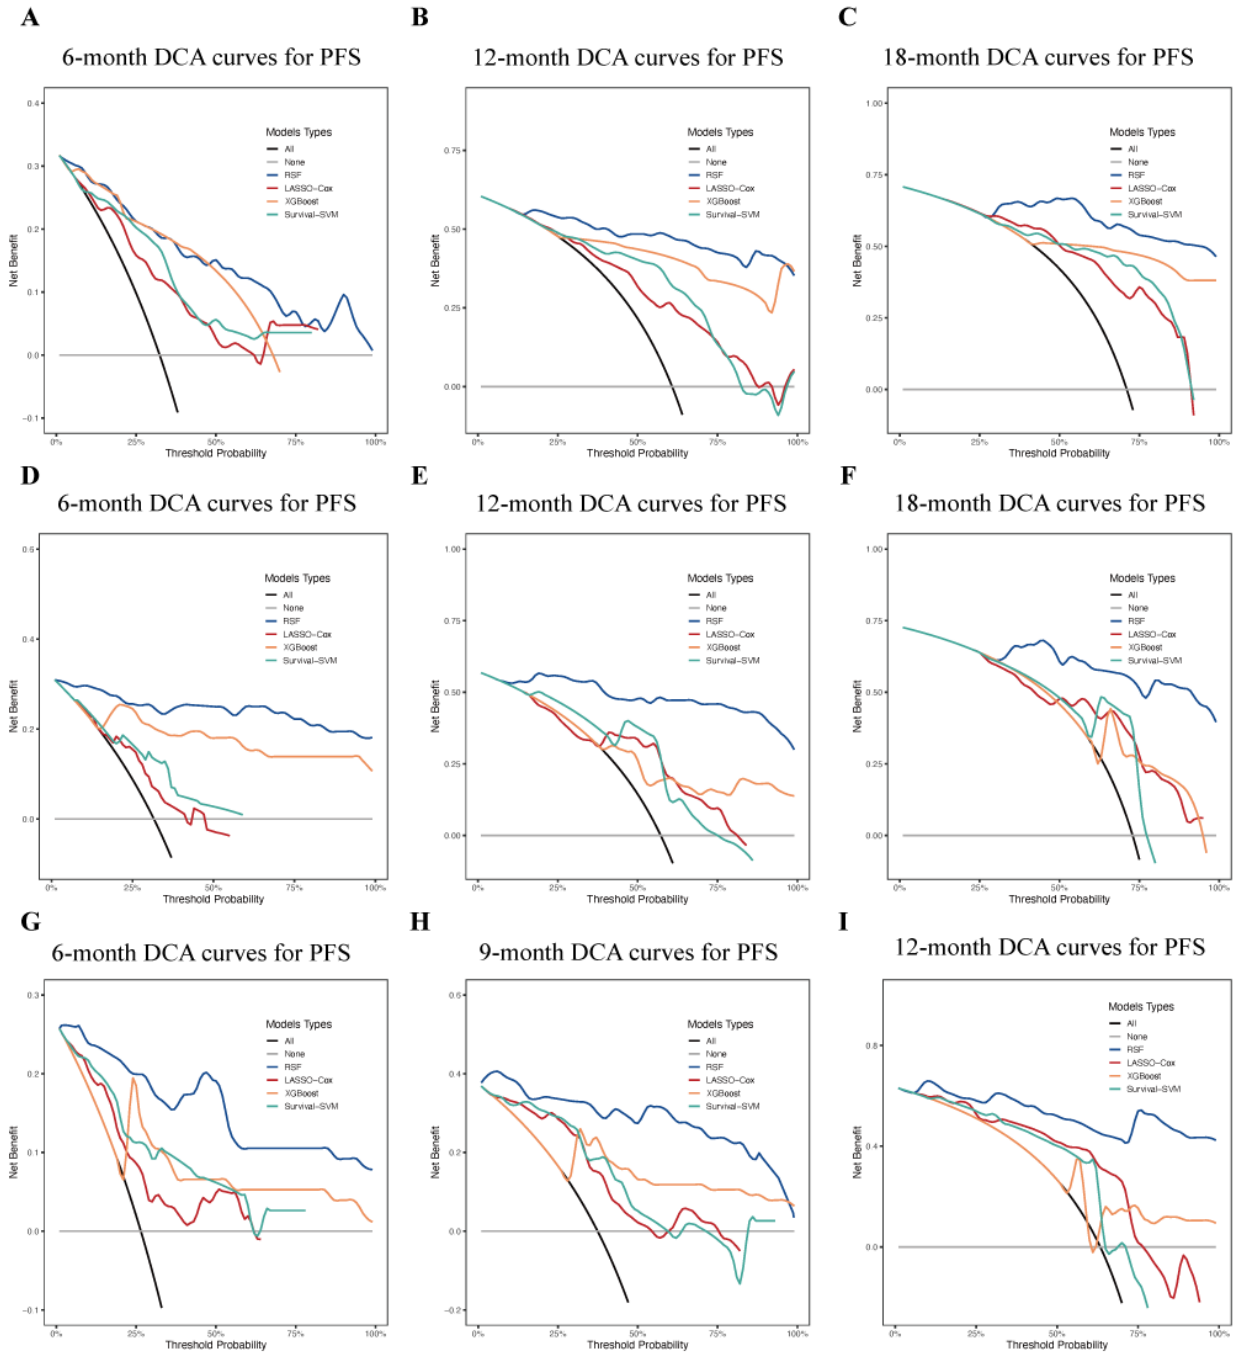
To assess the accuracy of the predictive models for PFS rates, we generated calibration curves. The x-axis represents the predicted PFS values, while the y-axis shows the actual PFS. The calibration curves for the training, internal validation, and temporal validation cohorts were all close to the ideal line, demonstrating that all 4 models are well-calibrated and that there is strong concordance between the predicted and observed outcomes. This further supports the predictive accuracy of the RSF model (Figures 5A-5I).

XSL•FO
RenderX

Figure 5. Calibration curves for the 4 models. (A-C) Calibration curves for the training cohort; (D-F) calibration curves for the internal validation cohort; and (G-I) calibration curves for the temporal validation cohort. LASSO: least absolute shrinkage and selection operator; PFS: progression-free survival; RFS: random survival forest; SVM: support vector machine; XGBoost: extreme gradient boosting.



Furthermore, the continuous AUC curves for the RSF model at different time points were consistently higher, further confirming its excellent and long-term discriminatory power in both the internal validation and temporal validation cohorts (Multimedia Appendix 7).

DCA, which evaluates the clinical utility of models by calculating net benefits across various threshold probabilities, demonstrated that higher net benefits correspond to greater clinical decision-making value. The DCA curves of the 4 models revealed that the RSF model exhibited consistently superior net benefits compared with the other 3 models in all datasets, including the training set, internal validation set, and temporal validation cohort (Figure 6A-I).

XSL•FO
RenderX

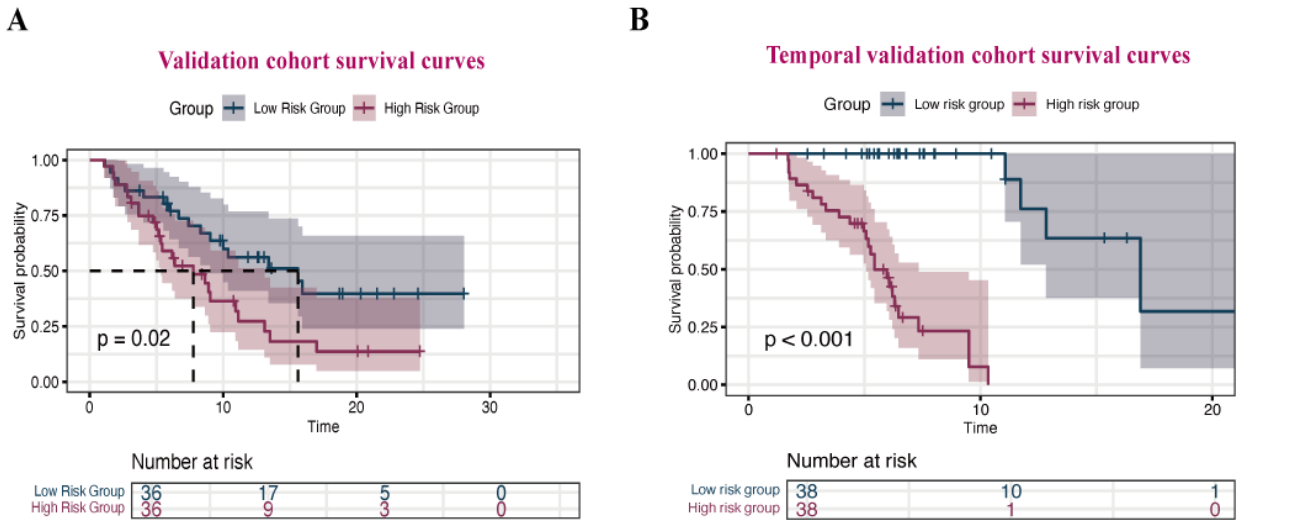


Figure 6. Decision curve analyses for the 4 models. (A-C) Calibration curves for the training cohort; (D-F) calibration curves for the internal validation cohort; and (G-I) calibration curves for the temporal validation cohort. DCA: decision curve analysis; LASSO: least absolute shrinkage and selection operator; PFS: progression-free survival; RFS: random survival forest; SVM: support vector machine; XGBoost: extreme gradient boosting.

Based on comprehensive comparisons of the 4 models in discrimination, calibration, consistency, and clinical net benefit, our findings indicate that the RSF model demonstrates superior predictive performance compared with the other 3 models. Patient risk stratification constitutes a critical component in guiding clinical management decisions. Using risk scores calculated by the RSF model, the optimal cutoff value for stratifying the cohort into high-risk and low-risk groups was determined as 55.42. Subsequent stratification revealed distinct survival outcomes, as illustrated by risk score distribution plots and KM survival curves. The KM analysis demonstrated significantly higher survival rates in the low-risk group compared with the high-risk group across both internal validation and temporal validation cohorts (Figure 7). These findings were statistically consistent regardless of the evaluation time frame.

Feature Importance Analysis

To elucidate the decision-making rationale of the RSF model in predicting PFS for patients with AGC receiving first-line immunochemotherapy, interpretability analysis was performed using SHAP. Figure 8 displays the feature importance bar plot and SHAP value bee swarm plot for the RSF model. The analysis revealed that features including age, histological subtype, pretreatment proportion of CD19 B cells, pretreatment proportion of CD16 CD56 NK cells, and presence of liver metastasis exhibited broad value ranges and substantial positive and negative effects in SHAP distributions, identifying them as pivotal predictors of PFS. Subsequent KM analysis of these 5 key predictors demonstrated that patients aged <63 years, those with signet ring cell carcinoma histology, elevated pretreatment proportion of CD19 B cells, reduced pretreatment proportion of CD16 CD56 NK cells, or presence of liver metastasis experienced significantly worse prognosis (Multimedia Appendix 8).

Figure 8. Feature importance ranking bar plot and Shapley Additive Explanations beeswarm plot of the random survival forest model. AFP: alpha-fetoprotein; HER2: human epidermal growth factor receptor 2; NK: natural killer; PD-L1: programmed death-ligand 1; TMB: tumor mutation burden.

Discussion

Principal Results

In this study, we developed and compared 4 prognostic models using a comprehensive set of baseline parameters to predict PFS in patients with AGC receiving first-line immunochemotherapy. Our principal finding is that an ML model based on the RSF algorithm exhibited superior predictive performance over the LASSO-Cox, XGBoost, and survival-SVM models. Specifically, the RSF model exhibited the highest discriminatory power (as measured by C-index and AUC) and the greatest clinical utility (as determined by DCA) across both internal and temporal validation cohorts. Furthermore, the RSF-derived risk stratification system effectively stratified patients into distinct high- and low-risk prognostic groups, underscoring its potential utility in guiding individualized therapeutic decisions. Interpretability analysis

XSL•FO
RenderX

subsequently identified 5 key predictors driving the model's performance: age, histological subtype, pretreatment proportion of CD19 B cells, pretreatment proportion of CD16 CD56 NK cells, and the presence of liver metastasis. Collectively, these findings establish a robust and clinically applicable tool for personalized prognostic assessment in this patient population.

In-depth analysis of these predictors revealed that tumor-infiltrating lymphocytes and liver metastasis status significantly influenced prognosis. Our study observed that patients with an elevated pretreatment proportion of CD19 B cells exhibited poorer outcomes. Analysis of the cohort demonstrated a mPFS of 7.4 (95% CI 6.67-8.9) months in the high CD19 B cells subgroup compared with 15.9 (95% CI 10.9-upper limit not reached) months in the low CD19 B cells subgroup. The function of B cells in cancer is highly heterogeneous, with distinct subsets capable of exerting either protumorigenic or antitumorigenic effects [33,34]. While the presence of B cells organized in tertiary lymphoid structure is often correlated with improved clinical outcomes and response to immunotherapy in many cancers [35], a substantial body of evidence also points to a protumorigenic B cell function. This negative role is frequently mediated by regulatory B cells (Bregs), which suppress antitumor immunity through the secretion of inhibitory cytokines like IL-10, IL-35, and TGF-β [36,37]. Our observation is consistent with studies specifically in GC, which have identified intratumoral Bregs (eg, $CD19^{+}CD24^{hi}CD38^{hi}$ or $CD19^{+}CD24^{hi}CD27^{+}$) that produce IL-10 [38]. Furthermore, IL-35-secreting B cells have been found to be elevated in patients with AGC and correlate with an accumulation of other immunosuppressive populations, such as regulatory T cells [39]. Therefore, it is plausible that the high $CD19^{+}$ B cell population identified in our poor-prognosis cohort represents a dominance of these immunosuppressive Breg subsets, which dampen T cell effector function and contribute to therapeutic resistance. Conversely, other B cell subsets in the tumour microenvironment (TME) function as potent antigen-presenting cells to prime T cell responses or differentiate into plasma cells that produce tumor-specific antibodies [40]. The continued development and application of advanced analytical approaches, such as single-cell and spatial omics, are essential for comprehensively dissecting B cell heterogeneity and elucidating the precise mechanisms by which B cells modulate the immune response in GC.

NK cells are cytotoxic innate-like lymphocytes essential for tumor immunosurveillance, hardwired to recognize and kill stressed or malignant cells [41]. Evidence from mouse models confirms this, as long-term NK cell depletion results in increased tumor incidence and severity, demonstrating their fundamental role in suppressing tumor development [42]. NK cells deploy multiple antitumor mechanisms. Their activity is often perforin-dependent, highlighting the importance of direct cytotoxicity. Furthermore, NK cells express activating receptors like the high-affinity Fc receptor CD16, enabling them to mediate antibody-dependent cell-mediated cytotoxicity [43]. This function, critical for many antibody-based therapies, triggers the killing of antibody-coated cells and cytokine release. Beyond direct killing, recent work reveals a crucial "sentinel" function: NK cells detect nascent tumors and recruit dendritic cells to the TME, thereby mobilizing the adaptive immune response [44,45]. Clinically, numerous studies from The Cancer Genome Atlas correlate high NK cell infiltration with improved OS outcomes in diverse cancers, including melanoma, breast cancer, and GC [46-48].

Additionally, liver metastasis emerged as an independent adverse prognostic factor for the efficacy of first-line immunochemotherapy in AGC. KM curve analysis confirmed that patients with liver metastasis responded poorly to immunochemotherapy compared with those with distant metastases in other organs. Mechanistically, this is attributed to the formation of a highly immunosuppressive TME within the liver [49]. Numerous studies support this, revealing an increased presence of cancer-associated fibroblasts, myeloid-derived suppressor cell-like macrophages, tumor-associated macrophage-like macrophages, and naive T cells in liver metastasis. Conversely, conventional dendritic cells and effector $CD8^{+}$ T cells were diminished [50,51]. This aligns with existing literature. Liver metastasis is known to upregulate immune checkpoint molecules like PD-1 or PD-L1, which can induce systemic exhaustion of tumor-specific $CD8^{+}$ T cells and attenuate immunotherapy efficacy [52].

In summary, this study is the first to develop and rigorously validate an ML-based prognostic model specifically for patients with AGC receiving first-line immunochemotherapy. A key advantage of this model is its foundation on readily available, baseline clinical variables, offering a cost-effective and easily implementable prognostic tool in contrast to more complex omics-based assays. We demonstrated that the RSF model provides superior predictive performance and clinical utility, effectively stratifying patients into distinct high- and low-risk groups. This model is driven by key predictors identified in our analysis, including baseline immune cell proportions ($CD19^{+}$ B cells and $CD16^{+}CD56^{+}$ NK cells) and the presence of liver metastasis. Consequently, the RSF model represents a robust tool that offers quantifiable decision support, holding significant potential for guiding individualized therapeutic strategies and enhancing clinical decision-making in this setting.

Limitations and Future Work

Despite successful validation of the RSF model's performance in predicting outcomes for patients with AGC receiving first-line immunochemotherapy via internal and temporal validation cohorts, several limitations warrant acknowledgment. First, the single-center, retrospective design is a primary constraint that may introduce selection bias. Our cohorts were derived from a single institution with specific patient demographics, referral patterns, and clinical management protocols. Consequently, the model may be overfit to these local characteristics, and its external validity remains to be determined. Second, the high prevalence of missing values for established biomarkers, notably PD-L1, MSI status, and TMB, presented a significant limitation. This data sparsity precluded a direct comparative analysis of the prognostic accuracy of our RSF model against these established biologically based predictors. Furthermore, it inhibited our ability to investigate whether the integration of these potent biomarkers could have further augmented the

XSL•FO
RenderX

model's predictive performance. Third, our findings are based on a multiple imputation approach, which assumes that data are missing at random, a potential source of bias if violated. However, the robustness of our main conclusions was confirmed by a sensitivity analysis, mitigating this concern.

Future research will focus on a multistage approach designed to rigorously validate, enhance, and ultimately translate our RSF model into clinical practice. The most immediate priority is to address the current limitation of generalizability. This requires rigorously testing the model's performance and robustness in independent, prospective, and multicenter cohorts to definitively establish its external validity. Following successful validation, the next phase will involve enhancing the model's predictive power by incorporating broader multiomics data, such as genomic, transcriptomic, or proteomic profiles. This integration not only promises to refine prognostic accuracy but may also uncover deeper biological insights into the mechanisms of immunochemotherapy response. Contingent upon this robust validation and enhancement, the final objective is the translation of the optimized model into an accessible clinical decision support tool. We envision the development of a user-friendly platform, such as a web-based calculator or a simplified score system. This would provide clinicians with a practical means to generate real-time, individualized predictions for prognosis and recurrence risk, thereby advancing personalized treatment strategies for patients with AGC.

Conclusions

In conclusion**,** this study draws the following findings. First, 4 prognostic models were developed in this study, with comparative analyses demonstrating that the RSF model outperformed others in discriminative ability, calibration, and clinical utility. Second, SHAP analysis of the RSF model identified age, liver metastasis, histological subtype, and tumor-infiltrating lymphocytes as critical prognostic predictors for patients with AGC undergoing first-line immunochemotherapy. Third, this study is the first to use ML to construct a prognostic model for assessing treatment efficacy in patients with AGC receiving first-line immunochemotherapy. The results underscore the model's significant clinical value in prognostic evaluation and therapeutic decision-making. This study provides methodological innovation and evidence-based medical rationale for advancing precision therapy in AGC, offering substantial potential for clinical translation.

Acknowledgments

The authors thank the researchers from The First Affiliated Hospital of Nanjing Medical University for their help with data recording and collection.

Funding

This study was supported by the Health Development Promotion Project (BJHA-CRP-071), Beijing Xisike Clinical Oncology Research Foundation (sy2018-249), and the Clinical Ability Improvement Project (JSPH-MB-2020-3).

Authors' Contributions

XC designed the study, collected and analyzed the data, and wrote the paper as the first author. EM contributed to data collection. XC contributed to the statistical analysis of the results. PL and HW verified the analytical methods. HW investigated and supervised the findings of this work and assisted with language editing. XW contributed to the data collection of the temporal validation cohort and reviewed the paper. HW was in charge of the overall direction of the study as the corresponding author. All authors gave final approval of the paper for submission.

Abstract

Background: Accurately predicting left ventricular ejection fraction (LVEF) recovery after percutaneous coronary intervention (PCI) in patients with chronic coronary syndrome (CCS) is crucial for clinical decision-making.

Objective: This study aimed to develop and compare multiple machine learning (ML) models to predict LVEF recovery and identify key contributing features.

Methods: We retrospectively analyzed 520 patients with CCS from the Clinical Deep Data Accumulation System database. Patients were categorized into 4 binary classification tasks based on baseline LVEF (≥50% or <50%) and degree of recovery: (1) good recovery, defined as an LVEF increase of >10% compared with ≤0%; and (2) normal recovery, defined as an LVEF increase

XSL•FO
RenderX

of 0% to 10% compared with ≤0%. For each task, 3 feature selection strategies (all features, least absolute shrinkage and selection operator [LASSO] regression, and recursive feature elimination [RFE]) were combined with 4 ML algorithms (extreme gradient boosting [XGBoost], categorical boosting, light gradient boosting machine, and random forest), resulting in 48 models. Models were evaluated using 10-fold cross-validation and assessed by the area under the curve (AUC), decision curve analysis, and calibration plots.

Results: The highest AUCs were achieved by RFE combined with XGBoost (AUC=0.93) for preserved LVEF with good recovery, LASSO combined with XGBoost (AUC=0.79) for preserved LVEF with normal recovery, LASSO combined with XGBoost (AUC=0.88) for reduced LVEF with good recovery, and RFE combined with XGBoost (AUC=0.84) for reduced LVEF with normal recovery. Shapley Additive Explanation analysis identified uric acid, platelets, hematocrit, brain natriuretic peptide, glycated hemoglobin, glucose, creatinine, baseline LVEF, left ventricular end-diastolic internal diameter, heart rate, R wave amplitude in V5, and R wave amplitude in V6 as important predictive factors of LVEF recovery.

Conclusions: ML models incorporating feature selection strategies demonstrated strong predictive performance for LVEF recovery after PCI. These interpretable models may support clinical decision-making and can improve the management of patients with CCS after PCI.

KEYWORDS

chronic coronary syndrome; left ventricular ejection fraction; percutaneous coronary intervention; machine learning; prognostic modeling

Introduction

With changing lifestyle habits and aging populations, coronary artery disease (CAD) has emerged as a leading global threat to health and mortality. It is projected that CAD will cause 7.8 million deaths worldwide by 2025 [1-4]. CAD is generally categorized into acute coronary syndrome (ACS) or chronic coronary syndrome (CCS) [5]. Among these, CCS is characterized by stable but progressive myocardial ischemia, presenting substantial challenges in long-term management and risk stratification [6].

Percutaneous coronary intervention (PCI), a mainstay treatment for CAD, aims to restore myocardial perfusion and is extensively used in patients with CCS [7]. However, despite successful revascularization, not all patients experience improved cardiac function, leading to poor long-term prognosis [8,9]. Recovery and remodeling of ventricular function critically influence PCI outcomes, and left ventricular ejection fraction (LVEF) is a key metric for assessing these changes [10-12]. Dynamic changes in LVEF are closely associated with myocardial recovery, heart failure incidence, hospital readmission, and cardiovascular mortality [13-15]. Therefore, identifying patients with varying degrees of LVEF recovery after PCI is essential for early risk stratification and personalized clinical management.

Traditionally, research on post-PCI recovery has focused primarily on patients with reduced LVEF, while those with preserved baseline LVEF have received less attention [16,17]. However, several studies have shown that a large proportion patient with preserved LVEF progress to reduced LVEF during follow-up, and this transition is usually associated with a worse clinical prognosis [14,18]. Thus, stratified modeling based on baseline LVEF is essential to capture the heterogeneity of post-PCI recovery and to enable early identification of potential high-risk patients.

In recent years, machine learning (ML) has been increasingly applied to PCI outcome prediction. However, most existing studies have focused on ACS populations and short-term events, such as major adverse cardiovascular events, mortality, or readmission [19-23]. By contrast, limited studies and datasets exist for the CCS population, in which post-PCI myocardial recovery plays a central role in long-term prognosis. Moreover, few studies have addressed the heterogeneity across baseline LVEF subgroups or incorporated interpretable ML approaches to elucidate the determinants of ventricular recovery. Therefore, this study aimed to develop and validate ML-based predictive frameworks to assess LVEF recovery within 6 to 12 months after PCI in patients with CCS with different baseline LVEF levels. Furthermore, we aimed to identify key factors influencing LVEF recovery to optimize post-PCI follow-up and treatment strategies, ultimately enhancing the long-term prognosis of patients with CCS.

Methods

Data Source

This study used the Clinical Deep Data Accumulation System (CLIDAS) database. Briefly, CLIDAS involves 6 university hospitals and 1 national center hospital in Japan, namely, Tohoku University, Jichi Medical University, Jichi Medical University Saitama Medical Center, University of Tokyo, National Cerebral and Cardiovascular Center Hospital, Kyushu University, and Kumamoto University [24,25]. The database includes data on patients' backgrounds, blood test results, medication prescriptions, echocardiography data, electrocardiogram data, long-term prognosis, and information on cardiac catheterization [26].

Ethical Considerations

This retrospective study was reviewed and approved by the Institutional Review Board of Jichi Medical University Hospital, Jichi Medical University, Tochigi, Japan (reference 23-158), and was conducted in accordance with the Declaration of Helsinki. The requirement for written informed consent was waived owing to the retrospective study design. All patient

XSL•FO
RenderX

information was anonymized before analysis. JD and GL had full access to all the data in the study and take responsibility for its integrity and the data analysis.

Study Population

We retrospectively analyzed patients with CCS who underwent PCI between April 2013 and December 2018 and were registered in the CLIDAS database. The inclusion criteria were as follows: (1) patients diagnosed with CCS and undergoing PCI for reasons other than ACS; (2) at least one echocardiogram showing LVEF within 30 days before PCI, that is, baseline LVEF (including day 30 before PCI and the day of PCI); (3) at least one echocardiogram showing LVEF during follow-up (180-365 days after PCI), that is, follow-up LVEF (including days 180 and 365 after PCI); and (4) available blood test data, demographics, electrocardiogram records, echocardiography examination records, cardiac catheterization insertion reports within 1 month before PCI (including day 30 before PCI and the day of PCI), and medication records within 10 days of PCI and before PCI. In total, 520 patients were included.

Group Classification and Definition

The patients were grouped according to the change in their LVEF values (ΔLVEF; ΔLVEF=follow-up LVEF−baseline LVEF) to specifically characterize the improvement or deterioration of LVEF after PCI. For baseline and follow-up LVEF, only values closest to days 0 and 180, respectively, were considered. Good LVEF recovery was defined as ΔLVEF>10%, normal recovery as ΔLVEF>0% to ≤10%, and nonrecovery as ΔLVEF≤0%. Although the most recent European Society of Cardiology guidelines have introduced a new subtype of heart failure with a mild reduction in ejection fraction (ie, LVEF 40%-49%), this subtype is uncertain and is underrepresented in many clinical trials. In addition, owing to observer variability during echocardiographic procedures, this subtype is more difficult to differentiate and can lead to serious misclassifications.

Both American and Australian heart failure guidelines prefer to categorize heart failure with preserved ejection fraction and heart failure with reduced ejection fraction using a 50% LVEF threshold [27]. Therefore, in this study, the 50% baseline LVEF threshold was used to classify the patients into the preserved LVEF group (ie, LVEF≥50%) and the reduced LVEF group (ie, LVEF<50%). Subsequently, different degrees of LVEF recovery were combined with the 2 aforementioned groups, resulting in 4 distinct groups. These groups were used for model development and validation, with the aim of investigating the similarities and differences in factors influencing the varying degrees of LVEF recovery in these patients.

Predictive Variables

A total of 131 predictor variables were analyzed. These included blood test data, demographic data, electrocardiogram recordings, echocardiogram recordings, cardiac catheterization reports within 30 days before PCI, and medication records within 10 days before PCI. Given that the same patient may have multiple measurements for each predictor variable, except for medication records, the one closest to the date of PCI was used. The number of medications was very large; thus, the medications were divided into categories to narrow them down, and the categories were converted into categorical variables using one-hot encoding. As the vascular locations of PCI implementation vary in cardiac catheterization reports, namely, the right coronary artery (RCA), left main trunk (LMT), left anterior descending artery (LAD), and left circumflex artery (LCX), 4 new binary variables were created to indicate the PCI implementation site: site_RCA, site_LMT, site_LAD, and site_LCX.

Data Preprocessing

We first examined the distribution of missing data across the entire cohort and found no apparent systematic pattern. Therefore, data processing was conducted under an approximately missing at random assumption.

Variables with more than 30% missing data were removed. For variables with 10% to 30% data missingness, multivariate imputation by chained equations was applied, while variables with <10% data missingness were imputed using the median and mode value [28].

Feature Selection

Three feature selection strategies were applied: all 131 variables (no selection), least absolute shrinkage and selection operator (LASSO) regression, and recursive feature elimination (RFE). LASSO selects features by penalizing the coefficients of less important variables, whereas RFE iteratively removes the least important features based on model performance. Both LASSO and RFE were implemented with embedded cross-validation to ensure the robustness and stability of feature selection across data partitions.

Model Development and Evaluation

We constructed predictive models for each task using 4 ML algorithms: extreme gradient boosting (XGBoost), CatBoost, LightGBM, and random forest. Models were trained using 10-fold cross-validation to mitigate overfitting. Hyperparameters were optimized using the Optuna Bayesian optimization framework (Preferred Networks). Model performance was primarily evaluated by the receiver operating characteristic (ROC) and area under the curve (AUC), complemented by decision curve analysis (DCA) and calibration plots.

Model Interpretability

To interpret and visualize model predictions, we used Shapley Additive Explanation (SHAP), which quantifies the contribution of each feature to the model's predictions, facilitating clinical interpretability.

Statistical Analysis

For baseline characteristics, categorical variables were expressed as percentages and compared between the groups using the chi-square test. The Kolmogorov-Smirnov test was used to assess the normality of the distribution of continuous variables. Normally distributed continuous variables were presented as the mean (SD) and compared using 2-tailed Student *t* test. Nonnormally distributed continuous variables were presented as the median (IQR) and compared using the Mann-Whitney *U* test. All statistical analyses and the model construction process were performed using Jupyter Notebook 6.4.8 (Project Jupyter)

XSL•FO
RenderX

and Anaconda Navigator 2.3.2 (Anaconda Inc). The programming language used was Python 3.9.12. Statistical significance was set at $P<.05$, and it refers to the predefined threshold.

Results

Baseline Characteristics

We included 520 patients from the CLIDAS database. The average age of the total population was 71 (SD 10.49) years, and 401 (77.1%) patients were male. Diabetes mellitus and hypertension were present in 200 (38.5%) patients and 431 (82.9%) patients, respectively. According to the baseline LVEF, 418 (80.38%) patients belonged to the preserved LVEF group and 102 (19.61%) to the reduced LVEF group. The distribution of patients across baseline LVEF and recovery categories is presented in Table 1. The baseline characteristics of the preserved and reduced LVEF groups are summarized in Tables S1 and S2 in Multimedia Appendix 1, respectively. Owing to the large number of clinical variables, representative variables from each category are presented here. In the preserved LVEF group, hemoglobin, hematocrit (Hct), left ventricular end-systolic internal diameter, and baseline LVEF were substantially different between patients with and without functional recovery. In the reduced LVEF group, serum creatinine (Cre) and glucose (GLU) demonstrated sizable differences between recovery and nonrecovery patients.

Table 1. Group inclusion (N=520).

Group	Recovery, n (%)	Nonrecovery, n (%)
Baseline LVEF[a] ≥50%		
Preserved LVEF with good recovery[b] (n=229)	43 (8.26)	186 (35.77)
Preserved LVEF with normal recovery[c] (n=375)	189 (36.35)	186 (35.77)
Baseline LVEF<50%		
Reduced LVEF with good recovery (n=68)	44 (8.46)	24 (4.61)
Reduced LVEF with normal recovery (n=58)	34 (6.54)	24 (4.61)

[a]LVEF: left ventricular ejection fraction.

[b]Good recovery: an LVEF increase of >10% compared with ≤0%.

[c]Normal recovery: an LVEF increase of 0% to 10% compared with ≤0%.

Predictive Performance of the Models

A total of 48 predictive models were developed by combining 3 feature selection strategies (all features, LASSO, and RFE) with 4 ML algorithms (XGBoost, CatBoost, LightGBM, and random forest) across 4 prediction tasks. Model performance evaluated using the AUC score is summarized in Table 2. Additional details, including task-specific feature selection, ROC curves, calibration, and DCA plots of all models, as well as other performance metrics for the best-performing models are presented in Figures S1-S3 and Table S3 in Multimedia Appendix 1.

[a]XGBoost: extreme gradient boosting.

[b]CatBoost: categorical boosting.

[c]LightGBM: light gradient boosting machine.

[d]RF: random forest.

[e]pG: preserved left ventricular ejection fraction with good recovery.

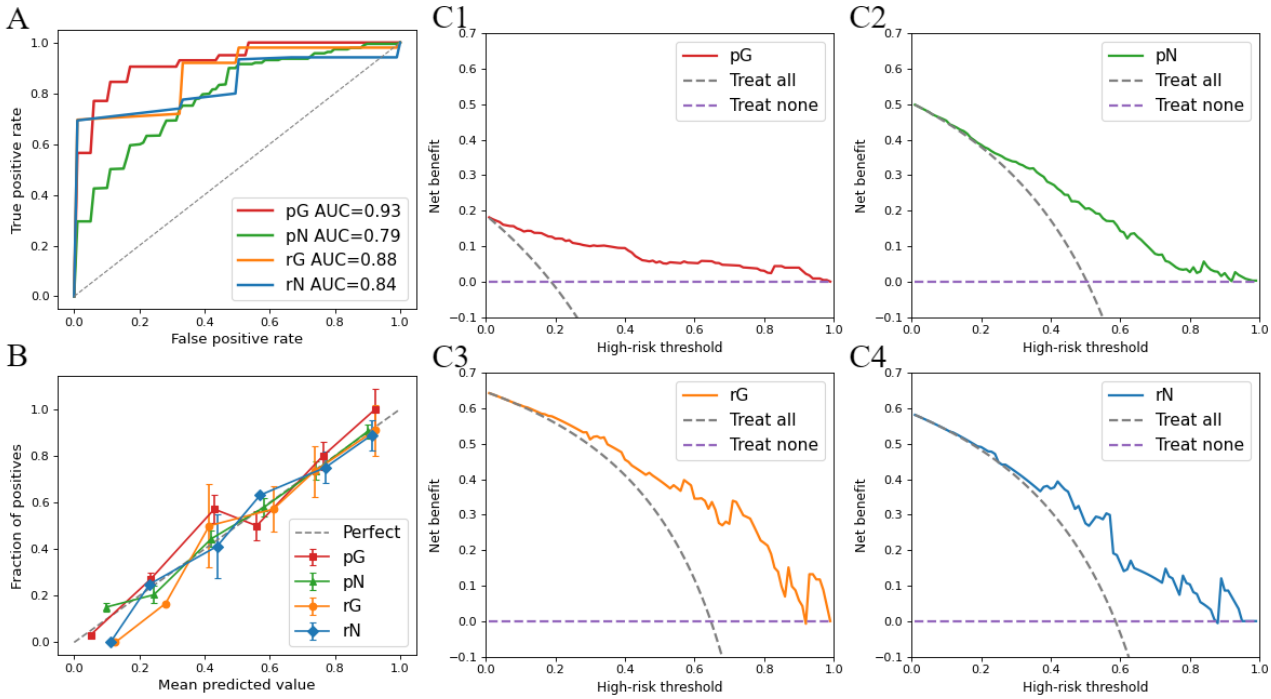
[f]LASSO: least absolute shrinkage and selection operator.

[g]RFE: recursive feature elimination.

[h]pN: preserved left ventricular ejection fraction with normal recovery.

[i]rG: reduced left ventricular ejection fraction with good recovery.

[j]rN: reduced left ventricular ejection fraction with normal recovery.



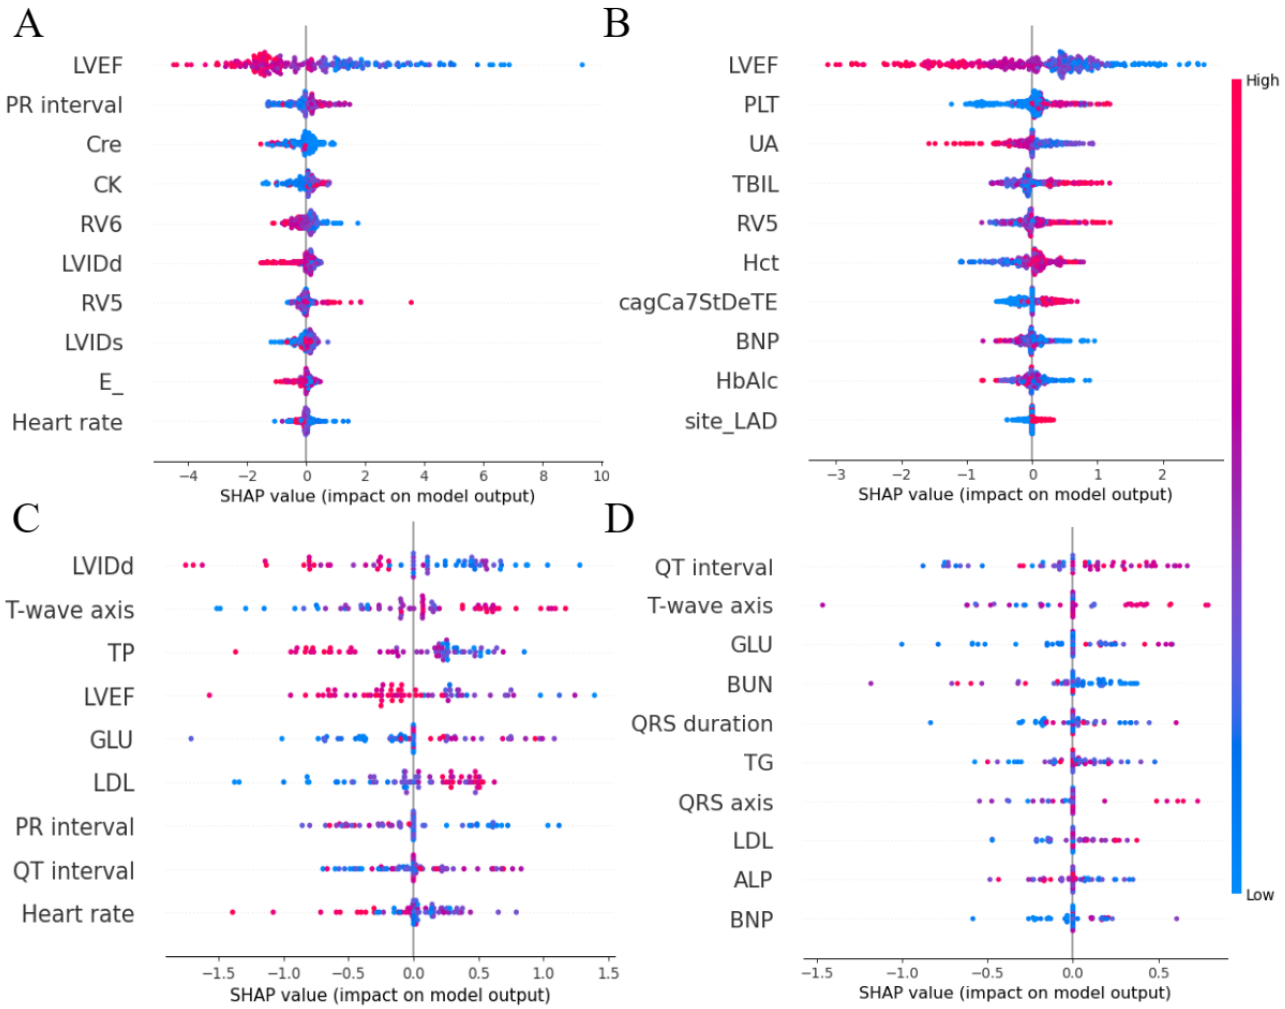
The best-performing models for each task were as follows:

- Preserved LVEF with good recovery: RFE+XGBoost (AUC=0.93)
- Preserved LVEF with normal recovery: LASSO+XGBoost (AUC=0.79)
- Reduced LVEF with good recovery: LASSO+XGBoost (AUC=0.88)
- Reduced LVEF with normal recovery: RFE+XGBoost (AUC=0.84)

Figure 1 shows the performance of the optimal models for each task. ROC curves demonstrated strong discriminative power across tasks, especially in predicting patient with good recovery tasks. Calibration plots showed the alignment of predicted probabilities with observations for different risk levels, providing a visual assessment of how well each model's predicted risk fits with actual event rates. DCA plots revealed substantial clinical net benefit of the optimal models compared to treat-all and treat-none strategies across a wide range of threshold probabilities, supporting their potential clinical applicability.

XSL•FO
RenderX

Figure 1. Model performance of each task: (A) receiver operating characteristic curves for optimal models in each task, (B) calibration curve of the 4 optimal models, and (C1-C4) clinical decision curves of the optimal models for each task. AUC: area under the curve; pG: preserved left ventricular ejection fraction with good recovery task; pN: preserved left ventricular ejection fraction with normal recovery task; rG: reduced left ventricular ejection fraction with good recovery task; rN: reduced left ventricular ejection fraction with normal recovery task.



Subgroup analyses stratified by sex, age, and comorbidities demonstrated consistent model performance across clinically relevant patient groups (Table S4 in Multimedia Appendix 1).

SHAP Summary Plot

SHAP is a graphical method for interpreting ML models based on the concept of Shapley values in game theory. Each line in the SHAP summary plot represents a predictor variable, with variables that have a greater impact on the model output being closer to the top. The SHAP summary plots for the 4 optimal models are shown in Figure 2. Overall, some cardiac function–related parameters were identified as important. These included baseline LVEF; left ventricular end-diastolic internal diameter (LVIDd); R wave amplitude in V5 (RV5) or R wave amplitude in V6 (RV6); heart rate; and some laboratory parameters, including uric acid (UA), platelets (PLTs), Hct, brain natriuretic peptide (BNP), glycated hemoglobin (HbA_{1c}), GLU, and Cre.

XSL•FO
RenderX

Figure 2. Top important features identified by Shapley Additive Explanations (SHAP): (A) important features in the preserved left ventricular ejection fraction with good recovery task, (B) important features in the preserved left ventricular ejection fraction with normal recovery task, (C) important features in the reduced left ventricular ejection fraction with good recovery task, and (D) important features in the reduced left ventricular ejection fraction with normal recovery task. ALP: alkaline phosphatase; BNP: brain natriuretic peptide; BUN: blood urea nitrogen; cagCa7StDeTE: stenosis degree of coronary artery segment 7; CK: creatine kinase; Cre: creatinine; E_: mitral E wave velocity; GLU: glucose; HbA_{1c}: glycated hemoglobin; Hct: hematocrit; LAD: left anterior descending artery; LDL: low-density lipoprotein; LVEF: left ventricular ejection fraction; LVIDd: left ventricular end-diastolic internal diameter; LVIDs: left ventricular end-systolic internal diameter; PLT: platelet; RV5: R wave amplitude in V5; RV6: R wave amplitude in V6; TBIL: total bilirubin; TG: triglycerides; TP: total protein; UA: uric acid.

Discussion

Principal Findings

In this study, our models showed satisfactory performance across all groups after hyperparameter optimization and 10-fold cross-validation. The results indicated the strong discriminatory ability of ML models in predicting the recovery status of LVEF within 6 months to 1 year after PCI in patients with CCS. The application of feature selection strategies, such as RFE and LASSO, effectively improved model performance. Furthermore, UA, PLTs, Hct, BNP, HbA_{1c}, GLU, Cre, baseline LVEF, LVIDd, heart rate, RV5, and RV6 were identified as important predictors of post-PCI LVEF recovery in patients with CCS with different baseline LVEF levels. These findings can help clinicians better understand the factors influencing LVEF recovery, thereby supporting timely adjustments in treatment and follow-up strategies to improve patient outcomes.

Compared with previous studies, our work presents several methodological and clinical advancements. From a clinical perspective, our study moves beyond the traditional focus on adverse end points. Previous ML-based PCI studies have primarily focused on ACS populations and short-term event outcomes such as major adverse cardiovascular events or mortality [19-23], which capture only terminal prognostic states. In contrast, post-PCI LVEF recovery reflects the intermediate phase of cardiac repair, serving as a mechanistically meaningful and clinically actionable indicator of long-term prognosis. We focused on the 6- to 12-month post-PCI period, which captures the critical window of myocardial remodeling while minimizing interference from immediate or distant postoperative events. As most improvement or decline in LVEF occurs within this period [12,17], early prediction of recovery potential during this phase enables timely adjustment of medical therapy and secondary prevention strategies, providing a more proactive framework for improving patient outcomes [29]. Furthermore, our study addresses the real-world heterogeneity of CCS by

XSL•FO
RenderX

uniquely including patients across both reduced and preserved LVEF subgroups [30,31], thereby covering a broader clinical spectrum that was often overlooked in previous research. Methodologically, we used a more rigorous and transparent framework. Earlier post-PCI studies mainly relied on single statistical models or isolated ML algorithms, often neglecting subgroup variability and the robustness of feature selection [16,32,33]. In contrast, our framework systematically compared different feature selection methods (RFE and LASSO) and integrated SHAP analysis to enhance interpretability. This combination improved model robustness clarified the contribution of individual predictors, and strengthened clinical transparency and trust.

Interestingly, models generally perform better with larger, more balanced datasets [34]. However, in our study, the best-performing task was predicting good recovery in preserved LVEF, rather than the task with the largest and most balanced sample size. The results remained consistent after accounting for class imbalance through category weighting sensitivity analysis (Table S5 in Multimedia Appendix 1). In addition, the good recovery task was superior to the normal recovery task across different baseline LVEF groups, indicating that patients with substantial LVEF improvement after PCI may have more defined potential patterns and clinical characteristics. This phenomenon is consistent with previous studies, suggesting that clear patient characteristics typically yield higher prediction accuracy even with smaller datasets [35,36]. Identifying these unique clinical trajectories and patterns can accurately stratify patients, leading to targeted interventions and improved clinical management.

Currently, clinical practice and research in post-PCI management focus on patients with reduced LVEF due to their substantial myocardial dysfunction, while largely ignoring patients with preserved LVEF. However, a *normal* LVEF does not necessarily reflect normal myocardial function. Previous studies have shown that patients with preserved LVEF may exhibit abnormal myocardial strain, elevated ventricular filling pressures, and an increased risk of adverse outcomes [37-39]. Yoshihisa et al [18] reported that approximately 30% of patients with preserved LVEF had a reduction in LVEF to ≤50% within 6 months, which was associated with poorer clinical outcomes. Similarly, another longitudinal study showed that a significant proportion of patients with preserved LVEF converted to reduced LVEF during a 3-year follow-up [40]. These results highlight the importance of promptly and accurately predicting LVEF trends in patients with preserved LVEF after PCI. Our model provides a practical tool for the early detection of potentially high-risk patients with preserved LVEF, which can improve their long-term prognosis through close monitoring of key factors and timely intervention.

In this study, SHAP analysis identified several key predictors of LVEF recovery, including laboratory parameters (UA, PLT, Hct, BNP, HbA_{1c}, GLU, Cre), cardiac function–related variables (baseline LVEF, LVIDd, and heart rate), and electrocardiogram parameters such as RV5 and RV6. Among laboratory and metabolic indicators, higher UA levels were associated with predicted nonrecovery, consistent with the role of hyperuricemia in promoting oxidative stress, endothelial dysfunction, and inflammation that drive adverse ventricular remodeling [41,42]. This aligns with the findings of Akashi et al [25], who identified hyperuricemia as a risk factor for heart failure after PCI in patients with CCS. Low Hct impairs oxygen delivery, and Wang et al [43] found that Hct levels were significantly lower in patients with CAD than in healthy controls. Interestingly, higher PLT counts were positively associated with recovery probability. This finding may reflect the reparative function of PLTs beyond thrombosis, as they release bioactive mediators, including growth factors and cytokines, that promote myocardial repair, angiogenesis, and inflammatory resolution [44]. Beyond these hematologic and metabolic markers, cardiovascular and systemic biomarkers also aid in risk stratification. Elevated BNP reflects neurohormonal activation and ventricular wall stress and has been linked to adverse outcomes even in patients with preserved LVEF after revascularization [45,46]. Increased HbA_{1c} indicates chronic metabolic stress and impaired myocardial recovery potential, consistent with studies showing that poor glycemic control limits functional improvement after PCI in both diabetic and nondiabetic populations [47,48]. Elevated Cre, as a marker of renal dysfunction [49], was also correlated with impaired cardiac functional recovery [50]. GLU also emerged as an important predictor in some subgroups. As the myocardium relies predominantly on GLU oxidation for energy, moderate elevations in GLU may reflect adequate metabolic substrate availability, consistent with the positive association observed in our model [51].

Regarding cardiac structural and functional parameters, an enlarged LVIDd was negatively associated with recovery, reflecting impaired ventricular compliance and chronic remodeling, as also shown by Chen et al [52]. Higher resting heart rate predicted poorer recovery, plausibly because increased sympathetic activation elevates myocardial oxygen demand and exacerbates ischemic stress, consistent with the findings of Lei et al [2].

For electrocardiographic parameters, the SHAP analysis indicated that higher RV6 amplitudes and lower RV5 amplitudes were predictive of nonrecovery. These voltage patterns are typical of left ventricular hypertrophy and electrical remodeling, both of which reduce compliance and delay reverse remodeling after revascularization [42]. Repolarization features, such as longer QT intervals and greater T-wave axis deviations, were positively associated with recovery in the reduced LVEF group, possibly reflecting adaptive electrical remodeling during functional improvement.

Importantly, lesion-specific variables, such as stenosis degree of coronary artery segment 7 (cagCa7StDeTE) and site_LAD, were positively associated with predicted recovery in the preserved LVEF with normal recovery group. This positive association does not imply a beneficial effect of severe stenosis but rather reflects the efficacy of complete and timely revascularization in critical myocardial territory. Proximal LAD lesions compromise a large myocardial territory and are critical determinants of left ventricular function; therefore, successful PCI in these segments can lead to substantial recovery [45]. Patients in our cohort with severe LAD stenosis who underwent

XSL•FO
RenderX

PCI demonstrated superior LVEF recovery. This suggests that anatomically targeted revascularization meaningfully contributes to reverse remodeling, even in the preserved function group. The inclusion of these lesion-level features underscores our dataset's unique strength. It shows that the model captures not only systemic and biochemical predictors but also procedural and anatomical factors. This provides an additional layer of interpretability that has been rarely addressed in prior studies.

Limitations

First, the relatively small sample size and the inclusion of only patients with complete echocardiographic follow-up data may have introduced selection bias, although this was necessary to ensure outcome accuracy. Second, although the dataset was derived from a multicenter real-world cohort in Japan, external validation was not conducted due to the specificity of included variables, limiting generalizability. Third, as a real-world cohort, unavoidable data missingness existed. Removing variables with a high proportion of missing data may have affected model performance. Furthermore, if some variables were missing not at random, this could affect feature selection or model performance.

Future work should expand the cohort and include external datasets for validation, while prospectively collecting standardized data to allow a more rigorous evaluation of missingness mechanisms and model generalizability. Moreover, developing dynamic models to predict continuous changes in LVEF and integrating additional modalities, such as imaging and biomarkers, may further enhance predictive accuracy and clinical utility.

Conclusions

Our ML models, which integrated feature selection strategies, demonstrated strong predictive performance for LVEF recovery after PCI. SHAP analysis identified UA, PLT, Hct, BNP, HbA_{1c}, GLU, Cre, baseline LVEF, LVIDd, heart rate, RV5, and RV6 as key factors of post-PCI LVEF recovery.

Acknowledgments

The authors thank the Kowa Company for funding Clinical Deep Data Accumulation System (CLIDAS) and all members of the CLIDAS research group for their contributions. The authors also thank Yuri Matoba (Precision Inc, Tokyo, Japan) for her support.

Funding

This work was supported by Kowa Company, Ltd; the Health Labour Sciences Research Grant (22FA1016); and the Cross-Ministerial Strategic Innovation Promotion Program on "Integrated Health Care System" (JPJ012425).

Authors' Contributions

JD, GL, and MN contributed to the conception and design of the study. JD performed feature selection, developed the models, and drafted the original manuscript. GL conducted data processing and statistical analysis. TM, T Kohro, NA, T Kabutoya, MI, TN, and HS collected data and organized the database. All authors contributed to the critical revision of the manuscript and approved the final version.

Conflicts of Interest

The authors declare the following financial interests or personal relationships that may be considered as potential competing interests. TK has received scholarship funding from Abbott. KK has received a research grant from Otsuka Pharmaceutical, Sanwa Kagaku Kenkyusho, Daiichi-Sankyo, MSD, Astellas Pharma, Eisai, Taisho Pharmaceutical, Sumitomo Dainippon Pharma, Takeda Pharmaceutical, Mitsubishi Tanabe Pharma, Teijin Pharma, Boehringer Ingelheim Japan, Bristol-Myers Squibb, and Mochida Pharmaceutical; consulting fees from Kyowa Kirin, Sanwa Kagaku Kenkyusho, and Mochida Pharmaceutical; honoraria from Otsuka Pharmaceuticals, Daiichi-Sankyo, Novartis Pharma, and Mylan European Pharmaceutical Distribution; and served on the advisory boards of Daiichi-Sankyo and Novartis Pharma. HF received scholarship funds from Abbott Vascular and speaking honoraria from Novartis and Otsuka Pharmaceutical Co, Ltd and served as a consultant for Mehergen Group Holdings, Inc. KT has received personal fees from Abbott Medical Co, Ltd, Amgen KK, AstraZeneca KK, Bayer Yakuhin, Ltd, Daiichi Sankyo Co, Ltd, Medtoronic Japan Co, Ltd, Kowa Pharmaceutical Co, Ltd, Novartis Pharma KK, Otsuka Pharmaceutical Co, Ltd, Pfizer Japan Inc, and Janssen Pharmaceutical K.K.; grants from PPD-Shin Nippon Biomedical Laboratories K.K, Alexion Pharmaceuticals, Inc, Abbott Medical Co, Ltd, Bayer Yakuhin, Ltd, Boehringer Ingelheim Japan, Daiichi Sankyo Co, Ltd, ITI Co, Ltd, ONO Pharmaceutical Co, Ltd, Otsuka Pharmaceutical Co, Ltd, and Takeda Pharmaceutical Co, Ltd; and other funds from Abbott Japan Co, Ltd, Boston Scientific Japan KK, Fides-One, Inc, GM Medical Co, Ltd, ITI Co, Ltd, Kaneka Medix Co, Ltd, NIPRO CORPORATION, TERUMO Co, Ltd, Abbott Medical Co, Ltd, Boston Scientific Japan KK, Cardinal Health Japan, Fukuda Denshi Co, Ltd, Japan Lifeline Co, Ltd, Medical Appliance Co, Ltd, and Medtronic Japan Co, Ltd outside the submitted work. SY reports remuneration for lectures from Takeda, Daiichi-Sankyo, and Bristol-Myers Squibb and trust research or joint research funds from Takeda and Daiichi-Sankyo. TM has received lecture fees from Abbott, Bayer Yakuhin, and MSD and research funding from Amgen, Bayer Yakuhin, and Kowa. YM received research funds from Kowa Company, Ltd within the submitted work and from Tokyo Marine and Nichido Fire Insurance Co, Ltd, Fujitsu Co, Ltd, Softbank Co, Ltd, Saraya Co, Ltd, and Meiji Yasuda Life Insurance Company outside of the submitted work.

Abbreviations

ΔLVEF: change in left ventricular ejection fraction value
ACS: acute coronary syndrome
AUC: area under the curve
BNP: brain natriuretic peptide
CAD: coronary artery disease
CatBoost: categorical boosting
CCS: chronic coronary syndrome
CLIDAS: Clinical Deep Data Accumulation System
Cre: creatinine
DCA: decision curve analysis
GLU: glucose
HbA_{1c}: glycated hemoglobin
Hct: hematocrit
LAD: left anterior descending artery
LASSO: least absolute shrinkage and selection operator
LightGBM: light gradient boosting machine

XSL•FO

We appreciate the thoughtful comments shared in response to our viewpoint, "Digital Health Innovations to Catalyze the Transition to Value-Based Health Care" [1]. The correspondents have highlighted several critical dimensions that must be addressed for value-based health care (VBHC) to move from theory to real-world practice [2].

We agree that realizing VBHC requires much more than the adoption of digital technologies—it calls for a systemic reorientation of how health systems deliver, measure, and fund care. The points raised regarding patient co-design, digital equity, data interoperability, and integration into workflows align strongly with our original arguments [1]. As we noted, digital transformation must go beyond digitization and instead support participatory, patient-centered models that meaningfully engage patients and clinicians in decision-making processes.

We also concur that trust is foundational to successful adoption. As health systems increasingly rely on patient-reported outcome measures (PROMs) and patient-reported experience measures, transparent governance and ethical data practices will be key to building confidence among both patients and providers. Similar to prior recommendations in the literature [3], we view trust-building as integral to ensuring that patient-generated data are used responsibly to inform care decisions and improve outcomes.

The correspondents' emphasis on education and training for health care professionals is also well taken. As we continue to study digital PROM implementation in clinical settings, we are exploring structured capacity-building initiatives to strengthen clinicians' digital literacy and analytic skills—ensuring they can interpret and act upon PROM and patient-reported experience measure data in a timely, patient-centered manner.

Moreover, we appreciate the thoughtful expansion on sustainable financing and business models. We fully agree that aligning payment systems with outcomes is central to sustaining VBHC reforms. As highlighted in recent research on alternative payment models [4,5], outcome-linked incentives and cross-sector collaboration are essential to support the infrastructure, workforce, and long-term viability of value-based initiatives.

In conclusion, we share the correspondents' vision for a holistic and equitable transformation of health systems. Realizing the promise of digital health for VBHC requires concurrent progress in technology, governance, education, and financing. We echo their call for further empirical research across diverse health system contexts to identify actionable pathways for scaling digital innovations that deliver measurable value for patients, providers, and society.

digital health; value-based health care; VBHC; patient-reported outcome measures; PROM; digital transformation; health care innovation; patient-centric care; health technology; patient-reported outcome; PRO; outcome measure; telehealth; telemedicine; eHealth; personalized; customized; engagement; patient-centered care; standardization; implementation

Dear editor,

We read with great interest the recent viewpoint by Zhang et al [1] on leveraging digital technologies to integrate patient-reported experience measures and patient-reported outcome measures (PROMs) into value-based health care (VBHC). As researchers, practitioners, and educators committed to advancing VBHC, we share their enthusiasm and believe that digital tools have transformative potential.

However, this discussion is part of a longstanding struggle to operationalize VBHC in real-world practice. A fundamental shift is needed in how patient input is considered to both improve and innovate care delivery. Evidence suggests that survey-based approaches alone are insufficient; what is required is a more value-sensitive methodology that truly integrates the perspectives and needs of all stakeholders [2,3].

Such an approach demands horizontal and vertical engagement across the health system, embedding values through co-design processes. The example presented by Zhang et al illustrates this well: the collection of PROMs alone was not enough, but the oncology team's subsequent actions to adapt care pathways led to more personalized care. Importantly, contrary to common assumptions, this did not result in greater complexity or reduced efficiency, but instead in more patient-centered care and higher levels of engagement.

The promise of digital tools will only be realized if challenges around digital access, health literacy, and inclusivity are addressed. Without careful attention, technology risks amplifying inequities rather than reducing them. Sustainable implementation also depends on overcoming barriers such as data interoperability, integration into clinical workflows, and building trust among clinicians and patients in the use of patient-reported data. Embedding patient-reported experience measures and PROMs into routine care further requires equipping health professionals with the skills to interpret and act on these measures, highlighting the central role of education and training in driving meaningful change.

In addition, the business models and revenue streams that underpin value-based transformations remain underexplored. Value-based care is only viable through sustainable financial reforms, which require adaptive strategies. Provider organizations' legacy financial systems and processes are deeply rooted in fee-for-service payment, and it is difficult for them to transition to more advanced forms of alternative payment [4], supporting the need for incorporating strong financial incentives into VBHC and digital technology reforms. Previous studies

XSL•FO
RenderX

have also demonstrated that diverse stakeholders are crucial for the design and implementation of sustainable VBHC business models [5]. Psychological and behavioral mechanisms underlying financial incentives may stand as barriers to VBHC and digital technology adoption. We therefore echo Zhang et al's call for stakeholder involvement and argue that dynamic, participatory approaches to business model development are essential to achieving sustainable improvements in care quality and value.

In conclusion, digital technologies hold great promise in advancing VBHC, but realizing this potential requires more than technological adoption. It demands systemic reorientation toward value-sensitive design, stakeholder collaboration, equitable implementation, education and training of health professionals, and adaptive business modeling. We encourage future research that not only evaluates outcomes but also tests models for scaling and sustaining these approaches across diverse health systems.

Acknowledgments

We used the generative artificial intelligence tool ChatGPT by OpenAI to make minor copyedits to parts of the manuscript for conciseness and clarity, which were further reviewed and revised by the authors.

KEYWORDS

autism prediction; machine learning; data leakage

Wang and Avillach [1] developed a convolutional neural network (CNN)–based diagnostic classifier for autism spectrum disorder (ASD). After preprocessing the genomics data from the Simons Simplex Collection (SSC) [2], common variants that may be protective or pathogenic for autism were extracted based on a χ^2 test. The authors then designed a CNN-based diagnostic classifier for ASD with an accuracy and area under the receiver operating characteristic curve of 88% and 0.955, respectively. The predictor in Wang and Avillach [1] is currently considered the exemplar in the field, giving much more accurate predictions for autism than other studies [3].

However, when inspecting the code and repeating the analyses, we contend that the method used is flawed and leads to an approximately 30% overestimation of predictive ability.

Wang and Avillach [1] did not provide a GitHub link to the code that was used in their paper. However, code can be found in Dr Wang's GitHub repository [4] that matches the results and figures in the manuscript.

An error occurred in the data split for training and test sets. The methods state "...the SSC samples were partitioned into two sets based on random sampling of individuals into a training set (80%) and a hold-out test set (20%). There was no overlap of individuals across the two partitions" [1]. However, the code uses different indexing methods for the test and training sets (Multimedia Appendix 1). Because there appears to be no random seed in Wang and Avillach [1], we cannot reproduce the exact overlap that was mentioned in the manuscript. However, simulations (N=100) using the code identified an average of 80% (SD 1%) of the test dataset being represented in the training dataset.

We corrected this error in the code [5] and generated new models using the 100 features that were identified in Wang and Avillach [1] and the genomics data from the SSC [2]. Simulations (N=100) with these models result in an area under the receiver operating characteristic curve of 0.61 (SD 0.02) and an accuracy of 60% (SD 2%; Multimedia Appendix 1). This is 0.34 and 28% lower than the reported metrics, respectively, in Wang and Avillach [1].

The accuracy of the CNN-based diagnostic classifier for ASD presented in Wang and Avillach [1] is overestimated by ~28%. We contend that Wang and Avillach [1] should be retracted according to the Committee on Publication Ethics (COPE) guidelines.

Acknowledgments

We acknowledge Simons Simplex Collection project number 15286.1.1.

Data Availability

The code used for Wang and Avillach [1] is available on GitHub [4]. The clone of the code and corrected code are also available on GitHub [5]. Simons Simplex Collection is accessible at [6].

KEYWORDS

anemia; hemoglobin; spectroscopy; machine learning; risk warning model; Shapley Additive Explanation

We recently read with great interest the article by Zhang et al [1], which presents a noninvasive technique for diagnosing anemia using facial visible light reflectance spectroscopy, combined with machine learning (ML) algorithms for predictive modeling. Anemia is a widespread public health issue affecting over 1.7 billion people, with symptoms including fatigue and cognitive decline [2]. The study focuses on using facial spectral data to develop a risk warning model for anemia, providing a reliable alternative to conventional methods and holding promise for future clinical applications in noninvasive anemia diagnosis. Having perused the article, we wish to recommend some insights and clarifications to enhance the robustness of the results.

Anemia is affected by various factors, including physiological, nutritional, genetic, environmental, and socioeconomic factors. Zhang et al [1] applied stringent matching criteria for age, location, and gender. However, other factors, such as smoking and nutrient intake, can also impact anemia severity, which should be taken into careful consideration. Additionally, skin types in various regions and lighting conditions at different times can also affect spectral reflectance measurements. When light enters human skin, the epidermis and dermis along with the light-absorbing chromophores, such as water, lipid, hemoglobin, and melanin, constitute the scattering medium and determine the skin's spectral reflectance [3]. Thus, individual variations in skin moisture, temperature, and melanin levels can also significantly alter reflectance. To minimize these effects, standardized protocols for controlling environmental factors should be strictly enforced, and data from a broader range of skin types could be incorporated to enhance the generalizability of the results.

Application of ML methods in medical fields aims to enhance the reliability and predictability of disease diagnosis for future development. Zhang et al [1] used 10 ML algorithms to thoroughly analyze the classifiers, with the support vector machine (SVM) algorithm demonstrating the best performance. However, despite its superior performance, the SVM model may still be prone to overfitting due to the relatively small sample size. Additionally, the lack of external validation using independent datasets raises concerns about the model's actual performance. Future studies should incorporate cross-validation with larger datasets to enhance predictive accuracy and generalizability.

Noninvasive diagnostic methods are currently advancing rapidly. By analyzing facial light reflectance, this study pinpoints

XSL•FO
RenderX

specific facial regions and wavelengths strongly correlated with anemia risk. However, it would be beneficial to compare its diagnostic performance with that of other noninvasive hemoglobin measurements, such as the microwave resonant system [4] and photoplethysmography signal sensors [5]. A comparative study could help assess whether spectral reflectance provides higher accuracy and clinical utility than these methods or when combined with them.

In conclusion, the study identifies significant differences in the facial spectral characteristics of patients with anemia and develops a high-accuracy warning model for predicting anemia risk. This noninvasive technique provides valuable opportunities to analyze facial signs of anemia and offers a more affordable approach to facilitate diagnosis. Undoubtedly, this research reveals a promising direction for personalized patient management and lays the foundation for potential applications in community-based health screenings.

KEYWORDS

anemia; hemoglobin; spectroscopy; machine learning; risk warning model; Shapley Additive Explanation

We sincerely appreciate your thoughtful and constructive comments on our recent paper exploring noninvasive anemia diagnosis through facial visible light reflectance spectroscopy and machine learning [1,2]. Your attention and insightful suggestions greatly guide our efforts to enhance this work. We address your key points below, offering clarifications as needed. You noted that uncontrolled factors like smoking and nutrition might influence anemia severity and spectral data. While our initial focus was validating this approach by controlling core variables (eg, age and gender), we plan to broaden future data collection to include these factors, analyze their effects, and integrate them into our model to improve reliability. You also emphasized how skin types, lighting, and individual variations could affect reflectance. We standardized conditions and preparation to minimize variability yet acknowledge our sample's limited diversity. Given hemoglobin's specific absorption peaks, we hypothesize that certain wavelength bands may be less skin tone–dependent. To explore this, we intend to collect data from diverse regions and skin types, aiming to identify such bands and enhance model applicability.

We value your recognition of our SVM model's performance and your concern about overfitting due to sample size. Though it outperformed other algorithms, we are addressing this limitation by gathering more data via multicenter collaboration, applying 10-fold cross-validation, and validating with external datasets to boost accuracy and robustness. Our study focused on establishing facial spectral imaging's potential for anemia detection, but comparative analysis could better assess its clinical utility. We are particularly intrigued by multimodal integration, such as combining spectroscopy with photoplethysmography (PPG) to improve diagnostic precision. Future work will involve comparative experiments to evaluate metrics like sensitivity and specificity, exploring whether synergy yields superior results. However, PPG indirectly reflects hemoglobin via light intensity changes, suiting routine monitoring, whereas spectroscopy directly measures hemoglobin concentration through reflectance spectra, fitting clinical diagnosis and research. Thus, stand-alone spectroscopy for noninvasive hemoglobin measurement holds significant promise, which we aim to further investigate.

We are encouraged by your recognition of this technique's potential for community screening and personalized care. Thank you again for your rigorous review and profound insights. We look forward to further discussion and sharing progress or collaboration opportunities as our research advances.

KEYWORDS

artificial intelligence; large language model; ChatGPT; emergency medicine; clinical performance examination; history taking; clinical reasoning; empathy; patient experience

This letter is regarding the recent publication of the article titled "Clinical Performance and Communication Skills of ChatGPT Versus Physicians in Emergency Medicine: Simulated Patient Study" by Park et al [1]. The study makes a significant contribution to the growing field of artificial intelligence (AI) evaluation in medicine, and I congratulate the authors on their valuable work. However, I would like to highlight a potential methodological limitation in the written examination portion of the study. The authors state that their examination questions were taken from a 2018 textbook, *100 Cases in Emergency Medicine and Critical Care* [2]. The AI model they tested, ChatGPT (OpenAI), was trained on huge amounts of public text from the internet, which likely included this textbook. This means ChatGPT may have seen exactly the same questions and answers during its training.

This problem is known as "data contamination." If the AI has already seen the test questions, its high scores might show good memory, not good medical reasoning. This makes the comparison to human doctors, who were seeing the questions for the first time, unfair. The study found that ChatGPT performed much better than doctors on this written test, but this result could be due to this methodological limitation.

Other researchers in the field are aware of this problem and take steps to avoid it. For example, a study by Busch et al [3] on radiology used private, members-only cases that were not likely in the AI's training data to minimize this risk. Another study by Noda et al [4] on a Japanese medical examination used questions from an examination that took place after the AI's training data cut-off date.

These studies show the importance of using new and unseen questions when testing AI. Because the study by Park et al [1] did not use this approach, I believe the results of their written examination should be viewed with caution. Future studies must use methods like those in the Busch et al [3] and Noda et al [4] papers to ensure a fair and valid test of AI's abilities.

Acknowledgments

Google Gemini was used for language editing.

KEYWORDS

artificial intelligence; large language model; ChatGPT; emergency medicine; clinical performance examination; history taking; clinical reasoning; empathy; patient experience

We sincerely thank the author for the constructive commentary on our recent publication. Our study evaluated ChatGPT's performance across multiple dimensions—including history taking, diagnostic accuracy, communication skills, and empathic expression—through a clinical performance examination using simulated patients combined with written examinations [1].

In our study, the written examination was not intended to solely serve as a direct comparison of performance between ChatGPT and human physicians. Rather, it was included to support the interpretation of ChatGPT's communication skills and empathic responses observed during simulated patient interactions by providing additional context regarding the model's underlying clinical knowledge. A previous study has shown that patients may perceive ChatGPT's responses as empathic or trustworthy, even when those responses are clinically inappropriate [2]. However, effective clinical communication is not merely about verbal fluency or emotional tone; it must be grounded in adequate medical knowledge. For this reason, earlier studies evaluating artificial intelligence empathy have also assessed the clinical appropriateness of responses and compared them to those of human physicians [2,3].

Consistent with prior work, we also assessed the simulated patient conversations in terms of both clinical accuracy and empathic engagement, as evaluated by an emergency medicine professor. However, we recognize that physicians vary in their diagnostic styles and communication approaches. Subjective judgment from the evaluator may have influenced the ratings, especially given that the evaluated outputs were full conversations rather than single responses. To provide a complementary and more structured assessment, we incorporated a written test focused on 3 key domains: diagnosis, investigation, and treatment planning. Performance on this test may serve as a supporting element to help ensure that ChatGPT's interpersonal strengths were not misaligned with clinical reasoning.

As the author correctly pointed out, the questions in the written examination were adapted from a publicly available textbook

XSL•FO
RenderX

published in 2018 [4]. We cannot rule out the possibility that ChatGPT was exposed to this material or similar content during pretraining, due to the limited transparency regarding its training data. Therefore, part of the model's performance on the written test may have been influenced by data contamination. We fully acknowledge this methodological limitation and agree that the results from the written examination should be interpreted with caution.

We are truly grateful for the author's thoughtful engagement, which raises important considerations for future studies regarding the assessment of AI in clinical settings.

Acknowledgments

During the preparation of this manuscript, the authors used ChatGPT to assist with improving readability and correcting grammatical errors. After using this tool, the authors reviewed and edited the content as needed and take full responsibility for the content of the publication.

Correction of: https://medinform.jmir.org/2024/1/e53622

(JMIR Med Inform 2025;13:e71249) doi:10.2196/71249

In "Distributed Statistical Analyses: A Scoping Review and Examples of Operational Frameworks Adapted to Health Analytics" (JMIR Med Inform 2024;12:e53622) the authors noted four errors.

In subsection "Results Related to Objective 3," paragraph "Simple Averaging," three mathematical formulas have been corrected to include a matrix inversion as follows:

In "Textbox 1 . Algorithm 1 —simple averaging inference procedure,"

$\Sigma\hat{}SA=\varphi\hat{}SA\sum k=1Knw(k)2n(k)VMLE(k)$ *has been corrected to* $\Sigma\hat{}SA=\varphi\hat{}SA\sum k=1Knw(k)2n(k)(VMLE(k))-1$.

In the text below Textbox 1, $\Sigma SA=\varphi\sum k=1Kw(k)2p(k)T\beta(k)$ *was changed to* $\Sigma SA=\varphi\sum k=1Kw(k)2p(k)(T\beta(k))-1$ *and* $\Sigma\hat{}SA=\varphi\hat{}SA\sum k=1Knw(k)2n(k)VMLE(k)$ *has been corrected to* $\Sigma\hat{}SA=\varphi\hat{}SA\sum k=1Knw(k)2n(k)(VMLE(k))-1$.

Finally, in Multimedia Appendix 2,

$\Sigma SA=\varphi\sum k=1Kw(k)2p(k)T\beta(k)$ *has been corrected to* $\Sigma SA=\varphi\sum k=1Kw(k)2p(k)(T\beta(k))-1$. *Please note that the revised version has been attached here as Multimedia Appendix 1.*

The correction will appear in the online version of the paper on the JMIR Publications website on February 11, 2025, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Abstract

(JMIR Med Inform 2025;13:e80547) doi:10.2196/80547

In "Relationship Between Stroke Knowledge, Health Information Literacy, and Health Self- Management Among Patients with Stroke: Multicenter Cross-Sectional Study" (JMIR Med Inform 2025;13:e63956) the authors made one correction.

The affiliations for the first author have been changed from:

1. West China School of Nursing, Sichuan University, Chengdu, China

To the following, which has swapped the order of affiliations:

1. Health Management Center, General Practice Medical Center, West China Hospital, Sichuan University, Chengdu, China

2. West China School of Nursing, Sichuan University, Chengdu, China

The correction will appear in the online version of the paper on the JMIR Publications website, together with the publication of this correction notice, and the numeration of the other author affiliations have been adjusted sequentially. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Submitted 12.07.25; this is a non–peer-reviewed article;accepted 16.07.25; published 29.07.25.

Following the publication of "The Roles of Electronic Health Records for Clinical Trials in Low- and Middle-Income Countries: Scoping Review" [1], concerns were raised regarding the author Jiancheng Ye's rate of self-citation within the article's reference list. Further investigation into this matter identified that numerous self-citations were added to the manuscript following acceptance of the article without adequate disclosure.

All authors were contacted for a response regarding this matter. Authors Shangzhi Xiong, Tengyi Wang, Jingyi Li, Nan Cheng, Maoyi Tian, and Yang Yang indicated that they were unaware of the addition of references post acceptance. They did not consent to such changes and believed a number of the additions to be irrelevant to the content of the article and requested their removal. Author Jiancheng Ye responded with a scientific justification for each added self-citation within the published article.

Following review of these responses, the JMIR Publications Editorial Office determined that several of the added references were not relevant to the article or were used to support a generic statement where another reference could have been used instead of self-citation. Therefore, the JMIR Publications Editorial Office is issuing this corrigendum to remove the following references:

Abstract

Background: Patient portal use has been associated with improved patient health and improved adherence to medications, including statins. However, there is limited research on the association between patient portal registration and outcomes such as statin prescription refill adherence in the context of the National Health Service of England, where patient portals have been widely available since 2015.

Objective: We aimed to explore statin prescription refill adherence among general practice patients in England.

Methods: This study was approved by the Clinical Practice Research Datalink Independent Scientific Advisory Committee (ID: 21_000411). We used patient-level general practice data from the Clinical Practice Research Datalink in England. The data included patients with cardiovascular disease, diabetes, and chronic kidney disease, who were registered on the patient portal. The primary aim was to investigate whether statin prescription refill adherence, defined as ≥80% adherence based on the medication possession ratio, improved after patient portal registration. We used a multilevel logistic regression model to compare aggregate adherence 12 months before and 12 months after patient portal registration.

Results: We included 44,141 patients in the study. The analysis revealed a 16% reduction in the odds of prescription refill adherence 12 months after patient portal registration (odds ratio [OR]: 0.84, 95% CI 0.81-0.86) compared to 12 months before registration in the fully adjusted model for patient- and practice-level variables.

Conclusions: This study evaluated prescription refill adherence after patient portal registration. Registering to the portal does not fully explain the mechanisms underlying the relationship between patient portal use and health-related outcomes such as medication adherence. Although a small reduction in prescription refill adherence was observed, this reduction disappeared when the follow up time was reduced to 6 months. Given the limitations of the study, reduction in prescription refill adherence cannot be entirely attributable to patient portal registration. However, there may be potential confounding factors influencing this association which should be explored through future research.

Introduction

Patient portals are online websites or applications that are tethered to the health care system's electronic health record and typically offer services such as online appointment booking and repeat prescription ordering. It is suggested that patient portal use may improve patients' health through factors such as improving patients' efficiency, information access, and continuity of care. The mechanisms involved in patient portal use can facilitate communication and could help improve patients' health. For example, in a large integrated health care system in the United States, patients who found the use of patient portals to be more convenient than in-person care were more likely to report improved health as a result of using patient portals [1]. Patient portals provide access to medical record data on information such as diagnoses and test results and may

XSL•FO
RenderX

include patient education information on managing specific health conditions or general health advice. Furthermore, information access could also include collation of patients' information such as medications and consultations in one place, allowing patients to better manage their care [1], engage in shared decision-making, and understand their treatments [2]. Additionally, simple functionalities such as appointment booking and access to appointment records may help patients avoid missing appointments and enabling continuity of care [3].

It is hypothesised that patient portal use could improve medication adherence. A study among patients with diabetes reported that time without medication was reduced for those who exclusively used the refill function of the portal compared to those who did not use it [4]. Nonadherence to statins reduced by 6% (95% CI 4% - 7%) among patients with diabetes exclusively using the refill function compared to nonusers of the portal [5]. However, this relationship has not been studied within the National Health Service (NHS) in England, where all patient portals have been required to be offered in all General Practice (GP) practices since 2015 [6]. Studies reporting the relationship between patient portal use and medication adherence usually focus on specific functionalities of the portal. For example, studies may report the relationship between access to medical records, ordering medication through the patient portal (mainly repeat prescriptions), receiving reminder text messages, or booking appointments online. Studies also reported outcomes of patient portal use when coupled with another intervention such as telemedicine (technologies that enable remote medical consultations) or other digital interventions such as health monitoring devices or educational materials [7,8]. For example, a study found that digital technologies used for telemonitoring (which can be a feature of patient portals) that included monitoring patient health metrics and helping patients remember the time and type of medication improved medication adherence among patients with hypertension [7]. Additionally, telemonitoring may offer more accurate information on blood pressure values among patients with hypertension, which has been linked to improve therapeutic adherence to prescribed medications [7]. The digital technologies referenced in this study included apps, wearable decides, telemedicine, and digital monitoring tools (which include recording and reporting of health metrics to the health care system), and digital rehabilitation [7]. While the intervention considered in this study only includes access to medical records (Multimedia Appendix 1), descriptions of patient portals in the NHS (also known as online services) may also include features such as telemedicine, access to patient education materials, ability to book appointments, and ordering repeat prescriptions [6,9-11].

Statins are prescribed to patients both for primary prevention or secondary prevention of cardiovascular events; they are typically taken once a day and mostly continued for life, once prescribed to the patient [12]. Statin adherence could lower the risk of mortality [13]. Conversely, low adherence to statins increases the risk of death in the second year after a myocardial infraction and is also associated with increased risk of cardiovascular and cancer mortality [14-16]. A systematic review on factors associated with statin adherence for primary prevention of cardiovascular disease (CVD), included age, gender, or sex, diabetes status, hypertension, socioeconomic status, level of education, geographical region, race, and marital status [17]. This review also added that factors such as presence of dyslipidemia (high cholesterol), smoking status, work status, and comorbidity are either not associated or have mixed associations with statin adherence [17]. In this study we aimed to determine whether adherence to prescription refill statins improved after registering to patient portals among general practice patients using the Clinical Practice Research Datalink (CPRD), focusing on patients with adverse cardiovascular events, chronic kidney disease (CKD), CVD, and diabetes. This article is based on Chapter 4 of the author's PhD thesis [18].

Methods

Ethical Considerations

The study protocol was approved by CPRD's Independent Scientific Advisory Committee (ID: 21_000411). In the context of CPRD data usage, informed consent is not required for the anonymized data provided to CPRD from participating GP practices. The data is anonymized to the extent that individual patients cannot be identified. Participants have the option to opt out of having their health records shared for research purposes [19]. The original study approval covers secondary analyses, eliminating the need for additional consent from participants. No compensation was provided to participants in this study. Approved researchers could gain access to the data after submitting a study protocol.

Study Design

This was an observational study using longitudinal data on prescribed medication (statins) extracted from electronic health record data to compare patient-level aggregate adherence 12 months before and 12 months after patient portal registration, Adherence was measured using the medication possession ratio (MPR) with a threshold of 80% as an indicator of adherence. The data source, CPRD Aurum, comprises electronic health record data from GPs in England, where GPs are the gatekeepers of the health care system, and almost all of the population is registered with a GP [20]. The study period varied by patient and ranged from January 1, 2014, to August 15, 2021.

Study Population

To determine our population, we first included all patients in CPRD Aurum who had a patient portal registration code (available in Multimedia Appendix 1) recorded on or after January 1, 2015, when online services were required to be offered by all GPs in England [6]. Eligible patients had a diagnosis of at least one of the following conditions: adverse cardiovascular event, CKD, CVD, or diabetes, using codes in the study by Davidson et al [21]. These patient groups were chosen because they may be prescribed statins according to National Institute for Health and Care Excellence (NICE) guidelines for CVD prevention [22]. Although not all patients with diabetes will be prescribed statins, we included them due to the interest in the literature on the association between patient portal use and diabetes-related outcomes, including statin adherence [23].

XSL•FO
RenderX

Variables

Outcome Variable

The statin prescription refill adherence was determined through several steps. First, we extracted the codes of statin prescriptions using the codes provided in the study by Davidson et al [21], and aggregated the duration variable (defined as duration of treatment in days)for the period of one year before and one year after patient portal registration [24]. We assumed that if a patient duration was recorded as equal to zero, it was either entered by error or that it did not represent an actual statin prescription, as medication cannot be prescribed for zero days; therefore these observations were removed. Next, we calculated the MPR, which is a measure created by dividing the number of days of supply of the prescribed medication for all prescriptions within a time interval by the time interval [25]. In our study, we divided the aggregated duration by 365 (ie, 1 yr-period). The MPR was calculated twice for each patient for each time-period—one year before and one year after patient portal registration. We assumed that patients who did not have any record of statin prescriptions either before or after patient portal registration, to have an adherence of zero for that period. The MPR was then categorized into a binary variable of prescription refill adherence, with an 80% threshold by considering all values of ≥80% as adherent, and those <80% as nonadherent. The 80% cut off point was chosen to create easy-to-interpret binary variable for adherence following the same measure used in a previous CPRD study [26], as recommended research that determined 80% MPR to be a reasonable cut off point for categorizing the patient as adherent or nonadherent [27]. However, we have considered other cut off points, including 50% and 65% to compare the differences between these measures. The same logic was applied for adherence values of 65% and 50%. The various adherence values only indicate a change in the level of MPR that is considered adherent. Patients were considered adherent at the 80% threshold if they had an MPR ≥80%, at 65% if they had an MPR ≥65%, and at 50% if they had an MPR ≥50%. Patients having an MPR of ≥80% were considered adherent at all lower thresholds.

Predictors

The description of other variables included in the study including the predictor variable (ie, patient portal registration status) are described in Table 1. While multiple factors are associated with statin adherence, the research team decided to use the same variables included in our previous studies on at factors associated with patient portal use in NHS GP practice settings [28]. We also included all of the factors that are essential to the model such as gender, age group, ethnicity, and level of deprivation, which are associated with both patient portal use and medication refill adherence [17,28]. Hearing loss was added as a predictor because it can be associated with patient portal use and has been included in other studies on patient portal use in NHS GP settings [28-30].

RenderX

Table . Description of study variables, their categories, and sources. Adapted from [18], under CC BY-NC license [31].

Variables	Description and categories
Gender	Gender is provided by Clinical Practice Research Datalink (CPRD) and consists of 3 categories including male, female, and indeterminate [24]. However, there were no patients with the indeterminate gender category in this cohort.
Patient portal registration status	We identified 6 codes that indicated registration or access to patients' online medical record and used them as a proxy for patient portal registration in CPRD to search patients' observation files for identifying the codes that indicate patient portal registration (Multimedia Appendix 1). We used registration to patient portals as a proxy for patient portal use due to lack of data in CPRD on the actual usage of patient portals.
Date of patient portal registration	The date of patient portal registration was determined as the observation date of the patient portal registration code. As patients only needed to register to the portal once, most patients only had one observation for patient portal registration. For those that had more than one code and therefore more than one observation date, we maintained the latest observation date as the patient portal registration date.
Age at registration age groups	CPRD provided only birth-year record of patients over 16 years. To calculate age, we assumed all patients were born on July 1 and calculated their age in reference to their patient portal registration date. We categorized age into 6 age groups: 16-44, 45-54, 55-64, 65-74, 75-84, and >85 years.
Self-reported ethnicity	Self-reported ethnicity was extracted from the observation files of patients using code list for ethnicity provided in the study by Davidson et al [32]. Ethnicity was categorized into 5 Office for National Statistics groups: White, Black, Mixed, South Asian, and other. Patients who did not have a code for ethnicity were placed in the 6th category "unknown." Patients who had more than one code for ethnicity were categorized into the ethnicity that had the majority of codes. If patients had multiple ethnicities with an equal number of codes for each ethnicity category, we assigned them the most recent ethnicity category as their ethnicity.
Index of multiple deprivation (IMD) quintiles	IMD 2019 was calculated using patients' postcodes and was provided by CPRD as linkage data on request.
Hearing loss	Hearing loss codes were extracted from the study by Head et al [33] using patients' observation files, and a binary variable was created to indicate whether the patient had hearing loss.
General practice rurality	2011 rural-urban classification at lower layer super output area level.

Statistical Methods

All analyses were performed using RStudio software (version 2023.06.0+421; R Foundation for Statistical Computing). We compared statin prescription refill adherence (measured by MPR ≥80%) 12 months before and 12 months after patient portal registration using multilevel logistic regression. We assumed that once patients were prescribed statins they would be for long-term use, indicating that they should have ordered statins consistently over the 12-month period before and after patient portal registration. The multilevel logistic regression was performed in three major steps:

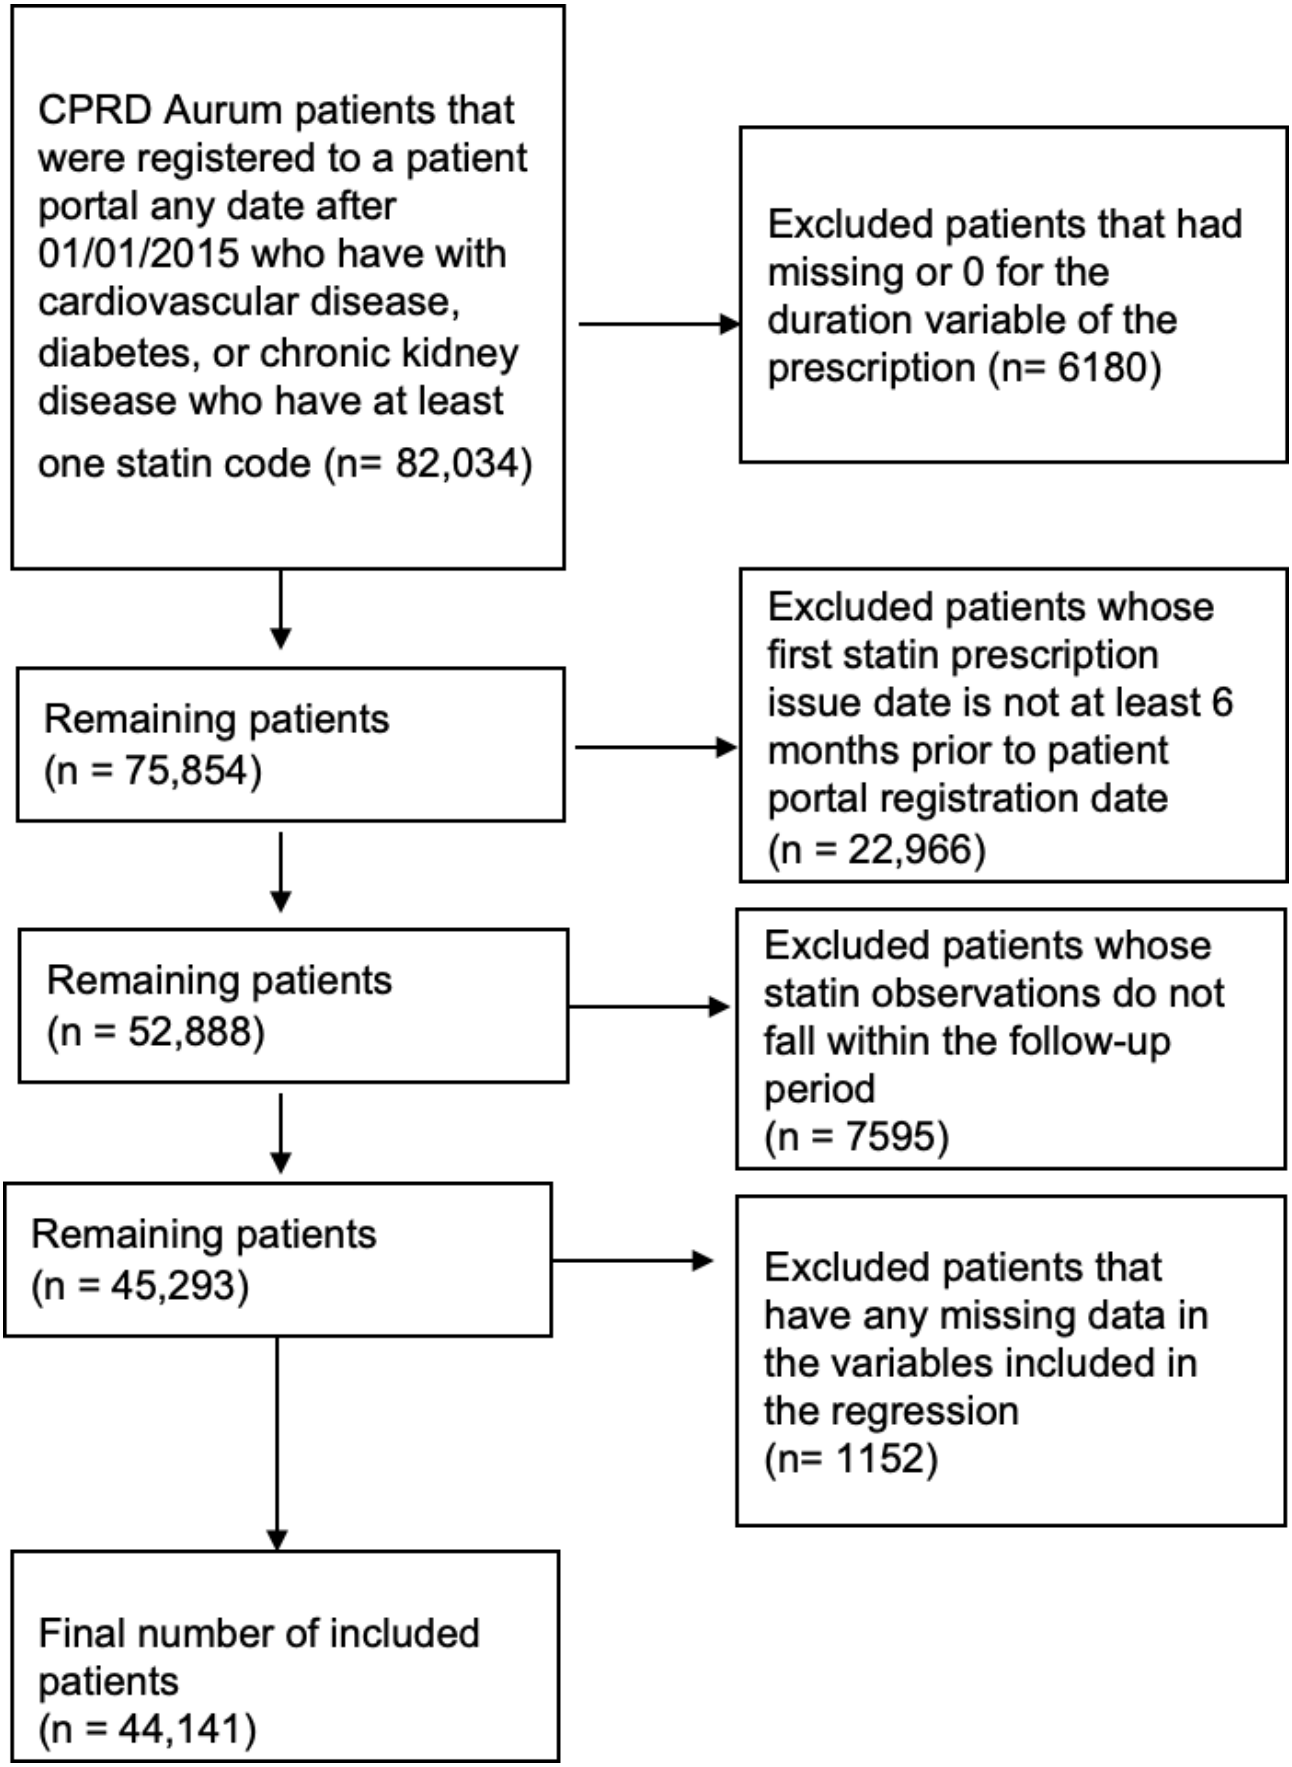
1. First, we created a null model with only the outcome variable and added GP practice as the grouping variable. This step helped observe if clustering by GP was present. We checked the interclass correlation coefficient (ICC), which ranged from 0 - 1. A value of 0 ICC indicates no clustering at the group level and a value of 1 indicates perfect clustering at the group level.
2. At step 2, we added patient-level characteristics, as multilevel modeling requires separate steps for variables from two different levels (in this case, patients at level 1 and GP practices at level 2) [34]. Therefore, step we added all the predictor variables that were at the patient-level, including gender (male, female), age group (16-44, 45-54, 55-64, 65-74, 75-84, >85 years), self-reported ethnicity (White, Black, mixed, South Asian, and other), Index of Multiple Deprivation (IMD) quintiles (1-5), and hearing loss (yes, no).
3. At step three, we added rurality of the GP practice as the GP practice-level variable.

Sensitivity Analysis

We reduced the follow up time to 6 months instead of 12 months before and after patient portal registration to examine potential differences in association. Additionally, we performed a sensitivity analysis including all patients that were initially excluded from the study due to missing IMD measure data.

XSL•FO
RenderX

Results



Study Size

Patients who had missing duration or 0-duration prescriptions were excluded (n=6180) (Figure 1). We excluded all patients whose first statin prescription was recorded at least 12 months before patient portal registration date (n=22,966) (Figure 1) to ensure that patients had at least 12 months of follow-up before patient portal registration. All patients whose statin observations did not fall within the required follow-up period (12 months before and 12 months after patient portal registration date) were excluded (n=7595) (Figure 1). Finally, we only included patients with complete data in the analysis, and excluded all patients that had missing IMD quintile data (n=44,141) (Figure 1). There were no missing data in any other variable except ethnicity, which was included as a separate category in the analysis.

Figure 1 is reused from PhD Thesis by Alturkistani [18].

Summary Statistics

A total of 44,141 patients were included in the study. The majority (n=13,812) of the patients were men aged 65 - 74 years at the time of patient portal registration and had a prescription refill adherence of 80% or higher (n=27,208) (Table 2).

Table . Summary statistics of the study population. Reused from Alturkistani [18] under CC BY-NC license [31].

Association Between Patient Portal Registration and Statin Prescription Refill Adherence

Table 2 presents the results of the fully adjusted, multilevel logistic regression for the outcome variable (statin prescription refill adherence of ≥50%, ≥65%, and ≥80%). The odds ratio (OR) for statin prescription refill adherence of ≥80% was 0.84 (95% CI 0.81-0.86), indicating a 16% reduction in the odds of statin prescription refill adherence at this threshold after patient portal registration, compared to 12 months before registration (Table 3). The OR for adherence at 50% and 65% thresholds also indicated a reduction in adherence after patient portal registration, indicating that even patients with lower baseline adherence were less likely to remain adherent after patient portal registration (Table 3). The ICC varied for different levels of adherence but were generally 15% or lower, indicating the proportion of adherence variance that can be attributable to practice-level factors. For example, an ICC of 15% can be interpreted as 15% of the total variance in adherence by patients can be explained by differences at the GP practice level.

Table . Results of the fully-adjusted multilevel logistic regression model of patient portal registration status on statin prescription refill adherence of ≥50%, ≥65%, and ≥80% (level 1, N=88,282 observations of 44,141 patients; level 2, n=1190 general practices) 12 months before and 12 months after patient portal registration. Reused from [18] under CC BY-NC license [31].

Results of the Sensitivity Analysis

When the time of follow up was reduced to 6 months, the OR for statin prescription refill adherence of ≥80% was 1.01 (95% CI 0.98-1.04) in the fully-adjusted model, indicating no difference in statin prescription refill adherence 6 months after patient portal registration compared to the 6 months before patient portal registration (Multimedia Appendix 2).

The OR differed by only 0.01 - 0.02 of sensitivity analyses, which included patients who had missing IMD quintiles data (results not shown).

Discussion

Main Findings of the Study

After registering to the patient portal, patients had lower odds of achieving adherence of 50%, 65%, and 80% thresholds. However, this relationship was attenuated when the follow-up time was reduced to 6 months before and after patient portal registration and indicated no change in adherence after registration. This study found a reduction in prescription refill adherence after patient portal registration, which may be due to several reasons. Patients in this study were only registered to the portal once, and it is likely that may have enrolled at a time of high health care utilization. This could lead to increased medication requests prior to patient portal registration, compared to after registration. Additionally, patients may have overall reduced adherence to statins after using it for some time due to factors such as side effects, continuity of care, disease severity, or socioeconomic factors, which could all affect adherence to ordering prescriptions [26,27].

Comparison to Prior Work

Previous studies revealed that factors such as experiencing side effects, CVD severity, continuity of care and income, or other indicators of deprivation may influence adherence to statins [26,27]. Other factors that could be associated with statin adherence but were not examined in this study include the type of statin, intensity of the dose, timing of prescribing statins (eg, before or after puberty) [17]. Given that statin adherence reduced when patients were followed up for one year but not over 6 months, it is possible that statin adherence naturally reduced over time. Since the codes used for patient portal registration in this study indicated to access medical records, we could not explore potential mechanisms involved between accessing medical records and medication adherence. We acknowledge this as a limitation of the study, as registration to the patient portal does not necessarily mean continued use of the patient portal, discussed further in the limitations and strengths subsection [35].

Among features of patient portals, the ability to order prescriptions through the portal is most strongly associated with medication adherence. For example, one study reported that when medication is ordered through a patient portal, it can have less errors and more clear instructions (compared to hand-written prescriptions), which in turn improves adherence to treatment [36]. Having a higher supply of statin (eg, a supply of 60 d vs 30 d) was associated with improved adherence, which can be achieved by using a patient portal (by providing instant access to ordering medication) [17].

Limitations and Strengths of the Study

This study is relevant in the wake of increased popularity of using patient portals and other remote or digital health care services, particularly during and post-COVID-19 pandemic, both in England and other countries. Although widely offered within the NHS, this technology is rarely studied. We were unable to study active or continuous patient portal use, as this information was not recorded in CPRD, despite it being a rich source of data for clinical patient records. This study highlights the need to improve recording of the use of technologies to enable research in this field. To the authors' knowledge, this is the first study using CPRD data to examine patient portal use. Although the study was only able to capture registration to patient portals, the records of registration were obtained from an objective source (ie, electronic health records), which is a reliable method.

A strength of this study was that it controlled for clustering of patients within GP practices by using a multilevel model and including GP practices as a fixed effect, using a model which controls for the hierarchy of the data [37]. This could be attributed to patients from the same practice being more similar to each other, patient portals varying in functionalities, and knowledge and encouragement of their staff including GPs in using the patient portal [9].

One limitation in our study was that we could not measure or report the differences in patient portal functionalities that were included in the study, as our study included more than 1000 GP practices. Despite this, by including a large number of practices, we were able to analyze a more representative sample. We attempted to account for the differences between practices by running a multilevel model, recognizing that patients from the same GP practice may have more similar outcomes due to various factors including the type of patient portal offered in the practice and type of education and training available to both staff and patients [9].

While registration to the patient portal is the first step needed to benefit from its functionalities, studies show that without continuous or active use, patients cannot benefit from the technology. Registering to the portal does not guarantee continuous use of the portal, [38] which is essential to observe benefits associated with patient portal use [39]. A major limitation of this study was only using codes that indicated registration for accessing medical record as a proxy for patient portal use. This limited our study in two ways. First, access to medical records may have a minimal impact on prescription refill adherence. Second, patient portals offered through the NHS GPs, typically offer various functionalities beyond access to medical records, including online appointment booking and repeat prescription ordering [40]. However, as described in Multimedia Appendix 1, our search for codes that indicate patient portal use in CPRD Aurum only identified codes that indicate access to the medical records. This presented a challenge as patients using other portal functionalities, such as online appointment booking and prescription ordering, were not reflected in their electronic health records. Consequently,

XSL•FO
RenderX

we could not determine if patients without these specific codes (codes in Multimedia Appendix 1) were indeed nonusers of patient portals and therefore, suitable as controls for our study. While we recognize that this limitation reduces the robustness of the results, it was the most suitable approach to examine this relationship that remains unexplored within the NHS, despite a wide availability of patient portals for nearly a decade. Further information about the use of patient portals such as prescription refill requests or appointment bookings made through the portal could better inform the relationship between patient portal use and medication adherence. Additionally, our study population included patients with chronic diseases including CVD, CKD, and diabetes, who may be less likely to use patient portals and more likely to enroll or register to patient portals [41]. According to a study conducted in the United States, patients with certain circulatory diseases such as heart failure, myocardial infraction, peripheral vascular disease, and those with diabetes and renal disease were less likely to use the patient portal of the health care system [42]. Given that patients included in this study included those with CVD, CKD, and diabetes, it is possible that although they were registered to the patient portal, these patients may not have been active users. Therefore, we cannot conclude whether the patient experienced reduced adherence to refilling their prescriptions due to the patient portal use based solely on the findings from this study.

Conclusion

In this study, patients had a slightly reduced adherence one year after patient portal registration, although adherence did not change after a 6 months follow up. This could be attributed to other mechanisms, including those mentioned above, that could influence medication adherence and were not included in this study. Registration to the portal alone does not influence health-related behaviors such as medication adherence. Future studies on recording of patient portal use in electronic health records such as log files of functionality use in patient portals (eg, appointment booking, messaging health care providers, or requesting medications) could enable studying health related outcomes and explain mechanisms involved between patient portal use and health outcomes.

Abstract

Background: Planning for coronary artery bypass grafting (CABG) necessitates advanced spatial visualization skills and consideration of multiple factors, including the depth of coronary arteries within the subepicardium, calcification levels, and pericardial adhesions.

Objective: This study aimed to address these requirements by reconstructing a dynamic cardiovascular model, displaying it as a naked-eye hologram, and evaluating the clinical utility of this innovative visualization tool for preoperative CABG planning.

Methods: We used preoperative 4D cardiac computed tomography angiography (4D-CCTA) data from 14 patients scheduled for CABG to develop a semiautomated workflow. This workflow enabled time-resolved segmentation of the heart chambers, epicardial adipose tissue (EAT), and coronary arteries, complete with calcium scoring. Methods for segmenting cardiac structures, quantifying coronary calcification, visualizing coronary depth within EAT, and assessing pericardial adhesions via motion analysis were incorporated. These dynamic reconstructions captured spatial relationships, coronary stenosis, calcification, and depth in EAT, as well as pericardial adhesions. Dynamic cardiovascular holograms were then generated and displayed using the Looking Glass platform (Looking Glass Factory Inc). Thirteen cardiac surgeons assessed the utility of the holographic visualization tool on a Likert scale. In addition, a surgeon visually scored pericardial adhesions using the holograms of all 21 patients (including 7 undergoing secondary cardiac surgeries) and compared these scores with actual intraoperative findings.

Results: Cardiac surgeons highly rated the visualization tool for its utility in preoperative planning, with a mean Likert score of 4.57/5.0 (SD 0.5). The hologram-based scoring of pericardial adhesions showed a strong correlation with intraoperative findings (correlation coefficient r=0.786; P<.001).

Conclusions: This study delineates the structural framework of a visualization tool specifically designed for preoperative CABG planning. It produces high-quality, clinically relevant, dynamic holograms from patient-specific volumetric data, with clinical feedback confirming its practicality and effectiveness for preoperative surgical planning.

Introduction

Coronary artery disease (CAD) is one of the leading causes of death worldwide [1]. Coronary artery bypass grafting (CABG) is the most frequently performed cardiac surgery globally [2]. Compared with percutaneous interventions or medication therapy alone, CABG provides a survival advantage for patients with complex coronary artery disease [3]. Accurate identification of the coronary arteries and careful selection of the anastomotic site are critical for surgical success. If the chosen anastomosis site is located too deep within the thoracic cavity, the limited operating space may hinder surgical maneuverability. Furthermore, when a coronary artery lies deep within epicardial adipose tissue (EAT) or within the myocardium, intraoperative localization becomes challenging. This can lead to longer operative times, increased tissue trauma, and a reduction in the morphological quality of the anastomosis. In addition, plaque may obstruct suturing, and pericardial adhesions can increase

XSL•FO
RenderX

the risk of injury to the heart or major vessels, further prolonging the procedure and raising its overall risk. Therefore, collecting detailed information on pericardial adhesions, spatial orientation, coronary artery depth within EAT, stenosis, and calcification is crucial for preoperative CABG planning.

Enhanced 3D cardiac models that incorporate multiple functional imaging modalities provide more comprehensive insights [4]. A practical strategy to realize precision medicine in cardiovascular care is through the digital twinning of the cardiovascular system, using coronary angiography, echocardiography, and coronary computed tomography angiography (CTA) data [5]. Compared with ultrasound and magnetic resonance imaging (MRI), CTA offers superior spatial resolution and is widely used for reconstructing patient-specific 3D models. While MRI techniques such as 4D cardiac MRI and cine multislice MRI offer excellent temporal resolution along with good spatial resolution and are well-established in clinical practice, 4D cardiac computed tomography (CT) imaging offers sufficient spatial and temporal resolution to support advanced visualization. This enables dynamic and functional assessments of cardiovascular conditions. Although 3D and 4D visualization technologies with effective depth cues are already established in clinical practice, enabled by robust 3D viewers that allow simultaneous multiview display and free-angle reformatting of volumetric datasets, our study hypothesizes that holographic displays may provide additional benefits for specific surgical planning tasks, warranting further investigation.

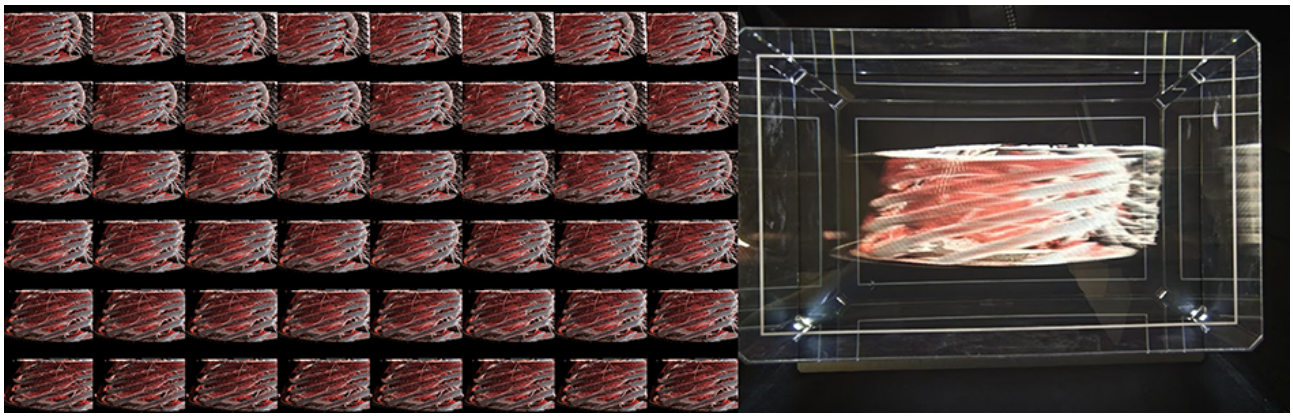
Building upon the established foundation of clinical 3D visualization, our research explores whether holographic displays can provide complementary benefits for CABG planning. Rather than suggesting limitations in current clinical displays, we aim to explore whether the stereoscopic nature of holography offers added value for specific surgical planning scenarios. Effective communication among health care team members can be hindered by individual differences in spatial visualization abilities. Researchers have made significant progress in representing medical 3D images through virtual and augmented reality (VR and AR) technologies, as well as various stereoscopic display systems. In recent years, holographic display technology has made notable advances in the fields of surgical planning and intraoperative navigation, with the Microsoft HoloLens emerging as the leading AR and MR headset [6-10]. Holography is widely considered the most advanced form of display technology, as it incorporates all human visual cues, including stereopsis and accommodation, allowing for naked-eye visualization [9]. Although modern head-mounted devices have become more lightweight and support networked multiuser viewing, they still present significant limitations. One persistent issue with VR is “cybersickness”—a condition marked by symptoms such as headaches, nausea, and vomiting [11]. In addition, these devices often fall short in providing true depth perception [10]. The HOLOSCOPE is the world’s first medical-grade holographic system. Bruckheimer et al [10] demonstrated the creation of real-time, internet-based 3D digital holograms without the need for headgear, using actual patient voxel data from 3D rotational angiography and intraoperative real-time 3D transesophageal echocardiography in patients with structural heart disease for preoperative assessment [12]. Looking Glass Factory has introduced the world’s first group-viewable holographic displays [13], offering a significantly more affordable alternative to the RealView HOLOSCOPE, which typically costs hundreds of thousands of dollars. In contrast, entry-level Looking Glass devices are priced at just a few thousand dollars. These displays offer substantial advantages for simultaneous multiuser viewing, collaborative discussion, and cost-effectiveness, making them particularly valuable for surgical planning in procedures like CABG, which often require input from multidisciplinary teams.

Building on a strong medical-industrial collaboration, our study addresses critical challenges in preoperative CABG planning by designing a 4D cardiovascular hologram based on 4D-CCTA data and evaluating the feasibility of using this holographic visualization tool for surgical planning.

Methods

Study Design and Overview

A total of 21 patients scheduled for cardiac surgery were evaluated using 4D-CCTA before the procedure. This cohort included 14 patients with complex coronary artery lesions who were candidates for CABG, with a mean age of 53.6 (SD 8.9) years; 13 of them were male. Because pericardial adhesions are common in patients undergoing repeat cardiac surgery, we selected 7 patients undergoing secondary procedures as a control group for evaluating pericardial adhesions. These patients had a mean age of 55.5(SD 11.5)years , and 6 were male. Operative reports confirmed extensive pericardial adhesions in all patients undergoing reoperation and the absence of adhesions in all patients undergoing first-time surgery. All reoperations involved heart valve procedures, with the interval between the initial and repeat surgeries ranging from 1 to 35 years. Among these patients, 3 had valve dysfunction following corrective surgery for congenital heart defects; 1 had infective endocarditis after left ventricular outflow tract unblocking, mitral valve replacement, and CABG; 1 developed infective endocarditis following mechanical valve replacement; 1 experienced tricuspid insufficiency after left heart valve surgery; 1 had mitral valve insufficiency after mitral valve plasty; and 1 had mitral valve insufficiency following prior left heart valve surgery. Inclusion criteria for the study were: (1) patients with complex coronary lesions meeting the clinical indications for CABG and no history of previous cardiac surgery; (2) patients undergoing secondary surgery in whom the autologous pericardium had been closed during the initial procedure. Exclusion criteria included poor-quality imaging data.



Our study aimed to construct a 4D cardiovascular hologram using individualized patient imaging to address key challenges in the preoperative planning of CABG. Clinicians will evaluate the effectiveness of the holographic visualization tool by comparing it with patients’ preoperative and intraoperative data, in order to assess the system’s practical utility for surgical planning. The surgeon will not use the holograms to guide the procedure or make clinical decisions based on these images.

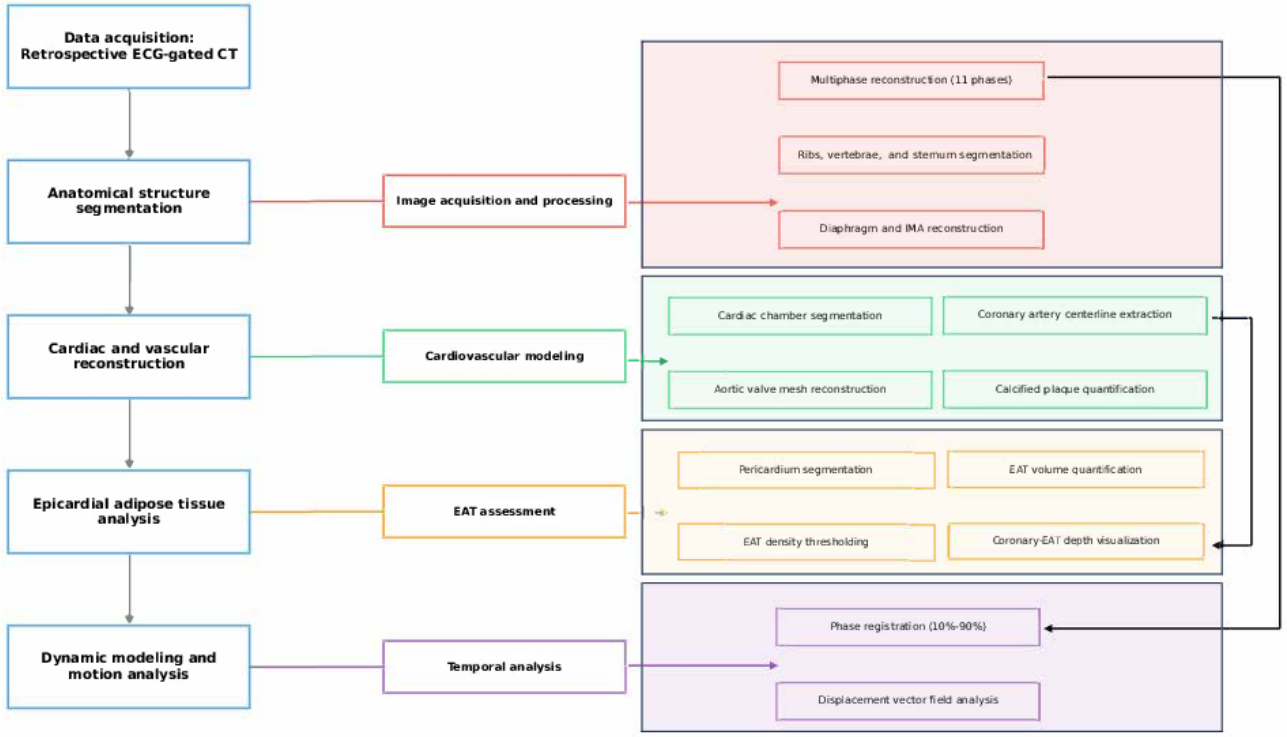
Hologram Visualization System

The holographic display used in this study is the 8.9-inch Dev Kit from Looking Glass Factory Inc, which leverages advanced light field technology to produce highly realistic 3D visualizations of cardiovascular structures. This system generates true volumetric imagery by projecting 48 distinct horizontal perspectives of the same visual content through calibrated lenticular arrays, allowing multiple observers to simultaneously view and interact with the 3D cardiac models from various angles without positional restrictions (Figure 1).

Figure 1. Holographic display system consisting of 48 viewing angles.

The dynamic cardiac hologram is displayed at 60 frames per second, closely replicating the visual fluidity of normal cardiac cycles. The system provides a horizontal viewing angle of 58°, enabling up to 5 observers to simultaneously view the same holographic image from different perspectives without distortion. Depth perception is significantly enhanced by the system's ability to render between 45 and 100 discrete depth planes along the z-axis, producing a seamless sense of depth that is crucial for interpreting complex cardiac anatomy. These complementary features—multiple horizontal perspectives and discrete depth planes—combine to deliver a truly immersive 3D visualization experience.



Unlike conventional VR or AR solutions, this technology does not require head-mounted displays or specialized eyewear, allowing surgical teams to communicate naturally while examining patient-specific anatomy. Interaction with the holographic model is enabled via a Leap Motion controller (Ultraleap Ltd), which supports intuitive, gesture-based manipulation. Users can rotate the model along any axis, zoom into regions of interest, adjust the playback speed of the cardiac cycle, and selectively display or hide specific tissue layers—including epicardial fat, coronary vessels, and calcification sites—using natural hand movements. This gesture control system is particularly valuable during preoperative planning sessions, where multiple specialists can collaboratively examine and manipulate complex anatomical structures while maintaining full situational awareness and unimpeded lines of communication.

Images and Processing

CT images were acquired during end-expiratory breath-hold and in sinus rhythm using a GE APEX CT scanner (Revolution Apex; GE Healthcare) with a retrospective electrocardiogram-gated protocol to optimize cardiac motion compensation. An iodinated contrast agent (Iohexol, 350 mg I/mL) was administered at a volume of 70 mL, followed by a 40 mL saline chaser at a flow rate of 5.5 mL/s via antecubital venous access. SmartPrep bolus tracking (GE Healthcare) was used to ensure optimal contrast timing. The z-axis coverage was 157.5 mm, encompassing the entire heart from above the carina to below the diaphragmatic surface. A noncontrast scan was performed before contrast-enhanced CCTA to allow for coronary calcium scoring. Images were reconstructed across 11 temporal phases, each corresponding to a range of R-R interval values from −5% to 106%. Slice thickness was 0.625 mm with matching intervals, and the in-plane resolution was 0.23 × 0.23 mm. The mean effective radiation dose, calculated according to European guidelines for multislice CT, was 14.93 mSv (DLP: 1066.66 mGy·cm, using a conversion factor of 0.014 mSv/mGy·cm). Coronary plaque quantification and Agatston scoring were performed using GE's cardiac analysis software (AW VolumeShare 7), specifically the SmartScore module. As illustrated in Figure 2, our processing pipeline for cardiac CT data follows a sequential workflow beginning with retrospective electrocardiogram-gated image acquisition. The methodology proceeds through 4 key analytical stages. First, anatomical structure segmentation is performed, including multiphase reconstruction and skeletal structure delineation. Second, cardiac and vascular reconstruction is conducted with detailed cardiovascular modeling of chambers, vessels, and pathological features. Third, the EAT assessment quantifies the distribution and characteristics of pericardial fat deposits. Finally, dynamic modeling and motion analysis are achieved through temporal registration and displacement vector field analysis. This integrated approach enables a comprehensive evaluation of cardiac anatomy, function, and associated tissue characteristics, supporting both advanced clinical applications and research objectives.

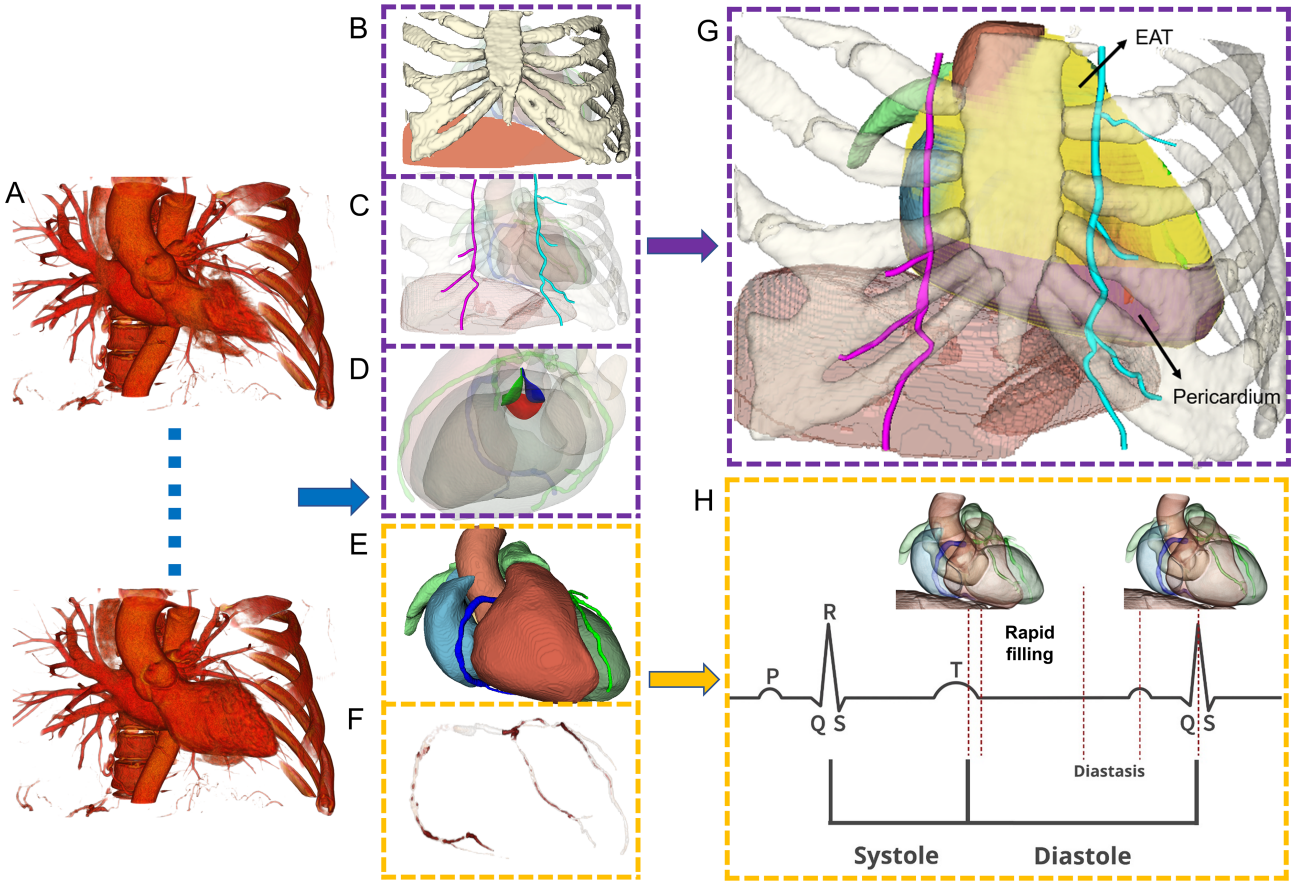
RenderX

Figure 2. Comprehensive cardiac computed tomography imaging pipeline for cardiovascular analysis. CT: computed tomography; EAT: epicardial adipose tissue; ECG: electrocardiogram; IMA: internal mammary artery.



First, we implemented our approach using MONAI [14] (Medical Open Network for Artificial Intelligence; NVIDIA), an open-source framework for deep learning in health care imaging, using its Auto3DSeg project (a component of the MONAI framework) for automated 3D segmentation. We segmented and reconstructed the ribs, vertebrae, sternum, diaphragm, and internal mammary artery from end-diastolic phase (70% R-R interval) CT images (Figure 3B-C). Next, we applied HeartDeformNet [15] to automatically segment the left ventricle, right ventricle, left atrium, right atrium, left ventricular myocardium, aorta, and pulmonary artery across all phases of the cardiac cycle (Figure 3A,E). A slightly modified version of DeepCarve [16] was used for aortic valve mesh reconstruction (Figure 3D). The primary modification involved using a template from an end-diastolic segmented left ventricle model, which contained fewer distorted elements. An experienced cardiologist manually marked and recorded arterial contours on planes perpendicular to the vessel centerline using SimVascular-v2023.03.27 [17], thus achieving segmentation of the coronary arteries from the 70% phase image (Figure 3F). Subsequently, we imported 9 cardiac phases (10% - 90%) and registered them to the selected 70% phase. This registration provided the transformations needed to adjust the 3D surface model points of the coronary arteries. These transformations were then used to generate a time-dependent sequence of 3D coronary artery models (Figure 3G,H), completing the process of dynamic modeling.

Second, for the visualization of calcified plaques, we followed the Agatston method [18]. We first identified contiguous calcium voxels within the 3D space of the binarized calcium image (Figure 4A). Three quantitative indices—Agatston score, mass score, and volume score—were calculated for the major branches of the coronary arteries (Figure 4B,C). In the calcified regions, medium and heavily calcified plaques were highlighted in red (Figure 4D). Fiz et al [19] classified plaque calcium density into tertiles: light (130 - 210 HU), medium (211 - 510 HU), and heavy (>510 HU) (Figure 4).

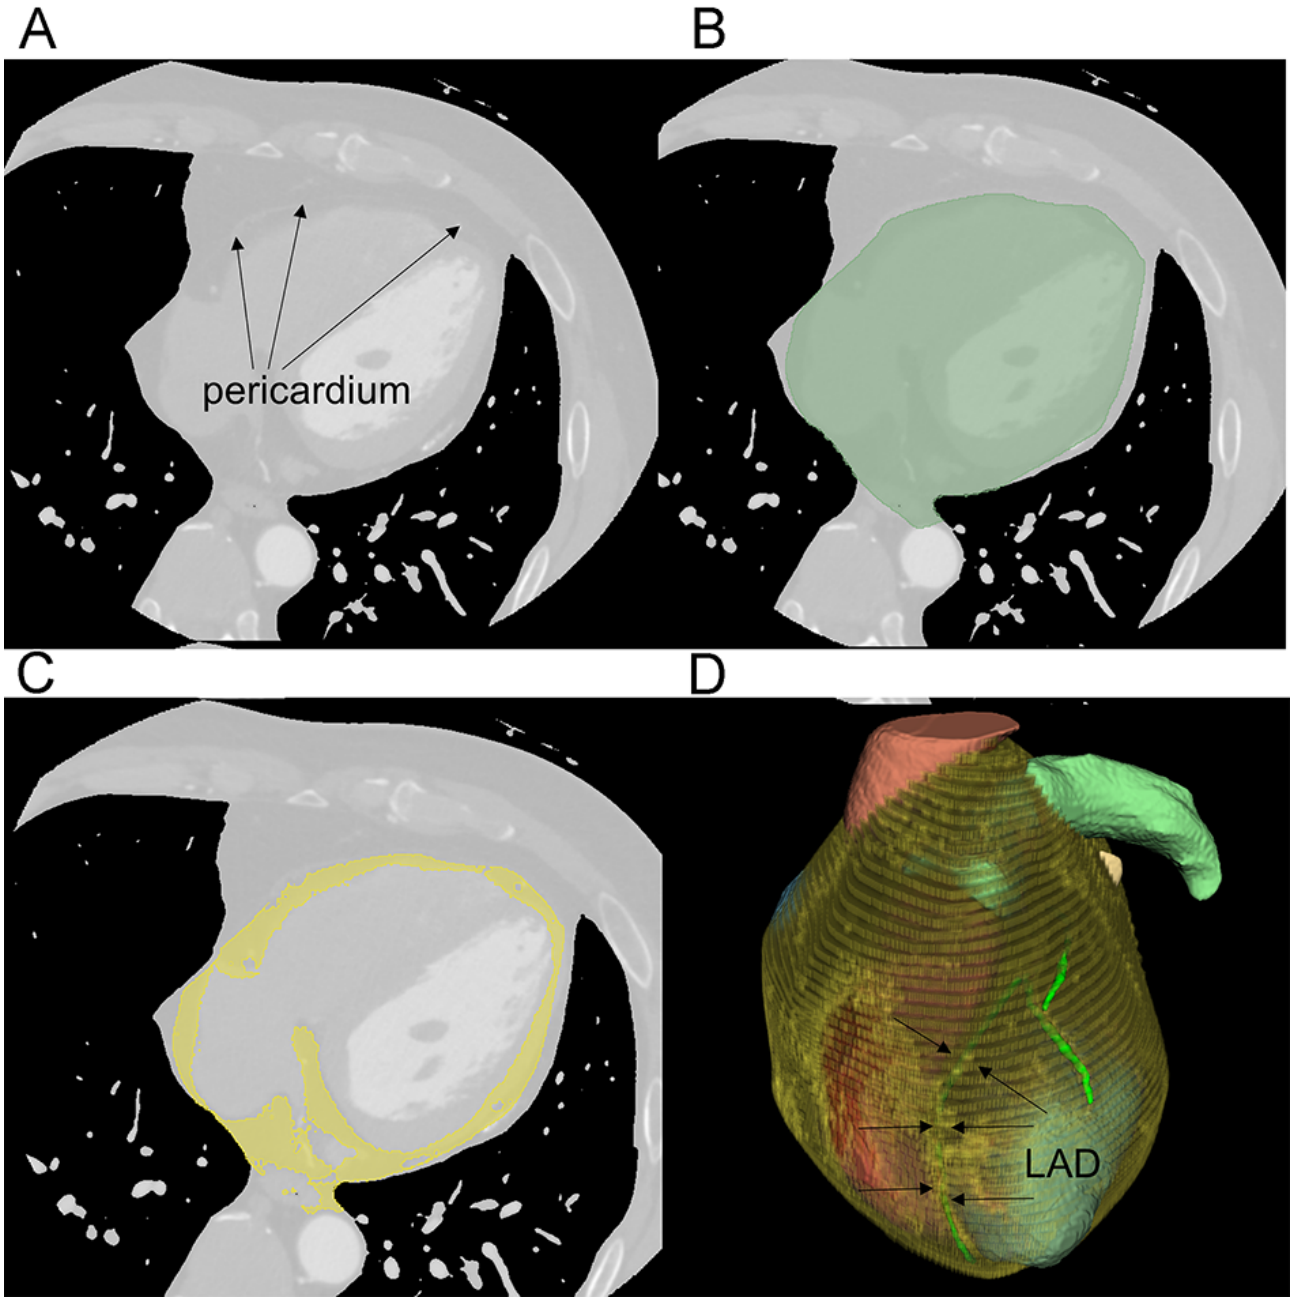
Figure 4. Calculation and visualization of quantitative indices for coronary artery calcification. (A) Original cardiac computed tomography angiography image. (B) Coronary artery segmentation showing the contours of major coronary vessels. (C) Semantic segmentation with different coronary artery branches marked in distinct colors. (D) Quantitative analysis of calcified plaques, with visualization of calcification areas (marked in red) on the left, and a table on the right showing quantitative results including Agatston score, calcium mass, and volume for each coronary artery branch. CCTA: cardiac computed tomography angiography; LAD: left anterior descending artery; LCX: left circumflex artery; LMA: left main artery; RCA: right coronary artery.



Type	Agatston score	Mass	Vol
LMA	98	15	27
LAD	14	3	19
LCX	95	16	50
RCA	107	14	47
Total	314	48	143

Third, to visualize the depth of coronary artery travel, we modeled EAT to assess how deeply the coronary arteries are embedded within it. EAT measurements were performed using a semiautomated procedure (Figure 5A). Expert analysts segmented the pericardium using 3D Slicer v5.2.2 [20] in a sequential, slice-by-slice manner. EAT was measured from the bifurcation of the pulmonary trunk to the apex of the heart. Manual pericardial contours were drawn on every 5 - 10 slices (Figure 5B), followed by interpolation and corrections where necessary. Contiguous voxels with attenuation values between −190 and −30 Hounsfield units were used to define and quantify EAT (Figure 5C) [21]. A fusion display combining EAT and coronary artery models was used to present depth information, visualized through variations in coronary artery fluoroscopy (Figure 5D).

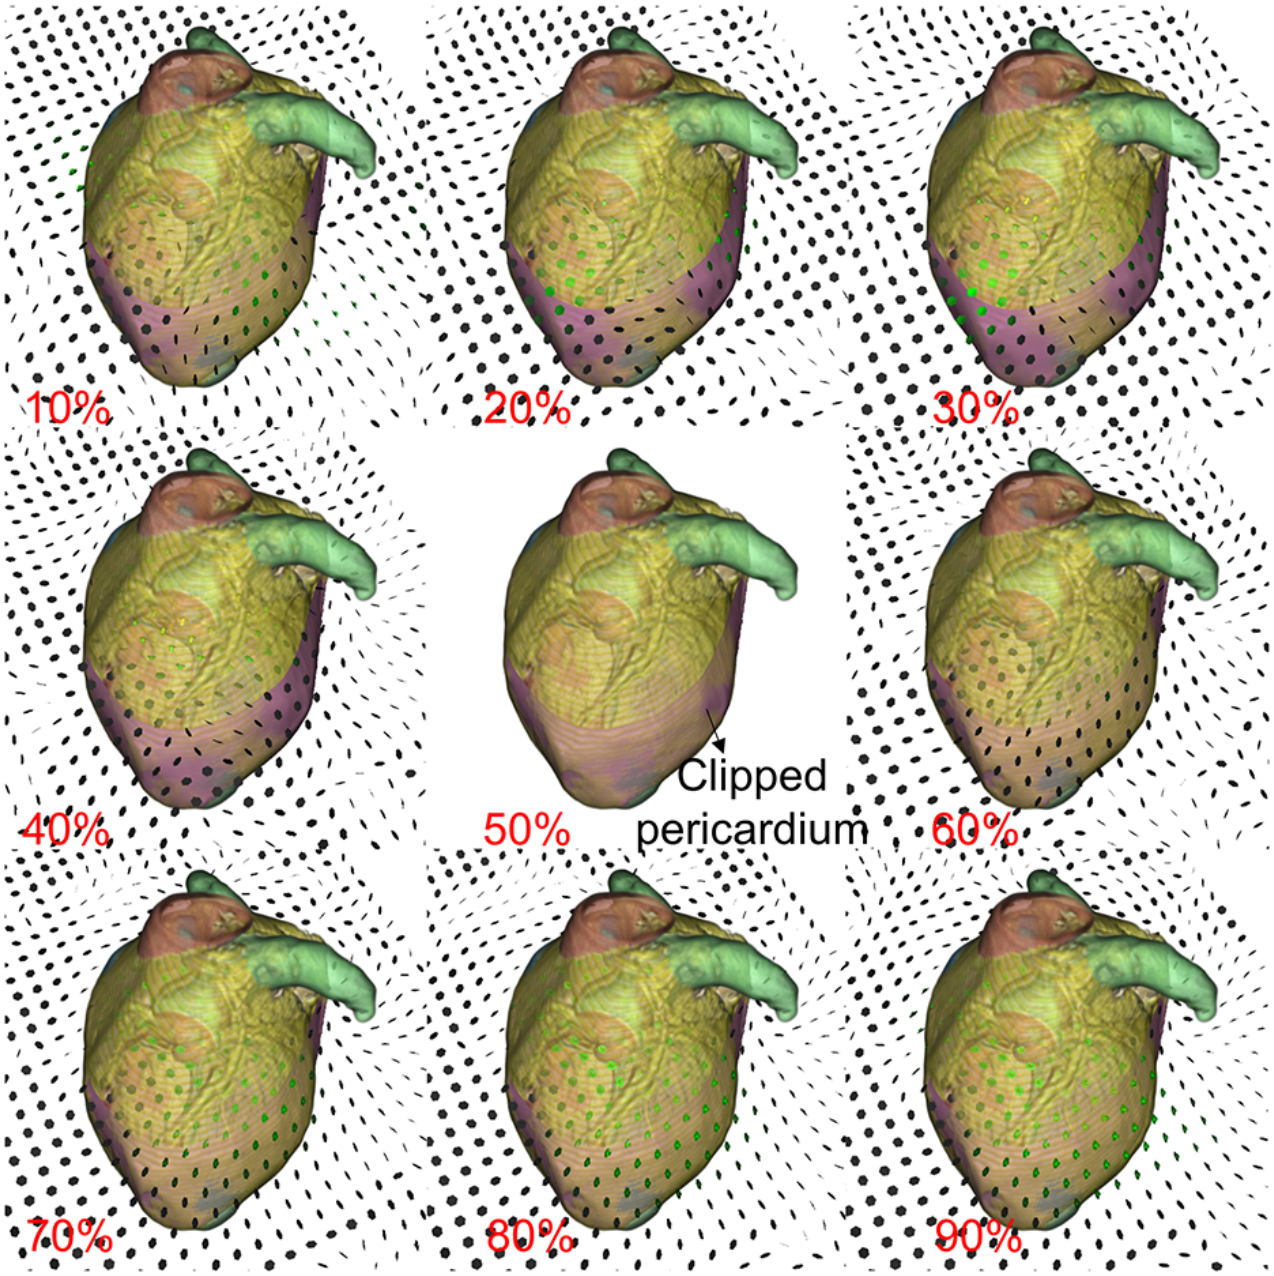

Figure 5. Proposed epicardial adipose tissue segmentation method. (A) The pericardium appears as a thin white line in the coronary computed tomography angiography image. (B) The region encompassing the pericardium is first segmented by manual labeling (green region). (C) The threshold method is used to segment the adipose tissue within the pericardial mask (yellow region). (D) The volume rendering result of the segmented epicardial adipose tissue. LAD: left anterior descending artery.

Finally, when adhesions exist between the pericardium and the heart, the motion of the 2 structures tends to be synchronized. In contrast, the absence of adhesions results in noticeable differences in their relative motion. To observe this, we dynamically reconstructed both the pericardium and the outer cardiac tissue. Nine cardiac phases (10% - 90%) were imported and registered to the selected 50% phase. This registration used the symmetric diffeomorphic algorithm proposed by Avants et al [22], generating a sequence of transformations represented as a time-varying 3D displacement field. This sequence was then applied to deform the pericardium and EAT (Figure 6). The pericardium is cut open to help observe the inner EAT structures. The corresponding deformation field of the cutting plane is visualized using arrows, where each arrow represents the displacement vector, indicating the direction and magnitude of displacement originating from its starting point on the plane.

Evaluation of Outcomes

Evaluation of Naked-Eye Holographic Display

The outcome parameters were assessed qualitatively. Thirteen cardiac surgery clinicians evaluated various aspects of the holographic display, including display quality, realism of 3D spatial positioning, identification of calcified plaques, perception of coronary artery alignment depth, realism of dynamic visualization, and detection of pericardial adhesions. Evaluations were conducted using a Likert scale, based on preoperative and intraoperative data from 14 patients scheduled for CABG. In addition, the researchers evaluated participants' attitudes toward the system's usefulness in preoperative planning and clinical education, as well as their willingness to adopt the system in practice. A score of 5 represented the most positive evaluation, while a score of 1 indicated the least favorable response (see Questionnaire 1 in Multimedia Appendix 1).

Evaluation of Pericardial Adhesions

Pericardial adhesions were classified as either 0 or 1, where 0 indicated no adhesions and 1 indicated significant adhesions requiring the removal of a substantial portion of the pericardium. The intraoperative score was derived from the patient's operative report. Adhesion severity in the holograms was visually assessed by an experienced cardiovascular surgeon trained in interpreting holographic representations of pericardial adhesions, including the significance of the color schemes. The surgeon was blinded to all patient information. To assess intrarater reliability, the same evaluator performed a second blinded evaluation of the same hologram samples 2 months later.

XSL•FO
RenderX

Statistical Analysis

The Spearman rank correlation test was conducted using SPSS version 25 for Windows (SPSS Inc) to evaluate the correlation between hologram-based adhesion scores and intraoperative adhesion scores. Statistical analysis of the holographic display evaluation scores was performed using Microsoft Excel (version 2021 MSO). All statistical analyses were descriptive. Continuous variables were summarized using the mean, standard deviation, minimum, median, and maximum values, while categorical variables were reported as counts and percentages.

Ethical Considerations

Ethics approval was granted by the Ethics Committee of the General Hospital of the Chinese People's Liberation Army (approval number: S2024-580). This study was conducted in accordance with the Declaration of Helsinki. Informed consent was obtained from all individual participants included in the study. No compensation was provided to the participants of the study.

Results

All 13 cardiac surgery professionals who tested the hologram system were male. The group consisted of 6 attending physicians and 7 senior doctors, with ages ranging from 34 to 54 years (median: 37 years).

When viewing the holograms from various angles (see Figure 7A-D; Video 1 in Multimedia Appendix 2), all participants—regardless of their level of expertise—agreed that the system offered a realistic visualization and allowed for accurate identification of the major coronary artery branches, the locations of severe stenosis, and calcified plaques. In addition, by zooming and rotating the model, users could clearly view the spatial relationships among the heart, coronary arteries, and internal mammary artery within the thoracic cavity (median rating: 5/5, Table 1). However, 2 experts assigned scores of 2 and 3, respectively, for the identification of coronary stenosis and calcified plaques. They expressed concern that CCTA data may not reliably discriminate coronary stenosis and noted that intravascular contrast enhancement could impact plaque identification, potentially leading to inaccurate results. To assess interrater reliability, Fleiss κ coefficients were calculated for each evaluation item. The results indicated substantial to almost perfect agreement among evaluators across all assessment criteria (κ ranging from 0.68 to 0.85). The highest agreement was observed for comparisons with traditional 2D displays (κ=0.85) and dynamic display fidelity (κ=0.82), reflecting strong consensus regarding the system's superiority over conventional visualization methods. While all criteria demonstrated substantial agreement, coronary calcified plaque visualization received the relatively lowest κ score (κ=0.68), suggesting some variability in expert perception of this feature. Overall, the high κ values confirm the reliability of the evaluation results and strengthen the validity of the positive assessments across all measured dimensions.

Figure 7. Typical scenarios on a holographic viewing system. (A) Dynamic 3D coronary artery scene segmented from computed tomography data, medium and heavily calcified plaques are marked in red. (B) A 4D chest scene including the heart, coronary artery, internal mammary artery, ribs, vertebrae, sternum, and diaphragm. (C) Scenes demonstrating coronary depth. (D) Dynamic pericardium and cardiac motion scene.

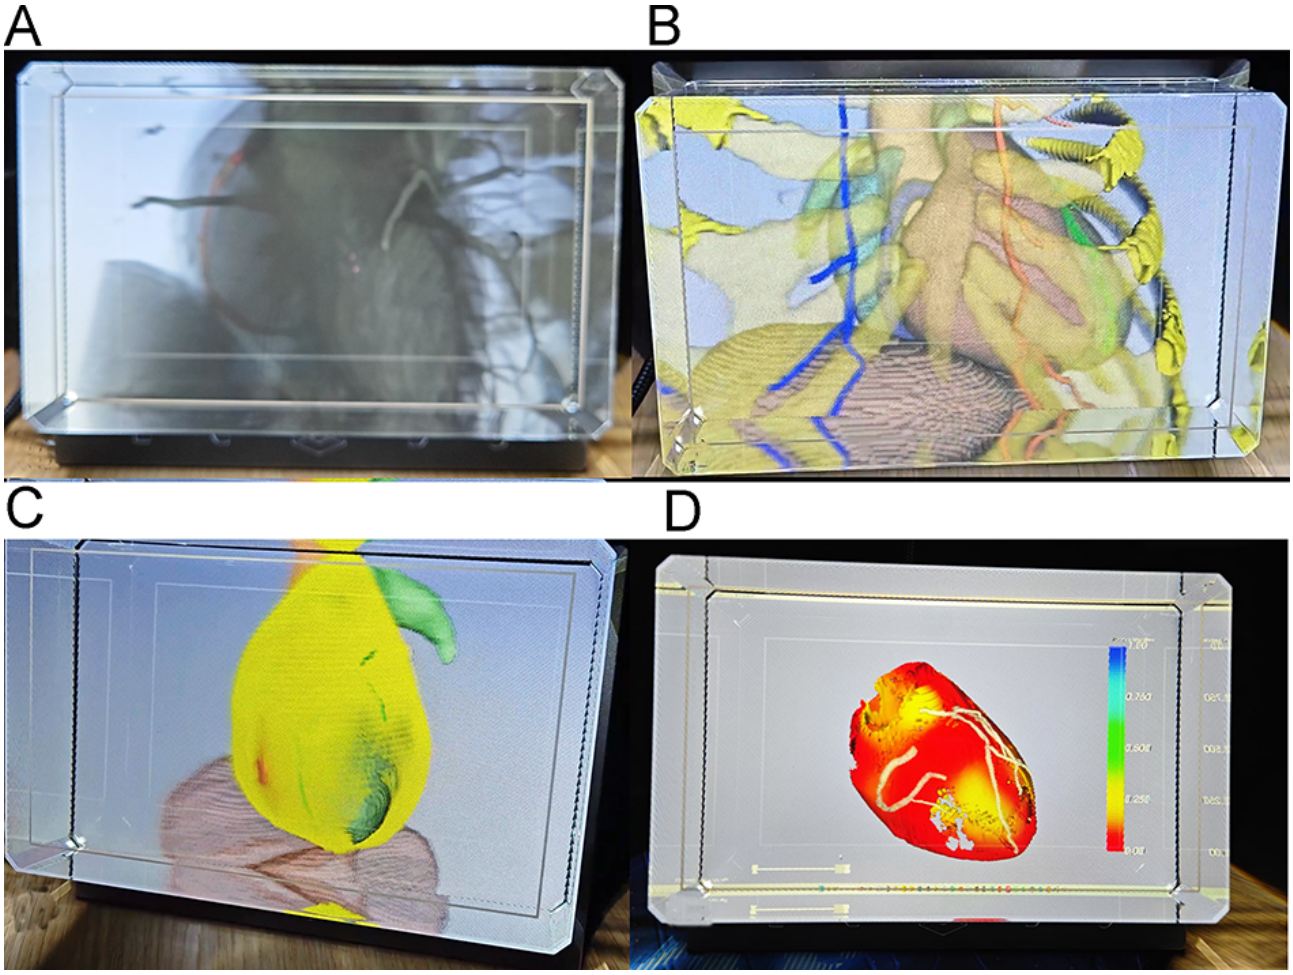

Table . Holographic experience reviews and attitude toward (future) use of holographic imaging system.

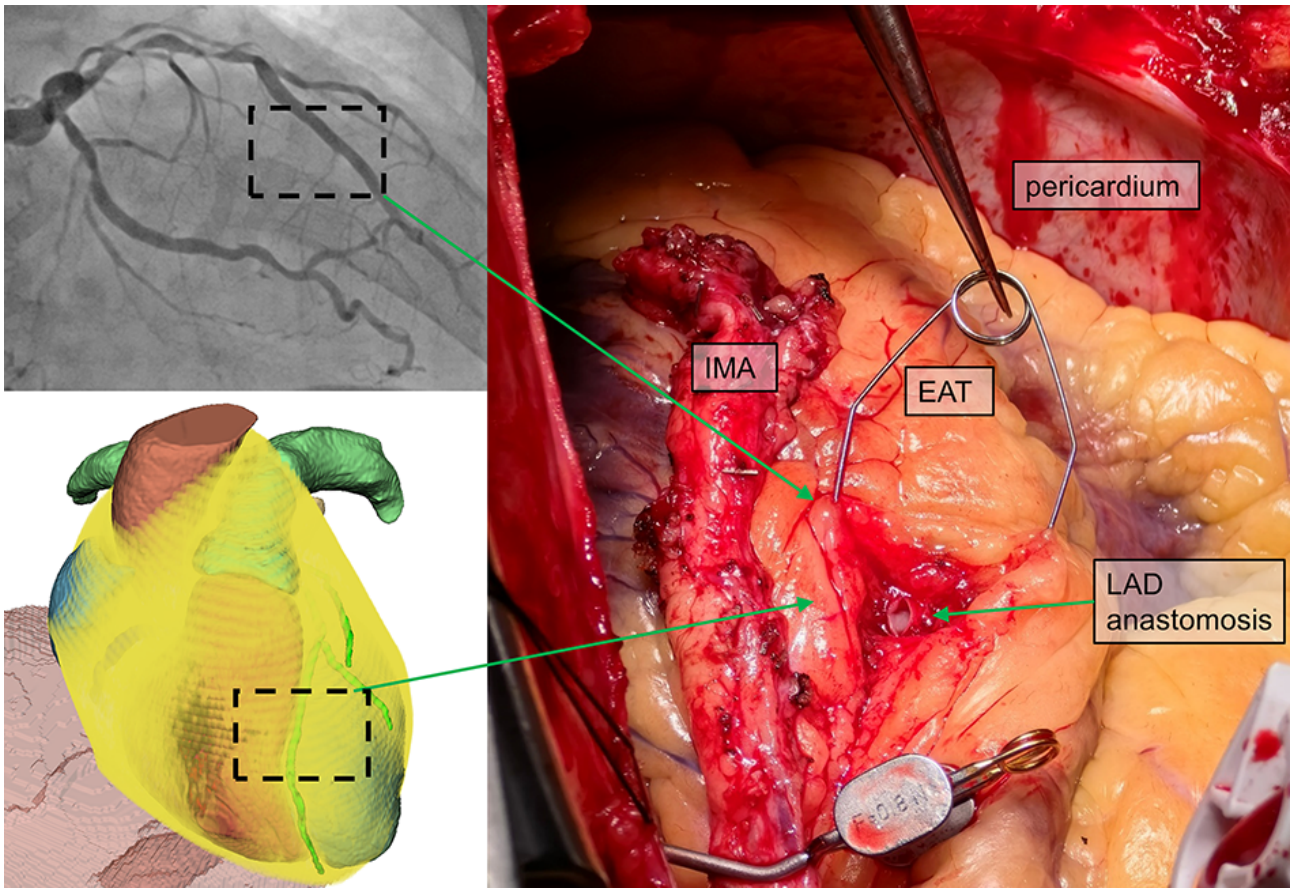


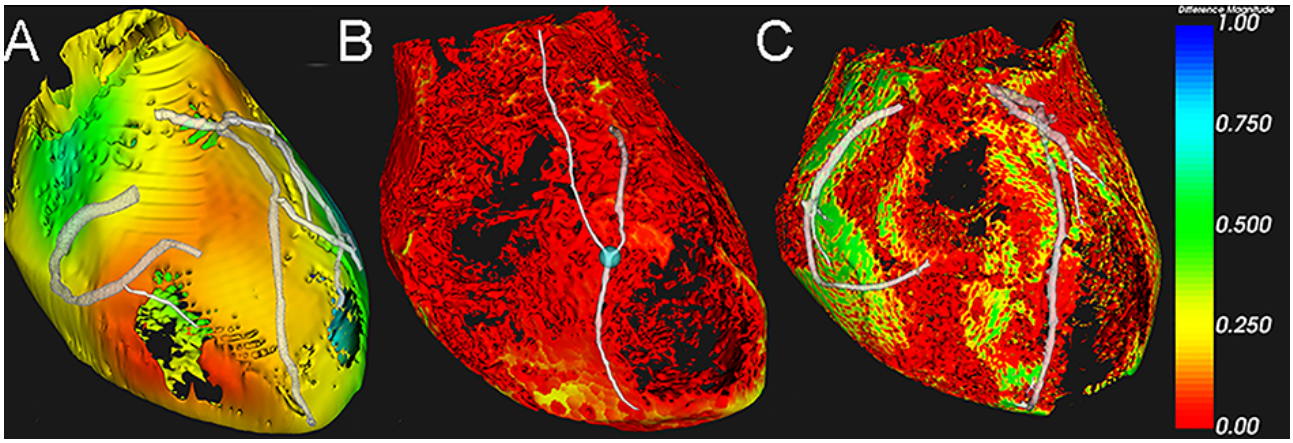
Assessment items	Mean (SD)	Median rating (1–5)	Interrater agreement (κ)
Spatial perception	4.78 (0.4)	5	0.79
Coronary calcified plaque	4.28 (1.0)	5	0.68
Coronary depth	4.71 (0.5)	5	0.76
Dynamic display fidelity	4.78 (0.4)	5	0.82
Pericardial adhesions	4.64 (0.6)	5	0.73
Basic tools (rotate, zoom)	4.71 (0.5)	5	0.79
Compared to traditional 2D screens	4.85 (0.4)	5	0.85
Overall evaluation	4.71 (0.5)	5	0.74
Helpful for preoperative planning	4.57 (0.5)	5	0.71
Beneficial for clinical teaching	4.78 (0.4)	5	0.81
Useful for patient education	4.64 (0.5)	5	0.72

Anterior descending superficial myocardial bridges were observed in 2 of the 14 CABG patients based on CTA images. Evaluators perceived the depth trajectory of the coronary arteries within the EAT by noting a progressive transition in the holograms, from a blurred proximal segment to a clearer mid-to-distal segment. This trend corresponded with intraoperative findings, where anastomotic selection could not avoid the bridged region due to limitations in internal mammary artery length (Figure 8). Depth perception scores for the coronary arteries were consistently rated as “agree” or “strongly agree,” with a median score of 5/5. As demonstrated in patient number 9, the anterior descending branch anastomosis proposed before surgery was located deep in the EAT, with the anterior descending branch alignment appearing straight in preoperative

XSL•FO
RenderX

coronary angiography, implying potential myocardial bridges. The hologram produced results consistent with both the intraoperative situation and the diagnostic results of preoperative imaging.

Figure 8. Figure 8. The intraoperative situation of patient number 9. EAT: epicardial adipose tissue; IMA: internal mammary artery; LAD: left anterior descending artery.



Conventionally, images are viewed on a 2D screen following 3D reconstruction of the heart and coronary arteries using 3D Slicer software. To compare approaches, we asked evaluators to respond to assessment item 7 “Compared to traditional 2D screens”: in obtaining the information needed for preoperative evaluation, it provides more intuitive and comprehensive insights compared to observing static 3D cardiovascular CT images on a 2D screen. The mean score was 4.85 (SD 0.4), with 5 representing the most positive evaluation and 1 the least. Cardiac surgeons who participated in the evaluation agreed that the visualization method used in this study provided superior insights compared with traditional techniques. Key advantages included enhanced depth perception and more detailed cardiac modeling, particularly in representing coronary artery travel depth and pericardial adhesions.

The hologram-based adhesion score showed a strong correlation with the intraoperative adhesion score (r=0.786; P<.001; 95% CI 0.53 - 0.92), confirming the validity of the data. All participants acknowledged the effective visualization of pericardial adhesions (median score: 5/5; Figure 9), and noted that the holographic display provided a more intuitive and 3D representation than traditional ultrasound images. For example, patients without prior cardiac surgery showed clear relative motion between pericardium and epicardial adipose tissue (Figure 9A), while those with previous operations demonstrated restricted motion, indicating adhesions (Figure 9B). Notably, one case showed discordance between operative findings and holographic assessment (Figure 9C). The dynamic visualization of pericardial motion and adhesion patterns can be further observed in the supplementary video demonstration (Video 2 in Multimedia Appendix 3). The hologram-based adhesion score showed a strong correlation with intraoperative findings. Among the 20 cases evaluated, 14 cases with hologram score 0 corresponded to intraoperative score 0, while 6 cases with hologram score 1 matched intraoperative score 1, demonstrating excellent agreement (r=0.786; P<.001; 95% CI 0.53-0.92). A second blinded evaluation was conducted two months later to assess repeatability. The intrarater reliability, measured by the κ coefficient, was 0.85, indicating strong consistency in the evaluation results.

XSL•FO
RenderX

Figure 9. Visualization images of pericardial adhesions. (A) Patient number 6, scheduled for first-time CABG, exhibits significant relative motion between the pericardium and EAT, suggesting the absence of pericardial adhesions. (B) Patient number 7, who underwent left ventricular outflow tract unblocking, mitral valve replacement, and CABG one year ago, demonstrates poor relative motion between the pericardium and EAT, indicating the presence of pericardial adhesions, consistent with intraoperative findings. (C) Patient number 2, who had an aortic valve replacement one year prior, shows extensive pericardial adhesions in the operative report, but the hologram pericardial adhesion score is rated as 0, suggesting no adhesions. CABG: coronary artery bypass graft; EAT: epicardial adipose tissue.

Discussion

Principal Findings

Holograms have demonstrated the ability to provide realistic depth perception, enhancing the intuitive understanding of a patient's 3D anatomy. However, the complexity of current hologram production methods has limited the widespread adoption of this technology in routine clinical practice. In addition, existing head-mounted display devices are often uncomfortable and can hinder effective communication among health care team members. This study presents an approach to use real patient volumetric data—specifically 4D-CCTA—to generate high-quality, naked-eye–viewable, 3D, color dynamic holograms relevant to CABG surgery. This visualization tool eliminates the need for clinicians to rely on personal spatial imagination to synthesize relevant anatomical information. Instead, it offers a more intuitive, comprehensive, and vivid representation of the data required for preoperative CABG planning. The holograms can be simultaneously viewed and discussed by multiple surgeons or with patients, without the need for headgear. Unlike most existing cardiac and coronary models, this study introduces a specialized modeling framework tailored for CABG preoperative planning. It includes a dynamic representation of the pericardium, heart, and coronary arteries, all derived from the patient's 4D-CCTA data. Presenting volumetric patient data as dynamic, multicolor, and internet-based holograms represents a potential advancement in cardiac medical imaging. This study outlines the fabrication process, structural framework, and preliminary feasibility assessment.

The preprocessing time for each patient dataset requires approximately 15 min, making it clinically feasible for use in preoperative planning. However, coronary artery segmentation remains the most time-consuming and technically challenging component—especially in patients with advanced CAD. In cases of significant vessel occlusion or calcification, which are common among CABG candidates, automated segmentation methods often require manual refinement to ensure clinical accuracy. This limitation is well recognized in the field and represents a key area for future algorithmic development.

In this study, the EAT, pericardium, and coronary arteries were segmented to characterize their relative motion and structural features in order to extract clinically relevant information regarding coronary artery depth and pericardial adhesions. Pericardial adhesions increase both the difficulty and risk of minimally invasive or median sternotomy procedures and must be identified preoperatively. Currently, pericardial adhesions are typically evaluated using ultrasonography, which detects motion discrepancies between the pericardium and outer myocardium, or CT imaging, which assesses changes in pericardial density [23]. However, thickening of the pericardium on CT does not reliably correlate with adhesions, and although ultrasonography can reveal relative motion, it lacks 3D detail and fails to provide a comprehensive view of adhesion location relative to the coronary arteries. Another significant challenge is assessing the depth of coronary artery travel within the EAT. This is clinically important because intraoperative identification of deeply embedded coronary arteries can be difficult. Accurately obtaining this anatomical information preoperatively can significantly inform the selection of an anastomotic site during surgery. CCTA is currently the preferred modality for evaluating EAT [24]. Traditionally, EAT has been studied in terms of its volume or composition to explore its relationship with the progression of CAD [25]; however, these approaches offer limited insight into spatial relationships relevant for surgical planning. In this study, we dynamically fused models of epicardial fat and coronary arteries to represent their positional relationship and visualize the depth trends of the coronary arteries. Combined with a holographic display, this approach achieved the intended visualization effect. The accuracy of coronary artery depth representation was supported by comparison with intraoperative findings. Furthermore, the strong correlation between preoperative holographic assessments of pericardial adhesions and intraoperative scores provides preliminary validation of the system's clinical reliability.

RenderX

Comparison With Previous Work

Several research teams have explored the application of holographic imaging technology in the medical field. Our work shares some commonalities with these studies but also presents significant innovations.

Tanwani et al [26] developed a head-mounted holographic needle guidance system for enhanced ultrasound-guided neuraxial anesthesia. They used the Microsoft HoloLens mixed reality headset to project a hologram of the ideal needle path, helping operators replicate the correct needle angulation. While this work demonstrated the value of holographic technology in surgical navigation, its primary focus was on visualizing a single surgical path, whereas our system provides a dynamic holographic representation of the complete cardiac anatomy, including the complex spatial relationships between coronary arteries and surrounding tissues. Liu et al [27] demonstrated in a randomized controlled trial how 3D holograms with mixed reality techniques can improve medical professionals' understanding of pulmonary lesions caused by COVID-19. Their study showed that holographic visualization significantly enhanced physicians' ability to identify lung lesions compared to traditional 2D CT, especially for medical students and nonspecialist doctors. This aligns with our findings that holographic visualization can bridge gaps in specialist knowledge, but our work further extends this concept by transforming static anatomical structures into dynamic visualizations that capture anatomical changes throughout the cardiac cycle. Parekh et al [28] developed a method for depth estimation and visualization of dermatological lesions, using neural networks and explainable AI for lesion classification, and holographic projection to display lesion depth. Their work focused on generating 3D holograms from 2D images, while our approach directly uses 4D CT data to capture the dynamic nature of the heart, providing surgeons with more comprehensive anatomical information.

Compared with these previous works, our research demonstrates innovation in several key areas: (1) dynamic visualization: our system not only displays static anatomical structures but captures the dynamic changes of coronary arteries throughout the cardiac cycle, which is crucial for CABG surgical planning. (2) Naked-eye holographic technology: unlike solutions requiring specialized headsets, our system allows multiple clinicians to simultaneously view and interact with the same anatomical structure, facilitating collaborative discussion among the surgical team. (3) Enhanced depth perception: we specifically focus on the depth variations of coronary arteries within epicardial fat tissue, critical information that traditional imaging methods struggle to adequately display and which has significant value for CABG surgical planning. These innovations make our holographic system a powerful tool not only for assisting surgeons in CABG surgical planning but also as a bridge for doctor-patient communication, helping patients and their families better understand the necessity and potential risks of surgery.

Limitations

First, our initial assessments were subjective and qualitative in nature and, therefore, not amenable to rigorous statistical analysis. Although clinician feedback was generally positive, we did not use validated quantitative metrics to compare the utility of the holographic visualization with conventional imaging techniques. Future studies should incorporate standardized assessment tools and objective performance measures to quantitatively evaluate the impact of holographic visualization on surgical planning and clinical outcomes.

Second, we did not perform quantitative analyses of calcified plaques, coronary artery travel depth, or pericardial–cardiac motion differentials. While we strived to maintain data fidelity throughout the visualization pipeline, it is important to recognize that the segmentation process inherently introduces variability and potential distortion. This may be influenced by factors such as the choice of segmentation algorithms, parameter settings, and manual corrections. Although experienced radiologists reviewed all segmentations to ensure clinical accuracy, this oversight does not entirely eliminate the risk of error. These limitations may have affected the accuracy of the spatial relationships depicted in our holograms.

Third, we did not quantify segmentation error or validate the geometric accuracy of our models against the original source data, which represents a significant limitation of the current methodology. Future work should include rigorous validation of segmentation accuracy and quantification of model fidelity relative to the source CT data to better understand clinical reliability.

Fourth, due to the limitations of current CT imaging, coronary stenosis still requires coronary angiography as the clinical "gold standard." While our approach integrates information from both CCTA and angiography, it does not yet match the diagnostic accuracy of invasive angiography for stenosis assessment. Future iterations could address this limitation by incorporating computational fluid dynamics to better evaluate the functional severity of stenosis.

Fifth, this study represents only a preliminary feasibility assessment of holographic visualization. We did not conduct quantitative or comparative studies of procedures performed using conventional imaging alone versus those supported by holographic assistance. Such comparative studies are essential to determine the practical utility, effectiveness, and broader applicability of holographic imaging in real-world clinical settings.

Future Perspectives

The potential impact of holographic technology on medical imaging is substantial, particularly in the context of minimally invasive surgery. These procedures involve small incisions and a limited field of view, making a clear understanding of patient-specific spatial anatomy crucial. In future studies, we plan to further investigate the use of holographic imaging systems for preoperative planning in minimally invasive cardiac surgery. This includes integrating internet-based tools and hemodynamic analyses and exploring the possibility of overlaying holograms onto the real intraoperative environment with internet-based manipulation for real-time surgical guidance.

XSL•FO
RenderX

Conclusions

This study presents a structural framework for a visualization tool specifically designed for preoperative planning of CABG procedures. By leveraging patient-derived volumetric data, the system generates potentially clinically relevant, dynamic holograms that provide depth perception, detailed coronary stenosis and calcification information, alignment depth data, and 4D spatial insights. Clinician feedback was positive, supporting the tool's potential utility for preoperative planning. The system also shows promise for applications in medical education, including surgical demonstrations for interns and preoperative education for patients. While further development and validation are needed, this work represents an important step toward enhancing visualization capabilities in cardiac surgical planning.

Abstract

Background: The integration of digital tools into psychotherapy has gained increasing attention, particularly for practices such as routine outcome monitoring (ROM), which involves the regular collection of patient-reported data to inform treatment decisions. However, despite the potential benefits, the adoption of digital platforms remains limited, partly due to usability concerns and workflow misalignment.

Objective: This study aimed to assess the usability of a digital platform, Mindy, designed to support psychotherapists in implementing ROM and to explore broader challenges associated with the integration of digital tools into psychotherapeutic practice.

Methods: This study adopted a qualitative, 2-stage approach. Sixteen psychotherapists participated in semistructured interviews, which included task-based usability testing and reflective discussions. Participants interacted with Mindy by performing typical clinical tasks, such as creating patient profiles, managing session data, and sending questionnaires. The first stage of analysis used a deductive thematic approach focused on predefined platform functionalities. The second stage followed an inductive methodology to identify broader themes related to the integration of digital tools in psychotherapy.

Results: The usability assessment identified strengths in the platform's appointment scheduling, questionnaire delivery, and dashboard functionalities, which were perceived as intuitive and supportive of ROM practices. However, limitations were reported in areas such as documentation flexibility, interoperability with other systems, and control over information sharing with patients. Broader thematic analysis revealed three main challenges: (1) the tension between standardized documentation and the need for narrative and implicit information; (2) difficulties in embedding digital platforms into existing therapeutic workflows, especially for clinicians less familiar with technology; and (3) concerns about confidentiality and the potential for misinterpretation when sharing therapeutic notes with patients.

Conclusions: These findings underscore the importance of considering both technical and contextual dimensions when developing and implementing digital platforms in mental health care. Tailoring digital tools to the needs and practices of psychotherapists may improve adoption and ultimately enhance the quality of care.

KEYWORDS

digital mental health; psychotherapy; routine outcome monitoring; usability; digital tools

Introduction

Digital technologies, such as electronic health records (EHRs) and digital mental health platforms (DMHPs), have become increasingly relevant in psychotherapy [1-3]. These technologies offer several benefits, such as improved documentation and legibility, enhanced information sharing and communication among providers, timely information retrieval, and increased accountability [4]. However, their implementation also presents several challenges, including issues with standardization and codification, the time burden placed on clinicians, potential negative impacts on therapeutic relationships, usability and learning curve difficulties, and privacy concerns [4]. Certain practices and approaches in psychotherapy are notably enhanced

XSL•FO
RenderX

by digital technologies, with routine outcome monitoring (ROM) being a prime example [5]. ROM has been studied and implemented under different names, including "progress monitoring" [6], "feedback-informed treatment" [7], and "outcome monitoring feedback" [8,9], "measurement-based care" [10], and "outcome feedback" [11]. ROM consists of the systematic collection and analysis of patient progress and outcome data throughout therapy sessions, using standardized self-report measures at regular intervals to provide valuable insights to optimize treatment strategies. The information derived from these measurements is typically presented in graphical form and provided to the therapist and possibly the patient to facilitate monitoring of the patient's improvement trajectory over time. Historically, implementing ROM has been hindered by challenges such as the continuous monitoring of patients and the timely delivery of feedback to therapists [5]. The adoption of digital solutions, however, has been shown to significantly mitigate these obstacles, facilitating a more efficient process [5]. Before these innovations, the collection of patient data was predominantly based on paper-based practices, which were often incomplete, lacked comprehensiveness, and were prone to memory bias [5,12]. The advent of digital technologies has enabled real-time collection of more detailed and objective patient data, allowing therapists to assess information both before and after the visit and thereby reducing reliance on patient memory [13].

The American Psychological Association (APA) has long advocated the use of ROM and feedback practices in psychological therapy [14]. A recent advisory committee appointed by APA governance further recommended the creation of comprehensive guidelines regarding the integration of outcome and process monitoring systems into therapeutic practice. These guidelines state that therapists should undertake regular evaluations of the treatment process and outcomes, integrating this evidence-based practice into clinical practice [12].

Despite substantial scientific evidence supporting the clinical benefits of ROM, its adoption remains limited in certain contexts. This hesitation can be attributed to several factors, such as the lack of tailored validation studies, insufficient technological infrastructure, and cultural resistance within clinical practice. Moreover, there is a broader challenge of translating evidence-based approaches into actionable practices in health care systems that may be underresourced or overly reliant on traditional methods [15].

This research is part of the broader OutProFeed project, which is conducting the first randomized controlled trial in Italy focused on ROM.

Within the framework of this larger initiative, the paper addresses 2 specific objectives. The first is to assess the usability of Mindy, an integrated EHR-DMHP platform, designed to support ROM implementation. This usability assessment aims to evaluate how effectively the platform aligns with clinicians' workflows [16,17].

The second objective stems from a broader reflection on the current state of research on digital platforms in mental health. While the effectiveness of these tools for data collection and patient monitoring is widely addressed in the literature [18], often focusing on their technical functionalities, advantages, disadvantages, and impacts on clinical outcomes [18], there is limited evidence on how psychotherapists integrate such platforms into their daily routines [2,19,20]. As a result, adopting a holistic and integrated approach to the design and implementation of digital tools in mental health appears increasingly important. Through the specific case of Mindy's use of ROM, this research aims to contribute to this underexplored area by analyzing the challenges involved in integrating digital platforms into psychotherapeutic practice.

Methods

Overview

This study used a single dataset but followed a 2-pronged data analysis approach to address distinct objectives. The research began by assessing the usability [16,17] of the Mindy digital platform, focusing on its features and collecting feedback from psychotherapists. A deductive thematic analysis [21-23] was applied to organize the data into predefined categories aligned with the platform's features, such as appointment scheduling, patient profile management, and session data entry. The findings were synthesized into actionable recommendations for improving the platform, which were communicated to Mindy's technical and development teams during 2 feedback stages: after a preliminary usability testing phase and following the main evaluation.

However, during this usability analysis, recurring patterns emerged that extended beyond platform features, pointing to broader challenges in integrating digital tools into psychotherapeutic workflows. Recognizing the significance of these themes, the research team conducted a second round of data analysis using an inductive approach [21,23,24]. This phase revisited the data without predefined categories, identifying emerging themes, grouping them into broader concepts, and ultimately into aggregate dimensions. This 2-stage analysis allowed the study to address both the usability of the platform and the deeper, systemic challenges faced by psychotherapists when incorporating digital tools into their daily practice.

The following sections provide a detailed description of the Mindy platform's features, outline the data collection process, and explain the 2-stage data analysis approach.

Key Features of the Platform Under Assessment

Mindy is the digital platform under assessment, and its functionalities include a calendar for scheduling appointments, a document management system for tasks such as handling informed consent forms, session reports, and patient management. It also features an integrated system for administering questionnaires, which provides automatic and standardized scoring of copyright-free measures. In addition, the platform includes a dashboard for monitoring patient progress and the therapeutic alliance, based on patient responses to predefined, validated questionnaires. An overview of the features is provided in Table 1, while screenshots of the main interface for these features are available in Multimedia Appendix 1.

XSL•FO
RenderX

Table . Main features of the "Mindy" platform.

Feature	Description
Agenda and appointment booking	The platform provides therapists with access to a calendar in monthly or weekly views, enabling the scheduling of patient appointments in both in-person and remote modes. Upon booking, an email reminder is automatically sent to both the patient and therapist. For remote appointments, the system also sends the patient a link to the virtual meeting room.
Patient profile creation	Therapists can use the platform to register new patients, collect their personal information, and create a dedicated folder for each individual. Following registration, an informed consent form is automatically emailed to the patient, who must download, sign, and return it electronically or in paper format.
Management of session data with the patient	The platform includes a section for recording details of patient visits, with fields available for annotations and attachments (free-text notes); mandatory fields (eg, current symptoms, examination findings, and preliminary diagnosis) that must be completed to finalize the visit and generate a report; detailed data (optional fields for lifestyle recommendations, observations, or care plans); and questionnaires (predefined forms that can be automatically delivered to patients, with timing specified by the therapist and responses viewable in a dedicated section).
Report delivery to patients	The platform enables therapists to generate and send reports to patients, primarily containing information recorded in the mandatory fields
Dashboard to monitor patient progress and the therapeutic alliance	The platform includes a dashboard where therapists can track patient progress and assess the therapeutic relationship. For instance, therapists can send predefined questionnaires to patients to monitor their condition over time. The results are automatically processed by the platform and presented graphically for review.
Online session system	The platform facilitates online therapy sessions by allowing therapists to initiate video calls directly from the system. A link to the virtual meeting is automatically sent to the patient before the session begins.

Data Collection Process

The data collection process involved semistructured interviews with psychotherapists (refer to Multimedia Appendix 1 for the interview outline), conducted remotely via Microsoft Teams to ensure flexibility and allow direct observation of participants interacting with the platform.

Each session lasted 30 - 45 minutes and followed a 2-part structure. In the first part, participants were asked to complete tasks simulating typical psychotherapeutic activities, such as creating a patient profile, scheduling an appointment, filling out a session report, and sending a questionnaire. These tasks were selected to range from relatively straightforward but essential for basic platform use to more complex tasks critical for implementing ROM through the platform. This progression was designed to reflect both the importance of these activities in psychotherapeutic workflows and their potential to highlight areas where users might encounter challenges.

During these tasks, the thinking-aloud approach [25-27] was used, encouraging participants to verbalize their thoughts while navigating the platform. This approach provided insights into how participants interacted with the system and identified any usability challenges. Interviewers intervened only when participants struggled to articulate their thoughts, using prompts such as, "What are you thinking?" or "What are you trying to do?" In the second part, participants stopped screen sharing to respond to questions exploring their experiences with the platform and its potential integration into their clinical workflow. These questions sought feedback on specific features and how the platform could fit into daily practice.

To ensure familiarity, participants were given 3 days before the interview to explore the platform independently, performing activities such as creating patient profiles or scheduling appointments. Before each session, interviewers clarified that the study aimed to evaluate the platform, not the digital skills of the participants, fostering a noncritical and supportive environment. The choice of a qualitative methodology to assess usability was driven by its capacity to provide detailed insights regarding the usability of Mindy, emphasizing the reasons behind observed behaviors and the contextual factors shaping them [26,28]. Unlike quantitative approaches, which prioritize measurable metrics such as task completion times or error rates [16,17,29], the qualitative method allows for a richer analysis of user interactions [28]. This approach was considered most appropriate for the objectives of the study, as it facilitated the identification of usability issues while simultaneously offering a deeper understanding of how the platform could be integrated into psychotherapists' daily workflows.

All interviews were recorded with consent to capture verbal and nonverbal data for later analysis. Informed written consent was obtained from all participants before their inclusion in the study.

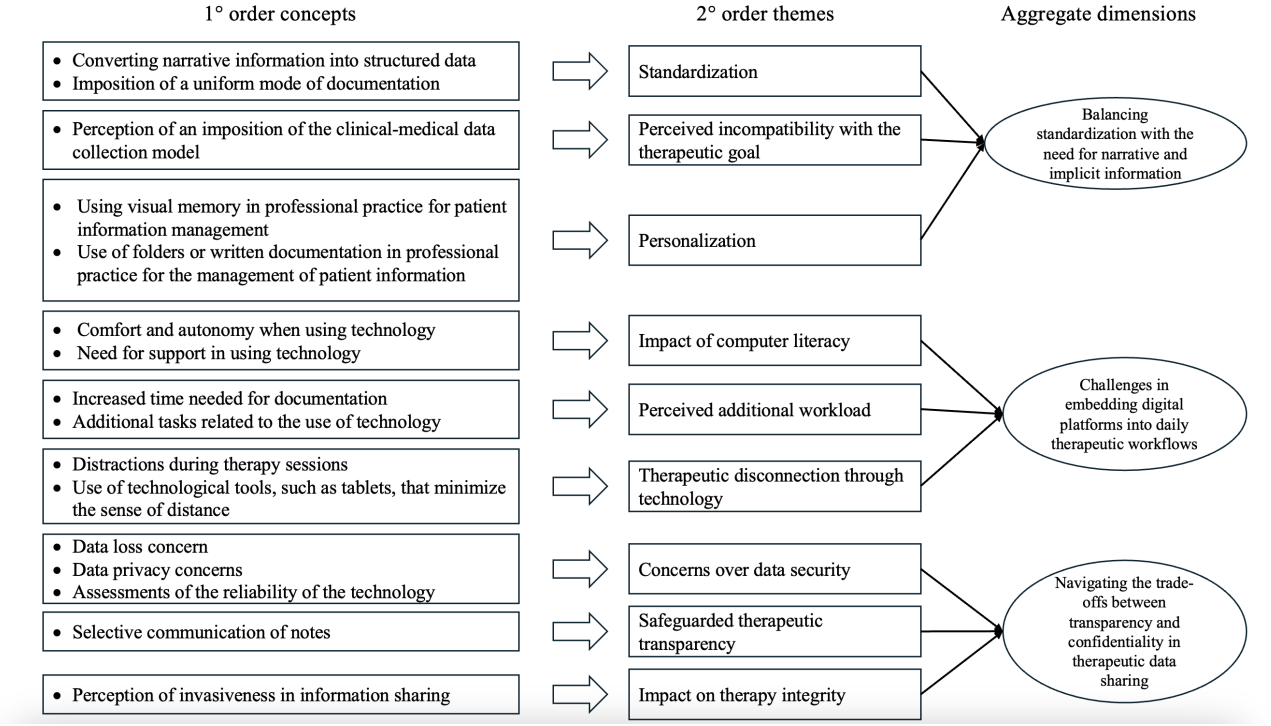
Sample

Among those who participated in the broader OutProFeed project, 16 psychotherapists were recruited for this study using a convenience sampling approach. Recruitment and interviews

XSL•FO
RenderX

were conducted from June 15, 2024, to July 20, 2024. No maximum number of interviews was predefined, as the focus was on reaching data saturation [30], ensuring that additional interviews would not yield new insights. However, a minimum number of 15 participants was established based on Food and Drug Administration (FDA) guidelines [31], which emphasize the importance of collecting sufficient data to identify usability issues and gather comprehensive feedback.

A preusability testing phase was conducted with 3 therapists to pilot the initial methodology, which involved only semistructured interviews without direct interaction with the platform. This phase highlighted the limitations of the initial approach, as the lack of hands-on interaction made it difficult to obtain detailed and actionable feedback. Consequently, the methodology was revised to include a user testing phase using the thinking-aloud method, enabling therapists to interact directly with the platform while verbalizing their thoughts.



The psychotherapists who participated in the study had varying levels of professional experience, with the majority (n=8) reporting 1 - 4 years of practice, followed by those with 5 - 9 years (n=6), and a smaller group with over 10 years (n=1). The sample was predominantly female, with 15 of 16 participants (94%) identifying as women and only 1 of 16 (6%) as a man. In terms of specialization, most participants practiced cognitive behavioral therapy (n=8), while others specialized in transactional analysis (n=4) and integrated approaches (n=4). This distribution reflects a diverse sample in terms of experience and therapeutic orientation, providing a well-rounded perspective for the study.

Two-Round Data Analysis

The data analysis followed a 2-stage approach. In the first stage, a deductive approach was used [21-23], guided by Braun and Clarke's [32] thematic analysis methodology. This phase involved coding the data and organizing it into themes directly linked to the predefined features of the Mindy platform, such as appointment scheduling, patient profile creation, and session data management. This structured approach ensured that participants' feedback was systematically categorized according to the platform's functionalities, allowing for a targeted assessment of usability issues and areas for improvement.

The second stage used an inductive approach [21,23,24], based on the Gioia methodology [33], to explore broader themes that emerged from the data. Open coding was used to identify first-order concepts, which were subsequently grouped into second-order themes and finally into aggregate dimensions. The data structure is provided in Figure 1.

Figure 1. Data structure.

Ethical Considerations

This study received ethical approval from the Comitato per l'Integrità e l'etica della ricerca of the University of Bergamo (reference no 2024_04_08) during the meeting held on April 15, 2024 (minutes no 04/2024). The committee issued a favorable opinion without identifying significant critical issues regarding the study design or execution. All procedures were conducted in accordance with institutional and national ethical standards and adhered to the Declaration of Helsinki. Informed written consent was obtained from all participants before their inclusion in the study. Participants were provided comprehensive information regarding the study's nature, purpose, procedures, and data usage. The privacy and confidentiality of all participants were rigorously protected. Video interviews were conducted, and all recordings are securely stored in the institutional archives of Politecnico di Milano in compliance with European privacy regulations, General Data Protection Regulation (GDPR), and ethical committee requirements, with access restricted to authorized research personnel only. No

XSL•FO
RenderX

financial or material compensation was offered or provided to the participants in this study.

Results

Overview

The results are presented and discussed in 2 parts. The first part focuses on the usability study, outlining the issues identified and linking them to specific functionalities of the Mindy platform. The second part explores broader themes that emerged from the data, highlighting the challenges of integrating digital platforms into psychotherapeutic practice.

Results From the Usability Study

To organize the feedback collected, a summary table was created (Table 2), which groups usability evaluations by platform functionality. The rows of the table represent the various functionalities of the platform, while the columns are divided into 3 categories: positive evaluations, negative evaluations, and suggestions for improvement.

Each intersection between a functionality and a category includes detailed descriptions:

- “Positive evaluations” highlight aspects of the functionality that therapists found effective or beneficial.
- “Negative evaluations” describe elements identified as problematic or inadequate.
- “Suggestions for improvement” provide recommendations for enhancing the usability of the functionality.

XSL•FO
RenderX

Table . Results from usability assessment.

Functionality	Positive evaluation	Negative evaluation	Suggestions for improvement
Agenda and appointment booking	Intuitive and easy-to-navigate layout; automatic reminders sent 24 hours before appointments streamline scheduling	Limited flexibility: no integration with external calendars; restricts comprehensive appointment management across platforms	Consider integrating with external calendars (eg, Google Calendar) to provide a unified view of schedules; this feature would enhance organization and reduce scheduling conflicts
Patient profile creation	Comprehensive data collection aligns with therapists' practices; quick and clear data entry ensures ease of use	Gender options are restricted to male and female; inability to attach identity document scans complicates work, especially for minors	Add an "Other" option for gender selection to accommodate diverse patient identities; enable attachment of scanned identity documents for compliance and better record-keeping
Automatic sending of the informed consent form	Easy-to-use feature that automatically sends forms after patient data is entered; customizable templates allow personalization for different therapists	Requires physical printing, signing, and scanning of consent forms, reducing digital efficiency	Enable patients to upload signed forms directly via a secure link; add support for digital signatures to allow seamless consent management; facilitate secure digital storage of signed forms to eliminate paper documentation
Annotations and attachments section	Flexible, unstructured format allows personalized and spontaneous note-taking; supports diverse documentation needs during or after sessions	Requires a laptop, which can distract therapists during sessions; incompatible with tablets or digital pens, limiting usability for many practitioners; online-only access risks data inaccessibility during connection issues	Enable uploading of scanned handwritten notes or photos; ensure compatibility with tablets and support digital pen input for flexible note-taking; introduce an offline mode or a synchronization feature to maintain access during outages
Mandatory fields and detailed data sections	Helps therapists remember to document important details during sessions	Requires frequent updates to rarely changing data (eg, medical history), leading to inefficiencies; overly medicalized structure does not align with all therapy needs	Make certain fields permanent for stable information, avoiding repeated updates; add a feature for incremental updates, enabling therapists to log changes only when necessary
Dashboard to monitor patient progress and therapeutic alliance	Graphical progress display is intuitive and provides a clear visual overview; it helps therapists quickly identify patient progress or regression	Graphs lack dates, limiting the ability to contextualize progress over time	Add dates to the horizontal axis of graphs, linking progress to specific sessions or events; this improvement would enhance trend analysis and treatment planning
Sending questionnaires	Fast and efficient process that allows results to be stored directly in the patient's file; simplifies data collection and organization	No option to include custom questionnaires, reducing flexibility for therapists	Allow therapists to upload and manage custom questionnaires in a dedicated section; this would increase adaptability to specific patient needs
Sending reports to patients	Automatic report generation is quick and easy to use	Therapists cannot control what content is shared in the report; reports are sent automatically after each session, limiting flexibility in timing; lack of control can cause confusion if all details are not relevant for immediate discussion	Allow therapists to customize which information is shared in the report; make report sending optional, giving therapists control over the timing and content; this flexibility would improve communication and align report sharing with therapeutic goals

Challenges of Integrating Digital Platforms Into Psychotherapeutic Practice

Three main themes emerged from the inductive analysis of the data, offering insights into the challenges of integrating a digital platform such as Mindy into psychotherapeutic practice: (1) balancing standardization with the need for narrative and implicit information; (2) embedding digital platforms into daily therapeutic workflows; and (3) navigating the trade-offs between transparency and confidentiality in therapeutic data sharing.

With respect to ROM practices, the feedback gathered on dashboards to monitor patient progress and questionnaire management (Table 1) was particularly relevant. These features are central in ROM practices enabled by digital systems, as they allow easy and intuitive management of clinical data on outcomes and therapeutic processes. These tools increase the therapist's responsiveness [34], which in turn can impact patient change from one session to the next [35]. The literature has shown that ROM data, especially those managed by digital systems, can increase therapists' awareness of how they have affected patients, improve their humility and empathy, increase patients' understanding of themselves, and involve them more

XSL•FO
RenderX

actively in treatment [36]—aspects that influence the quality of therapy [8]. The perceived importance and usefulness of ROM methods by therapists will influence their adoption [37]. Therefore, any implementation efforts should seek to improve awareness and understanding by providing data on the empirical basis and clinical efficacy of ROM as an evidence-based practice, which enables personalization of therapy, improves outcomes even in the most difficult cases, and reduces patient drop-out rates [34].

Balancing Standardization With the Need for Narrative and Implicit Information

The Mindy platform introduces a structured system for psychotherapeutic documentation that promotes uniformity and consistency. However, this shift has raised concerns about the loss of flexibility and personalization that are central to psychotherapeutic practice. Traditionally, therapists relied on free-text notes to capture nuanced details such as tone, body language, and contextual observations. In contrast, Mindy requires the use of structured fields, drop-down menus, and predefined scales, which some therapists find limiting. One therapist commented:

> *Instead of having a window with options for the objective examination, it would be more effective to use an open-ended question. That way, after formulating a diagnostic hypothesis, I would have the opportunity to add arguments and details to support that initial diagnosis.*

The rigidity of standardized documentation risks oversimplifying therapeutic interactions and reducing the richness needed to fully understand a patient's unique case. A therapist observed:

> *This section, in my opinion, is completely useless unless one works exactly with DCA and decides to use this questionnaire. I, for example, would not use it.*

While some therapists appreciate the structured fields for reminding them to cover key aspects during sessions, others emphasize the importance of flexibility. One explained:

> *Sometimes one leaves room for the flow, not the free association of the patient, and forgets to ask determined things.*

To address these concerns, introducing customizable templates and free-text options could help Mindy balance standardization with the flexibility therapists require. Such changes would allow therapists to retain the depth and personalization critical to effective documentation without compromising consistency.

Challenges in Embedding Digital Platforms Into Daily Therapeutic Workflows

Integrating Mindy into psychotherapists' daily workflows presents challenges, particularly for those accustomed to paper-based methods. Many therapists perceive the transition as requiring significant effort and time, which they already find scarce. One therapist noted:

> *Compared to what I need, it asks me for a major effort, so I don't do it.*

Computer literacy also plays a role in adoption resistance, especially among experienced therapists less familiar with digital tools. Despite some willingness to adapt, as one therapist stated:

> *It might be useful, but I would have to change my way of working a little bit, being very paper-based.*

Therapists also expressed concerns about how the use of digital tools during sessions might create a barrier between them and their patients. For instance, one therapist remarked:

> *When I do the examination, I don't keep the desk in front. I stand in the chairs in front of the patient, so I don't have anything technological in front of me.*

Another added:

> *Using the PC unhooks me too much. I tried it, but it creates too much of a boundary between me and the patient.*

Data security is another significant concern, as therapists are responsible for safeguarding highly sensitive information. Any perceived vulnerabilities in the platform's security could deter adoption. Addressing these challenges requires a user-centered design approach, targeted training, and direct engagement with therapists to ensure that the platform aligns with their workflows and supports, rather than disrupts, their practice.

Navigating the Trade-Offs Between Transparency and Confidentiality in Therapeutic Data Sharing

Mindy's secure environment for managing therapeutic data offers significant advantages, but sharing session notes with patients raises concerns about misinterpretation. Traditionally, therapists' notes were intended for personal use, containing preliminary observations and reflections that could be misunderstood if taken out of context. One therapist explained:

> *I never send notes to the patient unless they specifically ask me. Otherwise, they might misunderstand what I'm writing.*

Unmediated sharing of notes risks undermining the therapeutic alliance by introducing confusion or unnecessary anxiety. A reflective comment, for example, might be mistaken for a definitive diagnosis, potentially straining the trust between therapist and patient. Another therapist elaborated:

> *Sometimes I write things that are hypotheses, ideas to explore further, and I wouldn't want the patient to think those are fixed conclusions. It could create unnecessary worry.*

To mitigate these risks, Mindy should include customizable sharing options that allow therapists to control what information is shared with patients and when. This would preserve the confidentiality and trust essential to effective therapy while enabling transparency where appropriate.

Discussion

Overview

This study aimed to evaluate the usability of the Mindy platform and explore broader challenges in integrating digital tools into psychotherapeutic workflows. Usability has long been

XSL•FO
RenderX

recognized as a critical factor in the adoption and effectiveness of digital health technologies [16,17]. By combining a usability evaluation with an exploration of systemic challenges, the study builds on existing research emphasizing the importance of human-centered design and contextual integration [37,38]. Platforms such as Mindy hold significant potential to enhance therapeutic practices, particularly in supporting ROM, but the integration of such tools often encounters barriers related to design, workflow alignment, and therapist adoption. Addressing these challenges is essential for maximizing the benefits of digital health technologies in psychotherapy.

On the Usability of Digital Platforms in Psychotherapy

The usability evaluation of the Mindy platform identified a range of strengths and weaknesses in its design, offering valuable insights for broader considerations in developing and implementing DMHPs. Although this study focused on Mindy, many of the observed usability issues reflect challenges that are likely to arise with similar platforms, emphasizing the importance of prioritizing user-centered design to address clinicians' needs [16,17].

One of the platform's key strengths lies in its intuitive and easy-to-navigate interface, particularly its scheduling and appointment booking functionality. Features such as appointment scheduling and automatic email reminders facilitate streamlined workflows and reduce the risk of missed sessions. However, the lack of integration with external calendars limits the platform's broader utility, as therapists often manage their schedules across multiple systems. This aligns with previous findings highlighting how insufficient interoperability can hinder workflow efficiency in digital health tools [39]. Incorporating calendar interoperability could make digital platforms more adaptable to real-world practices, enhancing usability and reducing scheduling conflicts.

The patient profile creation feature demonstrated another usability strength, offering a comprehensive approach to data collection and ensuring quick and clear data entry. Nevertheless, certain limitations restrict its inclusivity and functionality. The binary gender options fail to accommodate diverse patient identities, and the inability to attach scanned identification documents complicates the process of working with certain patient groups, such as minors. These issues reflect a broader need for platforms to adopt inclusive design principles, such as customizable gender fields and support for uploading supporting documentation, to enhance usability and accessibility for diverse users [40].

Similarly, the system for handling informed consent forms reflects a mix of strengths and weaknesses. While the automatic sending of consent forms is valuable, the reliance on physical printing, signing, and scanning introduces inefficiencies, reducing the platform's potential to streamline administrative tasks. Supporting digital signatures and enabling secure uploads of signed forms would align the platform with modern standards for digital efficiency, as observed in previous studies advocating for the use of technology to minimize manual processes [38].

The annotations and attachments section, which allows for flexible note-taking, underscores the importance of accommodating diverse practitioner preferences. While the unstructured format supports various documentation needs, requiring a laptop for note-taking can distract therapists during sessions and limit functionality for those who prefer using tablets or digital pens. Such device limitations reflect broader issues of compatibility that must be addressed to ensure platforms are adaptable to different clinical settings [39]. Adding offline functionality and synchronization features would further enhance accessibility, ensuring that therapists can work even in environments with limited connectivity.

The mandatory fields and detailed data sections illustrate the tension between standardization and flexibility. While mandatory fields ensure essential information is documented consistently, the frequent updating of rarely changing data, such as medical histories, creates inefficiencies. In addition, the overly medicalized structure of these fields may not align with therapeutic needs, particularly for less diagnostic-focused approaches. Simplifying data entry by introducing permanent fields for stable information and incremental updates could address these inefficiencies and improve alignment with diverse therapeutic approaches.

The dashboard for monitoring patient progress represents a key strength, offering an intuitive graphical display to visualize patient trajectories. However, the lack of dates on progress graphs limits therapists' ability to contextualize changes over time, an important feature for treatment planning and trend analysis. Including time-stamped data would enhance the dashboard's utility and align it with therapists' needs for precision and longitudinal tracking [38,39].

The functionality for sending questionnaires highlights the platform's potential to simplify data collection, but is constrained by its inability to include custom questionnaires. Allowing therapists to upload and manage custom questionnaires would increase adaptability to specific therapeutic needs. Similarly, the feature for generating and sending reports to patients, while efficient, lacks flexibility in controlling content and timing. Offering greater control over report customization and dissemination would align the platform's functionalities with therapeutic goals and minimize potential patient confusion.

These findings underscore the need for usability improvements that extend beyond individual features to address how digital tools integrate into broader clinical workflows. The challenges identified reflect broader systemic issues noted in previous research, including the need for flexibility, inclusivity, and integration [39,40].

On the Integration of Digital Platforms Into Psychotherapeutic Practices

The introduction of a structured digital system for documentation, such as Mindy, has raised significant tensions between the need for standardization and the inherent flexibility required in psychotherapeutic practice (first theme—"balancing standardization with the need for narrative and implicit information"). While structured fields and predefined scales facilitate consistency and quantitative analysis, they risk oversimplifying or omitting critical narrative details, such as tone, body language, and contextual observations. This issue

XSL•FO
RenderX

aligns with previous literature, which suggests that EHRs in mental health care often interfere with the richness of documentation required for effective treatment [38]. The rigidity of standardized fields may constrain therapists' ability to adapt documentation to individual patients, reducing the depth necessary to fully capture therapeutic dynamics [41]. This concern is particularly pronounced in psychoanalytic approaches, where patient narratives and nonverbal cues play a crucial role in treatment [40]. Addressing this challenge requires a balance between standardization for uniformity and flexibility to accommodate the personalized nature of psychotherapy. Looking forward, the emergence and popular use of artificial intelligence–based scribes [42] present an intriguing development that may reshape perceptions of platforms such as Mindy. AI scribes, which automatically transcribe and summarize clinical interactions, have the potential to reduce the documentation burden on clinicians while preserving the richness of narrative and implicit information. These technologies could complement platforms such as Mindy by enabling therapists to focus more on patient interaction rather than manual data entry. However, their widespread adoption raises new questions about data security, integration with existing systems, and the ethical implications of AI-mediated documentation.

The adoption of digital platforms presents both technical and operational challenges for psychotherapists, particularly regarding their integration into daily workflows (second theme—"challenges in embedding digital platforms into daily therapeutic workflows"). The study highlighted difficulties related to time management, computer literacy, and resistance to change. Experienced therapists, in particular, expressed reluctance to move away from established practices, perceiving digital tools as an additional workload rather than a resource for streamlining processes. Similar issues are noted in the literature, where the adaptation to EHRs has been shown to demand significant cognitive and operational adjustments [40]. Moreover, the study revealed concerns about how using digital tools, even in face-to-face sessions, can create a perceived barrier between therapist and patient, potentially disrupting the therapeutic alliance—a phenomenon also discussed in telehealth contexts [43]. In addition, concerns about data security were prevalent, with therapists emphasizing the importance of robust protections against unauthorized access, echoing findings by Golz et al [39]. To overcome these barriers, platforms such as Mindy must prioritize user-centered design, offering clear training and flexible integration strategies to minimize disruption to professional routines.

The final theme ("navigating the trade-offs between transparency and confidentiality in therapeutic data sharing") revolves around the management of transparency and confidentiality in sharing sensitive therapeutic data. While transparency can strengthen the therapeutic alliance [44], unmediated sharing of session notes poses risks of misinterpretation and patient distress. For example, preliminary observations or speculative diagnoses might be misunderstood as definitive, leading to unnecessary anxiety or erosion of trust. This study supports previous literature advocating for selective and context-sensitive sharing of documentation [45]. In particular, therapeutic notes may be better suited for selective disclosure, depending on the stage of treatment and the specific needs of the patient. Digital platforms must, therefore, incorporate customizable sharing options to ensure communication is adapted to the therapeutic context while maintaining the foundation of trust essential to effective psychotherapy.

Conclusions

This study examined the integration of digital technologies into psychotherapy [1,15,38], focusing on usability and broader implementation challenges associated with platforms such as Mindy. While EHRs and DMHPs offer benefits such as improved documentation, enhanced communication, and timely information retrieval [38], their adoption in psychotherapeutic practice is hindered by challenges related to standardization, workload, usability, and impacts on the therapeutic relationship [38]. These challenges are particularly relevant in the context of ROM, a practice that digital platforms are intended to support but that also introduces specific constraints [5].

The usability analysis of Mindy revealed that while its structured fields and predefined formats facilitate consistency and support ROM implementation, they limit therapists' ability to personalize documentation. This lack of flexibility affects the capacity to capture the complexity and depth of therapeutic interactions, which is essential for tailoring treatments to individual patients. In addition, the inductive analysis identified 3 main dimensions that represent broader challenges of incorporating digital platforms into psychotherapeutic workflows.

Understanding how digital tools can be effectively integrated into clinical practice necessitates approaches that focus on the human-computer interaction, as emphasized by usability studies [17,26,27,27,28]. These studies, which observe how users interact with technology in real-world settings, provide valuable insights into the challenges faced by professionals. By capturing both immediate usability issues and broader themes emerging from these interactions, the study demonstrated how usability methods are critical not only for identifying technical barriers but also for uncovering contextual factors that influence the adoption of digital tools in psychotherapy.

In contributing to the broader goals of the OutProFeed project, this study highlighted the importance of a multidisciplinary approach to improving Mindy's usability and integrating it into professional workflows. The findings underscore the need for collaboration between clinicians, software engineers, and researchers, each bringing distinct expertise and perspectives. While these groups often approach the design and implementation of digital tools with different priorities and terminologies, fostering a shared understanding is essential to ensure that technical features align with clinical needs.

Abstract

Background: It is estimated that 88% of Ontario physicians still use fax technology to share patient information. Transitioning to electronic referral (eReferral) has been shown to have numerous benefits, but the major barrier to adoption of eReferral is the need for both sending and receiving clinicians on the same platform to enable information sharing. The traditional onboarding process takes time and effort. An innovative method is required to improve eReferral adoption by bridging the gap between eReferral senders and fax referral receivers.

Objective: This study aimed to explore the technological feasibility of leveraging a business automation workflow (BAW) platform to connect the digital (eReferral) and nondigital referral platform (fax), enabling eReferral senders to send referrals to fax receivers, thereby improving the clinician experience.

Methods: An eReferral via eFax solution was developed and evaluated on the BAW platform to connect the eReferral platform and the clinicians using fax. A selected number of fax receivers were identified and enabled on the eReferral platform as eFax receivers. Sending clinicians initiated eFaxes through the familiar eReferral workflow, with eFaxes transmitted to BAW and delivered to the target receiver via fax. Retry and reminder logic were built to improve the user experience. If the eFax failed after all retries, a message was sent to the sending clinician through the eReferral platform explaining the failure reason. The appointment information was entered into the eReferral platform by the sending clinicians to trigger patient email notifications. Surveys and focused interviews were conducted to collect clinicians' feedback.

Results: From May 2022 to December 2023, 224 eFax receivers were enabled on the platform, processing 4504 eFaxes for 4132 unique patients and 843 unique senders across the province. Nearly 70% (3137/4504) of patients consented and received email notifications; 19% (875/4504) received appointment details after manual entry in the eReferral platform. On average, eFax referrals contained 5.6 pages, with a minimal 0.7% exceeding 30 pages. Initially, fax service retries were disabled to observe delivery error rates. This resulted in a 37.7% (1023/2712) fax failure. However, after implementing new retry logic in March 2023, the failure rate dropped significantly to 9.9% (304/3082), and 98.7% (2770/2806) of eFaxes were successfully delivered after automatic retries. Clinician feedback revealed a positive impact on sending clinicians' experience, maintaining their familiar workflow while accommodating fax-reliant receivers who can gradually transition to eReferral at their own pace.

Conclusions: This project demonstrates the potential of the BAW platform to bridge the gap between fax and eReferral systems. It minimizes disruption for sending clinicians while allowing fax receivers to incrementally adopt the new platform. This technology can significantly expedite eReferral adoption by reducing the reliance on receiving clinics to adopt eReferral, ultimately enhancing the experience for both clinicians and patients.

Introduction

When a medical referral is necessary in the Canadian health care system, the sending clinician selects the most appropriate receiving clinician and forwards the patient's relevant information through fax or other digital technologies, like an electronic referral (eReferral) system [1]. eReferral simplifies the referral process by enhancing communication between primary care clinicians and specialists or organizations, enabling quick and secure referrals to be sent and received through an electronic platform. The eReferral system has been proven to be more secure, can reduce wait times, improve tracking, and lower costs [2,3]. eReferral has also demonstrated the ability to improve patients' experience [4]. To relieve physician burnout, the Ontario Medical Association recommended enabling electronic information sharing between clinicians to reduce the administrative burden and free up more time to provide patient care [5].

Surprisingly, fax machines are still widely used in health care globally. Fax technology is the lowest common denominator when it comes to physicians who are not working on the same electronic medical record (EMR) systems to share information. It is estimated that around 75% of medical institutions in the United States still rely on faxing for communication [6]. In the United Kingdom, despite the National Health Service's (NHS) call in 2018 for a complete phase-out of fax use by April 2020 [7], 1 in 6 NHS trusts was found still using fax machines in 2023 [8,9].

The 2021 National Survey of Canadian Physicians indicated Ontario ranked the first in the percentage of physicians sharing information electronically, with 39.9% of the respondents using eReferral to request or receive care from specialists or other physicians for their patients [10]. Although significant progress has been made with eReferral in Ontario, 88% of doctors still have to use fax technology to share patient information [5]. Doctors who already adopted eReferral technology cannot completely move away from the fax technology and have to maintain duplicate workflows to be able to refer to receivers who have not adopted eReferral yet. This has resulted in a significant admin workload for the sending clinicians. In 2023, the Ontario government announced that fax machines would be phased out with digital communication alternatives at all Ontario health care clinicians within the next 5 years in the document, entitled Your Health- A Plan for Connected and Convenient Care [11].

One of the key barriers to eReferral adoption is peers not using eReferrals, the need for both sending and receiving clinicians to have a linked health information system through a shared EMR or an independent eReferral platform [1,2], sometimes also referred to as a "chicken-and-egg" problem. Onboarding the sending and receiving clinicians to the same platform takes time and requires enormous change management support [12]. In a hybrid environment where some receivers adopted the eReferral platform and others are still using fax machines, sending clinicians have reported experiencing frustration over the management of a duplicate workflow in selecting appropriate technologies to prepare and submit the referrals to support patient care.

A new and innovative solution was designed using the business automation workflow (BAW) platform as middleware to bridge the gap between the eReferral senders and the fax receivers. This helps explore the technological feasibility of leveraging the BAW platform to connect digital and nondigital (fax) referral platforms to improve the current referral experience, especially for the sending clinicians. The Amplify Care team (previously eHealth Centre of Excellence) started a Proof-of-Concept (PoC) project in 2022 called eReferral via eFax to better understand using a BAW platform to support managing fax-based referrals by leveraging the existing digital referral platform, to measure fax failure risks and to improve the short-term fax failures and retries management, and in the long term, to support migrating away from fax-based referrals. Eventually, the solution will help expedite the eReferral adoption.

Methods

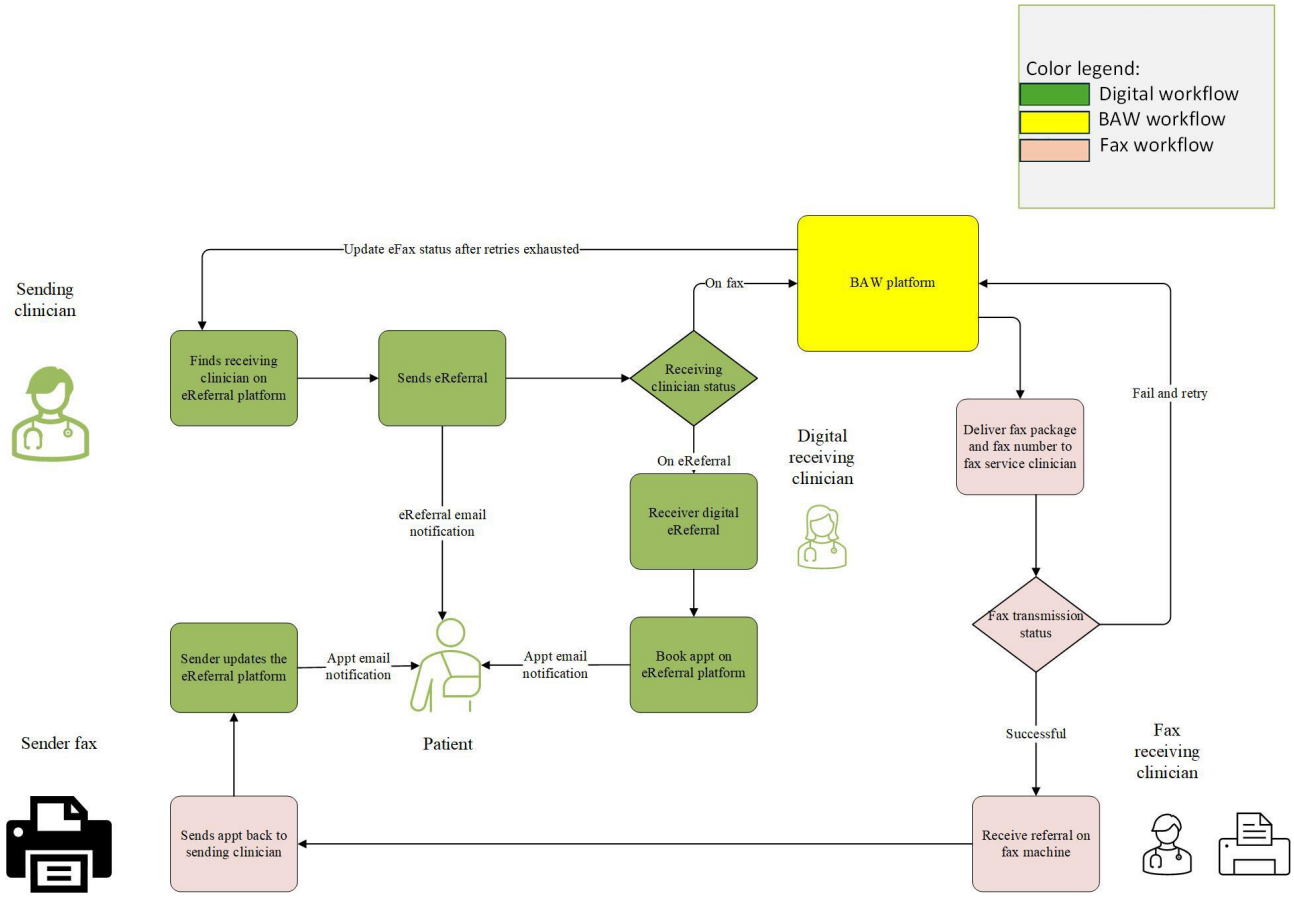
Overview

The design of the solution tried to minimize the impact on the existing workflow for both referral senders and receiving sites so that senders can manage their referrals on one single referral platform, with no need to switch between eReferral and fax workflow and have a seamless experience. At the same time, the receivers can maintain their current workflow to receive the referral on their fax machines. With the new technology implementation, senders should be able to send referrals to a larger group of receivers including those who are still using fax machines, while the fax receivers will start to be exposed to the eReferral technology and this should accelerate their eReferral adoption.

Platform

The BAW platform has the key capability to receive and deliver information through standard Application Programming Interfaces and it also supports workflow customization based on clinical needs to help automate the tasks and gain insight [13]. This is essential when handling the complex fax failures in daily practices that usually require human intervention.

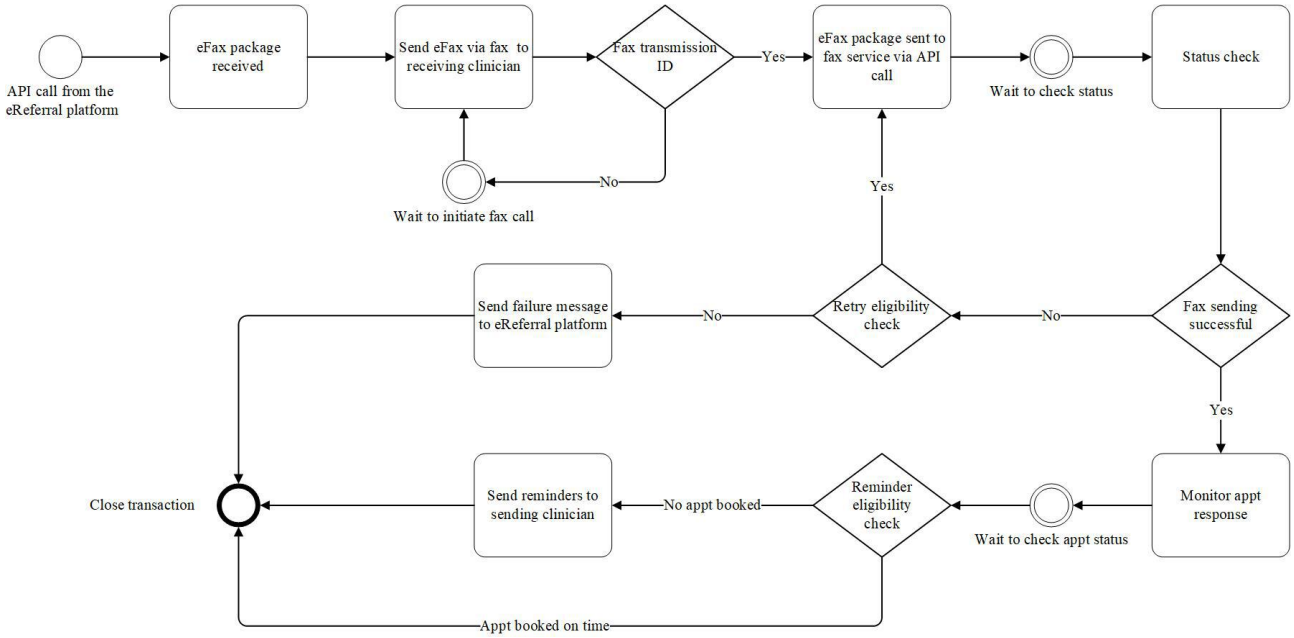
To bridge the gap, we developed and configured the BAW platform as the middleware to connect the digital referral platform and the fax receivers. Through integration with the eReferral platform using Health Level Seven (HL7) Fast Healthcare Interoperability Resources (FHIR), the BAW platform will receive the pdf package, including the referral details and the required fax number [14-16]. The BAW platform will then automate the process following a predefined workflow and deliver information to the fax-based receiving clinician through the second integration with the fax service platform. Retry or reminder logic is built into the workflow to increase the success rate of fax delivery.



The Privacy Impact Assessment and Threat Risk Assessment were conducted to ensure the solution complies with Ontario's Personal Health Information Protection Act and met all privacy and security requirements.

XSL•FO
RenderX

Workflow Configuration



The workflow is configured on the BAW platform using business process model and Notation 2.0 to allow the BAW platform to comprehend and follow the defined clinical workflow (Figures 1 and 2). First, the sender starts the eFax using the same workflow directly within the eReferral platform as other digital referrals. Second, the eReferral platform packages the eFax into a PDF document with a cover page and sends it to the BAW platform together with the fax number through the Application Programming Interface. Third, the BAW platform receives the package or correct fax number and passes the information to the fax service following the defined process. Fourth, the fax service will deliver the pdf package to the fax number provided and provide a status update to the BAW platform once the task is completed or failed. Fifth, if the transaction failed, a notification message will be sent to the clinician via the existing eReferral platform to remind the clinician for further action or resubmission according to their discretion. Sixth, retry or reminder logic is included in the workflow to reduce the human interventions required. Seventh, when the patient is booked, the sender receives the response from the receiver using traditional means (fax machine). The appointment details can be entered digitally into the eReferral platform to enable patient notifications so the patient can enjoy the benefits of eReferral technology. Finally, a reminder message will be triggered to the sending clinician if no appointment is booked after a certain period (7 days for an urgent eFax, 30 days for a routine eFax).

Receiving Clinician Recruitment

The PoC started with a select number of clinicians. Working with multiple Ontario Health Teams, the team identified 229 high-volume receivers in the region who have not yet adopted eReferral technology in their practices. Communications were distributed through fax to the identified receivers, and they were provided the choice to "opt-out" if the receiver had concerns about the PoC. A total of 5 receivers reached out and were removed from the list since they were retiring and no longer accepting medical referrals. The rest (224) were successfully added to the referral platform.

Fax Retry Logic

The PoC was broken into 2 phases to better understand the current fax performance in the Ontario health care system and how the BAW platform can help address the issue. When the fax system communicates with the receiver's fax system, a status code is generated. The BAW platform then receives this status code and determines if a retry is necessary. The fax failure rate was used to track the fax service performance, which is defined as how often the BAW needs to trigger the retry after the eFax delivery fails. During phase 1 (10 mo, May 2022 to March 2023), the fax-service level retry functionality was disabled to observe the fax performance and understand how frequently the fax process will encounter errors. The BAW platform monitored and tracked every error encountered and the result was analyzed to inform the second phase enhancements. Furthermore, 7 of the most common error codes will trigger automatic retries, including "line busy", "no answer", "unexpected disconnect", "device timeout", "device busy", "canceled", and "no channels available". The BAW retries once every 30 minutes, up to 10 times, for routine referrals and once every 10 minutes, up to 10 times, for urgent referrals. After all the retries are exhausted, the BAW will mark the referral status as "declined", attach the reason for the errors encountered, and send the information back to the eReferral platform so the senders can review it for consideration of resubmission.

During phase 2 (March 2023 to December 2023), a new enhanced error handling logic was developed and deployed to retry all error codes and combine the BAW retries with the fax service's built-in retries to simplify the workflow. The fax service's built-in retries (every 5 min with total 5 attempts) were enabled to reduce the need for BAW intervention. BAW receives the last status code from the fax service and will trigger a retry during the 5-hour period if the status code is not "no errors." If the eFax is still not delivered within a 5-hour period, the eFax will be marked as "declined" and returned to the sender for further resubmission.

The retry logic for routine referrals has been updated to retry every 30 minutes during the 5-hour period. For urgent referrals, the BAW system will trigger a retry every 12 minutes.

Generic Referral Form Development

A working group led by the physician champions was created to discuss the referral forms and templates. Multiple review meetings were held with local clinicians to collect feedback, and a generic eFax referral form template was created and assigned to all eFax referral receivers. The generic form included the option to use a unique form if required by the receiving clinic, which could be included as an attachment[17].

Evaluation

Solution-generated data were collected from all 3 platforms, including the Business Automation Insights tool (IBM Corp), the eReferral solution, and the fax service portal. The solution-generated data included elements such as fax failure or success rates, page counts, sending and receiving clinician information, referral details like health service offering, referral processing details like status and time stamps, patient email inclusion, and appointment information (if included).

XSL•FO
RenderX

A combination of surveys and interviews collected qualitative data to understand the impact of the eReferral via eFax solution.

Surveys were sent out to all users who have sent or received at least 1 eFax between May 20, 2022 and September 30, 2022. Senders received the survey by email, and receivers received information on how to access the survey by fax. Due to low response rates, the top 10 receivers were contacted by phone to ask if they would participate in the survey. The Ontario Health Teams conducted focus group interviews to gather feedback from eFax senders and receivers. Patient survey data were monitored to see if the satisfaction rate was positively or negatively impacted. Focused interviews were conducted with the eReferral deployment team members to gather their experience onboarding the receivers who transitioned away from eFax to eReferral.

Ethical Considerations

This study does not require ethics approval as it is quality improvement in nature and uses both publicly available information and secondary analysis with nonidentifiable data as per the Tri-Council Policy Statement from the Government of Canada Panel on Research Ethics [18].

Results

eFax Receivers Information

A total of 224 receivers from Ontario Health Regions of Central, Toronto, and West were identified and enabled during the PoC. Of the total, 8 receivers (3.6%) are specialists practicing in academic institutions and hospital clinics, 11 receivers (4.9%) are from specialist group clinics, and the rest (91.5%) are independent specialists. As of December 26, 2023, 14 receivers (6.3%) converted to the eReferral platform (Table S1 in Multimedia Appendix 1). The receiver specialties are primarily in surgical pathways (Table S2 in Multimedia Appendix 1).

eFax Transaction Information

From May 2022 to December 2023 (as of December 26, 2023), a total of 4504 eFaxes were processed using the eReferral via the eFax platform for 4132 unique patients from 843 unique senders all over the province. Throughout the PoC, 3137 (69.6%) patients received notification emails about the referral details. In total, 875 (19.4%) appointment details were entered into the eReferral platform to support the wait 1 time calculation (Table 1). The receivers declined 158 (3.5%) eFaxes, and the sender entered the decline reason in the eReferral platform with the patient notification message.

[a]Appointment status as of December 26, 2023.

Fax Performance

The fax performance report is broken into 2 phases.

Phase 1

From May 20, 2022, to March 20, 2023, 1706 eFaxes were initiated and processed. As illustrated in Table 2, if the status code indicates “no errors,”, it means the eFax was successfully delivered. If there is a code other than “no errors,” the system counts it as a failure and will start the retry following the retry logic described in the method section. In total, 1658 eFaxes (97.2%) were sent successfully after 0 - 10 retries without manual resubmission, and 48 (2.8%) were marked as declined and required manual resubmission from the senders. Among the declined or failed eFaxes, 31 were resubmitted and delivered successfully. The other 17 eFaxes remained in the “declined” folder on the eReferral platform and required sending clinicians’ further attention or resubmission. During phase 1, senders submitted 1706 eFaxes, while BAW made 2712 delivery attempts due to the error codes encountered during the delivery process. Out of these, 1689 (99%) attempts successfully delivered the eFaxes, resulting in an average of 1.59 attempts per successful delivery. The overall fax failure rate was 37.7%. The most common error code is “line busy” (381/2712, 14%), followed by “unexpected disconnect”(224/2712, 8.3%).

XSL•FO
RenderX

Table . eFax status codes (May 2022-March 2023).

eFax status code	Count, n (%)
Success (no errors)	1689 (62.3)
Line busy	381 (14)
Unexpected disconnect	224 (8.3)
Invalid or missing number[a]	183 (6.7)
No answer	150 (5.5)
Error	63 (2.3)
Line failure	10 (0.4)
No dial tone	9 (0.3)
Incompatible fax machine	3 (0.1)
Total	2712 (100)

[a]This is a system-generated status code indicating there was no valid fax number recognized when communicating with the receiver's fax machine, although the fax numbers do exist.

Phase 2

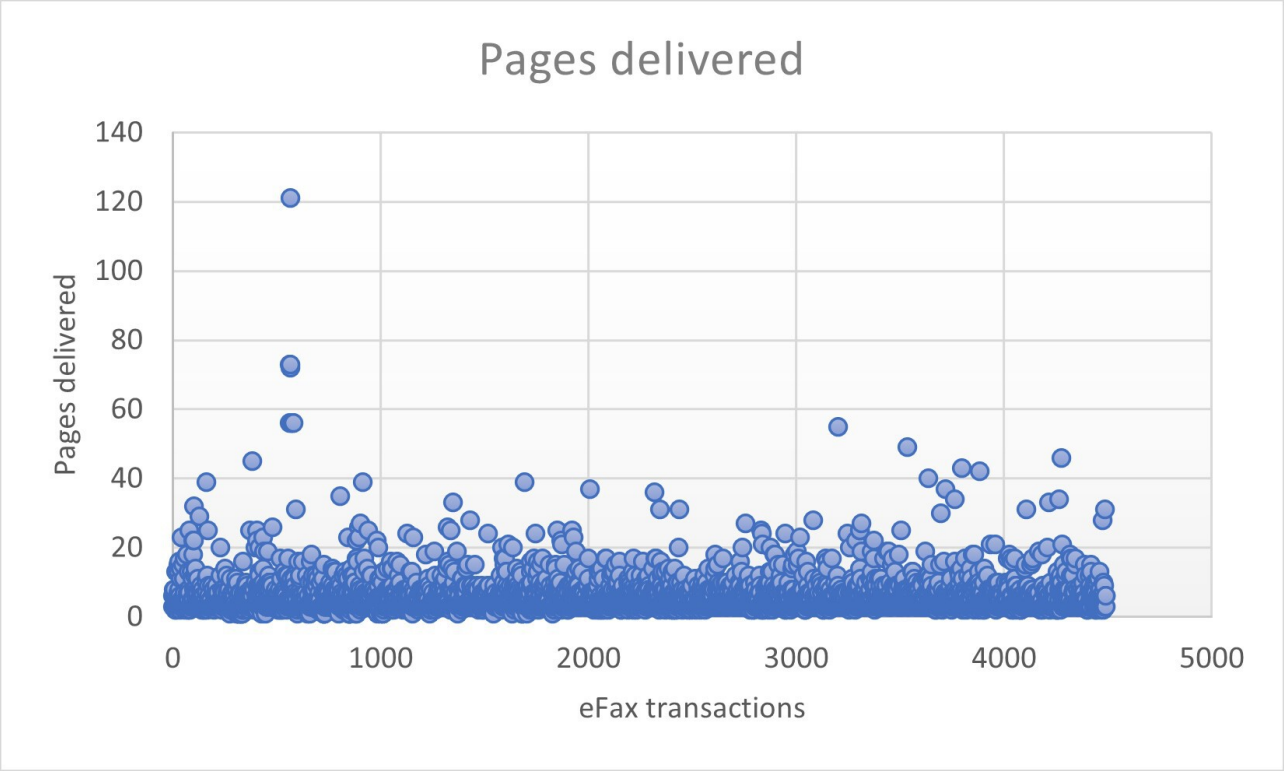
After March 20, 2023, the new retry logic was deployed to simplify the workflow. From March 21, 2023, to December 26, 2023, a total of 2806 eFaxes were initiated and processed. Of these, 2778 (99%) were successfully delivered to the receivers. Among the delivered eFaxes, 2770 (98.7%) were sent successfully without requiring resubmission, while 36 (1.3%) were marked as declined and required manual resubmission by the senders. Out of the declined eFaxes, 8 were resubmitted and delivered successfully. In contrast, the remaining 28 eFaxes stayed in the "declined" folder on the eReferral platform, needing further attention or resubmission by the sending clinicians.

As illustrated in Table 3, during phase 2, the BAW attempted to deliver 2806 eFaxes, making 3082 attempts in total. Out of these, 2778 (90.1%) attempts successfully delivered the eFaxes, resulting in an average of 1.11 attempts per successful delivery. Under the new retry logic, the fax failure rate, which is the number of times the BAW needs to trigger the retry, decreased to 9.9%. The top error during this period changed to "remote end did not answer" (107/3082, 3.5%), followed by "remote end busy" (89/3082, 2.9%).

Table . eFax status codes (March 2023- December 2023, post new retry logic deployment).

eFax status code	Count, n (%)
No errors	2778 (90.1)
Remote end did not answer	107 (3.5)
Remote end busy	89 (2.9)
Unexpected error	72 (2.3)
No fax was detected	25 (0.8)
Unable to negotiate fax session with remote terminal	7 (0.2)
An error occurred during the file rasterization process	2 (0.1)
Failure to confirm page reception by remote terminal	1 (0)
Remote terminal terminated the fax session unexpectedly	1 (0)
Total	3082 (100)

Referral Pages Count



The majority of eFaxes processed during the PoC were between 1 and 10 pages long (4115/4504, 91.4%), with the most common number of pages being 3 (1951/4504, 43.3%), and an overall average of 5.6 pages per eFax. A few outliners were observed, such as 32 eFaxes (0.7%) having more than 30 pages in the packages, with a maximum of 121 pages (Table 4 and Figure 3).

XSL•FO
RenderX

Table . eFax pages processed count.

Pages delivered	Transactions count, n (%)
1	38 (0.8)
2	151 (3.4)
3	1951 (43.3)
4	416 (9.2)
5	517 (11.5)
6	335 (7.4)
7	281 (6.2)
8	201 (4.5)
9	138 (3.1)
10	87 (1.9)
11 - 20	307 (6.8)
21 - 30	50 (1.1)
31+	32 (0.7)
Total	4504 (100)

Figure 3. eFax pages delivered scatter plot diagram.

Clinician and Patient Experience

During the PoC, the primary care sender survey was sent to 147 unique sending clinicians, and responses were received from 18 (12% response rate). Of the 18 responses, 72% (n=13) were satisfied with the eFax workflow, and 72% (n=13) felt the eFax has improved their ability to track or follow the referrals (Multimedia Appendix 2).

Multiple senders still noted that there were not enough receivers on the map. Furthermore, 4 out of the top 10 receiver clinics were able to answer a phone call from the PoC team, but none of them were aware of the eFax PoC work, although they did receive the most eFaxes during the PoC and multiple faxes were sent to their clinics. They did not notice the difference between the eFaxes and their regular fax-based referrals. The findings from the focus group interviews illustrated that the primary care senders felt that the new solution improved their workflow, helped them track the referral status, and that patients were more involved in the process. On the other hand, receivers noticed the eReferral platform logo, but there was no positive or negative

XSL•FO
RenderX

impact on their existing workflow. Patient experience data related explicitly to the eFax referrals processed over the evaluation period could not be segmented from the eReferral dataset. However, patient satisfaction rates remained consistently high during the PoC time, similar to those seen before the PoC was implemented, which could be an indicator that from patient perspective, satisfaction with the referrals made via eFax was high and similar to the satisfaction with eReferral. However, more data will need to be collected to prove this assumption. Feedback from interviews with 4 different deployment team members indicated that there was no significant difference in engaging the eFax receivers as compared with the routine flow when onboarding as an eReferral receiver.

Discussion

Study Rationale

Ontario has made several efforts to improve patient information sharing in clinical settings. The Ontario Medical Association has recommended transitioning from fax technology to the eReferral system to enhance efficiency and patient experience [5]. The Ontario eServices program was established to provide change management support and expedite the adoption of eReferral technology. Digital standards, such as the digital health information exchange framework and eReferral HL7 FHIR specifications, have been established to improve interoperability and secure information sharing [16]. In addition, the government has initiated a plan to phase out fax machines by 2028, promoting the adoption of digital communication alternatives [11]. While transitioning to eReferral offers numerous benefits, a significant barrier to its adoption is the requirement for both sending and receiving clinicians to be on the same platform for effective information sharing. The traditional onboarding process is time-consuming and labor-intensive. Therefore, an innovative method is essential to bridge the gap between digital eReferral senders and fax-based referral receivers, thereby expediting eReferral adoption.

This PoC study investigated the feasibility of using the BAW platform as a temporary solution to support eReferral adoption by connecting the eReferral platform and select fax services, enabling them on the eReferral platform as eFax receivers. This solution aimed to improve the sending clinicians' experience by expanding the available receiving clinicians on the platform, reducing workflow redundancy and leveraging the BAW platform to facilitate the senders' transition to eReferral. The solution is designed to provide a seamless user experience and can be used as a temporary bridging technology while the onboarding process is underway.

Clinician Experience Improvement

The solution design principle focused on minimizing the impact on the current workflow for both senders and receivers. Senders can reduce the need to maintain 2 separate workflows for eReferral and non-eReferral receivers, accessing an expanded list of eReferral receivers. eFax receivers can keep their current workflow with no alterations, as the referrals made to them look the same as fax referrals and do not require any workflow changes. The survey findings reflected that the clinicians felt the solution achieved the goals of the design principle; the senders were satisfied and they felt it improved their workflow while receivers' workflows were not interrupted and they noticed minimal changes throughout the PoC. The only behavioral change required was the need for senders to manually enter the appointment information back into the eReferral platform so that the patient can be notified through emails. Due to the extra tasks required, the entry percentage was 19.4% for the eFaxes booked (Table 1) with appointment dates documented in the eReferral platform, as compared with 57% of eReferrals within that same time period. As such, there is an opportunity for future enhancements to better capture the appointment information for eFaxes sent. Although this was lower than the automatic collection via the traditional eReferral workflow, this still presented an opportunity to calculate the wait time information so it can be published for eFax receivers, supporting clinician informed decision-making when initiating a referral for a patient.

In the current hybrid workflow, a sender needs to go back to the fax referral workflow if the receiver is not on the eReferral platform. Senders either need to maintain the duplicate workflow or prompt the receivers to adopt the eReferral technology, which usually takes a few weeks after the receivers agree to participate. By bridging the gap with the BAW platform, senders can ensure that they take advantage of the benefits of eReferral without experiencing any significant disruptions or delays. The enabled eReferral via eFax receivers list was expanded to allow eReferral to flow to the receivers unavailable through the traditional eReferral workflows. This solution allows for the eReferral platform to have more transactions flow through the solution reducing the need for eReferral users to maintain more than one referral pathway in order to provide care to their patient population. The more receivers are enabled through this solution, the less the need for senders to fax referrals, with the optimal goal to have senders send all referrals through a similar workflow, electronically.

Patient Experience Improvement

It is reported that eReferral can improve patients' experience with the referral process, and more specifically that 80% of patients felt they were more informed during the referral process [4]. The eReferral via eFax technology enables the patients to experience the benefits of eReferral even though the receivers were not onboarded to eReferral. Throughout the PoC, 3137 (69.6%) patients had their email included in their referral and received notification emails about the referral progress and updates. eFax specific patient experience survey results could not be segmented from the eReferral data set during the same period and therefore could not be assessed. However, the overall patient satisfaction rate remained consistently high throughout the PoC period.

This technology enables the option of patients being included in the communication loop on their referrals, regardless of whether the receiver of their referral is on fax or eReferral, as the solution enabled email notifications, keeping patients informed surrounding referral status updates, throughout the referral journey. This technology reduces the known issue for patients, as traditional fax referrals can never send an email notification to patient. This can contribute to fulfilling the

XSL•FO
RenderX

commitment of patient-centered care, even during this migration phase.

Cost Saving

The new bridging technology also helps to save costs. First, the technology reduces senders' need for paper usage, as they no longer need to print and fax documents. This can lead to significant cost savings. During the PoC, the average number of pages sent was 5.6 pages, translating to about 11 pages for both senders and receivers combined. It is reported that primary care clinicians send a median of 26 referrals per month [19]. The bridging technology can reduce half of that cost through the adoption of eFax and eventually remove all the paper costs when all the senders and receivers are onboarded to the eReferral platform. In addition, costs related to fax maintenance and printing ink would significantly be reduced over time.

Second, as part of the eReferral technology benefits, the eFax technology triggers email communication for patients, which can help avoid staff calls to the primary care clinic and reduce the time patients and clinical staff spend hunting down information [20-23]. This can lead to significant time savings for both patients and clinical staff. The new bridging technology is a step toward a more efficient and cost-effective health care system.

Third, the built-in BAW retry logic helped to reduce the human effort required to track the fax status and resend if the fax fails. The data from both phases illustrated in real practice when using the fax technology to communicate, the clinicians still need to manually monitor and resend the fax if the fax fails. Failures occurred in 37.7% (1023/2712) of transmissions without the fax service retry enabled (phase 1), compared with 9.9% (304/3082) with the retry enabled (phase 2). During phase 1, the BAW platform automatically retried failed eFax transactions to improve the delivery successful rate to 97.2%, avoided 37.5% (1017/2712) manual resubmission, and only 2.8% (48/1706) eFaxes required manual intervention. During phase 2, after the fax service automatic retry setting was enabled, the fax failure rate was reduced to 9.9%, which still required the built in BAW retry logic to automatically resend the failed eFaxes. The new updated retry logic improved the delivery success rate to 98.7% and further reduced the manual monitoring and resubmission to 1.3%.

There were improvements made in the eFax technology, and the BAW retry logic that reduced the failure rate but there is still increased value in transitioning to eReferral. eReferral requires extremely few retires, if any, due to the digital nature of the system. Unless there is a system or internet connectivity disruption, the eReferral will be delivered to the receiver immediately upon sending. There will be less failures and improved connectivity between the senders and receivers, limiting the risk of lost or failed referrals and decreasing the negative outcomes for the patient that might occur due to failures or lost transmissions.

System-Level Benefits

The eReferral via eFax platform provides system-level benefits that are only available using the eReferral platform and are otherwise unavailable in traditional nondigital workflows. In the fax referral workflow, transaction data are often recorded on paper, making tracking the referral flow from senders to receivers difficult. In addition, the wait times of receivers are generally not publicly available since it is challenging to track when and how appointments are booked. By leveraging the BAW platform, transactional data can be accessed earlier, and insights into the referral process can be gained that would otherwise be impossible. By providing visibility into the referral flow, the BAW platform can help optimize the referral workflows and improve the patient's experience. The BAW platform can also help identify bottlenecks in the referral process and take corrective action to improve the efficiency of the process. When the senders make referrals, essential factors like wait times and distance can be reviewed to support a more informative decision-making process, supporting better outcomes for patients.

The traditional onboarding process of an eReferral receiver includes multiple steps, such as the initiation of the discussion, referral form review and customization, EMR integration deployment, and end user training. Based on the learnings from the Ontario eServices Program, this process usually takes 6 - 8 weeks of change management support and sometimes even longer. Compared with the traditional receiver onboarding process, enabling the eFax workflow only includes receiver identification and validation, which usually takes a few minutes. The new process can drastically reduce the time required for the receiver onboarding process. The senders can start having a broader receiver list on the eReferral platform without disrupting the regular receiver onboarding process. It is very common for the senders to send referrals across regions (Table 1), and enabling the receivers through the proposed technology has the great potential to allow a large number of receivers enabled across the regions. Meaning, more receivers (as well as their wait times) will be visible on the eReferral platform to support the senders' decision making. It is beneficial to use relatively less effort to allow the maximum benefits that both senders and patients can start to experience. At the same time, the normal eReferral onboarding process can still take its own pace while increasing the number of receiving sites to support increased usage by those senders already within the eReferral network. The senders and their adoption of eReferral are currently restricted by the number of receivers present on the eReferral platform and users note that expanding the receiver list increases their usage of the tool. The lack of having a sufficient number of receivers that eReferrals can be sent to could lead to less opportunities to send eReferrals for clinicians and thus become a risk of discontinuing eReferral use by maintaining one workflow via faxing. This may lead to the need of re-engaging of clinicians to promote active use of eReferral, which in turn presents a monetary loss for the health system.

Future Work

There are more than 17,800 specialists registered in Ontario that might receive referrals [24]. With other hospital service providers and independent Health Facilities, Ontario's total possible medical referral receivers are likely more than 19,000. The Ontario eServices Program (previously System Coordinated Access) started to onboard clinicians to the eReferral platform in 2017. Using an approach that focused on both the onboarding

XSL•FO
RenderX

of primary care clinicians as well as receiving specialists, in just over 6 years, in Ontario 2000 receivers and 11000 senders were onboarded with change management supports, accounting for over 2 million referrals processed. There is still significant progress to be made. The eServices Program has been working on multiple strategies to increase the speed of adoption, such as exploring the use of the central intake models. A more innovative solution may be required to support eReferral adoption compared to the number of possible receivers.

The BAW platform could be used to bridge the gap between the fax system, that is widely used in the Canadian health care system, and the new eReferral systems, allowing minimal disruption of the sender's workflow while receivers using the fax system can take their pace being onboarded to the new platform. This approach presents a significant value for senders to adopt the eReferral solution, as it can provide access to a large number of referral receivers from the start of the initiative, which it can be difficult to attain through eReferral onboarding and change management initiatives alone. Senders may not wish to adopt the solution if it does not allow them access to a large number of receiving specialists, and specialists may not want to adopt the solution and introduce another workflow in their clinic as there may not be a sufficient number of primary care clinician senders onboarded on eReferral to send eReferrals to them. This presents a challenging dilemma on which to focus first, that can be minimized with the BAW platform allowing access to large number of receivers with minimal effort, presenting a favorable context for sender onboarding, followed by receivers.

The current evaluation demonstrates the effectiveness of expediting eReferral usage through the eReferral via eFax platform, while also highlighting the potential to further increase utilization by including additional receivers. In addition, there is a future opportunity to conduct a time-saving study to illustrate further the cost savings achieved by implementing this methodology.

Acknowledgments

The authors would like to thank Dr. Scott Laing for his efforts in creating the generic referral form to support the eReferral via eFax project. Our gratitude to Middlesex London Ontario Health Team (OHT), Northwestern Toronto OHT and Burlington OHT, for their support during the receiver identification and solution implementation. The authors appreciate Paul Sulker for his expertise and knowledge on digital health transformation strategies.

Funding for this project was provided by the Ontario Ministry of Health and Ontario Health. The funders were not involved in the study design, data collection, data analysis, or manuscript preparation, or in the decision to publish the results. The views expressed do not necessarily reflect those of the Province of Ontario.

Abstract

Background: We designed learning assignments for students to develop knowledge, skills, and professional attitudes about generative artificial intelligence (AI) in 2 different Master's level courses in health informatics. Our innovative approach assumed that the students had no technical background or experience in using generative AI tools.

Objective: This study aims to offer generalizable methods and experiences on integration and assessment of generative AI content into the higher education's health informatics curricula. The study's central driver is the preparation of graduate students with generative AI tools, skills, ethical discernment, and critical thinking capacities aligned with the rapidly shifting job-market requirements, independent of graduate students' backgrounds and technical expertise.

Methods: During the semester, students completed a pretest and posttest to assess knowledge about generative AI. Reflections explored their expectations and experiences using generative AI to complete their assignments and projects during the semester. Strong emphasis was placed on building skills and professional attitudes by using generative AI. Student engagement in behavioral, emotional, and cognitive domains was explored via detailed analysis of student reflections by faculty.

Results: Students at the University of Illinois Chicago increased their knowledge about generative AI from 81% to 93% through research of the basic generative AI concepts, as evidenced from outcomes of the open-book pre-and posttests given at the beginning and end of the capstone course. University of San Francisco students also improved from 77% to 80% by the end of the semester. Faculty analysis of student reflections upon completion of the course revealed primary interests in the essentials of generative AI, AI transformations to information and knowledge, and organizational changes influenced by AI adoption in the health care organizations, with ethics being a primary driver of students' interests and engagement.

Conclusions: Data from student reflections provided insight into generative AI skills that students developed and that health informatics programs can consider incorporating into their curricula. Building competencies in generative AI will prepare students for the 21st century workforce and enable them to build skills employers are seeking in the new digital health environment.

(JMIR Med Inform 2025;13:e76507) doi:10.2196/76507

KEYWORDS

generative artificial intelligence; student engagement; capstone experience; generative AI ethics; pedagogical innovation; generative AI; artificial intelligence; AI

Introduction

The current decade has seen much technological progress, but one of the most impactful and controversial areas has been generative artificial intelligence (AI). Since AI was first discussed in the 1950s [1] and especially since it exploded onto the technological scene in the 2020s, it has been a source of both wonder and fear about how it might help, hinder, and otherwise permanently alter human life. Today, in 2025, AI is a household term and a daily topic of news and discussion. It is easy to imagine a future in which AI is even more ubiquitous than it already is, but two of the most talked-about areas of AI incorporation today are education and health care.

AI use has both supporters and detractors in education and health care. Proponents of AI in education tout its potential to individualize learning experiences and thereby increase student engagement; they also advocate for AI's many supportive functions such as analyzing and managing various student data

XSL•FO
RenderX

and streamlining administrative tasks [2]. Meanwhile, AI has been used in health care since the development of a glaucoma consultation program at Rutgers University in 1976 [1]. Since then, exponential advancements in AI system design have led to a proliferation of clinical uses. ChatGPT, a popular tool developed by Open AI, for example, is being used in applications such as answering patient questions; assisting in clinical data analysis and decision making; responding to emergencies; assisting in practice management; and assisting in data management and other aspects of medical research [3].

Along with the advantages and benefits of generative AI's educational and health care applications, each presents specific challenges and raises questions. Detractors of generative AI in education cite the potential for students to cheat with AI. Some also warn against students leaning too heavily on AI to the diminishment of their own critical thinking abilities [2]. In both education and health care, questions arise about output accuracy plus such ethical issues as data privacy and output bias, among others.

Health informatics lies at the intersection of technology and health care, and as health informatics educators, we realize that whether we welcome it or fear it, AI will play a large role in our students' futures. In August of 2024, 28% of the US population aged 18 - 64 years reported using AI at work, with 1 in 9 using it on a daily basis [4]. More precisely, our students will graduate into a health care profession that is already regularly using AI, and they will work for employers who expect that they are well prepared to use it in their jobs. In fact, employers already prioritize AI competencies over prior non-AI experience [5] in the job candidates' profiles and believe AI skill sets are more important than many others [6]. Employers want graduates who can design, implement, and then manage needs-based AI systems; they also want graduates equipped with the specialized knowledge and skills to monitor and maintain those systems [7]. Job seekers need proficiency in using AI for data cleaning and management, performance management, and predictive analytics, among other knowledge and skills, to compete for positions in the most AI-advanced companies [8] Knowing that technology, including AI, advances vastly more quickly than official university curricula, we felt it imperative to transition some of our assignments so our students could begin using AI in a health informatics context now.

Let us first define what we mean by AI literacy. AI literacy is the critical ability to understand and mindfully interact with AI. It is more than just understanding how AI applications operate at a technical level. It is about understanding their functional level, benefits, challenges, and limitations [8]. AI literacy encompasses understanding the technical aspects of how it operates but also involves using critical thinking to assess its impact on humans, systems, society, and the environment [9]. AI literacy extends beyond a conceptual understanding of the theory behind it to also encompass the ability to ethically and responsibly use it to address problems, conduct research, or enhance productivity and growth. It is about actively using AI tools to solve problems and, in doing so, feeling engaged and interested in the process [10]. According to recent research, developing AI literacy involves 3 integrated skills: understanding fundamental AI concepts, evaluating the broader societal impacts of AI, and effectively using AI technologies in everyday contexts [9].

We represent two very distinct Master's in Health Informatics programs. University of Illinois Chicago (UIC) is an all-online, asynchronous program founded in 1999 and has been completely online since 2010. Many of our students are returning to school after time spent working; thus, they are older than traditional graduate students, and many already possess significant experience in health care, business, or technical fields. The UIC program has an overall focus on population-level social informatics and offers students courses and specialization options in data science, mHealth, and leadership.

University of San Francisco (USF) is a hybrid program. Students spend over half their time in-person on campus and the remainder of their time online. The USF's Master of Science in Digital Health Informatics is a young, dynamic program designed for small cohorts of approximately ≤20 students, offering personalized education through a combination of hybrid and in-person formats. Many students are recent bachelor's degree recipients with backgrounds in public health, business, health professions, nursing, medicine, and technology. The USF program focuses on data analytics, digital health, and clinical informatics, as well as offering course options in public health informatics, clinical leadership, and nursing informatics. The Master of Science in Digital Health Informatics program equips students with essential skills in health care, data science, and technology, emphasizing practical and project-based learning. Graduates typically pursue careers in hospitals, digital health startups, health care analytics companies, pharmaceutical companies, nonprofit organizations, and clinical research institutions, leveraging their specialized training to improve health care outcomes and informatics solutions.

In our endeavor to rapidly infuse AI into our curricula, we focused on 4 knowledge domains of AI competencies for health informatics education: essentials of AI; applications of AI to health informatics; AI transformations to information and knowledge; and organizational change and adoption of AI within the health care organization. We based these categories on prior work done in the development of a health data science concentration within a health informatics curriculum [11]. As part of that work, a list of 50 skills and competencies, categorized into 4 knowledge domains, was developed based on input from health informatics professionals and industry experts, health informatics faculty, and analysis of the health informatics labor market. We modeled the 4 knowledge domains of AI competencies for health informatics education on the original 4 knowledge domains for health data science. Within each of these AI competency categories, we listed knowledge, skills, and attitudes we believed our programs would need to provide for our students, leaving room for future ideas. Our new work builds on the previous work, incorporating generative AI skills and competencies into the same knowledge domains. The domains, skills, and competencies then enabled us to develop generative AI assignments.

During the fall 2024 semester, each program incorporated a generative AI assignment into a course, assessing each student's preliminary knowledge of AI, their knowledge of AI at the

XSL•FO
RenderX

conclusion of the assignment, and then each student's reflections on AI. UIC students participated in this study during BHIS 593, their capstone experience, the culminating course in the Master's in Health Informatics. This course requires students to research a topic of interest over the 16-week semester, delivering a paper or project at the end. The goal is for students to synthesize their learnings from their degree program and demonstrate competency as health informaticians.

USF students participated in this study during HS 633, *Exploring Generative AI Ethics: Intersection of Education and Health Ecosystems*, which they took approximately half-way through their master's program. This course, a hands-on workshop, incorporates the latest AI literature and tools and focuses on generative AI, AI ethics and governance concepts, AI applications, use cases, frameworks, and AI policies with special emphasis on health care. The goal is to equip students with foundational knowledge and practical skills in generative AI, preparing them to navigate the Silicon Valley tech ecosystem and the traditional health care landscape [11]. USF's generative AI Ethics course (HS 633) was conceived not as a technical deep dive into generative AI models and methods but as a framework-building course that foregrounds ethics and governance. This course was offered for the first time in Fall 2024 to coincide with this research study.

Our research questions for this multisite study were:

1. Did students learn (develop knowledge) about generative AI by doing the assignments?
2. Did students say they developed generative AI skills and professional attitudes by completing the assignments?

Methods

Design, Setting, and Participant Recruitment

This was a multisite study of assessment of assignments completed by Master of Health Informatics students at UIC and USF campuses in the fall of 2024. Across both sites, a total of 17 students participated in the research.

Ethical Considerations

The institutional review boards (IRB) of the UIC and USF approved this study under the exempt research determination under the UIC ID STUDY2024-0927 and USF's ID 2167. This was a multisite study of the assessment of assignments completed by Master of Health Informatics students at UIC and USF campuses in the fall of 2024. Across both sites, a total of 17 students participated in the research.

UIC Program

At UIC, the research was implemented in the online health informatics curricula for Biomedical Health Information Sciences in the capstone course required to complete the Master of Science in Health Informatics (MSHI) program. There were 10 (59%) participants from UIC. Students chose from the 4 areas of generative AI practice and developed their specific topics working with faculty to define the scope and deliverables for their project. Topics explored real-world questions of interest for which students developed a blueprint or prototype solution or a use case. Table 1 contains information about the 4 topic areas.

XSL•FO
RenderX

Table . Generative artificial intelligence (AI) topics.

Topics	Focusing questions	Description
Clinical uses	• How is generative AI being used to augment provider and clinician workflows? • What is the potential for generative AI to assist in improving health outcomes?	The information needed to make medical decisions (eg, medical history, laboratory and imaging results, and unstructured clinical notes) can be scattered across multiple records that exist in myriad formats and locations. Generative AI could be used to compile and organize this information—and put it into a format that is accessible and clinician-friendly—to accelerate and augment critical thinking. In addition, generative AI–enabled ambient documentation could pull information from clinician conversations and generate natural-sounding notes. Technology could also be trained to identify patterns that are too subtle for a human to recognize.
Patients or consumers	• What is the consumer or patient perspective on using generative AI for health care? • In what ways can generative AI improve the patient experience or patient engagement to manage chronic conditions?	Accurate real-time audio and SMS text messaging could be generated instantly, and in different languages, as frontline workers interact with people for health care and social services. Generative AI also could translate documents, websites, laws, regulations, and policies. Health advisories could make essential information accessible to a diverse population. Generative AI could also play a central role in optimizing and mitigating health and safety risks by generating worksite-specific safety training that replicates real-world settings and critical scenarios.
Frontline or first responders and public health, community social services use of AI	• How might generative AI be used to improve patient engagement (from the public health perspective)? • In what ways can generative AI be used to streamline emergency response in the field, urgent care, or the hospital emergency department?	Operational inefficiencies or limited capacity in the call center can translate to decreased customer satisfaction. Generative AI could help to create hyperpersonalized experiences with customers and patients. It could also help efficiently support customers and reduce call volume handled by associates. The technology might also assist human staff in generating responses to customer questions, insurance coverage, and other plan details. The customer service experience can have a direct impact on patient perception, even without any change in charged costs or appointment wait times.
Ethical use of generative AI	• How can organizations create an ethical framework for generative AI in health care (consider bias and hallucinations)? How can they use an ethical framework and still support team science and innovation? • What are the data governance policies and steps needed for quality control and validation of a generative AI model?	Set up an experiment that identifies and examines these issues. Recommendations for how organizations should proceed to build this into governance policies for generative AI and how it should be considered in building capabilities for using generative AI to increase AI literacy in the workforce.

All students enrolled in the course were given the opportunity to participate in the research at the beginning of the semester. Participation was voluntary, and students who chose not to do the research were still able to complete the course.

All data were collected via the Blackboard Learning Management System (Anthology Inc). In Blackboard, students completed a pretest to assess their baseline knowledge of generative AI. The same questions were given as a posttest at the end of the course to assess student learning. The purpose of the pre-post test was to determine any familiarity or knowledge of basic AI concepts. The questions were adapted from LinkedIn Learning courses available to UIC students. Questions were also generated by using ChatGPT with this prompt (Textbox 1):

XSL•FO
RenderX

Textbox 1. Prompt and sample questions

Provide 12 questions about generative AI that can be used as a pretest to assess health informatics graduate students' current understanding of generative AI. Make the questions multiple choice, true or false, and make 2 of them short answer. Provide the answer key and any citations that support the questions and that students can go to for more detailed information on the question.

Sample questions were as follows:

1. What is generative AI?

a. A type of AI that focuses on generating new data similar to existing data

b. A method for organizing data

c. A technique for visualizing data

d. A process for analyzing big data

Answer: a

2. Which of the following is a common application of generative AI in health care?

a. Predicting stock market trends

b. Generating synthetic medical images for training purposes

c. Analyzing social media trends

d. Managing electronic health records

Answer: b

3. Generative AI can only be used for creating images and text. True False

Answer: False

4. Describe one way generative AI can be used to improve health care outcomes.

In addition, students completed self-reflections about skills developed and their attitudes toward using generative AI and how they thought it might impact their health informatics work and careers. The reflections were also completed at the beginning and at the end of the semester (Table 2).

XSL•FO
RenderX

Table . Student reflections.

Reflection	Questions
Reflection 1	• As you look to the future, to what degree do you think generative AI[a] will be useful to your work in health informatics? To what degree do you think it might become part of your work process? • What generative AI skills do you think will be most valuable to you in your health informatics career? To what extent do you think generative AI has the potential to enhance your ability to do health informatics work or enhance your productivity? • What concerns do you have about using generative AI in your professional work? Are there aspects of generative AI that you anticipate might be problematic? What do you see as some of the drawbacks or challenges of generative AI use?
Reflection 2	• Describe how using generative AI for your capstone impacted your satisfaction with the work you produced. Do you think you were more or less satisfied with your results than you would have been without using generative AI? • Did you experience disappointment, worry, or anxiety about using generative AI to augment your capstone project? Describe any way in which using generative AI was disappointing or led to worry for you. Did this change over the course of the semester? • What impact did using generative AI have on your critical thinking as you worked on your capstone? Did it enhance your critical thinking? Did you experience reduced critical thinking due to overreliance on AI technology? • Overall, what was the best thing (the thing you enjoyed the most) about using generative AI for your capstone project? What was the worst thing (thing you enjoyed the least) about using generative AI for your capstone? • Please add any additional comments you would like to make about your learning experience and the use of generative AI.

[a]AI: artificial intelligence.

Student Assignments and Projects

For their projects, UIC students completed foundational readings. They conducted additional research exploring their chosen topic and developed prompts to use generative AI to assist in their research, brainstorm, and synthesize information. Students then drafted a 1-page description of the project scope and deliverables (final end-products) along with references that support their ideas for approval and feedback. For the rest of the semester, student projects were submitted at defined checkpoints during the semester and faculty provided feedback to guide the projects' development.

The generative AI projects in the capstone course were individualized, and faculty mentors guided students to do work that would explore their topic and use generative AI specifically for tasks such as brainstorming, research, policy and tool development, and prototype design. For example, for a project on *Ethical Implementation of Generative AI in Primary Care*, the student used a generative AI tool to generate a list of policies that the organization would need to revise or develop to establish organizational governance for using generative AI in primary care. This student then used generative AI to generate a list of roles and job titles that should be considered to participate in a subcommittee for generative AI governance. The student developed a governance structure diagram based on this research. Finally, a clinic-wide training program was developed with generative AI assistance that included basic awareness, role-based training, and ongoing support.

At USF, HS 633 introduces students to generative AI in digital health informatics through a scaffolded blend of technical foundations and applied ethical inquiry. Students are not expected to have prior coding or AI experience; instead, we begin with accessible primers on transformer architectures, natural language processing pipelines, and prompt engineering, grounding each concept in real-world health and ethical use cases. Alongside this, students engage in critical discussions about bias, transparency, and the societal impacts of large language models in clinical and public health contexts. Some of the classroom learning activities include conducting a literature review, interrogating deployment case studies, and prototyping generative AI–informed interventions and workflows.

The capstone assignment asks each student to design a credible generative AI deployment for a real-world clinical or operational problem—one that not only demonstrates feasibility but also foregrounds ethics, equity, and sustainability. Students articulate the problem space, quantify the opportunity, and craft a value-aligned solution that fits into existing health care infrastructures. The major components include market sizing using Total Addressable Market, Serviceable Available Market, and Serviceable Obtainable Market frameworks to assess reach and adoption pathways; ethical charter that explicitly addresses risks around privacy, bias, transparency, and Health Insurance

XSL•FO
RenderX

Portability and Accountability Act (HIPAA) compliance—with a mitigation plan for each dimension; evidence-based value proposition detailing projected outcomes, cost savings, and a 5-feature comparison against both legacy workflows and rival technologies; quality measurement strategy, including a 10-item Likert survey aligned to interoperability standards like Fast Healthcare Interoperability Resources, Health Level Seven International, or Systematized Nomenclature of Medicine—Clinical Terms; technical blueprint and product requirements document describing integration touchpoints with electronic medical records, mobile apps, and telehealth systems; scenario analysis exploring best- and worst-case implementation paths, resilience under public health emergencies, and tailored strategies for historically underserved populations; and scenario analysis exploring best- and worst-case implementation paths, resilience under public health emergencies, and tailored strategies for historically underserved populations.

- Technical blueprint and product requirements document describing integration touchpoints with electronic medical records, mobile apps, and telehealth systems
- Scenario analysis exploring best- and worst-case implementation paths, resilience under public health emergencies, and tailored strategies for historically underserved populations

Final deliverables include a written paper, a concise pitch deck, and a 10-minute oral defense. At the core of the assignment is an ethical charter that addresses privacy, bias, transparency, security, and HIPAA compliance, accompanied by a mitigation plan for each identified risk. Deliverables comprise a 15-to-20-page American Psychological Association–formatted concept paper, a 12 to 15 slide pitch deck with an appendix dossier, and a live scholarly defense. Assessment emphasizes the clarity of the argument, the rigor of ethical analysis, and practical feasibility, equipping graduates to articulate and implement responsible generative AI innovations in contemporary health informatics practice. Students are not only conversant in generative AI's capabilities and limits, but they are equipped to lead conversations at the intersection of innovation, governance, and health equity.

Knowledge was assessed using multiple choice and short answer tests. A pretest was given at the start of the semester, and an identical posttest was completed at the end of the semester. The tests were open book, administered on a learning management system with unlimited attempts. However, students were advised that these tests had no bearing on their grade for the course but were only for research purposes to get a baseline of what students know about generative AI.

An important part of this study was to identify skills that students will need in the workforce. AI skills and attitudes were identified using student reflections on student engagement topics exploring how they would use generative AI in their future career, concerns with using generative AI, and their satisfaction with the end product for their courses [12] At UIC, reflections were given at the beginning and end of the semester.

USF

The USF participants for this study are 7 out of 8 students who took the *Generative AI Ethics* course in the fall of 2024. A student absent from the initial survey distribution at the beginning of the fall 2024 semester was excluded from this study. The participants are in their second year of the Master's degree program in digital health informatics. USF students were introduced in class to the UIC+USF study and explained the purpose, inclusion criteria, privacy, and harm risk per the IRB-approved documentation. The 2 components of the survey (pre- or posttest and reflections) were explained to students. Students were told that participation was voluntary and would not affect their grades.

The initial USF pretest was distributed during in-person class time. Students were given ample time, up to 1 hour, to complete their surveys. Surveys identical to those used at UIC were delivered using the Google Survey app. The USF results were deidentified and remained in Google Cloud until the end of the semester. At the end of the semester, a second survey was administered via Google. This survey had 2 sections. The first section was identical to the pretest at the beginning of the semester. The additional second section was for the reflections of students who completed generative AI semester-long projects. USF's IRB approved the second test before distribution to the study participants.

The second USF survey, like the first, was distributed during in-person class time, their last before students presented their final semester-long *Generative AI Ethics* projects. Participants were given ample time, up to 1 hour in class to answer and reflect on their semester. The USF participants in the second survey were 6 out of 7 students who took the *Generative AI Ethics* course in the fall of 2024. The student absent from the initial study was excluded from the second survey for consistency. Once USF students completed the second survey, deidentified survey results were uploaded to UIC's secure box system for analysis.

The UIC capstone experience is a culmination of learning throughout the MSHI program. In their capstone, students personalize their project by pursuing an area of interest to them. This has the advantage of incorporating real-world scenarios and teaches critical divergent thinking and active learning. The USF's *Generative AI Ethics* course equips students with foundational AI knowledge that they can then bring into their work at the intersection of technology and health care. In both programs, assignment instructions included use of generative AI to support the creation of a final product.

Applying Established Frameworks

Prior to this study, we examined knowledge domains for health informatics education used in previous work by Krive and Isola [11] to create a data science concentration within the MSHI program, and we adapted the following knowledge domains for AI competencies:

1. Essentials of AI
2. Application of AI to health informatics
3. AI transformations to information and knowledge

XSL•FO
RenderX

4. Organizational change and adoption of AI within the health care organization

We developed a preliminary list of 33 competencies (Multimedia Appendix 1) as part of an effort to capture knowledge and skills employers would be looking for in health informatics graduates. The competencies came from multiple sources, including literature, job market analysis, input from industry experts, and our professional experience.

The current study was a first attempt to actually bring generative AI into the curriculum. We used Lo et al [12] as a framework to explore student reactions to using generative AI and also explore the 3 domains of students' emotional, cognitive, and behavioral engagement and disengagement with regards to ChatGPT use. Lo et al [13] conducted a systematic review that examined indicators of engagement and disengagement in each domain; they found that much remains to be researched about ChatGPT as a learning tool but that current research shows it leads to both beneficial and concerning emotional, cognitive, and behavioral outcomes [12].

The 23 pre-post test questions were foundational knowledge questions about generative AI that would be used in an introductory course assuming no prior knowledge of generative AI. The reflection prompts were based on Lo et al [13], exploring student engagement with generative AI. Using short answer prompts enabled us to gather qualitative data on student reactions to and experiences with using generative AI. Student responses were then examined against the list of AI competencies (Multimedia Appendix 1) for analysis in seeing what changes in knowledge, skills, and attitudes had taken place. These data can inform programs about key domains and concepts to consider when bringing generative AI into their curricula.

Main Measures

We collected data about developing student competencies in generative AI (knowledge, skills, and professional attitudes). The research questions were as follows:

1. Did students learn (develop knowledge) about generative AI by doing the assignments?

Regarding knowledge, students completed a pre- and posttest survey with 23 items each worth 1 point. Final scores for pretest and posttest were compared to see if students demonstrated higher scores on the posttest.

2. Did students say they developed generative AI skills and professional attitudes by completing the assignments?

Regarding skills and professional attitudes, student reflection data were collected.

Categorization of student responses was completed by 2 faculty members from UIC and 1 from USF. Each student response was evaluated to select the 1 primary element it contained and then was assigned to 1 competency category. Responses that were not related to the subject received no assignment (eg, "thank you" and "happy I took the class"). Due to this variety of the responses we received in terms of the content, depth, and clarity, we evaluated and counted all applicable student reflections across all domains. This method of evaluating all eligible responses (and excluding the most basic ones) from students explains why our numbers presented in the results exceed the number of students in the UIC and USF cohorts. Differences in faculty categorization were examined together in a work session to develop a consensus. To help us come to a consensus, we used some basic rules, that is, reflections related to ethics or accuracy were assigned to the AI transformations to the information and knowledge domain; and for longer student responses with multiple perspectives, raters assigned the knowledge domain that they agreed was the predominant domain. In most instances, such basic rules enabled us to arrive at an easy consensus with a higher degree of reliability, while in a smaller number of instances, we needed a larger discussion around the real meaning behind student reflections. The latter discussion component introduced minor variability to the qualitative outcomes of our work, since some student reflections were comprehensive and could be interpreted in more than one way.

Results

Pre-Post Test: Quantitative

Students completed a pretest survey of 23 multiple choice and short answer questions. Students demonstrated an improvement in knowledge from pretest to posttest in both courses, with UIC students improving from 81% to 93% at the end of the capstone course. USF students also improved from 77% to 80% by the end of the *Generative AI Ethics* course.

Reflections: Qualitative

To inform revisions to the preliminary list of skills, reflections were rated by 3 faculty members individually followed by a group review and consensus-building session using the knowledge domain definitions and preliminary list of skills (Multimedia Appendix 1). Results of the faculty classifications of student responses into the 4 knowledge domains are summarized in Table 3.

Discussion

Generative AI in Health Professions Education and Comparisons With Prior Work

The latest generative AI technologies are forging ahead and aim to change the ways students in health professions are educated [13] and medicine is practiced by emphasizing personalized care delivery based on individual characteristics of each patient derived from a wide variety of sources [14]. These technologies have already entered the medical field, whether educators are ready to address their impacts or not. So, despite faculty concerns over ethics, cheating in classrooms, and adjusting assignments to the current realities of the knowledge sources available to students, educators must ensure that generative AI is incorporated into the classroom. AI-assisted medical offices are already a reality for many health professions, and employers will have an expectation of this knowledge. The dialog about skills to be taught in the classroom, which is typically the combination of technical, medical application, and ethics perspectives [15] has already started via surveys of educators and practitioners [16], and analysis of the existing and upcoming programs and courses in clinical informatics [17].

Academic leadership in several fields of medicine has initiated inquiries into potential curriculum updates to embed AI, whether as a single course dedicated to AI or as modules embedded into existing courses to infuse AI competencies into curriculum [15,18, 19 20]. Research has explored how AI changes exam taking by comparing the performance of AI versus students on structured multiple-choice tests in medical specialties, subspecialties, and even a basic medical informatics course [20, 21]. These are interesting and valid perspectives for inquiry that will inevitably result in a solid basis for embedding generative AI into curricula and understanding how it will change classrooms of the future. However, educators have a more immediate task at hand—how do we prepare our graduates to face the realities of professional practice and employer expectations today, when the job market already requires generative AI skills? A productive dialogue among educators leading to future methods and models of education will not prepare current students for market realities. Therefore, while today's methodological efforts will result in strong foundations and understanding of the generative AI role in the classroom in the longer-term future, we assessed what could be done now to prepare our students for AI realities of the present day.

Principal Results

Differences between pre- and post-tests were noted, with higher scores achieved on the posttest. However, due to the open-book nature of the tests, performance increases may reflect the use of resources or research skills. The UIC capstone course is a research course, and students may have done research on the subject prior to and during the initial testing, despite instructions to use their existing knowledge for pretesting. Higher scores on the majority of the tests do indicate a high level of student engagement and interest in the subject, and if nothing else, these tests may have served to create interest in generative AI research among students. Because HS 633 is a novel course at USF that introduced students to generative AI concepts, emphasizing ethical frameworks rather than the technical details covered by the knowledge test, its content aligned less directly with the test domains, resulting in a smaller score gain for USF students.

A variety of perspectives was observed in the responses to the student reflection questions. Student reflection questions were developed to capture a broad range of potential reactions to using generative AI tools and asked about various dimensions of student engagement in behavioral, emotional, and cognitive domains as defined by Lo et al [13]. Students reported both satisfactions and dissatisfactions with using generative AI. Satisfaction can support creativity and innovation, build enthusiasm for the subject, and stimulate emergence in learning. This feature makes it worthwhile for educators to incorporate it into assignments. Responses included statements such as:

> *Excitement about building something and feeling empowered to build it. In the past, I would have "big" ideas that felt impossible to see through or felt like it was "just a dream." Now, with Generative AI, it's like building it can be a reality.*
>
> *Being able to experiment! I felt like keep on writing more and more prompts and keep reading the answers, that way I invested more time in the project and was able to dive in deeper in my project.*

Satisfactions were related to (1) the process of using generative AI, that is, "it helped me get the ball rolling with my project," and (2) satisfaction with results, that is, writing a paper with a

XSL•FO
RenderX

higher degree of confidence. There are several other observations of satisfaction, as follows:

- Generative AI helped to brainstorm and be more creative ("it brought the best side of me").
- Generative AI allowed me to focus on critical analysis while minimizing time spent on tedious tasks. It helped me to evaluate the analysis, improve the quality ("this is doing it better, not simply faster").
- Saved time and efficiency ("the point of using Generative AI is NOT just so you can do it faster, but it is so you can do it better-saving time allows you to do it better"). This must be explicitly conveyed to students and be part of the design of the assignments.
- Just to be trying it out ("as something new, it deserves exploration; it is a gift to be in on something exciting and new").

Dissatisfactions were more prominent early in the use of generative AI, and with experience and time, concerns decreased as students developed ways to cope with and address these concerns. Some examples of dissatisfaction were:

1. Using generative AI will be seen as cheating. Faculty should address this concern with students directly upfront, to clarify their requirements and expectations for using generative AI as a research tool in the learning process.
2. Concern about the impact on critical thinking, how to keep generative AI in the augmenting rather than dominating role. This was not a shared concern mentioned by most students, yet it is a legitimate and important one to bring up.
3. Lose originality of my work, become too reliant on generative AI. This is where students need help from faculty to understand the dividing line between using generative AI for background research versus becoming fully reliant on it to do the work and simply regurgitate and synthesize commonly available knowledge available on the Internet.
4. Inconsistency in generative AI's outputs, trusting the output. This aspect is good to address at the formative stage for building the initial generative AI skills, such as prompt engineering, or coming up with the right questions, so students feel empowered to use generative AI with confidence and to the best of their technical ability.
5. AI causing harm to patients, which is an ethical concern over the validity of the information provided by generative AI and the safety of patient information made available to generative AI.
6. Decreased anxiety, which is ultimately a positive factor in supporting student learning.

We also observed the following differences and similarities between UIC and USF student cohorts:

1. UIC students were more focused on clinical applications and process or ethics knowledge domains 2 and 3.
2. USF students were more focused on the technical and process or ethics knowledge domains 1 and 3.
3. Domain 3 (process or ethics) is the common domain of interest between students from both institutions.
4. USF students have a distinct technical focus, in addition to concerns over ethics and validity of the outcomes or information.
5. UIC students have a distinct clinical application and process focus, in addition to concerns over ethics and validity of the outcomes or information.

These differences could be attributed to variances in demographics and professional orientations of students, with USF graduates interested in positions in technology and consulting, and UIC students primarily expecting to be employed by health care providers, community, and public health organizations.

Student reflections were open format, allowing them to reflect on topics of their choice, and they frequently commented on more than one knowledge domain in a single response. This made reflections open to interpretation, and the evaluating faculty differed in how they categorized them. Using basic rules and the process of coming to a consensus among the three faculty who evaluated reflections helped us minimize the differences between faculty perceptions and normalize the numbers, leaving few differences between faculty classifications. We pursued this normalization process to be able to report on the top knowledge domains of interest by students together and on behalf of both USF and UIC institutions, as quantified by faculty based on which topics students focused on in their course reflections.

Table 3 shows the distribution of student responses across the domains. The data reveals that students responded more often to the topics of ethics, knowledge generation, organizational efficiency, and technology essentials, making them a high priority or area of interest or concern for our students. These interests consequently fall under domain knowledge 1 (essentials of generative AI) and domain knowledge 3 (ethics and knowledge of generative AI), followed closely by domain knowledge 4 (organizational change and efficiency). These choices by students indicate a high level of concern over proper technology selection and accuracy or appropriateness, compared to clinical applications, with organizational applicability and driving efficiencies as a secondary area of interest. A lower level of concern over application to health informatics is interesting, given that students are engaged in the informatics dialog and pursuing graduate education in health informatics. However, this might be explained by higher concern over proper selection and implementation of these technologies, which must be solved before medical applications are pursued with provider and patient safety in mind.

The competencies taught in accredited health informatics programs were examined recently by El-Gayar et al [22]. This group looked at the gaps in CAHIIM-accredited HI curricula competencies compared to skills/competencies employers are seeking in actual jobs posted on Indeed.com. They found that educational programs tended to focus on foundational competencies, while the job market demands were more focused on practical applications. Forty-six specific competencies were identified as gaps needed to prepare the health informatics workforce.

XSL•FO
RenderX

This analysis raises some questions about how well programs' stated competencies capture exactly what we are teaching in the courses at the assignment level. Competencies for the program may be defined more broadly and do not capture regular updates faculty make to courses and assignments. Programs may already be teaching some of the competencies El-Gayar et al [22] identify as gaps. However, this analysis also points out that areas of expectations between programs and employers may be disconnected. It is a useful starting point to inform further research and discussions about curriculum, with the goal of aligning Commission on Accreditation for Health Informatics and Health Information Management Education accreditation competencies, employers' needs with regards to AI and other knowledge and skills, and what instructors are actually teaching.

Limitations

This work was a collaboration between 2 distinctly different institutions of higher education in Illinois and California based on the common interest of swiftly bringing generative AI into the classroom. Our programs differ by student demographics, goals, and mode of education (hybrid vs online attendance). This allowed us to test various methods in 2 different academic environments. The cohorts of students were relatively small, and the courses were offered for one academic term, with plans for expanded offerings informed by these findings. We derive strengths by having two distinctly different academic environments and speed of innovation (summarizing results to quickly share with faculty colleagues around the world) and face limitations with our approach (small cohorts not allowing advanced statistical analysis, lack of identical course offerings, different student cohort characteristics). Demographic differences between our student cohorts introduce challenges to group comparisons and influence outcomes, making comparison methods potentially inaccurate. The knowledge test was foundational and may not equally reflect learning in both courses. Due to differences between the programs, we must be careful in making direct comparisons of outcomes between UIC and USF. However, these differences also represent opportunities to widen the scope of our work and generalize it to more schools and faculty looking to learn from our experience of introducing generative AI in various health informatics learning settings and to a wider audience of students. These factors could be excellent subjects of future scholarly inquiry.

Attrition of two UIC students at posttest indicates that they did not choose to complete the posttest. Even with a reminder message, those 2 students did not complete the posttest. We agree that this could also skew any reported improvement. One USF student was absent during the proctored, in-person posttest session and later requested to take the survey; this student's request was declined to avoid introducing uncontrolled variables. Both USF's before and after surveys were completed on students' laptops under faculty supervision, making it reasonable to assume they did not consult external materials while responding.

These 2 programs share a common goal of embedding generative AI into curriculum by teaching students to use cutting-edge technologies in a safe academic space where experimentation is both acceptable and highly encouraged. Thus, we demonstrate a practical approach for bringing generative AI into the classroom to prepare students to meet employer needs and the realities of future practice of health informatics. Therefore, implementation of generative AI assignments into the curriculum is beneficial to students immediately by building competencies, and it can inform faculty in the further development of the health informatics curriculum.

Our assessment of the students' first foray into generative AI was achieved through a combination of measurements and the subsequent dialog. Therefore, we report knowledge assessments as data and reflection responses in this discussion. More research would be necessary to study the introduction of additional assignments and measuring outcomes of their work, as generative AI curriculum continues to develop. However, this initial work to introduce practical generative AI curriculum in the graduate health informatics programs arms faculty with a glimpse into the potential successes and challenges of teaching generative AI and provides information on student perspectives which can further inform curriculum updates.

We did not formally calculate an interrater reliability statistic before engaging in dialog about the student reflections. Our faculty dialog and normalization of student reflections analyses to reach near-consensus on outcomes in identifying areas of interest and concern introduced a bias resulting from the ability to see each other's classifications by knowledge domain. This being an initial attempt to rapidly infuse AI into our curriculum and a first exploration of our qualitative findings, we contemplated this bias and ultimately decided that faculty dialog offered the greatest opportunity to arrive at usable results. We chose this bias as a better form of dialog to enhance usability and generalizability of our academic project and its reported outcomes. Still, we acknowledge that this bias may have influenced our results toward preestablished expectations and produced inaccurate overall ratings of student responses. Future research could include interrater reliability and blind ratings of student reflections to strengthen the rigor of the qualitative findings.

Implications of This Work on Building the Future Health Informatics Curriculum

Our success in implementing a modular approach to introducing generative AI within a larger health informatics context, and considering other AI implications in health care, has implications for health informatics education. Our work shows that health informatics programs may adopt generative AI competencies into their existing curriculum and then use them as guidelines in designing competency-building learning experiences in generative AI [7]. Existing courses can be modernized by rapidly infusing generative AI (and the overall AI) curriculum into the existing lectures and assignments, thus reducing the administrative overhead associated with a major effort to revamp the curriculum. Limited faculty time can be spent rapidly introducing generative AI to students as a hot-market skill. Major program revisions could also have implications for health informatics accreditation standards. To address employer desires for application skills, a next-level accreditation might ultimately require programs to go further into "doing" on the Miller Level

XSL•FO
RenderX

of Competence, perhaps reaching an 80 - 20 ratio of Doing to Knowing [22].

We propose rapid targeted curriculum updates as a productive form of delivering high-demand knowledge to students. Moreover, such a targeted approach may be the optimal route for all health professions educators to use when updating curriculum with generative AI content, due to limited resources within those programs which must also adhere to their accredited standards of education.

Taking a modular approach to updating the health informatics curriculum would also enable programs to assess the impacts of the changes from results received from small cohorts of students, because they would be able to introduce updates more rapidly and engage more students. Consequently, sample sizes for curriculum research studies would rise beyond a pilot in this initial study and provide deeper understanding of how generative AI, and AI education overall, impacts student satisfaction and preparedness to enter the job market upon graduation.

Implications of This Work on the Health Professions Curriculum

While we focused our efforts on the cohorts of health informatics students, our experiences and findings are generalizable to wider student populations preparing for careers in several health professions, particularly nursing, public health, pharmacy, and medicine, but also applicable to other health professions. The entire health care delivery system worldwide will be transformed by generative AI, and all programs are interested in updating their curriculum to include AI and prepare their students to face technological realities of the digital health care workplace. Some programs may decide to create entire courses dedicated to AI, while others will adopt modular approaches by embedding applicable AI topics across multiple courses. We presented 2 distinct ways of embedding generative AI content into the curriculum, so programs looking for a modular approach could learn from USF experience, while those looking for a deeper dive into the generative AI topic may learn from UIC experience of running a dedicated generative AI laboratory. Our 4 knowledge domains and skills-based approach to learning can be adopted by any health professions programs, while introducing clinical use cases and examples which are more unique to the subjects they teach.

Conclusions

Proliferation of generative AI and digital health education in the health professions curricula is in the early stages and is poised to grow into a large-scale academic debate about implementation, with consensus on the need to embed elements of AI expected from professional societies and graduate education commissions. Therefore, the need to define AI competencies and include them among educational outcomes stretches beyond informatics programs, expanding into the existing health professions [23] as well as emerging specialties such as Master of Digital Health [24,25]. There are ongoing attempts to define a clear set of skills to be taught in such digital health programs, with many of the grassroots efforts originating from experiences of the faculty [23]. By beginning with the AI competencies and designing learning experiences based on them, we innovatively addressed a gap in generative AI education in a health informatics program, tested 2 distinct cohorts of students in both online and hybrid content delivery programs, and shared our experiences and recommendations for rapidly infusing generative AI into the curriculum. These recommendations are generalizable to a wide variety of informatics and health professions education programs, to address the growing need for academia to update programs with the latest technology developments in clinical care and life sciences [24,25].

Acknowledgments

The authors want to thank their colleagues, students, and leadership at the University of Illinois Chicago (UIC) and the University of San Francisco (USF), whose enthusiasm for exploring generative AI in health informatics education inspired and enriched this work. All authors made significant contributions to the development of the methods described as well as the production and editing of this manuscript. MI, JK, and FS worked with students in the aforementioned courses at UIC and USF, collected student data and reflections, and organized student responses into spreadsheets for analysis. Additionally, JK and FS served as co-pricinpalprincipal investigators on the multi-institutional inistitutionalinstitutional review board submitted and approved to conduct this study.

At the time of the study, Freddie Seba served as Program Director and faculty in the MS in Digital Health Informatics program (School of Nursing and Health Professions) at the University of San Francisco (until May 2025). He was concurrently pursuing a Doctor of Education (EdD) degree in the School of Education at the University of San Francisco, with a dissertation focused on generative AI ethics and governance in higher education, which he successfully defended in December 2025.

Abstract

The administrative burden of clinical documentation contributes to health care practitioner burnout and diverts valuable time away from direct patient care. Ambient artificial intelligence (AI) scribes—also called “digital scribes” or “AI scribes”—are emerging as a promising solution, given their potential to automate clinical note generation and reduce clinician workload, and those specifically built on a large language model (LLM) are emerging as technologies for facilitating real-time clinical documentation tasks. This potentially transformative development has a foundation on longer-standing, AI-based transcription software, which uses automated speech recognition and/or natural language processing. Recent studies have highlighted the potential impact of ambient AI scribes on clinician well-being, workflow efficiency, documentation quality, user experience, and patient interaction. So far, limited evidence indicates that ambient AI scribes are associated with reduced clinician burnout, lower cognitive task load, and significant time savings in documentation, particularly in after-hours electronic health record (EHR) work. One consistently reported benefit is the improvement in the patient-physician interaction, as physicians feel more present during a clinical encounter. However, these benefits are counterbalanced by persisting concerns regarding the accuracy, consistency, language use, and style of AI-generated notes. Studies noting errors, omissions, or hallucinations caution that diligent clinician oversight is necessary. The user experience is also heterogeneous, with benefits varying by specialty and individual workflow. Further, there are concerns about ethical and legal issues, algorithmic bias, the potential for long-term “cognitive debt” from overreliance on AI, and even the potential loss of physician autonomy. Additional pragmatic concerns include security, privacy, integration, interoperability, user acceptance and training, and the cost-effectiveness of adoption at scale. Finally, limited studies describe adoption or evaluation of these technologies by nonphysician clinicians and health professionals. Although ambient AI scribes and AI-driven documentation technologies are promising as potentially practice-changing tools, there are many questions remaining. Key issues persist, including responsible deployment with the goal of ensuring that ambient AI scribes produce clinical documentation that supports more efficient, equitable, and patient-centered care. To advance our collective understanding and address key issues, *JMIR Medical Informatics* is launching a call for papers for a new section on “Ambient AI Scribes and AI-Driven Documentation Technologies.” As editors, we look forward to the opportunity to advance the science and understanding of these fields through publishing high-quality and rigorous scholarly work in this new section of *JMIR Medical Informatics*.

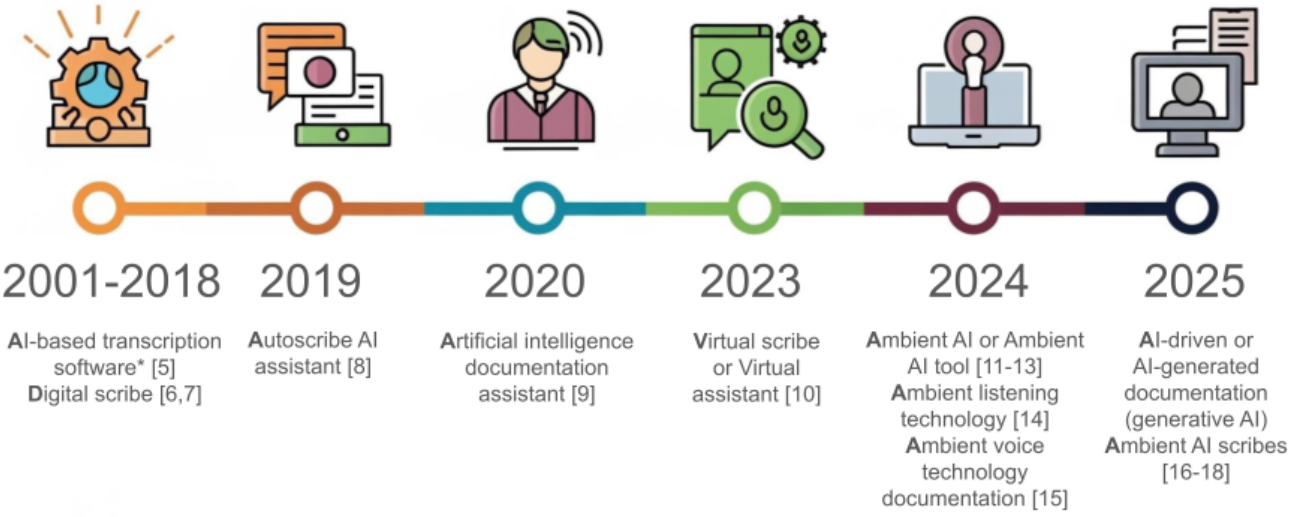
KEYWORDS

ambient AI scribe; digital scribe; AI scribe; virtual scribe; documentation assistant; ambient listening technology; AI assistant; artificial intelligence; clinical documentation; electronic health records; administrative burden

Introduction

Administrative burdens associated with widespread electronic health record (EHR) adoption are well documented, as are the associated clinician burnout and negative consequences for direct patient care and the patient experience. In response, ambient artificial intelligence (AI) scribes have emerged as promising transformative technologies. These technologies aim to listen to patient-practitioner conversations during clinic visits or other synchronous encounters; then, they generate clinical notes for health care practitioner review, revision, and approval. AI scribes are still in the early stages of adoption and evaluation; however, they are already seen operationally as powerful tools that could combat administrative burdens and clinician burnout. Accelerating efforts to install AI scribes in clinical practices are taking place, with a backdrop of long-standing efforts to automate all aspects of documentation workload, which typically includes clinical note generation and other forms of administrative burden, such as preparation of computerized order entry, prior authorization forms, and medical assessments



XSL•FO
RenderX

according to structured requirements, as well as coding and billing [1]. In this editorial, we describe our interpretations of the current landscape of ambient AI scribe technology and opportunities for further research and publication, as a part of the *JMIR Medical Informatics* call for papers on "Ambient AI Scribes and AI-Driven Documentation Technologies" [2].

Hype and Hope of Ambient AI Scribes

The conceptualization of ambient clinical documentation has evolved in parallel with the technology over the past several years (Figure 1), with a clear bibliometric trend of increasing research on the subject. There is no taxonomy of AI scribe technologies, although one appears to be emerging. One general operating definition of "digital scribe" is the use of automatic speech recognition technology or natural language processing to support clinical documentation [3]. Although the digital scribe concept does not explicitly exclude the use of AI technology, it is only in more recent years that AI has been explicitly labeled as a component of clinical documentation tools. One published literature review subdivided AI-driven documentation systems into generative AI and ambient AI, even if ambient AI may also make use of architecture comparable to that of generative AI [4].

Figure 1. Terminology used for artificial intelligence (AI)–based documentation technologies, based on published literature over the past decade [5-18]. *Transcription software in this period was based on different types of AI models, including one or more of the following: automated speech recognition, natural language processing, probabilistic graphical models (conditional random field), or logistic regression models [5].

Coiera et al [19] envisioned a progression through the following three stages: (1) human-led systems augmented by tools like dictation and templates (2); mixed-initiative systems where AI assists in converting conversations into summaries; and (3) computer-led systems that autonomously handle documentation, seeking human input only for exceptions. It would seem that in the last 3 years, health care organizations and physicians have been firmly shifting into the second stage, driven by the increasingly advanced technologies available and the salient burdens on clinical and patient care time, particularly in the United States, which has generated the largest proportion of published original research studies on ambient AI scribes. Professional societies and physician groups around the world are also engaged in the global dialogue on the role and promise of AI scribes in medical practice [20-22]. Ultimately, intelligent clinical environments, which capture and integrate data into the EHR, offer the promise of off-loading human-led documentation tasks onto a machine and doing so with an ability to integrate multimodal data from various sources, thereby freeing up the human in the loop and allowing them to focus cognitive efforts on clinical and medical decision-making. So far, initial evaluations have come from small-scale, short-term pilot studies [12,13] that often have volunteer participants who may be biased toward technology.

This excitement has no doubt been spurred by the introduction and widespread availability of large language models (LLMs), which, in terms of development and adoption, have rapidly outpaced other AI technologies underlying documentation support. Numerous industry products [1,23] and a rapidly increasing number of publications have emerged regarding ambient AI scribes using LLMs, even though other AI technologies for documentation tasks have been studied and used for the last 2 decades. A simple PubMed literature search on June 1, 2025, resulted in the retrieval of 940 potentially relevant articles published in the last 10 years (Multimedia Appendix 1); of the most relevant articles (ie, based on their titles), 7 have been published in 2025 (as of the search date) [12,13,17,18,23-25], 8 were published in 2024 [14,15,26-31], and 3 were published in 2023 [10,32,33]. Since this search, further studies have been published to guide ambient digital scribe evaluation [5,34]. During the course of preparing this editorial, authors identified more peer-reviewed literature on ambient AI scribes every few days. Undoubtedly, additional research is forthcoming as hype, hope, and operational needs coincide to drive further adoption.

Despite the rapidly growing published literature on ambient AI scribes and AI-driven documentation, we found that many still focus on similar objectives and evaluation metrics. Consequently, we felt that a call for papers on the topic in *JMIR Medical Informatics* would be valuable for collecting and publishing scientific studies and evidence-based perspectives on broader aspects of ambient AI scribe technologies. As a

XSL•FO
RenderX

starting point, we synthesized recent literature about their impact on clinical workflows, well-being, note quality, user experience, patient interaction, and medicolegal aspects, identifying opportunities for further investigation in this field (Multimedia Appendices 2-4).

Ambient AI Scribe Opportunities

The enthusiasm surrounding AI scribes is tempered by caution. An initial focus of evaluating the outputs of AI scribes is the quality of the note [4], which is assessed by using instruments such as the Physician Documentation Quality Instrument (PDQI-9) [35] or Sheffield Assessment Instrument for Letters (SAIL) [36]; usability is assessed with the NASA Task Load Index (NASA-TLX) [37], and burnout is assessed with various inventories. Results suggest that there is risk for hallucinations or fictitious information [4]. Other evaluations of stand-alone tools for audio recordings suggest potentially high rates of errors, including incorrect information, omissions, and hallucinations [11,29,38]. The high rates of omissions and hallucinations found in some studies underscore the need to evaluate for potential diagnostic errors or other long-term safety risks stemming from AI-generated content [4,10,29-32,39-42]. Others express caution regarding the potential for security risks or risks to medical decision-making in cases where LLMs can access and modify sensitive patient data [31]. Overviews on the topic emphasize the need for careful consideration of the ethical and practical integration of LLMs into clinical practice [1,4], cautioning about potential risks, such as automation bias, privacy concerns, and medicolegal implications [19].

Another major unexamined area is the impact on tangible clinical outcomes and patient safety. Although efficiency, time savings, and productivity are important, there are other measures that are also important. Assessments of note quality, accuracy, and impact on patient safety are essential; Gellert [32] raised a crucial point—there is currently no systematic data collection for evaluating the extent to which clinical errors or negative patient outcomes can be attributed to the use of medical scribes. More comprehensive evaluations of the safe and effective implementation of ambient AI scribe technologies (eg, along the dimensions of the seminal sociotechnological model of health information technology) are still lacking [43]. Additional diversity of clinical specialty applications, clinical disciplines, and practice settings also would be insightful. We identified studies published in a dermatology and urology journal but were unable to retrieve the full-text articles. One pediatrics application indicated positive outcomes during a digital AI scribe pilot in an outpatient pediatric setting [44]. Further, two conference proceeding papers described LLM applications in nursing documentation [27,45], as did a position paper from the Nursing and Artificial Intelligence Leadership Collaborative regarding multimodal LLM support for nursing documentation [46], although these stopped short of discussing AI scribe applications.

The most frequently mentioned gap is the limited study of patients' or caregivers' perspectives regarding AI scribes. Most studies rely on clinicians' perceptions of the patient experience, with very few directly capturing patient viewpoints. Additional research could directly measure patients' experiences, preferences, and patient-reported outcomes [4,47], especially given recent studies solely examining physicians' experiences of the patient-physician visit. Pelletier et al [44] incorporated the assessment of caregiver satisfaction in pediatrics, with the sole statistically significant finding being that caregivers' "provider-specific likelihood to recommend" was higher after the pilot digital scribe implementation. There are also potential patient benefits that remain unexplored. AI scribes may prove useful in providing rapid, patient-friendly visit summaries; outlining the diagnosis and management plan; scheduling appointments; and providing reasons to seek follow-up care [31]. They might also help to bridge communication gaps by highlighting misunderstandings or discrepancies between patient-reported details and those documented in EHRs [45].

The downstream effects of AI-generated notes on clinical communication and reasoning are also unknown. Note bloat—the well-established phenomenon of creating lengthy clinical documentation, which is most often attributed to the copy-paste phenomenon of digitizing documentation [42,48,49]—may also result from AI scribe use; whether large quantities of text redundancy change as a result of AI scribe use is unknown. With regard to clinical reasoning and cognition, as per preliminary evidence from nonmedical studies, such as a study by Kosmyna et al [50], one potential consequence of using generative AI for a writing task is "cognitive debt," where repeated reliance on AI for cognitive tasks may lead to the atrophy of critical thinking and memory skills. The study found that LLM use impaired memory recall and reduced the brain's neural engagement with the studied task. Although potentially dull, the documentation process may have beneficial effects on retention and memory. Learner experiences and consequences on expertise development, such as the formative diagnostic process for trainees, are underexplored [51].

Finally, system-level and economic outcomes require more rigorous investigation. Studies call for comprehensive cost-benefit analyses to justify the significant expense of AI scribe technologies [17]. On a broader scale, Gellert [32] cautioned about a largely unstudied systemic risk—the widespread adoption of scribes may decouple physicians from their EHRs and thereby impede the user-driven feedback necessary for the long-term evolution of next-generation clinical AI. In clinical informatics networks, user engagement in the co-design and development of AI scribes is seen as an essential component of the appropriate advancement and adoption of the technology, yet only one study has taken steps to pursue this ideal in evaluating primary care physician needs [9].

Conclusions

Ambient AI scribes, particularly with the widespread availability of LLMs, offer potential solutions to a previously difficult-to-bridge technological gap in clinical documentation. Although many health systems and physicians are welcoming this potentially practice-changing technology, there are many questions and areas that remain to be fully understood. Substantial clinical documentation also occurs adjacent to or outside of a clinical visit, and the applications of ambient AI

XSL•FO
RenderX

scribes and AI-driven documentation technologies in these areas are yet to be explored. Such areas involve various clinician types and health professionals, clinical settings, or community settings. As editors, we look forward to the opportunity to advance the science and understanding of these fields through publishing high-quality and rigorous scholarly work in the *JMIR Medical Informatics* call for papers on "Ambient AI Scribes and AI-Driven Documentation Technologies" [2].

Acknowledgments

Gemini 2.5 Pro and NotebookLM (Google) were used to help with article summarization and synthesis tasks during manuscript preparation. The prompts and responses used for the summarization tasks are available in Multimedia Appendices 2 and 3. Limited reuse of summarized text has been incorporated into portions of the manuscript, with manual editing and revisions by authors for clarity and style. Authors manually verified all claims and citations and are accountable for the content of this manuscript.

Abstract

Background: Amidst the COVID-19 pandemic, the proliferation of misinformation on social media, termed the “infodemic,” has complicated global health responses.

Objective: This study aims to identify research trends and information-making in the context of this challenge. This paper synthesizes key areas of scholarly investigation into the COVID-19 infodemic, both within China and internationally, to guide public health strategies and the management of public sentiment.

Methods: By employing a bibliometric approach, using CiteSpace software, we conducted a visual analysis of the global literature, covering a total of 1437 publications from the Web of Science and the China National Knowledge Infrastructure core databases between 2016 and 2025, focusing on publication trends, citation frequencies, and keyword clusters.

Results: After analysis, the results reveal distinct focal points in the research priorities of Chinese and international scholars. International studies often focus on machine learning and public psychology, while Chinese research tends to address information control and safeguarding. Common ground is found in the interest in preventing the spread of misinformation. While literature on COVID-19 abounds, cross-national systematic reviews are limited.

Conclusions: This paper fills this gap through a comparative bibliometric analysis, offering valuable insights for information management, media communication, and public administration, thus charting new directions for future research.

KEYWORDS

infodemic; bibliometrics; visualization; information spreading; social media; information governance

Introduction

The COVID-19 pandemic has precipitated unprecedented disruptions across global business, economic, and cultural landscapes. Simultaneously, the “infodemic” of misinformation has emerged as a formidable adversary, undermining efforts to restore social stability. Misinformation, typically characterized by the dissemination of unverified content via informal networks, lacks empirical substantiation and rational debate on matters of public importance [1,2]. The pandemic has expedited the spread of such misinformation, leading to widespread information anxiety and eroding public trust [3]. The infodemic’s narratives have been categorized into denial, remedial, and conspiracy discourses, progressively refining its conceptualization [4]. Recognizing its historical precedence, the World Health Organization in September 2020 emphasized the necessity to combat infodemics alongside the pandemic. In the digital age, social media platforms have become central to information dissemination, amplifying the reach and impact of misinformation during crises [5], thus underscoring the urgency of addressing the infodemic.

Scholarly efforts have begun to address the infodemic. The cornerstone of such a mechanism rests on robust government oversight and legal frameworks [6], suggesting a collaborative approach between administrative and legal interventions. Moreover, the varying quality among media practitioners, marked by a deficiency in humanistic values, critical thinking, and global outlook, exacerbates the infodemic. Furthermore, leveraging the strategic value of accurate information, particularly by tapping into public engagement on social media, can refine policy effectiveness. The psychological repercussions of the infodemic on COVID-19 patients are also a significant

XSL•FO
RenderX

concern, with the deluge of misinformation contributing to heightened uncertainty in treatment outcomes. Timely psychological interventions have been deemed essential, with studies revealing a correlation between increased social media exposure and psychological distress [7]. Additionally, the application of machine learning and algorithmic analysis in studying infodemic patterns provides empirical insights into topic evolution and public sentiment [8,9]. Advancements in deep learning models have enhanced the detection of misinformation [10], with integrated language and context analysis models proving effective in identifying false narratives [11]. These technological approaches could empower health care institutions to foster informed public discourse during health crises [12].

A review of the literature reveals that current research on the infodemic primarily focuses on the intersection of information governance and health care. While data science and machine learning offer innovative perspectives, comprehensive reviews synthesizing these areas are lacking.
