The spectrum of general improvements proposed by experts was broad. Two topics should be particularly underlined. First, in Germany, where the interviews took part, many hospitals are still not sufficiently digitally equipped to enable the use of AI-based CDSS. Given the combination of the high costs of digitalization and the financially strained situation of most hospitals in Germany, the burden cannot be borne by the hospitals alone. Therefore, more funded initiatives, such as the SmartHospital.NRW initiative are required. The aims of this initiative are, on the one hand, to develop a process model that can be transferred to hospitals with different levels of digitalization and, on the other hand, to develop and test innovative, AI-based applications for real-world use-case scenarios [39]. Second, interviewees expressed a high need for education, not only for medical professionals but also for the public. Even if the attitude toward AI is generally positive, there are also some concerns or perceptions. For example, consumers fear the dehumanization of the clinician-patient relationship, see a threat to shared decision-making involving patients, assume low trustworthiness of AI advice, and express uncertainty around fairness and equity in treatment allocation [40]. These concerns should be taken seriously and addressed through open and transparent communication about the opportunities and limitations of AI.

Implications

The suggested improvements should not be used without reflection because there is a risk that improvements will result in further problems. For example, experts suggested that information about the benefits of AI should be given. Thereby, on the one hand, acceptance could be improved, but on the other hand, there is a potential risk that users have too much confidence in the systems and are prone to blind trust, respectively automation bias. Another example is the critical attitude of users. Some experts stated that every decision proposed by the systems should be scrutinized. While, in general, this sounds comprehensible, it bears the risk that the systems might not lead to a significant reduction in workload and thus might become rejected by physicians.

Even if our research provides a variety of different improvement approaches, we did not search for an ideal match between existing problems and improvements. Even if, in some cases, the matching is obvious (eg, a lack of transparency could be reduced by providing decisive parameters), there are more complex interrelationships between some problems and solutions. For example, there is no direct solution for discrimination. Rather, various improvements should be considered here. An optimization of the system itself, the underlying database, or raising user awareness of the problem could be possible approaches. Therefore, further studies should be conducted to investigate such relationships.

The hierarchical framework from the study conducted by Kaiser et al [41] might serve as a starting point to identify the key implementation barriers and improvements that must be considered when introducing AI-based CDSS. According to this, the top level requires an effective implementation strategy (strategy level), the middle level should consider the capabilities and resources needed to successfully integrate an innovation, and finally the bottom level focuses on the implementation and change of processes and routines that are needed to accommodate the innovation.

Recommendations

On the basis of the results of this study, some actionable, solution-oriented recommendations can be proposed that could be practically implemented by stakeholders (Table 2). These recommendations are not specific to the German health care system, as they address cross-cutting challenges, such as data quality, user behavior, regulatory complexity, and clinical validation—issues that arise independently of national health care structures. Their relevance extends to many countries facing similar demands in safely and effectively integrating AI-based CDSS into routine care.

XSL•FO
RenderX

Table 2. Solution-oriented recommendations based on this study.

Number	Recommendation	Problem	Solution
1	Postmarket monitoring	AI[a]-based CDSS[b] should rely on the current state of medical knowledge. However, medical knowledge is subject to constant change, leading to concept and data drifts. Consequently, the original assumptions on which systems are based are no longer up to date, potentially reducing their accuracy or even their validity.	Regularly investigating the quality and reliability of AI-based systems might uncover drifts at an early stage. These verifications should not only be of a purely technical nature but also include actual use in care.[c]
2	Control mechanisms	A severe threat in using AI-based CDSS is automation bias.	Control mechanisms within the systems could be used to encourage users to think and avoid blindly implementing recommendations. One possible approach might be to provide system-based recommendations only after the assessment of the user.[d]
3	Comprehensive data pools	The quality and quantity of data are considered major problems. This may be particularly true for rare diseases.	Building supranational data pools can provide more data to train reliable AI-based CDSS. Common data standards, such as FHIR[e], can support standardization. However, the special characteristics of health care systems and patients, as well as other potential factors arguing against generalization, should also be considered.[f]
4	User training	The perception of AI differs greatly. The spectrum ranges from exaggerated fear to unrealistic expectations. There are problems in both directions: either the systems are rejected, or users trust them blindly.	By integrating AI into the curricula of medical faculties, future users can engage with the technology in a more informed way. This could provide the skills to critically engage with AI-based CDSS. Thus, both automation bias and irrational fear can be met at an early stage.
5	Implementation of studies	User acceptance presents a possible hurdle for the introduction of AI-based CDSS in health care. While studies could be convincing because of the proof of benefit, the implementation of studies is associated with high costs.	Studies are essential to establish the evidence of AI-based CDSS. While current studies mostly focus on the accuracy of the algorithms (eg, recall and precision), future studies should also examine the actual benefits of their use in a clinical setting. Preferably, this should be done with RCT[g] studies. However, as such studies are costly, they should be financed by national or supranational funds. Such an approach would enable universities and smaller independent institutes, in particular, to conduct research in this field.
6	Harmonization of approval procedures	The approval of medical systems is already associated with high effort, including outside Europe. This affects not only developers but also certifying bodies.	Future legislation (eg, the AI Act in Europe) should consider and harmonize existing regulations. This could significantly reduce workload and documentation burden. Possible areas include postmarket surveillance, risk assessment, safety and performance requirements, and technical documentation.

[a]AI: artificial intelligence.

[b]CDSS: clinical decision support systems.

[c]The European Union is introducing such postmarketing monitoring for high-risk products as part of the AI Act. The actual implementation is planned for February 2026.

[d]The actual design requires further research to prevent users from using "dummy inputs" to get recommendations. A cooperative process between the user and AI might be a promising approach.

[e]FHIR: Fast Healthcare Interoperability Resources.

[f]The European Union recently decided that such a data space ("the European Health Data Space") will be created for the member states.

[g]RCT: randomized controlled trial.

While these recommendations appear well-founded and may offer valuable insights for optimizing AI-based CDSS and their integration into health care, it is important to emphasize that they are derived from a qualitative, exploratory approach. Therefore, they should be considered preliminary and require further investigation and validation. This will be addressed in the context of our overarching research project "KI@work" [14]. On the basis of the results of these expert interviews, supplemented by a literature review, focus groups with physicians and nursing staff, a quantitative questionnaire survey and workshops with experts, and well-founded recommendations for action are to be developed that are more binding in nature.

Limitations

Some limitations of our research should be mentioned. First, we conducted a qualitative interview study. Therefore, the results are more exploratory than deterministic. In addition, the attitudes, values, and experiences of the interviewers may have

XSL•FO
RenderX

impacted the final results. To minimize this risk, only a structuring and no further interpretation of the results was carried out. In addition, we have presented the methodological approach as transparently as possible and provided data (eg, appropriate citations in the paper and systematization of the statements in Multimedia Appendix 4) to substantiate the results. In our study, we focused on the German health care sector. Therefore, we only interviewed German experts. This might have an impact on the results for two reasons. First, some of the improvements identified could be specific to the German health care system. While, from our view, only a few improvements are affected by this, one should always scrutinize whether the individual identified improvements are transferable to other health care systems. Second, in the context of this publication, it was necessary to translate the individual statements into English. To avoid translation errors, we conducted quality checks of the citations within the consortium to guarantee that the initial meaning was not distorted.

Rather than providing an exhaustive list of all possible improvements, the objective of this study was to offer comprehensive perspectives. Therefore, it is unlikely that data saturation was fully achieved for each expert group. More specialized research should focus on specific groups, such as caregivers, patients, medical product consultants, experts in ethics and law, or manufacturers of AI-based CDSS, to identify conclusive lists of group-specific problems and improvements. Furthermore, the present findings should be further investigated and elaborated on in more detailed studies focusing on individual improvement categories or individual starting points for improvements, as well as in quantitative studies. A further practical step would be to systematically map implementation studies from the existing literature and examine them for successful improvement strategies.

Because AI-based CDSS are relatively new, there is no conclusive knowledge about underlying problems and barriers. Consequently, new problems and barriers could occur and require further solutions. Therefore, both the problems and barriers, as well as the improvements, should be continuously investigated and developed.

Conclusions

There is evidence that AI-based CDSS have the potential to improve patient outcomes and optimize efficiency in health care. However, to fully realize these benefits and to guarantee safety for patients and a good user experience for medical staff, it is essential to urgently address the existing barriers and unresolved challenges. Possible strategies for improvement should address the systems, the users, and the environment in which they are used. Experts saw concrete points of contact in “technology,” “data,” “user,” “studies,” “law,” and “general.” These should serve as a starting point for further, detailed research.

Acknowledgments

This study is part of a larger research project (User-Oriented Requirements for Artificial Intelligence–Based Clinical Decision Support Systems [KI@work]; project 01VSF22050). The project is funded by the German Federal Joint Committee. The funders did not influence the study design, the conduct of the study, or the decision to publish or prepare the manuscript. The authors acknowledge support from the Open Access Publication Fund of the University of Duisburg-Essen.

Generative AI tools (ChatGPT and DeepL) were used exclusively to improve the linguistic clarity and comprehensibility of the manuscript.

Data Availability

With the exception of the full interview transcripts and the wording of all key statements, all relevant data can be found in the paper or in Multimedia Appendix 4. The complete transcripts, even in pseudonymized form, are not publicly available owing to data protection considerations. However, selected relevant passages are quoted verbatim in the manuscript to ensure transparency.

Authors' Contributions

All authors contributed to the conceptualization of the study and to acquiring funding. GDG, NB, and PR were responsible for data curation and investigation. GDG conducted the main data analysis. Project administration was managed by JW and NB. Methodology was developed by all authors. Resources were provided by the Institute of Health Care Management and Research at the University of Duisburg-Essen. NB supervised the project. Validation was carried out by NB and PR. GDG drafted the original manuscript, and all authors participated in the review and editing of the final version.

Abstract

Background: Recent advances in artificial intelligence (AI) have contributed to improved predictive modeling in health care, particularly in oncology. Traditional methods often rely on structured tabular data, but these approaches can struggle to capture complex interactions among clinical variables. Image generator for health tabular data (IGHT) transform tabular electronic medical record (EMR) data into structured 2D image matrices, enabling the use of powerful computer vision–based deep learning models. This approach offers a novel baseline for survival prediction in colorectal cancer by leveraging spatial encoding of clinical features, potentially enhancing prognostic accuracy and interpretability.

Objective: This study aimed to develop and evaluate a deep learning model using EMR data to predict 5-year overall survival in patients with colorectal cancer and to examine the clinical interpretability of model predictions using explainable artificial intelligence (XAI) techniques.

Methods: Anonymized EMR data of 3321 patients at the Gil Medical Center were analyzed. The dataset included demographic details, tumor characteristics, laboratory values, treatment modalities, and follow-up outcomes. Clinical variables were converted into 2D image matrices using the IGHT. Patients were stratified into colon and rectal cancer groups to account for biological and prognostic differences. Three models were developed and compared: a conventional artificial neural network (ANN), a basic convolutional neural network (CNN), and a transfer learning–based Visual Geometry Group (VGG)16 model. Model performance was assessed using accuracy, sensitivity, specificity, precision, and F1-scores. To interpret model decisions, gradient-weighted class activation mapping (Grad-CAM) was applied to visualize regions of the input images that contributed most to predictions, enabling identification of key prognostic features.

Results: Among the tested models, VGG16 exhibited superior predictive performance, achieving an accuracy of 78.44% for colon cancer and 74.83% for rectal cancer. It showed notably high specificity (89.55% for colon cancer and 87.9% for rectal cancer), indicating strong reliability in correctly identifying patients likely to survive beyond 5 years. Compared to ANN and CNN models, VGG16 achieved a better balance between sensitivity and specificity, demonstrating robustness in the presence of moderate class imbalance within the dataset. Grad-CAM visualization highlighted clinically relevant features (eg, age, gender, smoking history, American Society of Anesthesiologists physical status classification (ASA) grade, liver disease, pulmonary disease, and initial carcinoembryonic antigen [CEA] levels). Conversely, the CNN model yielded lower overall accuracy and low specificity, which limits its immediate applicability in clinical settings.

RenderX

Conclusions: The proposed IGHT-based deep learning model, particularly leveraging the VGG16 architecture, demonstrates promising accuracy and interpretability in predicting 5-year overall survival in patients with colorectal cancer. Its capability to effectively stratify patients into risk categories with balanced sensitivity and specificity underscores its potential utility as a clinical decision support system (CDSS) tool. Future studies incorporating external validation with multicenter cohorts and prospective designs are necessary to establish generalizability and clinical integration feasibility.

Introduction

Artificial intelligence (AI) has evolved, becoming integral to various fields, including health care, bioscience, and medical diagnostics. In the medical field, AI applications range from disease detection to drug prescription optimization [1]. Health care providers use AI for patient disease prediction and data anonymization, addressing the growing health care costs associated with increasing chronic diseases and life expectancy [2]. Recent studies have increasingly applied advanced machine learning and explainable artificial intelligence (XAI) methods to improve disease survival prediction. For instance, Yang et al [3] and Yau et al [4] have demonstrated effective survival modeling using time-to-event algorithms and survival tree analyses, respectively. Huang et al [5] applied explainable machine learning approaches to uncover important risk factors across major cancers, including colorectal cancer. These studies highlight the growing trend and validate the clinical relevance of AI-driven survival prediction.

Recent advances in medical imaging technology have enabled sophisticated tumor image analysis using AI models [6]. In the field of medical image analysis, active research is being conducted using convolutional neural network (CNN) models to predict responses to treatment in patients with colorectal cancer. Yang et al [7] built a model to evaluate the risk of recurrence and metastasis by applying deep learning technology to the data of patients with benign breast cancer. Full hematoxylin and eosin (H&E)-stained images were obtained from surgical specimens of patients with breast cancer, and a CNN was applied to them. The model used in the study achieved an area under the curve (AUC) of 0.76 and showed the potential for evaluating the risk of recurrence and metastasis in patients with human epidermal growth factor receptor 2 (HER2)-positive breast cancer. Althammer et al [8] conducted a study on image analysis to predict the response to durvalumab therapy targeting the programmed cell death-1/programmed cell death ligand-1 (PD1/PD-L1) pathway in patients with non–small cell lung cancer. The results showed that the median overall survival in patients receiving durvalumab was 21 months for those positive for the CD8xPD-L1 signature and 7.8 months for those negative (P<.001).

In particular, the image-guided tabular data (IGTD) method proposed by Zhu et al [9] showed that arranging numerical variables into a 2D matrix format can improve model performance by enabling CNNs to capture local feature interactions. Inspired by this approach, we developed an image generator for health tabular data (IGHT) encoding method tailored to our clinical dataset, converting 25 normalized features into a 5×5 image matrix. This fixed spatial layout allows the model to process tabular information through CNN-based architectures, facilitating the use of transfer learning and potentially enhancing predictive performance. There has been growing interest in transforming structured tabular data into image representations to leverage the power of CNNs in domains traditionally dominated by machine learning. For example, Lara-Abelenda et al [10] introduced low mixed image-guided tabular data IGTD (LM-IGTD), an enhanced pipeline based on the IGTD approach. Their method applies noise-based augmentation and preserves explicit feature-to-pixel mappings, allowing for the integration of post hoc explanation techniques, such as gradient-weighted class activation mapping (Grad-CAM) and saliency maps for better interpretability. These developments reflect a broader trend toward interpretable and robust AI in clinical settings.

In this study, we built upon this direction by applying a novel tabular-to-image transformation method, IGHT, which converts structured electronic medical record (EMR) features(tabular data) into images, enabling deep CNN architectures to extract spatial patterns for survival prediction in patients with colorectal cancer.

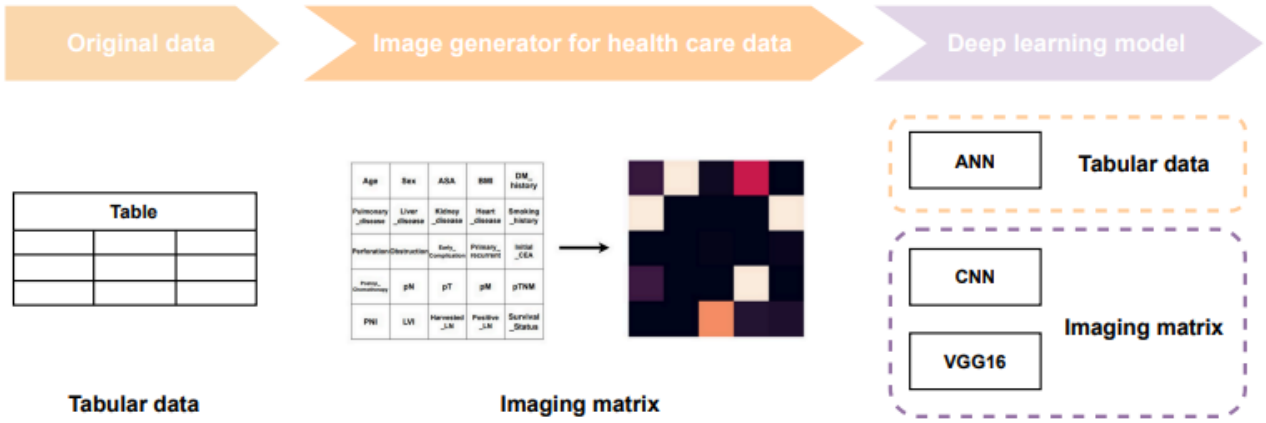
Building upon these developments, Sharma et al [11] introduced DeepInsight, one of the pioneering frameworks that enables CNNs to process tabular data by converting them into image representations. This method uses dimensionality reduction techniques, such as t-distributed stochastic neighbor embedding (t-SNE) or principal component analysis (PCA), to spatially arrange high-dimensional features in a 2D grid, while preserving interfeature relationships. Such transformations allow CNNs to extract local and global patterns from structured data—patterns that may be overlooked by traditional machine learning approaches. This early work demonstrated the potential of tabular-to-image conversion to enhance classification performance across domains, and it has laid the foundation for subsequent advances, including this study.

AI has shown strong performance in learning from existing patient information using big data and in predicting or recommending outcomes desired by clinicians, who are key decision makers. In particular, the clinical decision support system (CDSS), an AI system that helps clinicians make decisions, has attracted considerable attention. The CDSS trains an AI model with existing medical knowledge and patient data to predict outcomes and make recommendations for clinicians

XSL•FO
RenderX

based on new patient data [12]. Watson for Oncology (WFO), a representative CDSS, was developed by IBM Corp and is a system that analyzes more than 15 million pages of medical documents, 300 medical journals, and 200 guidelines [13]. The WFO was designed to recommend treatment options to oncologists and was first introduced and used in 2016 at the Gil Medical Center in Korea [14]. Although the WFO at the Gil Medical Center helped inform treatment decisions, it could not reflect regional characteristics due to differences in insurance coverage and medical costs [15].

Lee et al [16] compared the treatment recommendations generated by the WFO with the actual treatment received by 656 patients with stage 2, 3, and 4 colon cancer between 2009 and 2016 to determine the concordance rate. The results showed that the agreement rate between the WFO and the Gil Medical Center's treatment recommendations was low, at only 48.9%. Since the WFO was trained using data from Americans patients, the prescription recommendations did not match well with those for Korean patients. In addition, it was noted that the treatment recommendations under the Korean insurance system and those under the American insurance system differed, resulting in a low concordance rate with actual treatment practices. Therefore, it is important to establish a CDSS using Korean patient data.



To build a CDSS, many studies have been conducted to enhance the performance of medical data–based AI models. Park et al [17] used an oversampling technique to address data imbalance and predicted colorectal cancer chemotherapy based on data from the Gil Medical Center in Korea using a deep learning model. Kwon et al [18] used machine learning models, such as the gradient boosted model, the distributed random forest, the generalized linear model, and the deep neural network, for a stacking ensemble. They diagnosed breast cancer using the best-performing model in the stacking ensemble. Oh et al [19] classified colorectal cancer chemotherapy regimens using machine learning models: k-nearest neighbor (kNN), support vector machine (SVM), decision tree, and light gradient boosting machine (LightGBM), and compared the results across multiple models.

Colorectal cancer is the second-most common malignancy in South Korea [20] and the second leading cause of cancer-related mortality worldwide [21]. Surgery is the primary treatment for colon and rectal cancer [22], but due to its high postsurgical mortality rate, ongoing prognosis management is essential. Therefore, research aimed at extending patient survival is being conducted from various perspectives, including the prediction of overall survival, disease-free survival, and recurrence. Overall survival and disease-free survival periods are key indicators for assessing a patient's prognosis, and to extend life expectancy, further research is needed to evaluate prognosis based on patient-specific factors.

Studies on predicting the survival period have mainly been conducted in the clinical field using statistical techniques, such as the Kaplan-Meier method [23] and Cox's proportional hazards model [24]. Yeom et al [25] identified prognostic factors that increase the risk of death in patients with terminal cancer and predicted the survival period according to the number of these prognostic factors. Using the Kaplan-Meier method and the log-rank test, they investigated whether there were differences in the survival period according to clinical variables. Using Cox's proportional hazards model, they identified variables that increase the risk of death among clinical variables and used them as prognostic factors, which were then incorporated into the Weibull proportional hazards function model to predict survival periods.

Figure 1 presents an overview of the pipeline of this study. In this study, we aimed to develop and evaluate deep learning–based models for predicting survival using data from patients with colorectal cancer. This study used image data by converting tabular electronic medical record (EMR) data received from the health care system into image data to enhance their utility. These deep learning models are expected to improve the performance of predicting the prognosis of patients with colorectal cancer by effectively using EMR data.

Methods

Dataset

In this study, EMR data were retrospectively collected from the Gil Medical Center, a tertiary referral hospital in Incheon, South Korea. A total of 3321 patients who underwent elective surgery with curative intent for colorectal cancer between 2004 and 2018 were included. The dataset was constructed through iterative chart review conducted by colorectal cancer clinicians.

Demographics are patient characteristics that can typically be known without the need for surgery. These included basic information, such as age, sex, BMI, and the patient status, as classified by the American Society of Anesthesiologists physical status classification (ASA): "DM_history" refers to a history of diabetes mellitus; "Pulmonary_disease," a history of lung disease; "Liver_disease," a history of liver disease; and "Kidney_disease," a history of kidney disease.

Perioperative clinical features included information about each patient gathered before and after surgery: "Initial CEA" and "Initial Hb" represent the first blood tests performed at the time of cancer diagnosis (serum carcinoembryonic antigen [CEA] and serum hemoglobin [Hb] levels, respectively), "Transfusion_op" indicates whether a blood transfusion was performed during surgery; "Early_complication" is defined as a case of complications occurring within 30 days after surgery, and "Postop_Chemotherapy" indicates whether chemotherapy was used after surgery.

Histopathologic features can be known after a biopsy of the patient's tumor following surgery. Here, "pTNM" is a variable that integrates the pathological tumor, node, metastasis (TNM) stage and is classified into stages 1, 2, 3, and 4. The TNM stage classification was based on the *AJCC Cancer Staging Manual, Eighth Edition*. "pT" (pathological primary tumor) includes Tis, T1, T2, T3, or T4 (T4a, T4b) as the T stage; "pN" (pathological regional lymph node) includes N0, N1 (N1a, N1b, N1c), or N2 (N2a, N2b) as the N stage; and "pM" (pathological distant metastasis) includes M1 as the M stage.

In the "Intraoperative_tumor_location" variable, colon cancer is classified into cecum, ascending colon, hepatic flexure, transverse colon, splenic flexure, descending colon, sigmoid colon, and rectosigmoid junction cancer according to the location of the primary tumor. In the case of rectal cancer, 0-5 cm of the anal verge (AV) is classified as the lower rectum, 6-10 cm of the AV is the midrectum, and 11-15 cm of the AV is the upper rectum. The final colon cancer dataset consisted of 2091 patients, and the rectal cancer dataset consisted of 1190 patients.

Ethical Considerations

This study was reviewed and approved by the Institutional Review Board of the Gil Medical Center (GFIRB 2023-034). EMR data from the Gil Medical Center were used. Overall, data of 3321 patients were retrospectively collected through an iterative chart review conducted by colorectal cancer specialists. Due to its retrospective nature, the study was exempt from requiring informed consent from the participants.

Data Preprocessing

The variables were selected in consultation with a clinician. To select and use clinical variables to enhance the explanatory power of the results, pretreatment was performed after discussion with the clinician. Patient exclusion, variable categorization, missing value removal, and variable selection were performed in that order. All continuous variables were normalized to a (0,1) scale using min-max normalization to standardize the color intensity across features. Categorical variables were first one-hot-encoded and then similarly mapped to the image matrix, ensuring consistent scaling across data types during the image generation process. Images were constructed by arranging features sequentially based on the column order in the original dataset. No domain-driven grouping or clustering of related variables was applied to preserve reproducibility and avoid introducing subjective bias. Although the spatial arrangement of semantically related features may potentially affect CNN performance, this aspect was not explored in the study and is left for future investigation.

Prior to variable selection, patient cases excluded from the analysis were removed. In the case of "Kidney_disease," missing values were deleted. Patients who underwent surgery for recurrent colorectal cancer were also excluded.

After excluding patients, variable categorization was performed. Age was categorized by the number 65, which is a standard used to divide age. The BMI was categorized as 18 or less and 18 or more and as 25 or less and 25 or more. In addition, "DM_history," "Pulmonary_disease," "Liver_disease," and "Heart_disease," which are variables corresponding to the patient's medical history, were categorized by the presence or absence of a medical history.

Among the perioperative clinical features, "Initial_CEA," which indicates the first CEA level after diagnosis, was categorized according to 5 criteria, and 166 missing values were replaced with the average value. Missing values were removed for "Early_Complication," which indicates complications within 30 days after surgery. In particular, "Overall_Survival" was calculated from the date of surgery until the date of death for uncensored cases or until the date of last follow-up for censored cases. In addition, patients were categorized based on 5 years (60 months), which is the criterion for cure.

Among histopathologic features, missing values were removed and categorized in "Havested_LN," which represents the number of lymph nodes removed from the patient during surgery. If more than 12 pieces were removed, the operation was considered successful, and if less than 12 pieces were removed, the operation was classified as insufficient. Missing values were also removed from "Positive_LN," which indicates the number of metastatic lymph nodes that could be recognized during surgery. The final selected variables are listed in Table S1 in Multimedia Appendix 1.

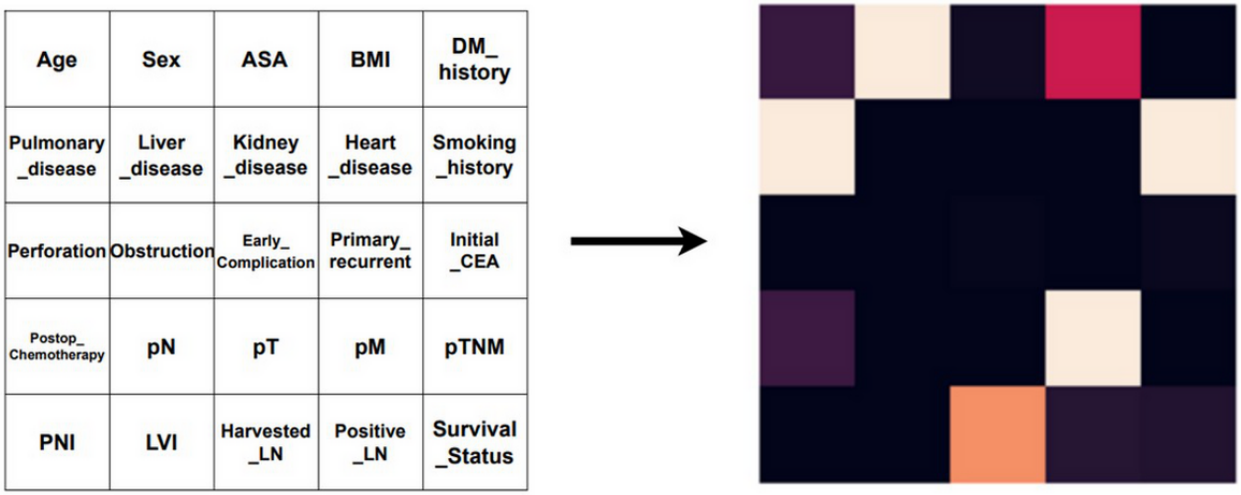

Image Generation Health Care Tabular Data Method

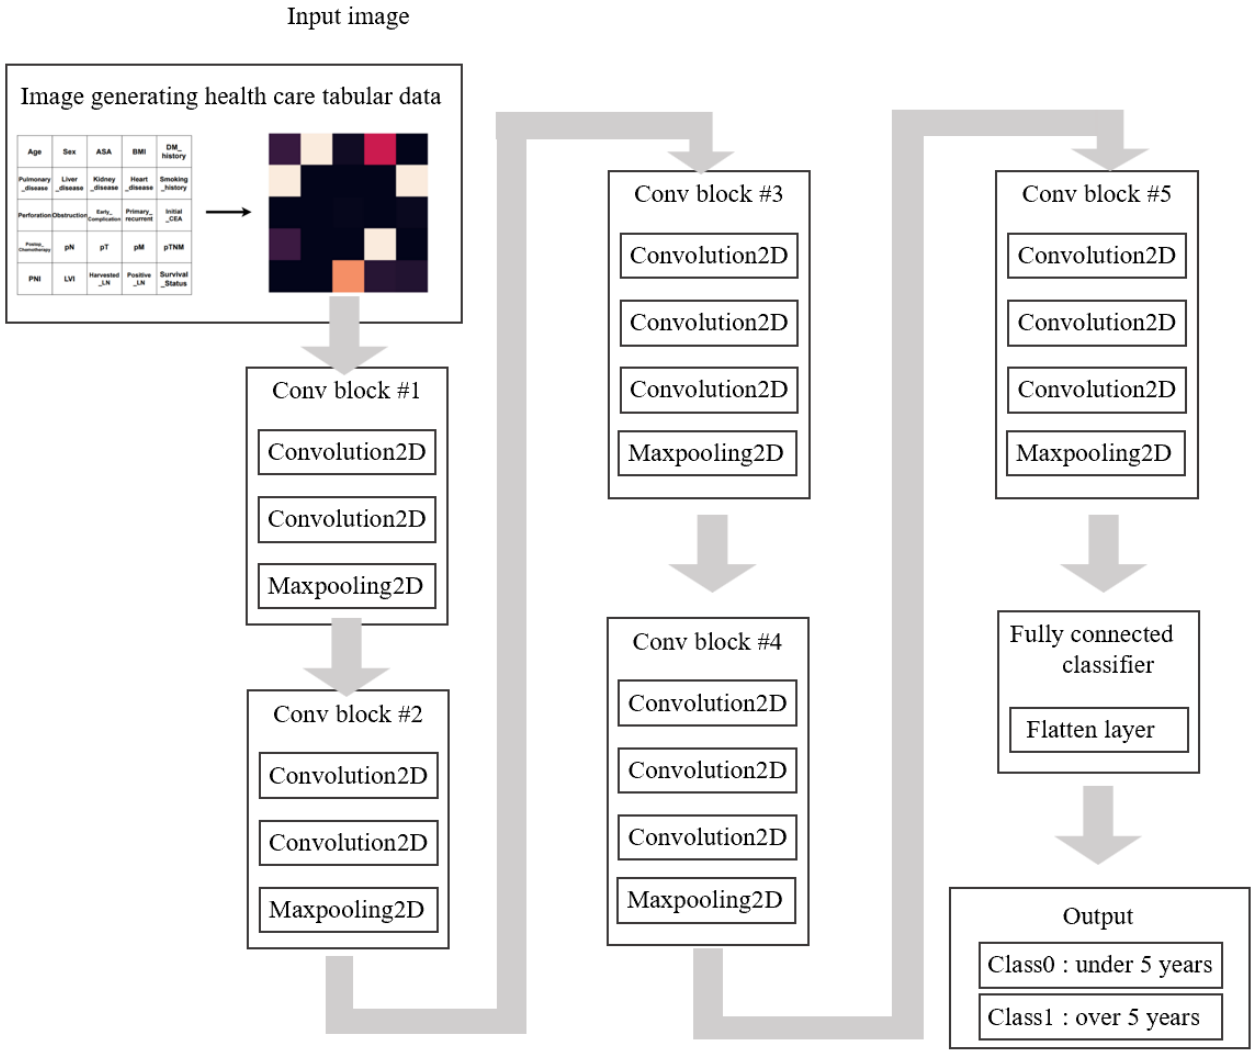
In this study, we aimed to convert the data from structured data into 2D unstructured image data to use as input to the deep learning model. The variables of the tabular data were visualized in matrix form and developed according to the data. Each

XSL•FO
RenderX

variable in Table S1 in Multimedia Appendix 1 was mapped to one column of the heat map and implemented in the form of an image. Figure 2 shows an example of an imaging matrix. The image is in the form of N×N, where N is 5, and the number of variables used for image conversion is 25.

Figure 2. Method of generating IGHT. ASA: American Society of Anesthesiologists physical status classification; CEA: carcinoembryonic antigen; DM: diabetes mellitus; IGHT: image generator health care tabular data; LN: lymph nodes; LVI: lymphovascular invasion; pM: pathological distant metastasis; pN: pathological regional lymph node; PNI: perineural invasion; pT: pathological primary tumor; pTNM: pathological tumor, node, metastasis.

In this study, we selected 25 clinically relevant variables and reshaped them into a 5×5 matrix to generate 2D images for input into the CNN models. Variables were categorized into three clinically meaningful groups: demographic, perioperative, and histopathologic features. These variables were mapped from left to right and top to bottom in the 5×5 matrix, following the order of these categories. This spatial configuration was carefully designed to enable the deep learning model to effectively capture interactions among clinically related variables. By organizing the input into a square-shaped matrix, the convolutional filters in the CNN architecture could exploit spatial proximities from the input layer, thereby enhancing the model's ability to learn joint patterns and improving both performance and interpretability.



We also considered scenarios where the number of input features may not perfectly form a square matrix. In such cases, possible strategies include (1) zero-padding to fill the remaining space without introducing clinical meaning and (2) modifying the CNN input layer to accept nonsquare (rectangular) input dimensions. Although these were not necessary in this study, they remain relevant for future extensions of this framework.

Deep Learning Model Prediction

Figure 3 shows a pictorial representation of the VGG16 model, proposed by the Visual Geometry Group (VGG), used in this study. The weights of VGG16 learned using a large dataset called ImageNet were imported and used to classify the imaging matrix. All modeling and analysis were conducted using Google Colaboratory with the following software environment: Python 3.7.13, TensorFlow 2.8.0, Keras 2.8.0, pandas 1.3.5, scikit-learn 1.0.2, NumPy 1.21.5, matplotlib 3.4.3, and seaborn 0.11.2.

For model interpretation, Grad-CAM was implemented using custom code adapted from tf-keras-vis and compatible TensorFlow visualization utilities. We divided the dataset of 3321 patients with colorectal cancer into two cohorts—colon cancer (n=2089, 62.9%) and rectal cancer (n=1232, 37.1%)—and trained separate models for each group. For both cohorts, the data were randomly split into training and testing sets in a 7:3 ratio.

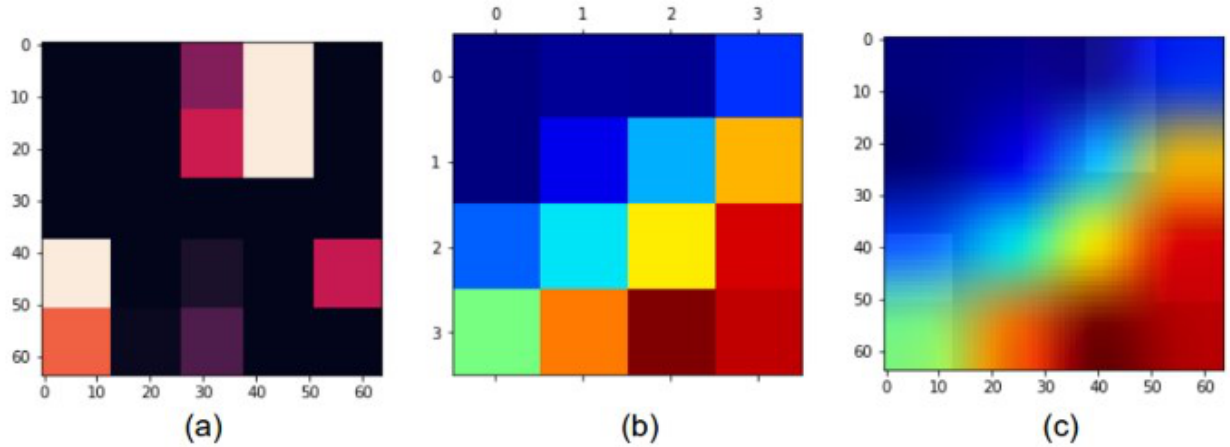
ANN and CNN models were trained using default hyperparameters. For the VGG16-based model, we adopted a transfer learning approach: the convolutional base of VGG16 pretrained on ImageNet was used (include_top=False), and all layers were set to be trainable. A flattened output was passed through a dense layer with 256 units (rectified linear unit [ReLU] activation), followed by a dropout layer (rate=0.25) and a sigmoid output layer for binary classification. The optimizer used was Adam with a learning rate of 0.01, and the loss function was binary cross-entropy. We also tested the Stochastic Gradient Descent (SGD) optimizer during model development, but it yielded inferior performance compared to Adam. Key hyperparameters, such as optimizer type, learning rate, and dropout rate, were selected based on empirical validation performance, rather than being used as default values.

Model performance was evaluated using the testing set, and the metrics reported included accuracy, sensitivity, and specificity.

ANN Model

After converting the tabular data into an imaging matrix, an ANN was constructed to compare and verify the AI model results. Instead of using the data converted to the imaging matrix (tabular data), the original dataset was used. Using the original dataset, an ANN was used to predict the survival period of patients with colorectal cancer and validate the results. Table S2 in Multimedia Appendix 1 lists the parameters of the baseline model in detail.

XSL•FO
RenderX



CNN Model

In this study, after transformation of data into an imaging matrix, a CNN model was applied. The model was constructed to classify the data by dividing the survival period of patients with colorectal cancer by 5 years. The classification performance of the patient survival period was confirmed using the CNN model, which showed good performance in image classification. Table S3 in Multimedia Appendix 1 lists the parameters of the CNN model.

VGG16 Model

In this study, transfer learning based on the VGG16 model created by Simonyan and Ziserman in 2014 was performed. The VGG16 model is a structure developed from the existing CNN structure, and because it is convenient to apply, studies using VGG16 are actively being conducted to improve classification performance. Table S4 in Multimedia Appendix 1 shows the structure of VGG16 used in this study. Figure 4 shows a pictorial representation of the transfer learning method used in this study. In this study, the weights of VGG16 learned using a large dataset called ImageNet were imported and used to classify the imaging matrix.

Figure 4. Example of Grad-CAM results: (a) original data from the image generator, (b) heat map produced by Grad-CAM, and (c) visualized image generated by Grad-CAM. Grad-CAM: gradient-weighted class activation mapping.

Gradient-Weighted Class Activation Mapping

To demonstrate the models' potential as a CDSS, we used Grad-CAM [26] to visualize important features for individual patient predictions. VGG16 is a CNN-based model that cannot explain the results of a model [27]. Therefore, Grad-CAM was used to increase the explanatory potential of the model results. Grad-CAM was used to generate heat maps that highlighted variables with notable influence on the models' prediction of the survival period of patients with colorectal cancer. The heat maps generated by Grad-CAM are highlighted in red and are a method of displaying the variable area that has a large influence on the prediction. Grad-CAM extracts features using weights extracted from the last convolutional layer of the models used for prediction [28].

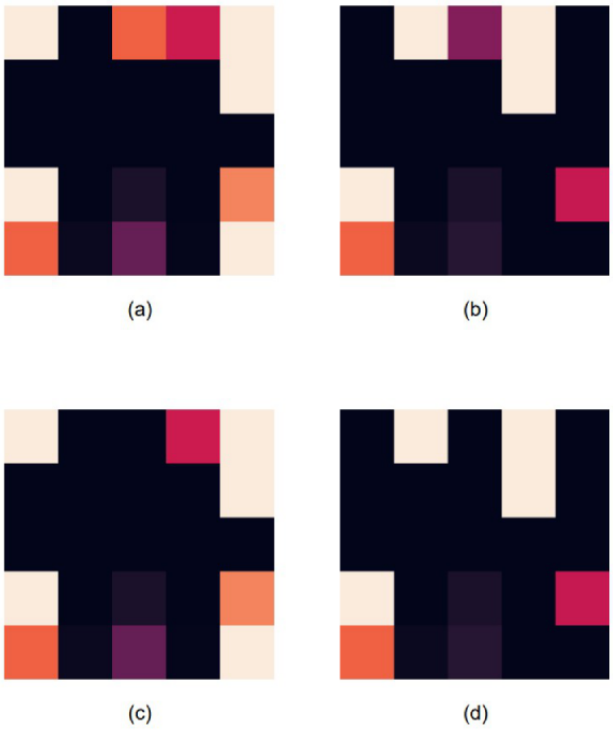
An example of converting Grad-CAM is shown in Figure 4. In the weight of the models trained using patient data (Figure 4a), the influence of the variable that affected the prediction result was converted into a heat map of the form in Figure 4b. Next, an image was created in a form that could intuitively determine the influence, as shown in Figure 4c, overlaid on Figure 4a.

Evaluation Metrics

The predictive performance of the models was evaluated using three key metrics: accuracy, sensitivity, and specificity.

Accuracy measures the overall proportion of correctly classified instances. Sensitivity (also known as recall) quantifies the proportion of true-positive cases correctly identified by the model, while specificity measures the proportion of true negatives correctly identified.

These metrics were calculated on the test datasets to assess the generalization performance of the models.



Results

Imaging Matrix Transformation

The transformation of tabular data into 5×5 imaging matrices using 25 variables from patients with colorectal cancer demonstrated distinctive visual patterns. The heat map representation, where values approaching 1 appear white and those approaching 0 appear black, provided an intuitive visualization of patient data. For survival period prediction, we established a binary classification. Figure 5 shows an example of the imaging matrix created. Class 0 represented patients with a survival period of less than 5 years, while class 1 represented patients with a survival period of more than 5 years.

XSL•FO
RenderX

Figure 5. Example of an imaging matrix: (a) class 0 image in colon cancer, (b) class 1 image in colon cancer, (c) class 0 image in rectal cancer, and (d) class 1 image in rectal cancer.

Comprehensive Model Performance Evaluation

We conducted an extensive comparative analysis across three distinct deep learning architectures, each revealing unique strengths in colorectal cancer survival prediction.

As shown in Tables 1 and 2, the accuracy and specificity of VGG16 were the best among the three models. However, the sensitivity of VGG16 was the lowest among the three models, which means that the model mistakenly thought that the actual survival period of a patient was less than 5 years but that the patient had a good prognosis. Compared to VGG16, the ANN and CNN showed higher sensitivities (84%-99%) in identifying patients with poor prognoses well. However, in terms of specificity, VGG16 showed better performance in correctly predicting patients with a 5-year survival period (89.55% for colon cancer and 87.9% for rectal cancer).

Table 1. Overall survival prediction in patients with colon and rectal cancer using ANN[a], CNN[b], and VGG16[c] models.

Model	Accuracy (%)	Sensitivity (%)	Specificity (%)	Precision (%)	F_1-score (%)
ANN	71.47	84.00	54.23	71.59	76.86
CNN	61.90	99.40	4.90	61.58	76.17

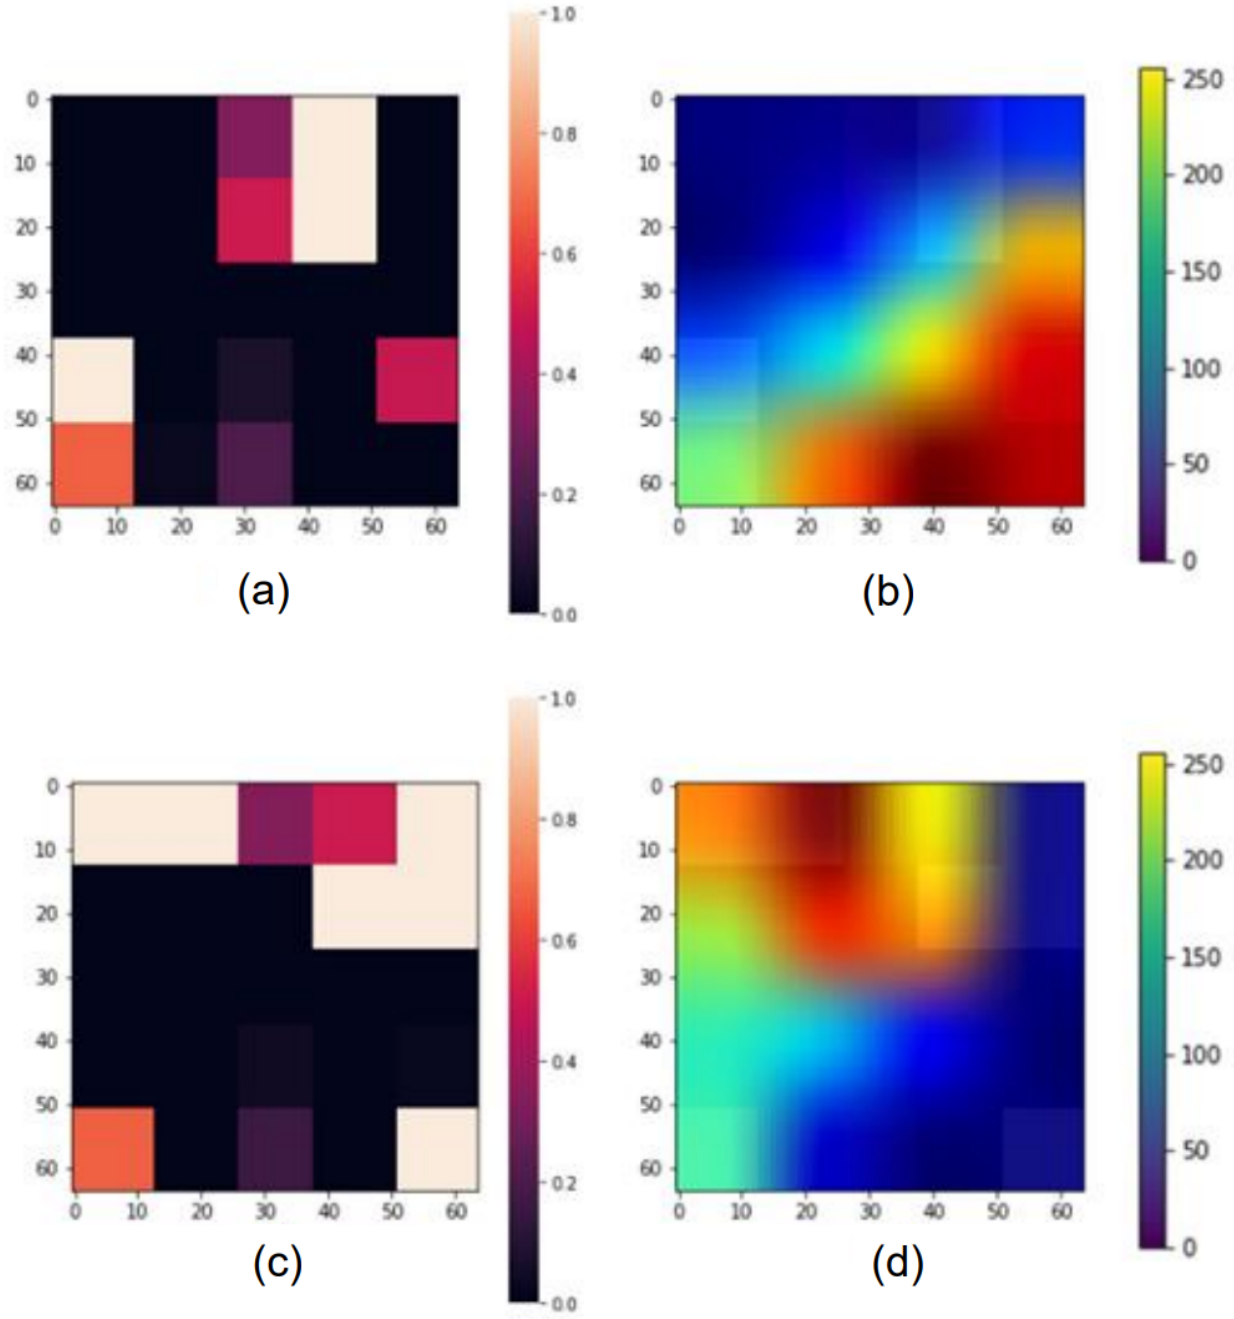
RenderX



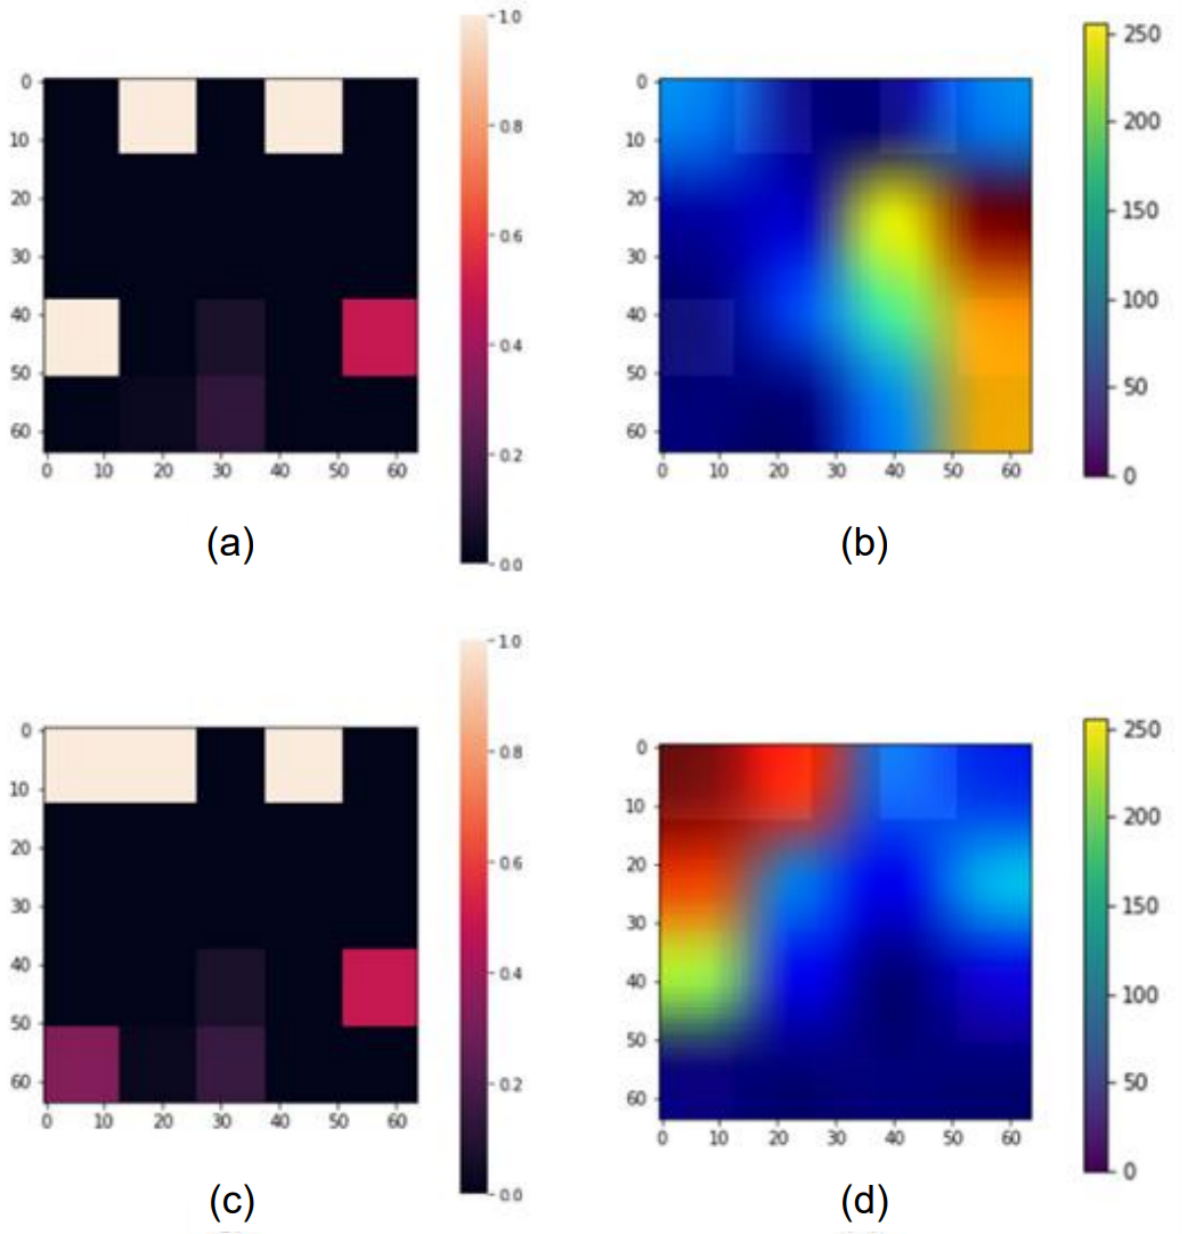
Gradient-Weighted Class Activation Mapping

Grad-CAM analysis was used to enhance the interpretability of the VGG16 model predictions. This technique generated heat maps highlighting variables that appeared most influential in the three models' survival period predictions.

Analysis of Patients With Colon Cancer

Figure 6 presents examples of heat map conversion results and Grad-CAM application results for patients with colon cancer. The patient has a survival period of more than 5 years and is a successful case of deep learning model prediction. Looking at Figure 6a, the patient was in an early pTNM stage. Considering this, it can be confirmed that the factor that played a major role in VGG16 predicting the survival of this patient was the pTNM stage. The results of Grad-CAM for patients without liver disease and a moderate ASA grade had an impact on predicting that patients would have longer survival times (Figure 6d).

Figure 6. Visualized results generated by Grad-CAM in patients with colon cancer: (a, c) original data from the image generator and (b, d) visualized image generated by Grad-CAM. Grad-CAM: gradient-weighted class activation mapping.



Analysis of Patients With Rectal Cancer

Figure 7 presents examples of heat map conversion results and Grad-CAM application results for patients with rectal cancer. Figures 7a and 7c are the learned images, and Figures 7b and 7d show the results of Grad-CAM as a heat map. As shown in the imaging matrix in Figure 7b, the smoking history, initial CEA level, and pTNM stage were indicated as variables that

XSL•FO
RenderX

had a major influence on the prediction of the model: there was no smoking history, the initial CEA level was moderate, and the TNM stage was early. As the patient's survival period was well predicted to be more than 5 years, it was found that the Grad-CAM analysis results were consistent with the results of existing clinical studies. As shown in Figure 7d, age, sex, the ASA grade, and pulmonary disease affected the survival time prediction results. For a patient with a high age, a low ASA grade, and no pulmonary disease, with a well-predicted survival of more than 5 years, because the ASA grade was low, the patient's physical condition was good, and there was no pulmonary disease, the survival period seemed to be predicted for a long time. As described earlier, Grad-CAM can be used to determine which variables have the most influence on the prediction of survival time for individual patients and their risk factors.

Figure 7. Visualized results generated by Grad-CAM in patients with rectal cancer: (a, c) original data from the image generator and (b, d) visualized image generated by Grad-CAM. Grad-CAM: gradient-weighted class activation mapping.

Discussion

Principal Findings

In this study, we developed a model to predict the survival period of colorectal cancer using EMR data and investigated which variables contributed to the prediction. In particular, we improved the performance of the model through an innovative approach to convert tabular medical data into image data. The results of the study showed that the VGG16 model achieves the best performance, which suggests a new methodology for developing a CDSS for patients with colorectal cancer in clinical settings.

Deep learning models performed important clinical predictions on whether the survival period of patients with colorectal cancer

XSL•FO
RenderX

who underwent surgery is more than 5 years. If the survival period of a patient with cancer is more than 5 years, it indicates that the patient's prognosis is good and the risk of cancer recurrence is low, which can provide clinically helpful information. Furthermore, it shows that doctors can use this as a reference to understand the patient's condition and support them in making better decisions.

In this study, the prediction accuracy of VGG16 was 75%, and that of the CNN was 61%, showing that the VGG16 model, which used more weights through transfer learning, performs better. The reason for the large performance difference between the CNN and VGG16, about 14%, is probably because the amount of data used in this study was less than that used in other deep learning models. However, VGG16 is a transfer learning model trained using a large ImageNET-based dataset and provides the weights obtained as a result. In this study, we used the weights of VGG16 for learning, and we were able to see that the prediction performance was improved by overcoming the limitations of quantitative data volume.

Given the class imbalance in our dataset and the differing behavior observed across models, a clear understanding of the trade-off between sensitivity and specificity is essential for clinical application. Although oversampling techniques, such as the synthetic minority oversampling technique (SMOTE), were initially considered to mitigate the imbalance, we ultimately decided not to apply them after consultation with clinical experts. It was determined that artificially augmenting the minority classes could compromise the clinical validity and real-world representativeness of colorectal cancer data. Therefore, we maintained the original class distribution and focused on evaluating model performance through sensitivity and specificity, which are more aligned with clinical priorities. To further enhance model interpretability and support clinical decision-making, we applied Grad-CAM to visualize the features contributing to model predictions.

Our best-performing model, VGG16, exhibited high specificity (88%-90%) but relatively low sensitivity (35%-40%). This indicates that when the model predicts early mortality (nonsurvival within 5 years), it is highly reliable, minimizing false positives in identifying high-risk patients. Such high specificity is valuable in clinical settings where unnecessary aggressive follow-up could impose physical, psychological, and economic burdens. Considering the class distribution (approximately 6:4 for positive to negative outcomes, where "positive" refers to patients surviving for more than 5 years), precision and F_1-scores provide further insight into model behavior. VGG16, which showed the highest specificity and precision, tended to make more conservative predictions regarding long-term survival, resulting in fewer false positives. From a CDSS perspective, its relatively high F_1-score and sensitivity suggest potential usefulness in identifying patients unlikely to survive beyond 5 years. Although the ANN and CNN also demonstrated comparable sensitivity, VGG16 maintained this without compromising specificity, indicating a more balanced performance that may help reduce false alarms in clinical practice.

The VGG16 model outperformed the ANN model by achieving an accuracy improvement of 6.76% (78.23% vs 71.47%) in colon cancer survival prediction and 1.76% (76.54% vs 74.78%) in rectal cancer survival prediction. Additionally, VGG16 demonstrated markedly higher specificity compared to the ANN (89.55% vs 54.23% for colon cancer and 87.9% vs 55.26% for rectal cancer), indicating improved ability to correctly identify patients with better survival outcomes.

In contrast, the CNN model showed substantially lower accuracy (61.9% for colon cancer and 61.8% for rectal cancer) and poor specificity (<5%), suggesting limited clinical utility in its current form. These findings highlight that although basic CNN architectures may underperform, deeper networks, such as VGG16, can capture complex patterns to improve prediction reliability.

However, the lower sensitivity implies that some patients who do die early are not identified by the model (false negatives), potentially missing individuals who could benefit from intensified monitoring or interventions. This limitation is crucial to acknowledge, as underdetection may reduce the model's effectiveness in guiding proactive clinical decision-making.

Conversely, the CNN model showed the opposite pattern, with high sensitivity but low specificity, which would result in many false alarms and potentially excessive interventions.

Therefore, the choice of model and classification threshold must be carefully tailored to the clinical context and intended use case. For example, a model prioritizing sensitivity may be preferred in screening scenarios to ensure at-risk patients are not missed, whereas one prioritizing specificity may be favored where reducing false positives is paramount.

Unlike the black-box model, the demand for a white-box model that provides a reason for the result is increasing [29]. A white-box model explains the results of an AI model and has recently been attracting attention under the name of XAI [30].

Although our model achieved an accuracy of 75%-78% in predicting 5-year survival, the existing literature indicates that this level of performance is clinically meaningful. Kos et al [31] used various machine learning models (eg, decision tree, stacking ensemble, and SVM) to predict survival rates from 1 to 10 years using large-scale data of patients with colorectal cancer in Australia. In this study, the 5-year survival prediction models showed an AUC of approximately 0.86-0.89 and an accuracy of over 70%, and the performance by cancer stage also showed an excellent predictive power of over 70%. Compared to the prediction accuracy of this study (78.4% for colon cancer and 74.8% for rectal cancer), both studies suggest that machine learning–based clinical data use is effective for survival prediction, and this study is particularly different in that it converted EMR data into images and applied them to a CNN-based model. Similarly, Gao et al [32] compared nine ML models against TNM staging alone (AUC=0.784) and found that most models only modestly outperform staging, often with overlapping CIs.

These findings suggest that our image-based deep learning model operates within a comparable performance band, while adding the benefit of interpretable Grad-CAM visualization.

XSL•FO
RenderX

Furthermore, staging-only approaches often fall short when applied to patients with stage II-III cancer, whose outcomes are less deterministic. Our model showed improved discrimination in this subgroup, indicating its potential to complement staging heuristics in borderline clinical cases.

Finally, the alignment between Grad-CAM highlighting (eg, pTNM stage, smoking history, age) and established prognostic factors enhances the model's trustworthiness and suitability for integration into explainable CDSSs. To help clinical decision-making, it is better for deep learning models to also provide reasons for their decisions. In this study, Grad-CAM was used to provide XAI in deep learning models. Grad-CAM can answer the reasons for individual patient outcomes, and the survival prediction model shows the possibility of providing tailored medicine as part of a CDSS.

Clinical Implications

Figures 6 and 7 show the results of analyzing the results for some patients with colorectal cancer using Grad-CAM. Among the patients with colon and rectal cancer, we randomly selected 2 patients and examined the heatmap from the Grad-CAM analysis results. As a result, the pTNM stage was found to be the variable that had the greatest influence on the model prediction in both cancer types. However, additional variables that affected each patient were different: age, gender, smoking history, ASA grade, liver disease, pulmonary disease, and initial CEA levels. The results of Grad-CAM analysis for patients in Figure 5d,e show that the pTNM stage has an influence on the prediction, which is consistent with existing medical knowledge [33]. Figure 6 shows that smoking history has a major influence on the prediction by the model. In existing clinical studies, smoking history has been identified as a relevant factor affecting patient survival [34]. Since various factors must be considered in order to determine the prognosis of patients with colon cancer, if we conduct an analysis that can identify the influential variables at once, such as Grad-CAM, we will be able to provide better clinical services.

Limitations and Future Work

When training a deep learning model using a small amount of data, overfitting may occur. If overfitting occurs, predictions may not work well with data other than trained data. Therefore, if we can collect more multicenter studies or data in future research, we will further increase the reliability of the study by conducting an analysis by stage.

To leverage the spatial learning capabilities of CNNs, we transformed 25 clinical variables into a 5×5 image for each patient. Each feature was min-max-normalized and assigned to a fixed position in the 5×5 matrix, ensuring consistent spatial encoding across all samples. Although clinical tabular data do not possess an inherent spatial structure, prior studies have shown that imposing a structured layout allows CNNs to effectively capture local feature interactions and complex nonlinear relationships that may be overlooked by traditional models. This image-based representation also enables the application of transfer learning using pretrained CNN architectures.

Although the variable layout was arbitrarily fixed in this study, future work may explore data-driven arrangements based on feature correlation or clinical relevance to further enhance the model's representational capacity.

The proposed model, although demonstrating strong predictive performance, must address several practical considerations to be implemented as a CDSS. Integration into existing EMR systems would require standardized data pipelines, interoperability, and real-time processing capabilities. Additionally, interpretability remains essential for clinical adoption. In this study, we used Grad-CAM to identify features contributing most to each prediction, providing visual explanations that could be embedded into future CDSS interfaces.

From a clinical perspective, prediction models for survival outcomes in colorectal cancer can serve as valuable tools, particularly in the postoperative setting. Previous studies have demonstrated the utility of machine learning for guiding surveillance and adjuvant therapy decisions [35,36]. Our deep learning–based model offers automated and objective risk stratification using routinely collected clinical data, supporting multidisciplinary teams in identifying high-risk patients. Within clinical workflows, the system could deliver actionable alerts—such as notifications flagging patients with poor predicted survival—to prompt timely follow-up or intervention. These alerts, coupled with interpretable Grad-CAM visualizations, can enhance clinical reasoning, build trust, and facilitate shared decision-making by clearly communicating risk to both clinicians and patients.

Although this study adopted a binary classification approach (predicting 5-year survival), we acknowledge that this represents a simplification of the underlying clinical reality. In oncology, the timing of events such as recurrence or mortality is often just as important as whether the events occur. Therefore, future work will explore modeling survival outcomes in a time-to-event framework using deep learning–based survival models. Methods such as DeepSurv, a Cox proportional hazards–based neural network, have shown promise in capturing complex nonlinear relationships, while preserving the structure of survival data [37]. These approaches could yield more clinically informative predictions, especially in patient-level prognostication and individualized treatment planning.

In addition, future enhancements could include the use of more advanced convolutional architectures, such as ResNet or EfficientNet, as well as ensemble learning strategies. These techniques may help improve both performance and generalizability, especially in heterogeneous clinical datasets.

The dataset used in this study was built through the EMR system of a single institution. For multi-institutional research, if a standardized medical information system for each type of medical institution in Korea is established and advanced, it will be possible to produce generalized prediction results using more patient data. Furthermore, if data construction standards for each institution are established, it is believed that the establishment of a data mart will help Korea's data ecosystem and contribute to the generalization of research results.

XSL•FO
RenderX

The dataset used in this study was limited as it was collected from a single institution. Therefore, the characteristics of the patient group in this study may not reflect the clinical features of patients in other medical institutions. In future research, we will present a generalized model that reflects the clinical features of patients in a multicenter study.

Conclusion

XAI research that enhances the interpretability of deep learning model results is actively progressing. In this study, we used the IGHT technique to convert structured data into images, which allowed us to capture relationships between variables effectively. Using this approach, we developed models to predict overall survival, a key indicator for determining the prognosis of patients with colorectal cancer after surgery.

An ANN model, a CNN model, and transfer learning with a pretrained VGG16 model were used to evaluate predictive performance. Our results suggest that image-based input leads to improved prediction compared to traditional tabular data analysis. Additionally, CNN-based models provide opportunities for enhanced interpretability through techniques such as Grad-CAM.

Abstract

Background: Falls among hospitalized patients are a critical issue that often leads to prolonged hospital stays and increased health care costs. Traditional fall risk assessments typically rely on standardized scoring systems; however, these may fail to capture the complex and multifactorial nature of fall risk factors.

Objective: This retrospective observational multicenter study aimed to develop and validate a machine learning–based model to predict in-hospital falls and to evaluate its performance in terms of discrimination and calibration.

Methods: We analyzed the data of 83,917 inpatients aged 65 years and older with a hospital stay of at least 3 days. Using Diagnosis Procedure Combination data and laboratory results, we extracted demographic, clinical, functional, and pharmacological variables. Following the selection of 30 key features, 4 predictive models were constructed: logistic regression, extreme gradient boosting, light gradient boosting machine (LGBM), and categorical boosting (CatBoost). The synthetic minority oversampling technique and isotonic regression calibration were applied to improve the prediction quality and address class imbalance.

Results: Falls occurred in 2173 (2.6%) patients. CatBoost achieved the highest F_1-score (0.189, 95% CI 0.162-0.215) and area under the precision-recall curve (0.112, 95% CI 0.091-0.136), whereas LGBM had the best calibration slope (0.964, 95% CI 0.858-1.070) with good discrimination (F_1-score 0.182, 95% CI 0.156-0.209; area under the precision-recall curve 0.094, 95% CI 0.078-0.113). Logistic regression had the lowest discrimination (F_1-score 0.120, 95% CI 0.100-0.143). Shapley Additive Explanations analysis consistently identified low albumin, impaired transfer ability, and the use of sedative-hypnotics or diabetes medications as major contributors to fall risk. In incident report analysis (n=435), 49.2% of falls were toileting-related, peaking between 4 and 6 AM, with bedside falls predominating in high or very high risk groups.

XSL•FO
RenderX

Conclusions: CatBoost and LGBM offer clinically valuable prediction performance, with CatBoost favored for high-risk patient identification and LGBM for probability-based intervention thresholds. Integrating such models into electronic health records could enable real-time risk scoring and trigger targeted interventions (eg, toileting assistance and mobility support). Future work should incorporate dynamic, time-varying patient data to improve real-time risk prediction.

Introduction

Falls among hospitalized patients represent a considerable concern that can adversely affect patient health outcomes and the quality of care. Falls are often associated with prolonged hospital stays and increased hospitalization costs [1]. The World Health Organization defines a fall as “an event that results in a person coming to rest inadvertently on the ground, floor, or other lower level, excluding intentional position changes to lean against furniture, walls, or other objects” [2]. Several studies have identified various risk factors associated with falls, including advanced age, a history of falls, reduced activities of daily living (ADL), the use of sleeping medications, and malnutrition [3-6]. Given the multifactorial and complex nature of fall risk, numerous guidelines for fall prevention in hospitalized patients have been established worldwide [7-9]. These guidelines recommend performing multifactorial assessments for each patient rather than relying solely on standardized fall risk scores. Similar to many other hospitals in Japan, at our institution, we adopt a scoring system based on a number of risk factors. This scoring system facilitates easy evaluation and achieves high sensitivity [10]. However, applying a uniform evaluation to all patients may limit specificity and fail to reflect varying clinical contexts; as a result, individual clinical differences and interactions among risk factors may be overlooked [11]. This limitation underscores the multifaceted and complex nature of fall-related risk.

In Japan, nurses primarily assess fall risk through bedside clinical observation. However, limited time for patient care and insufficient staffing of registered nurses are associated with higher fall rates, underscoring the need for effective prediction models [12]. To capture these complex risk factors more accurately, recent studies have increasingly focused on machine learning–based models for fall prediction models [13]. These models are capable of analyzing complex interactions among numerous variables and can identify patterns that traditional scoring systems may overlook. Previous studies conducted in Japanese university hospitals have primarily evaluated the performance of these models using the area under the receiver operating characteristic curve (ROAUC) and reported values between 0.78 and 0.90 [14-17]. However, in clinical practice, calibration accuracy is as important as discriminatory performance. Poor calibration may lead to excessive interventions for patients classified as high risk, increasing the workload of medical staff and health care costs. Conversely, insufficient care for patients classified as low risk could result in severe fall incidents, highlighting the critical need for calibration evaluation. Despite its importance, reports on the calibration performance of machine learning models remain limited.

In this study, we aimed to develop a fall prediction model for hospitalized patients and validate its performance using discriminatory and calibration metrics. Additionally, we aimed to elucidate the factors that contribute to falls to support the development and implementation of more effective fall-prevention strategies.

Methods

Study Design and Data Collection

This retrospective observational multicenter study was conducted using inpatient data from 2 affiliated hospitals of Nippon Medical School: Nippon Medical School Hospital and Chiba Hokusoh Hospital. The dataset was compiled from the Diagnosis Procedure Combination data and laboratory test results extracted from electronic medical records.

Ethical Considerations

Ethics approval for this study was obtained from the central ethics review committee of Nippon Medical School (approval M-2023-137). This study adhered to the principles of the Declaration of Helsinki. Informed consent was obtained using an opt-out approach, and the study was reported following the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) guidelines [18]. No compensation was provided to the participants because this study was a retrospective observational study using de-identified data.

Patients and Outcomes

All the patients included in this study were hospitalized between April 2018 and March 2023. Patients younger than 65 years of age and those with a hospital stay of less than 3 days were excluded. Patient and feature selection were guided by a fall risk assessment sheet used at the study facility. As the assessment sheet identified individuals aged 65 years or older as a fall risk factor, patients younger than 65 years of age were excluded accordingly (Table S1 in Multimedia Appendix 1). The outcome was defined as the first occurrence of a fall within 30 days of the admission date based on incident reports. These reports are considered highly reliable due to mandatory reporting requirements, and they contain detailed information such as the time, location, trigger of the fall, and classification into mild or severe cases.

RenderX

Variables

The Diagnosis Procedure Combination data contained information on all hospitalized patients, including demographic details (such as age and sex), physical metrics (height, weight, and BMI, calculated by dividing body weight in kilograms by the square of height in meters), and clinical information (comorbidities, procedures, medications, and consciousness levels at admission) [19]. Medications were defined according to those included in the hospital fall risk assessment protocol. The physical condition of the patients was assessed using the nursing care needs score on admission [19]. This score measures the level of assistance required for activities such as turning over, transferring, oral hygiene, eating, and changing clothes (0 points=no assistance, 1 point=partial assistance, and 2 points=full assistance). It also evaluated one's ability to understand medical instructions (0 points=yes and 1 point=no) and the presence of risky behaviors (0 points=no and 2 points=yes; Table S2 in Multimedia Appendix 1).

Blood test results were obtained from electronic medical records to assess known factors influencing falls, such as anemia, malnutrition, and electrolyte imbalance. The test results were defined as the closest sample collected to the admission date within 60 days prior to admission. To minimize missing values, we extracted blood test results and medication-related variables 60 days before the admission date, rather than strictly limiting extraction to the admission date. Before model development, we assessed multicollinearity among all candidate predictors by calculating the variance inflation factor (VIF). All variables had VIF values <5, indicating no concerning multicollinearity. Therefore, all variables were retained for model construction without further dimensionality reduction (Table S3 in Multimedia Appendix 1).

Imputation of Missing Data

Missing BMI values and blood test results were imputed using a single imputation in the Python *MissForest* package [20,21]. As the missing rate for all variables was below 20%, all variables were included in the analysis. A 20% threshold was used as the exclusion criterion.

Predictive Model Development

The dataset was randomly divided into 80% training and 20% test sets using stratified sampling to ensure that the end-point occurrence rates were preserved, as in the original population. We used extreme gradient boosting (XGB) to select the top 30 features based on their importance in the training data [22]. These selected features were used for subsequent modeling and analysis. The following predictive models were used: conventional logistic regression (LR), XGB, light gradient boosting machine (LGBM), and categorical boosting (CatBoost) [23,24]. To address class imbalance, we applied the synthetic minority oversampling technique algorithm to artificially increase the proportion of fall cases to 20% of the total cases in the training data [25]. Additionally, class-balanced loss functions were used during the training phase to mitigate the effects of imbalanced data. Hyperparameter optimization for each model was performed using Optuna for up to 500 trials (Table S4 in Multimedia Appendix 1) [26]. The average precision score was used as the evaluation metric. To improve model calibration, we used isotonic regression to adjust the predicted probabilities of each model [27]. Finally, all models were trained using a 10-fold stratified k-fold cross-validation.

Model Interpretation

Shapley Additive Explanations (SHAP) values were used to interpret the output of the machine learning models [28]. SHAP is a game-theoretic approach to explain individual predictions by calculating each feature's marginal contribution to the difference between the actual prediction and the average prediction across the dataset. SHAP values provide quantitative insights into the contribution (positive or negative) of each feature to the predicted fall risk for a given patient, thereby enhancing the interpretability and transparency of the decision-making process of the model.

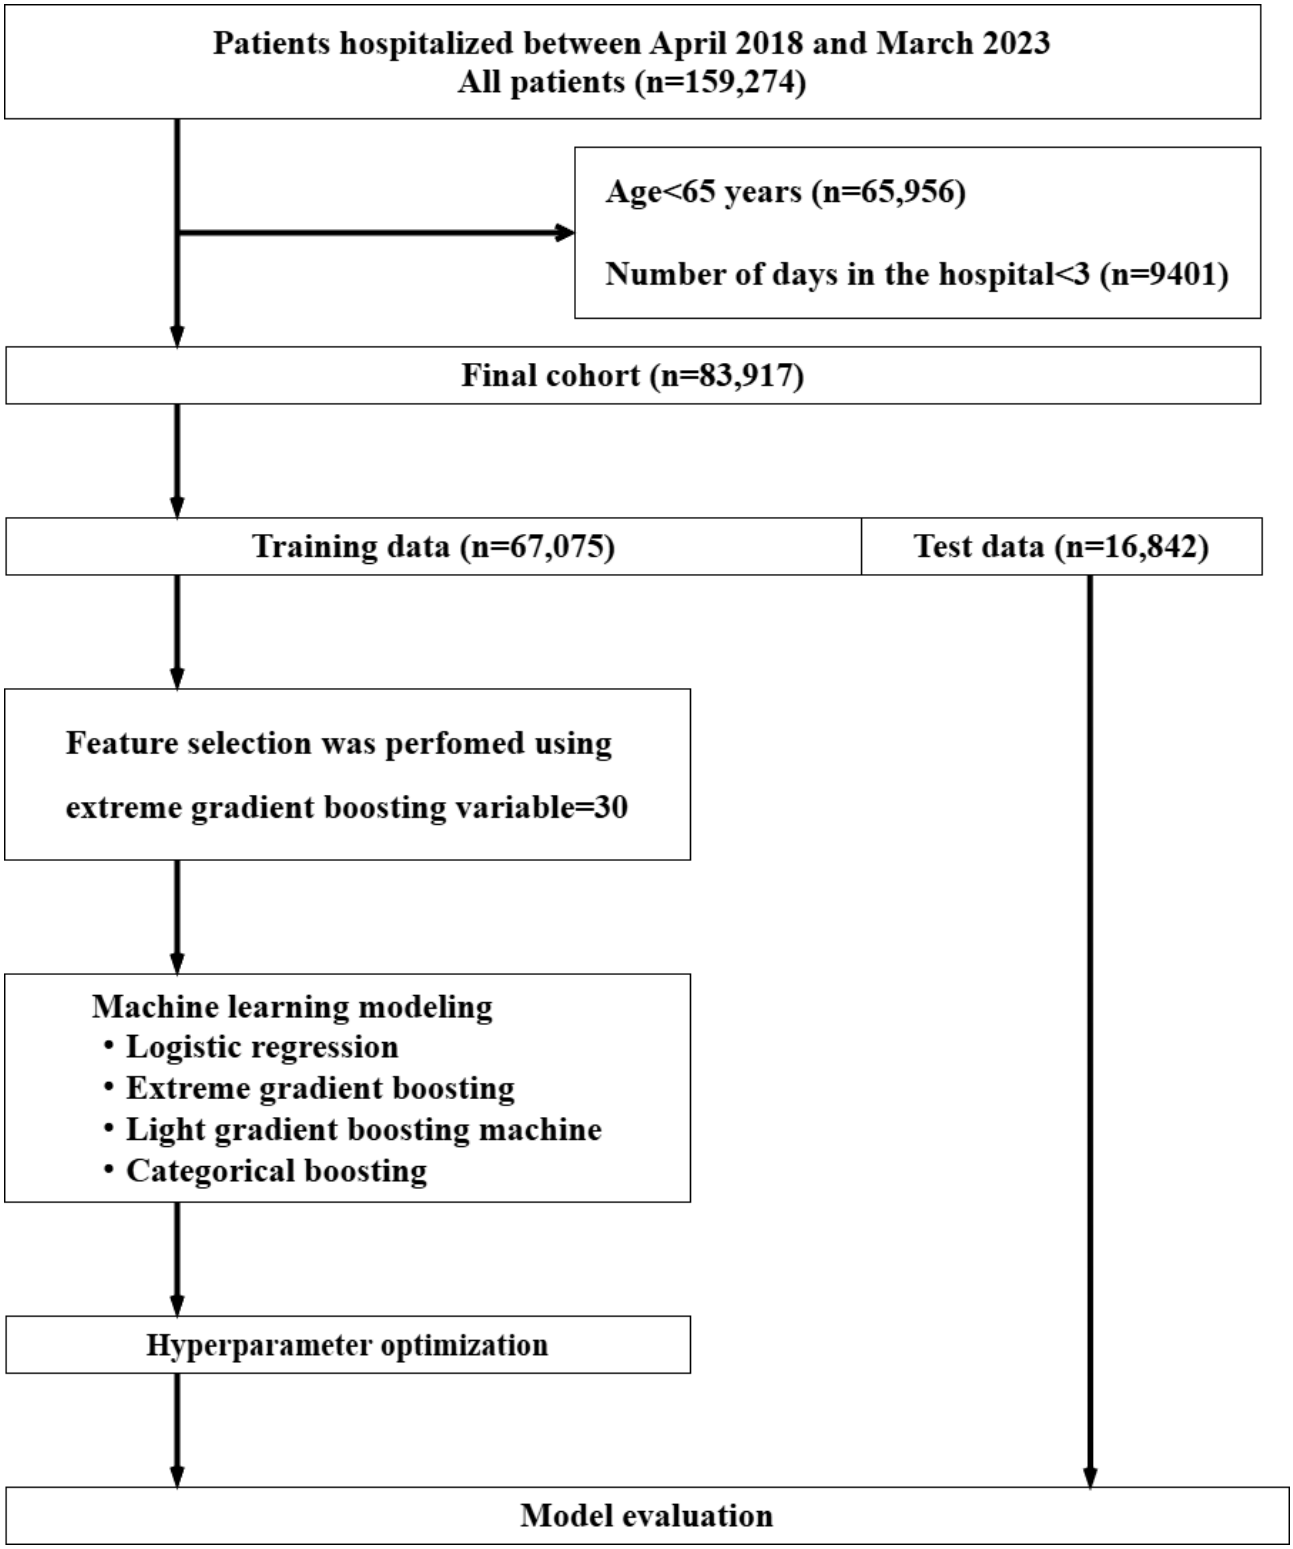
Model Validation

The optimal threshold for each model was determined by maximizing the F_1-score to achieve the highest possible predictive performance. Then, calibration was applied to ensure that the predicted probabilities accurately reflected the true probabilities. Additionally, the bootstrap method was applied to the test set to evaluate the performance of the predictive models. A total of 3000 bootstrap resamples obtained from the test set were used to calculate 95% CIs for each performance metric. The discriminatory ability of the model was assessed using the ROAUC and area under the precision-recall curve (PRAUC), a threshold-independent metric that quantifies the average precision across all possible recall values, providing a robust measure of the ability of a model to correctly identify positive cases, particularly in imbalanced datasets. The predicted probabilities for the calibration plots were divided into 10 percentiles, and the mean predicted and observed probabilities of the outcome for each bin were plotted. Two indices were used to evaluate the calibration: the calibration slope, which indicates the agreement between the predicted probabilities and the observed outcomes; and the Brier score, which measures the accuracy of the probability predictions. A calibration slope closer to 1 and a Brier score closer to 0 indicate ideal model performance.

Statistical Analysis

All statistical analyses were performed using Python (version 3.10.10; Python Software Foundation).

Results



Study Population and Baseline Characteristics

Among the initial 159,274 patients, 65,956 were younger than 65 years of age, and 9401 had a hospital stay of less than 3 days. Therefore, 83,917 participants were included in the final analysis after applying the exclusion criteria. Of these, 67,705 (80%) were allocated to the training dataset and 16,842 (20%) to the validation dataset (Figure 1). Table 1 presents the key variables included in the final prediction models, along with their descriptive statistics in the overall, training, and test datasets. Complete descriptive statistics for all candidate variables prior to feature selection, including VIF values, are provided in Table

XSL•FO
RenderX

S3 in Multimedia Appendix 1. Outcomes were observed in 2173 (2.6%) patients, and the characteristics of the training and test datasets were well balanced. The 30 selected features used in the analysis are illustrated in Multimedia Appendix 2. Multimedia Appendix 2 highlights the relative importance of each variable, with risky behavior (0.148), oral hygiene (0.086), and unconsciousness (Japan Coma Scale≠0; 0.044) among the top predictors, providing context for the feature selection process.

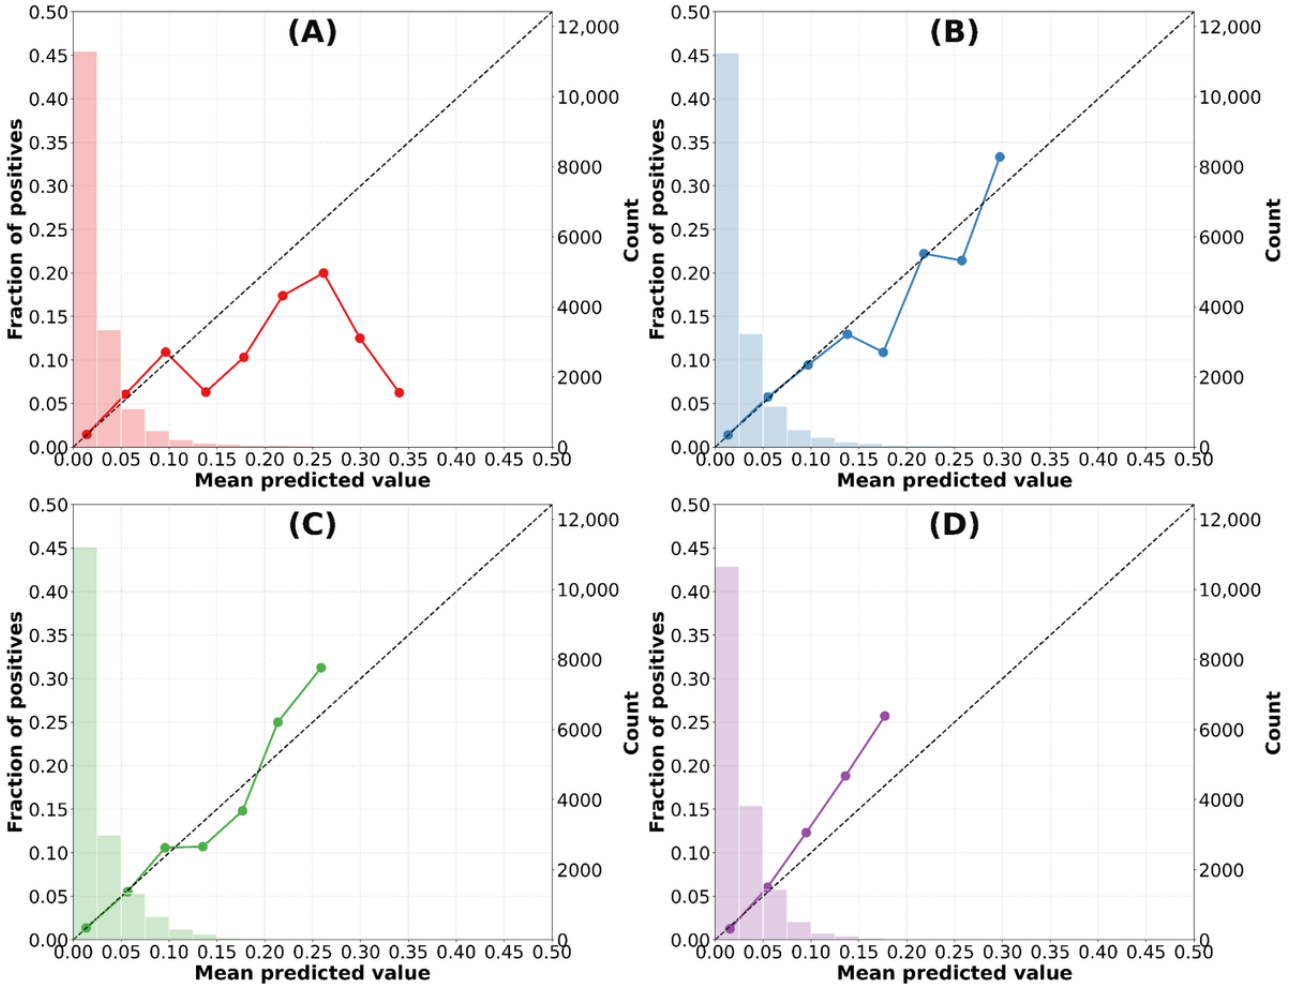
Evaluation of Prediction Models

We evaluated the performances of 4 classification models: LR, XGB, LGBM, and CatBoost. The performance of each model was assessed using the F_1-score, PRAUC, calibration slope, and optimal threshold, with a 95% CI provided for each metric. The LR model achieved an F_1-score of 0.120 (95% CI 0.100-0.143), with an optimal threshold of 0.069. Its PRAUC was 0.066 (95% CI 0.055-0.0792), and the calibration slope was 0.838 (95% CI 0.739-0.934). In comparison, XGB showed a slightly higher F_1-score of 0.182 (95% CI 0.157-0.207), with an optimal threshold of 0.074. It achieved a PRAUC of 0.098 (95% CI 0.081-0.117) and had an improved calibration slope of 0.937 (95% CI 0.829-1.040). Similarly, the LGBM model demonstrated an F_1-score of 0.182 (95% CI 0.156-0.209) and an optimal threshold of 0.0846. Its PRAUC was 0.094 (95% CI 0.078-0.113), and it demonstrated the most accurate calibration among all models at 0.964 (95% CI 0.858-1.070). Among the 4 models, the CatBoost model achieved the highest F_1-score of 0.189 (95% CI 0.162-0.215) and an optimal threshold of 0.0724. It also recorded the higher PRAUC at 0.112 (95% CI 0.091-0.136). Although its calibration slope of 1.120 (95% CI 1.000-1.240) was slightly above 1, it was close to the ideal value. While CatBoost outperformed the other models in terms of the F_1-score and PRAUC, the LGBM model demonstrated the most accurate calibration, with a calibration slope closest to 1, indicating superior reliability in risk prediction relative to the observed outcomes (Table 2 and Figure 2). The predicted probabilities of in-hospital falls were stratified assuming actual clinical use and compared with the observed in-hospital fall rates. The observed fall rates in the 4 defined risk categories (low, medium, high, and very high) fell within the range of predicted probabilities (Table 3).

Table 2. Model evaluation index.



Model	F_1-score (95% CI)	Optimal threshold	ROAUC[a] (95% CI)	PRAUC[b] (95% CI)	Calibration slope (95% CI)	Brier score (95% CI)
Logistic regression	0.120 (0.100-0.143)	0.069	0.729 (0.705-0.753)	0.066 (0.055-0.0792)	0.838 (0.739-0.934)	0.025 (0.023-0.027)
Extreme gradient boosting	0.182 (0.157-0.207)	0.074	0.774 (0.751-0.798)	0.098 (0.081-0.117)	0.937 (0.829-1.040)	0.024 (0.022-0.026)
Light gradient boosting machine	0.182 (0.156-0.209)	0.085	0.774 (0.751-0.797)	0.094 (0.078-0.113)	0.964 (0.858-1.070)	0.024 (0.022-0.026)
Categorical boosting	0.189 (0.162-0.215)	0.072	0.787 (0.764-0.809)	0.112 (0.091-0.136)	1.120 (1.000-1.240)	0.024 (0.022-0.026)

High: ≥0.05, <0.10	1727	143	0.08
Very high: ≥0.10	259	40	0.15

Model Interpretation

The contribution of each feature to the prediction of outcomes was visualized using the SHAP algorithm. The features were ranked in descending order of importance, with red indicating high influence and blue indicating low influence. All 4 models identified albumin levels, transfer, and neoplasms as key predictors, although the magnitude of their impact varied across the models (Figure 3). Additionally, medications—particularly hypnotics, sedatives, and diabetes treatments—were identified as important features in all models. These findings suggest that, in addition to medical conditions, functional abilities, such as transfer and dressing or undressing, play a significant role in predicting outcomes.

XSL•FO
RenderX

(A) Logistic regression, (B) extreme gradient boosting, (C) light gradient boosting machine, and (D) categorical boosting. JCS: Japan Coma Scale.

Classification From Incident Reports

We presented descriptive statistics of falls during hospitalization based on 435 incidents from the test data, categorized into different risk groups (low, middle, high, and very high) according to the predicted probabilities from the LGBM model (Table 4). These findings suggest that falls occur primarily at bedside, with the urge to defecate identified as the most common trigger. Notably, the characteristics of falls vary across risk groups; the proportion of bedside falls was higher in the high and very high risk groups (76/126, 60.3% vs 54/91, 59.3%, respectively), whereas falls occurring inside the patient room are more common in the low and middle risk groups (38/105, 36.2% and 41/113, 36.3%, respectively) These findings indicate that appropriately managing toileting needs and movements around the bedside is essential to prevent falls during hospitalization.

XSL•FO
RenderX

Table 4. Location and occasion of falls by risk.

	Overall (n=435)	Low (n=91)	Middle (n=124)	High (n=126)	Very high (n=94)
Occurrence date of falls during hospitalization, median (IQR)	9 (4-17)	8 (4-14)	11 (5-16)	7 (3-15)	9 (6-18)
Location of occurrence, n (%)					
Bedside	218 (50.1)	32 (35.2)	56 (45.2)	76 (60.3)	54 (57.4)
Inside the patient room	80 (18.4)	23 (25.3)	24 (19.4)	17 (13.5)	16 (17)
Inside the toilet	57 (13.1)	10 (11)	21 (16.9)	15 (11.9)	11 (11.7)
In the bathroom or washbasin area	15 (3.4)	5 (5.5)	5 (4)	3 (2.4)	2 (2.1)
Inside the hospital	63 (14.5)	21 (23.1)	17 (13.7)	15 (11.9)	10 (10.6)
Outside the hospital	2 (0.5)	0 (0)	1 (0.8)	0 (0)	1 (1.1)
Trigger of occurrence, n (%)					
Urge to defecate	214 (49.2)	39 (42.9)	58 (46.8)	64 (50.8)	53 (56.4)
Attempting to grab something	51 (11.7)	14 (15.4)	14 (11.3)	12 (9.5)	11 (11.7)
Standing or sitting position	79 (18.2)	14 (15.4)	22 (17.7)	31 (24.6)	12 (12.8)
Changing clothes	12 (2.8)	3 (3.3)	5 (4)	3 (2.4)	1 (1.1)
While walking	46 (10.6)	15 (16.5)	16 (12.9)	5 (4)	10 (10.6)
Others	33 (7.6)	6 (6.6)	9 (7.3)	11 (8.7)	7 (7.4)

Given that excretion-related falls accounted for the largest proportion of falls (217/435, 49.9%), we conducted a more detailed analysis of their characteristics.

Figure 4 presents the kernel density estimation of fall triggers by hour of the day, distinguishing between excretion-related triggers (such as the urge to defecate or urinate) and nonexcretion-related causes. The red curve indicates that excretion-related falls peaked in the early morning, particularly between 4 and 6 AM. In contrast, the blue curve representing nonexcretion-related falls displayed a broader temporal distribution, with a higher incidence in the afternoon. Among the 217 incidents involving toileting, 132 (61%) occurred while moving to the toilet, 52 (24%) occurred inside the toilet, and 33 (15%) occurred while returning from the toilet.

XSL•FO
RenderX

Figure 4. Factors in falls related to excretion. Kernel density estimation graphs showing the hourly distribution of triggers categorized by light gradient boosting machine–predicted probabilities ((A) low, (B) middle, (C) high, and (D) very high). The blue lines represent nonexcretion-related triggers (eg, other causes), and the red lines represent excretion-related triggers (urge to defecate or urinate). Density is plotted against the hour of the day (24-hour format).

Discussion

Principal Findings

This study evaluated the predictive accuracy and interpretability of machine learning models for assessing the in-hospital fall risk. Using LR, XGB, LGBM, and CatBoost, we aimed to identify high-risk patients and categorize falls based on their backgrounds and functional abilities. Our findings revealed that CatBoost achieved the highest F_1-score and PRAUC, whereas LGBM demonstrated the best calibration slope, closely approximating the ideal for risk prediction. Notably, functional abilities, such as transfer, and clinical factors, such as albumin and neoplasms, consistently contributed to fall prediction across the models. Further analysis of incident reports revealed that fall locations and triggers varied by risk level; falls near the bedside were more frequent in higher-risk groups, whereas excretion-related falls often occurred in the early morning hours. These findings suggest that proactive management of toileting and bedside movements may effectively reduce the incidence of falls among hospitalized patients.

In previous studies on machine learning–based fall prediction models, the reported ROAUC ranged from 0.7 to 0.9 [13]. Similarly, this study demonstrated a comparable predictive performance. However, it is important to note that model performance is influenced by several factors, including algorithms used, techniques for data balancing, data augmentation, and methods for handling missing values. To address class imbalance in this study, we applied the synthetic minority oversampling technique algorithm to increase the proportion of fall cases from 2.6% to 20%. While this approach improved model training, it may have altered the underlying data distribution and could lead to overestimation of predicted probabilities for the minority class (fall incidents). Therefore, such artificial balancing should be interpreted with caution, as it may introduce inherent bias into model performance metrics and clinical applicability. In comparing the models in this study, boosting algorithms exhibited a slight advantage over LR, likely due to their ability to capture the complexity of fall predictions more effectively. Although the existing literature on calibration is limited, the event incidence observed in each risk layer fell within the predicted probability ranges (low, middle, high, and very high), suggesting that appropriate risk stratification for falls was achieved. When evaluating the model utility, poor calibration can lead to overestimation or underestimation of risk, which poses substantial concern [29]. In clinical settings, overestimating fall risk could lead to inefficient allocation of nursing resources, potentially diverting attention from patients

XSL•FO
RenderX

truly at high risk, whereas underestimating risk may delay preventive interventions and increase adverse outcomes. Therefore, calibration is particularly important when predicted probabilities are linked to intervention thresholds or staffing decisions. The LGBM model developed in this study demonstrated reasonable calibration, as shown in the calibration plot, effectively mitigating the risk of overestimation and underestimation. Among the 4 models evaluated in this study, the boosting models exhibited good performance. Specifically, CatBoost proved more effective for discrimination, whereas LGBM was most suitable for calibration. In clinical application, the choice between models should depend on the intended use. Miscalibration may result in inefficient allocation of nursing resources or delayed preventive interventions, underscoring the importance of calibration when predicted probabilities are directly linked to intervention thresholds or staffing decisions. For scenarios where intervention thresholds are defined by predicted probabilities, a well-calibrated model such as LGBM may be preferable. In contrast, when resources are limited and identifying the highest-risk patients is the priority, CatBoost may be more advantageous. Future studies could also explore ensemble approaches that combine both strengths. Practical integration of the model into the electronic health record could allow nurses to view individualized fall risk scores in real time, and predefined thresholds could trigger tailored preventive interventions (eg, increased observation, assistance with toileting, or targeted rehabilitation exercises). Future prospective studies are needed to determine the optimal threshold settings and evaluate their impact on clinical outcomes. However, research on more precise calibration algorithms that use neural networks is ongoing, and the application of these methods could offer further improvements [30].

The key features identified in this study include decreased serum albumin levels, limitations in ADL, and the use of sedative-hypnotic medications, all of which are consistent with findings of previous reports [31]. Additionally, changes in gait, impaired balance, history of falls, muscle weakness, and polypharmacy have been identified as significant factors contributing to falls. These factors overlap with certain abnormalities in locomotive frailty, highlighting the importance of comprehensive assessment of nutritional status and ADL [32]. Importantly, these high-impact features are clinically modifiable to varying degrees. For example, low albumin levels may be addressed through nutritional supplementation, protein-enriched diets, and early mobilization programs. Impaired ADL, particularly transfer ability, could be targeted with physiotherapy and environmental adjustments to reduce mobility-related hazards. For patients receiving sedative-hypnotics or antidiabetic drugs, careful medication review, dose adjustment, or substitution should be considered to minimize adverse effects (eg, dizziness or hypoglycemia). Integrating these targeted interventions into clinical workflows could help translate model outputs into personalized fall-prevention strategies. From a pharmacological perspective, sedative medications and diabetes treatments have been identified as significant contributors to fall risk. Several studies have consistently reported that antipsychotics, antidepressants, and benzodiazepines are associated with a high risk of falls across [4]. Moreover, hypoglycemia and hyperglycemia during diabetes treatment increase the risk of falls in hospitalized patients. Abnormal blood glucose levels (either <70 mg/dL or >200 mg/dL) are associated with an increased risk of falls, and treatment with insulin or oral hypoglycemic agents is considered a contributing factor [33]. Patients with diabetes often present multiple comorbidities that can increase the risk of polypharmacy, further increasing the likelihood of falls [34,35]. These findings underscore the need for a comprehensive approach to reduce the risk of falls.

Toileting-related falls accounted for a significant percentage of the incidents (49.2%), particularly during the night. Nighttime toileting has been reported to be a significant risk factor, especially when associated with intravenous fluid infusion, history of falls, visual impairment, and gait instability [36]. The high frequency of falls occurring during transfer from beds or chairs to toilets supports these findings [37]. It has also been noted that the urge to urinate can increase walking speed and stride length, thereby heightening the risk of falls. This effect is closely related to the severity of urinary incontinence, and gait is strongly associated with complex cognitive functions. As cognitive function declines, executive function is also impaired, which can lead to abnormal gait patterns [38]. Additionally, the use of sleeping medications should be considered another factor contributing to toileting-related falls. These sleeping medications can impair reaction speed upon awakening in older adults, potentially affecting balance and muscle control [39,40]. Benzodiazepines and other sedatives have been shown to cause dizziness during nighttime awakening, further increasing the risk of falling during toilet-related activities. Therefore, it is essential to assess the use of sleeping medications and consider alternative drugs or dose reductions when necessary.

Limitations

This study has some limitations. First, as a retrospective study, the explanatory variables for the machine learning models were limited to those that could be easily collected from clinical data and had minimal missing values. Consequently, data such as fall history, vital signs, social factors, and implementation of fall-prevention measures were excluded. Second, because the study was conducted solely in medical facilities in Japan, the findings may not be generalizable to patients from other regions. Differences in health care delivery systems, patient demographics, and cultural practices related to fall prevention could influence the baseline risk and the effectiveness of prediction models. Therefore, future studies should validate the machine learning models using independent external data from hospitals in diverse geographic regions and health care systems, ideally in settings with different staffing models, resource availability, and fall-prevention protocols. Third, this study used only 4 machine learning algorithms (LR, XGB, LGBM, and CatBoost), whereas other algorithms, such as neural networks and support vector machines, may demonstrate superior predictive performance. Finally, the features used were limited to those available at the time of admission, and dynamic changes during hospitalization (eg, postoperative status, new-onset infections, and medication adjustments) were not considered. The absence of time-dependent variables, including repeated assessments of vital signs, mobility, nutritional status, and

XSL•FO
RenderX

mental state, may limit the ability of the model to capture short-term fluctuations in fall risk. Incorporating such dynamic patient data and continuous risk assessment throughout hospitalization could enable the development of models that more accurately reflect real-time risk and support timely, individualized preventive interventions. Future research integrating these factors, along with advanced transformer-based model architectures capable of capturing complex temporal and contextual relationships, may lead to more accurate and clinically useful prediction models [41].

Additionally, as with any machine learning approach, there is a potential risk of algorithmic bias, which may arise if certain patient subgroups (eg, older individuals, those with cognitive impairment, or those from resource-limited backgrounds) are underrepresented or systematically differ in predictor distributions. Such biases could inadvertently lead to unequal predictive performance across subpopulations, potentially exacerbating disparities in fall prevention efforts. Thus, future studies should include fairness assessment and bias mitigation strategies to ensure that prediction models are equitable and beneficial across all patient groups.

Conclusions

We developed a machine learning–based model for predicting inpatient fall risk and assessed its performance in terms of discrimination and calibration, achieving excellent calibration. SHAP analysis identified several factors associated with an increased risk of falls, including indicators of frailty and the use of sedatives, hypnotics, and diabetes medications. A detailed analysis of fall incidents revealed that toileting-related falls—particularly those occurring near the bedside during late-night and early morning hours—were prevalent. These findings underscore the importance of implementing preventive measures tailored to individual patient conditions and behaviors, such as mitigating risk during toilet transfers and maintaining balance upon awakening. We believe that these insights contribute to the development of more precise and effective fall-prevention strategies in hospitals.

Acknowledgments

The authors sincerely thank all the medical staff, technicians, medical engineers, nurses, pharmacists, and physicians at Nippon Medical School Hospital and Nippon Medical School Chiba Hokusoh Hospital for their dedicated care of patients. This work was supported by JSPS KAKENHI (grant 25K13474 to TN).

Data Availability

The datasets generated and analyzed during this study are not publicly available due to ethical restrictions and patient confidentiality concerns, as they contain sensitive information derived from Diagnosis Procedure Combination data and electronic medical records. However, deidentified data may be available from the corresponding author upon reasonable academic request and subject to approval by the institutional ethics committee.

Authors' Contributions

TN contributed to the conceptualization, methodology, investigation, original draft writing, and project administration. YK contributed to the conceptualization, methodology, investigation, review and editing of the manuscript, project administration, and funding acquisition. KM contributed to the methodology and review and editing of the manuscript. YM and NT contributed to the methodology and supervision. FY, HI, SS, AY, and MM contributed to data curation. KK, HJ, CK, YI, and HY contributed to conceptualization and supervision. All authors reviewed and approved the final version of the manuscript.

Abstract

Background: Sepsis-associated encephalopathy (SAE) represents a critical complication of sepsis, especially among older adults. Despite its clinical relevance, there remains a lack of accessible and practical tools specifically designed to predict 28-day mortality in this vulnerable population.

Objective: We aimed to enhance the practical applicability of the model by creating a web-based tool that allows real-time, individualized mortality risk prediction, facilitating early intervention and informed decision-making in clinical practice.

Methods: Using data extracted from the MIMIC-IV (Medical Information Mart for Intensive Care IV) database, we identified older patients (≥65 years) with SAE (n=2165) and divided them into a development cohort (n=1531) and a validation cohort (n=634). Key risk factors associated with 28-day mortality were identified, and a predictive nomogram was constructed. Model performance was evaluated using the concordance index, integrated discrimination improvement, net reclassification index, and calibration curve analysis. Clinical applicability was assessed through decision curve analysis and benchmarked against traditional intensive care unit (ICU) scoring systems. Furthermore, the nomogram was deployed as a web-based application, enabling clinicians to input data and generate individualized mortality predictions.

Results: A total of 2165 older patients with SAE were included, among whom 290 (13.4%) died within 28 days of ICU admission. Multivariable logistic regression identified lower body weight (odds ratio [OR] 0.985, 95% CI 0.975-0.994; *P*=.001), lower systolic blood pressure (OR 0.972, 95% CI 0.957-0.986; *P*<.001), lower hemoglobin (OR 0.984, 95% CI 0.974-0.995; *P*=.005), lower PaO2 (OR 0.996, 95% CI 0.994-0.997; *P*<.001), and lower Glasgow Coma Scale score (OR 0.825, 95% CI 0.786-0.864; *P*<.001) as mortality risk factors. Higher respiratory rate (OR 1.083, 95% CI 1.029-1.141; *P*=.002), increased anion gap (OR 1.081, 95% CI 1.031-1.135; *P*=.001), elevated blood urea nitrogen (OR 1.045, 95% CI 1.016-1.076; *P*=.002), prolonged partial thromboplastin time (OR 1.033, 95% CI 1.016-1.050; *P*<.001), and reduced urine output (OR>0.99, 95% CI 0.999-1.000; *P*=.002) were also predictive. Patients admitted to "other" ICU types had lower mortality compared with the medical ICU reference group (OR 0.327, 95% CI 0.176-0.609; *P*<.001). The nomogram achieved concordance index values of 0.899 (development) and 0.897 (validation), outperforming sequential organ failure assessment (0.692), Acute Physiology Score III (0.804), Logistic Organ Dysfunction System (0.771), Simplified Acute Physiology Score II (0.704), and Oxford Acute Severity of Illness Score (0.753), with significant integrated discrimination improvement and net reclassification index improvements (all *P*<.001). Calibration curves confirmed good agreement between predicted and observed outcomes, while decision curve analysis supported the model's superior clinical utility.

XSL•FO
RenderX

Conclusions: This study presents a novel, validated nomogram for predicting 28-day mortality in older patients with SAE, integrating routinely available clinical data. The deployment of the model as a digital tool enhances its accessibility and usability, providing clinicians with a practical resource for risk stratification and individualized patient management.

Introduction

Sepsis stands as a prevalent critical condition encountered within intensive care units (ICUs), presenting a formidable obstacle to global health care systems [1,2]. Characterized by diffuse cerebral dysfunction devoid of direct central nervous system infection or structural anomalies, sepsis-associated encephalopathy (SAE) emerges as a significant complication of sepsis [3]. The escalating global phenomenon of population aging has further accentuated the burden of sepsis [4-6], with a disproportionately heightened incidence observed among the older adult demographic [7]. Advanced age, in itself, emerges as an independent predictor of sepsis mortality, with older adult nonsurvivors succumbing earlier during hospitalization compared to their younger counterparts [7]. Nevertheless, older adult survivors of sepsis frequently necessitate specialized nursing or rehabilitative care post discharge [7]. Moreover, within the realm of older adult sepsis patients, the risk of developing SAE amplifies with advancing age, concomitantly exacerbating prognosis [6]. Precise prognostication of older adult patients with SAE holds paramount importance, facilitating risk stratification, fostering effective doctor-patient communication, and guiding clinical decision-making and therapeutic interventions.

The mortality prediction model, as a fundamental prognostic tool, epitomizes a distinct subset within clinical prediction models. Operating on the principle of predicting the unknown through the known, these models embody mathematical formulations wherein known variables are leveraged to compute the probability of an unforeseen outcome [8,9]. Central to the efficacy of such models lie the predictive variables, which serve as the bedrock for their construction [10]. When deliberating variable selection, considerations spanning economic feasibility, standardization, and accessibility necessitate careful scrutiny [10]. Conventional clinical parameters and hematological indices emerge as prime candidates for inclusion, owing to their cost-effectiveness, standardized measurement protocols, and ease of acquisition, thus positioning them as pivotal elements in the construction of robust clinical prediction models.

While several predictive models have been devised to anticipate mortality rates in cases of SAE [11-14], the development of such models tailored specifically for the older adult cohort remains, to the best of our knowledge, unprecedented. Therefore, this study aimed to develop and validate a clinically useful nomogram based on readily available clinical data from the MIMIC-IV (Medical Information Mart for Intensive Care IV) database. Additionally, we aimed to enhance the practical applicability of the model by creating a web-based tool that allows real-time, individualized mortality risk prediction, facilitating early intervention and informed decision-making in clinical practice.

Methods

Database

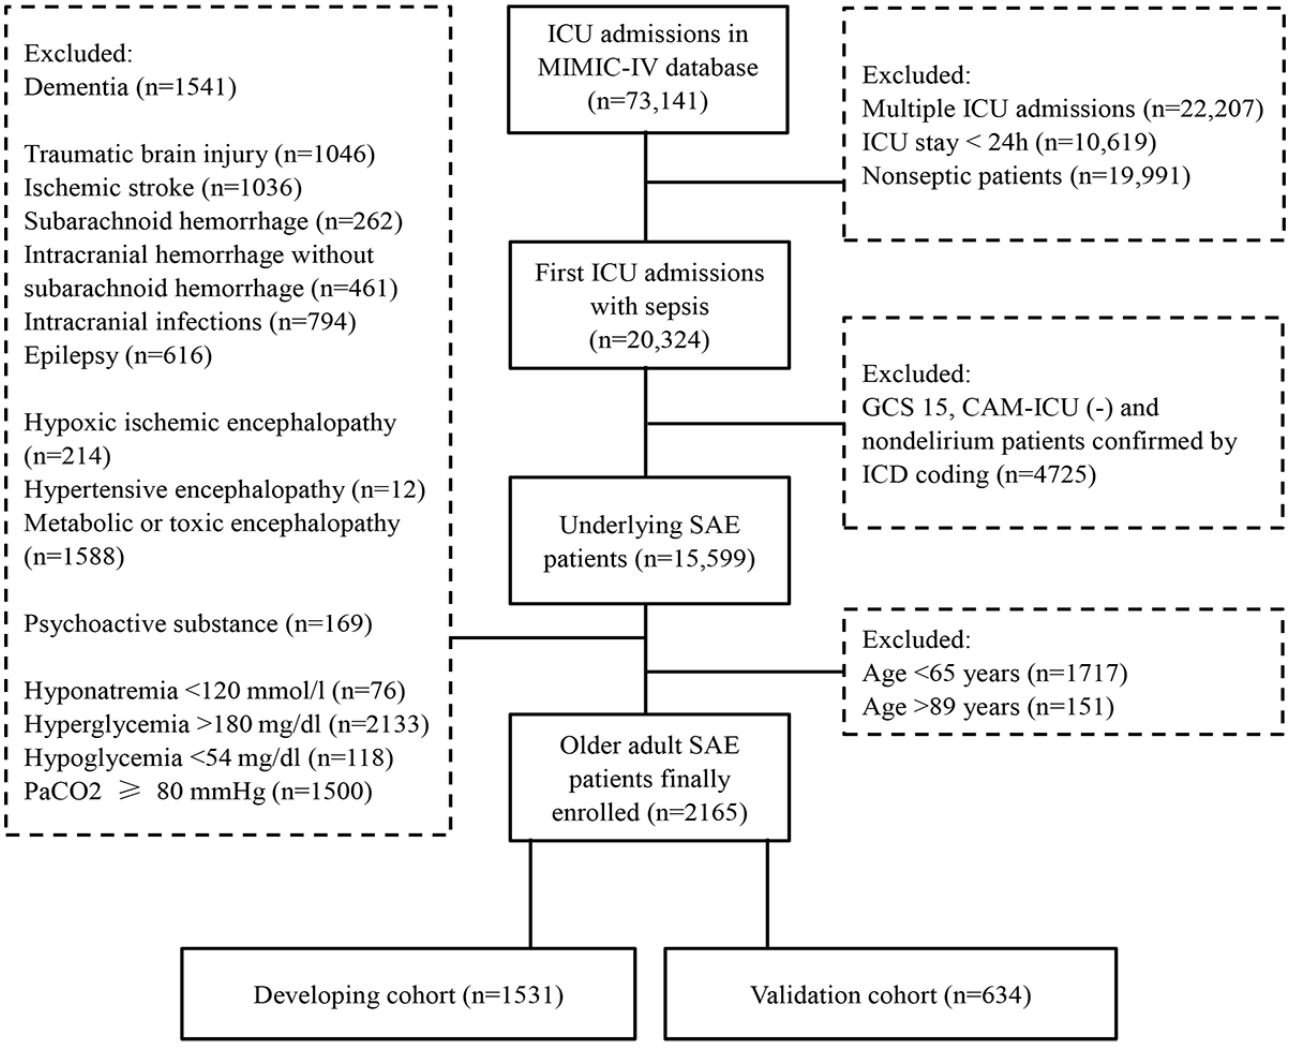
In adherence to the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) guidelines [9], this retrospective investigation harnessed data derived from the MIMIC-IV database, version 2.1, for the purpose of clinical predictive model development. MIMIC-IV serves as a repository for an extensive array of clinical data sourced from tens of thousands of patients treated at the Beth Israel Deaconess Medical Center in Boston, Massachusetts, encompassing a spectrum of vital signs, hematological parameters, and therapeutic interventions [15]. The primary investigator has undergone requisite human research training (certificate number 46141344) and has executed a PhysioNet-certified health data usage agreement, thereby obtaining authorized access to the MIMIC-IV database.

Ethical Considerations

The Institutional Review Committee at Beth Israel Deaconess Medical Center meticulously scrutinized the process of patient data collection and the establishment of the MIMIC (Medical Information Mart for Intensive Care) database [16]. Subsequently, the committee accorded an exemption from the requirement of obtaining informed consent and provided explicit approval for the dissemination of data as per the predefined data sharing protocol. In adherence to stringent privacy standards, a randomized cipher was used to substitute patient identifiers, thereby generating deidentified integer codes for patients, hospitalizations, and ICU admissions [16].

In accordance with prevailing national regulations governing research involving human subjects in life sciences and medicine, studies using human information data devoid of potential harm to individuals, sensitive personal details, or commercial interests may qualify for exemption from ethical review. Specifically, such exemptions apply to research endeavors using legally acquired public data or anonymized information. Our study satisfies the stipulated criteria for exemption from ethical review. Moreover, given the retrospective nature of our investigation, the requirement for individual informed consent has been waived in accordance with prevailing national regulations. No compensation was provided to participants.

Study Participants



The study cohort comprises older adult patients with SAE undergoing their initial admission to the ICU. Inclusion criteria were ascertained as follows [3,6,11-14]: (1) patients classified

XSL•FO
RenderX

as sepsis 3.0, denoting those diagnosed or suspected of infection within the MIMIC database with a SOFA (sequential organ failure assessment) score of ≥2. The MIMIC code library provides comprehensive codes for sepsis determination [17]; (2) SAE identification criteria: sepsis patients were deemed to have SAE if they met any of the following conditions on the first day after ICU admission: Glasgow Coma Scale (GCS) score=15 points with delirium, or GCS score <15 points. Delirium was determined based on positive Confusion Assessment Method for the Intensive Care Unit, or confirmed *ICD* (*International Classification of Diseases*) codes (2930, 2931, F05); (3) older adult classification: patients aged between 65 and 89 years (MIMIC encodes patients older than 89 years as 91 for deidentification purposes).

Exclusion criteria were formulated based on prior investigations [11,13,14], comprising: (1) records indicating second or subsequent ICU admissions; (2) ICU duration less than 24 hours; (3) diagnosis of dementia; (4) primary brain injuries, inclusive of traumatic brain injury, ischemic stroke, subarachnoid hemorrhage, intracranial hemorrhage excluding subarachnoid hemorrhage, intracranial infections, and epilepsy; (5) hypoxic ischemic encephalopathy; (6) hypertensive encephalopathy; (7) metabolic or toxic encephalopathy; (8) mental and behavioral disorders attributed to alcohol, drug, or psychoactive substance usage, including delirium induced by opioids, cannabis, cocaine, sedatives, hallucinogens, or other psychoactive substances; (9) concurrent severe electrolyte or blood glucose disturbances, such as hyponatremia (<120 mmol/L), hyperglycemia (>180 mg/dl), or hypoglycemia (<54 mg/dl) and PaCO2 (partial pressure of CO2) ≥ 80 mm Hg. The process of cohort selection is outlined in Figure 1.

Figure 1. Diagrammatic illustration of the patient selection protocol. CAM-ICU: Confusion Assessment Method for the Intensive Care Unit; GCS: Glasgow Coma Scale; ICD: International Classification of Diseases; ICU: intensive care unit; MIMIC-IV: Medical Information Mart for Intensive Care IV; PaCO2: partial pressure of CO2; SAE: sepsis-associated encephalopathy.

Data Extraction and Preparation

Data preparation and statistical processing in this study closely mirror methodologies used in our prior investigations [15,18]. Extracted research data encompass demographic particulars such as age, gender, weight, marital status, race, underlying medical conditions, and Charlson Comorbidity Index scores. Additionally, vital signs, pivotal laboratory parameters, use of

XSL•FO
RenderX

invasive mechanical ventilation, renal replacement therapy, administration of vasoactive agents, albumin infusion, GCS scores, and other critical care scoring metrics were captured on the inaugural day of ICU admission. Vasoactive drug use encompassed the administration of norepinephrine, adrenaline, dopamine, dobutamine, vasopressin, or milrinone. For variables measured multiple times on the initial day of ICU admission, MIMIC concepts were used to derive minimum, maximum, and, if applicable, average values.

The primary end point of interest was the 28-day mortality, ascertained based on survival status 28 days post-ICU admission.

Preliminary dataset preparation entailed outlier management and handling of missing values, executed using Stata software (version 17.0, Stata Corporation LLC). As illustrated in Figure S1 of Multimedia Appendix 1, the extent of missingness for each variable was visualized using the *DataExplorer* package in R (version 4.3.2, R Foundation for Statistical Computing). Variables with more than 20% missing values were excluded from further analysis to ensure data quality. Initial outlier detection entailed histogram analysis to pinpoint anomalies within the dataset. Subsequent to identification, winsorization was used to mitigate outlier influence by replacing extreme values with thresholds established at the 0.1% and 99.9% quantiles using the Winsor2 command. Addressing missing data conundrums necessitated the application of diverse interpolation techniques to generate 5 sets of interpolated data. For variables with ≤20% missingness, multiple imputation was performed using Stata under the multivariate normal regression framework, as implemented by the command. The imputation model included all candidate predictor variables, relevant demographic characteristics, comorbidities, and severity scores to preserve associations among variables and reduce bias. Five imputed datasets were generated with 500 iterations of Markov Chain Monte Carlo data augmentation following a 100-iteration burn-in phase. Collinearity was checked before imputation, and variables causing collinearity were omitted automatically by Stata. Post imputation, 1 randomly selected dataset was extracted for subsequent analyses, following Rubin rules for ensuring consistency across imputations. Descriptive checks confirmed that imputed values were within plausible clinical ranges and maintained the overall distributional properties of the observed data.

Statistical Analysis

Statistical analyses were conducted using R software (version 4.3.2). The cohort of older adult patients with SAE was randomly partitioned into development and validation subsets at a ratio of 7:3, using a seed size of 73. Univariate analyses were performed on both the development and validation cohorts using the "gtsummary" software package. Continuous variables demonstrating nonnormal distribution were summarized using median and IQR, while categorical variables were presented as numerical counts or percentages. Statistical significance was defined as P value <.05.

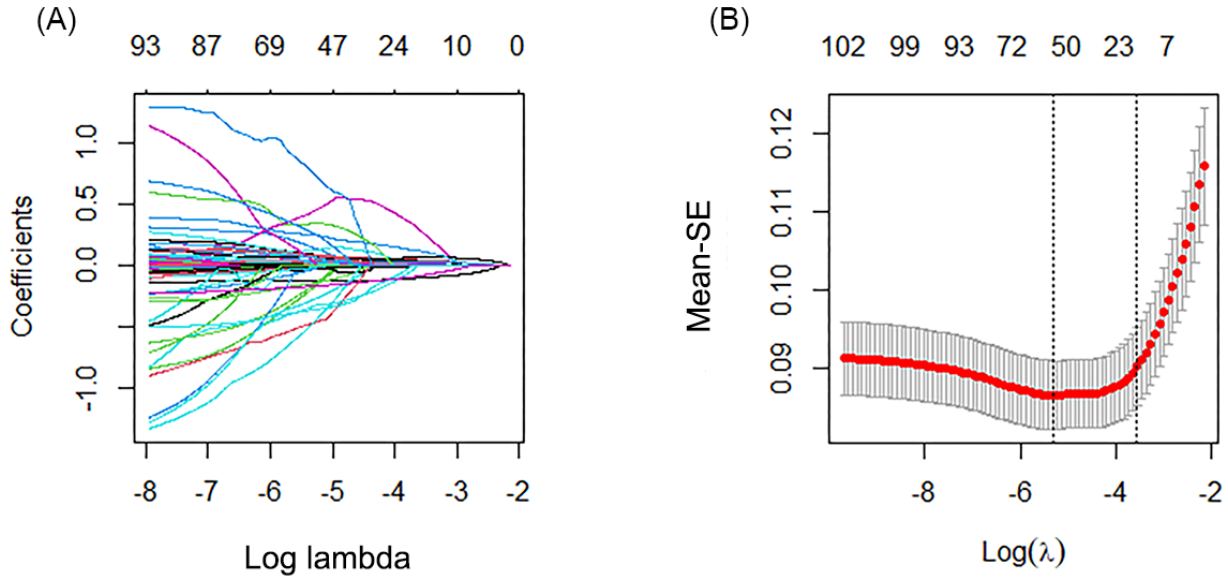
In the development cohort, LASSO (least absolute shrinkage and selection operator) regression, facilitated by the "glmnet" R package, was used to identify potential variables associated with 28-day mortality in older adult patients with SAE. Subsequently, multiple-factor binary logistic regression was conducted to discern the final independent risk factors. The "car" R package was used to compute the variance inflation factor, assessing collinearity between variables. A prognostic nomogram was constructed using the "rms" R data package.

To evaluate the predictive performance of the nomogram, the "pROC" R package was used to calculate the concordance index (C-index), while the "PredictABEL" R software package facilitated computation of the integrated discrimination improvement (IDI) and net reclassification improvement (NRI). Receiver operating characteristic curves for both the development and validation datasets were generated using the "riskRegression" R package to assess model sensitivity and specificity across different probability thresholds. Calibration of the nomogram was assessed via generation of a calibration curve using the "val.prob" function within the "rms" R data package. Additionally, the Hosmer-Lemeshow goodness-of-fit test was performed using the "hoslem.test" function in the *ResourceSelection* R package to further evaluate model calibration. Subsequently, decision curve analysis was conducted using the "rmda" R data package to meticulously evaluate the clinical utility and benefits conferred by the developed nomogram. We deployed the developed predictive model as a web-based tool using the *Shiny* and *rsconnect* packages in R. This web-based application allows users to input patient-specific data and obtain an estimated probability of 28-day mortality, facilitating clinical utility and accessibility of the nomogram.

Results

Baseline Characteristics

A total of 2165 older adult patients with SAE were included, among whom 290 (13.4%) died within 28 days of ICU admission. Table S1 in Multimedia Appendix 2 offers a comprehensive summary of the baseline characteristics observed across the entire cohort of older adult patients with SAE, delineating findings from both the developmental cohort (n=1531) and the validation cohort (n=634). Following meticulous examination, no statistically significant differences (P>.05) were discerned in demographic attributes, comorbidities, indices of disease severity, vital signs, common hematological parameters, or therapeutic interventions between the development and validation cohorts. Notably, the absence of statistically significant distinctions underscores the efficacy of random allocation methodologies in ensuring comparability between cohorts, thus underscoring the robust scientific underpinnings guiding cohort allocation. Older adult patients with SAE were stratified into distinct survival and mortality groups based on their 28-day survival outcomes. Baseline comparisons between these groups within the development and validation cohorts are presented in the supplementary materials for comprehensive elucidation.



Variable Selection and Nomogram Construction

Using a hybrid approach of LASSO regression coupled with 10-fold cross-validation (Figure 2A and 2B), potential clinical determinants correlating with 28-day mortality in older adult patients with SAE were identified. Subsequent binary multivariate logistic regression analysis corroborated the

XSL•FO
RenderX

significance of 11 distinct clinical factors or hematological parameters as independent predictors of 28-day mortality within this cohort (P<.05; Table 1). All included predictors demonstrated acceptable collinearity, with variance inflation factor values presented in Multimedia Appendix 3 (Figure S1), confirming that multicollinearity did not compromise the stability of the regression model. These discerned variables were subsequently integrated to devise a prognostic nomogram (Figure 3).

Figure 2. LASSO regression-based feature selection process with tenfold cross-validation. (A) The plot illustrates the relationship between the coefficients of clinical features and lambda values within the LASSO regression framework. (B) The graph depicts the 10-fold cross-validation curve used in LASSO regression, offering insights into model selection. The left dashed vertical line indicates the optimal log (lambda) value (λ=0.004900582) corresponding to the minimum mean SE. Additionally, following the 1 SE rule, the right dashed vertical line represents the model incorporating 11 variables (λ=0.02870281). LASSO: least absolute shrinkage and selection operator regression.

[a]OR: odds ratio.

[b]SICU: surgical intensive care unit.

[c]MICU: medical intensive care unit.

[d]Neuro SICU: neurosurgical intensive care unit.

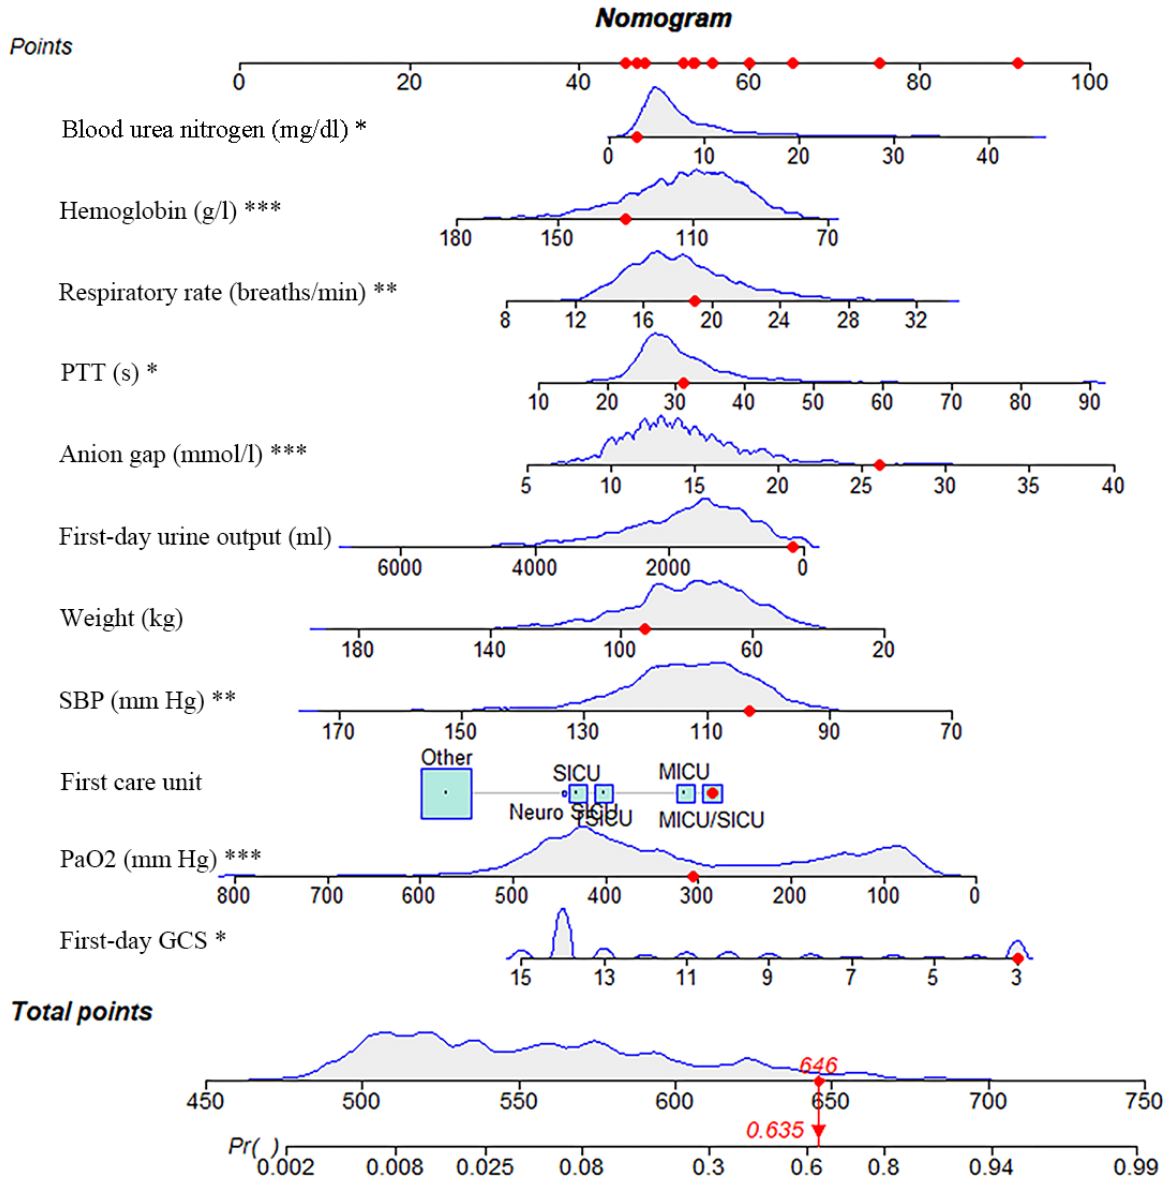
[e]TSICU: trauma surgical intensive care unit.

[f]SBP: systolic blood pressure.

[g]Denotes the mean values of relevant indicators observed during the initial day of intensive care unit admission.

[h]Indicates the maximum values of clinical parameters recorded within the first day of intensive care unit admission.

[i]Represents the minimum recorded values of essential indicators observed on the initial day of admission to the intensive care unit.



[j]PTT: partial thromboplastin time.

[k]GCS: Glasgow Coma Scale.

Figure 3 depicts a representative case: an older adult patient with SAE, weighing 93 kg, was admitted to the medical or surgical intensive care unit (SICU). On the initial day of admission, the patient exhibited the following clinical and hematological parameters: the lowest blood urea nitrogen level recorded was 2.86 mg/dl, the highest hemoglobin concentration was 130 g/l, the mean respiratory rate was 18.96 beats/min, the lowest partial thromboplastin time (PTT) was 31.1 seconds, the maximum anion gap (AG) was 26 mmol/L, the first day urine output was 185 ml, the average systolic blood pressure was 103.02 mm Hg, the highest partial pressure of arterial oxygen was 306 mm Hg, and the lowest GCS score was 3 points. Based on these findings, the cumulative score for this patient was calculated as 646 points, corresponding to a predicted 28-day mortality rate of 0.635.

XSL•FO
RenderX

Figure 3. Nomogram visualization for predicting 28-day mortality probability in geriatric patients with SAE. This graphical representation illustrates a nomogram tailored to estimate the likelihood of 28-day mortality among older adult individuals diagnosed with SAE. The nomogram operates by assigning points to specific variables based on their respective values. These points are then totaled, and the corresponding 28-day mortality rate can be determined by referencing the total points axis. This depiction elucidates the operational framework of the nomogram in forecasting personalized mortality risks for older adult patients with SAE. *Represents the minimum recorded values of essential indicators observed on the initial day of admission to the intensive care unit. **Indicates the mean values of clinical parameters recorded within the first day of intensive care unit admission. ***Denotes the maximum values of relevant indicators observed during the initial day of intensive care unit admission. GCS: Glasgow Coma Scale; MICU: medical intensive care unit; Neuro SICU: neurosurgical intensive care unit; PTT: partial thromboplastin time; SAE: sepsis-associated encephalopathy; SBP: systolic blood pressure; SICU: surgical intensive care unit; TSICU: trauma surgical intensive care unit.

Discriminative Performance and Calibration Assessment of Nomogram

The derived prognostic nomogram exhibited a calculated C-index of 0.899 (95% CI 0.877-0.921) in the development cohort and 0.897 (95% CI 0.864-0.929) in the validation cohort. Comparative analyses revealed that the discriminatory performance of the constructed nomogram surpassed conventional benchmarks, including GCS score and commonly used disease severity scoring systems (Table 2). Receiver operating characteristic curve analysis was also performed to assess model sensitivity and specificity across different thresholds, with the resulting curves for both the development and validation datasets presented in Figure S1 of Multimedia Appendix 4, further demonstrating the classification ability and clinical utility of the nomogram. Furthermore, evaluations using IDI and NRI metrics revealed substantial enhancements in the predictive accuracy of the devised nomogram for 28-day mortality (both P<.001; Table 3).

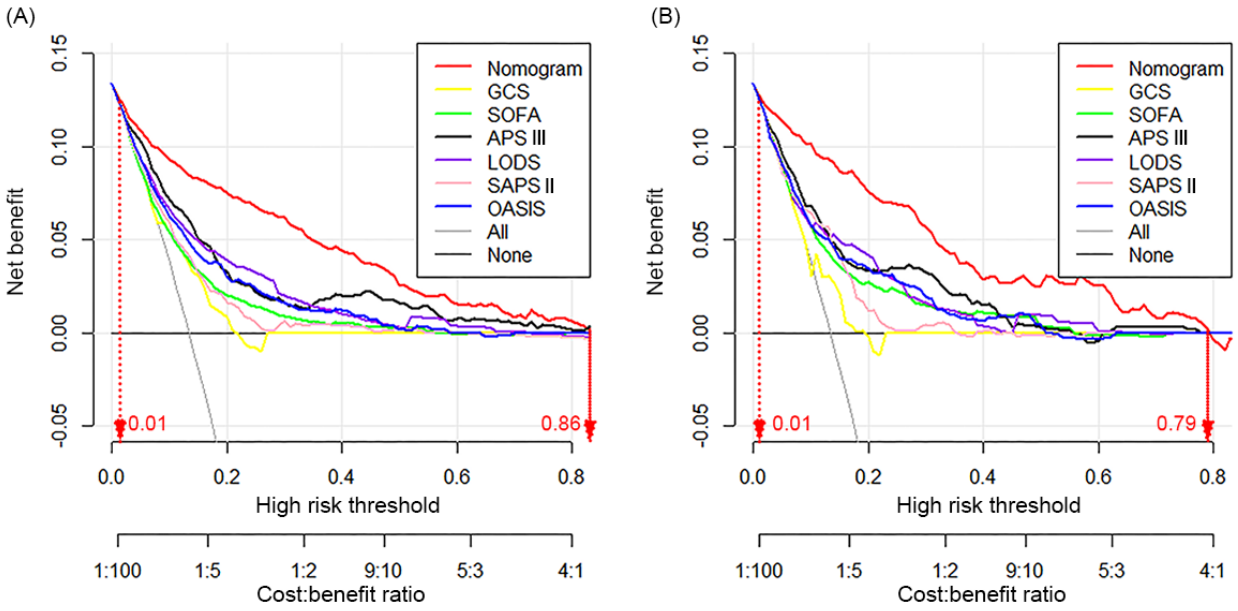
Significantly, a striking resemblance between the anticipated and observed 28-day mortality rates was observed, with statistical analyses revealing no discernible differences within both the development and validation cohorts (Figure 4A and

XSL•FO
RenderX

4B). The Hosmer-Lemeshow goodness-of-fit test further confirmed adequate calibration of the nomogram, with nonsignificant results in both the development cohort (χ^2_8=4.6, *P*=.81) and the validation cohort (χ^2_8=8.7, *P*=.37), indicating no evidence of lack of fit.

Figure 4. Calibration curve assessing the predictive accuracy of the established nomogram for 28-day mortality. This calibration curve illustrates the alignment between predicted and observed 28-day mortality rates in both the (A) development and (B) validation sets. The lack of statistically significant differences (*P*>.05) indicates the robustness and reliability of the predictive model, affirming its accuracy in estimating mortality outcomes. C (ROC): concordance index (receiver operating characteristic curve); D: discrimination index; Dxy: rank correlation between predicted probabilities and observed values; E90: 90th percentile of the prediction error; Eavg: average error; Emax: maximum absolute error; Q: quality index; R2: Nagelkerke-Cox-Snell-Maddala-Magee R-squared index; S:p: the *P* value of Spiegelhalter z-test; S:z: The z-value of Spiegelhalter z-test; U: unreliability index.

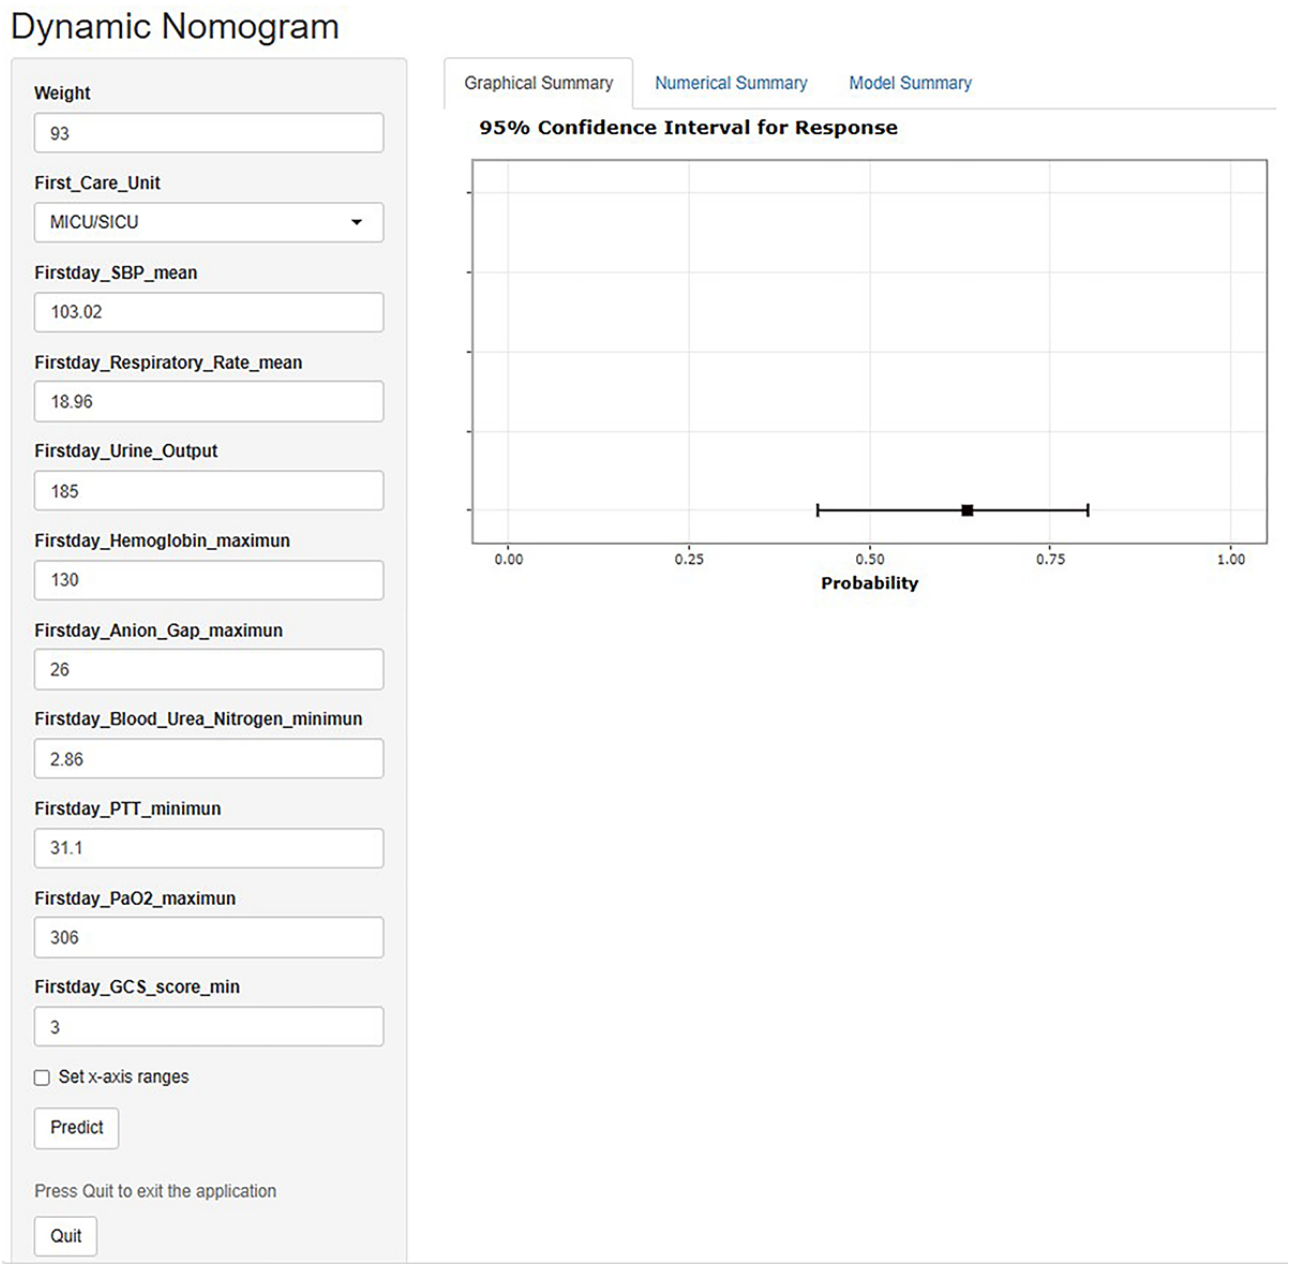


Evaluation of Nomogram Clinical Applicability in Predicting 28-Day Mortality in Older Adult Patients With SAE

As depicted in Figure 5, the graphical representation illustrates the pronounced net clinical benefit conferred by the developed nomogram, denoted by the red line, in comparison to established metrics such as the GCS score and widely used scoring systems. Across a probability threshold range of 0.01-0.86 in the development cohort and 0.01-0.79 in the validation cohort, the nomogram consistently demonstrated greater net benefit. Remarkably, our formulated nomogram demonstrates markedly heightened clinical effectiveness, underscoring its superior practical applicability and utility in prognostication relative to conventional scoring methodologies.

XSL•FO
RenderX

Figure 5. Evaluation of clinical utility through decision curve analysis: comparative assessment between the developed nomogram and established clinical scoring systems in the training and validation cohorts. Decision curve analysis is used to compare the clinical utility of the nomogram developed in this study with conventional clinical scoring systems in predicting outcomes. The red line represents the nomogram, which showed higher net benefit across the threshold ranges of 0.01-0.86 (training cohort) and 0.01-0.79 (validation cohort). APS III: Acute Physiology Score III; GCS: Glasgow Coma Score; LODS: Logistic Organ Dysfunction System; OASIS: Oxford Acute Severity of Illness Score; SAPS II: Simplified Acute Physiology Score II; SOFA: sequential organ failure assessment.



Deployment of the Web-Based Nomogram

To enhance clinical applicability, we deployed the developed nomogram as a web-based calculator using the *Shiny* and *rsconnect* packages in R. This web-based tool is accessible online [19]. Clinicians can input readily available clinical parameters to obtain an individualized estimate of 28-day mortality risk in older adult patients with SAE.

To illustrate the practical use of the web-based calculator, we applied the same patient case presented in Figure 3 to generate a predicted probability of 28-day mortality through the web interface (Figure 6). As shown in Figure 6, the model provides an intuitive visual output that complements the static nomogram, offering immediate clinical insight for bedside decision-making.

XSL•FO
RenderX

Figure 6. Web-based application demonstration using a representative patient case. GCS: Glasgow Coma Scale; MICU: medical intensive care unit; SBP: systolic blood pressure; SICU: surgical intensive care unit; PTT: partial thromboplastin time.

The web-based dynamic calculator interface for the 28-day mortality nomogram is shown. Clinical parameters from the same representative case in Figure 3 were entered into the web tool, generating an individualized prediction of 28-day mortality risk. The tool provides an intuitive output that enhances the model's accessibility and facilitates clinical application at the bedside.

Discussion

Principal Results

In the context of societal aging, precise evaluation of short-term prognosis among older adult patients with SAE becomes imperative. Regrettably, the current landscape lacks tailored clinical prediction models for this demographic subset. To our knowledge, our study marks the inaugural development and validation of a clinical prediction model meticulously crafted to forecast 28-day mortality rates in older adult patients with SAE. Moreover, the deployment of the nomogram as a web-based application enhances its accessibility and ease of use, offering real-time, individualized mortality risk assessments that can support decision-making in busy clinical settings.

Clinical prediction models for SAE have attracted increasing academic interest, with existing studies mainly focusing on 2 aspects: models predicting the occurrence of SAE and models predicting mortality among patients with SAE [11-14,20-23]. For example, a nomogram was constructed using 9 variables identified through multivariable regression analysis to predict the occurrence of SAE. However, it is noteworthy that the use of midazolam was also included as one of the predictive factors, which may be somewhat perplexing, because alterations in consciousness induced by midazolam require careful distinction

XSL•FO
RenderX

from those attributable to SAE [22]. Older adult populations have also received special attention, as SAE has been identified as an independent risk factor for in-hospital mortality among older adult ICU patients, and a nomogram has been established to predict the probability of SAE in this subgroup [21]. Machine learning methods have likewise been applied to SAE prediction, with 6 classifiers compared for their performance in predicting SAE occurrence. Among them, an Extreme Gradient Boosting–based model demonstrated superior predictive accuracy using simple clinical indicators while offering visual interpretability [23]. However, this model relied on predictors such as length of stay and ventilation duration [23]. In practice, such time-dependent indicators may only become available late in the hospitalization process, at which point SAE onset may already be apparent, thus limiting clinical utility.

Prediction models have also been developed for SAE-related mortality, using both nomograms and machine learning methods to estimate 30-day outcomes [11,13]. For instance, models using APS III (Acute Physiology Score III) and SOFA score as predictors have been reported [13], though their clinical applicability is hampered by the complexity of APS III calculation. More advanced machine learning approaches have even combined the 3 best-performing classifiers (elastic net, support vector machine, and Extreme Gradient Boosting) into a stacked ensemble model for predicting ICU mortality in patients with SAE. This model achieved an internal validation AUC of 0.807, but external validation revealed a reduced AUC of 0.671, raising concerns about generalizability and stability [20]. In comparison with extant clinical prediction models for SAE [11-14,20], our study shares a commonality in the inclusion of GCS scores and respiratory rate as key independent variables. This convergence offers novel avenues for future investigations into SAE-related prediction models. However, our investigation diverges by specifically targeting SAE mortality rates in the older adult population [11-14], leveraging the updated MIMIC-IV database. Notably, meticulous attention was devoted to refining inclusion and exclusion criteria for patients with SAE during data processing, ensuring the enrollment of cohorts with comprehensive data profiles and mitigating selection biases. Using the simplest supervised learning algorithm predicated on binary classification outcomes, our study used logistic regression, showcasing distinct advantages over alternative machine learning methodologies [8,24,25]. Notable benefits include a parsimonious model structure, robust fitting, and enhanced user-friendliness. Despite its simplicity, the nomogram devised in our study incorporates a select number of variables yet demonstrates commendable discriminative capacity. Furthermore, the nomogram's accessibility renders it amenable to integration into routine clinical practice, bolstering its utility in real-world health care settings.

Leveraging commonplace clinical data and hematological parameters sourced from the MIMIC-IV database, our model stands as a user-friendly tool poised to address this critical gap. Using LASSO regression for initial dimensionality reduction mitigates overfitting concerns and enhances model practicality and interpretability [26,27]. Logistic regression, a venerable statistical technique in clinical research, aids in identifying independent risk factors [28]. Our analysis pinpointed several variables, including type of first care unit, GCS score, weight, systolic blood pressure, respiratory rate, urine output, and hematological indices (blood urea nitrogen, hemoglobin, PTT, AG, and PaO2), as significant predictors. Evaluation metrics such as the C-index gauge predictive efficacy across development and validation cohorts [29], while NRI and IDI analyses highlight performance enhancements relative to conventional ICU scoring systems. Calibration curves attest to the alignment of predicted outcomes with actual observations. Furthermore, decision curve analysis underscores the superior practical utility and clinical decision-making benefits of our predictive model compared to existing scoring systems. Additionally, a user-friendly column chart has been devised for seamless clinical integration, thus facilitating wider adoption and dissemination of our model in clinical practice.

The GCS score stands as a pragmatic tool for clinical evaluation of consciousness impairment [30], serving as a cornerstone in defining SAE [6]. Even subtle alterations in mental status, such as GCS scores ranging from 13 to 14, independently correlate with mortality [31]. The prognosis of SAE may be intertwined with impaired brain autoregulation and inadequate cerebral perfusion. Continuous monitoring of cerebral blood oxygen levels via near-infrared spectroscopy enables delineation of the blood pressure range conducive to optimizing brain autoregulation, thereby enhancing cerebral perfusion in SAE [32]. The threshold for detrimental cerebral hypoperfusion manifests variably across individuals, and dysregulation in SAE may arise from blood pressure dipping below the optimal range [32]. Our findings align with this notion, indicating a detrimental association between lower blood pressure and poor prognosis in SAE. Additionally, respiratory rate, a fundamental vital sign, emerges as a pivotal indicator in emergency and critical care settings, exhibiting robust prognostic value in sepsis patients [33].

In terms of laboratory parameters incorporated into our model, blood urea nitrogen serves as a reflective indicator of renal function, in common with urine output. Sonneville et al [31], in a multicenter retrospective study, identified acute renal failure as a risk factor for SAE, attributing this association to biological alterations potentially impacting brain function, including severe acidosis and uremia. Additionally, diminished renal function may precipitate the accumulation of neurotoxic substances [31]. Notably, elevated blood urea nitrogen levels [13] and diminished urine output emerge as risk factors for short-term mortality in SAE, a conclusion echoed in our study among the older adult population. Hemoglobin levels, commonly used to assess the overall anemia status across diverse patient populations, and an investigation involving 8853 patients with SAE revealed that the ratio of hemoglobin to red blood cell distribution width offers enhanced prognostic value for ICU all-cause mortality in patients with SAE [34]. Moreover, activated PTT waveform analysis has been posited as an effective means to discern sepsis [35], with previous data indicating that coagulation abnormalities exacerbate mortality risk in sepsis patients [36]. Elevated activated PTT levels, indicative of coagulation dysregulation, have been closely associated with SAE mortality [14], corroborated by our findings within the older adult population. Hypoxemia presents a prevalent concern among

XSL•FO
RenderX

ICU patients, with its severity proving to be an independent predictor of mortality within this cohort [37]. Reduced oxygen saturation has emerged as a mortality risk factor in SAE [12], paralleling our assertion that diminished oxygenation index poses a risk to 28-day survival in older adult patients with SAE.

The type of initial care unit, AG, and body weight constitute 3 pivotal variables within our model. Previous studies have suggested that the introduction of specialized neurocritical care teams, including a dedicated full-time neurointensivist, is associated with significantly reduced in-hospital mortality and length of stay, although no effect was observed on readmission rates or long-term mortality [38]. Moreover, the presence of a neurointensivist has been linked to improved clinical outcomes, particularly among patients with aneurysmal subarachnoid hemorrhage, whereas patients with intracerebral hemorrhage often exhibit poor prognosis regardless of the availability of a neurointensive care unit or physician [39]. In our analysis, however, the type of ICU (including neurosurgical intensive care unit) did not appear to exert a strong influence on short-term mortality in older adult patients with SAE. However, existing mortality prediction models for SAE have not thoroughly explored the interplay between these factors, including the initial care unit type, and SAE [11-14], necessitating further inquiry in forthcoming high-quality investigations. Body weight influences lifespan, and notably, BMI exhibits a U-shaped relationship with 28-day mortality rates in severe sepsis patients [40]. Nevertheless, in prognosticating sepsis outcomes, the focus should extend beyond mere BMI-mortality associations, emphasizing the nuanced interplay with disease severity [41]. A prospective cohort study involving 862 older adult individuals aged 65 years and older in South Korea unveiled high serum AG as a potential independent predictor of overall mortality in this demographic, with elevated AG also impacting cardiovascular and infection-related mortality [42]. Lower body weight and elevated AG emerge as mortality risk factors in older adult SAE, as delineated in our investigation.

Limitations

This study is subject to several inherent limitations warranting discussion. Primarily, despite the extensive clinical dataset available within the MIMIC-IV database, the presence of missing values and outliers poses a potential challenge. To address this concern, rigorous data cleaning and processing protocols were implemented to enhance data quality and mitigate potential biases. Second, certain pertinent clinical features, such as electroencephalogram data, central imaging techniques, cerebral oxygen levels, neurofilament light chain, and cerebral blood flow measurements, were not incorporated into our analysis due to their absence within the MIMIC database. Nevertheless, our study used rigorous inclusion and exclusion criteria to ensure well-defined cohorts. Moreover, this study focused on investigating a broad array of clinical features and hematological parameters that were readily accessible. Additionally, although variables such as lactate and white blood cell count were available, they were excluded during the LASSO regression variable selection process. Other potentially relevant inflammatory markers, including procalcitonin, C-reactive protein, serum amyloid A, and heparin-binding protein, were not included due to their unavailability in the database. To enhance the clinical practicality of the model, our study focused on commonly measured and readily accessible variables as candidate predictors. Third, our study solely undertook internal validation of the predictive model. Further external validation across diverse patient cohorts is imperative to ascertain the generalizability and robustness of the established nomogram. Lastly, the retrospective nature of this investigation underscores the imperative for future prospective studies to validate the clinical applicability and effectiveness of our developed nomogram. Prospective studies would afford opportunities to confirm the predictive accuracy of the nomogram in real-time clinical settings, thus enhancing confidence in its utility and informing clinical decision-making.

Conclusions

In this study, we developed and internally validated a nomogram for predicting 28-day mortality in older adult patients with SAE using commonly available clinical data from the MIMIC-IV database. The model demonstrated satisfactory discriminative performance and calibration, with potential clinical utility as compared to traditional ICU scoring systems. Additionally, by implementing the nomogram as a web-based tool, we aimed to improve its accessibility and practical use in clinical settings. While promising, further external validation and prospective studies are necessary to confirm its broader applicability and effectiveness in diverse health care environments.

Acknowledgments

The authors wish to acknowledge the creators of the MIMIC database and ChatGPT (OpenAI) service for their invaluable contributions to this research endeavor. Furthermore, the authors express their appreciation to Home for Researchers [43] for their assistance with paper preparation and journal selection. During the preparation of this work, the authors used ChatGPT 3.5 in order to improve the readability and language of this paper. After using this tool or service, the authors reviewed and edited the content as needed and take full responsibility for the content of the publication. Abstract

Background: Patients with diabetes are at higher risk of developing liver cancer. Nevertheless, risk factors and their interaction patterns have rarely been compared between patients with and those without diabetes, nor have their interactions been incorporated into scoring system development.

Objective: This study aims to compare risk factors, their interaction patterns, and resulting scoring systems for liver cancer risk according to diabetes and liver disease status using tree-structured algorithms.

Methods: A retrospective cohort study was conducted using electronic health records in Hong Kong. Patients who had used public health care services between 1997 and 2021 without cancer history were identified and followed up until December 31, 2021. Scoring systems were developed based on aggregate results from individual survival trees in random survival forest, and interaction patterns among factors were separately examined using conditional inference survival tree.

Results: Of the 190,971 patients included, 1275 developed liver cancer during follow-up (median 6.25 y). Across 4 scoring systems, alanine aminotransferase (ALT) levels, age, sex, and triglycerides were commonly chosen as predictors irrespective of diabetes and liver disease status. In the overall systems, liver cirrhosis was additionally selected as a predictor, with chronic viral hepatitis uniquely chosen in diabetes. In the absence of liver disease, fasting glucose and smoking were uniquely selected for diabetes and nondiabetes, respectively. Chronic viral hepatitis appeared as the strongest risk factor in diabetes but not in nondiabetes. Among people with diabetes, in the absence of chronic viral hepatitis, sex became the most important factor, followed by age, statin use, and ALT levels. Among people without diabetes, age became the most dominant risk factor. For older patients (>55 y), uncontrolled lipids and male sex became key risk factors in statin and nonstatin users, respectively, when the ALT level was higher (>43.4 U/L), while smoking became a key risk factor when the ALT level was lower (≤43.4 U/L). For younger patients (≤55 y), sex remained the most significant factor.

Conclusions: Patients with and those without diabetes exhibit distinctive interaction patterns among key factors on liver cancer risk. The resulting scoring systems reflect interaction patterns among predictors in individual survival trees. This study may help identify targets for public health interventions and provide clinical cancer risk prediction according to diabetes status.

liver cancer; diabetes; risk factor; interaction; risk prediction; risk score; risk stratification; decision tree; random forest; survival analysis

Introduction

Liver cancer is the third leading cause of cancer death worldwide [1]. Previous research has shown that diabetes is associated with an increased risk of cancer at several sites, including the liver [2,3]. Nevertheless, there is a lack of systematic comparison on the interaction patterns among key factors between patients with and those without diabetes. Nor have scoring systems been developed separately according to diabetes status.

While most risk prediction models for liver cancer focus on patients with known risk factors such as liver cirrhosis, chronic viral hepatitis, hepatic steatosis, and heavy alcohol use [4,5],

XSL•FO
RenderX

several risk scoring systems developed among patients with [6,7] and those without known risk factors [8] have incorporated diabetes as a predictor. Nevertheless, only a few risk scoring systems have been developed specifically for diabetes population [9,10]. Si et al [9] has developed a scoring system for liver cancer prediction among people with diabetes without chronic viral hepatitis or alcoholic cirrhosis from South Korea with only 3 predictors, namely age, triglycerides, and gamma-glutamyl transferase (GGT), where lower triglyceride levels were found to be predictive of an elevated risk of liver cancer. On the other hand, Li et al [10] have incorporated a number of predictors, including age, sex, smoking, alanine aminotransferase (ALT) levels, glycated hemoglobin, liver cirrhosis, chronic viral hepatitis, and lipid profile into a scoring system for liver cancer prediction developed among people with diabetes from Taiwan. However, these diabetes-specific scoring systems lack comparison with people without diabetes, nor were interaction patterns among covariates examined.

Existing scoring systems rarely incorporate interaction patterns into variable selection. Nevertheless, previous research suggests that factors associated with liver cancer are often interrelated. For example, while both chronic hepatitis B or C [11] and diabetes [3] are independent risk factors for liver cancer, previous studies have also shown that hepatitis B or C infection could be linked to an elevated risk of type 2 diabetes development [12,13]. Also, while sex-specific elevated ALT thresholds are available [8], the potential age dependence of ALT [14-16] has rarely been incorporated. Furthermore, despite the common coconsumption of alcohol and smoking, and heavy alcohol use as known cause for liver damage [11], the role of smoking in liver injury is less clear [17,18].

While Cox proportional hazards regression is conventionally applied to examine a time-to-event outcome, tree-structured (or recursive partitioning) algorithms are more suitable to handle interactions among covariates and nonlinearity between a set of covariates and an outcome. On one hand, single tree-structured algorithms are intuitively interpretable and could be visually illustrated to demonstrate the interaction patterns [19,20] among split variables. Unlike traditional tree-structured algorithms which often lack a theoretical foundation, conditional inference survival tree [21] is embedded with statistical theory of conditional inference. On the other hand, tree-structured ensemble algorithms tend to be more stable and their aggregate results have lower variance than results from individual trees. Recently, Xie et al [22] have proposed a framework to develop clinical scoring system by integrating random survival forest in variable selection and retaining the use of beta coefficients from Cox regression in generating a final scoring system, where interaction patterns among covariates are taken into account in scoring system development, and clinical interpretability is ensured in the final scoring system.

The objective of the study is to compare risk factors, their interaction patterns, and resulting scoring systems for liver cancer risk according to diabetes and liver disease status using tree-structured algorithms.

Methods

Study Design and Study Population

This is a retrospective cohort study performed using territory-wide electronic health records in Hong Kong. The Hospital Authority (HA) is a statutory body responsible for managing public health care services and maintains a centralized clinical data repository, which stores information on patient demographics (sex and year of birth), disease diagnoses, prescription records, laboratory measurements, clinical notes, and radiology reports. Data used in this study were linked to death records from the Immigration Department. Individual-level data across datasets were linked via pseudonymous identifiers. Disease diagnoses were coded according to the *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*), or the International Classification of Primary Care, 2nd Edition (ICPC-2). Data were accessed via HA Data Collaboration Lab.

Patients

Patients who had used public health care services between 1997 and 2021 were initially identified. Laboratory records on (1) ALT levels, (2) fasting glucose, (3) low-density lipoprotein (LDL) cholesterol, (4) high-density lipoprotein (HDL) cholesterol, and (5) triglycerides were extracted. Patients with at least one record on each of the above laboratory measurements were selected. Prescription records on antidiabetic drugs were extracted to determine diabetes status of patients. Those who were prescribed any antidiabetic drugs during the study period were identified as patients with diabetes, while those who did not receive any antidiabetic drugs during the study period were identified as patients without diabetes. Patients with diabetes who had at least 2 records on each selected laboratory measurement within 1 year of initiation of antidiabetic drugs or diabetes onset were further selected (n=161,790). Patients without diabetes who had at least 2 records on each selected laboratory measurement within 1 year of the earliest record of the above measurement were further selected (n=67,777). For each laboratory measurement, the mean value of at least 2 records closest to the baseline within 1 year was taken as baseline measurement. The index dates for patients with and those without diabetes were initiation of antidiabetic drugs and earliest selected laboratory record, respectively. For both patients with and those without diabetes, those with a cancer history at baseline were excluded. To exclude possible cases of type 1 diabetes, patients who were diagnosed with diabetes younger than 30 years [23], or those diagnosed with diabetes younger than 60 years and received insulin treatment within 1 year of diabetes onset [23] (but did not receive any other antidiabetic drugs during the study period) were excluded. In addition, exclusion of early insulin users may help remove more severe diabetes cases, since we intend to capture an incident diabetes cohort. Patients without diabetes younger than 30 years at baseline were also excluded. For both patients with and those without diabetes, to minimize reverse causality, those with less than 6 months of follow-up were excluded [24]. In addition, since the diagnosis of one cancer may influence the diagnosis of another cancer [24], those who were diagnosed with cancer types other than liver cancer during follow-up were

XSL•FO
RenderX

also excluded. In other words, only patients who developed liver cancer or remained cancer-free during follow-up were included. Finally, a total of 132,221 patients with diabetes and 58,750 patients without diabetes were included.

Outcome

The outcome of interest was diagnosis of liver cancer (ICD-10: C22) during follow-up.

Input Variables

The set of input variables included demographics (sex and age at baseline), disease history, lifestyle behavior (smoking), laboratory measurements, and medication use. Disease history included liver cirrhosis [11], chronic viral hepatitis [11], fatty liver [11], and common comorbidities (ischemic heart disease, cerebrovascular disease, heart failure, chronic obstructive pulmonary disease, pneumonia, tuberculosis, hematuria, and cystitis). Disease diagnoses were extracted from both inpatient and outpatient diagnosis codes. The presence of fatty liver was determined from diagnosis codes or radiology reports (ultrasonography, computed tomography, and magnetic resonance imaging). Smoking habits were extracted from clinical notes, and patients were categorized as ever versus never smokers. Laboratory measurements included fasting glucose, LDL cholesterol, HDL cholesterol, triglycerides, and ALT levels. Medication included antidiabetic drugs (metformin, sulfonylurea, insulin, dipeptidyl peptidase-4 inhibitors, acarbose, meglitinide, glitazone, sodium-glucose cotransporter-2 inhibitors, and glucagon-like peptide-1 receptor agonists), aspirin, nonsteroidal anti-inflammatory drugs, anticoagulants, antiplatelets, statins, antihypertensive drugs (alpha-blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, beta-blockers, calcium channel blockers, and diuretics). Medication use was defined as whether patients had taken a drug at baseline.

Data Analysis

Conditional Inference Survival Tree

Conditional inference survival tree [21] was applied to examine the interaction patterns among the set of candidate predictors. At each split, a global null hypothesis of independence between a set of covariates and an outcome is tested at a prespecified α level. If rejected, a set of partial null hypotheses of independence between each covariate and an outcome is then tested at the same α level. The covariate with the minimum Bonferroni-corrected *P* value smaller than α is then selected as the split variable. Partitioning is recursively conducted until the global null hypothesis cannot be rejected. For continuous variables, the cutoff point is the optimal value to maximize the between-group differences in survival probability. Each path from the root node to a terminal node represents an interaction pattern [20]. Two separate survival trees, which are independent of the random survival forest used in scoring, were generated according to diabetes status. The α and maximum depth of the survival trees were set at .01 and 4 respectively.

Advantages of this algorithm include (1) incorporating conditional inference framework into the partitioning procedures, (2) avoiding overfitting, (3) minimizing bias toward selecting covariates with many possible values, and (4) not requiring explicit pruning.

Scoring System Guided by Random Survival Forest

The scoring system development followed a previously proposed framework [22]. For each scoring system, patients were first split into 70% train, 10% validation, and 20% test sets by default. Variable importance was first ranked by random survival forest using the train set. Random survival forest is a tree-structured ensemble algorithm to produce aggregated results from a predetermined number of decorrelated individual survival trees. There are 2 random components in random survival forest, namely bootstrapping in sampling and random selection in feature selection. To build each tree, a bootstrapped train set is selected. At each split, a set of *k* number of predictors is selected from a full set of *m* number of predictors, where *k* is equal to the square root of *m* by convention. Considering computing time, the number of trees in the survival forest was set at 10. Each variable was then added to a Cox regression model sequentially according to their ranking in variable importance in the random survival forest. The performance of the model was then evaluated on the validation set using area under the curve as a metric. Variables for the final scoring system were then selected using model improvement and parsimony as criteria. For continuous variables, the cutoff points were determined by default quantiles. Fine-tuning of variable selection and cutoff points was conducted according to domain knowledge and existing literature. The chosen set of variables was then added into a final scoring system, where score assignment was based on beta coefficients in the Cox regression model and model performance was evaluated on the unseen test set using Harrell's concordance index (C-index) and integrated Brier score as metrics. In total, 4 scoring systems were separately developed according to diabetes and liver disease (presence or absence of liver cirrhosis or chronic viral hepatitis) status.

Advantages of this approach include (1) tree-structured algorithms have higher interpretability than other machine learning algorithms, (2) aggregate results from a tree ensemble may have lower variance than results from individual trees, (3) interactions among covariates on an outcome in single trees are taken into account in a tree ensemble, (4) adopting a more objective way to incorporating less established risk factors as predictors in variable selection process, (5) categorizing continuous variables in deriving scoring systems may help address nonlinearity, and (6) converting risk prediction models into point-based scores could be more clinically useful.

Ethical Considerations

Ethics approval for secondary data analysis was provided by the Chinese University of Hong Kong – Survey and Behavioral Research Ethics Committee (reference number: SBRE-22 - 0386). Patient consent was waived since individuals were not identifiable in this study.

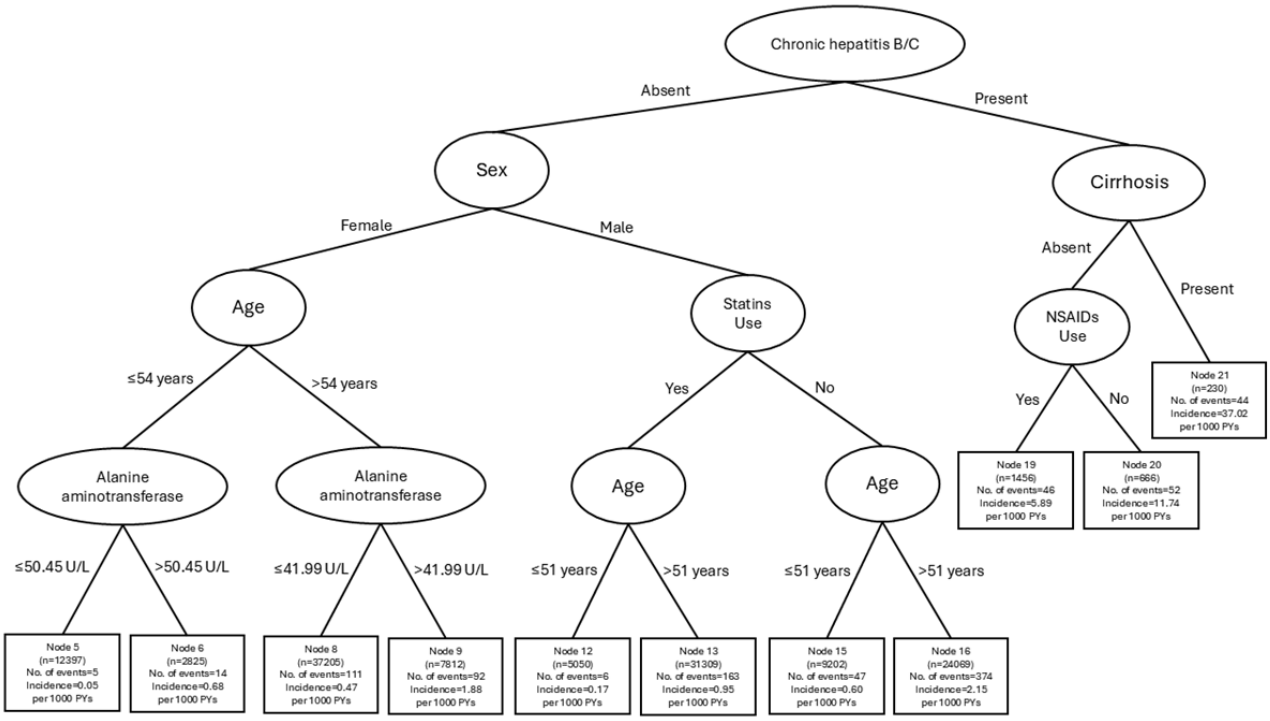
Results



Overview

A total of 190,971 patients were included. Among patients with (n=132,221) and those without (n=58,750) diabetes, 954 and 321 developed liver cancer during follow-up (median 6.25 y), respectively. The corresponding incidence rates were 1.04 and 0.61 per 1000 person-years. Among 129,609 patients with diabetes and 58,635 patients without diabetes in the absence of liver disease, 792 and 310 developed liver cancer during follow-up, respectively.

Interaction Patterns–Diabetes

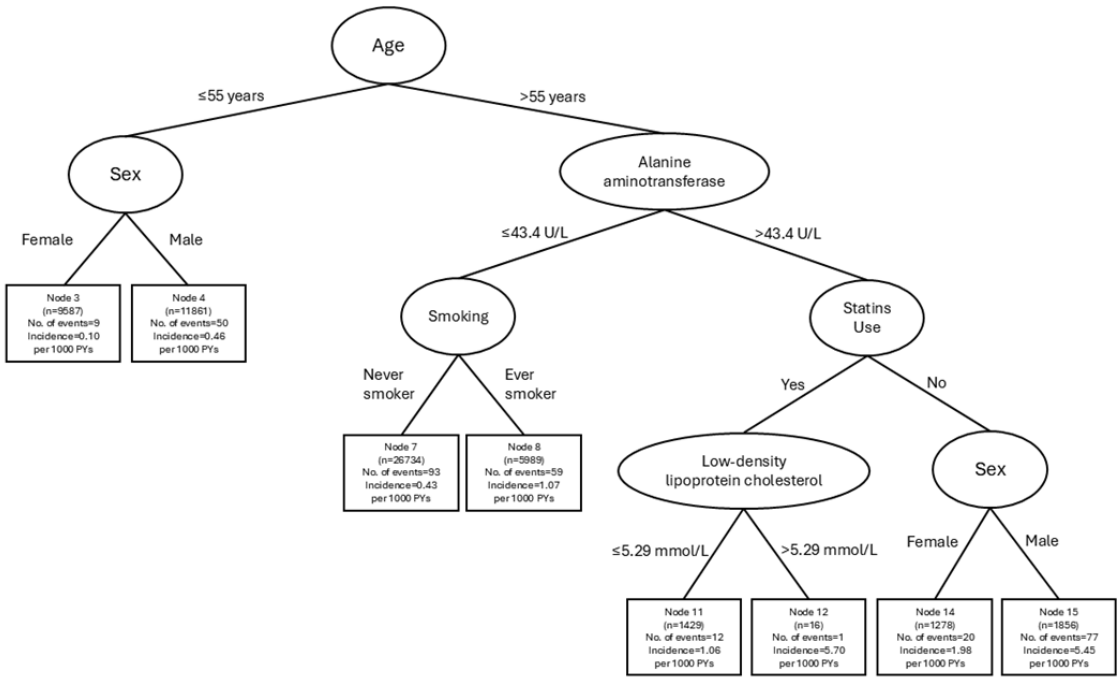
Chronic hepatitis B or C status emerged as primary factor in differentiating the risk of liver cancer. In the presence of chronic viral hepatitis, the most dominant risk factor was liver cirrhosis. On the other hand, in the absence of chronic viral hepatitis, sex became the most significant factor. In males, statin use and age were key factors. In females, age and ALT levels became key factors (Figure 1).

Figure 1. Conditional inference survival tree illustrating the interaction patterns among factors associated with the risk of liver cancer among patients with diabetes. NSAID: nonsteroidal anti-inflammatory drugs; PYs: person-years; U/L: unit per liter.

Absence of Chronic Viral Hepatitis, Male Sex, Statin Use, and Age

Among males in the absence of chronic viral hepatitis, statin use became the dominant factor in differentiating the risk of liver cancer. Across statin users and nonstatin users, an age of 51 years was symmetrically identified as optimal cutoff for differentiating liver cancer risk (Figure 1).

Absence of Chronic Viral Hepatitis, Female Sex, Age, and ALT Levels



Among females in the absence of chronic viral hepatitis, age became the subsequent dominant factor in differentiating the risk of liver cancer. Among older (>54 y) and younger (≤54 y) females, elevated ALT was identified as the most important risk factor at differential optimal cutoffs (41.99 and 50.45 U/L for older and younger females, respectively; Figure 1).

Interaction Patterns—No Diabetes

Age emerged as the primary factor in differentiating the risk of liver cancer. Among older patients (>55 y), ALT level became the dominant factor. For those with higher ALT levels, statin use, LDL cholesterol, and sex became key factors. For those with lower ALT levels, smoking became the dominant risk factor. Among younger patients (≤55 y), male sex became the most significant risk factor (Figure 2).

XSL•FO
RenderX

Figure 2. Conditional inference survival tree illustrating the interaction patterns among factors associated with the risk of liver cancer among patients without diabetes. PYs: person-years.

Older Age, Higher ALT Levels, Statin Use, and LDL Cholesterol or Sex

Among older patients (>55 y) with higher ALT levels (>43.4 U/L), uncontrolled LDL cholesterol (>5.29 mmol/L) and male sex became dominant risk factors in statin users and nonstatin users respectively (Figure 2).

Older Age, Lower ALT, and Smoking

Among older patients (>55 y) with lower ALT levels (≤43.4 U/L), smoking became the most important risk factor.

Overall Scoring Systems by Diabetes Status

In the overall scoring systems, liver cirrhosis, ALT levels, age, sex, and serum triglycerides were commonly included as predictors regardless of diabetes status. Chronic hepatitis B or C status was uniquely included in diabetes but not in nondiabetes (Table 1). Comparing to the overall scoring system for diabetes-only (D_0), generally, there was an increase in relative contribution of liver cirrhosis and triglycerides in the overall scoring system for nondiabetes-only (N_0). Nevertheless, triglycerides exhibited an inverse association with the risk of liver cancer across diabetes (D_0) and nondiabetes (N_0) models (Table 2).

Scoring Systems by Diabetes Status in the Absence of Liver Disease

In the absence of liver disease, ALT levels, age, sex, and triglycerides were commonly included as predictors irrespective of diabetes status. Baseline fasting glucose and smoking status were unique predictors in the scoring systems for diabetes (D_1) and nondiabetes (N_1), respectively (Table 1). The relative contributions of common predictors appeared comparable across 2 models (D_1 and N_1). In addition, triglycerides consistently demonstrated a negative relationship with the risk of liver cancer across diabetes (D_1) and nondiabetes (N_1) models (Table 3).

Model Performance

The C-indexes of D_0, N_0, D_1, and N_1 on unseen test sets were 0.80 (95% CI 0.76 - 0.83), 0.80 (95% CI 0.74 - 0.86), 0.75 (95% CI 0.71 - 0.79), and 0.82 (95% CI 0.77 - 0.88), respectively. The corresponding integrated Brier scores were 0.011, 0.006, 0.011, and 0.006, respectively.

Discussion

Principal Findings

This study compared risk factors, their interactions, and resulting scoring systems for liver cancer risk between patients with and those without diabetes. The resulting scoring systems took into account interaction patterns among the set of candidate predictors. Across four scoring systems stratified by diabetes and liver disease status, ALT levels, age, sex, and triglycerides were commonly chosen as predictors. Chronic viral hepatitis was uniquely selected in the overall system for diabetes. On the other hand, in the absence of liver disease, fasting glucose and smoking were uniquely chosen for diabetes and nondiabetes, respectively. Across all systems, triglycerides uniformly exhibited an inverse association with the risk of liver cancer. Among people with diabetes, chronic viral hepatitis remained the dominant risk factor for liver cancer. In the absence of chronic viral hepatitis, sex was identified as a subsequent key factor, followed by age, statin use, and ALT levels. Among people without diabetes, age became the primary factor. For older patients, statin use, LDL cholesterol, and sex became key factors when the ALT level was higher. On the other hand,

XSL•FO
RenderX

smoking became a key risk factor when the ALT level was lower.

Comparison to Previous Work

Overall scoring systems developed in this study included liver cirrhosis, ALT levels, age, and sex as common predictors across the diabetes-only and nondiabetes-only models. These variables have been commonly used as predictors of liver cancer [4,5]. Nevertheless, chronic hepatitis B or C status was uniquely chosen as a predictor for diabetes but not for nondiabetes. In the individual trees, chronic viral hepatitis only emerged as a primary factor for differentiating the risk of liver cancer in diabetes, but not in nondiabetes. Previous research suggests that hepatitis B or C infection [12,13] or hepatitis B virus (HBV)–induced cirrhosis [25] could be potentially associated with an increased risk of type 2 diabetes. Possible mechanisms include disturbances of insulin signaling pathways [12,13], alterations in glucose [12,13] and lipid metabolism [26], as well as induction of inflammation in promoting type 2 diabetes development [27]. These provide possible explanations for the more important role of chronic viral hepatitis in liver cancer development in diabetes found in this study.

In the absence of chronic viral hepatitis in diabetes, elevated ALT appeared as a key risk factor for liver cancer in females, with a higher cutoff for the younger group but a lower cutoff for the older group. While ALT is a marker for liver function [28] and a common predictor of liver cancer risk [4,5], a number of previous studies have found that ALT tends to decline with aging [14,15,29], possibly with stronger effects in males than females [16,30]. However, in this study, statin use was observed to be a more important factor in influencing the risk of liver cancer in their male counterparts. There are several possible explanations for the potential association between aging and reduced ALT thresholds for elevated liver cancer risk. In animal studies, the liver demonstrates slower and weakened regenerative ability, as well as reduced inflammatory response during aging [31]. Furthermore, in human studies, the liver appears to shrink its volume and have less blood flow during aging [32].

Moreover, in the absence of chronic viral hepatitis in diabetes, statin use emerged as a subsequent key factor in differentiating the risk of liver cancer in males, followed by age (with 51 y being symmetrically identified as optimal cutoff across statin users and non–statin users). Past observational studies have shown that statin use is potentially associated with a lower risk of liver disease [33] and liver cancer [33-35], particularly in Asian populations [34,35]. However, no effects of statin use on cancer risk have been demonstrated in randomized controlled trials [36].

Furthermore, in the presence of elevated ALT among older patients without diabetes, statin use emerged as a subsequent key factor in differentiating the risk of liver cancer, where uncontrolled LDL cholesterol and male sex were identified as dominant risk factors in statin users and nonstatin users, respectively. Previous research suggests altered lipid metabolism in carcinogenesis of the liver [26]. It is possible that under a state of potential liver dysfunction, as indicated by elevated ALT, statin use may confer protective effects against liver cancer development. Possible mechanisms of statins use against liver cancer include inhibition of tumor growth via downregulating the mevalonate pathway [37]. It has also been suggested that statins may exercise antagonistic effects against carcinogenic effects of HBV [34], potentially via suppressing cholesterol synthesis and HBV replication [38].

On the other hand, circulating triglycerides were selected as predictors and exhibited an inverse association with the risk of liver cancer across the 4 scoring systems regardless of diabetes and liver disease status. Epidemiological studies on the associations between circulating lipids and liver cancer risk remain conflicting [26,39]. Several studies found that lower levels of triglycerides [9] or total cholesterol [8,40,41] are predictive of elevated liver cancer risk in the presence [40-42] or absence [8,9] of chronic viral hepatitis. While lipids were not directly identified as a key factor in the diabetes-only individual tree, statin use emerged as a dominant factor among subgroups of patients across diabetes and nondiabetes subpopulations. Possible mechanisms linking low lipids to elevated liver cancer risk include higher lipids as indicator of preserved liver function [43], suppression of liver tumor growth via activating effector functions in natural killer cells [44], as well as uptake of circulating lipids by underlying liver tumor cells to meet their demand for lipids [39].

In addition, fasting glucose and smoking were chosen as unique predictors of liver cancer risk among patients with and those without diabetes in the absence of liver disease, respectively. The variation in baseline fasting glucose at the time of initiation of antidiabetic drugs among patients with diabetes may reflect their differential levels of diabetes severity. Previous studies have shown that fasting glucose could be individually associated with the risk of liver cancer [45]. The exact mechanism remains unknown. Possible mechanisms include upregulation of insulin-like growth factor-1 (which has a higher mitogenic and antiapoptotic potency than insulin) via hyperglycemia and hyperinsulinemia, as well as higher levels of proinflammatory factors under chronic inflammation [2,45]. On the other hand, smoking has been shown to be a carcinogenic agent to the liver in humans [46]. Several previously developed scoring systems for liver cancer risk [8,10] have also incorporated smoking as predictors. Possible mechanisms include conversion of chemicals in tobacco smoke into reactive carcinogenic metabolites in the liver, concurrent consumption of alcohol along with tobacco smoking, chronic inflammation, immunosuppression, and accelerated telomere dysfunction [47,48].

Furthermore, in the absence of diabetes, smoking emerged as a dominant risk factor for liver cancer among older patients with lower ALT. Previous research [17,18,49] suggests that smoking exposure does not directly induce liver damage, but may exacerbate liver injury caused by heavy alcohol use. Smoking was only shown to be positively associated with GGT in heavy alcohol users [17,18]. On the other hand, smoking was inversely linked to ALT and aspartate aminotransferase [17,49]. One possible explanation for elevated specific liver enzyme is that concurrent consumption of smoking and alcohol intensifies oxidative stress [50], since GGT is an oxidative stress marker [51]. In addition, previous research [52] has shown that smoking

XSL•FO
RenderX

is only associated with increased ALT levels in patients who are seropositive for hepatitis C virus, but not in those who are seropositive for HBV. This may help partially explain the dominance of smoking as a risk factor among older nondiabetes patients with lower ALT from a HBV-endemic region.

Implications

There are several public health and clinical implications of this study. First, chronic viral hepatitis appears to be a more dominant risk factor for liver cancer among patients with diabetes than those without diabetes. Second, while elevated triglycerides are one of the components of metabolic syndrome [53] and associated with adverse cardiovascular outcomes, they appear to be inversely associated with the risk of liver cancer in this study cohort. Third, in the absence of liver disease, several modifiable factors such as fasting glucose and smoking become more dominant in liver cancer risk prediction. Fourth, lipid control appears to be important to liver cancer prevention across diabetes and nondiabetes subpopulations. Fifth, the resulting linear scoring systems developed from ensemble tree-structured models reflect the interaction patterns among the set of candidate predictors in individual tree-structured models. Sixth, the risk scoring systems may help predict the risk of liver cancer in the presence or absence of liver disease across people with and those without diabetes. Further studies are needed to establish clinical thresholds to stratify patients into different levels of risk to potentially provide prioritization for public health strategies and guide clinical decision-making.

Limitations and Future Directions

Several limitations are potentially present in this study. First, diabetes status was defined by use of antidiabetic medication. Undiagnosed diabetes or nonuse of antidiabetic medications for diagnosed diabetes is potentially present. Fasting glucose or hemoglobin A_{1c} records were not checked for potential undiagnosed diabetes cases since it was not feasible. Second, while we intend to capture an incident diabetes cohort, some patients may have received a diagnosis of diabetes before the available prescription records period. Nevertheless, delayed diagnosis and treatment initiation is likely to be partially reflected in the presence of liver disease and levels of liver enzyme and fasting glucose in the risk scoring systems. Third, the possibility of reverse causality cannot be fully eliminated. Some risk factors such as fasting glucose and triglycerides could be influenced by subclinical liver dysfunction. Altered lipid and glucose metabolism may occur under liver dysfunction [26,54]. Fourth, some potential confounders such as adiposity indicators or alcohol use were not available in this study. Fifth, current and former smoking status was not differentiated since smokers may report inconsistent status between clinical visits. Differentiating current and former smokers may further subcategorize ever smokers into 2 different risk levels in the risk scoring system for patients without diabetes in the absence of liver disease (N_1). Sixth, information on serological tests for hepatitis virus was not available in this study. Seventh, further studies are warranted to evaluate generalizability to hepatitis C virus-endemic regions. Eighth, different populations may vary in prevalence [55], screening, diagnosis, and treatment of diabetes. Future research is warranted to examine generalizability to other populations with different diabetes management practices. Ninth, medication use and laboratory measurements were taken at baseline. However, these may change during follow-up. Tenth, the number of liver cancer cases in certain terminal nodes in the individual trees was low and may restrict generalizability of the identified optimal cutoffs beyond the study population. Eleventh, the optimal cutoffs in the scoring systems were defined by quantiles, and the values may vary across populations. Nevertheless, the optimal cutoffs could be fine-tuned [22] according to domain knowledge. Lastly, while variable selection in scoring development involves fine-tuning processes based on domain knowledge, split variable selection in separately built individual trees is automatic. Future research may consider undiagnosed diabetes, incorporate a broader list of candidate variables such as adiposity indicators and alcohol use, subcategorize current and former smoking status, evaluate serological status for hepatitis virus if available, establish clinical thresholds for risk scoring systems, and examine generalizability to other populations.

Conclusions

This study compared risk factors, their interaction patterns, and resulting scoring systems for liver cancer risk according to diabetes and liver disease status using tree-structured algorithms. Patients with and those without diabetes demonstrate distinctive interaction patterns among key factors on liver cancer risk. The resulting scoring systems reflect interaction patterns among the set of candidate predictors. Findings of the study may help identify targets for public health interventions and provide clinical cancer risk prediction for patients with and those without diabetes.

Abstract

Background: The unstructured data of Chinese cancer electronic health records (EHRs) contains valuable medical expertise. Accurate medical entity recognition is crucial for building a medical-assisted decision system. Named entity recognition (NER) in cancer EHRs typically uses general models designed for English medical records. There is a lack of specialized handling for cancer-specific records and limited application to Chinese medical records.

Objective: This study aims to propose a specific NER model to enhance the recognition of medical entities in Chinese cancer EHRs.

Methods: Desensitized inpatient EHRs related to breast cancer were collected from a leading hospital in Beijing. Building upon the MC Bidirectional Encoder Representations from Transformers (BERT) foundation, the study further incorporated a Chinese cancer corpus for pretraining, resulting in the construction of the ChCancerBERT pretrained model. In conjunction with dilated-gated convolutional neural networks, bidirectional long short-term memory, multihead attention mechanism, and a conditional random field, this model forms a multimodel, multilevel integrated NER approach.

Results: This approach effectively extracts medical entity features related to symptoms, signs, tests, treatments, and time in Chinese breast cancer EHRs. The entity recognition performance of the proposed model surpasses that of the baseline model and other models compared in the experiment. The F_1-score reached 86.93%, precision reached 87.24%, and recall reached 86.61%. The model introduced in this study demonstrates exceptional performance on the CCKS2019 dataset, attaining a precision rate of 87.26%, a recall rate of 87.27%, and an impressive F_1-score of 87.26%, surpassing that of existing models.

Conclusions: The experiments demonstrate that the approach proposed in this study exhibits excellent performance in NER within breast cancer EHRs. This advancement will further contribute to clinical decision support for cancer treatment and research. In addition, the study reveals that incorporating domain-specific corpora in clinical NER tasks can further enhance the performance of BERT models in specialized domains.

KEYWORDS

BERT; named entity recognition; cancer; electronic health records; deep learning

Introduction

Background

Cancer is one of the leading causes of mortality [1], imposing a significant psychological burden on patients and potentially triggering mental health disorders such as anxiety and depression [2]. The proliferation of electronic health records (EHRs) has provided a crucial source of demographic information, medical history, diagnostic tests, and clinical treatment data for cancer research, aiding in better diagnosis, prognosis, and treatment of the disease [3]. However, the large amount of unstructured text in EHRs presents significant challenges for clinical research and analysis. Structuring this unstructured information is essential for subsequent data analysis and mining to support clinical decision-making. Named entity recognition (NER) is a critical component of natural language processing (NLP), plays a key role in this process by identifying and classifying entities, allowing for transforming raw clinical texts into structured data,

XSL•FO
RenderX

thereby enabling large-scale data mining and supporting intelligent health care applications [4].

In recent years, many studies have explored different NER methods to structure EHRs. The widespread application of pretrained models such as Bidirectional Encoder Representations from Transformers (BERT) has significantly enhanced NER performance in the medical field [5,6]. These improvements are especially valuable in the medical domain, where precise recognition of specialized entities directly impacts the reliability of downstream analyses including cohort selection, clinical decision support, and the construction of medical knowledge bases [7,8]. However, most of these studies focus on English texts, and the differences between English and Chinese in terms of language expression may limit the generalizability of English medical NER methods when directly applied to Chinese medical texts.

Compared to medical texts in common diseases, cancer EHRs contain richer and more complex information. These records span multiple fields, including medicine, biology, and pharmacology, and encompass specific medical terminologies such as cancer staging, treatment plans, and drug names. They also include diagnostic and treatment records like surgical notes and pathology results, with a prevalent occurrence of nested entities. In current NER tasks for the cancer domain, models such as BERT and other deep learning approaches based on general corpora are often used without fine-tuning for the numerous specialized terms and specific expressions in this field, which may result in errors or omissions. In addition, there is no publicly available dataset benchmark for the cancer domain. Therefore, NER tasks for Chinese cancer EHRs remain both challenging and necessary.

To address the aforementioned issues, this study contributes the following:

1. We retrained the MC-BERT model using a corpus specific to the Chinese cancer domain, resulting in the ChCancerBERT pretrained model tailored for NER tasks in the Chinese cancer field. This approach effectively enhances the semantic representation capabilities of pretrained models in a specialized domain.
2. In the Chinese medical domain, we built a hybrid model to capture temporal features and bidirectional semantic information. This combination enhances the model's ability to perform multidimensional feature modeling.
3. To validate the model's effectiveness, we created a Chinese breast cancer EHR corpus with manual annotations. We applied various models to this corpus, and the experimental results demonstrated that our proposed model outperforms existing models, achieving superior performance. We also applied the model proposed in this study to the CCKS2019 dataset and compared the results with those from existing studies for evaluation.

Related Work

In the medical field, prior research has developed various NER methods for extracting information from unstructured data such as EHRs. Table 1 summarizes related studies and methods for clinical NER in the medical field.

NER techniques can be categorized into 3 main types: dictionary and rule-based methods, machine learning–based methods, and deep learning–based methods. Dictionary and rule-based NER methods rely primarily on researchers analyzing textual writing rules and establishing dictionaries, then using regular expression matching to achieve entity recognition and information extraction. For instance, Najafabadipour et al [9] extracted multiple cancer concepts such as tumor staging, mutation status, and patient presentation from lung cancer clinical records using regular expressions and the UMLS8 dictionary. Yim et al [10] used rule-based extraction to identify 3 liver cancer entities: tumor size, staging level, and percentage of tumors invading the liver. These methods are straightforward and efficient but lack generalizability and require significant human effort to build dictionaries [10]. Machine learning–based methods use sequence labeling and train models such as hidden Markov model, conditional random fields (CRFs), and maximum entropy Markov model on large manually annotated feature corpora to achieve NER. For example, Savova et al [11] developed the DeepPhe software, which uses a combination of rules, domain knowledge bases, and machine learning to extract cancer phenotypes from clinical records. Weegar et al [12] used a CRF model to extract cervical cancer symptom information.

In recent years, deep learning methods have made significant progress in medical NER tasks, demonstrating substantial advantages in NLP compared to traditional feature-based machine learning methods. These approaches typically predict the boundaries and types of entities by labeling each word, thereby capturing deeper and more abstract features. For instance, An et al [13] used a bidirectional long short-term memory (BiLSTM)-CRF model with a multihead attention (MHA) mechanism to perform Chinese clinical EHR NER. Kong et al [14] combined multilayer convolutional neural networks (CNNs) with an attention mechanism to improve NER in Chinese EHRs. The emergence of pretrained models like BERT has further enhanced the performance of NER. In the medical domain, existing research shows that BERT-based models can be effectively applied to medical information extraction tasks. Li et al [5] achieved excellent results using a BERT-BiLSTM-CRF model on the CCKS2018 and CCKS2019 datasets. Li et al [15] proposed an A Lite Bidirectional Encoder Representations from Transformers (ALBERT)-based model with a MHA mechanism for Chinese medical NER, validated on the CCKS2019 dataset. Chen et al [6] constructed a hybrid model combining MC-BERT, BiLSTM, CNN, MHA, and CRF to achieve NER in Chinese EHRs. Most of these studies primarily applied their deep learning models to publicly available datasets such as CCKS2017 and CCKS2019, without further testing them on specific medical departments or diseases.

Existing research indicates that using domain-specific text as training data, as opposed to general language models, can yield better performance. For the cancer field, Zhou et al [7] proposed CancerBERT, a pretrained model specifically designed for the English language in the cancer domain. Currently, there is no similar model for the Chinese cancer domain. Given the differences between Chinese and English in terms of vocabulary, sentence structure, grammatical rules, and semantic expression,

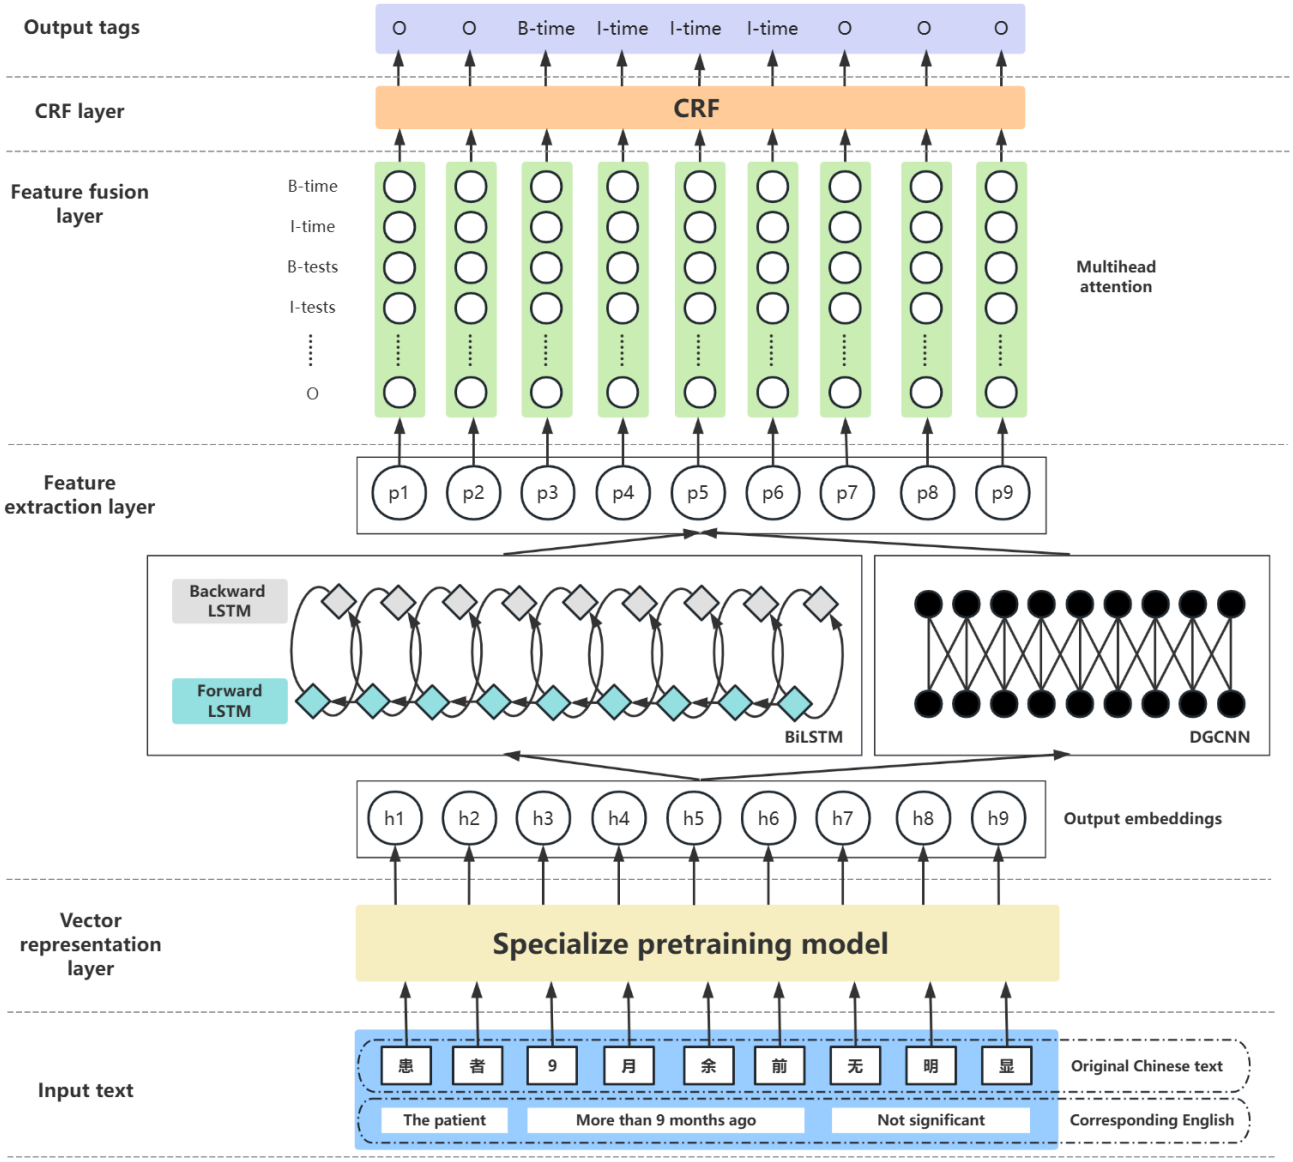
Methods

Ethical Considerations



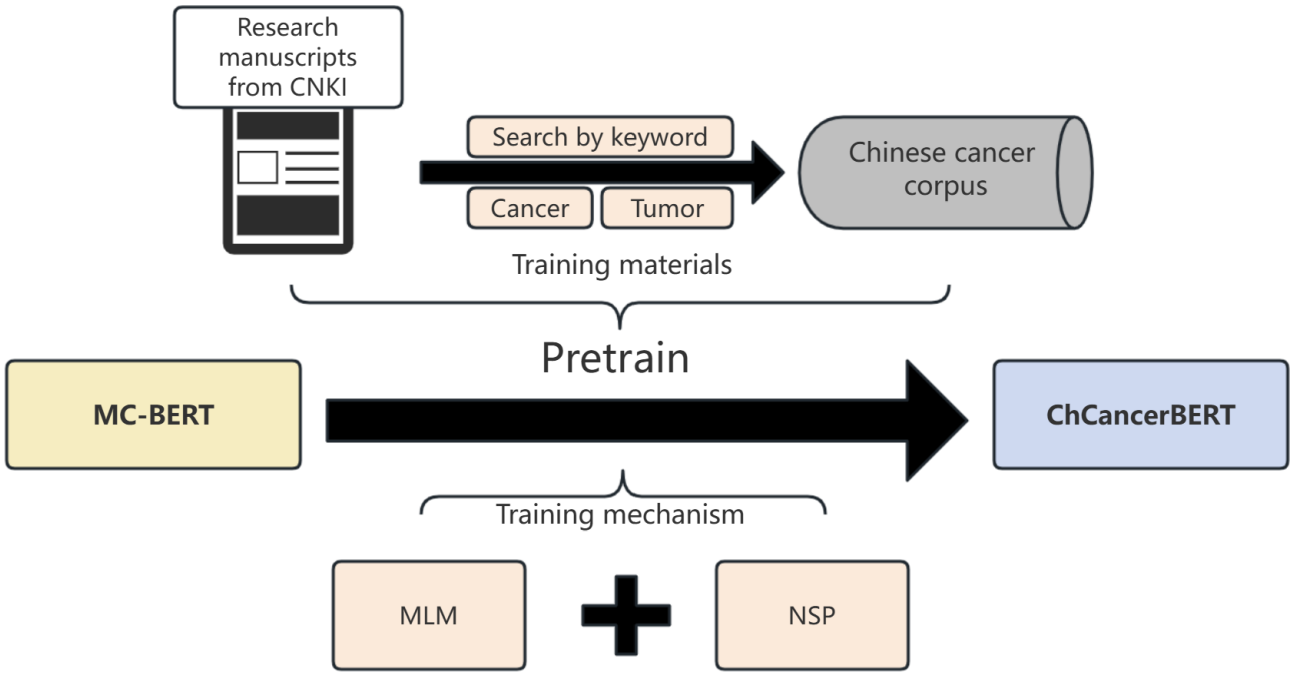
Based on Article 32 of the *Measures for Ethical Review of Life Sciences and Medical Research Involving Human Subjects* [17] research using human data or biological samples that does not cause harm to the human body, does not involve sensitive personal information or commercial interests, is eligible for exemption from ethical review. This exemption is intended to reduce unnecessary burdens on researchers and to facilitate the progress of life sciences and medical research. In our study, the dataset used has undergone thorough anonymization, with all personal patient information removed. In addition, the patients involved in the clinical activities at the hospital have already signed the relevant informed consent forms, confirming their agreement to the use of their data for research purposes. Therefore, as per the national regulations, our study did not require ethical review. The data were granted permission to be accessed by SD, who is the director of the Information Center of Dongfang Hospital Beijing University of Chinese Medicine, responsible for managing all the hospital's data, and he is listed as a contributing author.

Model Construction

The proposed model architecture in this study is illustrated in Figure 1.

XSL•FO
RenderX

Figure 1. The architecture of the proposed model, for ease of viewing and understanding, the input text examples in the figure are accompanied by corresponding English translations. BiLSTM: bidirectional long short-term memory; CRF: conditional random field; DGCNN: dilated-gated convolutional neural network; LSTM: long short-term memory.



The model comprises 4 parts: the vector representation layer, feature extraction layer, feature fusion layer, and CRF layer. The Chinese cancer EHR texts are input into the model, where the input text is segmented into individual characters to form the basic sequence X={x1,x2,…,xi}, where xi is the *i*-th character. Initially, in the vector representation layer, the input sequences X={x1,x2,…,xi} are represented as semantically rich character-level embedding vectors hi using the autonomously trained BERT model tailored to the Chinese cancer domain (ChCancerBERT), forming the embedding sequence H={h1,h,…,hi}. Subsequently, the sequence H={h1,h,…,hi} is fed into the BiLSTM and dilated-gated convolutional neural network (DGCNN) models within the feature extraction layer. The feature extraction layer uses BiLSTM to extract long-distance dependency associations and temporal features from the sequences, while DGCNN captures spatial features. In the feature fusion layer, a MHA mechanism with enhanced generalization capability dynamically fuses the features extracted by BiLSTM and DGCNN to enhance the model's feature representation capability. The CRF layer imposes constraints on the output to obtain the optimal labeling results. Finally, the model outputs a set of label sequences Y={y1,y,…,yi}, where each label yi corresponds to a character in the input text. For instance, "B-TIME" denotes the beginning of a TIME entity, while "I-TIME" denotes the inside of a TIME entity, with the label sequence indicating the model's classification results for each character.

Chinese Cancer Specialized BERT

To better capture semantics in cancer electronic medical records, this study trained a specialized BERT model tailored for the Chinese cancer domain (ChCancerBERT) to enhance the performance of extracting cancer-related phenotypes. Figure 2 illustrates the training process of the ChCancerBERT model.

XSL•FO
RenderX

Figure 2. The training process of ChCancerBERT models. BERT: Bidirectional Encoder Representations from Transformers; CNKI: China National Knowledge Infrastructure; MC: ;MLM: masked language model; NSP: next sentence prediction

Pretrained models are typically based on large-scale general corpora for data pre-training. Depending on the specific needs, they can also incorporate domain-specific vocabulary to calculate the probability P(S) of all possible language sequences.

$$(1)P(S)=p(\omega 1,\omega 2,\ldots,\omega n)=\prod i=1np(\omega|\omega 1,\omega 2,\ldots,\omega i-1)$$

The most commonly used pretrained model is the BERT model, a deep bidirectional language representation model that offers significant advantages in capturing textual semantic information and entity extraction [18-20]. Although BERT achieves good results in most domains, its generic nature may limit its ability to fully capture the specialized terminology and semantic nuances of the medical field [15]. MC-BERT fine-tuned on BERT by using different pretraining strategies to incorporate medical-specific and related vocabulary, enabling superior performance in medical NER tasks [6].

The ChCancerBERT model proposed in this study is further pretrained based on the MC-BERT model. The specific steps are as follows: firstly, a Chinese cancer corpus was constructed. Using keywords “cancer” and “tumor,” a search strategy retrieved relevant Chinese-language literature from the China National Knowledge Infrastructure (CNKI) database. The corpus included abstracts from the first 6000 articles, organized chronologically, resulting in a comprehensive dataset of 3,268,570 tokens. This dataset ensures that ChCancerBERT is exposed to terminology and context unique to the cancer domain, thus improving its capacity for semantic understanding. Second, the pretraining of ChCancerBERT used both masked language model and next sentence prediction tasks to enhance semantic representation. Based on the masked language model, the approach involves randomly masking certain characters within a sentence to learn the semantic information of each character in context. This encourages ChCancerBERT to learn nuanced semantic relationships, particularly for specialized terminology within cancer-specific contexts. In addition, the next sentence prediction model is used to learn the association between 2 consecutive sentences, enabling it to capture long-distance dependencies and contextual flows frequently present in medical records. This step is particularly beneficial for understanding the multisentence descriptions often found in medical documents.

BiLSTM Model

Long short-term memory (LSTM) is a specialized form of recurrent neural network that can capture larger and longer-distance information. By using a set of gate controllers, LSTM effectively addresses the gradient vanishing and exploding problems inherent in traditional recurrent neural networks [21]. An LSTM, the input gate it controls information into the current cell, the forget gate ft manages the forgetting of information, and the output gate ot controls the information output. ht records the output at the current time step, while ct preserves the current cell state and serves as input for the next cell. The sigmoid activation function is denoted by σ, the weight matrix by W, the bias term by b, and the current cell input by xt. st represents the updated state at the current time step, and the hyperbolic tangent activation function is denoted by tanh:

$$(2)ft=\sigma(Wf\cdot[ht-1,xt]+bf)it=\sigma(Wi\cdot[ht-1,xt]+bi)ot=\sigma(Wo\cdot[ht-1,xt]+bo)\tilde{c}t=\tanh(Wc\cdot[ht-1,xt]+bc)ct=ft\ast ct-1+it\ast\tilde{c}tht=ot\ast\tanh(ct)$$

BiLSTM consists of a forward LSTM and a backward LSTM, which respectively capture forward and backward information from the text sequence [22]. These are then concatenated to obtain the final hidden layer feature representation. Compared to a single LSTM model, BiLSTM provides a more nuanced understanding of bidirectional semantic dependencies and allows for more precise semantic discrimination [23].

In our model, BiLSTM is applied immediately after the vector representation layer, where ChCancerBERT generates the character-level embeddings tailored to the cancer domain. These embeddings are then fed into the BiLSTM, which consists of a forward and backward LSTMs, capturing both forward and

XSL•FO
RenderX

backward contextual information. By leveraging BiLSTM, the model can retain bidirectional semantic dependencies that are crucial in understanding complex medical texts.

DGCNN Model

DGCNN is a neural network model with residual connections that uses gated dilated convolutions to gather more information through stacked convolutional layers [4]. Its convolutional structure, which enables the model to analyze sequences in segments, examining local patterns that are essential to textual spatial characteristics, which are usually referred to the arrangement and relationships of words and phrases that form meaningful units [4]. These units include nearby dependencies and longer-range relationships, like multiword medical entities in EHRs. DGCNN's use of dilated convolutions allows it to capture these features at different scales or distances, enabling it to handle both close and distant relationships within the text [14]. The convolution operations proceed as follows:

(3)ct=Wc k=0rxt±k

In the model, Wc denotes a filter with window size *r*, and ct represents the output after convolution transformation. The symbol ⊕ indicates vector concatenation. Building on this, dilation is introduced for interval sampling of data, enabling the coverage of longer sentences. The calculation method for dilated convolution is as follows:

(4)ct=Wc k=0rxt±kδ

δ represents the dilation rate, and Wc is a filter with window size r. ct denotes the output, while ⊕ signifies vector concatenation. A gating mechanism is also incorporated to control data flow and reduce the risk of gradient vanishing. The operations within each convolutional gated unit are as follows:

(5)Y=X+Conv1D1(X)⊗σ(Conv2D2(X))

X represents the input. Conv1D1 and Conv2D2 are dilated convolutions with the same parameter structure but without sharing weights. σ denotes the sigmoid function, and ⊗ represents the Hadamard product of vectors.

After the ChCancerBERT model generates the character-level embeddings, these embeddings are input independently into the DGCNN model, extracting spatial dependencies and local features, which are essential for identifying nested entities and capturing complex structures within cancer-related records.

MHA Mechanism

The attention mechanism simulates human attention by scoring and weighting important content to highlight significant features [24]. The calculation formula is as follows:

(6)Attention(Q,K,V)=Softmax(QKTdk)V

The AttentionQ,K,Vvalue represents the attention score, where Qs the query vector matrix, K is the key vector matrix, and V is the value vector matrix. dk is the word vector dimension which normalizes the similarity between the query and key vectors calculated via QKT to prevent overly large results. Softmax normalization is then applied, followed by multiplication with the value vector to obtain the final attention value. When vector dimensions are high, a single attention calculation may not capture all features of a word. Thus, the MHA mechanism is used, linearly mapping Q,K,V into multiple subspaces and combining the calculated results:

This study uses an MHA mechanism to dynamically fuse the BiLSTM and DGCNN models. First, the outputs of both models are mapped to separate feature spaces, generating 2 sets of Q,K,V matrices. Next, the attention values for each model are calculated, resulting in 2 attention representation matrices. Finally, these matrices are combined into a single matrix through matrix multiplication.

CRF Model

CRF is a sequence modeling framework that incorporates constraints between labels to assign higher probabilities to reasonable label sequences [20]. This approach effectively addresses the issue of label bias.

The probability formula for obtaining the predicted label sequence X=(x1,x2,…,xn)given the input sequence Y=(y1,y2,…,yn) is as follows:

(8)P(Y|X)=eT(X,Y)∑Y′∈ YXT(X,Y′)

Given the true label sequence Y`, and all possible label sequences YX, the likelihood function for predicting the label sequence Y is as follows:

(9)ln (P(Y|X))=T(X,Y)−ln (∑Y′∈ YXT(X,Y′))

By maximizing the likelihood function, the most probable and reasonable label sequence is determined and output. The specific formula is as follows:

(10)Y∗=argy~∈ YXmaxs(X,y~)

Experiment Setups

Dataset Construction

The study's data were sourced from the inpatient EHRs at a renowned hospital in Beijing, China, spanning from 2013 to 2022. After excluding patients with unrelated admission reasons (ie, those who have previously had breast cancer but whose current reason for admission is not breast cancer), the illness histories from all patients' admission records within this time period were included. Each patient had 1 record per visit, and we ultimately obtained 876 records of patients with breast cancer (total tokens: 528,925, average length: 659.67, SD 354.23). The data received full approval from the hospital. All procedures in this research adhere to ethical standards. Patient privacy data were deidentified before manipulation, ensuring anonymity and confidentiality of personal information.

Annotation Procedure for the Dataset

The annotation of data from 876 admission records of patients with breast cancer was a collaborative effort involving 7 annotators. All of these annotators were the students of the Management School of Beijing University of Chinese Medicine and possessed relevant medical and computer expertise. To enhance the precision of the labeling outcomes, 2 oncology clinicians from the Beijing University of Chinese Medicine were enlisted to train the annotators. They also facilitated content segmentation and offered guidance throughout the labeling process. Based on information extracted from the

XSL•FO
RenderX

collected data, in conjunction with insights from pertinent clinical studies [25,26] and guided by categorizations and classifications in clinical literature, as well as referencing indicators present in public medical databases such as SEER, CCKS2017, CCKS2019, along with existing study labeling protocols [27], an index system (Table 2) and labeling criteria (Table 3) were formulated for this research. These encompassed symptoms, tests, treatments, and time.

Table . Index system of the annotated dataset for Chinese breast cancer electrical health records (EHRs).

Class	Entity
Symptoms	Nodule
Tests	• Vascular tumor thrombus and nerve aggress • Incisal edge • Lymph node dissection • Birads • TNM[a] • ER[b] • PR[c] • HER2[d] • Ki67
Treatments	• Surgery name • Chemotherapy • Radiotherapy • Targeted therapy • Endocrine therapy
Time	Time

Table . Entity labeling standards with examples[a].

Entity	Standard	Example	Example in English
Time	Date and time in various formats	2011年	2011
Surgery name	Name of a patient undergoing surgery	左侧乳腺癌根治术	Left breast cancer radical surgery
Nodule	Examination results and location of breast nodules	右乳腺肿物	Right breast mass
Chemotherapy	Patient chemotherapy regimen, medication, cycle	术后行辅助化疗6周期 (紫杉醇+环磷酰胺，具体剂量不详）	After surgery, undergo adjuvant chemotherapy for 6 cycles (paclitaxel+ cyclophosphamide, specific dosages not specified)
Radiotherapy	The patient's radiotherapy regimen and frequency	放疗25次，具体剂量不详	Undergo 25 sessions of radiation therapy, specific dosage not specified
Targeted therapy	Targeted therapy, drugs	后续贯赫赛汀靶向治疗18次	Followed by 18 sessions of trastuzumab targeted therapy
Endocrine therapy	Endocrine treatment options, drugs	阿那曲唑1mgQd口服内分泌治疗	Anastrozole 1mg once daily, oral administration for endocrine therapy
Incisal edge	Whether the incisal edge of the patient is cancerous	各皮肤切缘未见癌侵润	No cancer infiltration is observed at the margins of the skin
Vascular tumor thrombus and nerve aggression	Results of examination of vascular tumor thrombus and nerve aggression	侵及周围脂肪组织及神经纤维束，脉管中见癌栓	Involvement of surrounding adipose tissue and nerve fiber bundles, with cancer emboli seen in blood vessels
Lymph node dissection	The patient's lymph node dissection results	淋巴结未见转移癌 (0/21），腋窝淋巴结 (0/18），(右腋窝淋巴结）0/3	No metastatic cancer detected in lymph nodes (0/21), axillary lymph nodes (0/18), (right axillary lymph nodes) 0/3
Bi-RADS[b]	Bi-RADS classification of breast nodules	BI_RADS4b类[b]	BI-RADS4b[b]
TNM[c]	The patients' TNM stages	pT2N0M0, IIa期	pT2N0M0,IIa
ER[d]	Patient pathology reported ER results	ER (+++)	ER (+++)
PR[e]	Patient pathology reported PR results	PR (+++)	PR (+++)
HER2[f]	HER2 results were reported pathologically	HER2 (–)	HER2 (–)
Ki67	Patient pathology reported KI67 results	ki-67index约20%	Ki-67 index is approximately 20%

[a]All texts to be annotated are in Chinese; for ease of viewing and understanding, the annotated examples in the table are accompanied by corresponding English translations, the patient information presented is simulated.

[b]Bi-RADS: breast imaging reporting and data system.

[c]TNM: TNM classification of malignant tumors.

[d]ER: estrogen receptor.

[e]PR: progesterone receptor.

[f]HER2: human epidermal growth factor receptor-2.

The "symptom" labels serve to indicate pathophysiological alterations and breast cancer symptoms, including details about breast nodules such as their location and dimensions. The "tests" label designates the array of tests undergone by patients with breast cancer during diagnosis and treatment, aiding physicians in precise assessments. These encompass parameters like resection margins, vascular thrombosis, nerve invasion, lymph node dissection, Bi-RADS grading, TNM staging, and immunohistochemical markers (ER, PR, HER2, and Ki-67). The "treatments" label encompasses therapies previously administered to patients with breast cancer, comprising chemotherapy, radiation, targeted therapy, endocrine therapy, and surgery. The "time" label incorporates details regarding each temporal point within the admission record of a patient with breast cancer.

Data annotation was performed using Label Studio software (Human Signal). A total of 7 trained annotators, each responsible for a distinct portion of the dataset, performed the initial labeling

XSL•FO
RenderX

in strict accordance with the predefined annotation guidelines. The annotated corpus was then independently reviewed and revised by 2 experienced clinical oncologists, resulting in 2 expert-annotated versions. To assess interannotator agreement between the 2 experts, Cohen κ coefficient was calculated, which indicated almost perfect agreement (κ=0.82). Any discrepancies between the 2 expert versions were subsequently identified and resolved through discussion, leading to the final consensus gold-standard dataset. This finalized version was used for training and validation of the entity recognition model.

Data Partitioning

For evaluation, we use the hold-out method, partitioning the dataset randomly into training, validation, and test sets, distributed at a ratio of 6:2:2. Diverging from typical NER tasks, this model primarily deals with medical nouns or statements as named entities, with a particular focus on breast cancer–related terms. Table 4 illustrates the count of entities corresponding to each label within the training, validation, and test sets. Concurrently, the length of labels within each category was tabulated, and the outcomes are presented in Table 4.

Table . Distribution and length statistics of entities in training, validation, and test sets.

Class and entity	Train set, n (%)	Development set, n (%)	Test set, n (%)	Entities length		
				Minimum	Maximum	Mean (SD)
Symptoms						
Nodule	600 (61.66)	192 (19.73)	181 (18.60)	3	123	15.49 (17.84)
Tests

[b]TNM: TNM classification of malignant tumors.

[c]ER: estrogen receptor.

[d]PR: progesterone receptor.

[e]HER2: human epidermal growth factor receptor-2.

Evaluation Metrics

During the experiment, the evaluation of the NER model used 3 metrics: precision (P), recall (R), and F_1-score (F_1). The formulas for calculating precision, recall, and F_1-score are as follows:

$$(11)\{P=TPTP+FP\times100\%R=TPTP+FN\times100\%F1=2PRP+R\times100\%$$

where TP represents the number of true positive entities, FP indicates the number of false positive entities, and FN denotes the number of false negative entities.

Implementation Details

The experiments were conducted using the PyTorch 1.6 framework in a Python (version 3.7; Python Software Foundation) environment. The CPU used is Intel(R) Core i5-12500H, and the GPU used is NVIDIA T4 GPU. The ChCancerBERT model parameters were configured identically to the BERT model, with 12 transformer layers, 12 attention heads, and 768 hidden units. The hyperparameters for the NER experiment are detailed in Table 5.

Table . Hyperparameter settings.

Hyperparameters	Value
Batch size	8
Dropout	0.5
Learning rate	0.00003
Epoch	64
Maximum length	128
Embedding	768

Results

Using the partitioned dataset, we devised comparative experiments, ablation experiments, and separate pretrained model comparative experiments to facilitate a comprehensive assessment of the recognition efficacy across various mechanisms and models.

Results of the Comparative Experiment for NER Models

We applied our proposed model and the NER models mentioned in Table 1, which have been developed for medical and cancer fields in recent years, to our dataset to compare performance. Detailed results can be found in Table 6. We did not include Zhou et al CancerBERT model [7] in the comparison because it is not yet publicly available. Our results demonstrate that, for the Chinese breast cancer EHR dataset we constructed, our proposed model outperformed existing models, with F_1-scores increasing by 1.40%, 2.57%, and 1.13%, respectively.

Table . Comparative performance of baseline and proposed models on the breast cancer dataset.

Model	Precision (%)	Recall (%)	F_1-score (%)
BERT[a]- BiLSTM[b] -CRF [5]	85.77	85.38	85.58
ALBERT[c]-IDCNN[d]-MHA-CRF [15]	87.78	81.28	84.41
MC-BERT-BiLSTM-CNN[e]-MHA[f]-CRF[g] [6]	85.64	86.07	85.85
Our proposed model	87.63	86.34	86.98

[a]BERT: Bidirectional Encoder Representations from Transformers.

[b]BiLSTM: bidirectional long short-term memory.

[c]ALBERT: A Lite Bidirectional Encoder Representations from Transformers.

[d]IDCNN: iterated dilated convolutional neural network.

[e]CNN: convolutional neural network.

[f]MHA: multihead attention.

[g]CRF: conditional random field.

Results of the Ablation Experiment

We employ the fundamental BERT-BiLSTM-CRF model as a baseline to assess the impact of distinct mechanisms on the recognition of named entities within Chinese EHRs pertaining to breast cancer. Subsequently, BERT-DGCNN-CRF replaces the BiLSTM model within the baseline, while the baseline+DGCNN model merges the BiLSTM and DGCNN models. In addition, the baseline+DGCNN+MHA model introduces a MHA mechanism to the BERT-BiLSTM-DGCNN-CRF foundation. The corresponding experimental outcomes are detailed in Table 7.

Analysis of the ablation outcomes reveals that the substitution of the BiLSTM model with the DGCNN model results in a reduction of the precision and F_1-score on the dataset of this study by 0.37% and 0.14%. However, the amalgamation of the DGCNN model and the BILSTM model yields F_1-score increments of 0.35% and 0.49% compared to both the baseline and BERT-DGCNN-CRF models. This amalgamation also improves precision by 0.02% and 0.29%, and recall by 0.69%,

XSL•FO
RenderX

compared to the baseline and BERT-DGCNN-CRF models, respectively. This observation underscores that, within the context of feature extraction, the standalone DGCNN model presents no notable superiority over the BiLSTM model. Conversely, the combined application of these 2 models augments recognition effectiveness. Building upon this foundation, the incorporation of the MHA serves to enhance the extraction of pertinent information within the data, thereby mitigating the impact of irrelevant data. Consequently, the F_1-score experiences a supplementary enhancement of 0.17%, with a precision decrease of 0.46% offset by a substantial recall increase of 0.82%. This suggests that although the addition of the MHA slightly reduces precision, it compensates for this by capturing a broader range of relevant information, ultimately enhancing overall recognition effectiveness. Thus, based on the insights garnered from ablation experiments, it is ascertained that the optimal approach for this study involves the incorporation of the BiLSTM-DGCNN fusion model as the feature extraction layer, accompanied by the integration of the MHA mechanism.

Table . Results of ablation studies and pretrained model comparisons.

Model	Precision (%)	Recall (%)	F_1-score (%)
BERT[a]-BiLSTM[b]-CRF[c] (baseline)	85.77	85.38	85.58

Results of the Comparative Experiment for the Pretrained Models

Leveraging the model exhibiting the highest F_1-score from the aforementioned experiments, we proceeded to perform comparative experiments by substituting various pretrained models. Comparison experiments were conducted by integrating different pretrained models with both BiLSTM+CRF and DGCNN-BiLSTM-MHA-CRF architectures. All used pretrained models are available for download from the “Models-Hugging Face” website. The corresponding outcomes are presented in Table 7.

The results indicate that using the proposed pretraining model, ChCancerBERT, for character-level embedding outperforms various pretrained models compared in the experiment. Specifically, in the comparison experiment combined with BiLSTM+CRF, the F_1-scores of the ChCancerBERT model increased by 0.6%, 4.08%, 1.89%, 3.78%, and 0.88% compared to BERT, ALBERT, RoBERTa, XLNet, and MC-BERT, respectively. In the comparison experiment with the DGCNN-BiLSTM-MHA-CRF architecture, it achieved F_1-score

XSL•FO
RenderX

improvements of 0.88%, 1.20%, 0.66%, 0.26%, and 0.25% over BERT, ALBERT, RoBERTa, XLNet, and MC-BERT, respectively. In addition, regardless of the pretraining model used, the F_1-scores obtained with the DGCNN-BiLSTM-MHA-CRF architecture were consistently higher than those obtained with the BiLSTM+CRF model alone, further demonstrating that the DGCNN-BiLSTM-MHA model, by integrating multidimensional text features, possesses a stronger semantic representation capability than the BiLSTM model alone.

After using ChCancerBERT for character-level embedding and integrating it with the DGCNN-BILSTM-MHA-CRF model to fuse multidimensional text features, the semantic representation capability is further enhanced, and the F_1-score had a 1.4% improvement compared to the current mainstream BERT-BiLSTM-CRF (baseline) model. In addition, our model achieves a precision of 87.63% and a recall of 86.34%, which represents increases of 1.86% in precision and 0.96% in recall compared to the baseline BERT-BiLSTM-CRF model. This reflects both high detection accuracy and robustness in capturing target entities.

Error Analysis

We conducted a comprehensive analysis of the 4 main entity categories in this study, including their quantity, average length, as well as precision, recall, and F_1-scores. The specific results are presented in Table 8.

The results presented in Table 8 indicate that TIME entities are the most frequently occurring, totaling 4644 instances. The model demonstrates the highest recognition effectiveness for these entities, achieving an F_1-score of 92.79%. In contrast, although the treatments category also has a high number of entities, it shows the lowest recognition performance with an F_1-score of 74.24%. This lower performance can be attributed to the complexity and variability of treatment-related terms, which is further compounded by the fact that the average length of treatment entities is 17.27 characters, significantly longer than other entity categories. Treatment entities often contain multiple details, including various drugs, dosages, treatment methods, and frequencies, such as in the example: “Chemotherapy: Cyclophosphamide 1000 mg on day 1, Epirubicin 50 mg on day 1, 21 days per cycle, 4 cycles.” However, the model only identifies the drugs and their dosages used in chemotherapy, while ignoring the subsequent frequency information. The increased length and complexity of these entities make it more challenging for the model to accurately identify and classify them, resulting in a decrease in overall recognition accuracy.

Table . Performance obtained for each entity.

Class	Entity number	Average length	Precision (%)	Recall (%)	F_1-score (%)
Symptoms	973	7.62	82.86	84.89	83.86
Tests	640	7.82	82.61	81.40	81.02
Treatments	4184	17.27	76.90	72.30	74.24
Time	4644	8.01	92.62	92.96	92.79

Experiment on CCKS2019

In order to comprehensively validate the efficacy of the model proposed in this study, we applied it to the CCKS2019 dataset and conducted a performance comparison with models recently introduced in the literature. The CCKS2019 dataset, publicly accessible and broadly used within China’s medical NLP research community, offers a standardized evaluation platform for diverse NER models (CCKS2019 [28]). In total, we compared 8 models, including 3 models in 5.1, and the other 5 models are as follows:

- Embeddings from language models (ELMo)-lattice-LSTM-CRF model: this model uses the lattice LSTM-CRF architecture and integrates variant contextual character representations (Chinese Embeddings from Language Models [ELMo]) to enhance the use of character and word information in Chinese EHRs [29].
- ELMo-encoder from transformer–CRF model: this model fine-tunes the ELMo model using domain-specific clinical records and uses transformer (encoder from transformer) as an encoder to address long-context dependencies [30].
- All CNN model: this model incorporates Chinese radical characters to enhance the morphosemantic representation of Chinese characters [14].
- Graph attention network–BiLSTM-CRF model: this model uses a graph neural network to model lexical dependency inertia as syntactic semantics and integrates semantic information at various levels to enhance contextual representation [31].
- Chinese medical–NER model: this model enhances the MC-BERT model by incorporating graph convolutional networks and CRFs [16].

Table 9 presents a comparison of the performance of our proposed model on the CCKS2019 dataset with that of models introduced in recent literature. Our model achieves an F_1-score of 87.26%, surpassing recent models by margins of 2.64%, 2.24%, 2.13%, 1.67%, 1.63%, 1.34%, 0.99%, and 0.97%. These results strongly affirm the effectiveness of our model. The experimental findings clearly demonstrate that our cancer-specific named NER model outperforms existing models on the CCKS2019 dataset, highlighting its potential for effectively handling larger medical datasets.

Our proposed model	87.26	87.27	87.26

[a]BERT: Bidirectional Encoder Representations from Transformers.

[b]BiLSTM: bidirectional long short-term memory.

[c]CRF: conditional random field.

[d]ELMo: embeddings from language models.

[e]LSTM: long short-term memory.

[f]ACNN: all convolutional neural network.

[g]ET: encoder from transformer.

[h]ALBERT: A Lite Bidirectional Encoder Representations from Transformers.

[i]IDCNN: iterated dilated convolutional neural network.

[j]MHA: multihead attention.

[k]GAT: graph attention network.

[l]CNN: convolutional neural network.

[m]CM: Chinese medical.

[n]NER: named entity recognition.

Discussion

Principal Findings

Unstructured EHR data contains valuable patient information that can be used for clinical decision support and research [32]. In the Chinese breast cancer EHR corpus constructed in this study, there are 876 admission records, comprising a total of 528,925 tokens. Annotations were performed for 4 major categories and 17 subcategories of named entities, with each subcategory having more than 100 annotated instances. In the NER task, the model we propose outperforms other models currently applied in medical-related fields. The results of ablation experiments revealed that the fusion of the pretrained model with the DGCNN-BILSTM-MHA-CRF model effectively enhances entity recognition performance. Specifically, the introduction of the DGCNN structure on top of the baseline results in the maximum improvement of 0.35%. This enhancement is attributed to the structure's ability to mitigate the risk of gradient vanishing and facilitate information transmission across multiple channels, capturing a wealth of feature information. In addition, the incorporation of the MHA mechanism on this foundation not only enhances the model's generalization capability but also enables parallel attention computation, strengthening feature fusion capability [24]. This leads to improved use of valid information and reduced impact of irrelevant information, resulting in a further F_1-score improvement of 0.17%.

Comparing the results of the pretrained model experiments, it is evident that the proposed ChCancerBERT pretrained model outperforms various state-of-the-art BERT models, with the medical domain-specific MC-BERT model ranking second. This is attributed to MC-BERT incorporating more medical corpus training into BERT, and ChCancerBERT further including the Chinese cancer corpus on top of MC-BERT. This augmentation effectively enhances the model's semantic representation capability in the Chinese cancer domain, yielding superior results in the Chinese breast cancer corpus in this study. In addition, the study's results indicate that pretrained BERT models based on specific domains can lead to improved performance in downstream tasks [7].

Among the 4 categories extracted in this study, the performance in extracting time entities stood out, with an impressive F_1-score of 92.79%. This result can be attributed to the relatively high quantity of time entities in this dataset, amounting to 4644, and the fact that time entities exhibit a more standardized writing format compared to other entities, which, to some extent,

XSL•FO
RenderX

reduces the difficulty of recognition and enhances recognition accuracy [33].

We scrutinize the entity recognition outcomes of the most proficient fusion model derived from our experiments. Categories with infrequent occurrences in the dataset, such as TNM, Bi-RADS, and some other entities in class "tests," are prone to omission errors. These errors manifest as instances where entities that should have been identified remain undetected, suggesting a propensity of the model used in this study to overlook less common entity categories [34]. Such omissions may result in incomplete information extraction, which is crucial for disease diagnosis and the formulation of treatment plans. Therefore, downstream applications should incorporate clinician verification mechanisms or error correction modules to ensure safety in clinical use.

In this study, entities characterized by considerable length, such as chemotherapy, radiotherapy, and other in-class "treatments," are typically classified correctly by the model. However, the model is susceptible to boundary recognition errors [7], leading to either the exclusion of words at the sentence's periphery or the inclusion of extraneous words beyond the sentence, which may cause confusion in clinical documentation. Furthermore, on one hand, Chinese words frequently exhibit polysemy and ambiguity [33]; on the other hand, the dataset for this study contains instances where statements are nested within the entity categories of other entities. Such intricacies heighten the risk of erroneous entity category determinations.

Concurrently, we apply the model introduced in this research to the publicly accessible CCKS2019 dataset, and the findings illustrate its superior performance compared to prior research efforts, suggesting the ChCancerBERT framework has the potential to be extended to other cancer types and even broader clinical domains. Nevertheless, differences in documentation style and terminology across hospitals may affect generalization. Domain adaptation strategies such as continual pretraining on local EHR corpora and transfer learning can be explored to improve portability to other institutions.

Using our proposed model, vital clinical data encompassing timestamps, examination details, symptoms, and treatment modalities can be readily extracted from the EHRs of patients with cancer. The extracted entities provide important value for both clinical and research applications. Time, symptom, test, and treatment information can be structured into patient timelines to support disease monitoring, clinical decision support, population health analysis, and trial recruitment. These entities can also be mapped to standards such as International Classification of Diseases, 10th Revision, enabling interoperability and secondary use of structured cancer data.

Conclusions

This study designed and developed a pretrained model specifically tailored to the Chinese cancer domain, named ChCancerBERT. The model was then integrated with various NER models proposed in the field of computer science, resulting in the ChCancerBERT-DGCNN-BILSTM-MHA-CRF model. This integrated model was used to extract 4 major types of entities related to cancer from admission records in the oncology department of hospitals. We applied the model proposed in this study to Chinese breast cancer EHR data and CCKS2019 for experimentation and validation. The proposed model achieved an F_1-score of 86.98%, surpassing other models compared in the experiment.

The primary limitation of this study is the restricted data accessibility and relatively small sample size. This limited sample size may affect the statistical power and robustness of the findings. Moreover, potential variations in clinical documentation practices across different regions or institutions in China could pose challenges to the generalizability of the model. Despite these limitations, it is worth noting that the model demonstrated promising transferable capability by achieving competitive performance on the CCKS2019 medical dataset, which suggests its potential applicability beyond breast cancer data. Therefore, future research should aim to acquire EHR data for other types of cancer to further validate the generalizability of the proposed model. Furthermore, a NER system tailored for clinical application is envisaged to be constructed based on this model. This system aims to assist clinical researchers in data organization and extraction. In addition, plans encompass the establishment of a clinical decision support system to facilitate more effective treatment for patients.

Unsupervised Coverage Sampling to Enhance Clinical Chart Review Coverage for Computable Phenotype Development: Simulation and Empirical Study

Abstract

Background: Developing computable phenotypes (CP) based on electronic health records (EHR) data requires "gold-standard" labels for the outcome of interest. To generate these labels, clinicians typically chart-review a subset of patient charts. Charts to be reviewed are most often randomly sampled from the larger set of patients of interest. However, random sampling may fail to capture the diversity of the patient population, particularly if smaller subpopulations exist among those with the condition of interest. This can lead to poorly performing and biased CPs.

Objective: This study aimed to propose an unsupervised sampling approach designed to better capture a diverse patient cohort and improve the information coverage of chart review samples.

Methods: Our coverage sampling method starts by clustering by the patient population of interest. We then perform a stratified sampling from each cluster to ensure even representation for the chart review sample. We introduce a novel metric, nearest neighbor distance, to evaluate the coverage of the generated sample. To evaluate our method, we first conducted a simulation study to model and compare the performance of random versus our proposed coverage sampling. We varied the size and number of subpopulations within the larger cohort. Finally, we apply our approach to a real-world data set to develop a CP for hospitalization due to COVID-19. We evaluate the different sampling strategies based on the information coverage as well as the performance of the learned CP, using the area under the receiver operator characteristic curve.

Results: Our simulation studies show that the unsupervised coverage sampling approach provides broader coverage of patient populations compared to random sampling. When there are no underlying subpopulations, both random and coverage perform equally well for CP development. When there are subgroups, coverage sampling achieves area under the receiver operating characteristic curve gains of approximately 0.03 - 0.05 over random sampling. In the real-world application, the approach also outperformed random sampling, generating both a more representative sample and an area under the receiver operating characteristic curve improvement of 0.02 (95% CI −0.08 to 0.04).

Conclusions: The proposed coverage sampling method is an easy-to-implement approach that produces a chart review sample that is more representative of the source population. This allows one to learn a CP that has better performance both for subpopulations and the overall cohort. Studies that aim to develop CPs should consider alternative strategies other than randomly sampling patient charts.

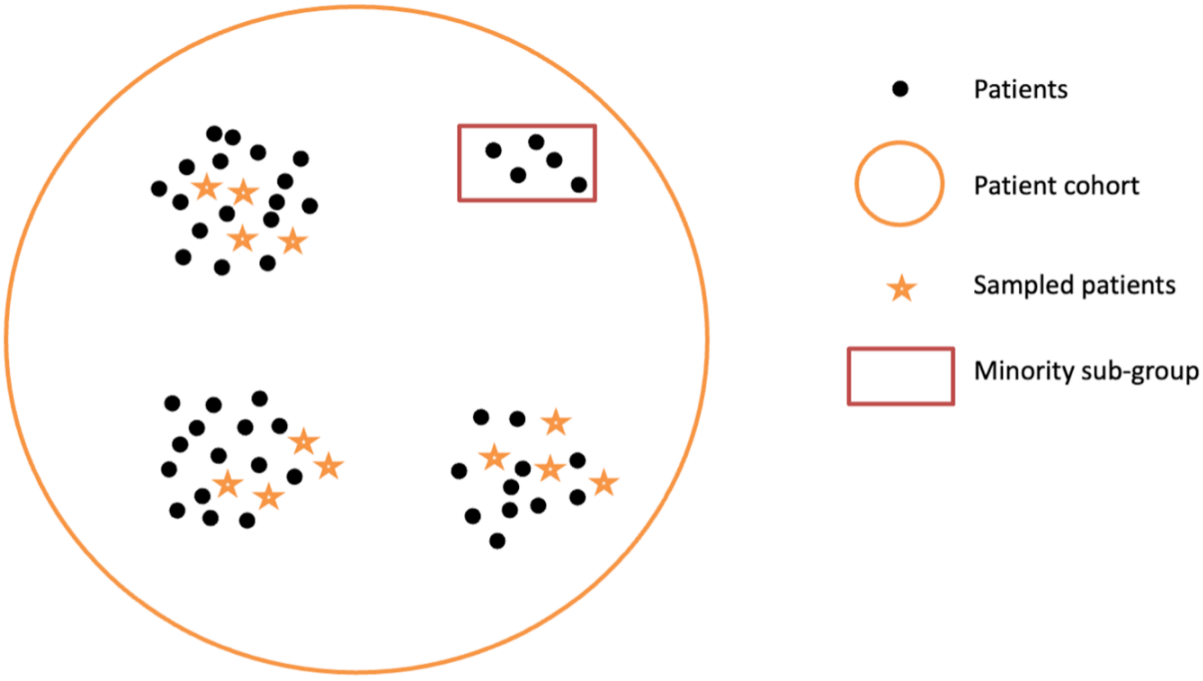
Introduction



Electronic health records (EHR) data are widely used in clinical research. While they contain dense, often granular information on a patient's health status, they also pose challenges for clinical studies since they lack explicit documentation for the reason for the health care encounter (eg, admission due to infection). In principle, the problem list, which provides a historical listing of previous health problems, can be used to identify chronic conditions, though it is often unreliable [1,2]. Similarly, fields such as discharge diagnosis may not accurately represent the reason a patient had a visit. Instead, information from diagnosis codes, laboratory test results, and prescriptions or administered medications is used to indicate the presence of a specific clinical

XSL•FO
RenderX

condition [3-5]. This is a well-known challenge in working with EHR data and has led to the growth of computable phenotypes (CPs). CPs are algorithms, typically Boolean, though sometimes probabilistic, that use multiple sources of clinical data—such as diagnoses, laboratory results, and medication records—to infer the clinical condition of a patient or the reason for a visit [6-8].

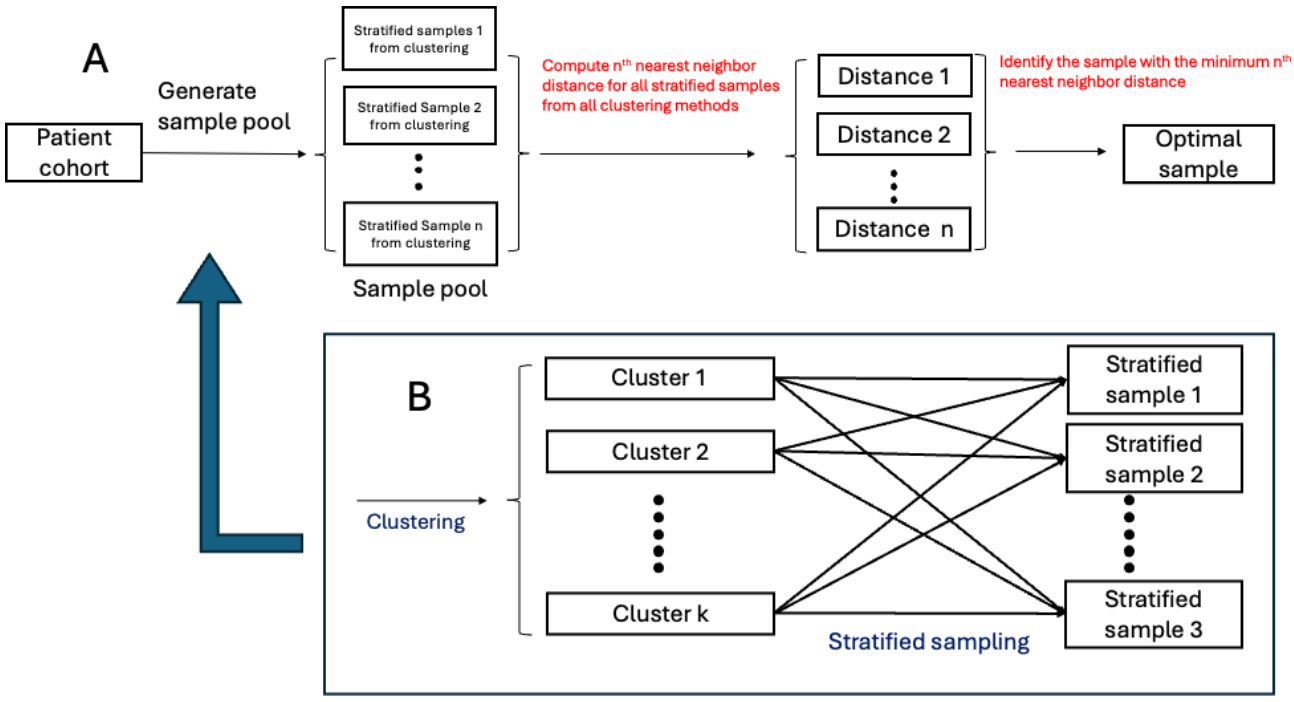
Creating CPs is a multiphase process that often requires significant collaborative effort from clinicians and informaticians [5,9]. One of the key components in CP development is the creation of a set of "gold standard" outcome labels. The outcome labels are typically generated based on manual review of a subset of eligible patient charts, which can require significant time [6-8,10]. The set of charts that are used to develop these gold-standard labels is usually sampled randomly [11]. While random sampling will, on average, produce a representative view of the population of interest, since one usually wants to review only a small number of charts, random sampling may not adequately represent the complete range of disease presentations or patient demographics. In the scenario shown in Figure 1, subgroups that have a rarer presentation within the larger data set (eg, rarer presentations of the disease of interest and disease presentation in minority subgroups) are less likely to be adequately covered based on random sampling. In this case, much larger sample sets are necessary to find a meaningful number of charts from people from these subgroups [12]. In such scenarios, random sampling strategies might not be effective in generating a sample covering all subgroups for chart review purposes and result in a CP that does not accurately capture the heterogeneity of the condition of interest. This can lead to a CP that performs worse for those subpopulations.

Figure 1. Example of the impact of random sampling on the representation of patient subgroups. The black dots represent unsampled patients; stars represent the sampled patients. The red box represents a subgroup that was missed by random sampling.

In recent years, various methods have been developed to enhance the coverage of labeled data [13-16]. However, these methods either rely on external population resources or focus solely on maximizing demographic coverage, which do not fully align with the chart review objective. Among these methods, active learning is one such approach that iteratively selects the most informative samples for labeling, aiming to optimize model performance with a minimal amount of data [17,18]. However, active learning typically requires an initial set of labeled data to train the model and guide the selection process [19]. Moreover, active learning methods are typically focused on identifying the samples that will provide the most leverage on the final model, as opposed to the ones that would best capture the diversity of the patient cohort [18-21].

In this paper, we propose a process for selecting medical charts for review to generate gold standard labeling when constructing CPs. The goal of this method is to ensure that our selection captures the diversity of the full patient cohort. To achieve this, we propose a clustering-based process to generate potential samples. We then introduce a novel metric to identify the most representative sample that should be used for label generation. By enhancing the information coverage of the training sample, our approach is expected to yield a better performing CP for both subgroups and the full patient cohort. To illustrate this approach, we use simulation methods coupled with a real-world data example to demonstrate how this novel sampling approach can match or even surpass the performance of random sampling.

Methods



Sampling Approach

The overall methodological approach is illustrated in Figure 2. We start by considering a study cohort for whom we want to create labels for the presence or absence of a condition of interest (eg, diabetes, cause-specific admission). We presume that our study cohort is large enough that we do not want to

XSL•FO
RenderX

review and label all patient charts. Instead, we want to generate an optimal chart review sample, from which we will develop or "learn" a CP. In this paper, our analytic task is to determine how to best identify that sample. We propose that the best sample is one that maximizes coverage of the cohort, providing information about all of the subgroups that compose the cohort (Figure 2A). In other words, the sample should be equally representative of each subgroup, rather than merely reflecting the source population distribution. To assess coverage, we define a novel metric, described below. A variety of methods can be used to generate the sample pool. In this study, we propose using a stratified sampling framework, in other words, clustering the data and then sampling from these clusters (Figure 2B). By identifying and then sampling from clusters, we hypothesize that we will be able to represent different patient subgroups, making the chart review sample more reflective of the entire patient cohort.

Figure 2. Diagram illustrating our sampling approach. (A) procedures for general coverage sampling; (B) procedures for generating the sample pool.

Optimal Sample Generation

After defining a cohort of interest, we start by clustering the individual patient records. As illustrated in our real data example, our groupings are driven by clinical factors, so we only use clinical features (ie, not demographic factors) to conduct the clustering. We then sample records randomly from each of the clusters. For example, if we prespecify that we want to review 100 charts, and we generate 4 clusters, we would sample 25 records from each cluster. While a variety of clustering algorithms can be used, we suggest hierarchical clustering. The nested cluster structure provided by hierarchical clustering is reflective of our proposed interpretation that the cohort consists of patient subgroups. For comparison, we also present results from K-means clustering. Notably, with a sufficiently large number of replications, we expect different clustering methods to generate similar optimal samples, resulting in comparable representative samples.

Coverage Assessment

A primary step is assessing data coverage. To do so, we propose a novel metric that measures the coverage of the sample for the full data cohort. We define the n^{th} nearest neighbor distance as:

$$\text{nth nearest neighbor distance} = \sum_{i=1}^{N} d_{in}$$

For each person, *i*, in the study cohort of size N, we calculate the Euclidean distance, *d*, to each person from the sampled set. din is the distance between the ith person in the cohort, to the nth nearest sampled person. For example, the 5th nearest neighbor distance refers to the sum of the distance between every patient *i* and its 5th closest sampled person. After generating the sample pool, we calculate the distance for each individual in the patient cohort to the nth nearest sampled person. We choose the chart review sample with the lowest nth nearest neighbor distance. The intuition for the nth nearest neighbor distance is to ensure that for each person in the full cohort, there is someone in the chart review sample that is "near" or representative of them. This should result in greater coverage for underrepresented subgroups and phenotypes compared to random sampling. For example, for a disease that can present clinically in a variety of ways (eg, diabetes), if a rarer presentation is not represented in the chart sample, then for a person i from this minority group, the closest sampled individuals will be in other subgroups, resulting in a larger nth nearest neighbor distance. Moreover, sampling to minimize the nth nearest neighbor distance will not adversely impact the majority presentation since group members will still have representative samples.

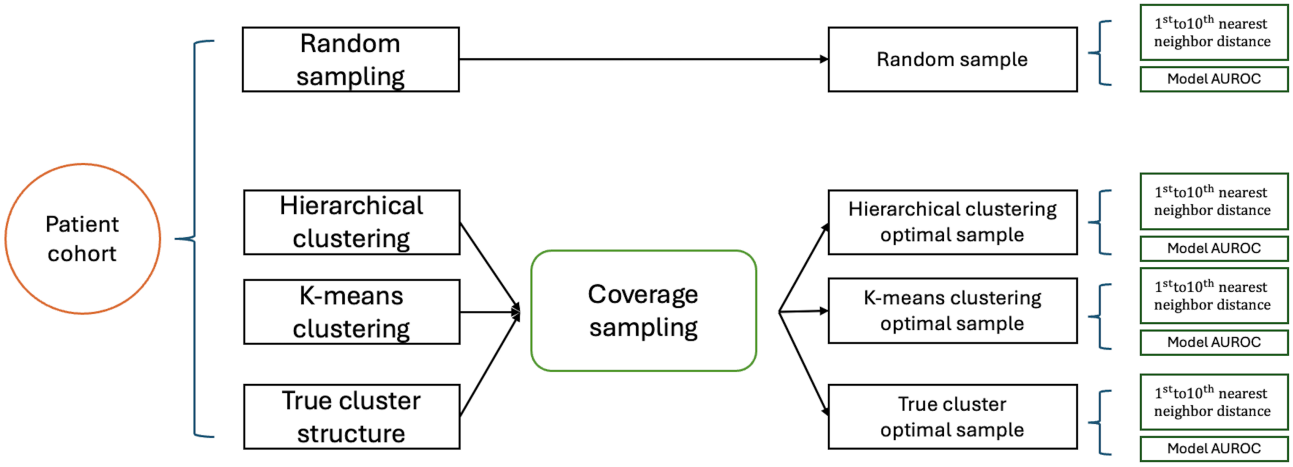
Our coverage sampling process can be summarized as follows:

1. Cluster the dataset based on clinical factors across a range of k clusters.

XSL•FO
RenderX

2. Conduct stratified sampling with a specified sample size across the clusters multiple times to generate the sample pool.
3. Calculate the nth nearest neighbor distance for each sample set in the sample pool and identify the sample with the minimal nth nearest neighbor distance.

The primary tuning parameter is n. This can be prespecified by the user, or *n* can be assessed over a range of values, and taking the mean distance. As we show below, the approach is not very sensitive to the choice of n. Although the results presented are based on Euclidean distance, given the mixed data types of the EHR data, we also assessed Manhattan and Gower distances and found that they had minimal impact on the final results.



Assumptions

The primary assumption of this procedure is that we have a broad cohort from which to sample that fully captures all individuals with the condition from which we wish to define a CP. Meaning, our identified patient cohort (ie, our denominator) has perfect sensitivity for the outcome of interest, and the analytic challenge is improving the specificity of the CP.

Evaluation Criteria

As shown in Figure 3, we assess the quality of a selected sample for chart review in 2 ways: cohort coverage and CP performance. For cohort coverage, we compare the nth nearest neighbor distance, with samples exhibiting smaller distances considered more representative of the study cohort. For CP performance, we train a classification model using a sample derived from either our proposed coverage sampling or random sampling methods. All the unsampled patients are regarded as the test dataset. We evaluate the efficacy of these models by comparing the area under the receiver operating characteristic curve (AUROC) using the test dataset. Samples that yield models with higher AUROC values are considered to be better.

Figure 3. Diagram to show the evaluation criteria of sample quality. The coverage sampling refers to the sampling procedure outlined in Figure 2. AUROC: area under the receiver operating characteristic curve.

Simulation Study

We conduct a simulation study to evaluate the efficacy of coverage sampling outlined above. We sample 120 patients from 250 simulated datasets with a size of 10,000 and 10 characteristic variables by both random sampling and coverage sampling. Across the datasets, we generate 4 clusters and create a sample with different proportions of each cluster: (simulation set 0: 1.0,0,0,0; simulation set 1: 0.25, 0.25, 0.25, 0.25; simulation set 2: 0.1, 0.3, 0.3, 0.3; simulation set 3: 0.1, 0.1, 0.4, 0.4 and simulation set 4: 0.1, 0.1, 0.1, 0.7). These samples can be interpreted as: no underlying cluster structure, equally distributed subgroups, 1 minority subgroup, 2 minority subgroups, and one majority group. The initial 2 simulation sets (sets 0 - 1) serve as baselines, where either no underlying cluster exists or all clusters are of equal size. The subsequent simulations (sets 2 - 4) delve into more complex scenarios, incorporating minority subgroups to assess their impact on the representation of subgroups within the samples.

To generate the clustered data, we used the R package fungible [13], which uses the following model:

$$X=DjB+e$$

Where X is the matrix of simulated observations, where each row representing an observation and each column representing a variable; Dj is a matrix of indicator for cluster j, identifying the membership of observation within this cluster; B is a matrix that represents the correlation between the cluster membership and observation scores), and e represents the deviations that generated from a mixture distribution.

To generate outcomes (ie, phenotypes to be derived), we apply the following model:

$$\text{logit}(P(\text{event}=1))=\alpha 0+\sum_{j=1}^{k} I(\text{clusteri}=j)\alpha j+\sum_{l=1}^{p} X il\beta l$$

Where Pevent=1 represents the probability of ith encounter outcome equal to 1. I(clusteri=j) is the indicator of whether the ith encounter belongs to jth cluster or not. *X* is the design matrix where each row represents one encounter, and each column represents one explanatory variable. $\alpha 0$, αi, and βl are the intercept and main effects corresponding to I(clusteri=j) and *X*. To more accurately reflect real-world conditions, only half of the explanatory variables were incorporated into the generation of the outcome variables, treating the remaining variables as noise (with respect to the outcome).

For each simulated dataset, we assessed information coverage and model performance across 3 samples. First, using the

XSL•FO
RenderX

procedure described in the optimal sample generation section, we averaged the 1st to 10th nearest neighbor distances to obtain a hierarchical-cluster-based sample of size 120 and a k-means-cluster-based sample of size 120. For comparison, we selected 120 random samples and 120 that were sampled from the true underlying clusters. In this manuscript, we refer to the 4 samples as hierarchical, k-means, random, and truth. All data not included in these samples were retained as test data for further analysis. For the model performance comparison, we used each of the 4 derived samples (hierarchical cluster coverage, k-means cluster coverage, random, truth) to fit a logistic regression model to learn a probabilistic CP. For the scenario without an underlying cluster structure, only hierarchical cluster coverage, k-means coverage, and random sampling results are presented, as there is no true cluster structure to compare against. We computed the AUROC to evaluate the model's performance and averaged the performance over 50 iterations.

Real-World Data Application

Our application is motivated by our previous work to develop a CP for a hospital admission due to COVID-19. During the height of the COVID-19 pandemic, hospitals tested all patients for SARS-CoV-2. Work by us [14] and others [15] has indicated that up to 38% of patients who tested positive for SARS-CoV-2 upon admission were admitted for reasons other than COVID-19. Therefore, a CP for admission due to COVID-19 would need to be more complex than simply a positive SARS-CoV-2 test. Our goal then is to define a sample of patients for chart review, in aid of learning a CP for admission due to COVID-19. Since COVID-19 patients could have different presentations, we hypothesize that our coverage sampling approach would be better for learning a CP.

Data Source

We abstracted data from the Duke University Health System EHR system. Duke University Health System consists of 3 hospitals on a common, EPIC-based EHR system. The clinical data are organized into a research-ready datamart, based on the PCORnet Common Data Model [16].

Source Cohort

Our study cohort consisted of all patients with an inpatient admission and a positive test for SARS-CoV-2 from March 2020 to March 2023 (when routine testing stopped). This definition has perfect sensitivity, but poor specificity, for capturing admissions due to COVID-19. Following our previous work, we split this cohort into training and testing data. The testing data consisted of 441 patients admitted from January 16 to 22, 2022 and were already chart reviewed for operational purposes. Additional information regarding the testing data can be found in [14]. The training data consisted of the other 7743 unlabeled patients with positive SARS-CoV-2 tests from 2020 - 2023.

Features Used

For coverage sampling and CP generation, we used 46 clinically relevant features such as encounter characteristics (encounter type, admitting source, and discharge disposition), diagnoses, laboratory tests conducted, and medications administered. Table S1 in Multimedia Appendix 1 provides full details on features used. While we extracted demographic characteristics, we did not include these in the sampling or CP development steps.

Sampling and Outcome Labeling

We generated 2 samples of 100 using coverage and random sampling from the training dataset of 7743 patients. For the coverage sampling, we used hierarchical clustering and identified the cluster structure that minimized the *1st* nearest neighbor distance. An infectious disease specialist (JHH) chart reviewed and labeled the encounter as due to COVID-19 or related sequela, or not.

Method Evaluation

We compare the patient characteristics for the samples that were selected from each sampling approach. Then, using the criteria defined above, we evaluate the coverage of the sample of the full cohort. Finally, we used each sample to learn a probabilistic CP based on a least absolute shrinkage and selection operator logistic regression. We evaluated each version on the independent test data.

All analyses were conducted in R version 4.3.2. The source code used in these experiments is available at GitHub [22].

Ethical Considerations

This study was approved and declared exempt by the Duke School of Medicine IRB, protocol Pro00109397 (9/14/2021). We used a limited analytical dataset within a secure computing environment, and patients did not receive any compensation.

Results

Evaluation of Sampling Methods Using Simulated Data

Figure 4 presents the mean 1st to 10th nearest neighbor distances for both random and coverage sampling methods across 4 distinct scenarios. Figure 4A illustrates a baseline scenario where all clusters are of equal size, while Figure 4B-D depict scenarios with 1, 2, and 3 minority subgroups, respectively. In each scenario, the coverage samples consistently exhibit smaller nearest neighbor distances compared to those from random samples. As minority subgroups are incorporated into the simulated cohort, the advantage of the coverage sample over a random sample increases. Notably, the distances in the hierarchical and k-means-clustered coverage samples are closely aligned with those observed in true cluster configurations, indicating similar coverage of the cohort.

XSL•FO
RenderX

Figure 4. From 1st to 10th nearest neighbor distance mean across 200 simulated data samples for 4 cluster ratios. The red line represents the random sample; the blue line represents the coverage sampling based on hierarchical cluster; the orange line represents the coverage sampling based on k-means clustering; the green line represents the coverage sampling based on the true cluster. (A) All simulated data follows the baseline cluster ratio (0.25,0.25,0.25,0.25). (B) All simulated data follows cluster ratio (0.1,0.3,0.3,0.3). (C) All simulated data follows cluster ratio (0.2,0.2,0.4,0.4). (D) All simulated data follows cluster ratio (0.1,0.1,0.1,0.7).

XSL•FO
RenderX

After generating the samples, we used the data to learn a probabilistic CP and tested its performance. Table 1 presents the mean 1st to 10th nearest neighbor distance and the mean logistic model's AUROC between a random sample and coverage samples generated using hierarchical clustering, k-means clustering, and a true cluster structure of size 120 across 250 simulated datasets. Values highlighted in asterisk (Table 1) indicate AUROCs that are significantly higher than those of the random sample at the 0.05 significance level. The visualization of the AUROC results is shown in Figure S1 in Multimedia Appendix 1. Consistent with coverage results, in the baseline scenario without any minority subgroup or any underlying cluster structure, coverage samples exhibit similar AUROC compared to random samples. However, with the introduction of a minority subgroup, the coverage samples based on hierarchical, k-means, and true cluster structures all produced significantly higher AUROC values compared to random samples. Additionally, we observed that the coverage samples using hierarchical clustering and k-means clustering exhibited similar performance, suggesting that the choice of clustering method has minimal impacts on coverage sampling, provided there are sufficient repetitions.

Evaluation of Sampling Methods Using Real-World Data

In real-world data, the true number of clusters or patient subgroups is unknown. We therefore explored a range of potential cluster structures, including 2, 3, 4, 5, 10, 15, and 20 cluster structures. Based on simulated data results, with enough replications, the choice of clustering method does not impact our sampling approach; thus, we only evaluated hierarchical clustering in the real-world data analysis. Figure 5 shows the difference in the mean 1st to 20th nearest neighbor distances in samples generated using the coverage and random samples (ie, coverage sample nth nearest neighbor distance subtracted from random sample nthnearest neighbor distance). The results

XSL•FO
RenderX

demonstrate that for smaller sample sizes (50 and 100), samples drawn from structures with 2, 3, and 4 clusters provide a more accurate representation than their random counterparts. However, as the chart review sample size increases from 400 to 800, the nth nearest neighbor distance of the coverage samples aligns more closely with that of random samples. It is noteworthy that samples derived from 10, 15, and 20 cluster structures perform less effectively across all sample sizes.

Figure 5. Mean n^{th} nearest neighbor distance difference (random sample distance–coverage sample distance) over 100 replications for real-world data.

We conducted a chart review of the 100 random samples and 100 coverage samples. Our coverage sampling approach selected a sample based on 1st nearest neighbor distance. Assessing the clusters using nearest neighbor distance indicated that 2 clusters were the optimal cluster structure. Major clinical differences between the 2 clusters included the C-Reactive protein test, D-dimer test, and BMI (Table S1 in Multimedia Appendix 1). Moreover, while clustering was performed using only clinical variables, the resulting clusters also exhibited meaningful demographic differences, with cluster 1 consisting of an older population compared to cluster 2 (50% vs 25% individuals older than 65 y old). Additional details regarding the cluster characteristics are provided in Table S1 in Multimedia Appendix 1. Table 2 presents the demographic characteristics of the full 7743 patient cohort, as well as the demographics of the coverage and random samples. The standardized mean differences of the random sample and coverage sample are also shown. Notably, the coverage sample includes a higher percentage of young adults (24/100) compared to the random sample (11/100), with other demographic variables showing similar prevalence patterns in both samples.

[a]SMD: standardized mean differences.

After generating labels, we fit a least absolute shrinkage and selection operator logistic regression model to learn and test a CP. Table 3 presents the *1st* nearest neighbor distance for both the coverage sample and random sample, as well as the AUROC for the learned CP. Additionally, we plot the 1st to 20th nearest neighbor distances of coverage and random sample in Figure S2 in Multimedia Appendix 1.

Given that the true cluster structure is unknown, we report the AUROC at the demographic variable level. The 1st nearest neighbor distance and the AUROC results indicate that the coverage sample slightly outperforms the random sample. This pattern is also observed at the demographic feature level; however, these differences did not reach statistical significance. Nonetheless, in terms of magnitude, coverage samples demonstrate a notable improvement in the coverage of young adults compared to random samples. Of note, we found that increased coverage of demographic groups is not directly correlated with model performance. For example, the coverage and random samples both have similar proportions of males and females. However, the coverage sampling performs nominally better within each sex group. This supports not including demographics in the clustering step and relying on clinical drivers of differentiation. We further evaluated the performance of coverage sampling using additional model architectures, including random forest and XGBoost, for real-world data. Across all models, the coverage sampling approach consistently performed as well as, or better than, random sampling. More details can be found in Table S2 in Multimedia Appendix 1.

For very small subgroups, the performance of the coverage sample may vary. For instance, in the “Other race” group (n=12), the coverage sample shows a substantial AUROC improvement over random sampling (0.611 vs 0.925). In contrast, for the “Other payment” group (n=27), the coverage sample performs slightly worse than random sampling (0.805 vs 0.820).

Discussion

Principal Findings

CPs are a key component of secondary research with EHR data [23,24]. A required step in CP development is conducting a manual chart review to establish a set of "gold-standard" labels to identify patients with and without the condition or outcome of interest. This manual review can be highly time-consuming [25,26]. Little work has been conducted on how to optimally select charts for review, with investigators most often using random chart selection [11]. This can lead to inefficiencies as potentially informative or edge cases can be missed. To address this concern, we have proposed a sampling strategy to select charts for review that captures the diversity of a population of interest. The key aspect of our method is identifying the optimal sample using a new metric that we have termed the nth nearest neighbor distance. We assessed our method using both simulated and real-world data, evaluating both the information coverage and CP performance. Our findings indicate that coverage sampling performs as well as, if not better than, random sampling. We recommend using a representative sample when developing a computable phenotype. Alternatively, if the phenotype has already been developed, it should be recalibrated using a representative sample of the population before deployment.

One of the motivations for this approach is the presumption that within any group of patients with a particular condition, there are patient subgroups that may have a different presentation of that condition. For example, while many patients with diabetes will have glycosylated hemoglobin test values >6.5% there will be some individuals with controlled diabetes and normal glycosylated hemoglobin values; however, these patients still have diabetes [27]. Such scenarios require the creation of complex CPs that can identify patients with diabetes who have a variety of disease presentations [28]. If these patient subgroups are small enough, a random selection of charts may not provide sufficient coverage of these subgroups to ensure that the CP performs equitably for all patient subgroups. As our results demonstrate, coverage sampling has its greatest impact in CP performance when minority subgroups are present. However, the presence of such minority subgroups is not a requirement for the method to perform well. In scenarios without minority subgroups, our method performs comparably to random sampling, highlighting the robustness of the approach. Moreover, even when there is no underlying cluster structure at all, coverage sampling performs as well as random sampling.

XSL•FO
RenderX

A novel aspect of our approach is the development of a metric, the nth nearest neighbor distance, to measure the coverage of a given sample. While previous methods have used nearest neighbor distances to detect and quantify spatial randomness, they have primarily focused on analyzing spatial patterns in populations [29]. Existing representativeness metrics, such as Simpson's Diversity Index and Shannon's Entropy, quantify overall variability across multiple demographic features [30]. Simpson's Diversity Index measures the probability that 2 individuals randomly selected from a sample will belong to different categories, thereby emphasizing the dominance or evenness of group representation [31]. Shannon's Entropy quantifies diversity by accounting for both the abundance and the evenness of the categories present, using information theory to assess the uncertainty in predicting the category of a randomly chosen individual [32]. While these metrics effectively address general diversity measurement goals, they do not directly align with our specific goal of evaluating the representation and coverage of minority subgroups. The nth nearest neighbor distance explicitly evaluates the distance between records in the unsampled group to those in the sampled group. This targeted focus enables a more precise assessment of the extent to which minority subgroups are included in study samples, thereby avoiding underrepresentation in the set of records used for CP development. As our real data analysis results showed, we can use the nth nearest neighbor distance to choose an optimal number of cluster k from which to sample. In particular, choosing too large of k leads to suboptimal performance.

Although the construction and generation of a chart review sample has not been widely discussed in the CP literature, parallel work exists in the active learning literature. Current active learning methods can be categorized as query-acquiring (pool-based) or query-synthesizing [20,33]. We focus on query-acquiring active learning, as query-synthesizing methods are not directly analogous to our work. Query-acquiring active learning uses various sampling strategies, including uncertainty sampling or information-theoretic measures, to identify which sampling strategies would be most impactful for continued labeling [18,34]. Therefore, the underlying burden for query-acquiring active learning is the same as in our method: an efficient need for labeling [35,36]. Most existing methods, including uncertainty sampling or information-theoretic measures, focus on identifying the most influential records to enhance the performance of a given prediction task [20,21,37-40]. In contrast, our method is not based on a supervised objective. Further, our method seeks to select records that best capture diversity, rather than records that are most representative. While representativeness and diversity may be related, they are not necessarily equivalent.

To illustrate our approach, we tested our method with the real-world task of identifying hospital encounters due to COVID-19. During the height of the COVID-19 pandemic (2020 - 2023), all patients admitted to our health system's hospitals were tested for SARS-CoV-2. As we and others have noted, approximately 38.2% of patients with a positive SARS-CoV-2 test were admitted for reasons other than COVID-19 [14,15]. Therefore, if one wanted to identify patients admitted due to COVID-19, a positive SARS-CoV-2 test would not be a sufficient CP because of its poor specificity. We compared the performance of the chart review sample based on a random selection of charts and our coverage sampling method. Overall, the coverage sample yielded a comparable performing CP. So, while coverage sampling did not yield better performance, the results conform to the simulation findings, which indicate that coverage is robust even when there is no underlying cluster structure or minority group.

While we selected charts based solely on clinical data elements, there were meaningful demographic differences between samples derived from randomly selected charts and through coverage sampling. For example, cluster 1 includes a much older patient population, with 50.2% (2959/5897) over the age of 65, compared to 25.3% (467/1846) in cluster 2. Patients in cluster 1 also have longer hospital stays (9.42 d on average) than those in cluster 2 (3.52 d). Additional details on cluster characteristics are provided in Table S1 in Multimedia Appendix 1. Consequently, the coverage sample exhibits a different distribution than the random sample. Specifically, the coverage sample included younger patients, a greater number of non-Hispanic Black patients (though fewer Hispanic patients), and more individuals with public insurance compared to the cohort derived from random sampling. This result highlights one of the key opportunities in this approach: deriving a less biased sample on which to build a CP. As others have described, one of the mechanisms of algorithmic bias is having unrepresentative samples used to develop the algorithm [41]. For instance, in the context of rare diseases, the typical ratio of patients with a given rare condition to those without the condition is approximately 100:1 [42,43]. In such scenarios, using random sampling may result in underrepresentation of minority subgroups in the chart review sample. When the review sample does not accurately reflect the patient population, the resulting CPs can produce biased results. For example, if certain demographic groups are underrepresented in the dataset, the CP may not learn to make accurate predictions for these groups, leading to disparities in performance [44]. To account for this, algorithmic solutions have been proposed, including data augmentation [45,46], resampling techniques [47,48], and algorithmic adjustments [49]. However, instead of addressing this problem algorithmically, we propose addressing it via design. As such, by clustering the data and sampling equally from the obtained clusters, we aim for the chart review sample to better represent the patient population. An advantage of our method is that it does not require the researcher to prespecify groups. Moreover, as our empirical results show, we are able to capture demographic diversity with just clinical data.

Limitations

While our approach shows promise, there are some limitations. First, while our simulation results illustrate the potential improvement for coverage sampling, our real-world data example only showed nominal improvement. Further work should be conducted in other contexts. Second, the performance of our method is related to the quality of the cluster analysis. As others have noted, clustering methods can be highly variable [50]. This variability may be more obvious in EHR data, which often experience data quality issues. Because the clustering step is a means of obtaining a representative sample, we address this

XSL•FO
RenderX

by generating multiple samples from multiple cluster structures and selecting the one with the best coverage. In principle, it is possible to skip the clustering step and directly choose an optimal sample, leading to more robust results. While such an approach is worthy of further exploration, it would be more computationally expensive and would not necessarily yield meaningfully better results. Third, while our study suggests that coverage sampling is not very sensitive to the choice of *n*, its robustness warrants further evaluation. Future researchers are encouraged to test a small range of *n* values (eg, n=1, 5, 10), as different choices of *n* may yield different samples. Another potential limitation is that the coverage sample (intentionally) generates a sample that will likely have a different event rate than the true event rate within the full patient population. While this does not present a problem for rank-based metrics like AUROC, it may affect the calibration of other metrics, such as Kullback-Leibler divergence [51]. When calibration is a priority, recalibration methods can be used [52].

Conclusions

Overall, our results show that our coverage sampling method can provide a more representative sample than random sampling, especially when the source cohort contains minority subgroups. This approach can lead to the generation of a CP that has better performance in the overall study population as well as within subgroups. While CP development is a key part of secondary research with EHR data, little work has been done on how best to derive samples for learning CPs. This work addresses this gap and seeks to spur more investigation in this area. Ultimately, this sampling method has the potential to improve future clinical research by making gold-standard chart review labeling a more efficient process.

Abstract

Background: With rising patient volumes and a focus on quality, our health system had the objective to create a more efficient way to ensure accurate documentation of colorectal cancer (CRC) screening intervals from inbound colonoscopy reports to ensure timely follow-up. We developed an integrated end-to-end workflow solution using machine learning (ML) and robotic process automation (RPA) to extract and update electronic health record (EHR) follow-up dates from unstructured data.

Objective: This study aimed to automate data extraction from external, free-text colonoscopy reports to identify and document recommended follow-up dates for CRC screening in structured EHR fields.

Methods: As proof of concept, we outline the process development, validity, and implementation of an approach that integrates available tools to automate data retrieval and entry within the EHR of a large academic health system. The health system uses Epic Systems as its EHR platform, and the ML model used was trained on health system patient colonoscopy reports. This proof-of-concept process study consisted of six stages: (1) identification of gaps in documenting recommendations for follow-up CRC screening from external colonoscopy reports, (2) defining process objectives, (3) identification of technologies, (4) creation of process architecture, (5) process validation, and (6) health system–wide implementation. A chart review was performed to validate process outcomes and estimate impact.

Results: We developed an automated process with 3 primary steps leveraging ML and RPA to create a fully orchestrated workflow to update CRC screening recall dates based on colonoscopy reports received from external sources. Process validity was assessed with 690 scanned colonoscopy reports. During process validation, the overall automated process achieved an accuracy of 80.7% (557/690, 95% CI 77.8%-83.7%) for correctly identifying the presence or absence of a valid follow-up date and a follow-up date false negative identification rate of 32.9% (130/395, 95% CI 29.4%-36.4%). From the organization-wide implementation to go-live until December 31, 2024, the system processed 16,563 external colonoscopy reports. Of these, 35.3% (5841/16,563) had a follow-up date meeting the relevant ML model threshold and thus were identified as ready for RPA processing.

Conclusions: Implementation of an automated workflow to extract and update CRC screening follow-up dates from colonoscopy reports is feasible and has the potential to improve accuracy in patient recall while reducing documentation burden. By standardizing data ingestion, extending this approach to various unstructured data types can address deficiencies in structured EHR documentation and solve for a lack of data integration and reporting for quality measures. Automated workflows leveraging ML and RPA offer practical solutions to overcome interoperability challenges and the use of unstructured data within health care systems.

Introduction

Colorectal cancer (CRC) is the second most common cause of cancer-related death in the United States [1] and has a growing incidence rate, particularly among younger individuals [2]. Effective CRC screening is a cornerstone of preventive health care, significantly reducing both the incidence and mortality rates associated with CRC [3]. To realize the full benefit of CRC screening, an accurate and timely recall of patients for follow-up screening is needed.

Despite the availability of electronic health record (EHR) tools to facilitate reminders for CRC screening follow-up, these tools often fail to address clinician needs [4,5]. The limited interoperability of health information exchanges between health care systems and reliance on unstructured data to convey recommendations for follow-up place a high documentation burden on clinicians, leading to substantial missed opportunities for improved CRC follow-up screening and surveillance [6-8].

EHR tools are rarely responsive to patient-specific factors or colonoscopy and pathology findings. Consequently, recalling a patient for more frequent follow-up screening requires a manual update [9]. To enhance CRC screening follow-up accuracy, while minimizing documentation burden, solutions that automate the retrieval and processing of colonoscopy results are needed. An automated process for updating CRC screening follow-up–based colonoscopy findings is likely to increase the number of patients with a documented guideline-concordant CRC follow-up screening interval [10,11].

As with nearly 80% of EHR data [12], colonoscopy and pathology findings are frequently documented within the EHR as free text [13]. Further complexity arises when colonoscopy results are received as inbound medical records from external sources. These records, often received via fax, mail, or email, require additional steps to document the relevant data into the EHR, posing a significant administrative burden for documenting CRC screening due dates [14].

Natural language processing (NLP) models have the potential to address barriers associated with leveraging unstructured data and accurately extract relevant data from free-text colonoscopy and pathology reports [15]. However, NLP alone cannot address all workflow steps required to convert text-based reports into structured fields in the EHR. It is essential to pair the model with supplemental tools for data entry. A solution is needed that orchestrates multiple technologies to address each step in the workflow necessary to update the appropriate CRC follow-up dates.

With rising patient volumes and a focus on quality, our health system needed a more efficient way to ensure accurate documentation of CRC screening follow-up intervals from inbound colonoscopy reports. To address this, we developed an integrated workflow using machine learning (ML) and robotic process automation (RPA) to extract and update follow-up dates from unstructured data. With the objective of demonstrating a proof of concept, in this paper, we outline the process and validity of an approach to process inbound colonoscopy reports that integrates available tools to automate data retrieval and entry within the EHR. We hypothesize that this framework can be adapted to other clinical information to improve reporting, data accuracy, and workflow efficiency.

Methods

Overview

This proof-of-concept study was part of an institutional initiative to improve the accuracy of documented CRC screening follow-up recommendations extracted from unstructured colonoscopy reports from external organizations. The study developed an integrated workflow using existing technologies to address this care gap and assessed its validity. This study consisted of six stages: (1) identification of gaps in operationalizing recommendations for follow-up CRC screening from external colonoscopy reports, (2) defining process objectives, (3) identification of available technological tools, (4) creation of process architecture, (5) process validation and refinement, and (6) health system–wide process implementation.

Study Setting and Participants

The New York University Langone Health (NYULH) system is a private, nonprofit hospital system serving the greater New York area and Florida with over 9 million patients. The NYULH system uses Epic Systems as its EHR platform. For the process validation component of this study, EHR data were extracted prospectively for a series of 4 sequential simple random samples of scanned colonoscopy reports from adult patients aged 45 to 75 years from external sources between August 2023 and September 2023.

Health Informatics Care Gap

Ensuring timely follow-up for CRC screening was identified as an important quality measure for the health system. Accurately tracking patients due for CRC screening is facilitated by having the next colonoscopy follow-up date documented discretely in the EHR's health maintenance (HM) activity.

Gaps in this process frequently occur when colonoscopy reports from external organizations are scanned into the health system's EHR. Since these documents contain unstructured data, critical information remains inaccessible unless manually transcribed into the EHR [12,13]. If this information is not updated manually, the HM follow-up screening interval defaults to 10 years, which may not be appropriate for many patients [8]. As a result, the HM activity often fails to reflect the recommended follow-up intervals indicated in the colonoscopy report unless users manually update it. Factors such as procedural findings, pathology results, and patient-specific risk factors may necessitate more frequent surveillance. To ensure transparency and awareness for both patients and clinicians, as well as for accurate reporting, this information should be documented discretely in the appropriate fields within the EHR.

Manually updating the HM follow-up intervals is time-consuming, often leading to unchanged follow-up dates in the EHR and failing to reflect the appropriate recall time frame. This documentation gap can result in missed or delayed surveillance, potentially impacting patient outcomes. To address this challenge, an efficient and effective process is needed to

XSL•FO
RenderX

extract and process unstructured text from colonoscopy reports to automatically update HM follow-up intervals.

Defining the Process Objective

After identifying the care gap, the objective was to develop a process to automate updating the HM based on the external colonoscopy reports. We sought to leverage ML to identify follow-up recommendations within the reports and RPA to automate the entry of recommended recall dates into the HM activity.

It was also determined that the process must operate within the following constraints: (1) use existing technologies within the health system, (2) not override any recommendations that have been manually entered by a clinician, (3) ML engine identifies follow-up date above a technical performance threshold of >70% confidence; and (4) No human intervention after the colonoscopy report has been scanned into the EHR.

Although pathology results should ideally serve as the gold standard for assessing follow-up intervals, due to limited availability, the recommendation listed within the colonoscopy report was deemed a sufficiently accurate alternative for the purpose of updating HM.

Orchestrated Workflow Development

To develop the orchestrated workflow, the team first broke the process into concrete steps. We then mapped out existing technological components within the healthy IT ecosystem needed for each action. The steps included: (1) daily extraction of scanned external colonoscopy reports, (2) a mechanism for an ML model to receive and analyze those reports to identify the next follow-up date, and (3) an automated process that updates the HM activity when appropriate.

The team established care assumptions to guide when the process updates would take precedence over existing HM follow-up frequencies. These assumptions included: (1) all updates must be associated with a colonoscopy order; (2) the bot should only update HM if the scanned report is more recent than the last documented colonoscopy; (3) the scanned report would not override manual entry; (4) the bot should not update a follow-up date if the patient has an existing earlier follow-up date; (5) if the ML engine's determination of follow-up date is below the performance threshold, the report should be queued for manual review; (6) if an outstanding colonoscopy order exists and the procedure date is after the order date, the report should be scanned to that order; and (7) if there is a range of follow-up dates (eg, return in 3 - 5 y) the bot will use the earlier date. Based on these assumptions, business exceptions within the decision rules were defined to establish scenarios in which it would be inappropriate for the bot to update the HM.

Identified Technological Tools

Overview

Existing technologies were evaluated for their applicability to each workflow step, resulting in a process comprising six key components, including: (1) an internally developed ML model, (2) fax management software, (3) a document management platform, (4) input spreadsheets, (5) RPA, and (6) Epic's HM activity.

Fax Management Software

RightFax (OpenText) is an enterprise fax server software that allows the organization to send and receive faxes. It also transforms faxes for easier management and integration into other digital systems, including the EHR [16]. RightFax was used to receive colonoscopy reports from external sources.

ML Techniques

ML techniques, including optical character recognition and NLP, enable systems to "read" documents and extract relevant information [17,18]. ML is a subset of artificial intelligence (AI) that enables systems to learn patterns from data and make predictions or classifications without explicit programming. These classifier algorithms can identify patterns, structures, and key data within various document formats, automating the extraction process and reducing the need for manual intervention. This capability is widely used in data entry, document analysis, and information retrieval. A proprietary model was internally developed to identify the follow-up dates for the next screening. The model was trained on 7021 unique documents, 90.6% (6358/7021) of which were colonoscopy reports, 6.7% (473/7021) were pathology reports, and 2.7% (190/7021) were other types of documents. Details of the ML model training data set can be found in Multimedia Appendix 1. This process required model training by a clinical subject matter expert.

The ML was validated using a 4:1 patient-based split with manual review of a sample of 1758 documents and associated RPA actions in the EHR. The validation documents included 90.8% (1597/1758) colonoscopy reports, 6.5% (114/1758) pathology reports, and 2.7% (47/1758) other types of documents. Details of the ML model validation data set can be found in Multimedia Appendix 1.

RPA Technology

UiPath RPA is a technology that uses software robots, or "bots," to automate repetitive and rule-based tasks typically performed by humans. These RPA bots can work across platforms and mimic human actions such as data entry, processing transactions, and managing records, thereby increasing efficiency and reducing errors. Unlike AI, RPA follows predefined workflows and does not learn or adapt on its own [19]. In this case, the RPA tool "read" the output of the ML engine, updated the HM activity date if applicable, and documented the actions taken. If any business exceptions existed, they were similarly documented. Finally, the RPA sent a summary of the completed process to operational leadership for review.

Document Management Platform

OnBase is an enterprise content management platform developed by Hyland Software. It helps organizations manage documents in a unified system, acting as a digital filing cabinet with advanced automation capabilities. OnBase supports document storage, quick retrieval, and task automation, enhancing efficiency and compliance [20]. In this process, OnBase is used as the underlying application where the reports were scanned

XSL•FO
RenderX

into the EHR. A specific directory was created to process incoming colonoscopy reports so that they can be processed by the ML model.

Input Spreadsheet

The input spreadsheet was a Microsoft Excel document that was used as a working tool to list the findings and follow-up dates of the colonoscopy reports as identified by the ML model. Any findings with low confidence were indicated as such. The RPA solution reviewed the spreadsheet, "read" the follow-up dates, and documented what actions it took.

HM EHR Feature

Epic Systems' HM activity is an EHR feature designed to help providers manage and track preventive care and chronic disease management for patients. It allows health care organizations to set up and monitor recommended screenings, vaccinations, and follow-up care based on clinical guidelines, patient demographics, and medical history. It serves as a designated location in the EHR to document completed colonoscopies and the recommended follow-up date. However, it is not linked to clinical notes and must be manually updated to reflect changes due to pathology findings or patient-specific conditions [6].

Process Validation

Overview

Prior to systemwide activation, outcome validation was performed via manual review of a sample of colonoscopy reports and associated RPA actions in the EHR. The measures of outcome validity were the number of reports with a missed follow-up date, and the number of reports with a correctly updated HM. Each colonoscopy report was reviewed by trained clinical analysts (DR and CM) for accuracy. Discrepancies were reviewed with the physician informaticist lead (AS). The validation outcomes were divided into two phases: (1) ML evaluation, determining whether a follow-up date was identified within the colonoscopy report and ready for bot processing; and (2) RPA bot action documented in the EHR. Reports not ready for the bot were categorized as (1) correct, with no follow-up date specified; (2) incorrect, having a follow-up date listed that was not picked up by the ML; or (3) an inaccurate follow-up date was identified. Outcomes for reports processed by the RPA update were categorized as: (1) a correct HM update; (2) correct business exception assignment; or (3) incorrect HM update. Four rounds of validation testing were performed with a prospective sample of 690 reports manually reviewed until a saturation of automated outcomes was observed.

Process Refinement

A protocol was established to modify and refine the ML algorithm and bot activities if error patterns were identified during validation. After each round of validation testing, if an error was addressable, the team adjusted either the ML model or RPA based on the error source.

Governance Approval

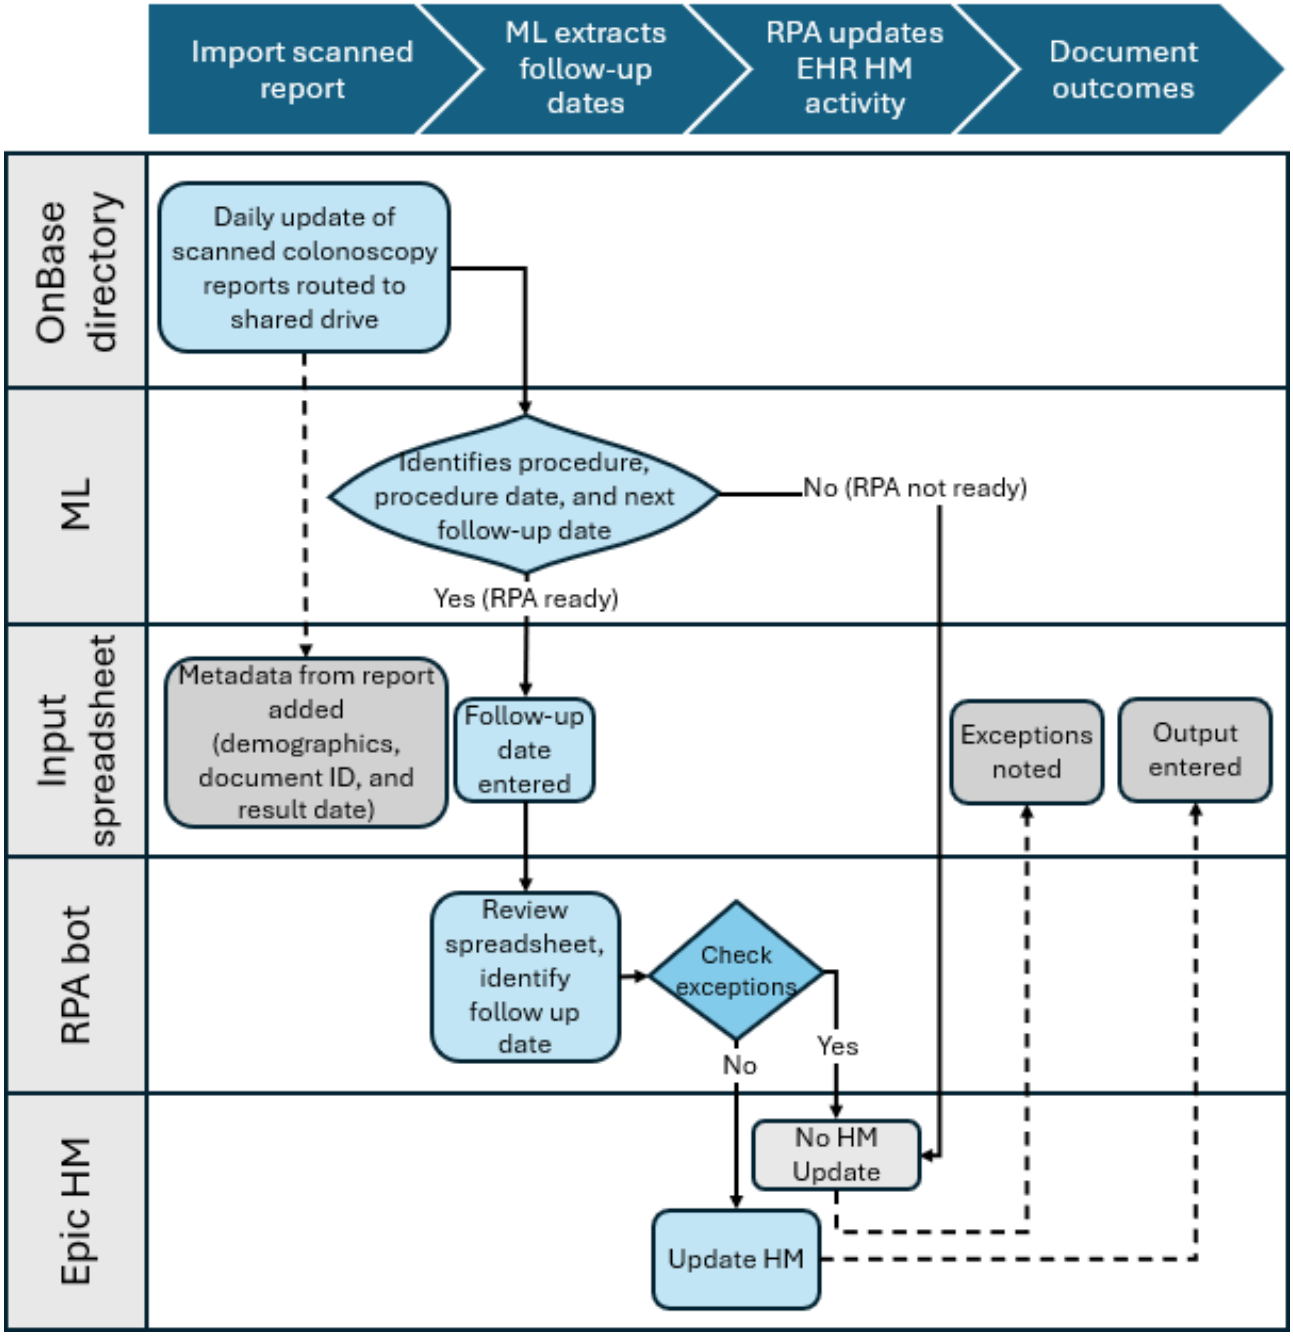
Validation study findings were presented at leadership committee meetings to obtain governance approval for system-wide implementation. Besides confirming the process's validity, the approval process emphasized potential improvements in HM follow-up date accuracy compared to the current reliance on a default 10-year interval and limited manual updates by clinicians.

Process Implementation

After validation, refinement, and all necessary approvals, the process was implemented in the live environment. The implementation was performed for received documents labeled as colonoscopy reports only, not all document types used in the training and validation of the ML model. This began with a period of careful monitoring of the process known as hypercare [21]. The automated process was first implemented in the live environment as small batches, where 10 reports were run through the process and assessed for validity before proceeding to the next 10. This procedure was performed until it was determined that the process performed appropriately in the live environment. After the initial phase, the process was expanded to analyze all prospectively received external colonoscopy reports.

Ethical Considerations

As an operational quality improvement project, the NYULH institutional review board waived the need for approval for the study procedures. A waiver of Health Insurance Portability and Accountability Act (HIPAA) authorization and consent was included to access patient medical records. All study procedures complied with institutional ethical and privacy standards. Informed consent was waived and no compensation was provided.



Results

Overview

Our system established a streamlined, 3-step process integrating preexisting technologies to automate updates to the CRC screening follow-up date based on external colonoscopy results. The process steps, the workflow, and technology resources used for each function are presented in Figure 1.

XSL•FO
RenderX

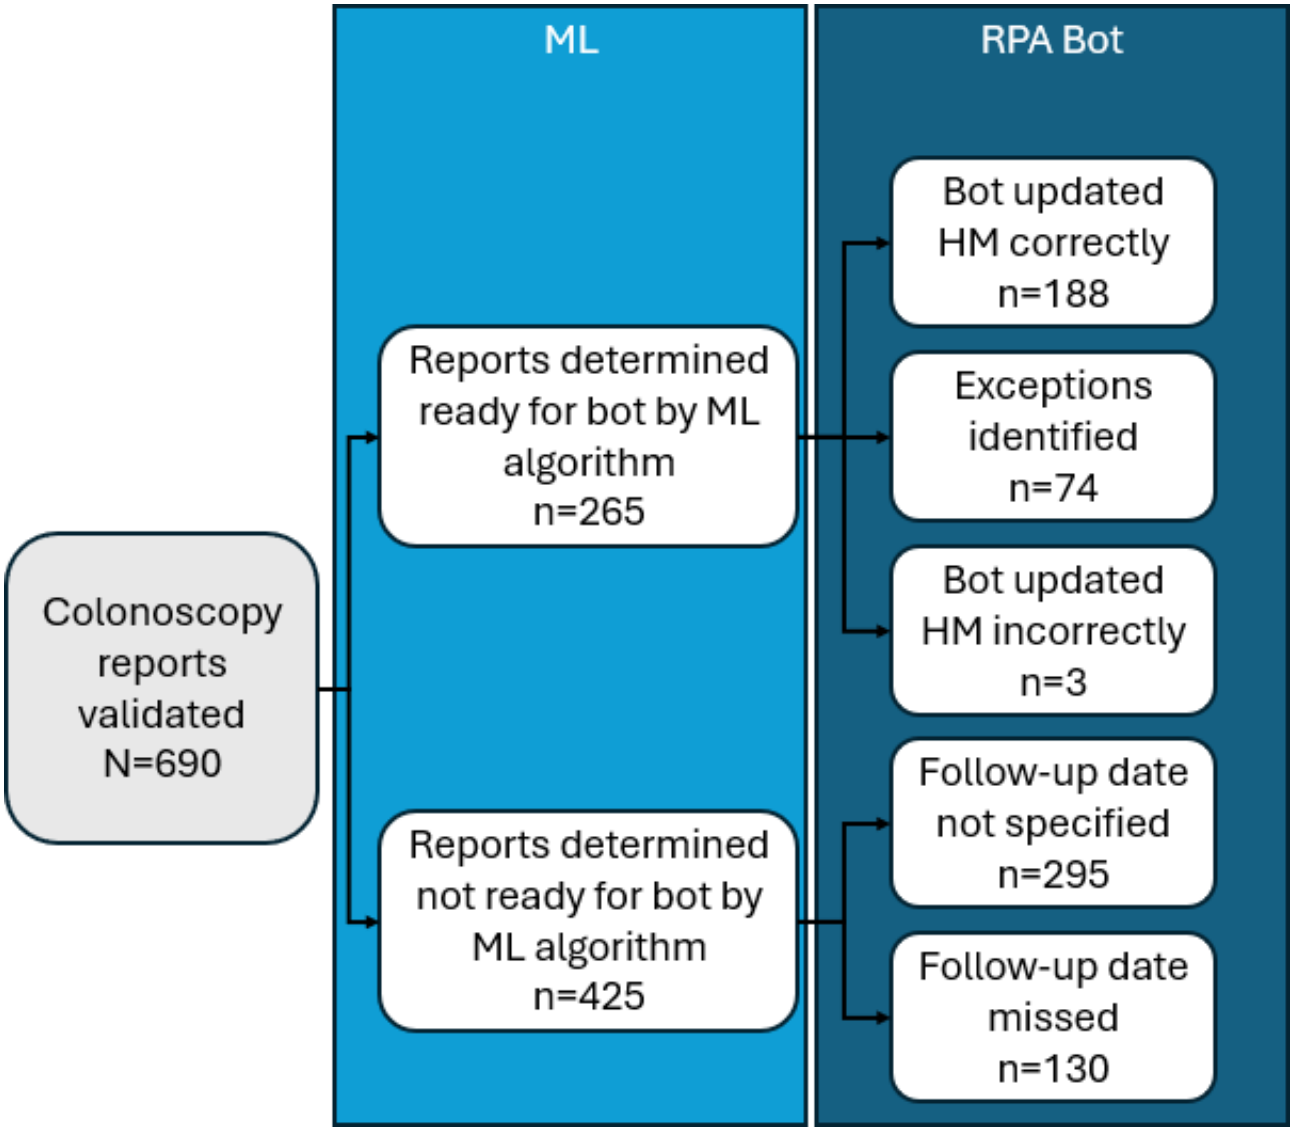
Figure 1. Automation process and technology tools used in each process step for the automation proof of concept to identify and convert unstructured colonoscopy results into actionable data note: HM: health maintenance; ML: machine learning; RPA: robotic process automation;

The three steps are as follows:

1. Documentation identification and routing: scanned colonoscopy reports are identified and sent to a designated work queue in the OnBase shared drive.
2. ML processing: an ML model verifies that the document is a colonoscopy report, then extracts key data, including patient ID, report date, and follow-up recommendations. If data meets predefined accuracy thresholds, it is added to an input spreadsheet and labeled "RPA ready." If below thresholds, the document is marked "RPA not ready" and sent to a work queue for human validation. ML model details, including model parameters, training processes, and performance are reported in Multimedia Appendix 1.
3. RPA execution: the bot processes "RPA ready" entries by accessing the patient's EHR, comparing the extracted follow-up date with existing HM follow-up frequency, and updating the recall date if no business exceptions are detected. All processed data, including business exceptions, are documented in the input spreadsheet.

Business Exceptions

Nine business exceptions were defined such that if any criteria were met, the bot would not update HM. These criteria included: (1) the follow-up date in the scanned document is longer than existing HM follow-up frequency, (2) a patient has a HM frequency modifier that sets a patient-specific screening frequency, (3) the next HM due date has been manually assigned after the scanned procedure date and these exceptions ensure



XSL•FO
RenderX

the bot never takes precedence over a provider-set screening frequency or patient-specific factors, (4) the report has a follow-up date over 10 years, (5) the input spreadsheet cannot assess follow-up date, (6) the procedure date linked to that document does not match the scanned document date, (7) the patient does not have the colonoscopy screening topic assigned in Epic due to age criteria, (8) the patient is not found, or (9) an order for the scanned colonoscopy report is not found. This exception ensures that the HM updates are associated with an appropriate colonoscopy order.

Process Validation Outcomes

Figure 2 presents the validation outcome findings. Process validity was assessed for 690 scanned colonoscopy reports. Of these, 61.6% (425/690) were categorized by the ML algorithm as not ready for the bot. Of those, 30.6% (130/425) listed a follow-up date not detected by the ML algorithm and 69.4% (295/425) did not specify a follow-up date. Among the reports identified as ready for the bot, 70.9% (188/265) HM were correctly updated, 27.9% (74/265) were flagged with an update exception, and 1% (3/265) HM were incorrectly updated. During the process validation, the final document processing overall automated process had an accuracy of 80.7% (557/690, 95% CI 77.8%-83.7%) for correctly identifying the presence or absence of a valid follow-up date (a measure that requires both the identification of the follow-up interval and the result date), determining the absence of a follow-up date, or recognizing a business exception that precluded updating the follow-up date. The process demonstrated a false negative identification rate of 32.9% (130/395, 95% CI 29.4%-36.4%) for follow-up date identification. Based on validation data, we estimate that this process correctly identified and updated 27.2% (188/690) of cases, either correcting instances that would have otherwise defaulted to an incorrect interval or confirming a 10-year follow-up interval was appropriate. Validation outcomes for the ML model specifically can be found in Multimedia Appendix 1.

Figure 2. Process validation outcomes for the automation proof of concept used to identify and convert unstructured colonoscopy results into actionable data note: HM: health maintenance; ML: machine learning; RPA: robotic process automation.

XSL•FO
RenderX

Process Refinements

During validation, the three incorrectly updated HM were due to (1) the bot creating an update based on an older report and (2) overriding a provider modification. These errors led to process refinement by updating the RPA steps to validate clinical information. The process error rate of 32.9% (130/395, 95% CI 29.4%-36.4%) for missing an available follow-up date was deemed acceptable, as refining the model to be more sensitive led to the extraction of incorrect dates, seen as a greater issue than missing a date.

System-Wide Implementation

The solution was implemented system-wide on October 4, 2023. From go-live until December 31, 2024, the system processed 16,563 external colonoscopy reports. Of these, 35.3% (5841/16,563) had a follow-up date meeting the ML model threshold and thus identified as "RPA Ready." Of the "RPA Ready" documents, the HM topic was successfully updated in 77.2% (4512/5841) of patient records. Among all processed reports, 72.8% (12,051/16,563) were not updated; this included 22.8% (1329/5841) that were "RPA Ready," but had business exceptions. Of the "RPA Ready" documents, 3.9% (225/5841) had a patient-specific follow-up date modifier, 3.2% (189/5841) had a more recent procedure, 6.8% (398/5841) were manually updated by a provider, 8.3% (485/5841) were outside standard screening age and did not have a colonoscopy HM topic assigned, and 0.6% (32/5841) had a discrepancy where the procedure result date did not match the scanned document.

Discussion

Principal Findings

This proof of concept demonstrated the feasibility of using ML and RPA to develop an automated process capable of extracting key clinical information from unstructured documents and converting it into discrete, accessible data. The system improved the accuracy of CRC screening follow-up dates while reducing the documentation burden on clinical staff. This pragmatic and innovative approach represents one of the first end-to-end solutions to address the challenges of processing faxed, text-based results by converting free text into structured data. This work provides a template for health care systems to reduce documentation burden, improve follow-up date accuracy, and address care gaps arising from a lack of system integration.

The process automates all workflow stages from the initial receipt of the free-text report to the entry of the follow-up date into the EHR. The use of ML combined with RPA allows for the process to function across workflow stages and software that would not be possible without human intervention if using existing NLP- and rule-based methods alone. Traditionally, this information would be difficult to locate within existing workflows, limiting its influence on patient recall processes. By structuring and integrating this data, the system ensures timely follow-ups and supports downstream workflows to recall patients within recommended timeframes, ultimately improving preventive care management.

Many important data elements are not updated in the EHR because updating them is time-consuming [11]. This strategy reduces documentation burden while minimizing data entry errors. As demonstrated in the process validation study, this process improved the accuracy of HM CRC screening dates by nearly 30% by updating records that would have otherwise remained unchanged. This has the potential to substantially impact downstream patient outcomes. The process was designed to err on the side of being clinically conservative (eg, selecting earlier recall dates if a range was present in the colonoscopy report). While selecting the earlier date in the recall range is a clinical guideline-concordant decision, this conservative approach may increase the rate of colonoscopy compared to selecting the mid- or end-range recall date [22]. During process validation, the accuracy for finding a valid follow-up date was slightly lower than the recall found in the ML model testing (Multimedia Appendix 1). This was anticipated, as a follow-up date is a measure that requires both the identification of the follow-up interval (recall 99.9%) and the result date (recall 86.7%) as well as the recall of other document features; however, this decline in performance from the ML model to the complete process should be considered during process development. Future research should examine whether the increase in screening date accuracy and conservative follow-up date selection translates into improved CRC clinical outcomes.

Beyond improving follow-up date accuracy, this workflow reduces the administrative burden on clinical staff, ensuring timely and appropriate care. By automating the update of recall dates for nearly 30% of scanned colonoscopy reports, health systems can save significant labor time. Even if each report requires just a few minutes of manual processing, the time savings can add up to hundreds of hours—especially in large health systems like NYULH, which may order upwards of 80,000 colonoscopies annually. Transforming unstructured text into structured data also has significant implications for quality reporting. By automating data extraction and integration into the EHR, health care systems can more effectively track completed screenings and tests, ensuring comprehensive reporting on quality measures, closing care gaps, and improving population health management.

Comparison With Prior Work

The use of automation, including RPA, has previously been proposed as a theoretical solution to address limitations in the EHR and other elements of data-driven health care [23-27]. However, prior literature has not presented a fully integrated end-to-end automated workflow. Prior research has primarily focused on data automation in structured formats [27], such as health care claims [25,26] and the extraction and processing of EHR data for research [27-32]. A few studies present cases for using ML and AI for other data types [30,32], but their full integration into health system operations remains hypothetical. Our work builds upon previous research to demonstrate the feasibility and validity of implementing a pragmatic, automated workflow within the EHR to address real-world challenges. While we developed a proprietary model to extract follow-up dates from colonoscopy reports, we anticipate advancements in generative AI will enable multimodal large language models to achieve similar outcomes. However, validation testing is needed to determine large language model accuracy in these use cases. These models can support this use case and be scaled

XSL•FO
RenderX

to extract other critical clinical data from unstructured text, reducing documentation burden and enhancing automation in health care systems.

This process framework can address inefficiencies from the lack of EHR interoperability or discordant information within various areas of the EHR. Despite the progress of EHR interoperability, health care organizations still rely on electronic fax transmissions of clinical information containing important yet unstructured data. Our institution has adapted the described process to automate the documentation of follow-up dates for internally performed colonoscopies documented within ancillary systems and interfaced back as free text reports. Before a recent 2023 institutional effort to code colonoscopy pathology findings [11], all colonoscopy reports were stored as unstructured text. Using a modified version of this automated process, the institution has retrospectively processed 80,864 internal reports from May 2020 to April 2023, updating 71.8% (58,060) CRC screening HM follow-up dates. This successful application of ML combined with RPA highlights their potential to address other high-burden, low-complexity tasks in the EHR and could address deficiencies in structured EHR documentation. By standardizing data ingestion, extending this approach to various unstructured data types can address deficiencies in structured EHR documentation for tests performed at outside organizations and solve for a lack of data integration and reporting for quality measures. Moreover, scaling similar processes to other report types with discrete values, such as cholesterol or HbA_{1c}, may demonstrate an even greater success.

Incorporating ML into the workflow was critical to the automated process's utility. Nearly 80% of EHR data [12], including colonoscopy reports and pathology findings, are documented as free text [13]. Therefore, the critical information within the reports remains inaccessible in the EHR unless manually transcribed [12,13]. Most proposed automations cannot use free-text data and rely on discretely stored data, such as laboratory result values [27], which is unavailable for many EHR data sources unless data entry systems and clinician behaviors are modified. By documenting discrete data without requiring behavior change or system structure modifications, these tools may facilitate broader data capture automation. As AI advances, integrating more sophisticated large language models may further refine and scale these efforts. Future work should evaluate the long-term impact, scalability across different health care systems, and additional opportunities for automation to support clinical workflows, quality reporting, and patient care.

Limitations

This study had several limitations. First, as this workflow integrates multiple disparate technologies to create an automated process, it is susceptible to technical issues from changes to any of the individual components. For example, system updates can change the user interface, causing the bot to no longer recognize its inputs. To address this, the process requires consistent monitoring and maintenance that may incur long-term maintenance costs.

Second, using colonoscopy reports rather than pathology results as the source for follow-up interval means some dates may require updating after pathology results are available. However, as colonoscopy reports are more commonly transmitted from external sources, this decision was pragmatic and provided a sufficiently accurate representation to process the greatest number of results. Future iterations may consider incorporating logic based on the pathology results if included along with the colonoscopy report.

In addition, the ML model used as a component of this intelligent document processing pipeline was not validated on an external dataset and was only validated within 1 health system. While training and internal validation included multiple data sources (ie, Cologuard and colonoscopy, pathology results, documents received from various external clinics), validation in only 1 health system may limit the generalizability of this tool, and adaptation may be needed for other health care environments, particularly those with different EHR systems. While efforts were iteratively made to improve the model as more types of report formats are received, regular refinements including larger data training sets are needed to increase model recall. However, due to finite resources and available backup manual processes, the accuracy was deemed sufficient for operational purposes and our model is not regularly refined. The percentage of follow-up dates updated by the process, however, was lower than would be expected based solely on estimated model performance. While approximately 31% (130/425) of not identified follow-up dates were due to the ML model's technical limitations, the limited update rate was primarily due to clinical factors as well as purposeful operational decision-making. Clinically, the process's effectiveness was limited by the high rate of missing elements in the received colonoscopy reports [33,34]. From an operational perspective, this process was likely to remain largely unsupervised once deployed. While automation outperforms existing human-only workflows for updating HM, the automation of clinical documentation can pose ethical and safety concerns if errors occur. To ensure accountability and trust, governance safeguards are essential, and taking a more cautious approach is advisable when designing automated systems intended to fully replace manual oversight. To mitigate potential risks, we institute a number of business exceptions designed to function as safeguards, thereby erring on the side of caution. These business exceptions included limiting overwrites of prior clinician input, allowing clinician overrides, reviewing records with high uncertainty, and clearly assigning responsibility to prevent overreliance on automation. Therefore, a substantial number of records were not updated by the automation process due to available prior clinician input, even if the model correctly identified a follow-up date. If no clinician actions were taken prior to the process being executed, the rate of update would be expected to be higher than what was seen in a real clinical setting.

Conclusions

This study demonstrates the feasibility of developing a high-validity, automated process to update CRC screening follow-up recommendations within the EHR using scanned colonoscopy reports. By leveraging ML and RPA, we successfully extracted key clinical information from unstructured documents and converted it into structured, actionable data. The

XSL•FO
RenderX

success of this approach highlights the potential for similar automation strategies in other high-volume, low-complexity documentation tasks in healthcare, enhancing efficiency, reducing manual errors, and improving patient outcomes.

Acknowledgments

Artificial intelligence was not used in the writing of this manuscript.

Funding

This work was funded by operational funds from New York University Langone Health.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to privacy of clinical data used in the study and as an operational initiative, the code underlying the machine learning model falls under the purview of intellectual property and confidential business information, but is available from the corresponding author on reasonable request.

Authors' Contributions

All authors meet the criteria for authorship stated in the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals*. The specific areas of contributions are as follows: study concept and design (ERS, PT, AM, and A Szerencsy); data acquisition (CM, DR, YI, AC, and DP); analysis and interpretation of data (all authors); drafting of the manuscript (ERS, AS, and AS); and critical revision of the manuscript for important intellectual content (all authors).

Conflicts of Interest

None declared.

Abstract

Background: Several studies have used electronic health records (EHRs) to build machine learning models predicting the likelihood of developing gestational diabetes mellitus (GDM) later in pregnancy, but none have described validation of the GDM "label" within the EHRs.

Objective: This study examines the accuracy of GDM diagnoses in EHRs compared with a clinical team database (CTD) and their impact on machine learning models.

Methods: EHRs from 2018 to 2022 were validated against CTD data to identify true positives (TP), false positives (FP), true negatives (TN), and false negatives (FN). Logistic regression models were trained and tested using both EHR and validated labels, whereafter simulated label noise was introduced to increase FP and FN rates. Model performance was assessed using the area under the receiver operating characteristic curve (ROC AUC) and average precision (AP).

Results: Among 3952 patients, 3388 (85.7%) were correctly identified with GDM in both databases, while 564 cases lacked a GDM label in EHRs, and 771 were missing a corresponding CTD label. Overall, 32,928 (87.5%) of cases were TN, 3388 (9%) TP, 771 (2%) FP, and 564 (1.5%) FN. The model trained and tested with validated labels achieved an ROC AUC of 0.817 and an AP of 0.450, whereas the same model tested using EHR labels achieved 0.814 and 0.395, respectively. Increased label noise during training led to gradual declines in ROC AUC and AP, while noise in the test set, especially elevated FP rates, resulted in marked performance drops.

Conclusions: Discrepancies between EHR and CTD diagnoses had a limited impact on model training but significantly affected performance evaluation when present in the test set, emphasizing the importance of accurate data validation.

electronic health records; gestational diabetes; label noise; pregnancy; validation; machine learning

Introduction

Electronic health records (EHRs) are an important source of real-world data, offering detailed, longitudinal patient information historically stored in medical charts, and forming the basis of real-world evidence [1,2]. Together with advancements in artificial intelligence and machine learning (ML), EHRs are increasingly being used to develop models that improve the prediction of health and disease outcomes [3].

Integration of EHRs into clinical research offers numerous opportunities for advancing health care delivery and patient outcomes. However, EHR data is often stored in unstructured formats such as free text, requiring information extraction algorithms to enable ML applications [4]. This extraction process can introduce data quality concerns due to various issues such as data entry errors and cut-and-paste errors [5]. The quality and consistency of EHR data are particularly critical when the target variable, that is, the variable being predicted, is used in ML models.

Inaccuracies in EHRs present challenges for developing and applying ML algorithms in health care, primarily due to the dependency on data quality and accuracy of target labels [6]. This "label noise," which refers to inaccuracies or inconsistencies in the data labels (eg, diagnosis codes) extracted from EHRs, can significantly impact model performance by introducing errors in the target variable, leading to potentially misleading conclusions [7]. Training ML models on unvalidated EHRs may lead to systematic errors in the model output with

XSL•FO
RenderX

the potential for the model to miss, underestimate, or overestimate clinically significant relationships [8,9].

Accurate diagnosis and recording of gestational diabetes mellitus (GDM) in EHRs is important not only for effective patient management but also for informing public health strategies and economic forecasting in national health care planning [10,11]. EHRs are often used to train ML approaches that support clinical decision-making and care pathways that improve pregnancy outcomes [12]. However, the utility of EHRs remains a concern due to potential discrepancies in data recording practices [8]. When using ML in GDM prediction [13], the accuracy of input data is paramount because inaccuracies can lead to flawed prediction models and ineffective or adverse clinical decisions [14].

Several studies have used EHRs to build ML models predicting the likelihood of developing GDM later in pregnancy [15], but none have described validation of the GDM "label" within the EHRs. This study has 3 primary aims: first, to assess the accuracy of reporting of GDM diagnoses in EHRs by comparing them to a database maintained in real-time by the hospital's clinical team; second, to evaluate how discrepancies in GDM reporting impact ML models; and third, to examine ML model performance using varying levels of simulated label noise in the dataset. By identifying discrepancies between these data sources, we aim to highlight the importance of data validation for advancing digital health and ML-driven health care.

Methods

Study Design

A retrospective validation design was used to assess the accuracy of GDM diagnoses recorded in the EHRs of a national maternity hospital (The Coombe Hospital, Dublin). We matched patient ID between the EHR system and a reference standard established by a real-time clinical team database (CTD) of those formally diagnosed with and managed for GDM, which served as a ground truth. This approach allowed for direct comparison between the recorded GDM status in the EHRs and the validated GDM status from the CTD, enabling identification of true positives (TP), false positives (FP), true negatives (TN), and false negatives (FN) in the EHRs. Further, the effect of label noise on ML model performance in predicting the development of GDM (binary classification) was evaluated by first examining its impact in our current EHR dataset, and then second, simulating progressively increasing levels of label noise to understand its effect on ML model performance both in terms of training and testing.

Data Source and Validation

The EHR system serves as the repository for patient medical histories, including diagnoses, family history, and outcomes for pregnant women receiving care at the institution. The data are collected routinely from all women by trained midwives using standardized questions and are then computerized onto the electronic system of the hospital, "Euroking K2." EHRs were collected from 2018 to 2022 and consisted of over 35,000 pregnancies during this time. The dataset from the CTD spanned from 2018 to 2022; thus, the timeframe for this analysis spanned from 2018 to 2022 (inclusive). Women aged 18 years or older with complete information on GDM status were included in the analysis. Pregnancies with missing or incomplete data for critical variables, women without a recorded GDM status, and pregnancies with pre-existing diabetes were excluded. ML models were trained and tested on pregnancies with complete EHR data up to the 12th week of gestation.

GDM diagnoses were extracted from the EHRs based on information recorded in a column titled "medical problems during pregnancy." When this column contained the entry "diabetes developed during pregnancy," the patient was coded as having GDM in a newly created column designated for this study's analysis, referred to hereafter as "EHR-GDM." Patient records not meeting this criterion were coded as not having GDM. The legacy EHR has a single structured problem field; it does not store *ICD* (*International Statistical Classification of Diseases and Related Health Problems*) or SNOMED (Systematized Nomenclature of Medicine) codes. GDM is recorded exclusively by selecting "diabetes developed during pregnancy" from that field's drop-down list. No alternative structured or coded location exists.

Patient IDs from the EHRs were then matched with a separate database maintained in real-time by the clinical team responsible for diabetes care, with patient details entered each day upon confirmation from the hospital laboratory of a diagnosis of GDM from an oral glucose tolerance test following the IADPSG (International Association of the Diabetes and Pregnancy Study Groups) guidelines. The CTD was considered the definitive ground truth for GDM diagnoses, given its real-time, clinician-entered, laboratory-confirmed data recording process. This matching process produced a merged dataset for validating EHR-recorded GDM diagnoses against the CTD database, leading to the creation of 2 comparison columns: "EHR-GDM" for EHR-identified cases of GDM and "CTD-GDM" for cases of GDM recorded by the CTD.

The validation process involved comparing the GDM diagnosis status in the EHR ("EHR-GDM") with that in the CTD ("CTD-GDM") to examine the agreement between the 2 datasets. This comparison allowed for the identification of TPs (positive in EHRs and present in CTD), FPs (positive in EHRs and not present in CTD), TNs (negative in EHRs and not present in CTD), and FNs (negative in EHRs and present in CTD), and thereby enabled evaluation of the accuracy of the reporting of GDM diagnosis in the EHRs. An additional column, validated gestational diabetes mellitus label (only in cases where electronic health record and clinical team database labels matched; VAL-GDM), was created indicating a positive or negative diagnosis of GDM for cases where the EHR-GDM and CTD-GDM labels matched, that is, for TPs and TNs, excluding records with FPs and FNs. Thus, for the purpose of the following stage of ML modeling, only records that matched between EHR-GDM and CTD-GDM were used, reducing the risk of bias from either dataset. The TPR, FPR, TNR, and FNR were calculated for the dataset [16].

Evaluation of Label Noise on ML Modeling

To evaluate the impact of label noise on the performance of ML models in predicting GDM, we used logistic regression (LR),

XSL•FO
RenderX

where the dataset was split into 70% training and 30% test sets to ensure robust evaluation. Default model hyperparameters were used, as the primary objective was to compare performance across different training datasets rather than optimizing hyperparameter settings. The training and testing data comprised EHR data that was available during the first booking visit, typically the 12th week of gestation, and included 79 training features. The target label was GDM. The dataset contained both categorical and numerical features. Categorical features were processed using OneHotEncoder with the "first" category dropped, and numerical features were standardized using StandardScaler. While the goal of this paper is not to produce an end point AI model, a self-assessment checklist for reporting was followed to ensure that adequate information about the ML model was present [17].

We trained 2 ML models: one with the EHR-GDM labels and the other with the VAL-GDM labels. Both models were evaluated using the same test set, which used VAL-GDM labels, to facilitate a direct comparison of the effects of label noise during training on a consistent test set. The year 2020 was excluded from these analyses due to emerging research demonstrating reduced detection of diseases during this period [18], something that we confirm in our results below. By using both the "raw" and "validated" datasets, the study aimed to demonstrate the impact of label noise on model performance in the prediction of GDM, providing insights into the importance of accurate label validation in developing reliable predictive models using ML. In addition to the LR model, we replicated this process with other ML models to ensure any effects were not model specific. External validation datasets were sought, but this was not successful, as documented [19].

Additionally, varying levels of label noise were introduced to determine the threshold at which label noise significantly affects model performance. This simulation was performed by progressively increasing the number of FPs and FNs in the VAL-GDM training set from 0% to 90%, that is, changing a percentage of the positive labels to negative labels (creating FNs) and changing a percentage of negative labels to positive labels (creating FPs). This approach resulted in the training of 100 different models. Next, in a separate analysis, we applied this progressive noise insertion to the VAL-GDM test set to specifically assess the impact of test set label noise on model evaluation, that is, evaluating these test sets using a model trained with the "clean" VAL-GDM labels. For reproducibility, the code used to perform the label noise simulation is made available in the Simulated Label Noise section.

Statistical Analysis

The validation findings were quantitatively assessed using accuracy, precision, recall, F_1-score, and overall agreement measured by Cohen κ, between the EHR-recorded GDM (EHR-GDM) and the CTD (CTD-GDM) diagnoses. The performance of the LR ML models was evaluated using the area under the receiver operating characteristic curve (ROC AUC) and the average precision (AP) score. Additionally, the calibration of the model's predictions will be examined visually by calibration curves and quantitatively by the slope and intercept. The statistical and ML analyses were performed using Python (version 3.8.8; Python Software Foundation) with libraries including NumPy 1.23.5, pandas 1.2.4, and scikit-learn 1.2.1.

Ethical Considerations

Ethical approval was granted by The Coombe Hospital Research Ethics Committee (Study No. 06–2023; Exploring the Utility of Machine Learning for the Classification of Gestational Diabetes Risk During the First Antenatal Visit).

Results

Population Characteristics

The dataset comprised 37,651 EHRs from 31,100 unique patients. The mean patient age was 32 (SD 5) years, and BMI was 26.2 (SD 5.5) kg/m^2, with 20.7% exhibiting a BMI greater than 30.0 kg/m^2. The prevalence of GDM according to the EHRs was 11%, whereas the prevalence according to the CTD was 10.5%. Patient characteristics for the most important features in the ML models are presented in Table 1.

XSL•FO
RenderX

Table . Patient characteristics for the most important features in the machine learning models, according to the validated dataset (n=27,561). The validated dataset represents a dataset where both the EHRs[a] andCTDs[b] agree.

Characteristics	Values
Age (years), mean (SD)	32 (5)
BMI (kg/m^2), mean (SD)	26.2 (5.3)

[a]EHR: electronic health record.

[b]CTD: clinical team database.

[c]ISCO: International Standard Classification of Occupations.

[d]GDM: gestational diabetes mellitus.

Diagnosis Discrepancies

Of 3952 patients with matching IDs in both databases, 3388 were correctly identified with GDM in both EHR-GDM and CTD-GDM (9% TP and 85.7% true positive rate [TPR]), while 564 lacked a corresponding GDM label in EHR-GDM (1.5% FN and 14.3% false negative rate [FNR]). Additionally, 771 patients were incorrectly identified with GDM in EHR-GDM without matching IDs in CTD-GDM (2% FP and 2.3% false positive rate [FPR]). In EHRs, there were 32,928 (87.5%) TN cases (97.7% true negative rate [TNR]). The accuracy, precision, F_1-score, and Cohen κ are reported in Table 2.

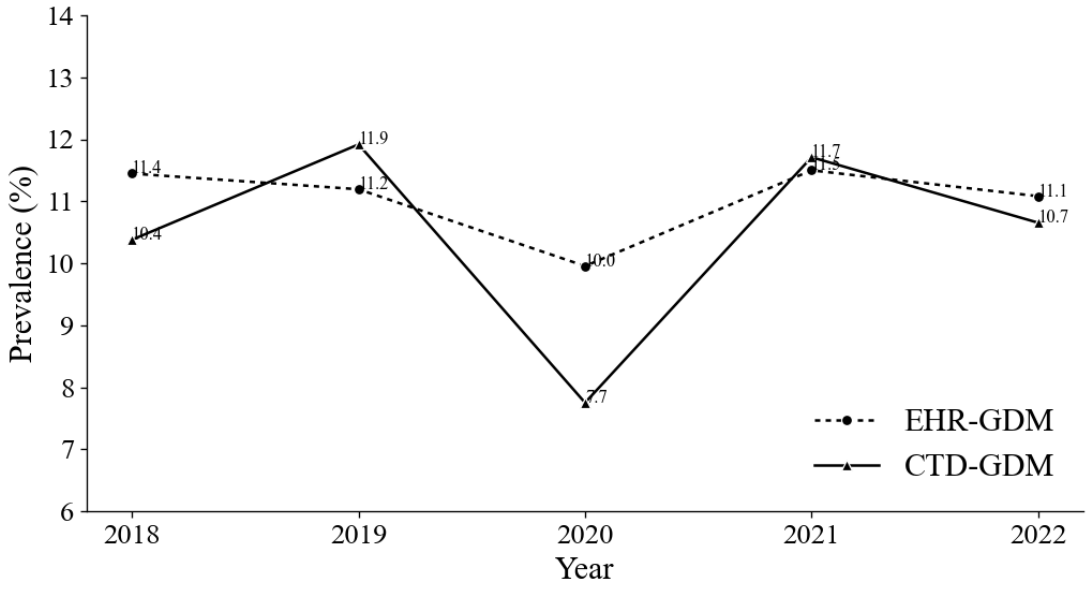
[a]GDM: gestational diabetes mellitus.



[b]EHR: electronic health record.

[c]CTD: clinical team database.

Yearly Data Comparison

Ninety-eight patients identified in CTD lacked corresponding entries in EHRs. In total, 67 (68%) of these discrepancies were observed in 2020. Furthermore, GDM prevalence for both EHRs and CTD datasets revealed a notable reduction in 2020 (recorded at 10% in EHRs and 7.7% in CTD), indicating a deviation from the trend observed in other years (Figure 1). These discrepancies align with COVID-19–related disruptions to screening practices within the hospital between March 2020 and September 2020.

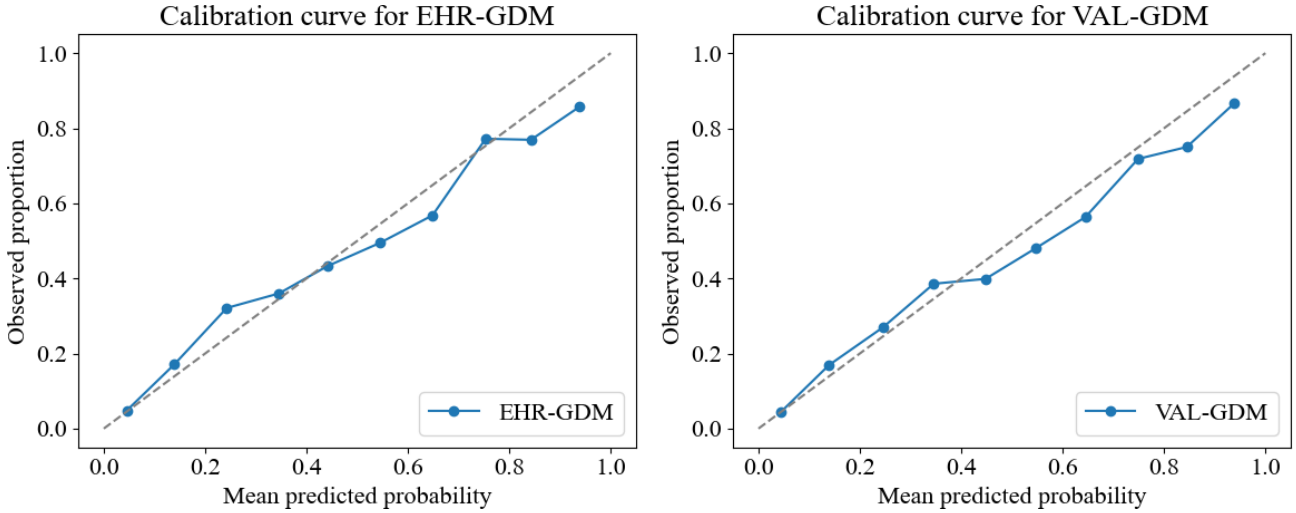
Figure 1. Comparison of prevalence rates of EHR-GDM data and CTD-GDM data from 2018 to 2022. The solid line represents the CTD data, and the dashed line represents the EHR data. CTD: clinical team database; CTD-GDM: gestational diabetes mellitus label as recorded in the clinical team database (reference standard label); EHR: electronic health record; EHR-GDM: gestational diabetes mellitus label as recorded in the EHR.

Label Noise in EHRs

The performance of LR models trained using the raw (EHR-GDM) and validated (VAL-GDM) labels was evaluated using a test set with VAL-GDM labels only. The model trained using the EHR-GDM labels achieved an ROC AUC of 0.817 (95% CI 0.802 - 0.833) and an AP score of 0.451. The calibration curve is shown in Figure 2, with an intercept of 0.093 and a slope of 0.984. In comparison, the model trained using the VAL-GDM labels showed an ROC AUC of 0.817 (95% CI 0.803 - 0.832) and an AP score of 0.450 (Figure 3), indicating a minor impact of label noise in training the model for this dataset (intercept −0.027 and slope 0.955). However, when the performance of the LR ML model trained using VAL-GDM labels was evaluated on a test set with EHR-GDM labels, an ROC AUC of 0.814 and an AP score of 0.395 was achieved, which demonstrates a greater impact of label noise when it is present in the test set.

XSL•FO
RenderX

Figure 2. (Left) Calibration curve for the EHR (electronic health record)-GDM model, which was trained on EHR-GDM labels. (Right) Calibration curve for the VAL-GDM model, which was trained on the subset of cases where electronic health record and clinical team database labels agree. Both are evaluated against the identical standard reference labels. EHR-GDM: gestational diabetes mellitus label as recorded in the EHR; GDM: gestational diabetes mellitus; VAL-GDM: validated gestational diabetes mellitus label (only in cases where the EHR and clinical team database labels matched).



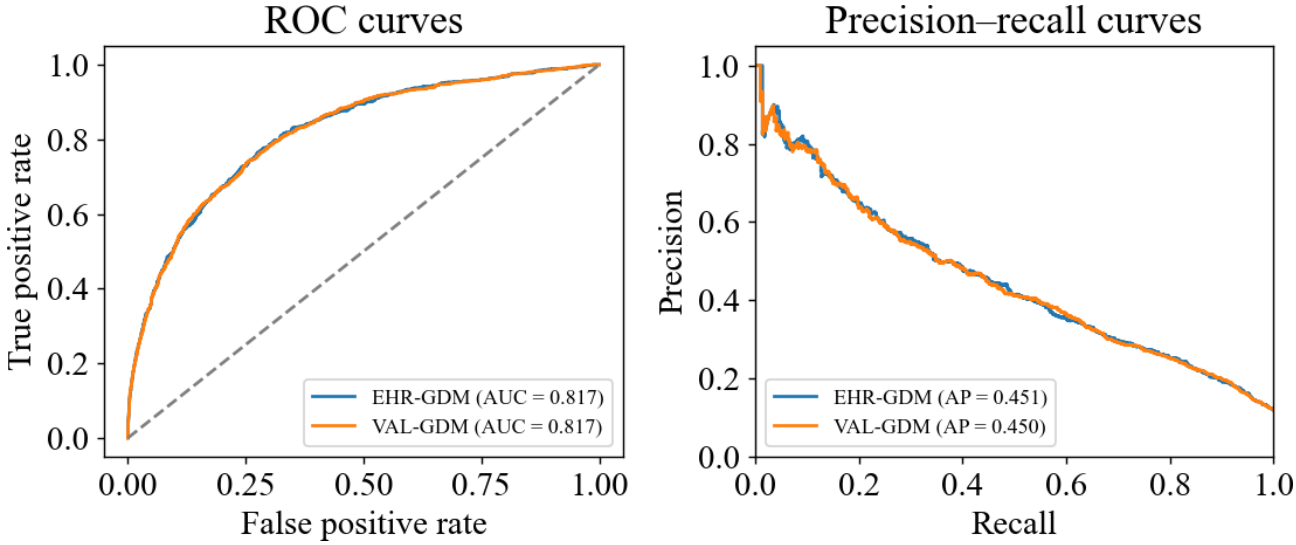


Figure 3. (Left) ROC curves and (right) precision - recall curves showing the performance of 2 logistic - regression models for predicting GDM. "EHR-GDM" refers to the model trained on electronic health record (EHR)–GDM labels, and "VAL-GDM" refers to the model trained on the subset of cases where the EHR and clinical team database labels agree. Both models are evaluated against the same reference labels (VAL-GDM). EHR: electronic health record; EHR-GDM: gestational diabetes mellitus label as recorded in the EHR; GDM: gestational diabetes mellitus; ROC: receiver operating characteristic; VAL-GDM: validated gestational diabetes mellitus label (only in cases where EHR and clinical team database labels matched).

In addition to LR, random forest, XGBoost (Extreme Gradient Boosting), and an Explainable Boosting Machine were assessed to compare their performance and robustness to label noise. As shown in Table 3, all 3 models achieved performance metrics in a similar range to the LR model, with none of the models demonstrating large changes in evaluation metrics regardless of the validation data used.

Table . Comparison of ROC AUC[a] and average precision for machine learning models predicting GDM[b] trained on the EHR[c] data and VAL[d] data, and validated against the VAL data.

Model	ROC AUC		Average precision		Intercept		Slope	
	EHR-GDM	VAL-GDM	EHR-GDM	VAL-GDM	EHR-GDM	VAL-GDM	EHR-GDM	VAL-GDM
Logistic regression	0.817	0.817	0.451	0.450	0.093	−0.027	0.984	0.955
Random forest	0.797	0.801	0.418	0.419	−0.747	−0.618	0.553	0.638
XGBoost[e]	0.780	0.782	0.389	0.393	−0.427	−0.507	0.619	0.608
EBM[f]	0.818	0.816	0.456	0.450	0.078	−0.047	0.975	0.940

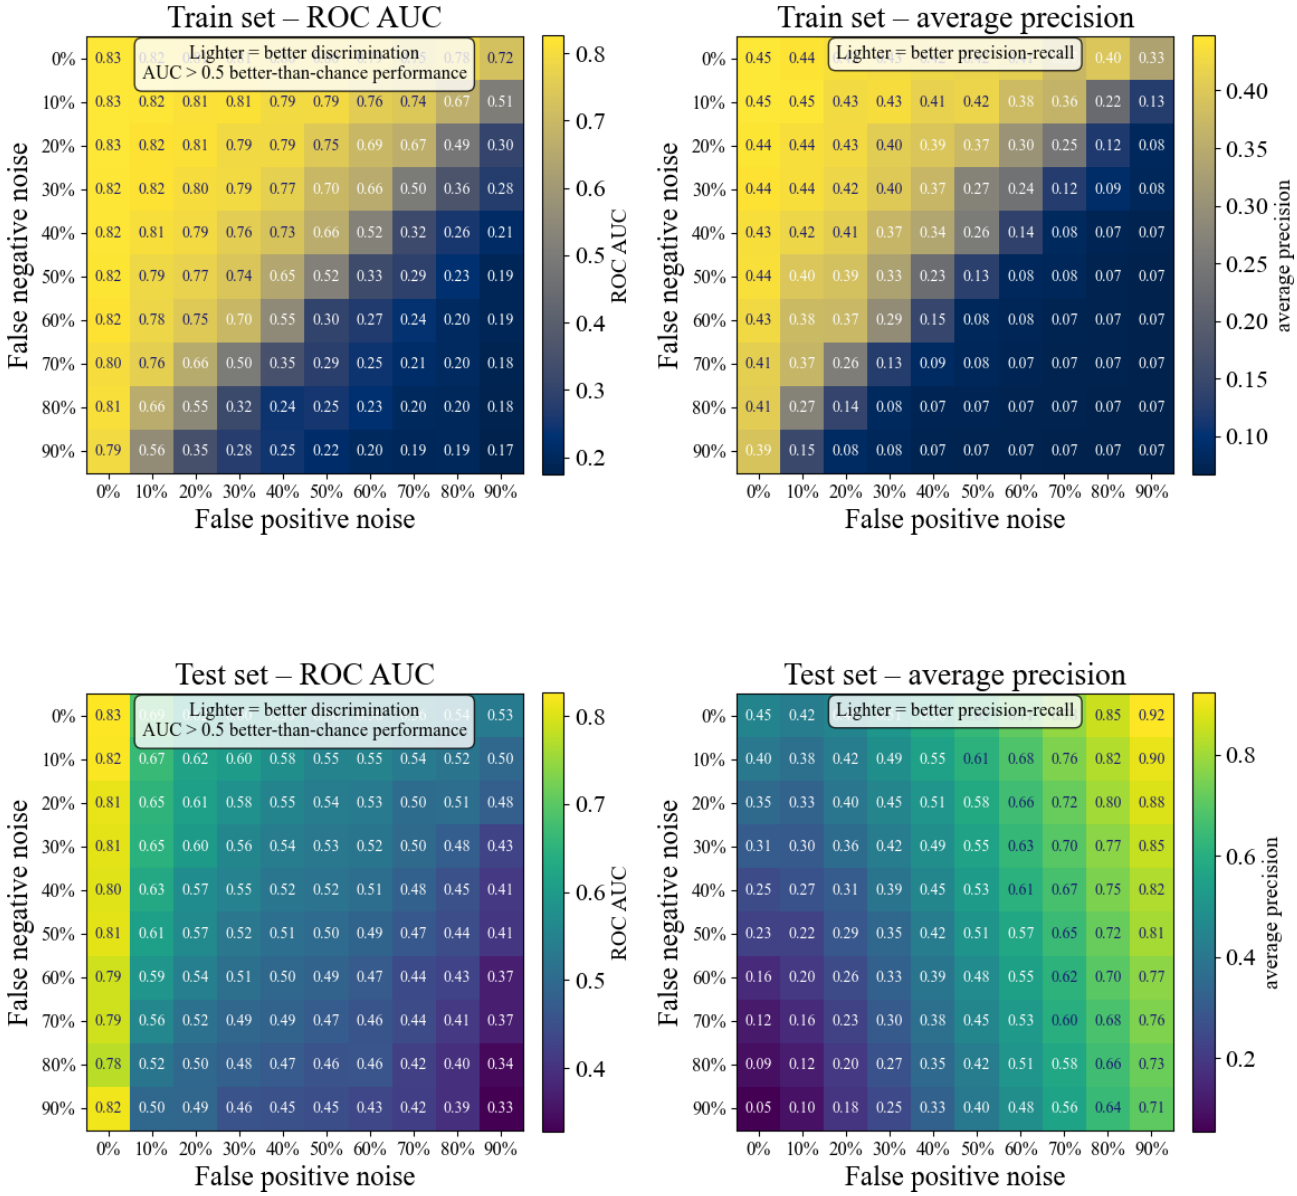
[a]ROC AUC: area under the receiver operating characteristic curve.

[b]GDM: gestational diabetes mellitus.

[c]EHR: electronic health record.

[d]VAL: validated.

[e]XGBoost: Extreme Gradient Boosting.



[f]EBM: Explainable Boosting Machine.

Simulated Label Noise

The impact of simulated label noise on model performance was assessed by progressively increasing the number of FNs (FN noise) and FPs (FP noise) in the training set (where 0% noise equates to the original VAL-GDM labels) without modifying the testing set. The results demonstrate a decline in model performance as the level of label noise increases (Figure 4).

XSL•FO
RenderX

Figure 4. Heatmaps illustrating how gradually introducing random label noise (NAR) degrades model performance. In each panel, the x-axis denotes the percentage of true negatives flipped to false positives, and the y-axis denotes the percentage of true positives flipped to false negatives. In the top-left heatmap, the ROC AUC on the training set is plotted; lighter cells signify stronger discrimination, and values above 0.5 represent performance better than random chance. The top-right heatmap presents the corresponding average precision on the same noisy training data, with lighter colors indicating a more favorable precision-recall trade-off. The bottom-left and bottom-right heatmaps repeat these experiments on the held-out test set, showing ROC AUC and average precision, respectively, under increasing label noise in the test data. The unusual behavior of average precision is discussed in this paper. Each cell is annotated with the exact metric value for that combination of false positive and false negative noise levels. AUC: area under the curve; NAR: noise at random; ROC AUC: area under the receiver operating characteristic curve.

Further analysis of noise in the test set showed that model performance metrics, particularly ROC AUC and AP scores, were sensitive to increasing levels of noise, especially FP noise. As the FP rate was increased, the ROC AUC consistently decreased, while the AP score initially decreased before increasing. The introduction of FN into the test set had a less pronounced effect on performance compared to FP, unless both types of noise were combined, which led to a more substantial impact (Figure 4).

Discussion

This study highlights significant discrepancies between GDM diagnoses recorded in EHRs and those validated by the CTD. Correcting label noise in the training set had a negligible impact on the performance of an LR-based ML model developed from EHRs to predict GDM from early pregnancy data. However, correcting label noise in the test set improved the model's AP, underscoring the importance of accurate labeling for evaluating model performance accurately. This study also found that increasing label noise in the training set led to a gradual decline in model performance, while increasing FPs in the test set had a particularly strong negative impact on ROC AUC, but counterintuitively increased AP scores. FNs had a less pronounced impact on ROC AUC unless combined with FP, which then caused a decline in model performance.

Approximately 14% (564/3952) of GDM cases were not recorded in the EHRs, while 18.5% (771/4,159) of positive GDM diagnoses in EHRs did not align with CTD records.

XSL•FO
RenderX

Overall, there were 32,928 (87.5%) TN, 3388 (9%) TP, 771 (2%) FP, and 564 (1.5%) FN. The FPR (2.3%) remained low in comparison to the FNR (14.3%). Similar discrepancies in accuracy of EHRs have been reported in previous studies within Irish maternal hospitals, though with higher agreement in other contexts, such as miscarriage measurements (k=0.92) [20]. More widely across Europe, wide variations exist in the accuracy of reporting in EHRs as it relates to acute cardiovascular outcomes, with sensitivity reported at <66% for heart failure diagnoses in particular [21]. A key challenge in these studies is the absence of a recommended reference standard for validating EHR data, leading to the use of various data sources [8].

The impact of COVID-19 on screening and diagnostic practices, especially in 2020, manifested in a relative reduction of 31% in GDM diagnoses, that is, 11.2% across 2018, 2019, 2021, and 2022 compared to 7.7% in 2020. These observations align with research indicating reduced diagnosis rates for various medical conditions during the first year of the pandemic [18], and suggest caution is warranted when using EHRs during this year for the purpose of health care modeling. The decrease in recorded GDM cases in 2020 was likely driven by changes in clinical protocols at the onset of the COVID-19 pandemic. The Irish Health Service Executive adopted procedures recommended by the Royal College of Obstetrics and Gynecologists in the United Kingdom, which recommended alternative testing strategies for screening pregnant women for GDM that focused on replacing the 2-h oral glucose tolerance test with other tests of shorter duration [22].

Correcting label noise has been shown to mitigate its adverse effects on model performance, underscoring the importance of "clean" and accurate datasets for training and validating ML algorithms to ensure their efficacy in clinical decision support systems [23]. For example, training a model on a "clean" dataset resulted in an accuracy of 73.6%, whereas with 30% label noise the accuracy fell to 64.1% (−9.5%) [23]. However, the current analysis demonstrated that training an LR model using EHR-GDM labels versus VAL-GDM yielded negligible differences in performance metrics, with ROC AUCs of 0.817 and 0.817, respectively (Figure 3), a performance in line with previous research using EHRs to predict GDM [13,15]. This is presumably due to the low overall representation of FN and FP in the dataset of 3.5% combined, which limited the impact of label noise on the training process.

Previous work has simulated noisy labels with artificial introduction of different levels of label noise (10%, 20%, and 40%) into the training set and demonstrated a gradual decline in the accuracy of all models (mean AUC of all models at 80.3, SD 3.3, 10%; 79.3, SD 3.4, 20%; and 77.6, SD 3.0, 40%) as label noise increased [24]. The approach taken in the present study differs in that it introduces systematic label noise using noise at random [25], increasing both the FP and FN rates linearly. Introducing noise into the training set resulted in a gradual decline in model performance, with both ROC AUC and AP scores decreasing as the level of noise increased. The model was particularly sensitive to FP, which caused a more pronounced decline in performance compared to FN. Introducing noise into the test set also impacted model performance, but the effects were more complex. The ROC AUC consistently decreased as FP rates increased, indicating that the model's ability to distinguish between classes was compromised. However, the AP score showed a different pattern, with an initial decline followed by an increase as noise levels were increased. The introduction of FN in the test set had a less pronounced effect on performance compared to FP, unless FP and FN were combined, which led to a more marked decline in the model's overall performance.

The counterintuitive increase in the AP score as the FP rate in the test set increased can be attributed to the method of calculating AP. AP evaluates the precision-recall trade-off across different thresholds, specifically calculating the proportion of TP to the sum of (TP + FP). When most of the negative class in the test set is artificially converted to positive, the opportunity for FP to occur is significantly reduced. This reduction in potential FP leads to an increase in precision, which in turn increases the AP score. Additionally, this manipulation dramatically alters the (eg, class balance from 90% negative to 90% positive), further influencing the precision-recall dynamics and contributing to the observed ostensible increase in AP. In practical terms, this finding emphasizes that certain performance metrics such as AP can behave unexpectedly in the presence of extensive label noise or class imbalance, underscoring the importance of using multiple evaluation metrics that are robust to changes in classes (discrimination and calibration) to fully understand model performance. These results reinforce that deploying predictive models trained on unvalidated EHR data can amplify false-positive and false-negative risks.

This study has several limitations that may affect the generalizability of these findings. First, the analysis was conducted using data from a single hospital and did not perform any external validation with data from other hospitals or a formal temporal validation using a future period. Therefore, it is uncertain whether the findings would directly generalize to different clinical settings, particularly those with different screening practices, disease encoding, and EHR systems. Second, the CTD, which is treated as the ground truth, is manually maintained by the clinical team. While it is likely more accurate than the EHR, it is not immune to possible human errors or omissions. Any such errors in the CTD would affect the data validation results by erroneously labeling some EHR entries as false positives or false negatives. However, this should minimally impact ML modeling as only data that had agreement across both databases were included. Third, there is potential for model overfitting due to the lack of an external validation set and default parameters, which we attempted to mitigate with the use of k-fold cross-validation, a relatively simple linear model, and a hold-out test set. Finally, noise at random linearly increases the FP and FN rate in the dataset, which may not accurately reflect how errors in EHRs typically occur.

In conclusion, the identified discrepancies in EHR-recorded GDM diagnoses compared to "true" GDM diagnoses reflect broader concerns about the accuracy of EHRs for public health and ML applications. Further, the magnitude of inaccuracies may play an important role in maximizing the utility of EHRs in enhancing health care outcomes, particularly for conditions such as GDM. However, when these discrepancies remain a small percentage (eg, <5%) of the dataset, such as in the case

XSL•FO
RenderX

of this study, there was no noticeable impact on model training performance. Conversely, the risk of incorrect model evaluation increases when the test set labels are impacted by noise, as this has a more pronounced effect on performance metrics. These observations emphasize the importance of incorporating robust data cleaning, preprocessing, and validation methodologies in the development of ML models for health care. Future efforts should aim at developing standardized validation protocols for EHRs to ensure high data quality for training and evaluating ML algorithms. Such protocols could include harmonizing how GDM diagnoses are recorded across different sites, implementing automated consistency checks (for instance, prompting for a GDM diagnosis entry in the EHR when a laboratory result confirming GDM is received), and performing regular audits comparing EHR records with reference databases or laboratory results. By improving the integrity of data entry and maintenance in EHR systems, these measures could reduce discrepancies and enhance the utility of EHR data for both clinical care and ML applications.

Acknowledgments

The authors are grateful to The Coombe Hospital for their collaboration, without whom this analysis would not be possible. This work has emanated from research supported in part by a grant from Science Foundation Ireland (18/CRT/6183).

Data Availability

The datasets analyzed in this study are not publicly available because patient IDs were used to match the corresponding databases. The code has been made available online [26].

Abstract

Background: Medical consortiums take the integration of electronic health records (EHR) as a breakthrough point and the construction of an integrated medical service system as the ultimate goal. However, their establishment has disrupted the balance between the original medical order and interest patterns. While promoting active cooperation among hospitals, it has also intensified active competition between them.

Objective: This study aimed to explore the internal evolution mechanism of the co-opetition strategies adopted by the superior and subordinate hospitals in the medical consortiums, providing a theoretical foundation and policy reference for achieving EHR integration.

Methods: On the basis of analyzing the structure of the main players in the co-opetition game and their game motivations, we established an evolutionary game model, analyzed the impact mechanism of key parameters, simulated the dynamic evolution process of the co-opetition strategies using MATLAB (MathWorks), and finally proposed actionable policy recommendations.

Results: The results indicate that three factors positively promote EHR integration: (1) EHR complementarity, (2) hospitals' willingness and ability to use EHR, and (3) the average revenue per unit of EHR. Conversely, the investment cost per unit of resources hinders EHR integration. Neither the original income of hospitals nor the stock of EHR significantly affects the evolution direction of the game system.

Conclusions: Medical consortiums should actively involve all levels and different types of medical institutions, and continuously improve hospitals' willingness and ability to use EHR through training, assistance, support, and sinking of medical resources, etc. The government should establish a reward and punishment system, optimize the operation and supervision mechanism of medical consortiums, and monitor and punish opportunism behaviors such as "free-riding." It is also crucial to strengthen the construction of hospital informatization infrastructure and improve the technical, content, and sharing standards for EHR construction. In addition, designing reward and punishment mechanisms as well as cost accounting based on "unit EHR resources" is also of great significance for promoting the EHR integration.

Introduction

In the traditional health care delivery system, medical institutions were fragmented and scattered, and hospitals competed for access to patients in order to achieve the goal of maximizing their own interests, but active cooperation in medical care was basically nonexistent. To address this fragmentation and scattering of health care services and achieve an integrated health care delivery pattern of services, responsibilities, benefits, and management [1]. Medical consortium building has become a major strategic choice for

XSL•FO
RenderX

countries around the world. Medical consortiums are a type of health care alliance that has gained attention in China in recent years. In China, medical consortiums, a form of health care alliance that has gained significant attention in recent years, primarily manifest in 4 organizational models: urban medical groups, county-level medical communities, cross-regional specialty alliances, and telemedicine collaboration networks [2]. Medical consortiums typically use electronic health records (EHR) integration as a foundational strategy to realize the objectives of "primary diagnosis at grassroots institutions, two-way referrals, tiered treatment for acute and chronic cases, and coordinated care across different levels of healthcare providers," and ultimately building an integrated medical service system. However, the development of medical consortiums has broken the balance of the original medical order and interest pattern, and has intensified active competition among hospitals while promoting active cooperation among them. Consequently, in the process of promoting the EHR integration within medical consortiums, hospitals inevitably adopt co-opetition strategies to safeguard and maximize their own interests.

Brandenburger and Nalebuff [3], who developed the concept of co-opetition, believe that the organization's operating activities are not all zero-sum games, but also win-win nonzero-sum games, and that the strategy to achieve this win-win outcome is "co-opetition strategy." In fact, competition and cooperation are the driving force for sustainable economic and social development [4]. The social value of medical consortiums predominantly stems from the co-opetition relationship among member. Regarding EHR integration, hospitals at all levels are characterized by imperfect rationality and imperfect information. Evolutionary game can be used to reveal the competition and cooperation relationship between players and the law of their strategy selection. Existing studies have primarily examined: (1) individual hospitals' data-sharing willingness [5], (2) access control models [6], and (3) the game between the government and the hospital [7]. However, these studies have inadequately analyzed the competition and cooperation relationship between the superior and subordinate hospitals in depth from the perspective of medical consortiums, and also failed to reveal the evolution mechanism of competition and cooperation strategies choices, which has limited the practical reference value of research results for policy optimization.

As far as the related research is concerned, evolutionary game theory is favored because its finite rationality assumption is more realistic, and has wide applications in the fields of multivariate governance, organizational synergy, and information behavior [8]. For instance, evolutionary game models have been used to analyze interest equilibria in open data ecosystems [9], revealing the impact of the changing psychology of individuals on group behavior [10]. In health care applications, evolutionary game theory has been principally applied to investigate: (1) privacy disclosure behaviors in "online health communities" [11], (2) quality assurance strategies for emergency medical supplies [12], (3) selection behaviors regarding internet hospitals [13], (4) models of epidemic information dissemination [14], and (5) hierarchical diagnosis and treatment strategy and 2-way referral mechanism [15,16]. The related research reasonably explains the evolution mechanism of relevant strategy selection behavior, and establishes a solid methodological foundation for our study.

China's EHR development has progressed through 3 evolutionary phases, namely independent construction, system integration, and shared usage. In the initial phase, EHR was built separately by each hospital, realizing a breakthrough from scratch, and the construction is effective and widely applied within the hospital. The EHR integration is the premise and foundation of crossinstitutional "sharing and utilization," which is the key link in releasing the EHR application, and also the bottleneck in the EHR development at present. There exists an urgent need to elucidate the co-opetition strategies between superior and subordinate hospitals facilitating EHR integration within medical consortiums, thereby establishing a theoretical foundation for policy optimization. Previous studies suggested that evolutionary games provide a valuable framework for elucidating the emergence and maintenance of cooperative behavior [17]. Accordingly, this study uses evolutionary game theory to uncover the intrinsic mechanisms governing co-opetition strategy evolution between superior and subordinate hospitals during EHR integration within medical consortiums. The study comprises three key components: (1) from the perspective of the evolution of co-opetition strategies, analyzing the structure of competition and cooperation game subjects and their game motivations; (2) establishing a game model for the evolution of the competition of the superior and subordinate hospitals; and (3) simulating the dynamic evolution process of the co-opetition strategy using MATLAB (MathWorks). This study bridges the previous gap of focusing only on superficial policy recommendations and neglecting to reveal the game mechanism of multiple subjects behind the policies. The findings provide both theoretical foundations and policy-relevant insights for achieving EHR integration objectives.

Methods

Research Design

This study followed the research approach of "basic assumptions - model construction - result analysis - numerical simulation." First, for the convenience of modeling and analysis, combined with the actual situation of EHR integration in China, the superior hospital A and its subordinate hospital B were randomly set as research objects within the medical consortiums. Referring to related studies on cooperative competitive games in the big data innovation alliance and information ecosystem [18,19], the basic assumptions were put forward from 6 aspects: game players, co-opetition relationships, value-added benefits, synergistic effects, co-operation costs, and reward-punishment system. Second, an evolutionary game model of the competitive and cooperative behaviors between the superior and subordinate hospitals was constructed. Then, we analyzed the influence mechanisms of key factors on the selection of competition and cooperation strategies, and MATLAB was used to conduct simulation experiments on the model operation. Finally, targeted policy recommendations were proposed to highlight the practical reference value of the research conclusions.

XSL•FO

Underlying Assumptions

Game Players and Co-Opetition Relationships

In China, medical consortiums consist of dozens or even hundreds of hospitals at different levels and scales, including tertiary hospitals, secondary hospitals, county hospitals, community hospitals, and rural hospitals. These hospitals belong to different levels of administrative divisions. In the existing medical order designed by the "hierarchical diagnosis and treatment" system, these hospitals present an unstructured hierarchical relationship with each other. When a patient is transferred from a county hospital to a tertiary hospital for treatment, the county hospital becomes a subordinate hospital to the tertiary hospital; when a patient is transferred from a community hospital to a county hospital for treatment, the county hospital is again a superior hospital to the community hospital. Obviously, "superior and subordinate hospitals" is a relative concept, but it can accurately portray the main structure of the co-opetition game among hospitals at each level in medical consortiums. Therefore, we classify the players participating in the co-opetition evolutionary game into superior hospitals and subordinate hospitals.

The superior and subordinate hospitals have not only formed a cooperative relationship based on policy requirements and integration goals but also formed a competitive relationship due to risk avoidance and interest maximization. They continuously create and add value through both competition and cooperation. In summary, the co-opetition relationship between superior and subordinate hospitals manifests in the following four situations [20]: (1) Creation of integrated medical value (cooperation): improves health care service quality and alleviates the social contradictions of difficult and expensive access to health care; (2) pursuit of patient volume (competition): the number of patients directly determines the hospital's financial gains; (3) policy and contractual regulation (cooperation): hospitals must comply with the requirements of the hierarchical diagnosis and treatment system, share EHR and implement referral regulations; and (4) opportunistic behavior (competition): may include cost-input bargaining, income concealment, inaction, and "free-riding" situations.

Hospitals are profit-seeking entities that aim to maximize their own interests in the co-opetition process [21]. Hospitals compare their benefits and strategies with reference hospitals and adjust their strategies accordingly, resulting in various game behaviors. Influenced by changes in external factors and constrained by imperfect rationality and incomplete information, hospitals can only continuously adjust their strategies according to a certain probability to maximize income, which forms an evolutionary game. Assume both hospitals *A* and *B* have 2 optional strategies in EHR integration, namely competition and cooperation. The probability of hospital *A* choosing cooperation is *x*, then the probability of hospital *A* choosing competition is 1-*x*; similarly, hospital *B*'s g cooperation probability is *y*, making its competition probability 1-*y*. where x,y∈[0,1] and *x* and *y* are both functions of time *t*.

Value-Added Benefits and Synergistic Effects

The EHR integration can easily realize "two-way referral," enabling *A* and *B* to gain value-added benefits. The value-added benefits include not only economic benefits, but also noneconomic benefits, such as social reputation, brand image, collective honor, hospital responsibility, superior praise, promotion, and public praise. The benefits that hospitals were able to obtain before EHR integration can be referred to as the original benefits and are denoted by Ri. Whether EHR integration can generate value-added and the magnitude of the value-added depends on the hospital's willingness to use EHR ρi)(0≤ρi≤1,i=A,B), the ability to use EHR (μi)(0≤μi≤1,i=A,B), and the number of the other's health records shared (ri)(0≤μi,i=A,B). It is assumed that the average benefit per unit resource is *I* (*I*≥0).

A hospital's willingness to use EHR is fundamentally determined by the decision makers' cognition, which includes both the decision makers' awareness of realizing the social value of the medical consortium and their perceived future expected use. Therefore, a higher ρi indicates that the decision makers perceive greater value and future utility of EHR integration, while a smaller value of ρi represents that the decision makers pay more attention to immediate and local interests. The ability to use EHR reflects the level of medical care in the hospital, and it includes both the ability of physicians to use the EHR and the medical equipment conditions that the hospital has to use the external EHR. The number of EHRs shared is proportional to the value-added benefit of the other party. The more EHRs shared by the sharing party, the greater value-added benefit the user may gain. Therefore, the value-added benefits received by hospital *A* and *B* are ρAμArBI and ρBμBrAI, respectively.

Usefulness, the ultimate goal of the game, refers to the material or spiritual benefits players obtain through the game [22]. Synergistic effects refer to the enhanced profitability from mutual EHR sharing among hospitals, representing the core objective of medical consortia in promoting EHR integration When both *A* and *B* choose the "cooperation" strategy, synergy will occur, which depends on the hospital's willingness to use EHR (ρi), the ability to use EHR (μi) and the EHR resources complementarity (β). Then the synergy benefits of *A* and *B* are βρAμArAI and βρBμBrBI respectively.

Cooperation Cost and Reward-Punishment Mechanism

EHR integration can impose additional costs on hospitals, such as direct costs (IT infrastructure modification and file formatting), risk costs (data privacy/security issues), opportunity costs (potential patient attrition), and indirect costs (reduced revenue from test information reuse) [23]. Existing research suggests that high fines can not only prevent free riding but they also demotivate some of the most generous altruists [24]. To promote the smooth integration of EHRs in medical consortiums, local governments often establish reward and punishment systems to achieve cost compensation while reducing opportunism. The reward and punishment system are the most easily regulated and more frequently adjusted factor, and its changes are more likely to cause changes in the competing strategies of the superior and subordinate hospitals, which in

XSL•FO
RenderX

turn affects the evolutionary game direction. Assuming that the average input cost in terms of human, financial, and other resources required to integrate unit resources is *C*, the input costs of *A* and *B* are rAC and rBC, respectively. When hospitals actively share and use EHRs for integration purposes, the government grants a unit resource subsidy of *H*, otherwise a unit resource penalty of *H* is granted.

According to the game motives of the players and the above assumptions, the co-opetition relationship between the 2 sides of the game can be portrayed by the following scenarios. First, when both players choose "cooperation," the benefits obtained by both players include the original benefit (Ri), value-added benefit (riI), and government incentive (riH). The synergy benefits generated by *A* and *B* are βρAμArAI andρBμBrBI. Also considering the costs rAC and rBC due to the inputs in the cooperation, we can derive the benefit functions of *A* and *B* as RA+ρAμA(rBI+βrAI)+rAH-rAC and RB+ρBμB(rAI+βrBI)+rBH-rBC. Second, when 1 player chooses "cooperation" and the other chooses "competition." When *A* chooses "cooperation" and *B* chooses "competition," *A*'s benefits include the original benefit R_A and financial subsidy rAH, and *A* incurs investment costs rAC due to the choice of cooperation. At this time, *A* cannot use *B*'s EHR, and *A*'s value-added benefits are 0. Therefore, *A*'s benefit function is RA+rAH-rAC. The benefit of *B* includes both the original benefit R_B and the value-added benefit RB+ρBμBrAI-rBH from free-riding. At this point, *B* has no input cost but receives a penalty rBH from the government. Therefore, the benefit function of *B* is RB+ρBμBrAI-rBH. Similarly, when *B* chooses "cooperation" and *A* chooses "competition," the benefit function of *A* is RA+ρAμArBI-rAH, and the benefit function of *B* is RB+rBH-rBC. Finally, when both players choose "competition," both players gain only the original benefits R_A and R_B, and the penalties for both players are rAH and rBH.

When 1 player chooses "cooperation" and the other chooses "competition." When *A* chooses "cooperation" and *B* chooses "competition," *A*'s benefits include the original benefit R_A and financial subsidy rAH, and *A* incurs investment costs rAC due to the choice of cooperation. At this time, *A* cannot use *B*'s EHR, and *A*'s value-added benefits are 0. Therefore, *A*'s benefit function is RA+rAH-rAC. The benefit of *B* includes both the original benefit R_B and the value-added benefit RB+ρBμBrAI-rBH from free-riding. At this point, *B* has no input cost but receives a penalty rBH from the government. Therefore, the benefit function of *B* is RB+ρBμBrAI-rBH. Similarly, when *B* chooses "cooperation" and *A* chooses "competition," the benefit function of *A* is RA+ρAμArBI-rAH, and the benefit function of *B* isRB+rBH-rBC.

When both players choose "competition." Both players gain only the original benefits R_A and R_B, and the penalties for both players are rAH and rBH.

Model Construction

As a result, an evolutionary game payment matrix can be constructed for hospitals *A* and *B*, as shown in Table 1.

Table . Evolutionary game payment matrix.

Players and optional strategies	Subordinate hospital *B*	
Superior hospital *A*	Cooperation (*y*)	Competition (1-*y*)
Cooperation (*x*)	RA+ρAμA(rBI+βrAI)+rAH-rAC	RA+rAH-rAC
	RB+ρBμB(rAI+βrBI)+rBH-rBC	RB+ρBμBrAI-rBH
Competition (1-*x*)	RA+ρAμArBI-rAH	RA-rAH
	RB+rBH-rBC	RB-rBH

According to Table 1, the expected benefit EA1 of the cooperation strategy chosen by *A* is:

(1)EA1=y[RA+ρAμA(rBI+βrAI)+rAH−rAC]+(1−y)(RA+rAH−rAC)

The expected benefit of the competitive strategy chosen by *A* is EA2:

(2)EA2=y[RA+ρAμArBI−rAH]+(1−y)(RA−rAH)

Then the average expected benefit E−A of superior hospital *A* is:

(3)E−A=xEA1+(1−x)EA2=RA+xrA(2H−C)+y(xβrA+rB)ρAμAI−rAH

Therefore, the replication dynamic equation of the cooperation strategy chosen by the superior hospital *A* can be derived as follows:

F(x)=dxdt=x(EA1−E¯A)

(4)=x(1−x)[rA(2H−C)+yβρAμArAI]

Similarly, the expected benefit EB1 of the cooperation strategy chosen by *B* is:

(5)EB1=x[RB+ρBμB(rAI+βrBI)+rBH−rBC]+(1−x)(RB+rBH−rBC)

The expected benefit of the competitive strategy chosen by *B* is EB2：

(6)EB2=x[RB+ρBμBrAI−rBH]+(1−x)(RB−rBH)

Then the average expected benefit E-B of subordinate hospital *B* is:

(7)E−B=yEB1+(1−y)EB2=RB+yrB(2H−C)+x(rA+yβrB)ρBμBI−rBH

Therefore, the replication dynamic equation of the cooperation strategy chosen by the subordinate hospital *B* can be derived as follows:

(8)F(y)=dydt=y(EB1−E−B)=y(1−y)[rB(2H−C)+xβρBμBrBI]

Ethical Considerations

No formal ethical approvement was necessary for the study according to the China Science and Technology Ethics Committee.

Results

Stability of Equilibrium Points and Their Evolutionary Path Analysis

In the evolutionary game process, hospitals *A* and *B* participate in the game through repeated trial and error, learning and imitation, constantly adjusting their own strategies, so that the dynamic system will eventually reach a stable state. According to the stability theorem of differential equations, let:

(9)F(x)=dxdt=0F(y)=dydt=0

By solving equation (9), 5 local equilibrium points of the dynamic evolutionary game system can be obtained, which are *O* (0,0), *F* (0,1), *G* (1,0), *K* (1,1), *and T* (C−2HβρBμBI, C−2HβρAμAI). These 5 equilibrium points together constitute the boundary (x,y)0≤x≤1;0≤y≤1of the evolutionary game system solution domain of superior and subordinate hospitals in EHR integration.

The Jacobi matrix can be obtained by solving the partial derivatives of (4) and (8) with respect to x and y, respectively.

J=[∂F(x)∂x∂F(x)∂y∂F(y)∂y∂F(y)∂x]

(10)[1−2y(C−H)+βρAμAAI(1−2x)βρAμAAI(1−x)βρBμBBI(1−2y)βρBμBBI(1−y)]

For a 2-party behavior dynamic system described by differential equations, whether the above 5 local equilibrium points are evolutionary stable strategies of the dynamic system can be determined by the sign of the det(J) and tr(J) of the Jacobi matrix [8,25]. When 2H>C, the stability of the 5 equilibrium points can be obtained as shown in Table 2. This situation is theoretically valid but difficult to realize in reality. When 2H<C, Since 0<C−2HβρBμBI<1 and 0<C−2HβρAμAI<1, we can obtain βρBμBI>C−2H and βρAμAI>C−2H, and then obtain the stability of the 5 equilibrium points as shown in Table 3 and Figure 1 (2H>C). This situation is more realistic and has a solid practical basis. Therefore, we chose this situation to carry out an in-depth analysis in order to clarify the influence mechanism and influence effect of key factors on the evolutionary game system. The evolutionary path of the dynamic system is shown in Figure 1, where 1 denotes the cooperative strategy and 0 denotes the competitive strategy.

Table . Equilibrium points of evolutionary game system and their stability (2H>C).

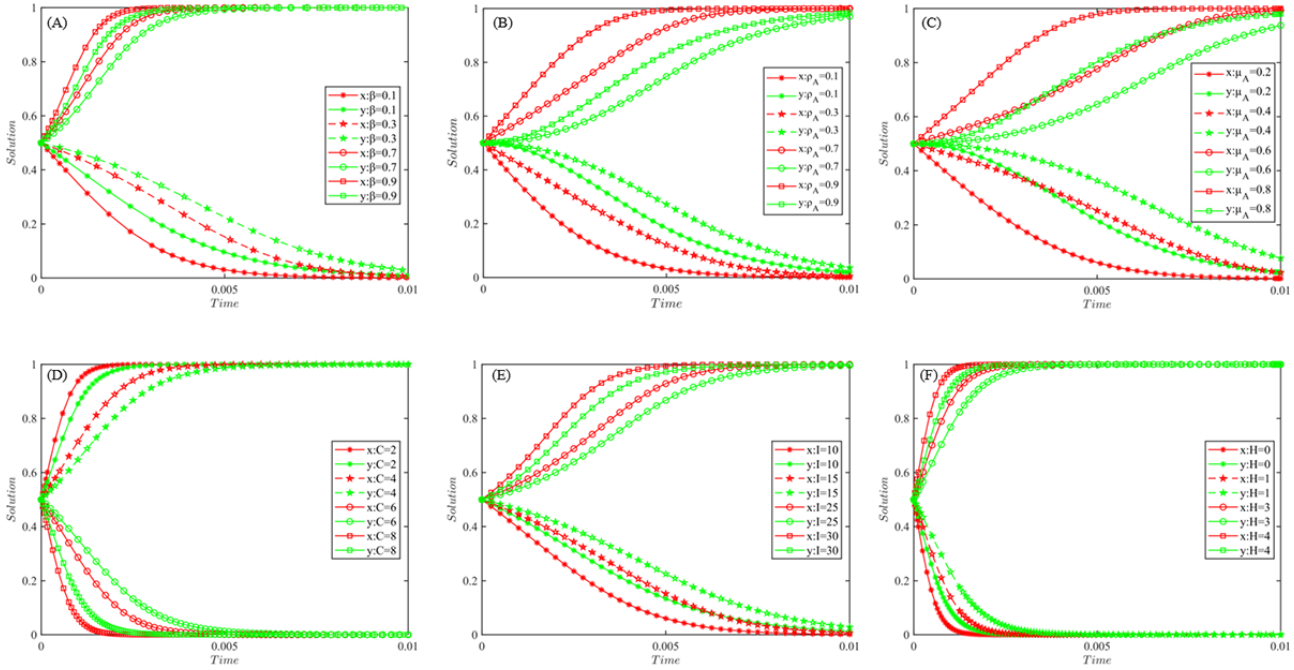
XSL•FO
RenderX

Figure 1. Evolutionary path phase diagram.

It can be seen from Table 2 and Figure 1 (2H<C), the evolutionary game system has 2 stable points, *O* (0, 0) and *K* (1, 1). The game strategies corresponding to the stable points are {competition, competition} and {cooperation, cooperation}. *F* (0, 1) and *G* (1, 0) are the unstable points, and their corresponding game strategies are {competition, cooperation} and {cooperation, competition}, respectively. The equilibrium points *T* (x*, y*) is a saddle point located in the plane(x,y)0≤x≤1;0≤y≤1. When the initial state of the dynamic system is within the FTGK region, the evolutionary result will converge to the stability point *K* (1, 1), that is, both the hospitals *A* and *B* choose the cooperation strategy to actively promote the EHR integration. When the initial state of the dynamic system is within the FTGO region, the evolutionary result will converge to the stability point *O* (0, 0), that is, both A and B choose the competition strategy. The final convergence of the evolutionary game system to that stable point depends on the prediction and judgment of both sides of the game on their own ability and the other side's strategy choice. The willingness and ability of hospitals to use EHR, the number of EHR shared by the other party, and the complementarity of EHR have positive effects on the integration.

Analysis of the Influence Mechanism of Key Factors

It can be seen from Figure 1 that the size of FTGK area depends on the location of saddle point *T* (C-2HβρBμBI,C-2HβρAμAI). The location of *T* point is influenced by the complementarity of EHR resources (β), hospital's willingness (ρi) and ability to use HER (μi), the average income of unit EHR resources (*I*), unit EHR resource sharing cost (*C*), and unit resource reward and punishment (*H*). The influence mechanism of the relevant parameters is analyzed below. Where the area of the FTGK region can be expressed as follows [26]:



$$S_{FTGK}=1-\frac{1}{2}(x^*+y^*)=1-\frac{1}{2}\left(\frac{C-2H}{\beta\rho B\mu BI}+\frac{C-2H}{\beta\rho A\mu AI}\right) \quad (11)$$

The Influencing Mechanism of Original Revenue Ri and EHR Stock ri

The location of the saddle point T in Figure 2 determines the likelihood of the evolutionary direction of the game system. The position of saddle point T depends on the combined effect of multiple factors. However, according to the model solution results equation (11), it can be seen that these factors do not include the original revenue Ri and the stock of EHRs ri. This indicates that hospitals' original revenue and EHR stock have no substantial effect on the evolutionary direction of the gaming system. One reason is that the superior hospitals we conceptualize are not equivalent to large hospitals, and subordinate hospitals are not equivalent to small hospitals either. More importantly, incentives, penalties, and costs are calculated on the basis of "EHR resources per unit," not on the basis of the hospital's original revenue and total EHR.

RenderX

Figure 2. Simulation results of influence effects based on MATLAB. (A) Effect of β on the evolutionary game system, (B) effect of ρi on the evolutionary game system, (C) effect of μi on the evolutionary game system, (D) effect of C on the evolutionary game system, (E) effect of I on the evolutionary game system, and (F) effect of *H* on the evolutionary game system.

The Influencing Mechanism of EHR Resource Complementarity (β)

Let SFTGKtake the derivative of β, we can get

∂SFTGK∂β=12C-2Hβ2ρBμBI+C-2Hβ2ρAμAI(12)

Since equation (12) is always greater than zero, it means that SFTGK is an increasing function of the EHR resource complementarity (β). The area of the region SFTGK in the upper right of the polyline ETG increases with β. With the increase of resource complementarity, the willingness of participating institutions of medical consortiums to use EHR will increase, which will help promote close cooperation between superior and subordinate hospitals, and thus promote the creation of integrated medical value by medical consortiums. On the contrary, if the EHR complementarity is low, then hospitals at all levels will be more willing to use their own generated EHR. Even if it is mandatory under the policy, hospitals are likely to only share their own EHR and will not take the initiative to use the EHR shared by other hospitals. This would go against the original intention and social expectations of EHR integration. The impact path of the EHR complementarity (β) on the co-opetition strategy of the superior and subordinate hospitals is reflected in the phase diagram, that is, as β increases, the saddle point T will keep moving toward the *O* (0, 0), which makes the upper right area of ETG keep increasing, which keeps increasing the probability of the superior and subordinate hospitals choosing the {cooperation, cooperation} strategy.

It is important to note that because β, ρi, μiand*I* have similar mathematical properties, meaning that these 4 parameters have the same mechanism of action on the influence of the co-opetition strategies of the superior and subordinate hospitals. That is to say, with the increase of the value of the 4 parameters of EHR resource complementarity (β), hospital's willingness (ρi) and ability (μi) to use EHR, the average income of unit EHR resources (*I*), the probability of the superior and subordinate hospitals choosing the {cooperation, cooperation} strategy will increase, and then the game system will evolve to the {1, 1} stable point.

The Influencing Mechanism of Unit EHR Resource Sharing Cost (C)

Let SFTGKtake the derivative of C, we can get

∂SFTGK∂β=-121βρBμBI+1βρAμAI(13)

Because equation (3) is constantly less than 0, meaning that SFTGK is a decreasing function of the unit resource sharing cost *C*, the area of the region SFTGK at the top right of the polyline ETG decreases with the increase of *C*. With the increase of unit resource sharing cost, the willingness of participating institutions of medical consortiums to use EHR will diminish, indicating that the higher the unit resource sharing cost *C*, the lower the willingness and probability of hospitals to participate in the EHR integration. On the contrary, if the unit resource sharing cost *C* is low, the motivation of hospitals at all levels to share and use EHRs will increase, which is a strong impetus to achieve the goal of EHR integration. The impact path of unit resource sharing cost *C* is reflected in the phase diagram, that is, with the increase of *C*, the saddle point *T* will continue to move to the point *K*, making the area of the upper right of the ETG continue to decrease, weakening the motivation of the superior and subordinate hospitals' choice of {cooperation, cooperation} strategy; With the decrease of *C*, the saddle point *T* will keep moving toward the point *O*, making the upper right area of ETG keep increasing, keep increasing the probability of the superior and subordinate hospitals choosing the {cooperation, cooperation} strategy.

XSL•FO
RenderX

The Influencing Mechanism of Unit EHR Resource Reward and Punishment Intensity (H)

Let SFTGKtake the derivative of H, we can get

$$\partial SFTGK\partial\beta=1\beta\rho B\mu BI+1\beta\rho A\mu AI \quad (14)$$

Since equation (14) is strictly positive, SFTGK becomes a monotonically increasing function of H, indicating that the area of region SFTGK located in the upper-right quadrant relative to the polyline ETG grows with H. With the increase of the unit resource reward and punishment, the probability of using EHR in participating institutions of medical consortiums will keep increasing, indicating that the greater the unit resource reward and punishment intensity *H* the greater the motivation of hospitals at all levels to participate in the EHR integration. On the contrary, if the reward and punishment of unit resources intensity *H* is low, the enthusiasm of hospitals at all levels to share and use EHR will be weakened, which will hinder the realization of the goal of EHR integration to a certain extent. The impact path of *H* on the co-opetition relationship between the superior and subordinate hospitals is reflected in the phase diagram, that is, with the increase of *H*, the saddle point *T* will continue to move toward the point *O*, making the upper right area of the ETG continue to increase, thus increasing the probability of the superior and subordinate hospitals to choose the {cooperation, cooperation} strategy; with the decrease of *H*, the saddle point *T* will continue to move toward the point *K*, making the upper right area of the ETG continue to decrease, and the probability of hospitals choosing the {competition, competition} strategy will increase.

MATLAB-Based Simulation of Influence Effects

In order to more intuitively describe the influence effect, and to verify the reasonableness and reliability of the analysis of the influence mechanism of the key factors, MATLAB R2018b was used to carry out numerical simulation and analysis of the differential equation (equation 9). When a parameter was simulated, other parameters ware taken as fixed values. The initial values of each parameter are set as follows: $rA=800, rB=500, \beta=0.4, \rho i=0.5, \mu i=0.5, I=20, H=2, C=5$, x and y are taken as 0.5. The simulation results are shown in Figure 2.

Effect of EHR Resource Complementarity (β)

From Figure 2A, the lower the EHR resource complementarity (β), the more hospitals tend to choose the competitive strategy. With the increasing complementarity of EHR resources, the strategy choice of superior and subordinate hospitals gradually shifts from competition to cooperation. And after the critical state, the evolutionary game system converges to {cooperative, cooperative} stable strategy at a faster speed. Complementarity refers to the nonoverlapping content of EHRs owned by each of the superior and subordinate hospitals. The more frequent the “up and down referrals” are, the greater the nonoverlap of EHR contents. Therefore, the medical consortiums should actively involve different types of hospitals in the region, and continuously improve the complementarity of EHR resources between superior and subordinate hospitals, while expanding the patient’s right to choose medical treatment.

Effect of Hospitals’ Willingness (ρi) and Ability (μi) to Use EHR

From Figure 2B and (C), it can be seen that the willingness and ability to use EHR of superior and subordinate hospitals have similar effects on the evolution of the evolutionary game system. With the increase of hospitals’ willingness or ability to use EHR, the probability of dynamic game system tending to {cooperation, cooperation} state will keep increasing, and vice versa. Both the willingness and ability to use the EHR are prerequisites for creating benefits after EHR integration. The stronger the willingness and ability, the stronger the hospital’s perception of use, the more confident it will be in the expected benefits, and the more motivated it will be to participate in EHR integration.

Effect of Unit EHR Shared Cost (*C*)

As can be seen from Figure 2D, when the other parameters are taken as fixed values, the probability of choosing the cooperation strategy for superior and subordinate hospitals gradually decreases as the unit EHR sharing cost *C* keeps increasing. When the unit EHR sharing cost *C* is less than the critical value, the probability of the superior and subordinate hospitals chooses to actively cooperate increases continuously with the decrease of *C*. At present, the technical standards and content formats of EHR, EMR and other systems used by different hospitals are likely to be different. To achieve EHR integration, hospitals may need to revamp system interfaces, format content, optimize management practices, and even staff more technical personnel. The increased difficulty of integration will lead to higher integration costs, which will objectively reduce the enthusiasm of hospitals to implement the integration of EHR, and ultimately lead to the evolution of the game system towards a stable strategy of competition.

Effect of Average Revenue of Unit EHR (*I*)

From Figure 2E, it can be seen that the evolutionary game system gradually converges to the {cooperative, cooperative} state as the average revenue of unit EHR (*I*) keeps increasing, when the other parameters are taken constant. When the average revenue of unit EHR (*I*) is below a critical value, both superior and subordinate hospitals choose a competitive strategy to ensure that their respective interests are maximized. Both the unit EHR sharing cost (*C*) and the unit EHR average benefit (*I*) are crucial to ensure the sustainable development and usage of EHR, and they have a decisive impact on the hospital’s revenue as well as rewards and penalties. Therefore, while promoting the EHR integration, medical consortiums must continuously develop and expand the channels for creating value and revenue, and adopt advanced technologies and measures to gradually reduce sharing costs.

Effect of Rewards and Punishments of Unit EHR (*H*)

It can be seen from Figure 2F that when the other parameters take fixed values, the probability that both sides of the game choose to cooperate gradually increases with the increase of the unit EHR rewards and punishments (*H*). In order to promote hospitals to actively share and use EHR, and to avoid opportunistic behaviors such as “free-riding,” reward and punishment mechanisms are often established to protect the

XSL•FO
RenderX

legitimate benefits of superior and subordinate hospitals. Compared with the unit EHR resource sharing cost (*C*) and the average benefit of unit EHR (*I*), the reward and punishment intensity (*H*) is the easiest to regulate and control. The evolutionary game system is more sensitive to *H*. It means that the strength of rewards and punishments will play a more obvious role in promoting the medical consortiums to achieve the goal of EHR integration.

Discussion

Principal Findings

To make both the superior and subordinate hospitals *A* and *B* choose the cooperation strategy and promote the smooth implementation of EHR integration in the medical consortiums, it is necessary to ensure that the initial probability of both sides of the game to choose the cooperation strategy is within the FTGK region (as shown in Figure 2). At this time, the probability requirements for the superior and subordinate hospitals *A* and *B* to choose cooperation are as follows:

$$x>x^{*}=C-2H\beta\rho B\mu BI;\ y>y^{*}=C-2H\beta\rho A\mu AI \quad (15)$$

The complementarity of EHR resources, hospitals' willingness and ability to use EHRs, and the average benefit of unit EHRs have a positive effect on the realization of EHR integration in medical consortiums. The input cost of unit EHR resource has a negative hindering effect on achieving EHR integration. The original revenue of the superior and subordinate hospitals *A* and *B*, and the stock of EHRs have no effect on the evolutionary direction of the game system. In other words, whether it is a superior hospital or a subordinate hospital, no matter how much or how little EHR that can be shared and used, there is no substantial impact on achieving the goal of the EHR integration in medical consortiums.

Designing a reasonable reward and punishment mechanism is great significance to promote medical consortiums to realize the EHR integration, especially in the initial stage. The integration progress can be accelerated if the rewards and punishments are more than half of the sharing cost. In the initial stage, rewards and punishments can be appropriately increased to speed up the progress of EHR integration. The goal of EHR integration can also be achieved when the rewards and punishments are less than half the sharing cost under the condition of $\beta\rho i\mu iI>C-2H$. Therefore, with the deepening of the EHR integration, the increasing willingness and ability of hospitals to use EHR, and the increasing efficiency of sharing EHR, government subsidies can be appropriately reduced or even eliminated according to the actual situation, thus reducing financial pressure.

Management Insights

To promote the enthusiasm of superior and subordinate hospitals to share and use EHR, and increase the probability of choosing cooperation strategies, the following aspects need to be emphasized. First, the medical consortiums should actively involve different levels and various types of medical institutions (general hospitals, maternal and child health care centers, specialized hospitals, rehabilitation hospitals, etc.) to improve the complementarity of EHR resources. Second, we should continuously improve the subjective willingness and ability of hospitals to use EHR through training, assistance, support, medical resources sinking and other ways. Third, the government should establish a reward and punishment system, optimize the operation mechanism and supervision mechanism of the medical consortiums, supervise and punish opportunistic behaviors such as "free-riding," and ensure that the goals of the hospital are consistent with those of the medical consortiums. Fourth, hospitals should continuously strengthen the construction of information infrastructure, actively improve the technical standards, content standards and sharing standards for the EHR construction [27], further improve the benefits of EHR, and reduce the investment cost of EHR sharing and use.

The decision-making groups are the actual game players of the hospital. The hospital's willingness to use EHR is fundamentally determined by the cognitive level of the decision-making groups. Therefore, the choice of hospital decision makers also has an important influence on the promotion of EHR integration. In the appointment of hospital decision makers, especially the head of the appointment, the cognitive pattern, medical values, social responsibility, dedication and commitment of the appointment candidate should be fully considered. At the same time, medical consortiums should adopt a wide publicity and mobilization, design and announce a reward and punishment system at the early stage of embarking on the integration of EHR to improve the motivation of hospital decision makers to adopt the cooperation strategy. Ensure that the policies and measures can receive positive response and support from the hospital's decision-making collective, to lay a solid foundation for the realization of the EHR integration.

Hospitals participating in the same consortium should have the same institutional constraints, both at superior hospitals and subordinate hospitals. There should be no differentiation in the system based on the size of the hospital. More importantly, in order to promote the active participation of both superior hospitals and subordinate hospitals in the integration of EHR, the design of incentive and penalty mechanisms and cost accounting should be based on the "unit EHR resources," rather than on the original revenue of the hospital and the total amount of EHR.

Research Limitations

In this paper, we take superior and subordinate hospitals within the medical consortium as the research object to explore the evolution mechanism of co-opetition strategies in the EHR integration. Therefore, we adopted a 2-party evolutionary game without considering the game scenario involving more stakeholders, such as the government, integrators, and patients. In addition, due to the lack of real data in practice, only the MATLAB simulation method was used to verify the model rationality, while failing to use empirical methods to test the accuracy of the model. With the continuous deepening of practice, it is necessary to continuously collect relevant data in the future and use empirical methods to further test the scientific validity of research findings.

Abstract

Background: Electronic health records (EHRs) play a critical role in today's health care by enhancing data management, improving workflows, and supporting clinical decision-making. However, EHR implementation introduces technical and clinical challenges that can compromise patient safety. The Safety Assurance Factors for Electronic Health Record Resilience guides, developed by the Office of the National Coordinator for Health Information Technology, provide a structured framework for evaluating and optimizing EHR safety practices. Despite extensive research on EHR safety in developed countries, little is known about its implementation in regions with differing health care systems, such as Kuwait.

Objective: This study aims to examine the EHR safety across hospitals in the State of Kuwait via (1) conducting a proactive risk assessment examining current safety practices and (2) proposing recommendations to improve EHR safety practices.

Methods: A quantitative approach was used to evaluate EHR safety practices in 6 public hospitals. Multidisciplinary teams completed the Safety Assurance Factors for Electronic Health Record Resilience self-assessment questionnaire, scoring their implementation status of 165 recommended practices as "fully," "partially," or "not" implemented across 9 Safety Assurance Factors for Electronic Health Record Resilience guides. Data were analyzed to calculate the percentage of "fully implemented" recommended practices for each hospital, guide, and EHR safety domain. Standard deviations were calculated to assess data variability, and comparative analysis was conducted to identify implementation patterns.

Results: The findings revealed significant variability in the implementation of recommended safety practices, with an average of 53% rated as "fully implemented" across hospitals. Infrastructure-focused guides, such as system configuration (77%) and system interfaces (80%), had the highest implementation rates, while clinical process guides, such as clinician communication (25%), scored the lowest. Among the 9 guides, 16 recommended practices were unanimously rated as "fully implemented," while 8 were predominantly rated as "not implemented." The high-priority guide showed notable variability, with implementation rates ranging from 17% to 89% across hospitals. Hospitals with longer EHR adoption periods tended to perform better, though hospital size and implementation type showed inconsistent effects on safety practices scores.

Conclusions: The study highlights variability in EHR safety practice implementation across Kuwait's public hospitals, with stronger performance in technical domains and gaps in clinical processes. By applying the Safety Assurance Factors for EHR Resilience guides in a non-US context, the study offers a foundational understanding of EHR safety implementation in Kuwait's public health care system. Given the study's limited scope and reliance on self-reported data, findings should be interpreted with caution. Future research should adopt broader sampling and mixed methods approaches to validate these results and inform the development of context-specific strategies to enhance EHR safety and patient outcomes.

Introduction

Health IT is defined as "the application of information processing involving both computer hardware and software that deals with the storage, retrieval, sharing, and use of healthcare information, data, and knowledge for communication and decision making" to improve and maintain health care quality and patient safety [1,2]. Today, many hospitals rely on robust

XSL•FO
RenderX

health IT solutions in their clinical practice, one of which is electronic health records (EHRs) [1,3].

In the United States, 78% of office-based physicians use EHRs in their medical practice [4-6]. EHRs include a set of documented information related to patient health care, such as demographics, progress notes, problems, medications, vital signs, medical history, immunizations, laboratory data, and imaging reports [7,8]. EHRs can also integrate with other advanced systems and features like clinical decision support (DS) systems, computerized physician order entry, health information exchange, and safety alerts [8,9].

With all these data, systems, and features, EHRs can support physicians in collecting medical history easily, providing better health care, and maintaining patient safety compared to relying on paper-based records [8]. Thus, EHRs contribute to improved data tracking and follow-up over time, which in turn helps guide health care providers (HCPs) in decision-making [8,10]. Moreover, the secondary utilization of EHRs offers the potential to transform existing data into actionable insights through health research, public health surveillance, quality improvement initiatives, and safety monitoring [11-13]. These applications are critical for identifying and addressing patient safety challenges within health care processes and for improving the quality of patient care [11,14].

The World Health Organization estimates that 1 in every 10 patients in developed countries is harmed while receiving health care in hospitals. Medical errors, often associated with diagnosis, prescription, and medication use [15], can be broadly categorized into two types: (1) adverse events that directly affect the patient, resulting in minor or severe injury or death, and (2) near misses that are intercepted before reaching the patient in unsafe conditions that elevate the risk of a future safety incident. These errors can lead to significant consequences, including fatalities, disabilities, poor health outcomes, increased health care costs, and legal complications [16-19].

A recent study in Kuwait found that approximately 60% of the frequency of medical errors ranged from incidences of prolonged hospital stays, adverse events, life-threatening complications, and fatalities. The causes of these medical errors included high workload, the lack of EHRs, HCPs' non-compliance with safety guidelines, untrained or inexperienced administrative staff, and poor communication with patients and between HCPs [20]. While EHRs are designed to reduce the workload of HCPs and improve practice efficiency, cost, and error reduction, some studies reveal that implementing and using EHRs increases the work burden on HCPs [8,16,21,22].

In the United States, many physicians reported spending twice their working hours on EHR-related tasks, with some dedicating an additional 1-2 hours after work [8,23]. Consequently, this increased workload may elevate the risk of medical errors, ultimately compromising health care quality and patient safety [8,16,20,24]. Achieving the safe and effective use of EHRs presents several challenges, including usability issues, concerns about data integrity, safety risks, and the need for proper and ongoing system maintenance [10,25-29].

Evidence suggests that EHRs have demonstrated potential in reducing medication errors and adverse events and improving care quality [30-32]. In Kuwait, while health care professionals have shown acceptance of EHR adoption and expressed positive expectations, most hospitals remain in the early stages of implementation [33,34]. However, the adoption of EHRs introduces new risks that can adversely impact patient safety. These risks often stem from challenges related to system design, implementation, and usage. Specific issues include system downtime, poor usability, data entry errors, inadequate implementation processes, weak security measures, and malpractice by EHR users [35-37]. Addressing these risks is crucial to ensuring the safe and effective utilization of EHRs in health care settings [3,35].

Given that many health care organizations and HCPs prioritize patient safety, conducting regular assessments of EHR safety becomes essential [38]. EHR safety refers to the strategies and practices that ensure EHRs are used safely, securely, and effectively. These measures protect patients by preventing errors, harm, or any compromise to the quality of care [3,39-41]. The Office of the National Coordinator for Health Information Technology published a report highlighting key issues related to EHR safety and called for the development of proactive risk assessment tools [42].

One such tool is the Safety Assurance Factors for EHR Resilience (SAFER) guides, which provide a proactive risk evaluation framework that contributes to ensuring EHR safety, thereby supporting overall patient safety [42,43]. Furthermore, it is imperative to note that ensuring EHR safety requires a collaborative approach, with shared responsibilities between clinical and technical experts to optimize the use of EHRs [44].

In the State of Kuwait, the health care system is comprised of 2 main sectors: public and private. The public sector provides about 70% of health care services for citizens and residents, offering primary, secondary, and tertiary care within 6 health regions under the Ministry of Health [45,46]. Primary health care services are provided by polyclinics and health care centers located in residential areas. Notably, these centers and polyclinics offer initial diagnosis and treatment for patients, coordinating referrals to specialists in secondary and tertiary care if necessary. In contrast, secondary health care services are provided by 6 general hospitals distributed across the 6 governorates in Kuwait, while specialized health care services are offered by various specialized hospitals and centers [46-48].

This empirical study aims to conduct a proactive risk assessment examining the current EHR safety practices across public hospitals in Kuwait, with the goal of helping optimize EHR safety practices. To our knowledge, no prior studies have explored this topic in Kuwait or in comparable health care systems.

Methods

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki, and the protocol was approved by the Standing Committee for Coordination of Health and Medical Research

XSL•FO
RenderX

in the Ministry of Health in the State of Kuwait (1615/2021). All participants voluntarily signed the informed consent form before participating in the study procedures (Multimedia Appendix 1). Participants in the study were not paid for their participation. To maintain confidentiality and protect privacy, the names of the participating hospitals and health care staff have been anonymized throughout the study.

Data Collection

This study used a quantitative approach to evaluate the current EHR safety practices among public hospitals in the State of Kuwait using the SAFER guides. [43,49,50]. Hospitals were selected based on the presence of EHR systems, whether fully or partially implemented. Initially, 6 public secondary care hospitals were targeted; however, 1 was excluded due to the absence of an EHR system. To maintain the sample size and ensure data relevance, a tertiary care hospital from the same health region was included as a substitute. The participating hospitals were targeted to complete the SAFER self-assessment questionnaire, rating their implementation status as "fully," "partially," or "not" implemented (Multimedia Appendix 2).

Each participating hospital was required to assemble a multidisciplinary team of health care staff, following a similar approach to a previous study [49]. A letter was sent to the hospital administration requesting the formation of a multidisciplinary team to complete the questionnaire or to designate an authorized and experienced individual who could assemble an appropriate team to evaluate the recommended practices using the SAFER guides, ensuring a comprehensive approach to patient care. This team typically included physicians, nurses, allied health professionals, and other specialists relevant to the study objectives.

Prior to data collection, the researchers conducted training sessions on the SAFER guides for the hospital teams, providing guidance and support to facilitate the completion of the questionnaires. During these sessions, a PowerPoint presentation was used to explain the purpose of the SAFER guides and the mechanism for completing the assessment. Additionally, researchers provided their contact information for assistance and distributed QR codes linking to instructional videos, the official SAFER guides website, a demographic information collection form for participating hospitals, and an Excel spreadsheet template of the SAFER questionnaire for data entry to ensure ease of use and consistency [49].

The SAFER guides, introduced in 2014 by the Office of the National Coordinator for Health Information Technology, were designed to support health care organizations in conducting proactive risk assessments of their EHR practices, with the goal of enhancing and advancing EHR safety. The SAFER guides include 165 recommended practices related to EHR safety, distributed across 9 guides [50]. Of these, 8 guides comprise 147 unique recommended practices, while the ninth, the high priority guide, consolidates 18 of the most critical recommended practices from the other guides.

In previous studies [49,51], the total number of recommendations was reported as 140 because the high priority guide was excluded from the count. Additionally, an audit and comparison of the official SAFER guides website with prior studies concluded that 7 recommendations were omitted due to thematic similarity with those already included in the high priority guide, which did not significantly impact SAFER guide scores. However, this study considers all 165 recommendations [50] to provide a more comprehensive assessment of EHR safety practices.

Overall, the SAFER guides are organized into three primary areas: (1) foundational guides, (2) infrastructure guides, and (3) clinical process guides. Foundational guides focus on high-priority practices and organizational responsibilities. Infrastructure guides involve contingency planning, system configuration, and system interfaces. Clinical process guides focus on areas such as patient identification, computerized provider order entry (CPOE) with DS, test results reporting and follow-up, and clinician communication. Each guide includes between 12 and 29 recommended practices, structured into 3 domains: Safe Health IT, Using Health IT Safely, and Using Health IT to Monitor and Improve Safety [42,43,49,52].

Data Analysis

Following a similar analysis conducted in a previous study [49], the collected data were analyzed as follows: (1) calculated the percentage of "fully implemented" recommended practices across all 9 guides for each hospital, along with the standard deviation to measure data dispersion; (2) determined the mean percentage of "fully implemented" recommended practices across all participating hospitals for each guide; (3) assessed the percentage of "fully implemented" recommended practices across all participating hospitals for each EHR safety-related domain; and (4) evaluated the percentage of "partially implemented" and "not implemented" recommended practices in the high priority guide for each participating hospital.

Results

Demographic Attributes of Participating Hospitals

In total, 6 public hospitals participated in the study by completing the SAFER self-assessment questionnaire: 5 hospitals providing secondary health care services and 1 hospital providing specialized tertiary health care services. The participating hospitals had varied characteristics with respect to size, EHR adoption experience, and EHR implementation type (hospital demographic information is shown in Table 1).

XSL•FO
RenderX

Table . Demographics of participating hospitals.

Participated hospitals (N=6)	Numbers of hospitals
Hospital type	
Secondary health care	5
Tertiary health care	1
Hospital size	
Small	1
Medium	3
Large	2
EHR adoption year	
2006	1
2008	1
2015	2
2018	1
2019	1
EHR implementation type	
Outsourced developed	5
In-house developed	1

Hospitals were classified by size based on the number of beds and the total number of health care staff, including clinical, technical, and administrative staff. Small hospitals had less than 200 beds and fewer than 3000 employees (n=1), medium hospitals had 200-799 beds and 3000-6500 employees (n=3), while large hospitals had 800 or more beds and over 6500 employees (n=2) [45].

The participating hospitals also differed in their EHR adoption experience, ranging from 3 to 16 years, with initial implementations occurring between 2006 and 2019. Their approaches to EHR implementation varied, with 5 hospitals outsourcing the process through contracts with private companies for system deployment and support. Of these, 3 hospitals used the same vendor, while the other 2 engaged different vendors. In contrast, 1 hospital implemented its EHR system in-house, relying on local support from Ministry of Health developers.

A total of 38 health care staff members, forming multidisciplinary teams, participated in completing the SAFER guides questionnaire. Of the participants, 20 were female and 18 were male. While 2 hospitals assembled multidisciplinary teams of 6 members each, the remaining 4 hospitals formed teams of 7 members each (participant demographic information is shown in Table 2).

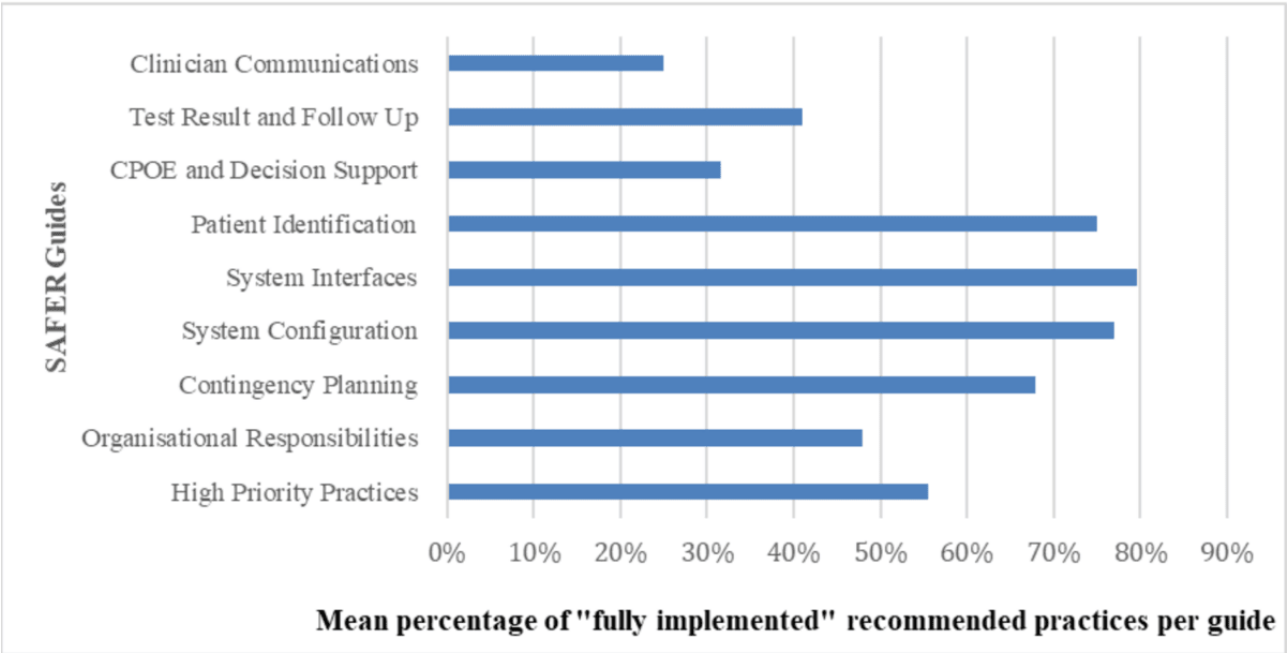
SAFER Guide's Responses

The percentage of "fully implemented" recommended practices across the 9 guides for each hospital, with a mean of 53% (SD 13), is shown in Figure 1. The highest percentage was 68% achieved by H1, while the lowest percentage was 32% achieved by H4.



XSL•FO
RenderX

Figure 1. Percentage of "fully implemented" recommended practices across the 9 SAFER (Safety Assurance Factors for Electronic Health Record Resilience) guides for each hospital.

The mean percentage of "fully implemented" recommended practices of SAFER guides across the 6 hospitals is shown in Figure 2. The system interfaces guide, with 18 recommended practices, achieved 80% and ranked the highest, while the clinician communication guide, with 12 recommended practices, reached 25% and ranked the lowest. Among the 3 SAFER guides broad classifications, infrastructure guides (contingency planning [68%], system configuration [77%], and system interfaces [80%]) achieved the highest mean percentage of "fully implemented" recommended practices. Hence, foundational guides ranked second with an average of 52%, while clinical process guides ranked third with an average of 43%.

Figure 2. Mean percentage of "fully implemented" recommended practices of SAFER (Safety Assurance Factors for Electronic Health Record Resilience) guides across the 6 hospitals.

Furthermore, the safe Health IT domain, which comprised 54 recommended practices, achieved 66% of "fully implemented" recommended practices across the 6 hospitals, exceeding the Using Health IT to Monitor and Improve Safety domain, which comprised 23 recommended practices (54%), and Using Health IT Safely domain, which included 88 recommended practices (45%).

XSL•FO
RenderX

Regarding high-priority guide recommended practices, the percentage of implementation status for each hospital is shown in Table 3. The percentage of "fully implemented" recommended practices ranged from 17 to 89%, with H6 achieving the highest and H2 the lowest. While the percentage of "partially implemented" recommended practices ranged from 11 to 83%, only 2 hospitals had recommended practices rated as "not implemented": H3 (22%) and H5 (11%).

Table . Percentage of implementation status for the high priority guide recommended practices for each hospital.

Implementation status	H1	H2	H3	H4	H5	H6
"Fully implemented"	78%	17%	67%	39%	44%	89%
"Partially implemented"	22%	83%	11%	61%	44%	11%
"Not implemented"	0%	0%	22%	0%	11%	0%

Examining hospital responses revealed that 16 recommended practices were unanimously rated as "fully implemented." These recommended practices were distributed across 6 SAFER guides: high priority; contingency planning; system configuration; system interfaces; patient identification; and test results and follow-up. The system interfaces guide contained the highest number of recommended practices (n=5). On the other hand, 8 recommended practices were predominantly rated as "not implemented" by most hospitals. These "not implemented" recommended practices were drawn from 3 SAFER guides: CPOE/DS; test results and follow-up; and clinical communications, with the CPOE/DS and test results and follow-up guides each containing the highest number (3 recommended practices). Both "fully implemented" and "not implemented" recommended practices are provided in Tables 4 and 5.

XSL•FO
RenderX

Table . SAFER (Safety Assurance Factors for EHR[a] Resilience) guide recommended practices were rated "fully implemented" by all 6 hospitals.

SAFER guide	SAFER recommendation
Total of 16 "fully implemented" recommended practices	
High priority	• "Information required to accurately identify the patient is clearly displayed on screens and printouts."
Contingency planning	• "Paper forms are available to replace key EHR functions during downtimes." • "Patient data and software application configurations critical to the organization's operations are backed up." • "Policies and procedures are in place to ensure accurate patient identification when preparing for, during, and after downtimes."
System configuration	• "There are an adequate number of EHR access points in all clinical areas." • "The EHR is hosted safely in a physically and electronically secure manner." • "System hardware and software required to run the EHR (eg, operating system) and their modifications are tested individually and as-installed before go-live and are closely monitored after go-live."
System interfaces	• "System-to-system interfaces are properly configured and tested to ensure that both coded and free-text data elements are transmitted without loss of or changes to information content." • "Changes to hardware or software on either side of the interface are tested before and monitored after go-live." • "The operational status of the system interface is clear to its users with regard to clinical use, such as knowing when the interface cannot transmit or receive messages, alerts, or crucial information." • "The organization monitors the performance and use of system interfaces regularly, including monitoring the interface error log and the volume of transactions over the interface." • "When interface errors are detected, they are reported, fixed, and used to construct new test cases to improve the interface testing."
Patient identification	• "Patient names on adjacent lines in the EHR display are visually distinct." • "Medical record numbers incorporate a "check digit" to help prevent data entry errors." • "Patients are registered using a centralized, common database using standardized procedures."
Test result and follow-up	• "After system changes in components or applications related to CPOE and diagnostic services, the data and data presentation are reviewed to ensure accuracy and completeness."

[a]EHR: electronic health record.

XSL•FO

Table . SAFER (Safety Assurance Factors for EHR[a] Resilience) guides recommended practices were most likely rated "not implemented" at the 6 hospitals.

SAFER guide	SAFER recommendation
Total of 8 "not implemented" recommended practices	
CPOE and DS[b]	• "Clinicians are required to re-enter their password, or a unique PIN, to "sign" (authenticate) an order." • "Users can access authoritative clinical reference materials directly from the EHR, including organization-specific information when available." • "Additional safeguards, such as double check by a second specialist, are implemented in the EHR before high-risk medications are prescribed."
Test result and follow-up	• "There is an EHR-based process for clinicians to either assign surrogates for reviewing notifications or enable surrogates to look at the principal clinicians' inboxes." • "There are mechanisms to forward results and results notifications from one clinician to another." • "The EHR has the capability for the clinician to set reminders for themselves and other responsible clinical staff for future tasks to facilitate test result follow-up."
Clinician communications	• "Electronic message systems include the capability to indicate the urgency of messages." • "The EHR displays time-sensitive and time-critical information more prominently than less urgent information."

[a]EHR: electronic health record.

[b]CPOE and DS: computerized provider order entry with decision support.

Discussion

Principal Findings

EHR implementation provides a valuable opportunity to optimize health care safety, services, procedures, processes, and outcomes [53]. The conducted assessment helps health care staff engage appropriately across various specialties and tasks to deliver better EHR safety, considering all relevant aspects. Data from the 6 hospitals were analyzed to evaluate the extent to which they have implemented the best recommended safety practices related to EHR adoption and usage, using the SAFER guides.

SAFER Scores Variability

The percentage of "fully implemented" recommended practices from the SAFER guides across participating hospitals showed significant variability, with an average implementation rate of 53%, as illustrated in Figure 1. For instance, the implementation rates ranged from 4% to 92% for the organizational responsibilities guide, 23% to 100% for the system configuration, and 0% to 58% for the clinician communication guide. While previous studies mention that hospital size, years of EHR adoption, and type of EHR implementation affect EHR safety [54,55], the findings indicate an imperfect relationship between these factors (hospital demographics; Table 1) and the scores of "fully implemented" SAFER-recommended practices, with no clear and consistent direct or inverse relationship.

Hospitals with longer EHR adoption periods generally perform better, but variations in safety outcomes suggest that experience alone does not fully determine EHR safety. Similarly, in this study, hospital size showed no clear correlation with SAFER scores, as medium and large hospitals exhibit differing results likely influenced by other factors. The type of EHR implementation (in-house or outsourced) also did not directly predict SAFER scores, as both types displayed wide variations in implementation levels.

Accordingly, this variability highlights the significance of hospital-specific factors in determining EHR safety effectiveness. More influential than demographic characteristics alone, these factors include available resources (human and financial), safety culture, technical capabilities, workflow integration, quality of staff training, implementation strategies, and leadership commitment. These critical elements significantly impact EHR safety outcomes and the extent to which EHR safety measures and recommended practices are implemented [54,56,57].

Infrastructure and Technical Focus

Out of the 165 recommended practices in the SAFER guides, only 16 (10%) were "fully implemented" by the participating hospitals. The researchers observed that all participating hospitals focus more on infrastructure and technical aspects across guides or domains. The implementation rate for infrastructure guides gets a higher mean percentage (75%), specifically system configuration (77%) and system interfaces (80%). In contrast, the clinical process guides had a much lower implementation rate of only 43%.

Additionally, the percentage of implemented recommended practices varied considerably across each different EHR-related patient safety domain. Domain 2—Using Health IT Safely,

XSL•FO
RenderX

which focuses on ensuring the effective and safe utilization of EHRs by health care staff and patients—had an implementation rate of only 45%. Meanwhile, Domain 1—Safe Health IT, which emphasizes the technical protection aspects of EHR structure and functionality, reached 66%. Hospitals tend to be technically oriented for several reasons. Technical aspects, such as systems configuration, interface management, and interoperability, are fundamental to EHR functionality [58-60]. A secure, reliable, and robust technical setup is essential for the health care system to prevent failures and errors that could disrupt clinical care. Studies have emphasized the importance of solid testing environments in determining safety and usability issues during the system implementation phases [61-63].

Furthermore, EHR vendors can influence the hospitals' technical orientation. Many hospitals rely on external technology vendors to implement, develop, and support their EHR systems [64,65]. However, these vendors often lack a deep understanding of the clinical intricacies of specific hospitals [66]. Instead, they prioritize technical capabilities and compliance standards—such as security, databases, interoperability, and system function and updates—that are directly manageable and required for system credentials and regulatory compliance with governmental regulations [67-69].

Moreover, hospitals may find that technical issues (eg, data security, usability, and privacy) are easier to address than clinical process issues (eg, clinician communication and workflow integration), particularly in the early test cases [70,71]. Technical adjustments are generally more straightforward to standardize, implement, measure, and audit, whereas clinical workflows are inherently more complex [72,73].

Lastly, there is a common misconception that technical stability, including a well-functioning EHR, guarantees health care safety [27,68]. Many hospitals assume that if their EHR system is secure, interoperable, and compliant, it will inherently be safe for health care staff use and patients [23,61,74,75]. Thus, hospitals prioritize technical improvements to avoid system failures and mitigate risks. However, these efforts alone cannot address other critical issues such as health care staff acceptance issues, communication breakdowns, and workflow discrepancies, which often pose more significant risks to patient safety [76-79]. Therefore, achieving EHR safety requires a comprehensive approach that addresses both technical and clinical process factors [80].

These factors contribute to the hospital's tendency toward technical over clinical processes for EHR safety, which can lead to neglecting the significant effects on clinical practices and patient care. Addressing both aspects of the health care system is necessary for a robust and effective safety setting [80,81].

Clinician Communication Challenges

Communication between health care staff, particularly clinicians, is a fundamental aspect of clinical processes encompassing critical tasks and decisions. Communication breakdowns can directly affect patient safety, leading to medical errors and patient harm [50,82]. The implementation rate for the clinician communication guide's recommended practices was the lowest across the hospitals, ranging from 0% to 58%. This guide often receives the lowest scores in EHR safety evaluations due to several factors. First, there is a lack of robust integration features for communication tools. For instance, disjointed messaging systems lead clinicians to rely on multiple platforms or external solutions, and fragmented data through EHR's various sections make it difficult to reach, particularly during clinical discussion communications [83].

Additionally, usability challenges, such as poorly designed interfaces and alert fatigue, impact the efficiency of clinician communication. Interfaces may include many steps or unclear options, making it difficult for clinicians to follow. An overabundance of notifications or irrelevant alerts may lead to ignored or missed important communications [25,84]. Moreover, inconsistent communication and time constraints lead to workflow misalignment, creating barriers to facilitating clinical workflows. EHRs are mostly designed for individual duties, prioritizing their development (eg, data or order entry and individual decision-making) rather than promoting collaborative communications between health care team members. EHR communication tools can increase clinicians' burden, conflicting with their time-sensitive workflow [85,86].

Furthermore, health care staff attitudes and knowledge gaps, such as a lack of awareness and resistance to change, contribute to communication challenges. Clinicians may not have adequate awareness of using EHRs due to insufficient onboarding or training in EHR communication features. Many clinicians find that the traditional methods (eg, phone calls and face-to-face discussions) are easier and more effective than using EHRs [85,87]. Lastly, interdepartmental and interdisciplinary communication processes face significant obstacles. The lack of communication tools that meet various requirements for multidisciplinary teams hinders effective communication, especially among nonphysician or specialist staff. Besides, data may not be easily accessible or shareable across systems or roles within the same hospital [87]. These challenges should be considered, addressed, and improved to integrate seamlessly and effectively into clinical workflows. Developing clinician communications within EHRs requires simplified interfaces, adequate integration of collaborative tools, practical training, and adjustable workflow regulations [85,87].

Comparison With Prior Work

Previous studies have applied SAFER guides as a methodology. A study evaluating 8 health care organizations in the United States found that, on average, only 18% of the 140 unique safety recommendations were fully implemented [49]. Adherence was higher in the Safe Health IT domain (82.1%) compared to Using Health IT Safely (72.5%) and Monitoring Health IT (67%). This aligns with our study's findings, where technical infrastructure showed higher adherence, emphasizing a common trend of prioritizing technical domains over clinical processes and communication.

On the other hand, another study introduced a self-assessment focused on the Computerized Provider Entry system, using 2 SAFER guides—the CPOE with DS guide and clinician communication guide—which were filled out by nursing students [43]. The study demonstrated that such a tool could effectively uncover usability and safety issues, particularly

XSL•FO
RenderX

medication ordering and visual display issues. It explored nursing students' experiences with EHR safety, highlighting the importance of education and training in promoting safe EHR use. This underscores the need for comprehensive training programs to enhance EHR safety practices, a factor that may contribute to variability in adherence observed in our study. While our study did not focus on CPOE systems, the emphasis on self-assessment tools aligns with our study approach of using SAFER guides to proactively identify and address EHR-related safety concerns.

Several factors may be considered for the observed differences between our study and previous studies. The stage of experience with the system and EHR adoption can influence the implementation of safety recommendations [23,88]. Likewise, organizational commitment to implementing safety practices and the diversity of cultural attitudes toward patient safety can lead to variability in adherence levels [89]. Additionally, health care system differences between the State of Kuwait and other countries, such as variations in health care priorities, infrastructure, and policies, can impact the implementation of SAFER-recommended practices [90]. Furthermore, resource availability can influence the capacity to effectively implement EHR safety practices, including differences in technical, human, and financial resources [91,92].

Recommendations

EHR safety encompasses organizational, clinical, technical, and behavioral dimensions, all of which are essential and interdependent in ensuring health care quality and patient safety [56]. Achieving EHR safety requires shared responsibility among interdisciplinary health care teams, fostering collaboration to enhance safety practices and integrate clinical and technical workflows seamlessly [44,87,93]. Additionally, promoting awareness of EHR safety through comprehensive and ongoing training for health care staff can improve their proficiency and confidence in using EHR systems [63].

Hospitals must also commit to regularly conducting proactive risk assessments, such as those outlined in the SAFER guides, to identify potential vulnerabilities in EHR safety practices. These assessments allow for the implementation of preventive measures, mitigating risks before adverse events occur and improving health care outcomes and patient safety. Proactive assessments can further foster interdisciplinary collaboration among HCPs by bringing together diverse expertise, supported by strong leadership to establish organizational priorities, promote workflow adaptability, and actively involve EHR vendors in optimization initiatives [51,78,94].

EHR vendors should gain a comprehensive understanding of clinicians' workflows and the broader operations of health care teams to design systems that integrate effectively into clinical processes [86]. Actively involving health care staff as EHR users is critical, as they can provide valuable feedback to identify areas for improvement, emphasizing the need for established channels for user input [95].

Although not widely available at the time the SAFER guides were first introduced, advanced technologies such as artificial intelligence (AI) and machine learning (ML) now offer significant potential to enhance EHR safety [96,97]. Early evidence suggests that these technologies can improve DS, streamline workflows, and reduce clinician burden, particularly through advanced data entry automation and error detection mechanisms [98]. However, their impact on EHR safety remains in the early stages of evaluation, and further research is required to comprehensively understand their effectiveness.

Integrating AI and ML into the SAFER guides could provide a proactive framework for assessing and mitigating risks associated with these technologies while optimizing their benefits for EHR safety. This integration would support health care organizations in identifying best practices for leveraging AI and ML to address safety challenges, such as improving data integrity, detecting potential errors, and enhancing user experience. Future studies should focus on the long-term impact of AI and ML in real-world clinical settings and provide evidence-based recommendations for their inclusion in SAFER guides, thereby advancing EHR safety and patient care.

Study Strengths and Limitations

As with any research, this study has both strengths and limitations. First, it represents the first empirical investigation into EHR safety practices in public hospitals outside the United States using the SAFER guides. The lack of similar international studies restricts opportunities for benchmarking and cross-context comparisons, limiting the ability to generalize findings beyond Kuwait.

Second, although the study included only 6 public hospitals, it effectively captured nearly the entire population of secondary care facilities in Kuwait, providing a comprehensive snapshot of this health care segment. One secondary hospital was excluded due to the absence of an EHR system and was replaced with a tertiary care hospital from the same region. While this maintained the sample size and focus on EHR-active facilities, it may have introduced variability, as tertiary hospitals typically differ in patient complexity, resource availability, and EHR usage. Future studies should stratify by care level and include tertiary and private hospitals to enhance generalizability.

Third, a significant limitation of the SAFER guides is the reliance on self-assessment, which may not always yield objective evaluations of EHR safety practices. Because the tool depends on health care staff to assess their own systems and processes, the accuracy of the results is influenced by participants' understanding, perceptions, and interpretations of the recommended practices. This self-reporting approach introduces potential biases, as participants may overestimate adherence to best practices or fail to identify existing deficiencies. Lastly, the differences in health care system regulations and policies between Kuwait and the United States may affect how SAFER scores are interpreted and applied.

Nonetheless, the SAFER guides offer a valuable framework for health care staff and hospitals to identify gaps, enhance EHR safety practices, improve workflow efficiencies, and achieve better health care outcomes. To address these limitations, future studies should consider incorporating complementary methodologies, such as external audits, qualitative interviews, and observational studies. These approaches can validate

XSL•FO
RenderX

findings from SAFER self-assessments, provide more objective evaluations, and yield deeper insights into the practical challenges and successes of implementing the recommended practices across diverse health care contexts. Additionally, studies focusing on the long-term impact of SAFER-guided interventions could assess improvements in patient safety and organizational efficiency, contributing valuable knowledge to the global discourse on EHR safety and optimization.

Conclusions

This study used the SAFER guides as a structured framework to conduct a proactive risk assessment of EHR safety practices in Kuwait's public hospitals. The findings reveal considerable variability in the implementation of recommended safety practices, with stronger adherence observed in technical and infrastructure-related domains compared to clinical processes and clinician communication. These results underscore the importance of addressing both technical and clinical dimensions to achieve a balanced and effective approach to EHR safety.

The study contributes to the growing body of literature on EHR safety by demonstrating the applicability of the SAFER framework in a non-US context. While the SAFER guides proved useful in identifying gaps and strengths in current practices, the results do not establish causal relationships between hospital characteristics and safety outcomes. Instead, they offer a foundational understanding of EHR safety implementation in Kuwait's public health care sector. The unique regulatory and operational characteristics of Kuwait's health care system necessitate tailored strategies for effective implementation. Future research should build on these findings through broader sampling, mixed methods approaches, and longitudinal assessments to evaluate the impact of targeted interventions on EHR safety and patient outcomes.

Acknowledgments

We would like to acknowledge the support of the Ministry of Health in facilitating the project and sincerely thank all study participants for their dedication to patient safety and their support in participating in the study. Grammarly Premium was used to review, edit, and improve the manuscript's language structure. This work encompasses a subset of the work originally submitted in partial fulfillment of the requirements for the Master's degree in Computing Information Systems at Kuwait University.

Data Availability

All data generated and analyzed during this study are included in this published article. However, some datasets are not publicly available due to privacy and confidentiality protections but may be obtained from the corresponding author upon reasonable request.

Authors' Contributions

AH acquired the data and played a played a pivotal role in coordinating the study activities. DA supervised the project, and designed and conceptualized the study. All authors analyzed and interpreted the results of the data. AH drafted the manuscript, and DA provided critical feedback. All authors reviewed and approved the final version of the manuscript.

Abstract

Background: The World Health Organization highlights the essential role of effective self-management in the prevention and control of chronic diseases, noting that proper self-management can significantly slow disease progression. Stroke, which ranks as the third leading cause of death worldwide, is often accompanied by inadequate self-management among patients. While health information literacy (HIL) has been shown to influence self-management in conditions such as diabetes and hypertension, its role as a mediating factor linking disease perception and health behavior in patients with stroke remains insufficiently explored. Addressing this research gap is vital for developing targeted interventions.

Objective: The aim of this study was to investigate the current status of HIL, stroke knowledge, and self-management abilities among patients with stroke in Southwest China. Additionally, the study analyzed the relationships among these three factors and their mechanisms of action, providing evidence to inform the development of effective health education strategies for enhancing self-management in patients with stroke.

Methods: A multicenter cross-sectional design was employed, enrolling 514 patients with stroke from the neurology departments of three tertiary general hospitals in Chengdu between September 2022 and March 2023. Data collection used a standardized set of scales: the health information literacy questionnaire for stroke assessed HIL, the stroke prevention questionnaire evaluated knowledge levels, and the stroke self-management assessment scale measured self-management abilities. Regression analysis and bootstrap mediation effect testing were conducted using SPSS software (version 26.0).

Results: Patients with stroke had a mean (SD) score of 17.61 (6.46) for stroke knowledge, 61.17 (13.58) for HIL, and 158.70 (19.07) for self-management skills. Correlation analysis indicated a positive correlation of stroke knowledge with both self-management (r=0.668; P<.001) and HIL (r=0.138; P<.001). The mediation test showed a significant mediating effect of HIL between stroke knowledge and self-management (β=0.543; 95% CI: 0.431 - 0.663), with an effect share of 82.77%.

Conclusion: There is a correlation between HIL and self-management; the higher the HIL, the better is the self-management behavior. Furthermore, HIL partially mediates the effect of stroke knowledge on self-management.

Introduction

Stroke is the leading cause of adult mortality worldwide, particularly among Chinese adults, with a rapidly increasing incidence, poor prognosis, mortality, and varying degrees of disability among survivors. This imposes a significant economic burden on patients' families and society [1,2]. Inadequate health information about stroke leads to delayed consultation and suboptimal prevention and control due to the lack of timely

XSL•FO
RenderX

disease-related relief [3]. Therefore, increasing the awareness of patients with stroke has a positive impact on the prevention and management of stroke. In particular for the population with poststroke dysfunction, low health information literacy (HIL) affects treatment and recovery and significantly reduces their quality of life. Research has shown that improving HIL in patients with stroke is crucial to promoting overall well-being, as it improves public understanding of health and disease and positively influences patients' self-management practices [4,5]. Effective self-management can motivate patients to improve unhealthy lifestyles, increase their ability to monitor their disease, improve adherence to treatment, and consequently improve their quality of life [6]. HIL combines the concepts of health literacy and information literacy; it focuses on an individual's ability to obtain, understand, and use health information and services, and to make appropriate judgments and decisions to maintain and improve their health [7,8]. Existing studies have primarily investigated the current status of HIL in patients with stroke, with less investigation into the possible mediating effect of HIL on knowledge levels and self-management skills [9-11]. Therefore, the aims of this study were to analyze the relationship between stroke knowledge, HIL, and self-management in patients with stroke, to examine the mediating effect of HIL, to provide new ideas for interventions to improve patients' self-management ability, and to target the implementation of health education for patients with stroke.

Methods

Setting and Samples

This was an observational, multicentere, cross-sectional study, which included hospitalized patients with stroke from September 2022 to March 2023 in the emergency and critical care center of tertiary hospitals in three stroke centers: West China Hospital of Sichuan University, West China Tianfu Hospital of Sichuan University, and West China Shangjin Hospital of Sichuan University. The patient recruitment process of this study strictly adhered to the ethical review requirements as follows: physicians initially screened eligible patients with stroke according to the inclusion and exclusion criteria of the study, and after obtaining preliminary consent from the patients, the research team conducted extensive face-to-face communication with the patients. The survey consisted of three main questionnaires, and each participant took approximately 15 - 20 minutes to complete all the questionnaires; all the participants' questionnaires were collected at once. Quality control measures were implemented during the data collection process, with researchers receiving uniform language training and participants being interviewed face-to-face and asked to complete the questionnaires independently. For patients who were unable to complete the questionnaire, the investigators asked the items neutrally and objectively to ensure the accuracy of the questionnaire.

The inclusion criteria were (1) stroke diagnosis based on computed tomography or magnetic resonance imaging results, (2) mental and physical fitness to participate, and (3) willingness to participate and cooperate. The exclusion criteria were (1) severe complications and loss of self-management, (2) associated with psychiatric disease or intellectual disability, (3) unwillingness to participate in the survey, or (4) participation in other research projects at the same time.

Variables and Instruments

Sociodemographic and Clinical Characteristics

Based on the characteristics of stroke and relevant studies [12,13], the general information form included socio-demographic and disease-related information. The socio-demographic information included age, gender, residence, marriage, living conditions (primary caregiver), education level, occupation, history of tobacco and alcohol consumption, and type of health insurance. Disease-related data included age at onset and first symptoms. All variables above were categorical, and complete data were obtained.

The Stroke Prevention Questionnaire

The Stroke Prevention Questionnairewas developed by Zhang [14] to assess stroke knowledge of patients with stroke and contains 36 items with 8 dimensions (Cronbach α=.791), including lifestyle, diet, exercise, knowledge of risk factors, medication, blood pressure monitoring, knowledge of stroke signs and stroke management. Each item was scored on a scale of 0 and 1, where 0 indicated "wrong answer" or "don't know" and 1 indicated a "correct answer." The total score ranged from 0 to 36; the higher the score, the better was the stroke outcome.

The HIL Questionnaire for Stroke

The HIL questionnairewas a specific HIL assessment tool developed by Yao [15] and included 5 dimensions of health information with 21 items, such as health information awareness (4 items), acquisition (4 items), comprehension (4 items), evaluation (6 items), and application (3 items). The scale followed a Likert-5 scale, with each item having a minimum score of 1 and a maximum score of 5. The total score ranged from 21 to 105, with higher scores indicating higher levels of HIL. The instrument showed good reliability. The overall Cronbach α of the scale was 0.915, and the Cronbach α of each dimension ranged from 0.745 to 0.878, indicating a better model fit index and high structural validity.

The Stroke Self-Management Assessment Scale

The stroke self-management assessment scale was developed by Wang [16] and consisted of 50 items in 7 dimensions, including disease management, medication management, diet management, daily life management, emotional management, social and interpersonal management, and rehabilitation management. The options were mostly "no," "occasionally," "sometimes," "often," and "always," with total scale scores ranging from 50 to 255. Higher scores indicated better self-management. The scale had a Cronbach α of 0.835, content validity of 0.95, and structural validity of 0.594 - 0.771. The scores of the different dimensions were compared using the standard score index. The formula for the standard score index = (the actual score of this dimension/the highest score of the dimension) × 100%. The standard score index of <60% indicated poor self-management, 60% - 80% indicated moderate self-management, and >80% indicated good self-management.

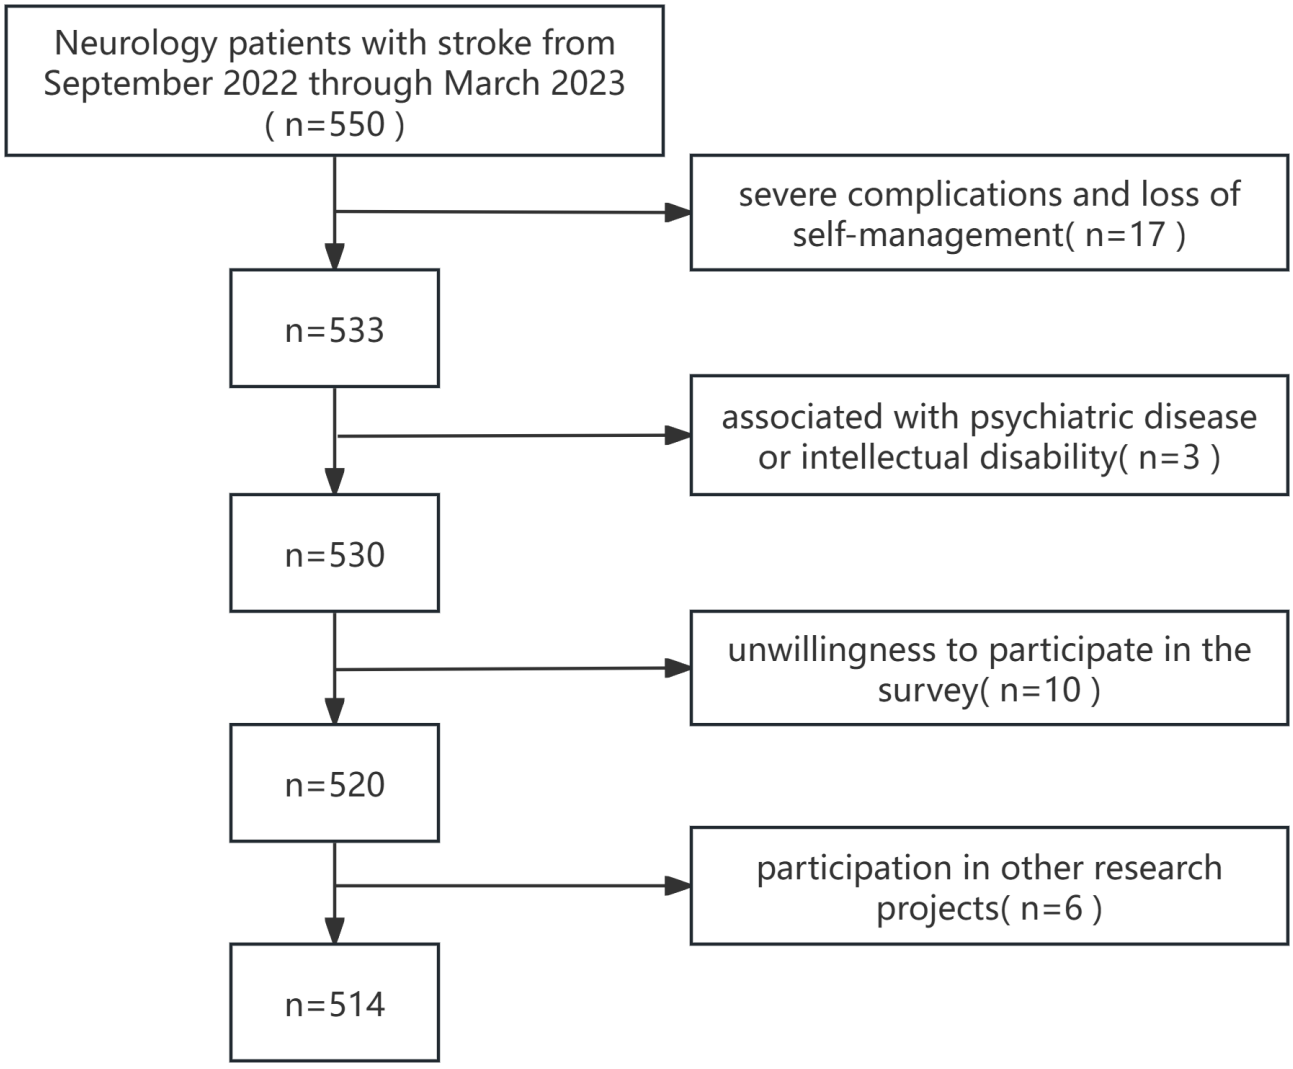
XSL•FO
RenderX

Data Analysis

SPSS software (version 26.0; IBM Corp) was used for data analysis, and Microsoft Excel spreadsheets were used for data entry. Quantitative data were expressed as mean (standard deviation), and comparisons between groups were made using *t* tests or one-way analysis of variance. Categorical data were expressed as proportions (%), and comparisons between groups were made using the χ^2 test. Regression analysis was performed to determine the relationship between HIL, stroke knowledge, and self-management. Regression analysis was also used to test whether HIL in patients with stroke mediated the relationship between stroke knowledge and self-management based on relevant analysis results. A *P* value <.05 was considered statistically significant.

Ethical Considerations

Prior to data collection, the study was approved by the Ethics Committee on Biomedical Research, West China Hospital, Sichuan University (2023 Review (688)). All participants provided consent to participate in the study on a voluntary basis, and the data were anonymized. No benefits or compensation were offered or given to any participant.



Results

Characteristics of Participants

A total of 550 stroke survivors were recruited and 514 valid questionnaires were recovered, with a valid recovery rate of 93.45%. The flowchart showing the inclusion and exclusion of patients is shown in Figure 1.

The general characteristics of the study participants are given in Table 1. Of the 514 participants, 338 (65.8%) were male and had a mean (SD) self-management ability score of 157.05 (18.78) points. Of the 514 participants, 465 (90.4%) of the participants were aged 50 - 85 years, among whom the minimum age of first stroke was 20 years. Furthermore, the distribution of residence locations revealed that the majority of the participants, 331/514 (64.4%), resided in urban areas, with a substantial proportion having completed middle school as their highest level of education (185/514, 36%). The initial incidence of stroke was predominantly observed among individuals aged 60 years and older.

Stroke Knowledge, HIL, and Self-Management Scores

The mean (SD) estimated stroke knowledge score of 514 patients with stroke was 17.61 (6.46) points, the mean (SD) total score on the HIL scale was 61.17 (13.58) points, and the mean (SD) total score on the stroke self-management assessment scale was 158.70 (19.07) points. The scores for each dimension are shown in Table 2.

Table . The scores of stroke knowledge, health information literacy (HIL), and self-management ($x \pm s$).

Variable and dimension	Dimension score, mean (SD)	Total score, mean (SD)
Stroke knowledge[a]		17.61 (6.46)
Lifestyle	4.14 (2.00)	
Exercise	1.74 (1.21)	
Diet	2.64 (1.30)	
Risk factors	1.76 (1.26)	
Medication	2.76 (1.14)	
Blood pressure monitoring	1.33 (0.70)	
Stroke signs	2.69 (1.45)	
Management	0.54 (0.75)	
HIL[b]		61.17 (13.58)
Awareness	12.76 (3.30)	
Acquisition	7.92 (2.95)	
Comprehension	10.64 (3.52)	
Evaluation	16.44 (4.79)	
Application	13.42 (1.94)	
Self-management[c]		158.70 (19.07)
Disease	20.54 (8.24)	
Medication	20.20 (2.97)	
Diet	30.53 (4.67)	
Daily life	31.61 (3.48)	
Emotion	18.98 (4.10)	
Social and interpersonal	19.98 (2.97)	
Rehabilitation	16.89 (5.63)	

[a]Stroke knowledge: actual score ranged from 4 to 35.

[b]HIL: actual score ranged from 26 to 97.

[c]Self-management: actual score scores ranged from 111 to 216.

Correlation Analysis (Stroke Knowledge, HIL, and Self-Management)

Table 3 shows the correlations between stroke knowledge, HIL, and self-management. Stroke knowledge was positively correlated with self-management (r=0.668, P<.001) and the HIL score (r=0.138, P<.001), while HIL was positively correlated with self-management (r=0.155, P<.001).

Table . Association between stroke knowledge, health information literacy (HIL), and self-management.

Variable	Self-management	HIL	Stroke knowledge
Self-management	1		
HIL	0.155[a]	1	
Stroke Knowledge	0.668[a]	0.138[a]	1

The Mediating Effect of HIL (Between Stroke Knowledge and Self-Management)

Based on the mediation effect testing process proposed by Wen and Ye [17], the theoretical model and rationale based on the construction by Tang and Wang [18] and Mao [19], a mediation model was established with self-management as the dependent variable, stroke knowledge as the independent variable, and HIL as the mediating variable. In the first step, regression analysis was performed, where stroke knowledge was the independent variable and self-management was the dependent variable, and the coefficient c was tested. In the second step, regression analysis was performed using stroke knowledge as the independent variable and HIL as the dependent variable, and the coefficient a was tested. In the third step, regression analysis was performed with stroke knowledge and HIL as the independent variables and self-management as the dependent variable, with coefficients b and c. The results showed that coefficients a, b, and c were significant, indicating a partial mediating effect of HIL between stroke knowledge and stroke self-management behaviors. Details are shown in Table 4.

Table . Mediating effect of health information literacy (HIL) on stroke knowledge and self-management.

Step	Dependent variable	Independent variable	Coefficient	Standardized β coefficient	*t* test[a] *(df)*	*P* value	Adjusted R^2
1	Self-management	Stroke knowledge	c	1.199	16.87 (1)	<.001	0.356
2	HIL	Stroke knowledge	a	1.957	14.622 (1)	<.001	0.293
3	Self-management	HIL	b	0.277	13.849 (2)	<.001	0.531
		Stroke knowledge	c	0.656	9.084 (2)	<.001	

[a] The t test was 2-tailed

Testing the Mediating Effects of HIL

The bootstrap mediation test was conducted using SPSS software (version 26.0). The bootstrap method is a repeated sampling method that treats the original sample as a whole, extracts a large number of new subsamples by repeated sampling with replacement, and obtains statistics. The 95% CI was calculated by repeating the sample 5000 times. The bootstrapped 95% CI for the overall effect of the model did not include a value of 0 (β=1.199, 95% CI 1.059, 1.339). The direct effect of stroke knowledge on self-management in terms of bootstrap 95% CI did not include a value of 0 (β=.656, 95% CI 0.514, 0.798). The mediated effect path was stroke knowledge, followed by HIL, and finally self-management, and the bootstrap 95% CI for its indirect effect did not include a 0 value (β=.543, 95% CI 0.431, 0.663), indicating a significant mediating effect of HIL between stroke knowledge and self-management (Table 5). The mediation pathway is detailed in Figure 2.

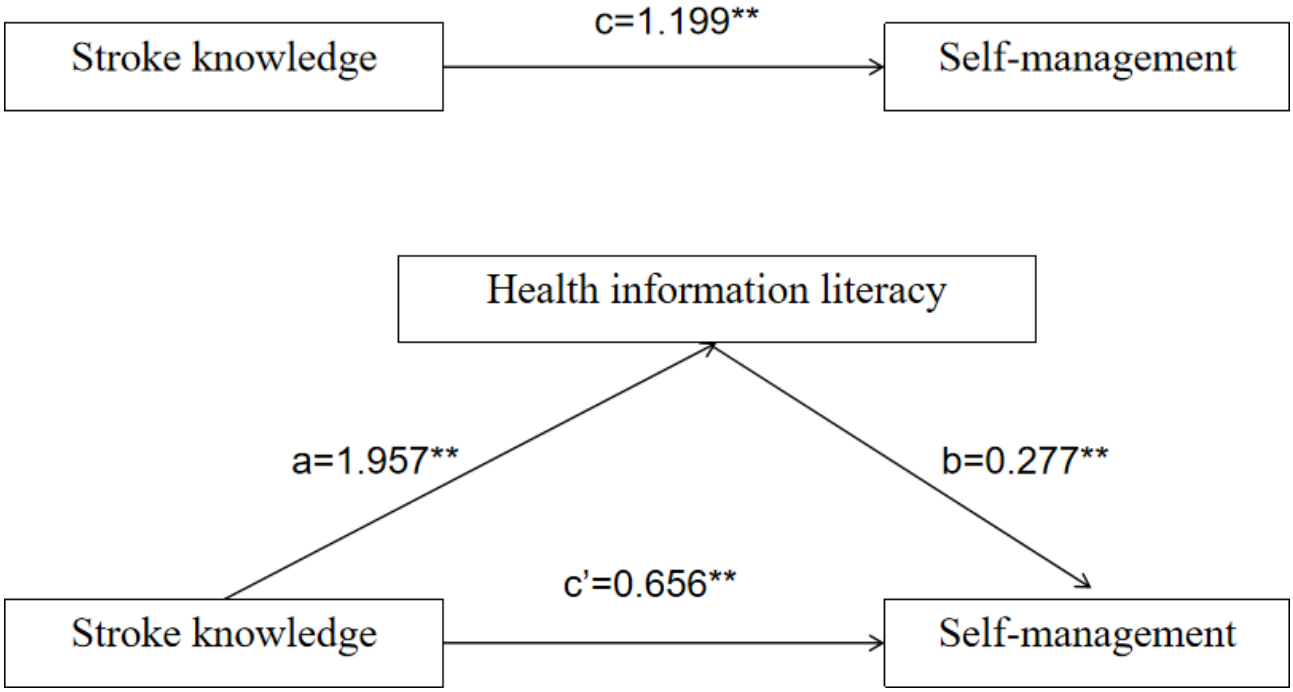

Table . Significance test of the mediating effect of health information literacy (HIL) on stroke knowledge and self-management.

Effect size	Effect	SE	*t* test *(df)*	*P* value	95% confidence limits
Overall effect	1.199	0.071	*t*=16.870 (512)	＜.001	1.059, 1.339
Direct effect	0.656	0.072	*t*=9.085 (511)	＜.001	0.514, 0.798
Indirect effect	0.543	0.058	—[a]	—	0.431, 0.663

[a]not applicable.

Discussion

Principal Findings and Comparison With Previous Works

There was a positive correlation between stroke knowledge, HIL and self-management. Using the Bootstrap test, the total effect, indirect effect, and direct effect of stroke knowledge on self-management were estimated to be 1.199, 0.543, and 0.656, respectively. The 95% CI did not include 0, indicating the significance of the total effect, indirect effect, and direct effect. This indicates that HIL partially mediates the relationship between stroke knowledge and self-management behavior; stroke knowledge and HIL can directly influence the level of self-management in patients with stroke. Stroke knowledge may also indirectly affect the self-management in patients with stroke through the partial mediating effect of HIL; the direct effect was larger than the indirect effect in this study.

The mean (SD) total knowledge level score of patients with stroke was 17.61(6.457), with the highest score in the dimension of lifestyle, and the lowest score in the knowledge of emergency measures for stroke, which was overall moderate. This result was slightly lower than that reported in other studies [20,21], which was related to factors such as differences in the patients' educational level and residence in the western region. This study mainly focused on elderly patients with primary and junior high school education, who have relatively weak learning and adaptation abilities [22]. The mean (SD) HIL score of the patients with stroke was 61.17 (13.58), with the highest health information evaluation score and the lowest health information access score among the dimensions, a result consistent with the findings by Wang et al [23]. Although patients with stroke had moderate levels of HIL, they lacked the ability to access high-quality health information. The mean (SD) total self-management score of patients with stroke was 158.7 (19.07) points, which was moderately low, lower than the survey results obtained by Zhou et al [21] but higher than that obtained by Huang et al [24], with the highest score for daily life management and the lowest score for rehabilitation and exercise management among the dimensions. This may be due to a general lack of knowledge about stroke and self-management skills among first-time patients with stroke and their families. Previous studies have shown substantial enhancements in self-efficacy, activities of daily living, and health-related quality of life in patients with stroke following the implementation of self-management interventions [25-27]. Consequently, it is imperative to enhance the self-management competencies of patients with stroke.

A positive correlation was identified between stroke knowledge, HIL, and stroke self-management behaviors. Sufficient knowledge about stroke is a necessary but not sufficient condition for establishing self-management behaviors. In this study, stroke knowledge had a direct effect on self-management, suggesting that the accumulation of more relevant knowledge about stroke disease or treatment and care may directly encourage such patients to adopt healthy coping behaviors and develop good habits. This was also observed by Fisher et al [28], who suggested that information may have a direct impact on behaviors in situations where novel behavioral skills or complex transformation processes are not required in prevention or self-care processes. Self-management is the process of translating professional knowledge guidelines into daily life [29,30]. The ability to obtain health information in HIL directly affects the level of stroke knowledge of an individual. Patients with lower levels of education have restricted access to information due to their limited reading and comprehension skills [18,31]. Health educators can provide more direct knowledge about stroke management through effective health education, such as hospital education, community health lectures, and health manuals. In community education, as shown

XSL•FO
RenderX

in the study by Yang et al [32] and Singh et al [33], community-based group rehabilitation and culturally relevant education are effective in improving patients' quality of life, HIL, and self-management.

HIL is the influencing factor of self-management behaviors. The higher the level of HIL, the more health information is sought, thus promoting more active self-management behaviors [18,22]. However, simple accumulation of knowledge does not necessarily lead to changes in self-management behaviors [34,35], that is, knowledge is not necessarily successfully translated into self-management behaviors. With the COM-B model [36], we can see that the translation of knowledge into behaviors also depends on the ability of patients to recognize the importance of this knowledge. This also depends on their ability to appropriately evaluate the applicability of the knowledge and apply it to health behaviors decisions, and involves a distinction between "knowing knowledge" and "whether to do it." Stroke self-management is a process that is highly dependent on individual health decision-making, and a weak ability to evaluate information may lead patients to engage in unhealthy behaviors [37,38], in line with the health empowerment theory model. For example, patients who are aware of stroke warning signals may not necessarily respond quickly and take appropriate coping measures, thereby missing the best time for rescue and treatment of the condition. Patients with varying degrees of HIL have unique needs regarding self-management educational content [4,39]. Health professionals must direct their focus towards the older population and those with low literacy levels within their clinical practice, using the HIL scale dimension score to identify patients' deficiencies and take the individual circumstances of patients into account when formulating a rehabilitation, exercise, and follow-up program as well as self-management education content that is both realistic and patient-centred.

Good HIL means that individuals are aware of the importance of health information and their performance in evaluation and applicability is more pronounced. Good HIL also helps patients to accumulate knowledge about stroke and to make full use of self-management knowledge in health decision-making. As posited by Alzayer et al [40], concerted efforts must be made to enhance awareness and educate the public. These measures ought to be initiated at the outset in order to enhance the HIL level of patients with stroke, facilitate the transformation of knowledge pertaining to stroke into self-management behaviors, and improve the self-management effect of affected patients to ensure optimal treatment outcomes.

Limitations

Some limitations of this study include the lack of control trials in healthy individuals. Only a population from three hospitals was included, and patients with stroke in the community were not included. The self-report instrument and convenience sampling method may have potential response bias. In addition, this study was a cross-sectional study and could not explore possible causal relationships. Further research should be performed in other regions to confirm and explore intervention studies.

Conclusions

The self-management of patients with stroke was found to be at a moderate to low level and needs further improvement. There is a correlation between HIL and self-management in various items; the higher the HIL, the better were the self-management behaviors. In addition, HIL is a mediating factor between stroke knowledge and self-management behaviors and can effectively promote the translation of knowledge into behaviors.

Abstract

Background: Improving processes regarding the management of electronic health record (EHR) requests for chronic antihypertensive medication renewals may represent an opportunity to enhance blood pressure (BP) management at the individual and population level.

Objective: This study aimed to evaluate the effectiveness of the eRx HTN Chart Check, an integrated clinical decision support tool available at the point of antihypertensive medication refill request, in facilitating enhanced provider management of chronic hypertension.

Methods: The study was conducted at two Mayo Clinic sites—Northwest Wisconsin Family Medicine and Rochester Community Internal Medicine practices—with control groups in comparable Mayo Clinic practices. The intervention integrated structured clinical data, including recent BP readings, laboratory results, and visit dates, into the electronic prescription renewal interface to facilitate prescriber decision-making regarding hypertension management. A difference-in-differences (DID) design compared pre- and postintervention hypertension control rates between the intervention and control groups. Data were collected from the Epic EHR system and analyzed using linear regression models.

Results: The baseline BP control rates were slightly higher in intervention clinics. Postimplementation, no significant improvement in population-level hypertension control was observed (DID estimate: 0.07%, 95% CI −4.0% to 4.1%; *P*=.97). Of the 19,968 refill requests processed, 46% met all monitoring criteria. However, clinician approval rates remained high (90%), indicating minimal impact on prescribing behavior.

Conclusions: Despite successful implementation, the tool did not significantly improve hypertension control, possibly due to competing quality initiatives and high in-basket volumes. Future iterations should focus on enhanced integration with other decision support tools and strategies to improve clinician engagement and patient outcomes. Further research is needed to optimize chronic disease management through EHR-integrated decision support systems.

(JMIR Med Inform 2025;13:e70752) doi:10.2196/70752

KEYWORDS

clinical decision support systems; population health; hypertension; electronic health records

Introduction

The contemporary electronic health record (EHR) enables patients and pharmacies to request chronic medication renewals, which comprise significant in-basket volumes that primary care teams must address. Typical EHR renewal request interfaces provide clinicians with limited information when addressing the refill request [1]. For patients not seen recently, it takes time for conscientious clinicians to review relevant electronic data to ensure that the requested renewal is appropriate for that patient's care plan. Ideally, physicians or a staff member would always review relevant data, including the date of the last clinician visit, presence of up-to-date laboratory monitoring, and prior documentation, to confirm that the medication is appropriately addressing important outcomes such as blood pressure, blood glucose, or cholesterol control [2]. However, in the context of rapidly increasing in-basket volumes, such diligence is unlikely in the absence of a supportive system, as

XSL•FO
RenderX

primary care providers (PCP) struggle to "get through one's in-basket" [3].

The EHRs have long been recognized as powerful tools that can provide real-time decision support to assist clinicians in cognitively demanding and tedious tasks. Examples of clinical decision support integrated into EHR medication prescription platforms include alerts when prescribing medications to which a patient may be allergic, medications that may have an unsafe interaction with another prescribed medication, and medications that would generate significant out-of-pocket costs for the patient [4-6]. Hypertension, the most common chronic condition treated in primary care [7], has shown that EHR-integrated applications, as described by Funes et al [8], can improve clinician workflows in chronic disease management. In addition, the American Heart Association and the American Medical Association have called upon primary care teams to better leverage protocols and team-based care to improve hypertension control [9]. This study is particularly timely, as the management of hypertension when patients are not in the office is becoming increasingly relevant for quality reporting and reimbursement [10]. As more health care systems transition to value-based payment [11], the management of uncontrolled hypertension will become a higher priority in clinical practice. Given this context, prescription renewal requests provide a valuable opportunity for the primary care team to ensure safe prescribing practices and improved management of this difficult-to-treat condition.

In this study, we describe the implementation and evaluation of an EHR-integrated clinical decision support tool, eRx HTN Chart Check, which incorporates relevant structured data necessary for monitoring hypertension management into the prescription renewal request interface. We aimed for this tool to improve care provided to both individual patients with hypertension and population-level control of hypertension.

Methods

Study Setting: Mayo Clinic Health System, Northwest Wisconsin and Mayo Clinic, Rochester, MN

The division of Family Medicine, Mayo Clinic Health System (MCHS)-Northwest Wisconsin (NWWI) employs 108 providers, including 80 physicians and 28 advanced practice providers (APPs), caring for approximately 96,000 patients in 11 primary care clinics across a five-county area centered around Eau Claire, Wisconsin. The Mayo Clinic division of Community Internal Medicine (CIM) in Rochester Minnesota, employs 75 PCPs (60 physicians, 15 APPS) caring for 35,000 patients at 5 primary care sites within a 40-mile radius of the community of Rochester, MN. Both sites are part of Mayo Clinic, a not-for-profit health care system providing both "destination" care for serious and complex issues and primary care for local communities.

The control groups consisted of the Department of Family Medicine in Southeast Minnesota, which employs 57 physicians and 88 APPs who care for 115,000 patients, and the Department of Internal Medicine in MCHS-Southwest Wisconsin, which employs 7 physicians and 3 APPs who care for 7,000 patients. All primary care practices included in this study have designated the management of uncontrolled hypertension as a quality management priority during the intervention period.

eRx HTN Chart Check Project and Team

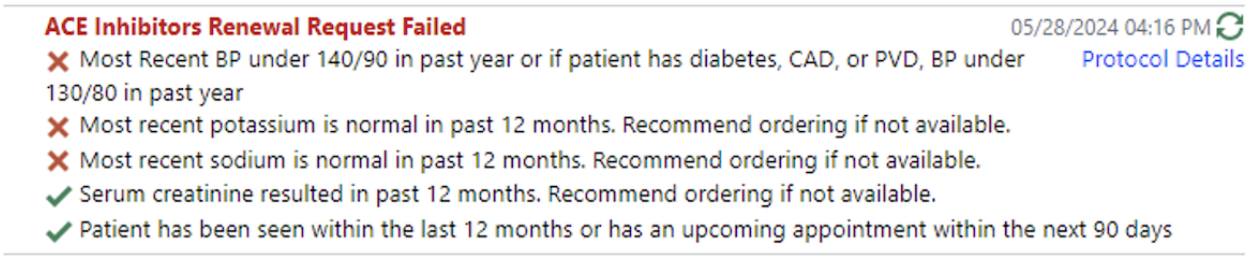
Before the eRx HTN chart check project, automated prescription renewal requests were sent directly to PCPs through the EHR in-basket without additional clinical information. Specifically, refill requests did not include relevant clinical information such as the patient's most recent blood pressure, most recent office visit, or relevant laboratory results.

In January 2022, a multidisciplinary team representing Mayo Clinic campuses in Rochester, MN, and Mayo Clinic Health System-NWWI was assembled. The project team aimed to integrate clinical decision support into the electronic prescription renewal process to improve clinical efficiency, provider experience, and the quality of care provided. The project team included a project manager, 3 physician leaders from the two participating sites, nursing leaders, a pharmacist informaticist, and a practice administrator.

Hypertension Chart Check Protocol Development

Internal EHR user data showed that PCPs spent significant in-basket time reviewing and approving chronic prescription medications. Antihypertensive medication renewals were selected as the initial target for integrated clinical decision support, given the importance of hypertension management in population health and the need for an interface to facilitate an efficient review of relevant clinical information. This included hypertension control, the date of the most recent office visit or blood pressure reading on file, and appropriate laboratory monitoring for specific medications.

The eRx HTN Chart Check integrated key clinical data (BP readings, visit dates, and laboratory results) directly into the prescription renewal interface. A pass/fail grading system flagged values based on predefined thresholds: BP readings from the past 24 months and laboratory results from the past 12 months. A detailed view, available to the clinician via hyperlink, displayed up to three recent values, with standing laboratory orders and future laboratory orders. For patients without an active hypertension diagnosis, the system excluded recent BP readings, and for those of childbearing age, it ensured no positive pregnancy test within the past 12 months.



The team, with selective input from Mayo Clinic experts and practice resources, determined appropriate monitoring and developed protocols for commonly prescribed classes of antihypertensive medications (Multimedia Appendix 1). The pass/fail criteria were determined through an iterative process involving a multidisciplinary team of physician leaders, pharmacists, nursing informaticists, and EHR specialists. Criteria were based on established clinical guidelines for hypertension management, including recommended monitoring intervals for BP measurements and laboratory assessments for antihypertensive medication safety. Adjustments were made based on Mayo Clinic expertise coupled with historical prescribing patterns to balance clinical rigor with practical usability. While no formal external validation was conducted, the criteria were aligned with national guidelines and vetted

XSL•FO
RenderX

through internal stakeholder feedback to ensure clinical appropriateness.

After completion of medication selection and protocol development, relevant discrete data for the medication renewal protocol were converted into a visual pass/fail display, which would appear directly below the renewal request message (Figure 1).

Figure 1. Pass/fail display in renewal requests. This figure illustrates how the eRx HTN Chart Check tool presents structured clinical data within the prescription renewal interface. Green checkmarks (✔) indicate that the required clinical data (e.g., recent BP reading, appropriate laboratory monitoring) meet predefined thresholds; red marks ( ) flag missing or outdated data, prompting clinician review before approving renewal.

Preimplementation efforts (April 2022) included clinician presentations and educational materials. The tool was launched at MCHS-NWWI on July 15, 2022, and at Rochester CIM on August 1, 2022. No modifications were made postimplementation, but periodic clinician meetings reinforced tool usage.

The eRX HTN Chart Check tool was adopted across both practice environments with minimal levels to workflows. Some physicians raised concerns about whether the eRx HTN Chart Check failure implied an expectation that the physician was responsible for addressing outstanding items. Clarification was provided to clinician teams that this was not the intent; rather, the information was presented only for the prescribing physician's awareness. In our subjective experience, most clinicians impacted by the change found the additional information available to be helpful in efficiently completing these renewal requests, although this finding was not quantitatively evaluated.

Study Design and Sample

We evaluated our eRx HTN Chart Check intervention using a DID design. The outcomes in the intervention group were collected through monthly hypertension control metrics, spanning 6.5 months before and 5.5 months after the intervention's implementation period, which occurred between June and August 2022. The specific dates of the intervention timelines are outlined in Table 1. The DID design allows estimation of the intervention effect by comparing the change in outcomes over time between the intervention group relative to the control group, accounting for secular trends. Visual inspection of these trends indicated similar trajectories, supporting the validity of the parallel trend's assumption. Additionally, no significant interaction between time and group was observed in the preintervention period when tested using regression analysis, further reinforcing this assumption. No patients or prescribers at either intervention or control sites were excluded.

Table . Timelines for baseline data collection, intervention implementation, and postimplementation data collection. The intervention was implemented sequentially at different sites, with clinician education provided before each launch. Postimplementation surveillance included monitoring clinician engagement and assessing hypertension control trends.

Study phase	Timelines for data collection	Intervention group	Control group	Activities

Ethical Considerations

The Mayo Clinic Institutional Review Board deemed this project as a quality improvement initiative and exempted it from formal review. All data were maintained on encrypted, password-protected systems behind the organization's firewall, with access limited to authorized project team members only. No patient identifiers were retained in the final analysis or manuscript, and all reporting is based on deidentified, aggregate

XSL•FO
RenderX

information to ensure confidentiality and compliance with institutional privacy standards.

Primary Outcomes

The primary outcome was the average percentage of patients with a recorded BP reading of <140/90 before and after the study period. This BP target of <140/90 was selected in accordance with the Minnesota Community Measurement program and National Quality Foundation standards [12,13]. The 6-month follow-up period for outcome assessment was chosen to allow the prescriber to evaluate the possible impact of subsequent BP management after an antihypertensive prescription refill request.

Secondary Outcomes

Secondary outcomes reflect measures related to antihypertensive refill volumes and the rates of clinician approval for medications prepared via the eRx HTN Chart Check protocol.

Data Sources and Analysis

The unit of analysis for the primary outcome was all eligible patients within each practice who had a formal diagnosis of hypertension in the EHR, compatible with definitions of the Minnesota Community Measurement program's definitions [12]. For secondary outcomes, the unit of analysis included patients whose eRx HTN Chart Check renewals were completed during the study period. We ascertained patient-level data on hypertension control through an internal EHR data platform used for quality improvement. We extracted eligible prescription renewal encounter data from the Epic EHR Cogito resources [14] (Workbench, SlicerDicer, and direct data queries with either internal or external visualization tools) to determine clinician response rates to eligible chart check encounters.

Statistical Methods

To assess changes in BP control across practices, we calculated the proportion of all eligible patients with a recorded BP at treatment goal (<140/90) within the preceding 12 months, consistent with National Quality Foundation guidelines [13]. We calculated these proportions by both study period and group and conducted a DID analysis using aggregated clinic-level proportions as the dependent variable and exposure to the intervention as the independent variable. We calculated the between-group differences using a linear regression model to adjust for the clustering of data within clinics. The model included fixed effects for time and group to control for baseline differences and time trends. The intervention effect was reported as the mean difference in proportions, with 95% CIs and *P* values. Statistical significance was defined as $P<.05$, and analyses were performed using Blue Sky Statistics (version 10.3.4; BlueSky Statistics LLC). Secondary outcomes were analyzed using descriptive statistics.

Results

Baseline Characteristics of Intervention Patients

We identified 15,591 patients in the NWWI division of Family Medicine and 11,766 patients in the Rochester CIM cohort in our baseline dataset. Relevant study characteristics are included in Table 2.

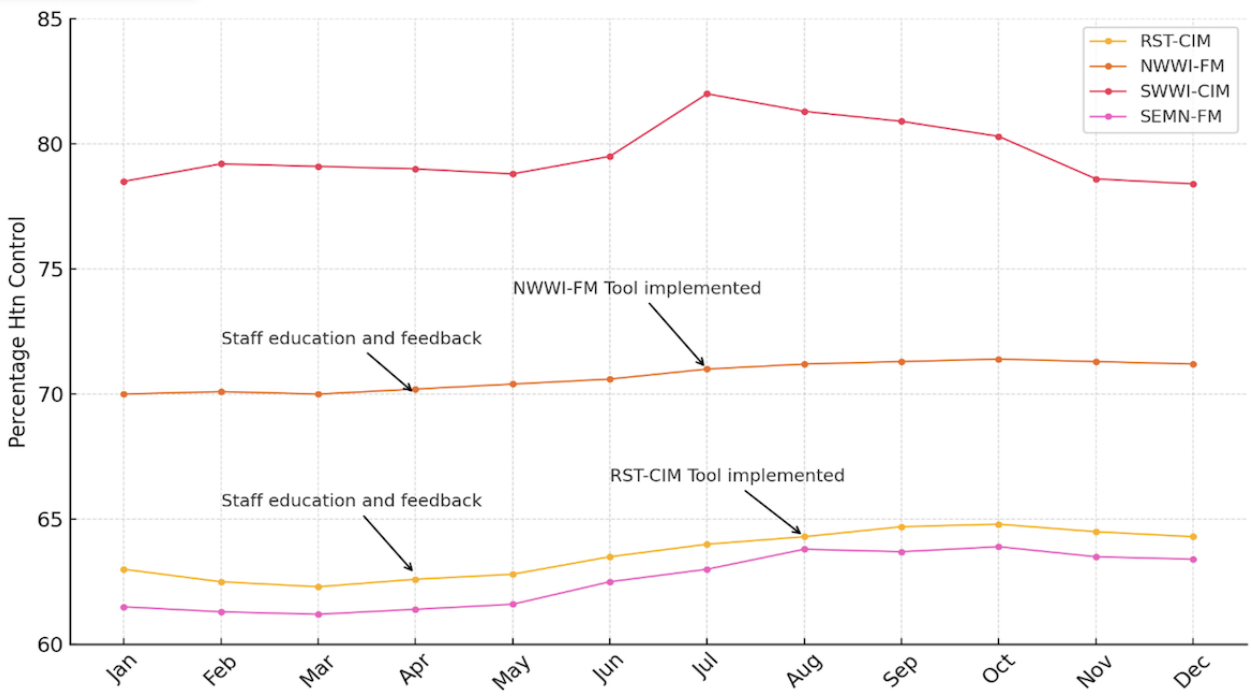
Table . Baseline preintervention patient characteristics.

Clinical site	Patients with essential hypertension (n)	Average number of total medications	Eligible patients taking antihypertension medication (N=15,591), n (%)	Average number of antihypertension medications (n)	Average age (years)	White patients, n (%)	English-speaking patients, n (%)	Smoker patients, n (%)
NWWI-FM[a]	15,591	11.6	14,439 (93)	2.1	66	15,159 (97)	15,441 (99)	1766 (11.3)
RST-CIM[b]	11,766	13.1	10,709 (91)	1.7	69	15,314 (88)	16,393 (94)	1096 (9.3)
SWWI-CIM[c]	3368	14.1	3154 (94)	2.1	70.9	3267 (97)	3354 (99)	242 (7.2)
RST-FM[d]	24,782	11.8	22,166 (89)	1.8	61.2	22,303 (90)	24,073 (97)	1437 (5.8)

[a]NWWI: Northwest Wisconsin-Family Medicine.

[b]RST-CIM: Community Internal Medicine.

[c]SWWI: Southwest Wisconsin-Family Medicine.



[d]RST-FM: Family Medicine.

We then performed a DID analysis to evaluate the impact of eRx HTN Chart Check implementation on clinic-level compliance proportions. The baseline compliance proportion was higher in the intervention clinics compared to the control clinics (difference: 3.32%, 95% CI 0.5%-6.2%; *P*=.02). Across all clinics, there was no significant change in compliance proportions from the baseline to the intervention period (difference: 1.29%, 95% CI: −1.6% to 4.2%; *P*=.37). The DID estimate, reflecting the interaction between intervention group and time period, was not statistically significant (difference: 0.07%, 95% CI −4.0% to 4.1%; *P*=.97). These findings suggest that the intervention did not result in a significant additional improvement in compliance proportions compared to the control group.

Figure 2 presents a line chart depicting BP changes before, during, and after the intervention across all analyzed patient cohorts. No significant DID was observed in compliance proportion changes between groups over the study period.

Secondary Outcomes: Chart Check Completion Rates and Subsequent Blood Pressure Re-Measurement

Secondary outcomes are displayed in Table 3. A total of 19,968 refills for antihypertensive medications were completed through the eRx HTN Chart Check process during the study period. Among these, 9,256 (46%) prescriptions "passed" or had all current monitoring information (Figure 2) available at the time of renewal.

Table . Secondary outcomes.

Clinical site	Refills submitted via chart check (n)	Number of refills "passed protocol", n (%)	Refills approved by clinician, n (%)
NWWI-FM[a]	10,771	5018 (47)	9225 (86)
RST-CIM[b]	9197	4238 (46)	8748 (95)

Discussion

Principal Findings

In this evaluation of the implementation of the eRx HTN Chart Check tool, we found that its use was not associated with significant improvements in population-level hypertension control when compared with practices in the same health care system that were unexposed to the intervention. While the eRx HTN chart check tool identified that approximately 50% of patients requesting prescription renewals had incomplete hypertension management parameters, most prescriptions were still filled, suggesting that this tool may not have significantly changed prescriber behavior.

There are several possible explanations that may account for why the eRx HTN Chart Check intervention did not result in improved population-level hypertension control compared with unexposed practices, as hypothesized. First, the management of hypertension was a concurrent quality priority across all health care system sites at the time of this intervention, and several ongoing efforts for patient outreach and enhanced office care and blood pressure rechecks. These efforts were already underway, including efforts to better capture home BP readings in the EHR and proactive follow-up for patients with hypertension, among others. Given the heightened awareness of hypertension management, clinicians may have relied on other interventions to address hypertension management rather than the eRx HTN Chart Check tool, which may have been used primarily to ensure appropriate medication monitoring. Additionally, changes in clinical guidelines, medication costs, insurer coverage, increasing telehealth utilization, and health care consumerism could have played a role in shaping hypertension outcomes independent of our intervention. While the DID analysis adjusted for baseline differences and time trends, the presence of multiple simultaneous initiatives limited our ability to isolate the specific impact of the eRx HTN Chart

XSL•FO
RenderX

Check intervention. Second, in the post-COVID period, primary care in-basket volumes increased substantially across our practice and other clinics nationwide [15]. This increased workload may have resulted in less clinician attention being allocated to prescription renewal requests. This premise is supported by the remarkably prescription approval rates reported in our secondary outcomes, suggesting that time constraints may have led clinicians to prioritize efficiency over detailed clinical review when addressing these requests. Third, the eRx HTN Chart Check intervention only appeared for refill requests that originated from the pharmacy, meaning it may not have effectively captured or been applied to all prescription renewal requests, including those sent directly from patients, thereby limiting the overall reach of this intervention.

This study applies a novel EHR clinical decision support (CDS) tool aimed at promoting chronic disease management through extant processes of routine medication renewals. The successful implementation of the eRx HTN Chart Check tool demonstrates that routine care processes such as chronic disease medication renewals can present opportunities for the integration of clinical decision support and current clinical workflows, as well as standardizing the information gathered across sites in a group practice. The eRx HTN Chart Check tool can be enhanced, adapted, and combined with other interventions to address important population health priorities such as control of hypertension. Additionally, other important outcomes, such as prescribing safety, appropriate monitoring, care escalation, patient engagement, provider satisfaction, and cognitive load should be explored in subsequent assessments of integrated CDS in the contemporary primary care setting.

This study is subject to the typical limitations of this study design, including the possibility of selection bias due to lack of randomization, regression to the mean, the Hawthorne effect, and time-related biases such as misattribution. These limitations were significantly mitigated by the inclusion of similar control groups practicing in comparable environments and with similar quality priorities. However, it is important to note that the findings may have limited generalizability due to the geographic, health care system, and patient population characteristics of the included sites. In health care systems with fewer resources, different clinician workflows, or alternative staffing models, the adaptation of this tool may vary. Additionally, patient populations served by community health centers or safety-net institutions may have different levels of medication adherence and follow-up needs. Therefore, future research should evaluate how this tool functions in other nonintegrated health care settings. Moreover, while our primary outcome focused on population-level hypertension control, we did not examine patient-level variables that could influence blood pressure outcomes, such as medication adherence, follow-up visit rates, or patient-reported measures of disease burden. These factors are critical in understanding hypertension management but were not captured in our dataset, which was limited to structured EHR-derived clinical data. Future research should incorporate patient-centered metrics—including follow-up care, medication adherence, and qualitative assessments of patient and provider experiences—to provide a more comprehensive evaluation of CDS interventions in chronic disease management.

Future efforts should be closely tied with other team-based efforts to maximize efficiency and leverage important patient touchpoints, such as prescription renewals, to improve care delivery and standardize practices enabling cross-clinic site support. Machine learning and artificial learning may serve as valuable future enhancements in potentially aiding clinicians in targeted interventions [16]. Additional efforts are needed to understand how organizations can optimally support PCPs in using valuable tools such as the eRx HTN Chart Check. Additionally, further alignment between add-on tools such as the eRx HTN Chart Check and other CDS tools such as Practice Advisories, Health Maintenance Navigators, and outreach platforms should be encouraged. This alignment would ensure a uniform approach, easier maintenance, and facilitate seamless updates as guidelines and protocols change.

Conclusion

In this controlled pre-post study evaluating the implementation of a CDS tool for antihypertensive medication refill requests, we found that implementation of this tool into existing workflows did not improve population-level BP control compared with groups unexposed to the intervention. Despite the lack of significant improvements in hypertension control, this study highlights the potential for EHR-based decision support tools to impact chronic disease management. Aligning the eRx HTN Chart Check with other EHR-based interventions such as automated patient outreach, remote BP monitoring integration, and machine learning may improve its utility and adoption. Future research should explore multimodal decision support strategies, clinician education initiatives, and the impact of interoperability with broader population health tools to optimize hypertension management in diverse clinical settings. Future research should focus on optimizing these interventions, exploring alternative implementation strategies, and expanding their application to other chronic conditions.

Abstract

Background: Integrated clinical databases from national biobanks have advanced the capacity for disease research. Data quality and completeness filters are used when building clinical cohorts to address limitations of data missingness. However, these filters may unintentionally introduce systemic biases when they are correlated with race and ethnicity.

Objective: In this study, we examined the race and ethnicity biases introduced by applying common filters to 4 clinical records databases. Specifically, we evaluated whether these filters introduce biases that disproportionately exclude minoritized groups.

Methods: We applied 19 commonly used data filters to electronic health record datasets from 4 geographically varied locations comprising close to 12 million patients to understand how using these filters introduces sample bias along racial and ethnic groupings. These filters covered a range of information, including demographics, medication records, visit details, and observation periods. We observed the variation in sample drop-off between self-reported ethnic and racial groups for each site as we applied each filter individually.

Results: Applying the observation period filter substantially reduced data availability across all races and ethnicities in all 4 datasets. However, among those examined, the availability of data in the white group remained consistently higher compared to other racial groups after applying each filter. Conversely, the Black or African American group was the most impacted by each filter on these 3 datasets: Cedars-Sinai dataset, UK Biobank, and Columbia University dataset. Among the 4 distinct datasets, only applying the filters to the All of Us dataset resulted in minimal deviation from the baseline, with most racial and ethnic groups following a similar pattern.

Conclusions: Our findings underscore the importance of using only necessary filters, as they might disproportionally affect data availability of minoritized racial and ethnic populations. Researchers must consider these unintentional biases when performing data-driven research and explore techniques to minimize the impact of these filters, such as probabilistic methods or adjusted cohort selection methods. Additionally, we recommend disclosing sample sizes for racial and ethnic groups both before and after data filters are applied to aid the reader in understanding the generalizability of the results. Future work should focus on exploring the effects of filters on downstream analyses.

Introduction

The rapid adoption of electronic health records (EHRs) in the past decade has greatly expanded the availability and accessibility of clinical data. This advancement enables health care professionals to harness vast amounts of information, driving medical research, personalized medicine, and overall improvements in health care delivery [1,2]. Additionally, it helps to build big data in health care, providing a foundation for advanced analytics and informed decision-making on a large scale. This supports the training and validation of artificial intelligence methodologies and models, leading to improved diagnostic accuracy, personalized treatment plans, and more efficient health care delivery. Therefore, the collected data significantly influence the results and hypotheses derived from these methods.

To improve diversity in health care, studies must include populations underrepresented in the biomedical, clinical, behavioral, and social sciences, such as individuals from racial and ethnic minority groups, those with disabilities, and people from disadvantaged backgrounds [3]. Fostering diversity is vital for producing more accurate, inclusive research outcomes that reflect the needs of all populations, ultimately leading to more equitable health care and improved patient outcomes [4,5].

However, the usefulness of available clinical data is limited if it does not reliably reflect the diversity of the underlying population. Bias in health care research refers to systematic errors or deviations that lead to inaccurate or skewed results, interpretations, or decisions. It usually occurs when certain factors, whether intentional or unintentional, disproportionately influence the research process, leading to outcomes that do not accurately represent the truth. Thus, scientific progress is delayed, flawed conclusions perpetuated, and disparities in health care outcomes are reinforced [6].

Lack of diversity, which may be due to systemic biases and discrimination against individuals and groups from minoritized populations, can lead to biased research outcomes that exacerbate health disparities [7-10]. This can lead to inaccurate conclusions about treatment or interventions that may not apply equally across different populations. In addition, there are still not enough big clinical longitudinal datasets, which are essential for understanding long-term health trends, progression of diseases over time, and evaluating treatment outcomes.

When conducting observational clinical data analysis, it is often preferable to aim for a dataset that is as complete as possible. However, well-meaning filters that improve completeness may introduce unintended biases in the target population [11].

Data completeness can be defined as the extent to which EHRs or other data sources capture all necessary and relevant information to accurately represent a patient's medical history, care processes, or outcomes. It includes both the presence and accuracy of essential data elements, such as diagnoses, treatments, laboratory results, and preventive care measures, ensuring a comprehensive and reliable foundation for clinical care, research, and quality assessment [12-14].

In this study, we aim to evaluate the effect of data completeness filters originally used by Weber et al [11] on different datasets and how various filters impact the patient cohort. This work extends the analysis to 4 large datasets, including the All of Us (AoU) dataset, UK Biobank (UKBB), and 2 geographically distinct academic medical centers. Specifically, we focus on identifying race and ethnicity biases introduced by commonly used filters [15].

Methods

We examined 4 distinct data sources, AoU, UKBB, Columbia University dataset, and Cedars-Sinai dataset comprising approximately 12 million patients. By analyzing the available data and applying each filter, we aimed to investigate the potential biases these filters may introduce.

All of Us

The AoU study, sponsored by the National Institutes of Health, has enrolled more than 814,000 participants as of June 18, 2024, with 80% of them coming from underrepresented populations [16]. These groups include racial and ethnic minorities, people with disabilities, those in rural or underserved areas, and individuals from lower socioeconomic backgrounds. Figure S1 in Multimedia Appendix 1 (provided by the AoU study) showcases the self-reported races and ethnicities of the participants who have completed the initial steps of the program, providing a diverse representation. The recruitment process spans all regions of the United States.

The AoU workbench encompasses a wealth of information gathered from EHRs, including data from Fitbit devices, survey responses, and socioeconomic factors. Notably, a recent release of data in April 2023 included approximately 245,400 whole genome sequencing records and 312,940 genotyping microarrays, further enhancing the dataset's depth and potential for analysis.

UK Biobank

The UKBB is a large-scale, population-based study that aims to improve the prevention, diagnosis, and treatment of various diseases. It involves the collection of extensive health-related data, including genetic information, from over 500,000 participants in the United Kingdom. Participants in the UKBB, recruited at ages 40 - 69 years, were registered with the National Health Service. Researchers can download the data through the UKBB's Data Showcase, which collaborates closely with the European Genome Archive.

Cedars-Sinai

Cedars-Sinai Medical Center (CSMC) is one of the largest hospitals in California, based in Los Angeles, and serves up to 1 million diverse patients every year across its 40 locations in Southern California. CSMC also serves as a large research center. The studied database comprises over 4 million patients.

Columbia University

Columbia University Irving Medical Center (CUIMC) is a clinical, research, and educational enterprise located on a campus in Northern Manhattan. They are home to 4 colleges

XSL•FO
RenderX

and schools that work on scientific research, education, and patient care. The studied database comprises over 5 million patients.

The self-reported race and ethnicity distributions of each dataset, along with the number of participants in each dataset, are presented in Table 1. In addition to those self-reported categories for race and ethnicity, we defined an all group, which includes every patient in that specific dataset. This group serves as a baseline for comparison within the dataset.

Table . Self-reported race and ethnicity percentages of each dataset, along with the total number of participants in each dataset.

Dataset	CSMC[a]	CUIMC[b]	All of Us	UKBB[c]
Total patients, n	4,031,307	7,121,848	287,012	502,364
Race, n (%)				
American Indian and/or Alaska Native	5695 (0.14)	8275 (0.12)	—[d]	—
Asian	205,978 (5.11)	100,046 (1.40)	8294 (2.89)	11,472 (2.28)

[d]Not available.

A straightforward approach to identifying subsets of patients whose data are suitable for research studies is to use heuristic computational filters [11] that exclude patients lacking various types of data in their records. For this study, we evaluated 19 different filters, which can be grouped into 3 categories. The first category is based on patient demographics. This includes filters that check whether the patient has both age and sex recorded (AgeSex), if the patient is alive at the time of the search (Alive), if the patient has a known address or zip code (Address or zip), and a set of age filters. The age filters have been applied to age at the time of any diagnosis, for example, the age filter≥65 selects patients who are 65 years or older than 65 years at the time of any of their recorded diagnoses.

The second category is a record-based filter, which checks whether patients have at least 1 recorded instance of various medical data. These filters are the presence of at least 1 diagnosis, the presence of medication records, and records for outpatient visits.

The last category is the time span or observational period filter, which selects patients who have had multiple interactions with the health care system during a specific period of time. The maximum time window for this category was the 6-year follow-up.

We used 19 filters, originally defined by Weiskopf et al [17] as a metric for evaluating the completeness of EHRs, to build patient cohorts within each dataset. These filters helped identify the types of data available after their application. To maintain consistency across datasets, we applied these filters to the patient populations with EHR data in each dataset. Detailed descriptions of each filter, along with their categories, are presented in Table 2.

XSL•FO
RenderX

Table . Filters used in our analysis, grouped by category and descriptions of each filter.

Group and filter		Description
Demographics		
	Alive	Patient is alive at the time of the query
	AgeSex	Patient has both sex and age recorded
	Age filter ≥18	Patient has a diagnosis at an age included in the filter
	Age filter ≤21	Patient has a diagnosis at an age included in the filter
	Age filter ≤40	Patient has a diagnosis at an age included in the filter
	Age filter ≤65	Patient has a diagnosis at an age included in the filter
	Age filter ≥65	Patient has a diagnosis at an age included in the filter
	Age filter ≤80	Patient has a diagnosis at an age included in the filter
	Address or zip code	Patient has an address or zip code recorded
Medical interactions		
	Diagnosis	Patient has at least 1 diagnosis recorded
	Medication	Patient has at least 1 medication prescribed and recorded
	Outpatient visit	Patient has at least 1 outpatient visit recorded
Observation period		
	1 week	Patient has a recorded observation period equal or longer than the filter span
	2 weeks	Patient has a recorded observation period equal or longer than the filter span
	1 month	Patient has a recorded observation period equal or longer than the filter span
	6 months	Patient has a recorded observation period equal or longer than the filter span
	1 year	Patient has a recorded observation period equal or longer than the filter span
	2 years	Patient has a recorded observation period equal or longer than the filter span
	6 years	Patient has a recorded observation period equal or longer than the filter span

First, we queried our databases to get a count of all the patients, grouping them by self-reported race and ethnicity. After establishing the initial groups, we applied each filter one at a time to see the effect of that filter on sample availability.

This study aimed to identify the biases of different types of filters that are used by researchers to evaluate data completeness in electronic EHR datasets. Our focus is biases that may be introduced upon applying these filters to races and ethnicities.

We then assessed the statistical significance of the filters' impact on different racial and ethnic subgroups through binomial testing. Comparing the expected sample to the observed filtered sample. For each group, we calculated the *P* values by comparing the observed proportion relative to the sum of that group and the white baseline group against an expected baseline.

$$\text{Observed proportion} = \frac{\text{filtered group n}}{\text{filtered group n} + \text{filtered White n}}$$

$$\text{Expected proportion} = \frac{\text{group total n}}{\text{group total n} + \text{White total n}}$$

Subsequently, we adjusted the *P* values for multiple hypothesis correction using the Bonferroni method.

Ethical Considerations

The research performed complies with all relevant ethical regulations; the institutional review boards (IRBs) that approved the study protocol are Columbia (IRB AAAL0601) and CSMC (IRB STUDY00003395). Patients were enrolled under a waiver of consent in CSMC and CUIMC. Consent in AoU and UKBB

XSL•FO
RenderX

is managed by each platform, respectively. During the study, we only accessed nonprotected health information and total counts, maintaining the confidentiality of every patient.

Results

Overview

We applied the filters to each dataset separately to assess their individual effects. Table 3 indicates the percentage of patients remaining after applying each filter for each dataset.

Table . Percentage of population remaining on each dataset after applying the different filters.

Filter	Cedars-Sinai, n (%)	Columbia, n (%)	All of Us, n (%)	UKBB[a], n (%)
Alive	3,852,435 (95.56)	6,774,829 (95.12)	283,806 (98.88)	467,333 (93.02)
AgeSex	4,026,072 (99.87)	6,002,422 (84.28)	28,701 (100)	502,364 (100)
Age filter ≥18	1,624,951 (40.30)	4,286,839 (60.19)	253,948 (88.48)	229,960 (45.77)
Age filter ≤21	127,771 (3.16)	1,328,385 (18.65)	21,881 (7.62)	82,953 (16.51)
Age filter ≤40	733,191 (18.18)	2,814,216 (39.51)	103,431 (36.04)	178,503 (35.53)
Age filter ≤65	1,348,000 (33.43)	4,393,121 (61.98)	227,072 (79.12)	225,790 (44.49)

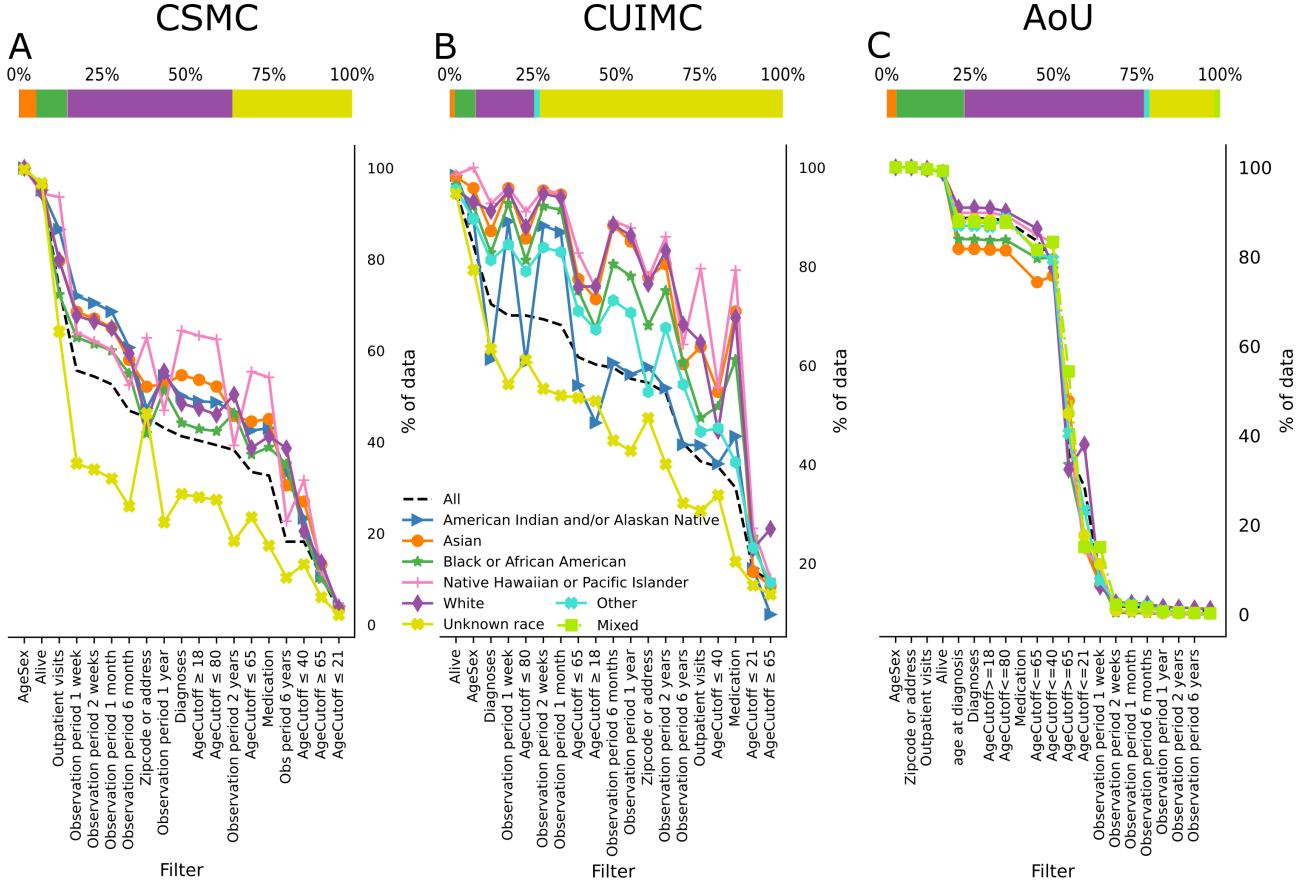
Cedars-Sinai

Figures 1A and 2A show the percentage of available patients in the CSMC after applying each filter. The results show that both unknown race and unknown ethnicity are the most affected groups when applying the filters. This causes the values for the group all to decrease too, and it is shown across every cohort.



XSL•FO
RenderX

Figure 1. Available percentage of patients' data upon individually applying all 19 filters in different ethnic subgroups in (A) the Cedars-Sinai dataset, (B) the CUIMC dataset, and (C) the AoU dataset. The filters are in descending order following the available percentage of the category, all. The points are connected to ease the visualization, but the filters are not cumulative. Stacked bar plots show the ethnicity distribution of the datasets in percentages. Stacked bar plot from CSMC has 8.55% (n=344,708) of Hispanic or Latino, 41.97% (n=1,691,775) of non-Hispanic or non-Latino, and 49.48% (n=1,994,824) of unknown ethnicity. Stacked bar plot from CUIMC has 9.23% (n=657,288) of Hispanic or Latino, 18.23% (n=1,298,181) of non-Hispanic or non-Latino, and 72.54% (n=5,166,379) of unknown ethnicity. Stacked bar plot from AoU has 18.83% (n=54,054) of Hispanic or Latino, 77.32% (n=221,935) of non-Hispanic or non-Latino, and 3.84% (n=11,023) of unknown ethnicity. The available percentage values can be found in Tables S2-S4 in Multimedia Appendix 1. AoU: All of Us; CSMC: Cedars-Sinai Medical Center; CUIMC: Columbia University Irving Medical Center.

XSL•FO
RenderX

Figure 2. Available percentage of patients' data upon individually applying all 19 filters in different racial subgroups in (A) the Cedars-Sinai dataset, (B) the CUIMC dataset, (C) and the AoU dataset. The filters are in descending order following the available percentage of the category, all. The points are connected to ease the visualization, but the filters are not cumulative. Stacked bar plots show the race distribution of the datasets in percentages. Stacked bar plot from CSMC has 0.14% (n=5695) of American Indian and/or Alaska Native, 5.11% (n=205,978) of Asian, 9.26% (n=373,130) of Black or African, 0.18% (n=7082) of Hawaiian Native or Pacific Islander, 49.42% (n=1,992,336) of white, and 35.89% (n=1,447,086) of unknown race. Stacked bar plot from CUIMC has 0.12% (n=8275) of American Indian and/or Alaska Native, 1.40% (n=100,046) of Asian, 6.26% (n=445,623) of Black or African, 0.09% (n=6693) of Hawaiian Native or Pacific Islander, 17.58% (n=1,252,219) of white, 14.56% (n=1,037,027) of another race, and 59.99% (n=4,271,965) of unknown race. Stacked bar plot from AoU has 2.89% (n=8294) of Asian, 20.30% (n=58,264) of Black or African, 0.12% (n=344) of Hawaiian Native or Pacific Islander, 53.89% (n=154,678) of white, 1.74% (n=5000) of mixed race, 1.65% (n=4727) of another race, and 19.40% (n=55,705) of unknown race. The available percentage values can be found in Tables S2-S4 in Multimedia Appendix 1. AoU: All of Us; CSMC: Cedars-Sinai Medical Center; CUIMC: Columbia University Irving Medical Center.

The results of the CSMC cohort show that every known race or ethnicity group is above "all" in almost every filter. However, both unknown race and unknown ethnicity are the most affected groups when applying the filters. This causes the values for the group all to decrease too, and it is shown across every cohort.

Nevertheless, it is important to note that in this dataset, the Black or African American population is the most affected group by the filters, being significantly more affected than the white population in 16 of 19 filters, as seen in Table S6 in Multimedia Appendix 1. Additionally, as the observation period filter increases, every race group becomes more affected than the white population.

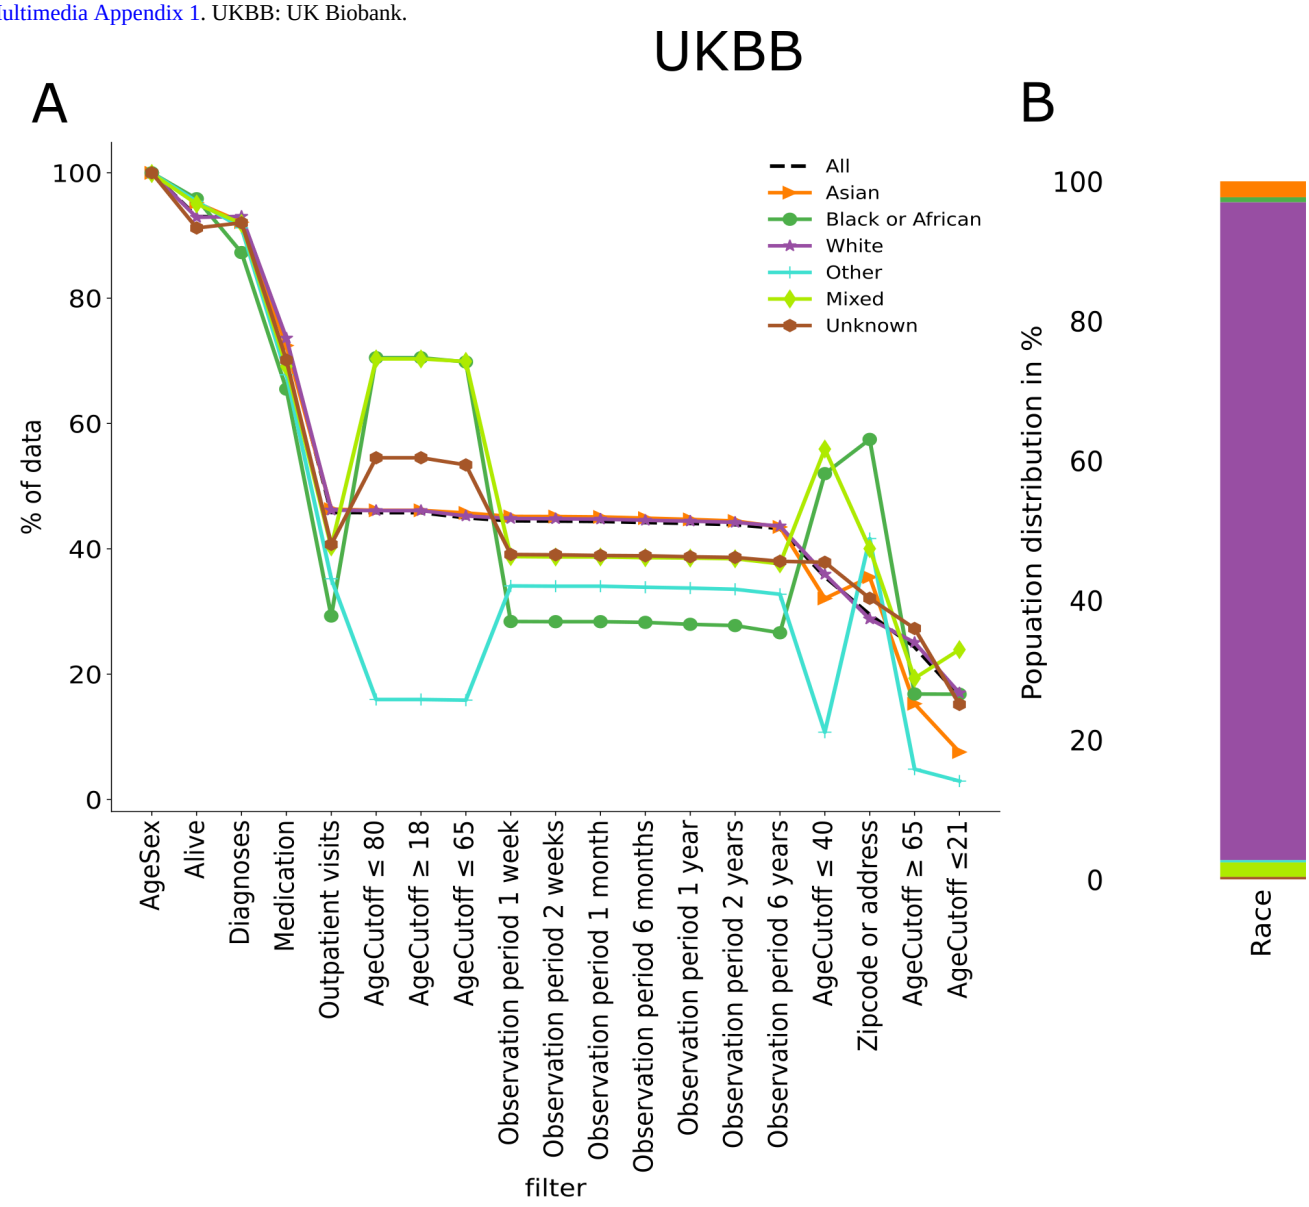
All of Us

For the AoU dataset, we applied the filters to the cohort of patients in the controlled tier 7 who had EHR records. This process reduced the number of patients from 410,235 to 287,012. Upon applying age or sex, medication, zip code or address (in this dataset, we have state of residence, so we used that instead of zip code), alive status, and outpatient visits, the initial cohort remained largely unchanged. However, as more stringent age filters were applied and the observational period was extended, the cohort population significantly decreased. Among all the races, the Asian group was most noticeably impacted, particularly when the observation period filter was applied, as shown in Figure 2A. Within this dataset, unlike at CSMC, the majority of racial and ethnic groups follow the same pattern when each filter is applied. It is remarkable that most of the groups experience significant data loss compared to the White group on the same filters, as shown in Table S7 in Multimedia Appendix 1.

Columbia University Irving Medical Center

Similarly to the cohort from CSMC, the unknown race or ethnicity and other values decrease the most when applying the filters, bringing down the overall percentage. The known races or ethnicities are again above the all group's percentage in almost every category. It is important to note that unknown race and ethnicity represent close to 60%(n=4,271,965) and 72%(n=5,166,379) of Columbia University Medical Center's cohort, respectively, contributing to the low baseline percentage for the all group.

XSL•FO
RenderX



Of the known races and ethnicities, we can see in Figures 1B and 2B that the American Indian and/or Alaska Native population is the most significantly affected by the filters, 18 of 19, even crossing the all line. This is followed by Black or African American, which takes the second place in 16 of 19. However, contrary to the CSMC cohort, the non-Hispanic or non-Latino ethnicity is the most affected by the filters, 10 of 19 filters.

UK Biobank

In the UKBB, race and ethnicity classifications differ from those used in American institutions. To ensure consistency in data presentation, we applied the UK government's recommended grouping strategy [18], aligning it with the US classification system for comparability. We included any other Black background, African, Black or Black British, and Caribbean under the category Black or African origin; any other Asian background, Asian or Asian British, Bangladeshi, Chinese, Indian, and Pakistani under the category Asian; any other white background, British, Irish, and white under the category white; do not know and prefer not to answer under unknown; any other mixed background, mixed, white and Asian, white and Black African, and white and Black Caribbean under mixed; and finally, other ethnic group under other.

After this grouping, there are some aspects to remark on from this dataset, white population represents close to 94%(n=473,353) of the group, which biases completely the all results. Having that in mind, we can see in Figure 3 how every other race was impacted more than the baseline, especially the Black or African origin group.

Figure 3. Available percentage of patients' data upon individually applying all 19 filters in different racial subgroups (**A**) in the UKBB dataset. The filters are in descending order following the available percentage of the category, all. The points are connected to ease the visualization, but the filters are not cumulative. Stacked bar plots show the race distribution of the datasets in percentages. (B) Stacked bar plot shows the racial distribution of the dataset in percentages, showing 2.28% (n=11,472) of Asian, 0.71% (n=3552) of Black or African, 94.22% (n=473,353) of white, 0.34% (n=1731) of mixed race, 2.07% (n=10,394) of another race, and 0.38% (n=1931) of unknown race. The available percentage values can be found in Table S5 in Multimedia Appendix 1. UKBB: UK Biobank.

XSL•FO
RenderX

We then analyzed the differences within the most prevalent groups in this dataset, evaluating only the 5 most common categories. We found that the British group accounts for 91%(n=442,973) of the total, only counting the top 5 groups. This approach yielded results similar to those of the complete one. The first 5 categories, in order of percentage, were the following: British (91.7%, n=442,973), ny other white background (3.4%, n=16,455), Irish (2.8%,n=13,346), Indian (1.2%, n=5,955), and other ethnic group (1%, n=4,609). These percentages account for the addition of the population of the top 5 groups and not the total.

A low adjusted *P* value (eg, <.001) suggests that the subgroup is significantly more affected by the specific filter than the white group used as a baseline. We see across every dataset that most of the groups are significantly more affected by the filter than our baseline, but it is particularly notable in groups like Black or African American and American Indian and/or Alaska Native. The Hispanic or Latino ethnic group also shows more significant data loss than non-Hispanic or non-Latino across every dataset. The *P* values can be found in Tables S6-S8 in Multimedia Appendix 1.

Discussion

Overview

Our study investigates the potential racial and ethnic biases introduced by applying common data quality and completeness filters in clinical research databases, including AoU, UKBB, and 2 academic medical centers. We analyzed 19 filters across approximately 12 million patients and discovered that certain filters significantly reduce data availability and have a differential effect on racial and ethnic groups.

The challenge with these filters lies in distinguishing between patients with missing data who could be relatively healthy, have not recently sought medical care, or have limited access to health care systems. Each group will have a low number of data entries in their records. Consequently, these filters might bias the resulting cohort by selecting sicker patients who interact with the health care system more frequently and/or those who have more access to health care systems. For example, in a cohort of 10,000 patients, those with poorer health status had more laboratory tests and medication orders, resulting in more comprehensive data in their records [19]. On the other hand, minoritized populations usually have less access to health care [20], which affects the data's completeness and reduces their data points when we apply different types of filters. We focused on bringing attention to the second point.

Principal Findings

Throughout the analysis of the 4 different cohorts, a consistent pattern emerged: applied filters disproportionately affected minoritized groups, particularly the Black or African American group, which consistently has one of the lowest data availabilities across all datasets, and the American Indian and/or Alaska Native group. These filters significantly reduced the already limited data points for minoritized groups, further diminishing the completeness and usability of their data compared to white or non-Latino patients. We observe a similar pattern in the Hispanic or Latino group, where data availability is consistently lower in every cohort compared to the non-Hispanic or non-Latino group.

In the self-reported race groups, we observe that almost every group has less data availability than the white group, which is the largest within the known self-reported races across all datasets except at CSMC. At CSMC, the most complete group varies by filter, alternating between Asian, Native Hawaiian or Pacific Islander, American Indian and/or Alaska Native, and white. In contrast, in the CUIMC dataset, the American Indian and/or Alaska Native group has the lowest data availability.

Among the 4 distinct datasets, only the AoU dataset closely reflects the diversity of the US population, with approximately 50%(n=132,334) of the data representing populations other than white. Upon applying different filters on this dataset, as shown in Figures 1C and 2C, most groups follow the same original pattern prior to applying the filters and deviate from the baseline to a lesser extent, demonstrating that it is possible to achieve a diverse and complete dataset.

Dataset diversity is essential for enhancing the generalizability and inclusivity of clinical research, addressing disparities, and improving health care outcomes for underrepresented populations. The AoU dataset, designed as a nationwide research program, aims to collect health data from a diverse population and succeeds at creating an equitable framework for research where most of the groups share the same data availability percentage. In contrast, the CUIMC and CSMC datasets reflect the specific patient populations of their respective regions, leading to localized diversity compared to the national scope of the AoU dataset. However, both are based in highly racially and ethnically diverse US cities, giving them a unique advantage over other institutional-level datasets. The information for the different populations and distributions of the locations for the 4 datasets can be found in Table S1 in Multimedia Appendix 1.

Both in the United States and the United Kingdom, the white population constitutes the majority. Minorities, as defined by the US Office of Management and Budget, include racial and ethnic groups such as American Indian, Alaska Native, Asian, Black or African American, and Native Hawaiian or Pacific Islander. These groups often face health disparities, which can result in reduced access to health care and underrepresentation in research cohorts [21]. This underrepresentation may lead to inaccurate clinical care decisions, skewed genetic associations, and suboptimal treatment strategies.

Limitations

Our findings highlight the importance of carefully selecting filters to ensure equitable research outcomes, particularly for minority populations. While we do not claim these are the most frequently used filters by researchers, nor the optimal ones for selecting patients with complete data, it is essential to investigate any potential biases that may be introduced upon applying each filter before conducting research on these populations.

Additionally, methods to mitigate bias must be used when possible. One example is artificial intelligence–driven synthetic data generation for bias mitigation, which can be done using

XSL•FO
RenderX

different methodologies such as generative adversarial networks, synthetic minority oversampling, or Bayesian networks [22]. Other techniques include reweighting, suppression, or multiple imputation [23]. Advanced statistical techniques like inverse probability weighting can also help address these challenges and enhance dataset diversity [24].

Future Directions

Future work should focus on understanding how the application of these filters affects the results of common downstream analyses, such as disease risk prediction tasks and genome-wide association studies, and how to improve existing techniques for bias mitigation. We also recommend that researchers begin including sample sizes for relevant racial and ethnic groups both before and after any used filters are applied so that readers can better contextualize the results of the study.

Addressing disparities in representation is critical to creating research cohorts that accurately reflect the target population. This work underscores the challenges of achieving data completeness and proper representation of racial and ethnic populations and other minoritized groups in clinical research. Strategies to mitigate these disparities, along with careful consideration of filters, are crucial for ensuring equitable research outcomes and enhancing the inclusivity of health datasets.

Conclusions

Our findings underscore the importance of using only necessary filters, as they may affect the diversity and completeness of sample data, which particularly affects underrepresented populations. Upon applying different filters to the 4 distinct datasets, we observed that only the AoU dataset maintained the original sample distribution along racial and ethnic groupings, with minimal deviation from the baseline, demonstrating the potential to achieve a diverse and complete dataset.

Researchers must consider their target population when conducting studies and proactively address unintentional biases that may arise in data-driven research as well as the impact of these biases on downstream analyses. While sample filters are often necessary, we recommend that researchers implement techniques to mitigate biases and provide sample size information across racial and ethnic groupings both before and after the filters are applied, so readers can better understand the generalizability of the study.

Future work should characterize how the application of these filters affects downstream analyses and improve on existing techniques to minimize their impact. We strive to achieve a state where the datasets accurately represent the target population of the studies and where research studies are performed on the same population that institutions serve.

Abstract

Background: Physician surveys provide indispensable insights into physician experience, but the question of whether responders are representative can limit confidence in conclusions. Ubiquitously collected electronic health record (EHR) use data may improve understanding of the experiences of survey nonresponders in relation to responders, providing clues regarding their well-being.

Objective: The aim of the study was to identify EHR use measures corresponding with physician survey responses and examine methods to estimate population-level survey results among physicians.

Methods: This longitudinal observational study was conducted from 2019 through 2020 among academic and community primary care physicians. We quantified EHR use using vendor-derived and investigator-derived measures, quantified burnout symptoms using emotional exhaustion and interpersonal disengagement subscales of the Stanford Professional Fulfillment Index, and used an ensemble of response propensity-weighted penalized linear regressions to develop a burnout symptom prediction model.

Results: Among 697 surveys from 477 physicians with a response rate of 80.5% (697/866), always responders were similar to nonresponders in gender (204/340, 60% vs 38/66, 58% women; P=.78) and age (median 50, IQR 40 - 60 years vs median 50, IQR 37.5 - 57.5 years; P=.88) but with higher clinical workload (median 121.5, IQR 58.5 - 184 vs median 34.5, IQR 0 - 115 appointments; P<.001), efficiency (median 5.2, IQR 4.0-6.2 vs median 4.3, IQR 0 - 5.6; P<.001), and proficiency (median 7.0, IQR 5.4 - 8.5 vs median 3.1, IQR 0 - 6.3; P<.001). Survey response status prediction showed an out-of-sample area under the receiver operating characteristics curve of 0.88 (95% CI 0.77-0.91). Burnout symptom prediction showed an out-of-sample area under the receiver operating characteristics curve of 0.63 (95% CI 0.57-0.70). The predicted burnout prevalence among nonresponders was 52%, higher than the observed prevalence of 28% among responders, resulting in an estimated population burnout prevalence of 31%.

Conclusions: EHR use measures showed limited utility for predicting burnout symptoms but allowed discrimination between responders and nonresponders. These measures may enable qualitative interpretations of the effects of nonresponders and may inform survey response maximization efforts.

Introduction

Symptoms of burnout among physicians have risen sharply in recent years [1], but burnout symptoms and other markers of physician well-being are currently identified by voluntary responses to surveys [2]. Such intermittent surveys often have low response rates and carry the risk of response bias, as physicians with burnout or other symptoms of poor well-being may have systematically different likelihood of responding [3]. Although prior analyses have shown few significant differences between early and late responders or between initial responders and those who respond to incentivized secondary surveys of nonresponders [1,4], in many studies, information about

XSL•FO
RenderX

nonresponders is limited to standard demographics. Evaluating survey results in relation to EHR use measures reflecting the work environment and experiences of each physician may allow a more detailed analysis of the differences between responders and nonresponders, thereby enabling extrapolations relevant to the well-being of nonresponders.

Symptoms of burnout affect primary care physicians disproportionately [1,4,5] and pose a threat to quality of care and patient safety [6,7]. Almost 50% of primary care physicians believe that the amount of time spent on clerical tasks is unreasonable [8], those with a high electronic health record (EHR) task load have a higher likelihood of burnout [9-11], and up to 75% believe that the EHR contributes to burnout [12,13]. Although these findings may suggest that EHR-based measures could be used to predict burnout symptoms, the performances of EHR-based measures in prediction models have been limited [14,15]. This combination of findings suggests that a more complex interplay exists among EHR use, physician well-being, and survey response.

This study sought (1) to identify systematic differences in EHR use measures between physician survey responders and nonresponders and (2) to provide a prediction modeling approach for estimating symptom burden among survey nonresponders using physician burnout as a use case.

Methods

Overview and Study Design

We used a repeated cross-sectional observational design to assess a wide range of EHR use characteristics in relation to burnout symptoms. EHR measures were compiled by the institution's EHR vendor (Epic Systems) or calculated from the local EHR data repository. Burnout measures relevant to this study were part of larger routine surveys on professional fulfillment at Stanford University School of Medicine.

Ethical Considerations

This study was approved by the institutional review board at Stanford University School of Medicine (IRB-49374) with deidentification processes enabling the waiver of informed consent. Data were deidentified prior to analysis. Incentives previously provided for survey completion are detailed below, but no further compensation was provided for inclusion in this study.

Study Participants

All primary care physicians at a large US academic medical center and its community affiliates were surveyed as part of routine quality improvement efforts and professional fulfillment benchmarking. Participants were invited via email, followed by 4 reminder email requests over the following 6 weeks at 2 time points (2019 and 2020). Participation was voluntary, with local department chairs, division chiefs, and well-being champions allowed to encourage participation at their discretion. At the academic medical center, a department-level financial incentive of US $50 per respondent was offered to the 3 departments with the highest response rates. At the community affiliate, survey completion was a prerequisite for individuals to receive their annual clinical bonuses. The primary stated purpose of the survey was to "help inform our efforts to make operational improvements to make Stanford University a better place for all to practice, educate, and conduct research." The survey was administered by a third party (SullivanLuallin Group), and all responses were deidentified to preserve confidentiality.

Each physician was categorized as a "never responder" if they did not provide survey responses at either time point, "always responder" if they responded to each yearly invitation received, or "partial responder" if they were invited both years but only responded once.

Burnout Measures

Surveys were distributed at the academic medical center in May 2019 and October 2020 and distributed at the community affiliate in March 2019 and March 2020. We used the Stanford Professional Fulfillment Index, which includes 10 prompts assessing burnout symptoms, 4 related to work exhaustion and 6 related to interpersonal disengagement. Details of this index and full burnout prompts are provided in prior publications [16,17]. In line with prior research [17], we calculated the mean score for these 10 burnout items, which are scored 0 - 4 on a Likert scale, then transposed to a 0 - 10 scale by multiplying by 2.5. Although all analyses were conducted on continuous scores, for ease of reporting, we dichotomized such that a score of ≥3.325 was considered indicative of burnout symptoms, in line with the validation results for this instrument [17].

EHR Use Measures

For each physician, we compiled EHR use measures for the 3-month period leading up to survey administration. We used Signal data compiled by Epic Systems to approximate key measures of workload, use, and efficiency, as defined in Epic's UserWeb. We calculated additional measures of workload from the institution's EHR data repository, including number of unique patients with appointments, number of patients with multiple appointments in a given month, sentiment scores of progress notes (range −1 to +1 for maximally negative to maximally positive sentiment), and principal components. We reduced this large feature set of 1677 overlapping predictors to a smaller set of 214 candidate predictors by manually curating to measures with low collinearity, high cardinality, and known or potential associations with physician well-being from published literature [8-11,18-27]. Introducing this manual curation step, compared to relying solely on automated machine learning methods, aligns with prior literature demonstrating that incorporating clinician expertise into feature generation can improve model performance [28]. We also extracted physician gender and birth year (binned in 5-year increments) from the EHR database as well as practice type and clinic (both hashed to preserve confidentiality).

Statistical Analysis

We used descriptive statistics including frequencies, means, and SDs to compare EHR use measures and demographics between survey responders and nonresponders using nonparametric methods to assess statistical significance, including Fisher exact test for categorical variables,

XSL•FO
RenderX

Kruskal-Wallis test for continuous variables with unpaired observations, and Wilcoxon signed rank for continuous variables with paired observations. Reference values were set at the modal value (categorical variables) or the lowest value (ordinal variables).

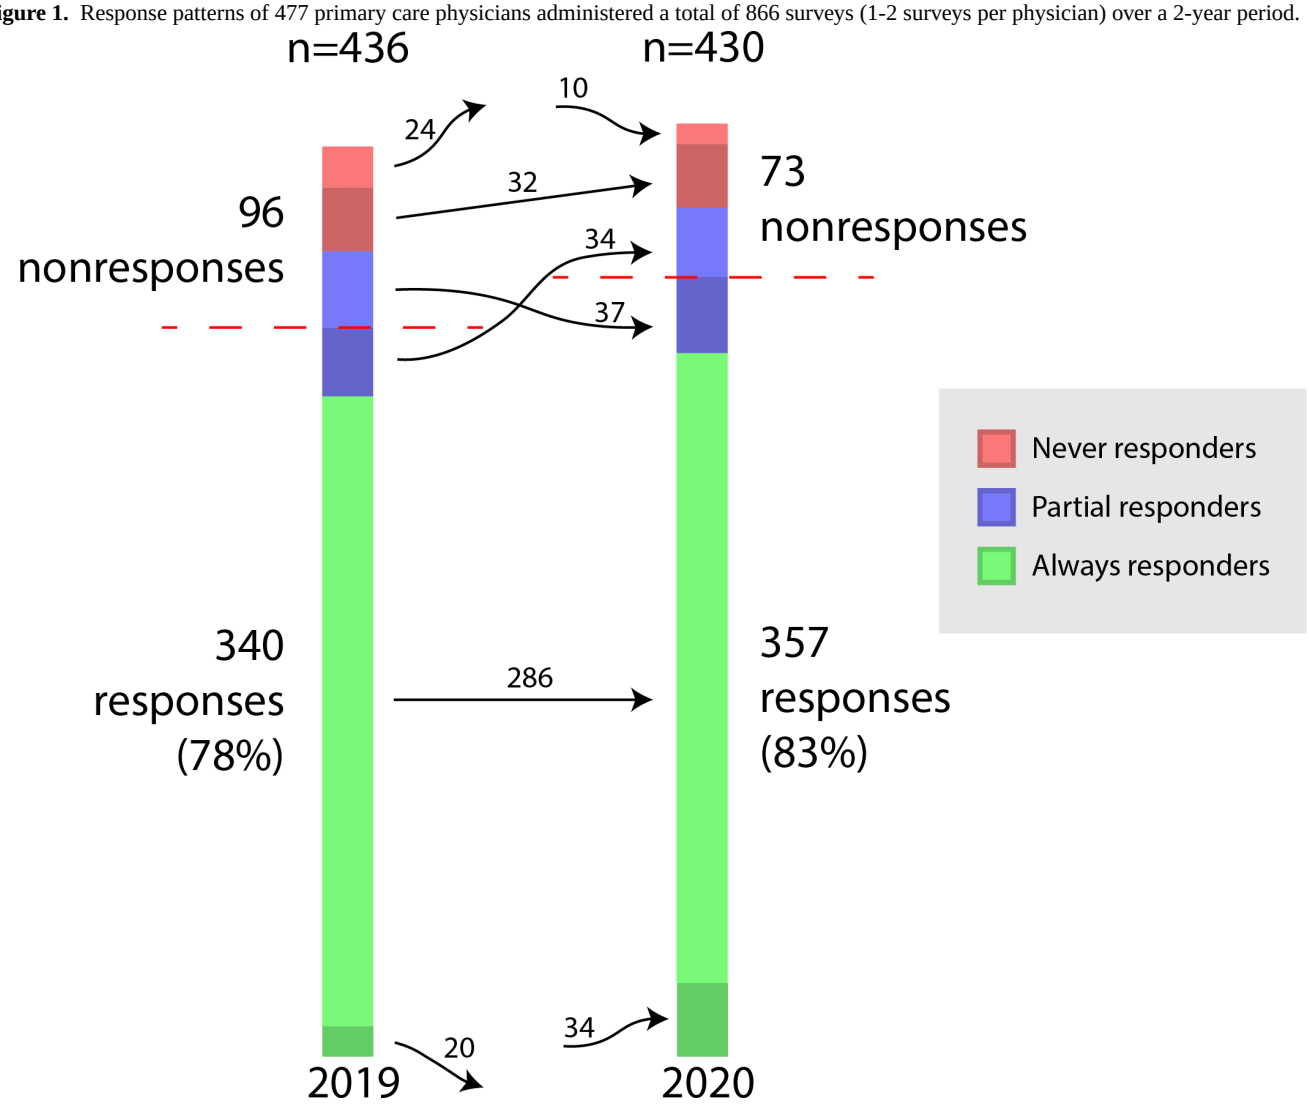
Because the population of interest (nonresponders) may differ from the population available for model training (responders), we developed a weighting schema to tune the model for predictions more heavily weighted toward individuals less likely to respond. To develop these weights for our prediction model, we developed propensity scores quantifying the likelihood of survey response (vs nonresponse) in any given year based on EHR use measures. We used penalized logistic regression with 10-fold cross-validation to generate these propensity scores for survey response, using the full dataset of survey invitations, with the binary outcome of survey response defined as answering ≥4 out of 10 burnout prompts. We then used these propensity scores, denoted by p, to inform 3 approaches to weighting in our predictive models for burnout score, lending varying levels of higher weight to observations more similar to nonresponders (unweighted, $1/p$ weighting, and $1-p$ weighting). Unweighted predictions approximate the population of responders by ascribing equal weight to all observations in the training set. $1/p$-Weighted predictions approximate the full population of responders and nonresponders by ascribing proportionately higher weight to responses with the lowest likelihood of response, with the lower limit of propensity scores truncated at 0.1 to prevent extreme weights. $1-p$-Weighted predictions approximate the nonresponders by ascribing lower weight to responses with a higher likelihood of response.

To create our ensemble prediction model, we used a sample of always responders to train 3 separate prediction models, then used the remainder of always responders to calculate bias-correction coefficients governing the weight of each of the 3 models in the final ensemble model. To accomplish this task, we trained penalized linear regression models to predict burnout scores using a random 272 (80% sample) of the 340 always responders, grouped by physician. We generated 3 burnout predictions (1 for each weighting schema) for the remaining 68 (20% sample) of the 340 always responders. On this held-out test set, we then applied a bias-correction step in which we regressed actual burnout scores on the 3 predictions (1 from each weighting schema), then extracted the resultant β coefficients for each weighting schema as bias-correction coefficients, such that predictions consistently over- or underestimating burnout scores would be adjusted accordingly in the ensemble (bias-corrected) prediction.

Because nonresponders may represent a systematically different population than our training set of always responders, we chose to test predictive performance using the held-out test set of partial responders (physicians who responded to the survey in 1 year but declined to respond in the other year). We chose the partial responders as the test set because this group of physicians may most closely approximate nonresponders while still providing usable survey data in 1 year. Using the models generated in the training step and the coefficients generated in the bias-correction step, the performance of the ensemble model was tested to predict burnout scores for these partial responders. For ease of interpretation, we converted burnout predictions to the likelihood of burnout score ≥3.325 using a sigmoid distribution.

Because the partial responders may provide the most relevant data for predicting burnout among nonresponders, we then retrained the model using all responses (from always responders and the response years of partial responders) and used this final model to predict burnout scores among nonresponders. We combined these predicted burnout scores with the observed burnout scores from survey responses to estimate the population-level burnout burden.

Recognizing that we cannot directly assess the performance of our final predictions of nonresponders but that our sample contained a strong response rate, we also performed additional validation in which we synthetically reduced our response rate by pseudorandomly selecting a subset of physicians to be synthetic nonresponders. This approach allowed us to estimate applicability to institutions or years with lower response rates. For this synthetic survey response reduction, each person's response propensity was jittered using a triangularly distributed random jitter from −0.5 to 0.5, centered at 0. Then we selected out the 20% of physicians with the lowest average response propensity as "candidate synthetic nonresponders." We repeated this process 100 times, then chose any physician who was a candidate synthetic nonresponder in at least 50 cycles as a final synthetic nonresponder, to be added to the actual nonresponders. We retrained the model using only the limited set of responses, and then predicted burnout scores among the larger set of nonresponses.



Due to the hypothesis-generating nature of these analyses, no corrections were made for multiple testing. Statistical analyses were performed in Stata (version 17.0; StataCorp) and Python (version 3.3; Python Software Foundation) with modules scipy and sklearn.

Results

A total of 477 unique physicians received 866 survey invitations (in 2019 alone: n=44, in 2020 alone: n=44, and in both years: n=389). The overall response rate was that 697 of 866 (80.5%) surveys were completed (in 2019: n=340, 78% and in 2020: n=357, 83%), with 66 never responders, 71 partial responders, and 340 always responders (Figure 1). Baseline demographics of the 3 groups of physicians are shown in Table 1.

[d]Physicians who joined or left the organization between survey administrations were only eligible to receive 1 survey. They were categorized with "always responders" if they responded or "never responders" if they did not respond. Full details are illustrated in Figure 1.

[e]EHR: electronic health record.

EHR use patterns for the 3 groups of physicians are also shown in Table 1, with never responders showing generally lower clinical workload and overall EHR proficiency, always responders showing generally higher clinical workload and EHR proficiency, and partial responders with intermediate values. In particular, never responders had a median of 5.9 (IQR 0.0-9.6) appointments per work day compared to 8.8 (IQR 6.9-11.7) for partial responders and 9.2 (IQR 6.2-11.7) for always responders. Although never responders exhibited the lowest summary EHR efficiency scores (partial responders: median 4.3, IQR 0.0-5.6 vs median 4.9, IQR 3.6-5.8 and always responders: median 5.2, IQR 4.0-6.2), they also showed the lowest minutes in notes per 8 hours of appointments (partial responders: median 42.8, IQR 0.0-68.6 vs median 60.2, IQR 34.9-93.9 and always responders: median 60.9, IQR 32.8-97.3), lowest minutes in EHR in basket per 8 hours of appointments (partial responders: median 9.6, IQR 0.0-27.9 vs median 29.1, IQR 9.2-48.1 and always responders: median 31.7, IQR 15.4-48.1), and lowest minutes in chart review per appointment (partial responders: median 1.0, IQR 0.0-3.8 vs median 2.5, IQR 1.3-37 and always responders: median 2.0, IQR 1.1-3.7).

Among the 71 partial responders, the year in which a response was given showed several differences in comparison to the nonresponse year as shown in Table 2. In particular, physicians responded in years in which they had higher clinical workload (eg, more appointments per work day: median 10.1, IQR 8.0-12.2 vs median 8.3, IQR 6.2-12.3; P=.03) but relatively similar EHR efficiency measures (eg, similar Epic efficiency score: median 5.0, IQR 4.1-5.9 vs median 4.7, IQR 3.4-5.8; P=.14). The results were similar when stratified by physicians who responded the first year and failed to respond the second year versus those with the reverse chronology.

[b]N/A: not applicable.

Prediction models for survey response using multivariable logistic regression achieved an area under the receiver operating characteristic curve (AUROC) of 0.88 (95% CI 0.77 - 0.91) as determined by 10-fold cross-validation grouped by physician. Prediction models for burnout score using multivariable linear regression with subsequent sigmoid transformation to probability of burnout achieved an out-of-sample AUROC of 0.63 (95% CI 0.57 - 0.69) on the unweighted model, 0.62 (95% CI 0.57 - 0.69) on the 1/*p* weighted model, and 0.57 (95% CI 0.50 - 0.62) on the 1–p weighted model as shown in Figure 2. The ensemble model achieved an out-of-sample AUROC of 0.63 (95% CI 0.57 - 0.70), sensitivity of 62%, specificity of 64%, and area under the precision-recall curve of 0.39 (95% CI 0.33 - 0.48) for predicting burnout symptoms as shown in Figure 3.

Results for the held-out test set of partial responders shown. Shaded areas represent 95% CIs obtained using bootstrap resampling methods. AUROC: area under the receiver operating characteristic curve.

XSL•FO
RenderX

Figure 3. Receiver operating characteristics curve for the bias-corrected ensemble burnout prediction model. Results for the held-out test set of partial responders shown. Shaded area represents 95% CI obtained using bootstrap resampling methods. AUROC: area under the receiver operating characteristic curve.

After final training on all available data (see Multimedia Appendix 1 for coefficients from the top-performing model), the ensemble model predicted 52% (95% CI 41% - 63%) burnout prevalence among the nonresponders, higher than the 28% rate observed in responders. These predictions suggest a population-level estimated 31% (95% CI 30% - 33%) burnout prevalence, after incorporating the observed 28% burnout prevalence among responders.

In secondary analysis with synthetic response rate reduction, the observed burnout prevalence was 26% (excluding the synthetic nonresponders—individuals whose responses were concealed for the purposes of this secondary analysis), while the predicted burnout prevalence was 46% (including predictions for true nonresponders and synthetic nonresponders). The resultant population-level estimate of 33% burnout prevalence represented a 2% increase in estimated burnout compared to the fully informed model.

Discussion

Principal Findings

In this study, we found well-being survey responses to be more common among physicians with higher clinical workload and higher EHR proficiency measures, with a strong ability to predict survey response status using routinely collected EHR measures. However, we achieved lower predictive performance to predict burnout scores, which were better (AUROC 0.63, 95% CI 0.57-0.70) than chance (AUROC 0.5), but below the threshold for clinical actionability when predicting outcomes in an individual (typically AUROC of at least 0.8). The ability of EHR measures to predict burnout was not markedly improved

XSL•FO
RenderX

by including propensity weighting schemas, though it remains possible that predictions on true nonresponders are more accurate as a result or that this approach may inform survey analysis strategies for other applications. Although we found predicted burnout scores among nonresponders to be higher than observed burnout scores among responders, there remains uncertainty regarding the magnitude of difference.

Comparison to Prior Work

Previous studies looking for systematic differences between well-being survey responders and nonresponders have consistently failed to show meaningful differences. Using a large national sample of physicians, Shanafelt et al [29] reported no substantial differences between early responders and late responders nor between responders to the initial survey versus an incentivized, multimodality survey of nonresponders (2 standard approaches to evaluate for response bias) [1,4]. Ortega et al [30] reported no differences in burnout prevalence among responders to 3 consecutive surveys versus those who provided only 1 or 2 responses. Cardell et al [31] also reported no differences in burnout among responders who fully completed a survey and those with selective responses. These findings are in line with other studies of physician surveys in ambulatory practice or oncology care [32-34]. Studies that identified demographic differences by response status primarily note small differences in age, gender, specialty, and urbanicity [35-38].

Our study largely confirms these findings, with similar demographics among all responder groups, but extends these findings by evaluating highly granular EHR measures related to the work environment of physicians, providing much greater detail than has previously been available for nonresponders. Although we are unable to directly evaluate the predictive accuracy of our model on nonresponders, our findings suggest that in this sample of physicians, nonresponders have EHR use measures more similar to physicians who reported higher symptoms of burnout. Notably, these nonresponders tended to exhibit a lower volume of clinical workload, but many of the predictive features in our model related rather to the composition of the clinical workload (ie, the proportion of appointments that are level 5 rather than the raw number of appointments). However, the relatively weak predictive performance of this model to predict burnout (when evaluated against the surrogate group of partial responders) suggests caution in interpreting the magnitude of any such effect. In addition, the 1-year interval between the survey time points and response or nonresponse years of the partial responders may reflect important differences in burnout symptoms or work experiences, further distancing their relevance as a surrogate test population.

Strengths and Limitations

Although burnout prediction accuracy falls below the threshold of actionability consistent with prior studies [14,15], the directionality of the difference between observed and predicted burnout may be valuable as a qualitative measure. Our findings suggest that institutions could leverage population-level EHR measures to identify if their nonresponders are expected to have better, worse, or similar symptoms to those measured among responders. In this way, comparisons may be better informed, particularly across years with different survey response rates. Although burnout was evaluated as a use case in this study, it remains possible that this approach may be more effective for predicting response to other survey instruments, particularly those with more direct conceptual connections with EHR use metadata (eg, EHR experience, control over schedule, or sleep-related impairment).

This study should be viewed in light of its design. As an observational study, we cannot infer any causality of the observed associations between EHR measures and burnout symptoms. Additionally, the nonresponders have survey results that are by definition not observable, and it remains possible that additional differences exist between nonresponders and our surrogate populations of partial responders and low-propensity responders. While this study population represents a large sample of academic and community primary care physicians, the results may not generalize to other specialties or institutions, and the necessary deidentification process prevented us from knowing the practice setting or clinic names of individual respondents. The response rates among this sample of physicians were relatively high due to strong institutional efforts to maximize responses, which may limit generalizability to institutions with lower response rates. The survey time points occurred both prior to and during the early phase of the COVID-19 response, which provided an exogenous shock to the health care delivery system including fluctuating visit volumes and a transition toward telehealth that may have unmasked relevant associations. However, changes in physician's work and personal lives since that time may affect future results. Although we evaluated burnout prediction as a use case, this framework applied to other survey measures may provide better or worse predictive performance.

Future Directions

We achieved moderate to strong performance in predicting survey response versus nonresponse. This finding highlights an opportunity to improve response rates by better targeting or incentivizing individuals predicted as less likely to respond. In general, the nonresponders appeared to exhibit a less clinically engaged phenotype with a lower workload and fewer EHR customizations. This phenotype may be reflective of reduced clinical load due to exhaustion, other academic or nonclinical responsibilities, vacation or sabbatical, or competing responsibilities in personal life. Decreased EHR proficiency as defined by EHR customizations may occur for many reasons, including lower clinical workload that may provide a lower payoff to an individual's efforts toward customization, perceptions of helplessness or reduced motivation to engage in available tools, or unfamiliarity with available customizations.

Allowing physicians to self-select their survey delivery format or providing protected time for survey completion [30,39-42] may improve response rates. In particular, evaluating phenotypes associated with nonresponse may further inform survey timing, delivery modes, or incentive structures to maximize response rates. For example, an institution that predicates a year-end clinical bonus on survey completion may inadvertently oversample those with high clinical loads, as their incentive will carry relatively more value. Alternatively, an institution that provides survey invitations and reminders during daytime

XSL•FO
RenderX

hours or posted only in clinical locations may inadvertently reduce engagement by physicians with infrequent or off-hours clinical work.

Conclusions

In this sample of primary care physicians in a large academic medical center and its community affiliates, we found that differences in EHR use measures may enable the prediction of physician survey response with moderate to strong accuracy, but that EHR use measures have limited ability to predict burnout symptoms. Our finding that nonresponders had EHR use measures more similar to responders with symptoms of burnout suggested that, if anything, nonresponders may have higher rates of burnout than responders. Further studies are needed to validate these findings in other settings and over a longer time horizon.

Acknowledgments

This research was supported by research grants from the Agency for Healthcare Research and Quality (K08 HS027837, PI: DT) and the Eunice Kennedy Shriver National Institute of Child Health and Human Development (R01 HD084679, PI: JP). All funders had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; nor the decision to submit the manuscript for publication.

Data Availability

The datasets generated and analyzed during this study are not publicly available due to the sensitive nature of the data and are not available to be distributed by the corresponding author in accordance with data use agreements.

Authors' Contributions

DT made substantial contributions to study design, interpretation of data, and drafting the manuscript; had full access to all the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis; and approved the submitted version. TDS, MB, and JP made substantial contributions to study design, interpretation of data, critically reviewing the manuscript, and approval of the submitted version.

Conflicts of Interest

TDS is coinventor of the Well-Being Index instruments (Physician Well-Being Index, Nurse Well-Being Index, Medical Student Well-Being Index, and the Well-Being Index) and the Mayo Leadership Index. Mayo Clinic holds the copyright for these instruments and has licensed them for use outside of Mayo Clinic. TDS receives a portion of any royalties received. As an expert on the well-being of health care professionals, TDS frequently gives grand rounds or key note lecture presentations and provides advising for health care organizations. He receives honoraria for some of these activities.

Multimedia Appendix 1

Standardized coefficients from top-performing model for features selected via penalized linear regression. Features are ordered by coefficient value, with the highest listed features associating with higher burnout scores and the lowest listed features associating with lower burnout scores.

Abstract

Background: Pharmacoepidemiology studies using electronic health record (EHR) data typically rely on medication prescriptions to determine which patients have received a medication. However, such data do not affirmatively indicate whether these prescriptions have been filled. External dispensing databases can bridge this information gap; however, few established methods exist for linking EHR data and pharmacy dispensing records.

Objective: We described a process for linking EHR prescribing data with pharmacy dispensing records from Surescripts. As a use case, we considered the prescriptions and resulting fills for psychotropic medications among pediatric patients. We evaluated how dispensing information affects identifying patients receiving prescribed medications and assessing the association between filling prescriptions and subsequent health behaviors.

Methods: This retrospective study identified all new psychotropic prescriptions to patients younger than 18 years of age at Duke University Health System in 2021. We linked dispensing to prescribing data using proximate dates and matching codes between RxNorm concept unique identifiers and National Drug Codes. We described demographic, clinical, and service use characteristics to assess differences between patients who did versus did not fill prescriptions. We fit a least absolute shrinkage and selection operator (LASSO) regression model to evaluate the predictability of a fill. We then fit time-to-event models to assess the association between whether a patient filled a prescription and a future provider visit.

Results: We identified 1254 pediatric patients with a new psychotropic prescription. In total, 976 (77.8%) patients filled their prescriptions within 30 days of their prescribing encounters. Thus, we set 30 days as a cut point for defining a valid prescription fill. Patients who filled prescriptions differed from those who did not in several key factors. Those who did not fill had slightly higher BMIs, lived in more disadvantaged neighborhoods, were more likely to have public insurance or self-pay, and included a higher proportion of male patients. Patients with prior well-child visits or prescriptions from primary care providers were more likely to fill. Additionally, patients with anxiety diagnoses and those prescribed selective serotonin reuptake inhibitors were more likely to fill prescriptions. The LASSO model achieved an area under the receiver operator characteristic curve of 0.816. The time to the follow-up visit with the same provider was censored at 90 days after the initial encounter. Patients who filled prescriptions showed higher levels of follow-up visits. The marginal hazard ratio of a follow-up visit with the same provider was 1.673 (95% CI 1.463 - 1.913) for patients who filled their prescriptions. Using the LASSO model as a propensity-based weight, we calculated the weighted hazard ratio as 1.447 (95% CI 1.257 - 1.665).

Conclusions: Systematic differences existed between patients who did versus did not fill prescriptions. Incorporating external dispensing databases into EHR-based studies informs medication receipt and associated health outcomes.

Introduction

Electronic health record (EHR) data have become a vital data resource for health outcomes and health services research [1]. These data provide detailed patient information, including demographics, diagnoses, prescriptions, and procedures, which can facilitate comprehensive studies that reflect real-world clinical practice [2]. EHR data are increasingly being used to support clinical decision-making with prediction models [3,4] and assess population health [5]. Additionally, EHR data facilitate clinical trial simulation by assessing assumptions and guiding study design of the actual trials [6,7]. They have also emerged as a key resource for the observation of long-term drug safety and effectiveness [8,9], providing insights into drug benefits, interactions, and side effects [10]. Beyond this, EHR data provide valuable opportunities for uncovering disease phenotypes, mapping treatment pathways, and informing drug repurposing and safety studies [11,12]. The use of EHR data in pharmacoepidemiology research can further our understanding of drug impacts and access, driving advancements in care [13].

Despite the utility of EHR data, a significant limitation arises for research focused on medication use. While EHRs contain granular information on medication prescriptions, commercial pharmacy data are typically held in a separate database that must be connected to the EHR. Because these databases are separate, prescription fill data may not be readily available and are often not directly connected to a specific encounter [14,15]. This discrepancy can lead to inaccuracies in understanding which patients have actually received medication and how medication receipt may influence patient outcomes [16]. This challenge can be thought of as a missing data or observability problem, which can ultimately bias the analysis and interpretation of EHR-based health outcomes research [17,18]. External pharmacy dispensing databases present a potential solution to bridge the information gap regarding prescription fills [19-21], thereby improving our ability to identify patients who have received a specific medication [22].

While commercial pharmacy databases such as Surescripts have begun to be integrated into EHR databases, there have been few studies that have directly linked Surescripts to EHR data for research purposes. Such linkages can be challenging due to the differences in how these various data streams are accessed and updated, and the different ontologies used for medications across systems. In this study, we present a process to link Surescripts and EHR data. To evaluate the utility of this linkage and the impact of evaluating prescriptions versus pharmacy fill data, we conducted an analysis of prescription fills among children and adolescents who were prescribed psychotropic medication. Identification of psychotropic medication receipt is of particular importance in pediatric populations [23-26]. The management of these conditions requires medication adherence and regular follow-up with a provider to ensure that the patient is being adequately treated and that the side effects of these medications are minimal and acceptable to the patient and their family. Notably, access to these medications can vary significantly based on social drivers of health, patient and family attitudes, insurance, and national and global supply chains [26,27]. Given the need for continued evaluation once a psychoactive medication is prescribed, we specifically evaluated patient and prescriber characteristics and the association between a pharmacy fill for a psychoactive medication and subsequent follow-up with the prescribing provider.

Methods

Study Environment and Data

This study included retrospective data from pediatric patients less than 18 years of age who received new psychotropic medication prescriptions within the Duke University Health System (DUHS). DUHS is a medium-sized health system in Durham, North Carolina. DUHS contains over 100 pediatric-serving clinics and is the primary health care provider for approximately 86% of children living in Durham county [28]. All EHR data were extracted from the Duke Clinical Research Datamart, an extract of structured DUHS EHR data that are curated using the standards of the PCORnet common data model [29]. The datamart additionally includes Surescripts prescription fill data, which are reconciled with patient charts within the Epic System. Surescripts facilitates the electronic transmission of prescriptions from EHR to pharmacies and also receives prescription dispense data from most major US pharmacies and pharmacy benefit managers; as of 2020, 96.5% of pharmacies in North Carolina are Surescripts-enabled [30,31]. Data are provided daily based on pharmacy reports and integrated into the EHR system for patient record matching. Pharmacy data for a given patient are updated within the DUHS EHR only upon scheduling of a clinical encounter within the health system.

Study Population

We identified children younger than 18 years of age with new psychotropic medication prescriptions written at an outpatient visit in 2021. Throughout this paper, the term “prescriptions” refers to psychotropic medication prescriptions. All prescriptions were identified using RxNorm concept unique identifiers (RxCUIs; Table S1 in Multimedia Appendix 1). RxNorm is a normalized naming system, and RxCUIs serve as an identifier assigned to an individual drug entity in RxNorm. A new prescription was defined as a prescription made to a patient who did not have a record of a psychotropic medication prescription or pharmacy fill in the 12 months prior to the date of the index prescription. Because Surescripts data are only incorporated for patients with a subsequent health care encounter, the patient cohort was limited to patients who had any DUHS encounter in 2022.

Medication Identification and Matching

A primary challenge in working with Surescripts data is the lack of a direct linkage between EHR prescriptions and pharmacy dispensing records. Moreover, the EHR and Surescripts data use 2 different ontologies for medications: RxCUIs and National Drug Codes (NDCs). NDCs provide package-level information about specific drugs, while RxCUIs can correspond to multiple NDCs for similar drug products with the same active ingredient, strength, and dose form but different package sizes or manufacturers. We first mapped the RxCUIs from the EHR to NDCs in the Surescripts data, incorporating

XSL•FO
RenderX

the drug name to ensure a correct match between RxCUIs and NDCs [32,33]. Second, using data from 2021 through 2022, we matched prescriptions with dispensing records by identifying the nearest fill date that occurred after the prescription date. Thus, prescriptions with matching NDCs and a fill closest to the prescribing date were considered potential matches. A cutoff of days was ultimately applied to define a valid prescription fill, as this interval aligned with an observed inflection point in the Kaplan-Meier curve of filling prescriptions (see Results section).

Contextual Variables

We assessed differences between patients who did versus did not fill their prescriptions on 22 contextual variables, including demographic information, clinical characteristics, encounter characteristics, and service use history (Table S2 in Multimedia Appendix 1). Variables included age, sex, race or ethnicity, BMI, the Area of Deprivation Index (ADI) state rank [34], diagnosis (one or more) at the prescribing encounter, prescription of a selective serotonin reuptake inhibitor (the predominant medication class for depression and certain anxiety disorders) versus other type of psychotropic medication [35], the presence or absence of a completed Patient Health Questionnaire-9 (PHQ-9), the PHQ-9 score (categorized as 0‐4=nonminimal, 5-9=mild, 10-14=moderate, 15-19=moderately severe, and 20-27=severe for patients who had a PHQ-9 in the 2 weeks prior to the index prescription) [36], the number of psychotropic medication prescriptions at the index encounter, the number of psychotropic medication prescriptions in 2021, insurance type at the index encounter [37], characteristics of the prescribing provider and clinic, including provider specialty, and health system service use history in 2020 or 2021, including outpatient, inpatient, and well-child visits [38].

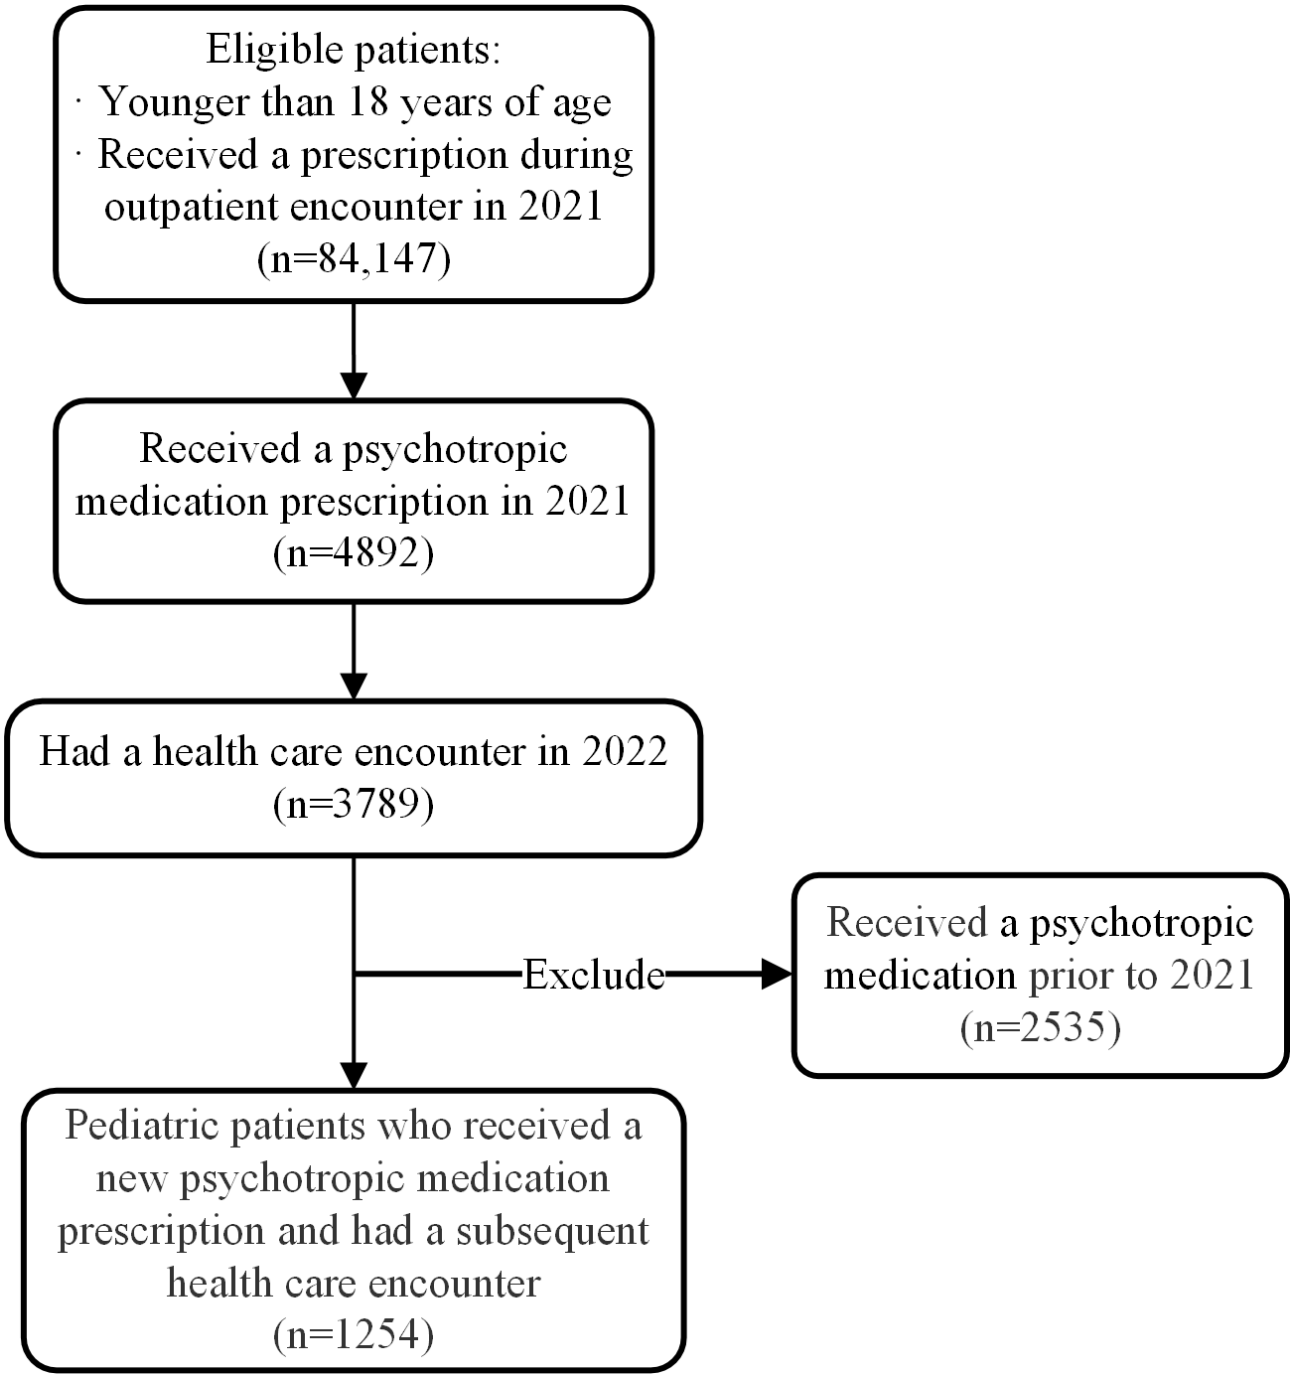
Data Analysis

We initially fit a Kaplan-Meier curve to assess the time from the encounter at which the prescription was created to when the prescription was filled. We then described the demographic and clinical characteristics of patients who did versus did not fill their prescriptions. Continuous variables were summarized using median and IQR. Categorical variables were presented as the number (percentage) for each group. The standardized mean difference was used to measure the magnitude of differences between patients who did versus did not fill their prescriptions, with a standardized mean difference greater than 0.10 indicating an imbalance between groups [39].

To further assess systematic differences between patients who filled their prescriptions and those who did not, we developed a predictive model to identify patients who filled their prescriptions. We applied the least absolute shrinkage and selection operator (LASSO) regression [40] to evaluate the predictability of prescription fills. Data were split into training and testing sets in a 9:1 ratio, with a 5-fold cross-validation conducted to optimize the regularization parameter using the training data and applied the final model to the test data. We evaluated the model performance via the area under the receiver operator characteristic curve (AUROC).

Finally, we evaluated subsequent health care use for patients who did versus did not fill their prescriptions. Using data through 2022, we conducted a time-to-event analysis to identify associations between whether a psychotropic medication prescription was filled and the time until a follow-up encounter with the prescribing provider. We limited eligible follow-up encounters to occur within 90 days of the encounter with the prescription. The period was chosen to provide a sufficient window for capturing relevant follow-up care, as this time frame allows patients to schedule appointments around potential barriers, such as availability or transportation issues, and aligns with common clinical practices for monitoring initial medication responses within 6‐8 weeks [41]. We estimated the marginal hazard ratio (HR) using the Cox proportional hazards model. We derived propensity scores (PSs) using predicted probabilities from the LASSO regression model (described in the Data Analysis section). Inverse probability weighting of PSs was used to adjust for potential confounders (ie, the contextual variables described earlier) by balancing the distribution of covariates between groups. This corrected for the bias that might arise from systematic differences between those who filled their prescriptions and those who did not. All analyses were conducted in R (version 4.1.3; R Foundation for Statistical Computing).

Ethical Considerations



This study was declared exempt by the DUHS institutional review board (PRO00091342). The institutional review board determined that the study posed minimal risk to participants, as it involved retrospective analysis of deidentified EHRs and pharmacy dispensing data. Patient privacy and data confidentiality were maintained by using deidentified datasets, and access to sensitive information was restricted to authorized study personnel.

Results

We identified 1254 pediatric patients with new psychotropic medication prescriptions in 2021 (Figure 1). In total, 976 (77.8%) patients had a fill within 30 days of the prescribing encounter, with only 64 prescription fills occurring more than 1 month after the prescribing encounter (Figure 2). Among a total of 1040 patients who filled their prescription, 950 (91.3%) filled it within 7 days, with 844 (81.2%) filling the prescription on the day of the encounter. We then set 30 days as the cutoff for a valid prescription fill. We found that 278 (22.2%) patients did not fill their prescriptions. These patients would have been misclassified as receiving psychotropic medication if only prescriptions were used to identify recipients of these medications.

Figure 2. Kaplan-Meier curve depicting time from prescription receipt to prescription fill.

We evaluated the demographic and clinical characteristics of patients who filled versus did not fill their prescriptions (Table 1). Notably, the 2 groups were similar in terms of race or ethnicity, age, and rates of inpatient and emergency department encounters. We observed a slight difference in sex, with more female patients receiving prescriptions and also a slightly greater proportion of female patients among those who filled their prescriptions. We additionally observed differences in patient BMI, ADI rank, outpatient health care use, and insurance type. Among patients who did not fill their prescriptions, we observed slightly higher BMIs, higher ADI ranks (indicating that patients lived in a more disadvantaged neighborhood), and a greater proportion of patients with public insurance or who were self-pay. Completion of a well-child visit, a marker of health care engagement and receipt of preventive care, was less common among patients who did not fill their prescriptions, but well-child visit rates did not differ significantly in the year after prescription receipt. We additionally observed differences related to the visit type and prescribing provider among patients who did versus did not fill their prescriptions, with a greater proportion of primary care prescribers among patients who ultimately filled their prescriptions. We found that patients diagnosed with anxiety and those who received a prescription for a selective serotonin reuptake inhibitor were more likely to be among those who filled their prescriptions. Patients who had not taken a PHQ-9 recently or who had a PHQ-9 score less than 5 were less likely to fill their prescriptions. Half of the patients (n=635, 50.6%) did not have a recent PHQ-9 score recorded, though some patients may have received the PHQ-9 modified for Adolescents, which was not extracted for this study. There was a slightly higher median number of psychotropic medication prescriptions throughout the year among patients who filled their initial prescription compared to those who did not (median 2, IQR 1-3 vs median 1, IQR 1-2).

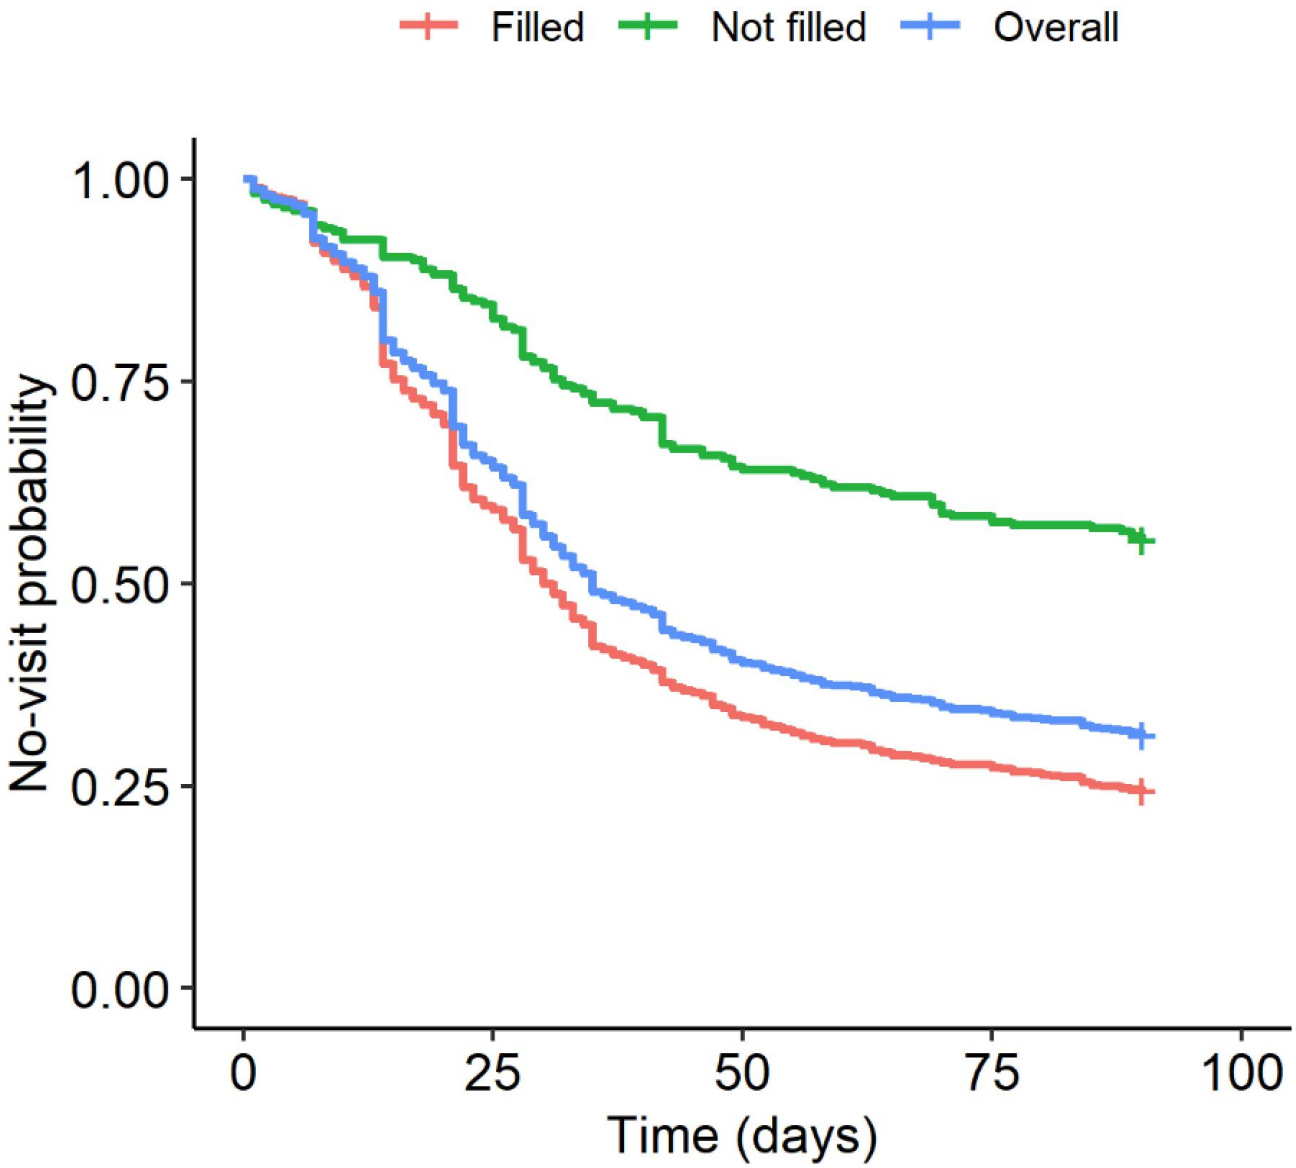
[a]SMD: standardized mean difference.

[b]ADI: Area Deprivation Index.

[c]ADHD: attention-deficit/hyperactivity disorder.

[d]It refers to psychotropic medication prescriptions.

[e]SSRI: selective serotonin reuptake inhibitor.



[f]PHQ-9: Patient Health Questionnaire-9.

Using these patient-level variables, we fit a LASSO regression model to discriminate between patients who did versus did not fill their prescriptions. The model achieved an AUROC of 0.816, demonstrating good discriminative ability, and further indicating that clinical and demographic variables differ significantly between patients who did versus did not fill their prescriptions.

We next evaluated the time to follow-up visit with the prescribing provider between patients who did versus did not fill their psychotropic medication prescriptions (Figure 3). Among patients who filled their prescriptions, 737 (75.5%) had a follow-up visit compared to 123 (44.3%) of those who did not. Patients who filled their prescriptions were more likely to have a subsequent appointment with their prescribing provider than patients who did not fill their prescriptions (marginal HR 1.673, 95% CI 1.463 - 1.913). To account for potential systematic differences between these 2 groups, we derived PSs using predicted probabilities from the LASSO regression model. Inverse probability weighting of PSs was used to adjust for potential confounders. After weighting, we calculated the propensity-weighted HR as 1.447 (95% CI 1.257 - 1.665).

Discussion

Principal Findings

While EHRs contain data on prescriptions, they often lack information on whether these prescriptions are subsequently filled. We sought to evaluate how prescription fill information influenced our understanding of which patients actually receive a prescribed medication and whether a prescription is filled is associated with subsequent health behaviors. We evaluated prescription fill rates among a cohort of pediatric patients who had received prescriptions for psychotropic medications and found that approximately 22.2% (n=278) did not fill their prescriptions. Moreover, there were systematic differences between patients who did versus did not fill their prescriptions. We additionally found that whether a prescription was filled was associated with the likelihood of having a follow-up visit with the prescribing provider. These findings demonstrate that pharmacy dispensing data provide important insights into medication use and contextual information about which populations receive medications and how medication receipt may influence health system interactions and patient outcomes. Importantly, the inclusion of prescription fill data was required to understand how medication receipt may influence subsequent health behavior.

Most prescriptions were filled within 1 week of prescription receipt, with 844 (81.2%) of those who filled doing so on the day of the prescribing encounter. Because these were all new prescriptions, it is likely that patients or their caregivers were motivated to fill the prescriptions to address an acute concern. We found that a greater proportion of female patients filled their psychotropic medication prescriptions compared to male patients. Our finding is consistent with the study by Chua et al [42], which found that female adolescents had a substantially higher monthly antidepressant dispensing rate compared to male adolescents between March 2020 and December 2022. We also found that non-Hispanic White patients and publicly insured patients were more prevalent among the group of patients who did not fill their prescriptions. Children and families with public insurance, such as Medicaid, are more likely to experience adverse social drivers of health [43], which may make it more challenging to follow up with treatment recommendations, including filling a prescription. Our finding that private

XSL•FO
RenderX

insurance is associated with higher prescription fill rates is consistent with trends observed in other populations, such as adults on antihypertension medications [44]. We found that a greater proportion of patients filled their prescriptions from a primary care or psychiatry provider compared to those who did not fill. Patients and families may have felt more confident in a course of treatment from a provider with behavioral health expertise than from providers practicing in other specialties. Results indicated that patients with an anxiety disorder were more likely to fill their prescriptions. Prior research has shown that almost three-quarters of pediatric patients who were newly diagnosed with an anxiety disorder received a psychotropic medication order within 5 years of their anxiety diagnosis [45]. Our findings revealed that patients who filled their initial psychotropic prescription had a higher median number of psychotropic prescriptions throughout the year. This suggests that patients who engage with their initial treatment might be more likely to continue with psychotropic medication management. Such findings align with literature emphasizing the importance of initial adherence as a predictor of sustained engagement in mental health care [46]. These findings support previous research that highlights the complex factors contributing to medication nonadherence [47].

The pronounced differences between children and adolescents who did versus did not fill initial psychotropic medication prescriptions underscore the potential risk of differential misclassification. This is particularly noteworthy, as differential misclassification can introduce bias in estimating associations [15,48]. For instance, if we rely only on prescription records, we may misclassify some patients who did not pick up their prescriptions as medication users. By incorporating dispensing records, however, we can more accurately identify actual medication users, as only those who filled their prescriptions would be classified as having received the drug. In our analysis, we found that patients who filled their prescriptions were more likely to have a follow-up visit than those who did not. This demonstrates how including dispensing records changes our understanding of patient behavior, providing a clearer picture of which patients are truly receiving the prescribed treatment.

Our LASSO regression model, which achieved an AUROC of 0.816, indicated that patient demographic and clinical factors were useful predictors of whether prescriptions were filled. This signifies the potential for developing a clinical decision support tool to indicate which patients are more likely to fill versus not to fill a prescription. Such a tool could guide providers in either tailoring additional follow-up or adjusting treatment modalities. It is also important to understand the factors underlying the reasons that patients do not fill a prescription, such as social drivers that may present barriers to filling a prescription, lack of education provided about the rationale for the medication and possible side effects, or not feeling comfortable telling a provider that they do not want to start a psychotropic medication. The LASSO model identified characteristics that may influence both prescription filling and follow-up visits. By using these predicted probabilities as PSs in our analyses on the association between filling and follow-up visits, we reduced potential confounding, strengthening the robustness of our findings.

We identified a significant association between filling prescriptions and follow-up visits with the prescribing provider. This result indicates that prescription filling behavior likely influences subsequent health care engagement and also highlights the importance of including prescription fill data in EHR analyses that account for medication receipt. It is recommended that youths who receive a prescription for a psychotropic medication have weekly to biweekly follow-up visits with their prescribing provider for the first 6 to 8 weeks after initiating a psychotropic medication to monitor treatment response and side effects [41]. We found that patients who filled their prescriptions were more likely to have a follow-up visit with their prescribing provider. Conversely, patients who did not fill prescriptions were less likely to have a follow-up visit. While this analysis is not able to establish whether medication adherence drives health care engagement or health care engagement drives medication adherence, this association nonetheless highlights the relationship between adherence to medication and health care interactions. At the very least, a lack of prescription fills could serve as an early marker of a lack of health care engagement. It is possible that patients did not return to care due to access challenges, reluctance to discuss not filling prescriptions with providers, or a perceived lack of necessity for medical monitoring. Future research should aim to understand patient outcomes when recommended treatment is not followed, especially if moderate to severe mental health symptoms are present.

Strength and Limitations

This study has some limitations. Of the 4892 patients prescribed psychotropic medication in 2021, a total of 1103 (22.5%) were excluded due to the absence of a follow-up appointment in 2022. While this criterion was applied to ensure complete capture of Surescripts data, it may limit the generalizability of our findings to patients with more consistent health care engagement. Additionally, 635 (50.6%) patients lacked a recent PHQ-9 score, and categorizing PHQ-9 modified for Adolescent scores as “not taken” for consistency limits our ability to interpret associations between PHQ-9 scores and prescription fills. Additionally, we focused on prescription filling behavior for a single prescription per patient; consequently, in instances involving multiple prescriptions on different dates, our matching methodology may require refinement to avoid matching the same dispensing record to more than 1 prescription and ensure each medication dispensing record corresponds to a specific prescription. It is challenging to determine whether prescriptions that lacked a corresponding dispensing record were indeed not filled or simply did not align with a dispensation entry. It is also possible that patients filled their prescriptions at non-Surescripts participating pharmacies, such as digital pharmacies or paid for their prescription out of pocket. Nonetheless, the dispensing rates observed align with prior studies [49]. Furthermore, we restricted our analysis to patients who received health care exclusively within the DUHS and focused only on the prescriptions for psychotropic medications rather than examining multiple health systems or a broader range of medication classes. Future work should investigate prescription filling behavior more broadly across different clinical and geographic populations. Finally, our sample size did not allow us to assess

XSL•FO
RenderX

differences in clinical outcomes between those who did and did not fill their medications.

Conclusions

Overall, our study established a process to link EHR prescription data and pharmacy dispensing databases and shows that the inclusion of dispensing data helps identify patients who have received a medication. This approach enhances our understanding of how medication receipt is associated with health care behaviors, such as follow-up visits. Our findings can potentially inform tools to improve patient medication receipt. The inclusion of dispensing data can be used to reduce potential biases in future pharmacoepidemiology studies.

Abstract

Background: Globally, the incidence and mortality of chronic liver disease are escalating. Early detection of liver disease remains a challenge, often occurring at symptomatic stages when preventative measures are less effective. The Chronic Liver Disease score (CLivD) is a predictive risk model developed using Finnish health care data, aiming to forecast an individual's risk of developing chronic liver disease in subsequent years. The Kanta Service is a national electronic health record system in Finland that stores comprehensive health care data including patient medical histories, prescriptions, and laboratory results, to facilitate health care delivery and research.

Objective: This study aimed to evaluate the feasibility of implementing an automatic CLivD score with the current Kanta platform and identify and suggest improvements for Kanta that would enable accurate automatic risk detection.

Methods: In this study, a real-world data repository (Kanta) was used as a data source for "The ClivD score" risk calculation model. Our dataset consisted of 96,200 individuals' whole medical history from Kanta. For real-world data use, we designed processes to handle missing input in the calculation process.

Results: We found that Kanta currently lacks many CLivD risk model input parameters in the structured format required to calculate precise risk scores. However, the risk scores can be improved by using the unstructured text in patient reports and by approximating variables by using other health data–like diagnosis information. Using structured data, we were able to identify only 33 out of 51,275 individuals in the "low risk" category and 308 out of 51,275 individuals (<1%) in the "moderate risk" category. By adding diagnosis information approximation and free text use, we were able to identify 18,895 out of 51,275 (37%) individuals in the "low risk" category and 2125 out of 51,275 (4%) individuals in the "moderate risk" category. In both cases, we were not able to identify any individuals in the "high-risk" category because of the missing waist-hip ratio measurement. We evaluated 3 scenarios to improve the coverage of waist-hip ratio data in Kanta and these yielded the most substantial improvement in prediction accuracy.

Conclusions: We conclude that the current structured Kanta data is not enough for precise risk calculation for CLivD or other diseases where obesity, smoking, and alcohol use are important risk factors. Our simulations show up to 14% improvement in risk detection when adding support for missing input variables. Kanta shows the potential for implementing nationwide automated risk detection models that could result in improved disease prevention and public health.

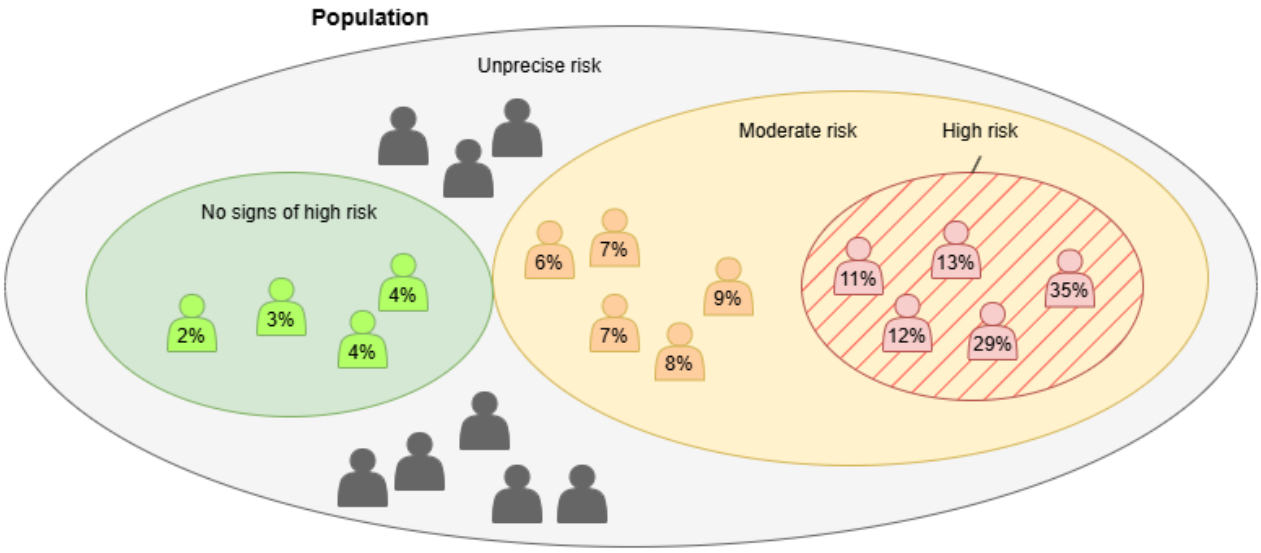
Introduction



Background

Even though health care risk models have been developed for a very long time and have been implemented to be available for individuals, health care still lacks automated health-risk analysis because of limited real-world data (RWD). The burden of liver disease increases yearly in Finland because the Finnish population age average grows, and obesity and overweight are more common problems in the Finnish population [1]. On average, there are 1000 deaths caused by alcoholic liver disease every year [2]. For the early detection of individuals from the general population at high risk for future severe liver disease, the CLivD (Chronic Liver Disease score) score was developed. It can be used to predict severe liver disease incidence in 10 years. The model itself was developed by linking data from Finnish population–based health examination surveys "FINRISK" and "Health 2000" with Finnish health care registries. The model has been validated using data from the United Kingdom, Denmark, the United States, and China [1,3-5].

Risk Model Application to RWD

The missing input data pose a challenge for the large-scale implementation of established risk models in real life [1]. To be able to calculate the exact risk value in many cases, we would not only require additional RWD sources but also changes in health care professionals' practices to ensure they regularly measure the correct parameters from patients. One problem is the negation of information, particularly in cases where data on behaviors, such as a person not smoking or not consuming alcohol, is missing. This leads to a problem where we cannot determine whether a person, for example, is a nonsmoker if there is no record of it. Despite the challenges, health care RWD enables early identification of individuals at high risk by analyzing their current characteristics, which is crucial for health care professionals in planning treatments. The exact risk value would be easy for everyday people to understand, but for health care professionals in preventive work and treatment planning, it is also important to detect potential high-risk cases as early as possible and identify if the person is a high-risk patient. For this kind of usage, we introduce a process that helps to detect high-risk and potential high-risk individuals. Figure 1 describes that kind of division at the population level.

Figure 1. Case example of population risk categorization based on a personal risk value.

The Finnish National Electronic Health Record System

Kanta Services is the Finnish National Electronic health record system where data are recorded from almost all Finnish health care providers including the public and private sectors and primary and special care [6]. Kanta Services entered production in Finland in 2010 and it has been used for more than 10 years in Finland overall [6]. However, Kanta has been developed in stages, resulting in different data types having different levels of availability. Kanta Services in general consists of four different parts: (1) the social health care part, (2) the prescription center, (3) the patient data repository (PDR), and (4) personal health records [7]. In this study, we only use data from the Kanta PDR.

In Finland, the 2019 Act on Secondary Law made it possible to use health care data for research purposes [8]. Before that, the data were available only for their primary use, which is patient care. Kanta is an exceptional RWD source because it covers almost the whole Finnish population and has recordings from more than 90% of all Finnish health care service providers. [6] This makes it possible to analyze previously developed health care risk models and develop new risk models by using large data sources that represent the entire national population.

XSL•FO
RenderX

Since data are continuously generated in Finnish day-to-day health care and all Finnish health care systems are integrated into Kanta, developed and tested risk models can also be applied in actual patient care. Popular well-being service providers have implemented automated health risk analysis based on data collected from the person regularly or data obtained from wearable devices like smartwatches [9]. These types of data still lack validation from health care professionals. Validation is a key element for incorporating automated risk analysis results in everyday patient care and using them as a diagnostic tool. The Kanta PDR contains only data validated by health care professionals, as only they are authorized to record information in the system [10]. Kanta Services also has a personal health records data repository containing data recorded by the people themselves. However, it is not used in this research as it is still under development. In this study, we aim to analyze data validated by health care professionals [11].

Methods

Overview

In this study, we aim to research the CLivD score risk model automation possibilities with Kanta PDR. We use Kanta PDR as the only data source for the risk model to have an overall picture of the data availability status. We consider four different scenarios of data usage possibilities: (1) first, we test the risk model results with the available structured data; (2) next, we aim to use other structured health care information to approximate missing information; (3) after that, we analyze the possibilities of using free text; and (4) finally, we analyze completely missing input variables. For this research, we have 2 main objectives:

1. To evaluate the feasibility of implementing an automatic CLivD score with the current Kanta platform.
2. To identify and suggest improvements for Kanta that would enable accurate automatic risk detection.

Dataset

In this study, we used the dataset consisting of the medical documents of 192,400 individuals archived in the Kanta PDR between 2014 and mid-2022. Data in Kanta are recorded using the Clinical Document Architecture Release 2 (CDA R2) format, as defined by Health Level 7 (HL7) [12]. CDA R2 documents are XML documents that follow a defined format [13]. In the Finnish health care environment, the local Finnish version of the global HL7 CDA R2 is defined by Health Level 7 Finland, Kela, and the Finnish Institute for Health and Welfare (THL) [12].

The dataset was chosen by Kela from Kanta and the study cohort was randomly selected across the whole Finnish population without any limitations to specific health care providers or locations. The dataset included all documents that were recorded in Kanta PDR after an individual turned 18 years old. Documents were pseudonymized by Findata and delivered in the original CDA R2 XML format to the secure Kapseli environment. Before the analysis was done, the dataset was split randomly into development and validation datasets. Data were evenly divided, with both development and validation datasets containing 96,200 patients. The data were split to accommodate future plans for using machine learning and other methods requiring validation in subsequent projects; however, in this project, only the first half of the data were used. After the data are split, CDA R2 XML documents must be processed so that all relevant data are parsed for analysis. For data processing, a separate data process library and data model were designed. Data parsing consisted of structured laboratory measurements, structured diagnosis data, structured physiological measurements, free-text sections of patients' ongoing treatment reports, and some basic information about the document and patient. We did not obtain access to death records because they are not recorded in Kanta and would have required separate permission and retrieval from the Digital and Population Data Services agency. A more detailed analysis of the dataset can be found in the study by Männikkö et al [14].

Risk Model Implementation

The original research on the CLivD score introduced 2 risk calculation models: $Model_{lab}$ and $Model_{nonlab}$. Both models predict the risk of chronic liver disease in people aged 40 years or older. The difference between models is that $Model_{lab}$ also considers the person's gamma glutamyl transferase (GGT) laboratory test result. Both risk calculators have 4 different exclusion criteria [1]. If a person meets even 1 of the exclusion criteria, there is a possibility that the risk calculator may not function as expected. Exclusion criteria are listed in Textbox 1.

For these risk models and use cases, we introduce a model for categorizing patients to 4 different categories: "low risk," "moderate risk," "high risk," and "not specified risk." Categorization is based on 2 risk values: "minimum risk" and "maximum risk." The risk calculation process itself was introduced slightly later. This approach is good from the Kanta development point of view, as future developments and the addition of more information to Kanta will allow risk categorization to be easily applied to the new data. The more data we collect from the person, the more reliable the model becomes, resulting in a significant reduction in the "Not Specified" category. Table 1 presents the cutoff values for each category.

XSL•FO
RenderX

Textbox 1. Chronic liver disease score risk model exclusion criteria.

Exclusion criteria

- Age: above 40 and under 71 years.
- Liver disease diagnosis: *ICD-10* (*International Statistical Classification of Diseases and Related Health Problems, 10th Revision*): K70-K77, C22.0; *ICD-8* (*The International Classification of Diseases, 8th Revision*) and *ICD-9* (*International Classification of Diseases, 9th Revision*): 570-573, 155.0.
- Chronic viral hepatitis diagnosis: *ICD-10*: B18.
- Current alcohol abstainer: previous alcohol use. Can be identified with *ICD-10* codes: F10.20 and other F10.2X.

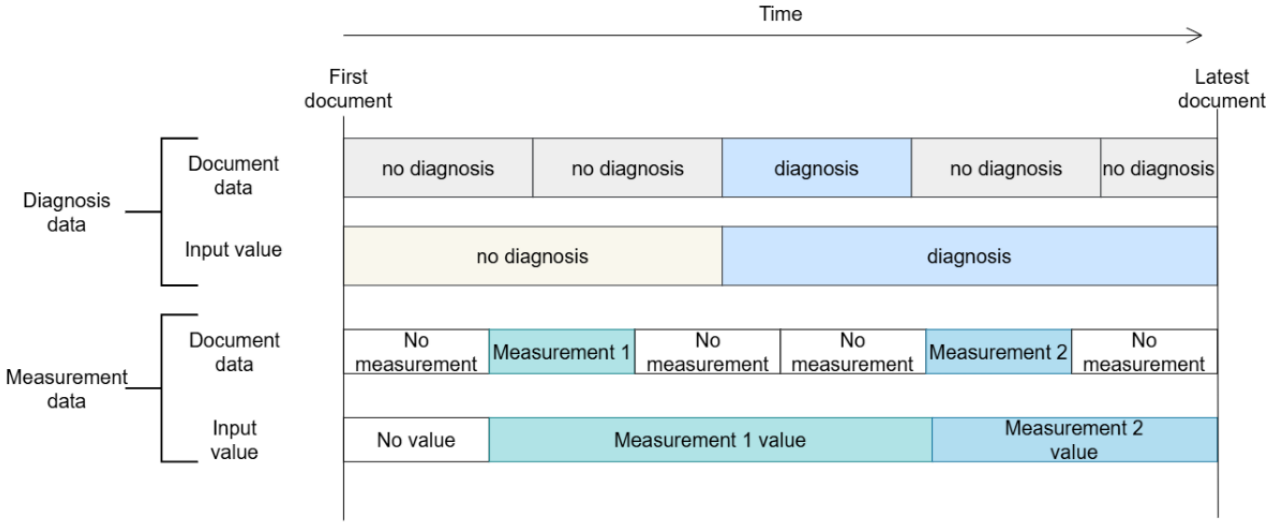


Table 1. Risk categories' cutoff values for minimum and maximum risk.

Risk	Low risk	Moderate risk	High risk	Not specified risk
Minimum risk	≤5%	>5% and <10%	≥10%	<5%
Maximum risk	<5%	>5%	≥10%	>10%

The CLivD score risk function was developed and validated using cohort studies, where the population is sampled, assessed at a certain time, and then followed for outcomes [1]. Kanta patient data are distributed over time, with measurements conducted at different points in time.

We use parameter lifecycles or lifetimes to do this, where we specify the length of time a measurement or diagnosis is valid, both before and after it appears in the medical record. In this work, we used 2 different lifecycles: 1-year lifecycles where measurements are valid for 1 year after measurement, and infinite lifecycles where they stay valid until the next measurement, or until the end of document history. For both lifecycle types, we used an infinite validity time for diagnoses. An example of parameter lifecycles is shown in Figure 2 with a finite (eg, 1 year) lifetime for measurements and an infinite lifetime for diagnoses.

Figure 2. In real-world data, the validity period of input parameters must be defined, as different measurements remain valid for varying durations both before and after the measurement.

We implemented the CLivD risk function in Kapseli using Python (Python Software Foundation). The implementation flow diagram is described in Figure 3. The timeline is formed by using all known relevant patient data and applying the previously discussed parameter lifecycles to it. Due to missing input variables, we calculate 2 risk values: the minimum and maximum risk. The minimum risk is obtained by substituting the missing variables with their lowest values, while the maximum risk is determined by using their highest value. The complete list of default values can be found in Table 2. Values are used in the case where the input value is not available from an individual's medical history.

By calculating the minimum risk and maximum risk, we obtain a risk range. A smaller risk range directly implies a more accurate risk value. Missing input parameters increase the risk value range. The goal is to narrow the risk value range toward the actual risk value in the long term. Possible ways to narrow the risk range are, for example, getting the exact missing value from other data sources, asking for information from the patient, or determining the magnitude of the missing information from free-text evaluation.

XSL•FO
RenderX

Figure 3. Risk categorization process flow. CLivD: Chronic Liver Disease; GGT: gamma glutamyl transference.

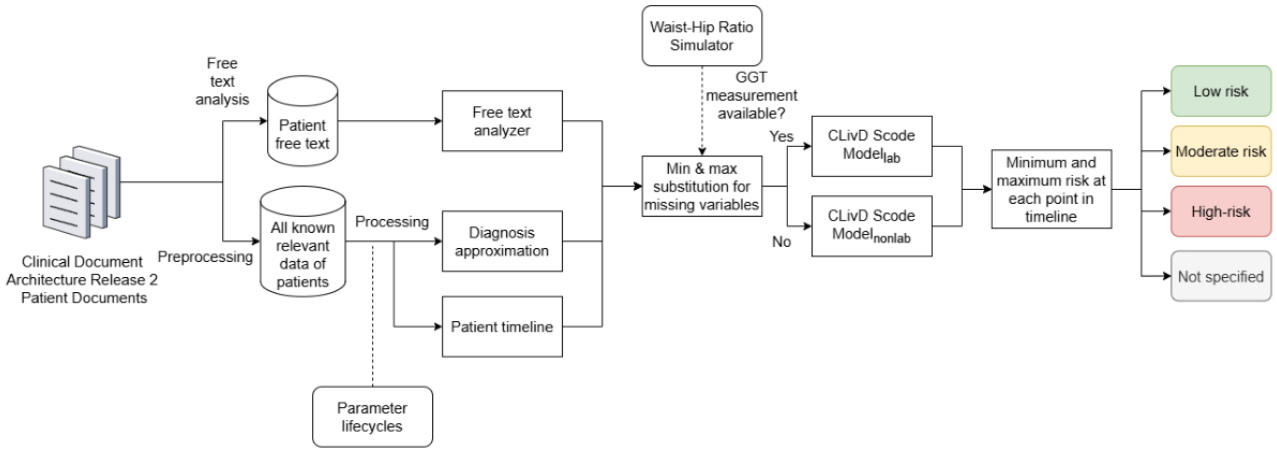

Table 2. Default values for risk calculation when an input parameter is missing.

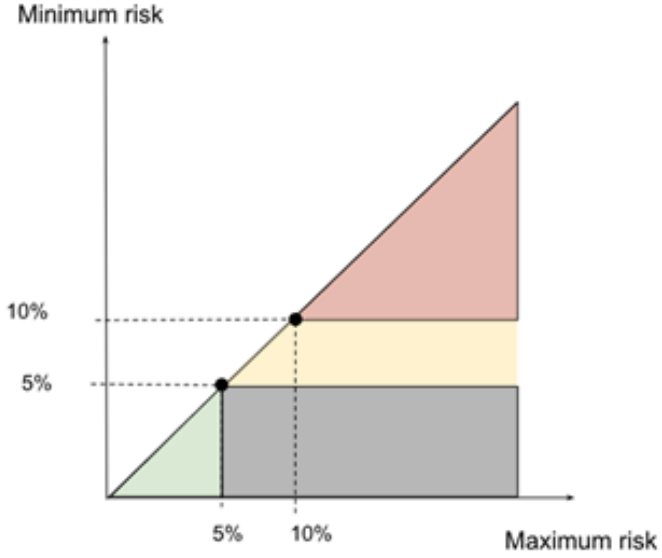

Input parameter	Default minimum value	Default maximum value
Gender	Always available	Always available
Age (years)	40 (basically, always available)	70 (basically, always available)
GGT[a]	Use non-GGT model	Use non-GGT model
WHR[b]	0.7	1.3
Smoking	False	True
Alcohol usage	0	49
Diabetes	False	True

[a]GGT: gamma glutamyl transferase.

[b]WHR: waist-hip ratio.

In Figure 4, an illustration and example goal for the risk value ranges are shown. The line represents an ideal case where all input variables are known, and an exact risk value with equal minimum and maximum risk can be calculated. The lower turquoise triangle represents an area where the maximum risk is below 5%, and the patient can be considered low risk. The upper red triangle represents an area where the minimum risk is above 10%, and the patient is at high risk. The yellow area is the moderate risk area where patients' risk value is higher than 5% but not high enough to determine the person as a high-risk patient. The gray-colored area represents the "not specified risk" category, where the risk range between the minimum risk and maximum risk is too wide to identify the correct category.

Figure 4. Risk categories in minimum and maximum risk plane.

XSL•FO
RenderX

In this study, we target these colored areas as a goal, as an exact risk value is not feasible with the missing data, but a risk range is still helpful for determining the course of action. The risk thresholds can be configured for different use cases. The complete risk calculation formula can be found in Multimedia Appendix 1.

Ethical Considerations

This study involved pseudonymized health care data produced in health care services in Finland. Data were collected, delivered, and pseudonymized under the legislation on secondary use of health care data in Finland. Finnish authority Findata validates data requests and project plans before granting permission to access data (THL/1851/14.02.00/2021). Findata also has the responsibility to create the data pseudonymization before delivery. Data were processed and analyzed in an audited secure computing environment known as "Kapseli" with restricted access to it. All the results presented in this paper have gone through the Findata anonymization validation process where Findata ensures that results taken out of a secure environment are anonymized. Ethical aspects of the project have been evaluated by Findata during the data request process.

Results

Overview

Analysis was made in 4 iterations. At first, we analyzed the structural data and its occurrences. After that, we tried to improve the model with the diagnosis use to determine the magnitude of missing input variables. After that, we used free-text for tobacco and alcohol information, and at last, we simulated waist-hip ratio (WHR) in cases where it would have been available from different data sources.

The study initially included 96,200 participants. After applying the exclusion criteria, only 51,275 eligible individuals remained for the risk model. A total of 44,925 individuals were left out of this analysis because they did not match the original criteria. Almost 50% of the individuals were excluded, with the age-related criteria being the most common reason for exclusion.

Structural Data

We can analyze the CLivD score risk calculation results using Kanta PDR structured data as a precise input parameter, without approximating the parameter magnitude. In Table 3, we describe the frequency of relevant variables appearing in a patient's medical history in a structured format. The occurrence of 1 means that the variable has been measured just once during the patient's medical history according to the Kanta data. Age and gender are registered in every document and are always available. The table shows that 0 measurements are the most common, and more than 5 measurements are a very rare case among risk model input variables.

WHR and alcohol use are not shown in this table as they are not present in a structured format in the Kanta data. Besides age and gender, the only input variables with at least 1% availability are GGT and fasting glucose, with approximately 5% and 13% total occurrence, respectively. As fasting glucose (7 mmol/L) is only used as an alternative to a diabetes diagnosis, it is not a required input variable. We interpret a missing measurement to mean that the patient does not have diabetes, provided the other criteria are not met. BMI and waist circumference are not input variables for the risk model but were investigated as possible alternatives to the missing WHR. Waist circumference measurements are very rare and will not considered further, whereas BMI has moderate availability and will be discussed later.

Table 3. Parameter occurrences in the Kanta patient data repository between 2014 and 2022 (N=96,200).

Occurrence during patient history, n	Fasting glucose, n (%)	Height, n (%)	Weight, n (%)	BMI, n (%)	Waist circumference, n (%)	Gamma glutamyl transferase, n (%)	Smoking, n (%)
0	84,521 (87)	76,815 (79)	78,003 (81)	80,651 (83)	95,812 (99)	91,891 (95)	96,193 (99)
1	9141 (10)	10923 (11)	9007 (9)	8482 (9)	349 (<1)	3144 (3)	7 (<1)

Diagnosis Use

Because the Kanta PDR is missing WHR data, and alcohol usage data and tobacco usage information are quite rarely found in a structured format, we need to use other health care information found in the Kanta PDR. For alcohol and tobacco usage, there are some *ICD-10* (International Statistical Classification of Diseases and Related Health Problems, 10th Revision) and ICPC-2 (International Classification of Primary Care version 2) diagnosis codes that can be used for risk calculation. With the smoking diagnosis codes, we get the information that an individual smokes. This serves as the exact value for the CLivD score model, as it does not consider the number of cigarettes a person smokes per week.

For alcohol usage, the CLivD score model uses the number of servings as an input. Consequently, by using diagnosis codes, we aim to estimate the magnitude of alcohol usage and narrow the risk range. For alcohol usage, we use diagnosis codes that relate to heavy consumption of alcohol. Based on those diagnosis codes, we can say that the person has consumed alcohol at above-average levels for some time before getting the diagnosis. The largest *ICD-10* group that will be used is F10 "Mental and behavioral disorders due to the use of alcohol" and from the ICPC-2 codes we will use P15 "Chronic alcohol abuse"

XSL•FO
RenderX

and P16 “Acute alcohol abuse.” For high-risk alcohol users, we use the “23 alcohol servings per week” approximation for men and the “12 alcohol servings per week” approximation for women [15]. The complete list of diagnosis code mappings to risk model input parameters can be found in Multimedia Appendix 2. Table 4 shows the statistics from diagnosis occurrences in our dataset.

Table 4. Alcohol and smoking-related diagnosis occurrences in the Kanta patient data repository between 2014 and 2022 (N=96,200).

Diagnosis code	Display name	Number of diagnoses, n
Alcohol-related		
F10.09	Unspecified alcohol intoxication	2158
F10.1	Alcohol abuse	18,141
F10.20	Alcohol dependence uncomplicated	3697
F10.24	Alcohol dependence with alcohol-induced mood disorder	3251
F10.25	Alcohol dependence with alcohol-induced psychotic disorder	3921
F10.26	Alcohol dependence with alcohol-induced persisting amnestic disorder	3328
F10.29	Alcohol dependence with unspecified alcohol-induced disorder	3268
F10.39	Alcohol withdrawal symptoms unspecified	1690
P15	Alcohol abuse (chronic)	4494
P16	Alcohol abuse (acute)	2417
Smoking-related		
Z72.0	Tobacco use	1102
P17	Tobacco abuse	465

Free-Text Analysis

Kanta PDR contains a lot of free text in patients’ ongoing treatment reports that describe the patient’s overall health status and living habits. As a result, the free text can be used to find information concerning alcohol usage habits and tobacco use. Due to the limitations on available resources, such as the lack of a graphics card in a secure “Kapseli” environment, we had limited options for free-text analysis. We were not able to use advanced machine learning models or any generic artificial intelligence for text analysis. Instead of those methods, we used a simple regex-based keyword search and converted found text phrases into usage categories. With this analysis, we aimed to understand how often tobacco- or alcohol-related texts appear in ongoing treatment reports and how it would improve the CLivD score model. For more precise free-text analysis, more advanced tools should be used to gain more reliable results.

Tobacco usage is simpler because we can find texts that indicate whether a person is a smoker or a nonsmoker. There are cases where the texts might state, “person has smoked 10 years ago,” making it difficult to determine whether the person currently smokes without additional context. However, in most cases, we can get quite good results by finding sentences related to smoking status.

Alcohol usage is different than tobacco use. Because alcohol servings are defined in a weekly servings format in the CLivD Score model, we must define alcohol usage categories also for free-text analysis. Based on the analysis, we converted phrases into alcohol usage categories. Category mappings are defined in Multimedia Appendix 3 and are based on the THL alcohol risk table [15]. We noticed that alcohol usage was described in free text using various ways and words. We also noticed that the amount descriptions were, in many cases, abstract, and the conversion to the alcohol usage category was not reliable. However, we managed to find clear and reliable cases of alcohol usage from the free text and managed to use them. For the text finding, we used keywords like “käytä alkohol,” “ei\s*\w*\s*alkohol,” “runsa\w*\s*alcohol,” and “vieroitus|vierotus|päihtymys|putki|katkaisu.” Multimedia Appendix 3 defines the alcohol usage categories used in free-text analysis. The categories are based on THL definitions for alcohol usage risk groups defined as alcohol servings per week. In each category, there is minimum and maximum alcohol usage. In the risk model when calculating the minimum risk, the alcohol usage category minimum value is used and vice versa. A complete list of alcohol usage and tobacco use text analysis keywords and mappings can be found in Multimedia Appendix 4.

Risk Calculation Results

We apply the risk function to the patient’s timelines and attempt to assign their risks to the colored areas shown in Figure 4. These risk areas would be enough to classify patients into low- and high-risk groups, with the uncolored area representing gray area where no definite conclusions can be made.

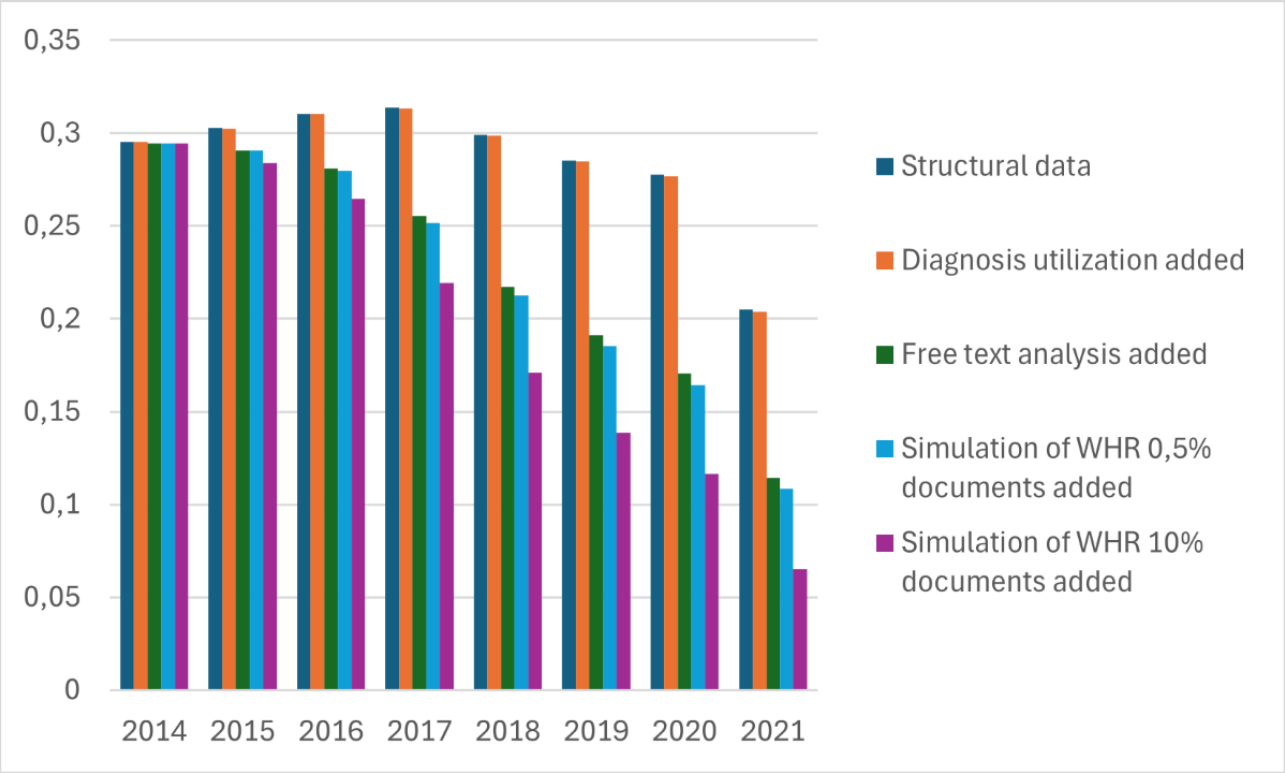
The average risk difference from our test runs is presented in Figures 5 and 6, with Figure 5 representing cases where an infinite timeline was used and Figure 6 representing cases where a 1-year lifetime was used. Risk difference is calculated by subtracting the minimum risk value from the maximum risk value. Smaller differences imply a more precise risk value. As we can see from the figures, the average risk difference has decreased as the data have been developed in Kanta. If we look

XSL•FO
RenderX

at the case where structural data, diagnosis, and free text all have been used, the risk difference has been reduced by almost 20% points. We can also see that the free text use and the high availability simulation of WHR have had the largest impact on the risk difference.

In the test run, we calculated the most precise risk value for each person throughout their history in Kanta and categorized them by that risk value. Results can be seen in Multimedia Appendix 5.

Figure 5. Average risk difference development between 2014 and 2021 with eternal parameter lifetime. WHR: waist-hip ratio.



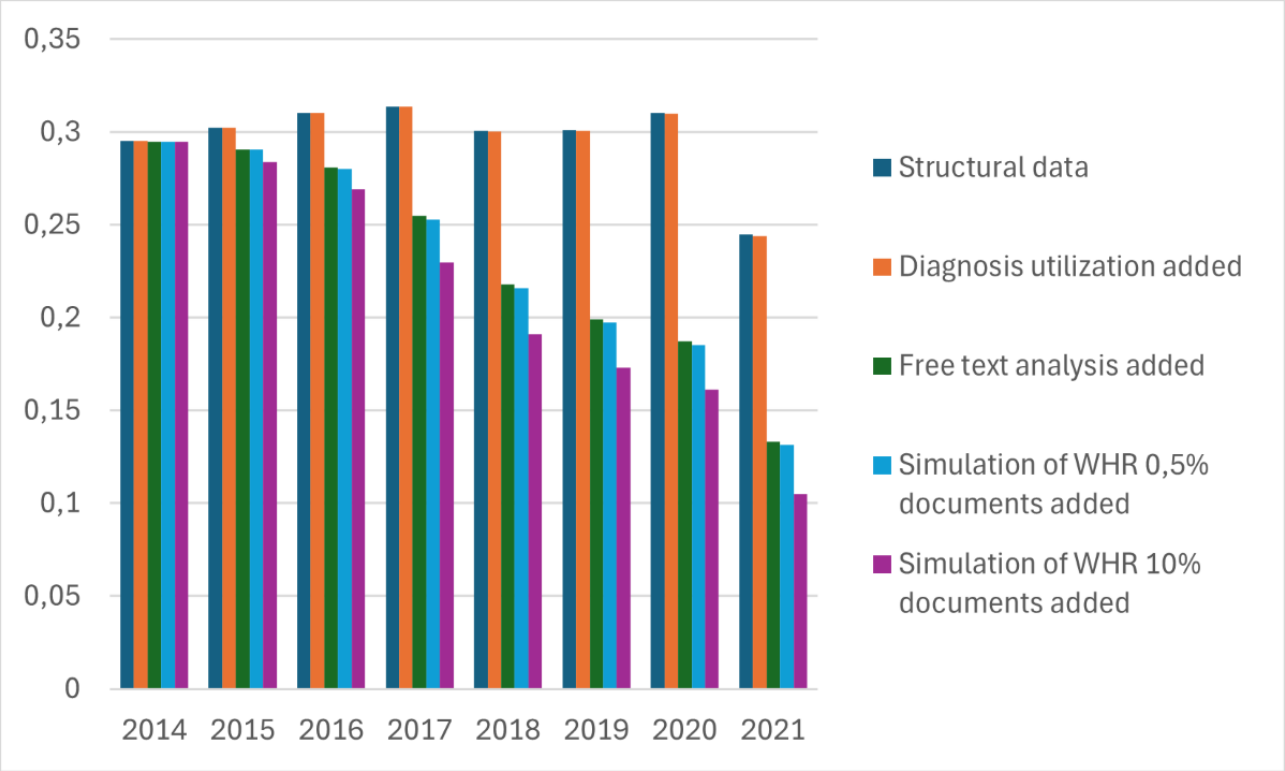


Figure 6. Average risk difference development between 2014 and 2021 with one year parameter lifetime. WHR: waist-hip ratio.

XSL•FO
RenderX

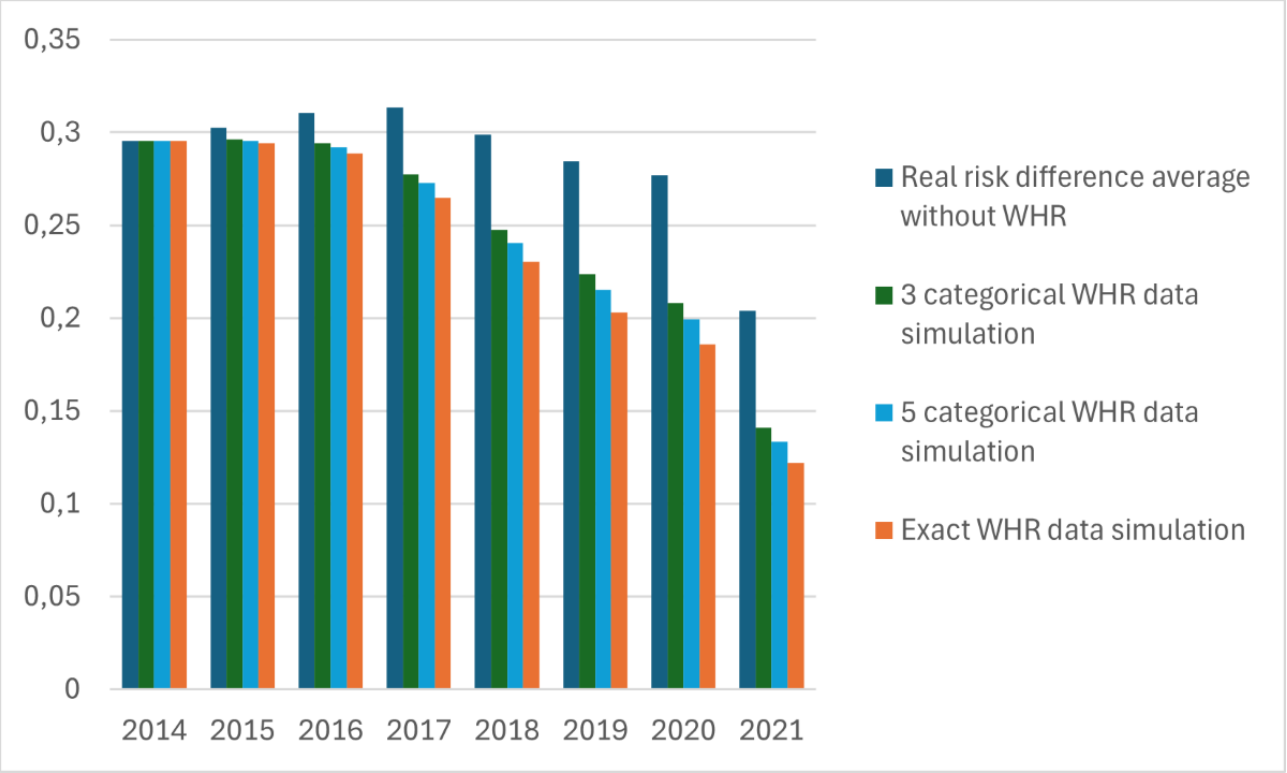
As we can see, based on the results with only structural data, we can only categorize 341 out of 51,275 (<1%) individuals into any category. By adding diagnosis use for approximation, we did not achieve notable improvement in categorization. When adding the free-text analysis, we were able to categorize 21,020 out of 51,275 people (41%). Even though we did not manage to categorize any person into the high-risk category, we managed to identify individuals who were not at high risk. Due to the high availability of WHR information, we can categorize 38,279 out of 51,275 people (75%). A small number of individuals may be incorrectly placed in the high-risk category in the WHR simulation due to an inaccurate WHR value relative to their overall health status. However, this does not affect the overall categorization percentage, as it represents the proportion of individuals successfully categorized rather than the distribution across specific categories. At the original CLivD score research, fewer than 2% of individuals were identified as high-risk from a cohort of 25,760 individuals. Approximately 3% were identified as being at moderate risk in the original research. In our categorization, 2125 out of 51,275 individuals (4%) were classified into that category [8]. Based on these results, we can say that the results match because the CLivD score development dataset was from before 2012, while our dataset was from after 2014, and the risk for chronic liver disease has increased in the overall population in Finland.

WHR Data

The WHR is among the most important variables for the CLivD risk score. Unfortunately, it cannot currently be obtained from Kanta data, as it is not supported in a structured format, and we were also unable to find it in the texts as well. As an alternative, we considered BMI, waist circumference, or hip circumference to predict the WHR. Of these, only BMI has meaningful availability in Kanta, so waist and hip circumferences were not considered further. BMI has been measured for 15,359 out of 51,275 (17%) individuals.

While associations between BMI and WHR can be found in the literature [16,17], the suitability of BMI as a predictor for severe liver disease has recently been disputed [18-21], with its suitability affected by gender and potentially other factors. Due to the seemingly complex and unclear nature of BMI and WHR interaction, we decided not to pursue WHR prediction for now.

For the analysis purpose, we simulated WHR data effect on the CLivD score risk model results in a few different scenarios. The first scenario involved obtaining the exact WHR data from the Kanta PDR, the second scenario involved the individual requesting their WHR data using the WHR groups, and the last scenario involved the individual measuring their exact WHR. These 3 scenarios were created because they serve as use case scenarios of the risk model differently.



The simulation was done by populating the timelines with WHR data. In the first case, 0.5% of all documents recorded in Kanta contained the WHR data, while in the second case, 10% of documents recorded in Kanta would have contained the WHR data. The first case represents the condition where WHR data would have the same kind of availability as all other basic physiological measurements currently in Kanta. The second case represents the condition where the WHR data would be highly available for individuals, for example, from other data sources. For the simulation, WHR values were generated using a normal distribution, with a mean of 0.96 for men, a mean of 0.84 for women, and a variance of 0.07. These values are found to be representative of the Finnish population based on research [22].

WHR as a measurement is slightly complicated for individuals to assess on their own, which raises the bar for using it in the CLivD score risk model. Because of this, we tested the cases to see if the simpler WHR categorization would give good results for risk categorization. The WHR categorization for a person could be easily implemented by displaying images of different body types and using these types to represent a WHR range. For the person, it would be easy to answer which image matches their own body. In this simulation, the exact WHR values were changed to the corresponding WHR category. After that, the average risk differences for the population were calculated for the cases, using 3 categories and 5 categories. WHR categorization definitions can be seen in Multimedia Appendix 3.

The results of the test run with the WHR simulation can be found in Figure 7. As we can see from the graph, there is no big change between the 3 categorical WHR data simulations and the exact WHR data simulation. If the WHR were requested by the individual, it would be simpler to assess body type using 3 categorical questionnaires rather than obtaining the exact WHR value.

Discussion

Principal Findings

We conclude that the current Kanta PDR data are not enough for precise risk calculation for the CLivD score or other risk models where obesity, smoking, and alcohol information are important risk factors. Our simulations show up to 14% improvement in risk detection when additional data sources are considered for obesity. Kanta shows excellent potential for implementing nationwide automated risk detection models that could result in improved disease prevention and public health.

Based on the results of this study, it is not possible to calculate precise risk scores using the CLivD risk model with the current data in Kanta PDR. However, risk categorization enables the possibility to use the CLivD risk model with Kanta PDR data so that it considers missing input parameters and enables future data development in Kanta. We noticed that risk categorization improved when the magnitude of input parameters was approximated using diagnosis information, and free text from the patient's ongoing treatment report was used for input parameter parsing. When using the structured data from Kanta PDR as an input, we were able to identify only 33 out of 51,275 (<1%) individuals in the "low-risk" category and 308 out of 51,275 (<1%) individuals in "moderate-risk" category. When diagnosis use and free-text analysis were added to the model, we were able to identify 18,895 out of 51,275 (37%) individuals in the "low risk" category and 2125 out of 51,275 (4%) individuals in the "moderate risk" category. In both cases, we were not able to identify any individuals in the "high-risk" category, because of the missing WHR data. When we added the WHR simulation to the risk model, we started to identify "high-risk" individuals. We evaluated 3 scenarios to improve the coverage of WHR data in Kanta and these yielded the most substantial improvement in prediction accuracy.

Comparison With Previous Work

In Finland, there is no systematic screening or automated risk assessment for chronic liver disease implemented in everyday health care. Diagnostics are quite random, and, in many cases, incidents are noticed during the treatment of other symptoms. Based on studies in Great Britain and Denmark, 70%-75% of cases of cirrhosis are only diagnosed when the patient ends up in the hospital's emergency room with a serious complication of cirrhosis. In this case, the mortality rate is very high. Although similar research has not been conducted in Finland, the situation is presumed to be equally concerning.

There are automated methodologies implemented to diagnose liver fibrosis, but large-scale systematic analysis and screening are still yet to be implemented because of missing nationwide data. One randomized controlled study developed a care pathway for identifying advanced liver disease in patients with type 2 diabetes in Hong Kong and Malaysia. In that study, the results show that automation can lead to an increase in the number of referrals for patients with type 2 diabetes and abnormal fibrosis scores [23]. Another study showed that nationwide screening helps the early detection of liver cirrhosis [24]. Both of these studies have shown that screening and automated risk assessment can improve liver disease detection and it would be beneficial to implement nationwide health care analysis.

Strengths and Limitations

The applied risk model used in this study has built-in flexibility for different availabilities of input data. This supports data quality development and enables flexible adaptation of different formats of input data. With this approach to risk assessment,

XSL•FO
RenderX

we do not obtain the exact risk value from the model. However, this provides flexibility, as the risk categories offer valuable information as the exact risk value.

Approximation of smoking status and alcohol usage can be extracted using free text or various *ICD-10* or ICPC-2 diagnosis codes. These are still approximations and have the possibility for errors. In particular, it is unusual to have exact values from free text for alcohol usage, as it can be described using various words. As we were not able to use modern models for text analysis, such as generative large language models, we were still able to identify texts that refer to alcohol usage and smoking status. This means that although multiple texts refer to that information in free text, a consistent model is needed to analyze the data and achieve more reliable results. For that, the modern and more developed models would be a better option. To mitigate the analysis risk, we should target to convert alcohol usage free text into predefined categories, which would decrease the magnitude of errors in the analysis results.

Defining the new measurement type in the Kanta structural data does not require much work, but transferring the measurement results to Kanta can be time-consuming since the changes need to be implemented across all patient management systems that record actual data. In addition to changes to the actual systems to support the new measurements, changes in health care professional's everyday patient care practices are also necessary to perform the actual measurement.

Future Directions

To enhance the accuracy of risk model results, WHR data would be required. There are several possible ways to obtain WHR information, and their effectiveness depends on the use case. For example, Kanta PDR could have a new measurement type and WHR measurement could be added to general measurements in health care visits. It would take several years for Kanta to achieve broader population coverage since data are recorded only from individuals who use health care services. The other possible way would be to ask for information from the individual and use that in the risk model. There are a few ways to request a value from an individual; an exact value, a categorical question, or a camera measurement. The exact value asking is beneficial for the risk model because it will give the best results, but the measurement is quite difficult for individuals to perform on their own. Categorical questioning is easier to answer for the individual and can be implemented by showing photos of different body types, allowing the person to select the one that resembles them the most. This method would have the most errors, but it would be the easiest way for individuals. The last option would be to use a smartphone to measure WHR through the camera. The body can be identified using artificial intelligence, and the ratio can be calculated accurately based on an image. This requires a little bit of effort from the person but gives a precise risk value as a result.

As an alternative, we could show the WHR ranges assigning a patient to the low- or high-risk category, or we may consider developing a new risk function using BMI instead of WHR. As a potential future development, we may consider using Kanta PHR where patients themselves could record their WHR or ask categorized questions from the patient about the WHR.

Even though the risk model could not identify any high-risk patients with current Kanta data, it would still be important to implement this kind of risk model to use in everyday health care, because it would give real-time feedback about Kanta data quality development and guide health care professionals to make correct measurements for the patient. Patient management systems could inform health care professionals during patient visits about the exact measurements missing from the Kanta, preventing the calculation of the risk.

One option for finding missing data is using local data sources or mobile wellness apps. Both cases have their strengths and weaknesses. Local data sources for each patient management system may contain richer data than what is stored in Kanta, but integrating them into each local system requires a lot of work and maintenance. The National Electronic Health Record system in this case offers greater flexibility and simplifies data use. Changes should be made so that local data sources record all key values to Kanta. On the other hand, mobile wellness apps like Apple Health, Google Fit, and so on, store a lot of valuable data from personal health perspectives. The problem is that with the current legislation, nonmedical device data cannot be used in health care. This means that this offers possibilities only for personal health risk assessments and not for health care professional use cases.

In future work, the time dimension could be further used to track a patient's risk over their whole patient history by plotting a graph of their minimum and maximum risk at each point in their timeline. This could help determine, for example, whether a change in their risk warrants an intervention or highlight a period of missing data in their history where the risk value is more uncertain.

In conclusion, the Finnish national electronic health record system has the potential to support automated risk detection models across the nation. However, capturing key chronic disease risk factors such as obesity, smoking, and alcohol use requires improvement.

Acknowledgments

The authors would like to thank Klaus Förger and Mika Torhola for helping in planning the initial project and revising the idea and MSc Esa Harju for helping with the analysis implementation. This study was funded by Pfizer.

Data Availability

Data were used under the secondary use of health care data law. The Finnish data permit authority Findata gave permission to use the data. The data were collected by Kela, the owner of Kanta Services. Data were processed in an audited secure environment

XSL•FO
RenderX

with limited access. To have access to similar data, you must apply to Kanta Services data through Findata and define the collected data types. After the permission has been granted, the secure environment can be ordered, and the data will be delivered to it. The generative AI model ChatGPT was used only for clarifying the language.

Authors' Contributions

VM contributed to writing the original draft. JT conducted formal analysis. ET contributed to conceptualization. O-PH managed supervision. FÅ handled review and editing of the manuscript.

Conflicts of Interest

ET and O-PH work for Pfizer Oy and own Pfizer stocks. VM and JT work for Atostek Oy. Atostek Oy provides an eHealth application programming interface gateway service that enables health care and social welfare providers a fast and easy connection to Finland's national Kanta services. The publication is related to the quality of data stored in the Kanta archive and improving the quality of the data could have a positive impact on Atostek's services. We do not consider this to be a conflict of interest as improving the quality of the data in the national Kanta archive is possible only through constructive criticism of the current situation.

Abstract

Background: Electronic health records (EHRs) are widely used in health care systems across the United States to help clinicians access patient medical histories in one central location. As medical knowledge expands, clinicians are increasingly using evidence-based point-of-care information (POCI) resources to facilitate clinical decision-making in medical practices. While these tools can improve clinical outcomes, few studies have assessed clinicians' opinions on integrating them with EHRs.

Objective: This study aims to assess clinicians' attitudes and the perceived value of POCI resources for finding medication- and disease-related information in clinical practice and their integration with EHRs.

Methods: Semistructured interviews were conducted with 10 clinicians from various roles and specialties between December 2021 and January 2022 at Brigham and Women's Hospital in Boston, Massachusetts. A content analysis approach was used to examine participants' responses and feedback on their current use of POCI resources, barriers and facilitators, mobile app use, and recommendations for improved integration.

Results: Of the 10 participants, 6 (60%) were female, 9 (90%) were aged <40 years, and 8 (80%) had ≤10 years of experience in clinical practice. While UpToDate was the most preferred disease-related information resource (n=9, 90%), preferences for medication-related resources varied, with 2 (20%) participants favoring Micromedex, 2 (20%) favoring Lexicomp, 2 (20%) favoring Brigham and Women's Hospital–specific drug administration guidelines, 2 (20%) favoring UpToDate, and 1 (10%) favoring Medscape. Most participants used their preferred tools weekly. Most clinicians preferred comprehensive POCI tools with clear, navigable layouts that eased and quickened the search for information. Features such as heavy text density, the lack of citations, and frequent log-ins to access the tool were viewed as barriers that limited content legibility, credibility, and accessibility. Access-related, tool-specific, and integration-related barriers were reported to negatively impact clinical workflow. Most (n=8, 80%) of the participants reported currently using mobile apps, reasoning that they facilitated quick and convenient searches for information; however, frequent updates, time-consuming log-ins, and high text density on smaller screens posed challenges. Most participants favored further integration of POCI resources with EHRs, with all reporting them being currently

XSL•FO
RenderX

available as embedded links that launch externally. Some recommended that further integration would allow us to leverage existing POCI tool features, such as chatbots and knowledge links, as well as aspects of artificial intelligence and machine learning, such as predictive algorithms and personalized alert systems, to enhance EHR functionality.

Conclusions: Participants favored integration to improve usability and optimize workplace efficiency by reducing the amount of time spent seeking answers to their medication- and disease-related questions. Recommendations on integration highlighted the need for stakeholder input in developing clinical decision support tools and interfaces that leverage advancements in artificial intelligence and machine learning while not compromising user experience or increasing time spent on tasks.

point-of-care tools; clinical decision support; artificial intelligence; point-of-care information; online databases; efficiency; quality of care; electronic health records; health information system interoperability; machine learning

Introduction

Background

Being a practicing clinician requires navigating and retaining an immense and evolving breadth of knowledge as the field of medicine progresses and standards of care change. To address the knowledge gaps that arise during a busy workday, clinicians use a variety of methods to support their clinical decision-making [1]. To be effective, clinical resources must be accurate, reliable, helpful, and quickly accessible in addressing clinicians' questions on various medical topics [1-3].

While it is common to use search engines, such as Google, clinicians have increasingly come to rely on evidence-based online information resources, such as point-of-care information (POCI) tools, to help answer medication- and disease-related questions that arise during patient care [1]. POCI tools are evidence-based online information websites and databases that support clinical decision-making by providing quick and reliable responses to clinical questions [1,4]. Clinicians can use these types of clinical decision support systems to find peer-reviewed literature and clinical practice guidelines to inform standards and practices used during patient care delivery [1,4]. BMJ Best Practice, DynaMed, Micromedex, and UpToDate are some examples of POCI tools that have different content areas of focus with a wide range of features, layouts, and modes of access [1,4]. Health care organizations often offer access to a variety of online resources via institutional subscriptions, including collections of electronic textbooks and journals, search tools for bibliographies and abstracts of primary literature (eg, PubMed or Embase), and more focused resources, such as the Natural Medicines Comprehensive Database [4].

Online information resources often include barriers that challenge their users at the point of care. For example, clinicians have reported that some POCI tools are difficult to navigate, thereby prolonging their search time, lack depth in their explanations, and provide unsatisfactory answers, all of which might affect their acceptance and use [2,5]. However, these resources have been proven to enhance the delivery of care and clinical outcomes when properly implemented by improving diagnostic accuracy and treatment plans [6,7]. Therefore, a need exists for innovative methods to address these barriers and optimize POCI tools to best meet clinical needs.

There have been increasing efforts to integrate POCI tools with electronic health records (EHRs) to improve usability and clinical workflow [8]. Examples include the ability to access a resource directly from the EHR without having to launch it via an external browser and the option to download apps to access the tools via mobile devices. If effectively implemented, integrating these tools may help optimize the speed of information retrieval and reduce clinician burden during searches for information to inform clinical practice [8]. Furthermore, clinicians' input on the integration of these tools can help identify potential areas for improvement due to their experience with using these tools in the clinical setting [2,5,8].

Objectives

This study aimed to assess clinicians' attitudes, current use, and the perceived value of POCI tools for finding medication- and disease-related information. In addition, this study examined the attitudes of clinicians toward the integration of POCI tools with EHRs, identified barriers and facilitators, and solicited recommendations for improved integration.

Methods

Study Design and Setting

We conducted semistructured interviews with clinicians (30-45 min) employed at the Brigham and Women's Hospital (BWH) in Boston, Massachusetts, from December 2021 to January 2022.

Study Participants, Sampling, and Recruitment

Our targeted recruitment method sought to engage clinicians from a diverse range of specialties and experiences. Physicians, physician assistants (PAs), pharmacists, and registered nurses providing patient care in internal medicine, infectious diseases, neurology, and critical care were included. We used purposive sampling to recruit from a pool of participants who completed a usability study on the combined DynaMed and Micromedex with Watson tool (DynaMedex, hereafter referred to as the combined tool), given their experience with this POCI tool [2,9,10]. Participants involved in the usability study were asked if they would be interested in taking part in a subsequent study; thereafter, all interested individuals were invited to participate in this study. The combined tool was selected for evaluation as it represented typical medication- and disease-related information resources that clinicians commonly use. It also

XSL•FO
RenderX

incorporated artificial intelligence (AI)–powered features, such as a conversational interface to facilitate search.

Interview Guide

A semistructured interview guide was developed in collaboration with subject matter experts (MGA, DLS, and DWB), a human factors expert (PMG), and an experienced qualitative researcher with expertise in the topic investigated in the study (RR; Multimedia Appendix 1). We added preliminary questions to better understand participants' clinical backgrounds and their previous use of the POCI resources to gather feedback on their experiences using these resources in their particular practice. The guide was then piloted with 1 clinician and the internal research team to identify areas for improvement and ensure perspectives could be shared without input from the interviewer. We integrated the feedback received from the pilot by revising the guide to address gaps and concerns.

The revised and final guide contained 15 open-ended questions divided into 4 parts. Part 1 comprised questions about participants' demographics and clinical backgrounds. Part 2 addressed their use of current clinical tools, part 3 inquired about Micromedex and DynaMed use, and part 4 explored their experiences with the combined tool and recommendations for integrating it with the EHR. The combined tool was deployed as a use case to assess participants' perceptions of the value of integrating the information resources.

Ethical Considerations

The study was exempted by the Mass General Brigham Institutional Review Board (protocol #2021P001813). All participants provided verbal informed consent to be interviewed and recorded before starting the interview. Participants could opt out and stop the interview at any time without providing a reason. All interview data were deidentified to protect participants' privacy and confidentiality and stored on password-protected computers behind the firewall at Mass General Brigham. Each participant received a US $50 Amazon gift card as compensation for their time participating in the study.

Data Collection and Analysis

All interviews were conducted on Zoom (Zoom Communications, Inc) by SD. The video recordings were transcribed by a professional transcription company. Using a content analysis approach, 2 reviewers (SD and MM) independently abstracted data from the transcripts and entered it into a Microsoft Excel document organized according to the sections of the interview guide. Similar ideas were grouped together to identify and summarize a set of concepts for each interview topic [11]. The reviewers cross validated each other's groupings to ensure that the data analysis was consistent and replicable [12]. To further validate their findings and ensure transparency in the review process, the reviewers met with the experienced researchers (RR and AS) to discuss discrepancies and achieve consensus [12]. The results were structured according to the concepts derived from each section of the interview guide and were titled as follows: participant demographics and clinical backgrounds, overview of current practices, use of preferred web-based tools in current practice, barriers to using web-based information resources in current practice, preferred mobile apps, and attitudes on integrating web-based information resources into the EHR. We subsequently report the study findings using the terms *a few* (30% or fewer participants), *some* (>30% and <70% of the participants), or *most* (>70% of the participants) to describe the frequency of perspectives shared and specific patterns in participant responses. Data saturation was reached after 10 interviews, as no new significant themes emerged, with key themes consistently repeated across participants, indicating that further interviews would not provide substantially different insights [13].

Results

Participant Demographics and Clinical Backgrounds

We contacted 12 clinicians from BWH and interviewed 10 with diverse clinical backgrounds and experiences (Table 1). Of these 10 participants, 3 (30%) physicians, 3 (30%) pharmacists, 2 (20%) PAs, and 2 (20%) nurses were interviewed. Most clinicians identified as female (n=6, 60%), were aged <40 years (n=9, 90%), and had ≤10 years of experience practicing (n=8, 80%). Half (5/10, 50%) of the participants self-reported being in leadership roles in their practice, and there were equal numbers working in inpatient and outpatient settings.

Overview of Current Practices

All interviewed clinicians reported using various web-based resources to look up information in clinical settings (Table 2). There was substantial overlap in the resources used to find medication- and disease-related information. Participants favored web-based tools that were available within the EHR as links from a pull-down resource menu. Most participants used POCI tools, such as Micromedex (6/10, 60%), UpToDate (5/10, 50%), or Lexicomp (3/10, 30%), to find medication-related information. UpToDate (9/10, 90%) or primary literature databases (4/10, 40%), such as PubMed and Google Scholar, were used most often to find disease-related information. A few participants reported accessing web-based content resources, such as hospital-based policies or clinical practice guidelines, before using POCI tools because they provided more specialty-specific information. A few participants relied on direct communication with others, such as calling a pharmacy or consulting with colleagues for medication-related questions.

XSL•FO
RenderX

Table 2. Reported use of web-based medication–related and disease-related information resources by study participants (N=10)[a].

Name of resource	Brief description[b]	Type of resource	Participants who reported using the medication-related resource, n (%)	Participants who reported using the disease-related resource, n (%)
Clinical practice guidelines[c]	Clinical practice guidelines provide best practice recommendations based on evidence-based research on how to identify and treat medical conditions [14].	Content resource	2 (20)	2 (20)
DynaMed	DynaMed is a clinical decision support tool that provides clinicians with evidence-based information for quick answers at the point of care [15].	POCI[d] tool	N/A[e]	1 (10)
Hospital-based policies[f]	Hospital-based policies are the rules and guidelines adopted by hospitals that guide decisions and standards of practice [16].	Content resource	1 (10)	1 (10)
Lexicomp (through UpToDate)	Lexicomp is a drug reference database that provides evidence-based recommendations to help clinicians treat and counsel patients on their conditions and medical histories [17].	POCI tool	3 (30)	N/A
Medscape	Medscape is an online platform that provides access to medical news, expert feedback, and medical and disease information while supporting clinicians with professional education opportunities, including continuing medical education [18].	POCI tool	1 (10)	1 (10)
Micromedex	Micromedex is a comprehensive database that provides information on medications, diseases, and toxicology to support diagnostic and treatment decision-making in clinical practice [19].	POCI tool	6 (60)	N/A
Primary literature databases[g]	Primary literature databases are platforms that provide access to journal articles on health and medical sciences and other related content [20].	Content resource	2 (20)	4 (40)
UpToDate	UpToDate is a subscription-based clinical decision support resource that helps clinicians access evidence-based medical information while facilitating patient care [21].	POCI tool	5 (50)	9 (90)

[a]Percentages added to >100% because participants reported using multiple tools.

[b]The descriptions were taken from the official websites of the products and tools.

[c]Examples are Johns Hopkins Antibiotic Guide, Fast Facts, drug administration guidelines, and the Centers for Disease Control and Prevention Opioid Guideline.

[d]POCI: point-of-care information.

[e]N/A: not applicable.

[f]Examples are Brigham and Women's Hospital policies, such as the empiric antibiotic guide.

[g]Examples are PubMed, Embase, and Google Scholar.

Use of Preferred Web-Based Tools in Current Practice

Overview

All participants expressed a preference for specific web-based resources. A few participants preferred Micromedex (2/10, 20%) or Lexicomp (2/10, 20%) to find medication-related information, and 10% (1/10) of the participants used both tools interchangeably. Other preferred medication resources included clinical practice guidelines (ie, BWH-specific drug administration guidelines; 2/10, 20%), UpToDate (2/10, 20%), and Medscape (1/10, 10%). UpToDate (9/10, 90%) was the most favored resource for finding disease-related information. Moreover, 10% (1/10) of the participants preferred using Medscape.

Reasons for Selection

The reasons for selecting preferred tools were similar for medication- and disease-related resources. Most participants preferred their tool due to its targeted information, function, and capabilities, while some favored their tool for its

XSL•FO
RenderX

comprehensiveness in combining both disease- and medication-related information into one place.

Most participants found it convenient to use tools that they were familiar with and were quickly accessible, often through the EHR. For example, one physician stated the following:

[I will] probably go to UpToDate because it is easily accessible, and I [am] familiar with that. UpToDate is my go-to...because of the familiarity and ease of access. [Internist]

Most participants also acknowledged that content and layout influenced the selection of their preferred tool, especially when the tool's design made it easy to find information quickly:

> *[It is] designed with the clinician in mind in the sense that you can search through it, you can click by topic, you can click within subtopics...You can narrow in on what it is that you need help with.* [Neurologist]

Given their reliance on evidence-based information, most participants selected tools based on their assessments of whether the information provided was reliable and credible. For instance, some participants favored evidence-based disease-related resources because they helped them learn about unfamiliar topics and clinically reason through possibilities while generating differential diagnoses for a medical case:

> *It's a good start for me to go to something like UpToDate for a disease state that I'm not familiar with, just because it does give you a general recommendation, but it also ties in a lot of the most recent guidelines of literature.* [Critical care pharmacist]

Finally, a few participants were encouraged to use their tool because it offered continuing medical education (CME) credits:

> *Because it also provides CME, I want to make sure that I have my information passed through because I can collect some CME through my searches.* [Internist]

Experience With Preferred Tool

Most participants reported positive experiences using their preferred information resource, finding it useful, usable, and informative. Some participants expressed their appreciation for clear layouts, bulleted formats, in-depth explanations, and embedded links to supporting literature, which helped provide evidence-based recommendations:

> *I think both are...usable. I appreciate that Micromedex has both the short version of things, but then you can also look at an in-depth version that expands beyond the monograph and to citing more data and the reason behind certain recommendations.* [Infectious disease pharmacist]
>
> *I think [it is] comprehensive. I think...[it is] accurate. I like that [there are] links to references so you can choose to read the primary research.* [Neurologist]

One participant felt it was important that their tool provided details on when the information was updated, and another mentioned the positives of being able to access information that is specific to their institution's policies through their tool on the EHR system.

While most participants reported positive experiences using their information resources, they also expressed shortcomings, such as a lack of depth in certain areas and longer times spent looking for information. These caveats are further explained as follows:

> *Sometimes [there are] specific questions that are a little bit more in depth that [are not] really covered by some of these resources, but [that is] expected...Resources [cannot] cover everything.* [Critical care pharmacist]
>
> *I think [in] UpToDate...you need to scroll a little bit more and the way [it is] laid out, I find it just takes me longer to read it.* [Neurologist]

In addition, a recurrent theme mentioned was high text density and large paragraphs, which made navigation difficult, especially when trying to quickly skim through the text. Some participants did not feel that the navigation bars helped to reduce the time spent looking for information, as mentioned in the following statements:

> *What I think [it is] missing is...sometimes the paragraph format is too long...I find that [it is] a little bit too much information. Sometimes, when [you are] reading something new or when [you are] not sure what [you are] looking for, [it is] harder to zone into exactly the point that you want.* [Neurologist]

It was also noted that it was more time consuming to find specific answers regarding disease-related questions as opposed to medication-related ones because disease-based sections were more text dense. For example, one participant stated the following:

> *You pretty much know, no matter what medicine you look at, how much content, and how is it laid out, and [that is] very predictable. I think for diseases, it can be a little bit more vast. Sometimes, you might need to narrow your search a little bit more or figure out which section you want to jump to because you really do not have time to read the whole thing, nor are the sections always finite because [they] can sometimes be super-long depending on the disease.* [Internist]

Accessing Resources

Most participants accessed their preferred resource through their institutional EHR system. Once in the EHR, some participants described a variety of pathways to their preferred resource, which all involved clicking an embedded link to launch an external web browser that redirected to the resource website. Information resources could be accessed through the resources drop-down in the EHR, the KnowledgeLink portal of the EHR, or the institution's handbook containing electronic references for clinical use. Resources were also located in the hospital employee intranet through Citrix Workspace. These pathways were discussed in the following statement:

> *For at least me, specifically, within Epic [there are] tabs that they have embedded links for clicking on*

XSL•FO
RenderX

> *access to UpToDate, Micromedex, so [that is] the easiest way for me to do so.* [Critical care pharmacist]

A few participants accessed the resources directly through a web browser because they found this to be a quicker and easier method. They expressed dislike for Internet Explorer (Microsoft Corporation) as a default browser, stating that it is not user-friendly. One pharmacist explained as follows:

> *I honestly generally just pull up a web browser tab and do it that way, because [that is] through Chrome, which is much quicker than if you click on it through Epic. It goes through Internet Explorer, which is an awful browser.* [Infectious disease pharmacist]

Frequency of Use

Half (5/10, 50%) of the participants estimated using their preferred medication-related resource either once or a couple of times a week. Conversely, 30% (3/10) of the clinicians used it daily, and a few used it monthly, depending on their clinical needs. Regarding preferred tools for disease-related queries, 60% (6/10) of the participants used them on a weekly basis, 30% (3/10) used them monthly, and 10% (1/10) used them on a daily basis.

Timing of Use

Most participants gave a broad range of answers for when they used their preferred resource in the context of patient care, regardless of their clinical background. All participants accessed their tool at different times throughout the patient care journey. Approximately 70% (7/10) of the clinicians used their tool before a patient encounter, often to learn more about the patient's condition; 70% (7/10) of the clinicians used the resources during encounters, and 60% (6/10) of the clinicians used them after an encounter while writing notes or looking up additional information. Moreover, 60% (3/5) of the inpatient clinicians also reported using their preferred resource during rounds. Most participants said they would be most likely to use a combination of the aforementioned time points, depending on their needs, as noted in the following response:

> *If I [have not] heard of a disease, then I would obviously want to learn about it just before going to see the patient...so I can understand what [we are] doing a little bit better if it impacts why [they are] in the hospital. Then, maybe after, if they have the new diagnosis on the differential, I would look into it just to make sure I totally understand what [they are] thinking is going on for a patient.* [Critical care nurse]

Page Utility

Most participants were on a specific page of the EHR when they decided to seek medication- or disease-related information in their tool. For instance, most participants reported using the clinical notes page when looking for disease-related information from their tool, while the medications list page was most frequently used when looking for medication-related guidance in their tool, as described in the following statements:

> *[There are] medication searches and disease searches, and those definitely have different views. The medication searches would happen on the medication tab, versus disease searches would probably be more likely in the Notes or the Past Medical History section.* [Infectious disease pharmacist]

> *I would most likely be on the medication administration page just because that [is] where the medication order is, and I have that in front of me. [That is] what I need to access to look up the information.* [Internal medicine nurse]

Notably, one pharmacist mentioned being on the results page of the EHR when they launched their medication-related resource, as articulated in the following statement:

> *If I'm looking to see about an adverse event, I might be on the Results tab to see how labs are trending compared to what might be published.* [Infectious disease pharmacist]

Another pharmacist reported using their tool for disease-related questions while navigating the medications list page to better understand how medications may impact a patient's condition.

Barriers to Using Web-Based Information Resources in Current Practice

Most participants reported a range of access-related, tool-specific, and integration-related barriers that negatively impacted clinical workflow (Multimedia Appendix 2). Specifically, some users found it challenging to rely on institutional permissions to access resources, efficiently navigate to their preferred tools from the EHR, and find information in the resources when the pages were too wordy.

Preferred Mobile Apps

Details about the use of preferred mobile apps and barriers to use in current practice are described subsequently. The use of mobile apps to access POCI resources reported by the study participants is given in the subsequent sections.

In total, 8 (80%) of the 10 participants reported currently using mobile apps to access POCI resources (Table 3). These participants accessed these apps on phones or tablets when a desktop computer was not available:

> *Folks that are running around and seeing dozens and dozens of patients, and only might have phone access between seeing patients.* [Infectious disease pharmacist]

XSL•FO
RenderX

Table 3. The current use of mobile apps reported by study participants to access point-of-care information resources.

Characteristic	Participants, n (%)[a]	Clinical roles
Name of mobile app (n=8)		
Lexicomp	1 (12)	1 pharmacist
Medscape	1 (12)	1 nurse
Micromedex	2 (25)	1 MD[b] and 1 pharmacist
UpToDate	6 (75)	2 MDs, 1 pharmacist, and 2 PAs[c]
Other[d]	6 (75)	2 MDs, 2 pharmacists, 1 PA, and 1 nurse
Frequency of use (n=8)		
Daily	3 (38)	2 PAs and 1 nurse
Once a week	1 (12)	1 pharmacist
Once a month	2 (25)	1 MD and 1 pharmacist
A few times per year	2 (25)	2 MDs
At what point in the patient encounter were the apps used? (n=8)		
Before	6 (75)	3 MDs, 1 PA, 1 pharmacist, and 1 nurse
During	3 (38)	1 PA and 2 pharmacists
After	6 (75)	3 MDs, 1 PA, 1 pharmacist, and 1 nurse
Other (pages, off shift, etc)	1 (13)	1 pharmacist
Patient rounds (inpatient clinicians only; n=5)	1 (20)	1 MD

[a]Centers for Disease Control Opioid Guideline, Fast Facts, Johns Hopkins Antimicrobial Guide, Sanford Guide, University of California–San Francisco Outpatient Medicine Handbook.

[b]MD: physician.

[c]PA: physician assistant.

[d]Frequency reflects the number of participants who mentioned using these mobile apps.

Most participants used UpToDate, Micromedex, and specialty-specific mobile apps that were also available as web-based versions. Most of the participants cited the ease of access, enhanced portability, the speed of information retrieval, and familiarity with the resources as reasons for using these apps. They found that these mobile apps were a convenient way to pull up specific resources quickly, with 38% (3/8) of the participants using these tools daily (Table 3). For example, one PA expressed the following:

> *UpToDate is certainly the thing I'm the most comfortable [with]. I think especially when [you are using a mobile device, I feel like your ability to navigate it quickly is a key to success actually, depending on what you're looking for. Also, when I'm looking something up on my phone [it is] not like [I am] looking to spend a long time reading something of interest. [It is] usually like, "I need to know something right now."* [Internal medicine PA]

Some participants used mobile apps to avoid barriers related to using desktop tools:

> *On my phone, I can just click on the app. I [do not] have to worry about logging in and [it is] faster. Going to the computer, you have to log in, load and all that stuff...I only use the app.* [Internal medicine nurse]

One physician appreciated that the mobile versions of the tools promised the same standards as the web versions. Most clinicians used the apps before and after patient encounters, and of the 5 inpatient clinicians, only 1 (20%) used an app during rounds. Physicians avoided using the tool during patient encounters, considering it would be inappropriate to be on a mobile phone in front of patients.

Barriers to mobile app use included challenges navigating copious amounts of text on smaller screens, updates, and log-ins. Some participants reported needing the content to be made app friendly:

> *[There is] usually either lots of text, if [you are] talking about disease state management, or lots of information, if [you are] talking about a drug monograph...you do a lot of scrolling on your phone to find what you need. It takes a little bit longer, versus on the larger screen.* [Infectious disease pharmacist]

One pharmacist described finding the log-in process time consuming:

XSL•FO
RenderX

> *Some of the barriers, like I mentioned, any Apple application having updates or login maybe if [they are] retyping a login and stuff like that that either cost time, or...[if] it was a hospital code [and] I forgot it [then] I [would not] have access.* [Critical care pharmacist]

Participants who no longer used the apps cited various barriers that affected their user experience. One physician reported no longer using a mobile app because the subscription renewal process and logging in were challenging and time consuming.

Attitudes on Integrating Web-Based Information Resources Into the EHR

Current Status of Integration With EHR

All participants reported that their preferred web-based resources were not fully integrated but were generally available as embedded links that launched external web pages:

> *[It is] a completely separate link. [It is] not like if you have atrial fibrillation in your note and [there is] a link [to] UpToDate. No, you have to open it as a resource.* [Neurologist]

A few participants described partial integration for medication orders, such as direct hyperlinks to medication information through an external browser:

> *In certain medication orders, there are hyperlinks directly so that it goes straight to the medication [information] from order in Epic.* [Infectious disease pharmacist]

One participant commented on the customizability of the EHR, noting that they were able to ease their access to their preferred tool by personalizing it to meet their needs:

You can set your settings. I had an Epic person...set that up for me. Epic modified my toolbar in [the] Epic menu and rearranged things...It tells you what you use the most. There [are] different ways to arrange things the way you want. [Neurology PA]

Participants considered full integration to provide quick and direct access to medication- and disease-related information within the EHR:

> *I honestly think the less there is clicking and the more something is going to directly take you to what you want the more it's going to get used.* [Internal medicine PA]

Preferences Regarding Integration

Most respondents favored accessing the resources via embedded links to external pages:

> *Probably better if it launches separately because when in [the] EHR, you [do not] want [what is] in front of your face to be hijacked by your search, necessarily.* [Internist]

A few preferred the information to be presented within the EHR. They reasoned that this would provide faster access to information by avoiding browser-related interruptions. For example, 20% (2/10) of the participants stated the following:

> *If it can be further integrated into EHR, it would definitely be useful. I think everybody benefits from getting quicker information.* [Internal medicine nurse]
>
> *I think in EHR. The only reason I say that is because of consistent browser issues.* [Neurology PA]

Suggestions for Improving Integration

Participants proposed a variety of solutions to improve integration with the EHR. To facilitate the quick retrieval of information resources, a couple of participants suggested the following:

> *You need to have it kind of like in a panel approach, so like, our EHR, Epic, has a side bar and then the main page, and the only way I can see it working well is if it was somehow integrated into that side bar, or in some sort of pop-up that you could still [see] the chart behind it.* [Infectious disease pharmacist]
>
> *You could even put it under the chart search bar so that [you are] really specifying are you searching the chart or are you searching information. You could also integrate it into the search so when you search the chart, [it is] like,"'[Here is] the patient information' or '[Here is] information about it.' What are you searching?" I think that it might be cool to put it where alerts pop up so if the contraindications pop-up comes up, it could have a link [to the resource].* [Neurologist]
>
> *[It would] be nice if there was either a dedicated activity within the EHR or a window or a corner or an icon where, when you click into it, it expands, and then [you will] see [the information resource], and then a search box opens up. Then, when you click enter, then [it is] okay if it opens up a new browser or window. Up to that point, it would feel a lot more integrated because you [are] able to type in your search string while [you are] still within your EHR.* [Internist]

It was also important to maintain a simple and user-friendly display with direct pathways to the resources embedded throughout the EHR, especially to make it easier for users to find the most relevant resource for their questions, as described in the following statement:

> *If I have a question and am not sure which part of the software I should be using, that is problematic, so there should be a way to guide you to the most appropriate application based off [the] question. The pathway needs to be really streamlined—it has to be really clear this is where I need to go.* [Internist]

Some participants identified existing features of the EHR that could be leveraged for integrating resources, given their current usefulness. For example, one participant discussed the potential use of KnowledgeLinks:

> *I can see a world in which you put diverticulitis down as a visit diagnosis and there [is] a little ⓘ next to diverticulitis and you click it, and it takes you to that*

XSL•FO
RenderX

> *page. That would be sweet for me.* [Internal medicine PA]

A chatbot was another feature favored by a few clinicians that could assist in finding information:

> *You know the little chat box at some websites, like [you are] on [a] travel [website] and [it] is like, "I can help?" Maybe if it was there and it was either just available as a search bar or if it had little suggestions based on what [you are] typing or what page [you are] on or stuff like that.* [Neurologist]

Some suggestions for integration involved using currently evolving capabilities to optimize the usability of the EHR. A few participants noted that AI could be used to identify critical information from patient charts, such as potential contraindications based on the medication list. They added that AI features could even evolve to provide alerts based on information from the resource for specific patient charts. This is expressed in the following comment:

> *You could incorporate [AI] to alert to contraindications. We get a bunch of alerts like, "Your patient is due for vaccines" or "Your patient needs the flu vaccine." I work [in] the inpatient [setting], but primary care, they also get a lot of alerts about guidelines around screening, stuff like that.* [Neurologist]

Concerns About Integration

Despite the widespread support for integration, some participants expressed reservations. They argued that integration must center on functionality, with a few citing concerns that it could interrupt their workflow by altering the current view of the EHR. For example, one participant stated the following:

> *A little bit of me is like if this is going to mess up how Epic looks, I'd rather have it be an external page that pins because then [it is] not in any way altering your view of [the] Epic screen.* [Internal medicine PA]

Similarly, most participants preferred that their resources existed as embedded, externally launched links, emphasizing that a poorly designed integration could lead to launching windows that obscure their view of patient information:

> *[It is] nice for me to be able to control whether or not I want to move that pop-up window or browser to the side or if I want to spend a moment and read all of it. This is where it sounds a little bit like [it is] paradoxical in a way. I want to integrate it, but I [do not] necessarily need it to take over the screen that [I am] working at.* [Internist]

> *The link right now that we have for UpToDate opens up a clunky Internet Explorer browser within the EHR, and [it is] not that user-friendly overall. I [do not] suggest that. Then, also, if it opens up in a new tab in your EHR in the first place, that kind of negates the point because then you [cannot] see patient [information] at the same time because [it is] covering it up.* [Infectious diseases pharmacist]

Discussion

Principal Findings

As medical knowledge rapidly evolves, web-based POCI resources have become common tools used to support complex decision-making in clinical practice. Although these tools have the potential to improve workplace efficiency, diagnostic accuracy, and treatment plans, few studies have examined clinician attitudes toward integrating them with EHRs [6,7]. This qualitative study examines clinician attitudes, current use, and perceived utility of POCI tools for answering medication- and disease-related questions during patient care delivery. Attitudes, barriers, and facilities regarding the integration of POCI tools with EHRs were also evaluated, in addition to recommendations for enhancing integration. Most participants preferred POCI tools and mobile apps with clear layouts that allowed for quick and easy access to medication- and disease-related information. Most participants supported the integration of POCI tools with EHRs, while some provided recommendations to improve the usefulness of the EHR, which included the addition of existing POCI tool features, such as chatbots and knowledge links, as well as AI and machine learning functions, such as predictive algorithms.

We conducted semistructured interviews with various clinicians to understand the current uses of POCI tools, barriers to and facilitators of use, and recommendations for integrating these tools with EHRs. We found that there were a variety of POCI tools used, most of which were large information databases that provided medication- or disease-related information, such as UpToDate and Micromedex, allowing users to access a wide breadth and depth of answers in a central location. In addition to an appreciation for comprehensiveness, there was a strong preference for POCI tools that eased the search for evidence-based information via clear, user-friendly layouts consisting of features such as bullets and embedded links that directed users to relevant information. The absence of such layouts in existing tools made it challenging for most users, who found disease-related pages to be text heavy, rendering navigation difficult and prolonging their search for information.

Comparison to Prior Work

These reported barriers and facilitators are consistent with previous studies where clinicians favored tools with minimalistic designs because they valued finding information easily and quickly [2,22]. The participants reasoned that complex layouts that are either too text dense or require multiple steps to locate relevant information reduced content visibility and tool accessibility, respectively [2,22]. They also emphasized that it was important for tools to cite sources supporting clinical information because it improved clinicians' understanding of the evidence for standards of care, which can enable adherence to clinical guidelines [6,22].

Participants also reported positive experiences using mobile web apps of their preferred POCI resources, reasoning that their portability, accessibility, and speed allowed them to find information quickly. In addition to frequent log-ins, participants reported that high levels of text density were still a barrier they experienced while using these apps. A previous study reported

XSL•FO
RenderX

similar findings, recommending that improvements to text and content clarity as well as offline access can support better participant experiences using mobile web app versions of POCI resources [23].

Regarding integration, participants had positive attitudes toward integrating these tools into the EHR, with most preferring that they be launched through embedded links while a few favored that they display directly within the EHR. It was important to most clinicians that integration leverage features that exist in both POCI tools and the EHR, including chatbots, knowledge links, and search functions, to improve resource navigability and usability. Recent studies reported positive experiences with integrating tool features into the EHR, including automatic calculations and assistance in treatment planning that improved clinician workflow and heightened quality care delivery [7,24].

Given the recent focus on AI and machine learning in medicine, a few participants proposed the use of AI predictive features to alert clinicians to relevant medical information, such as medication contraindications and patients in need of more individualized care. In recent studies, AI, natural language processing, and machine learning algorithms were found to increase the accuracy of clinical decision support systems in areas ranging from identifying at-risk patients requiring regular ophthalmology visits to facilitating laboratory diagnostics that account for patients' medical histories [25-27]. If implemented, some studies emphasized that alert systems apply customizable alert filtration schemes that tailor to the specific, clinically relevant needs of the clinician to limit the number of low-value alerts that contribute to alert fatigue [6-8,28,29]. These predictive features may also reduce clinicians' cognitive load and increase clinical task efficiency by reducing time spent searching for medically relevant information [27]. Effectively implementing predictive features could help detect clinicians' latent needs and improve patient safety through increases in diagnostic accuracy [30,31]. This will undoubtedly play an important role in the future. Overall, improvements to POCI resources and their integration with the EHR may have positive downstream effects on task efficiency by decreasing the number of actions performed to reach a desired outcome, resulting in enhancements to the clinician work experience by reducing time spent seeking information and increasing time delivering quality care [8,32].

Limitations

First, this study was limited to a small sample of clinicians with previous experience using POCI resources at the same academic medical institution. However, we were able to recruit a range of clinician types with a variety of experiences in the clinical setting to provide perspectives on the use of POCI resources and their integration with EHRs. Second, the insights and recommendations provided may not be generalizable to all clinical settings and clinicians' experiences, which may differ according to several factors, including the availability of health IT, geographic location, access to resources, and clinical experience. It is important that future studies account for a wide range of clinicians' perspectives on updates to POCI resources and EHRs to identify opportunities for improvement and workflow considerations that benefit clinicians' experiences in clinical settings and their ability to effectively care for their patients. Future research must also be conducted across a wider range of clinical settings and geographic locations to account for differences in access to and experience with health IT.

Conclusions

We evaluated the preferred features and uses of POCI resources of clinicians as well as their attitudes toward integration with the EHR. Clinicians had strong preferences for POCI resources that were comprehensive, user-friendly, and allowed them quick access to medication- and disease-related information. Suggestions for integration included optimizing EHR usability to improve workflow efficiency by reducing time spent navigating resources and searching for relevant clinical information. Novel advancements in AI and machine learning could also be incorporated into the EHR to assist clinicians with identifying risk factors, including adverse events, which could impact patient health outcomes. This study demonstrated that including clinician input in the development of clinical decision support and health IT is key to ensuring that clinical workflow needs can be met to improve both the clinician and patient experience in medical settings.

Acknowledgments

This work has been supported by International Business Machines (IBM) Watson Health, now known as Merative (Cambridge, Massachusetts, the United States), which was not involved in any of the interviews, data analysis, data interpretation, or manuscript preparation. Generative artificial intelligence was not used for any part of this study.

Abstract

Background: There have been suggestions that electronic health records (EHRs) should be expanded beyond clinical mental health care services to a broader array of care services that support mental health service users, which we call an integrated electronic care record (IECR). Previous research has considered service users' general views on information being stored and shared via an EHR. However, little consideration has been given to service users' attitudes toward how EHRs should be used in the provision of care or the concept of an IECR.

Objective: This study aimed to understand mental health care service users' perspectives on an IECR and how it should be used in practice when receiving care.

Methods: Ten people with lived experience of accessing multiple services in Australia's mental health care system were provided with 2 vignettes that depicted fictional service users making decisions about an IECR. Participants were asked to respond to several scenarios that the fictional service users might experience in their journey through the mental health care system with an IECR. Participants provided written responses and took part in a semistructured interview to discuss their responses. An interpretative phenomenological analysis was undertaken, which led to 5 major themes and 15 subthemes being developed.

Results: Service users wanted an IECR that they had control over, supported them as equal partners in their care, and contributed toward more collaborative and proactive mental health care. However, participants were concerned that care professionals' perspectives would be privileged in the IECR and overshadow service users' needs. Participants also had concerns that stigmatizing and discriminatory information documented in their IECR would negatively impact their interactions with the mental health care system and their access to care. Participants saw value in an IECR bringing together information to support collaborative and proactive care. However, participants thought that the benefits of the IECR had to be balanced with potential risks to their privacy. Participants thought that the IECR should contain only information relevant to their care and should be shared only with relevant care professionals. There were concerns that service users might lack the skills, resources, and information required to manage their IECR.

Conclusions: An IECR has the potential to fill the gaps in an increasingly complex and fragmented mental health care system but risks entrenching service users' experiences of stigma and discrimination unless service users are meaningfully involved in their IECR.

Introduction

Background

Electronic health records (EHRs) are increasingly adopted in mental health care services to improve information collection, sharing, and use [1]. EHRs promise more integrated and connected care [2-4], especially when they enable information sharing across different care services. EHRs may be especially promising in the mental health care system due to the complex array of services that service users access [5]. Recent attention has turned to how EHRs may enable information to be shared beyond clinical services to include the various social and community care services that people with mental health conditions access [1,6,7]. However, care professionals have raised numerous concerns about the adoption of EHRs in mental health care contexts, including how sensitive information should be documented and the impact of EHRs on the therapeutic relationship [2]. Most of the available research involving service users has focused on their general attitudes toward the electronic storage and sharing of their health data [3], especially secondary uses of EHR data [4]. There has been limited research on service users' attitudes toward how EHRs should be used in the provision of mental health care, especially EHRs accessible by multiple types of care professionals. We sought to explore service users' perspectives on how an integrated EHR, which would include clinical and social and community care services, could be used in their care.

Information and how it is managed is critical to modern health care, with the health record being central to providing quality care [5]. Information is managed through a range of information practices of both service users and care professionals, including disclosing, documenting, seeking, and sharing information [8]. The health record plays a key role in these information practices, including enabling communication among care professionals, providing a central source of information about a service user, and acting as an informal workspace [9]. Increasingly, health records are being replaced by EHRs, many of which can be accessed by multiple care professionals and service users [10,11]. Because EHRs are used mainly by care professionals, their experience and needs have been the primary focus of research in the design of EHRs [12-14]. However, there is increasing recognition of how EHRs shape service users' experiences of care and the need to design EHRs that contribute toward person-centered care [13,15].

Integrated Electronic Care Record

EHR is a broad umbrella term that captures a range of technologies used to collect, manage, and share information about service users [16,17]. Generally, an EHR is an electronic record of patient information that is accessible by care professionals within or across health services. Some EHRs provide service users with access via a patient portal. An increasing number of EHRs seek to collate information from all treating care professionals rather than from a specific service or type of service [18,19]. For example, Australia's My Health Record is a national summary record that allows any treating clinician to access and contribute information. However, EHRs tend to be limited to health care services and exclude many other social and community care services that play a critical role in mental health care [20].

There is increasing recognition of the need to improve information sharing between all the services that contribute to people's care, not just those in the health care system [21,22]. In Australia, a recent Royal Commission into Victoria's mental health care system recommended establishing a state-wide Electronic Mental Health and Wellbeing Record and a Mental Health Information and Data Exchange to facilitate information sharing between all services that contribute to people's mental health and well-being [23]. This is similar to a recommendation made by the Australian National Mental Health Commission [24] in 2014 that there was a need for an EHR accessible by services beyond the health care system. In this study, the term *integrated electronic care record* (IECR) is used to capture this concept of a digital record that all care services can contribute to and access regardless of whether they are within or outside the traditional health care system.

Experiences of EHRs in Mental Health Contexts

Care professionals have raised concerns that EHRs will impact the therapeutic relationship and how sensitive information is documented [25]. The concerns regarding the therapeutic relationship relate to how an EHR might impact communication between service users and care professionals [13]. For example, studies exploring the adoption of EHRs have found that they can act as a barrier to communication in clinical encounters [26]. The issue of documenting sensitive information is related to whether such information is appropriate for other health care professionals to view, the perceived risk of sensitive information being shared too widely, and the risk of service users experiencing an adverse reaction when accessing their EHR [2,27].

There is limited research on mental health service users' attitudes toward EHRs. A recent scoping review of EHRs in mental health contexts found that 10% (4/40) of the studies included a service user perspective. A service user perspective is important because they have different views compared to care professionals regarding how EHRs should be used in mental health care [28]. Previous research has focused on mental health service users' general attitudes toward the storage and sharing of mental health information via an EHR and electronic health information exchange more generally [3,4,29]. In comparison, research with care professionals has focused on how an EHR is used in practice [25]. Because mental health care involves various sensitive information practices, such as people sharing a range of sensitive and potentially stigmatizing information [30,31], and service users may experience stigma from health professionals [32], the increased availability of information via an EHR may be concerning for service users. There is evidence

XSL•FO
RenderX

suggesting that EHRs may affect service users' decisions to disclose information to care professionals due to privacy and security concerns [33]. However, at the same time, service users may be more likely to want their information shared if they see a practical benefit for their care [3].

We aimed to understand mental health care service users' perspectives regarding an IECR and how it should be used in practice when receiving care and to answer the following questions: (1) on the basis of service users' experience of the mental health care system, how do they think an IECR would be used in their care? (2) If an IECR were implemented in mental health care contexts, how would service users want it used in their care?

Note on Terminology

In this paper, we use the term *care professional* to capture everyone who provides care across the health, mental health, and social and community care systems.

We specifically chose to use the term *service user* rather than terms such as *patient*, *consumer*, or *person*. We acknowledge that each of these terms comes with certain assumptions. For this study, *service users* best captured our intention to focus on people actively engaging with the mental health care system.

Methods

We used qualitative vignettes and semistructured interviews to answer the research questions by exploring service users' attitudes toward an IECR. We were informed by the Critical Appraisal Skills Programme's checklist [34] for qualitative research.

Context

Australia's mental health care system is split across several systems and levels of government [35]. Primary health care, including general practitioners and psychologists, are private services that service users receive rebates to access through the federally funded Medicare system. Secondary mental health services, including community mental health care, are funded by state and territory governments. Another critical source of care is the National Disability Insurance Scheme (NDIS), which provides funding for disability support services, including psychosocial support, and sits separately from the health and mental health care system. Other support services such as housing and homelessness services, drug and alcohol services, and community support are provided by the state, territory, and local governments.

Study Design

We used a qualitative vignette method to answer the research questions. Vignettes are short stories or scenarios involving a fictional individual, which can be used to explore participants' perspectives on specific scenarios [36,37]. Qualitative vignettes include concrete examples of people, behaviors, and systems and can provide the opportunity to explore people's interpretation of specific scenarios and sensitive issues or cases in which subjective judgment is required [36,37]. There are various approaches to how participants respond to vignettes [36]. In this study, participants were asked to consider the advice that they would provide to a fictional character in the vignette based on their own lived experience. Vignettes have been used in other studies to explore service users' attitudes toward and perceptions of EHRs [38].

Ethical Considerations

The University of Melbourne Human Research Ethics Committee approved this study under application 13697. Participants were emailed details of the study, including a plain-language statement and consent form. Participants were compensated for their time with an AUD $80 (US $51.51) gift card. Written responses, interview recordings, and transcripts were assigned a number, and all identifying information was removed.

Study Instruments

Two vignettes were developed involving fictional characters and situations designed to reflect common experiences identified in the literature and our previous research on service users' experience of the mental health care system. Central to the vignettes was the concept of an IECR, with the vignettes including a 1-paragraph description of the IECR (Textbox 1). The description of the IECR was purposefully short to encourage participants to ask questions and identify issues that they would need to consider if an IECR was implemented. A similar approach is taken in the use of technology probes in human-computer interaction research, which are minimally designed to explore how participants see this technology fitting into their lives [39]. Two narratives presented different contextual factors that may resonate more with certain participants. The vignettes and questions are provided in Multimedia Appendix 1, with the key differences outlined in Textbox 2. Participants were provided with a written and audio version of the vignettes and questions that they were asked to provide written responses to before taking part in a semistructured interview. The written responses and interviews were used as a form of triangulation to support the credibility of the results. Participants who struggled to provide written responses to the vignettes were invited to read and respond to the vignettes and questions during the interview.

The interview schedule included 3 sections. First, participants were asked to give their general reflections on the vignettes. Second, specific follow-up questions were asked based on their written responses. The follow-up questions focused on answers in which participants had made assumptions, asked questions, or provided limited detail. Third, general questions were asked about some of the themes identified in the previous literature and in the introduction to this paper regarding how stigma and the retelling of their story should be managed in the context of an IECR.

RenderX

Textbox 1. Description of the integrated electronic care record in the vignettes.

Jona

Recently, Jona's general practitioner told him that they had adopted an "Integrated Electronic Care Record (IECR)." This IECR would allow all the services Jona accesses—the GP, homelessness service, psychiatrist, and pharmacist—to access and share information online through a secure internet site. Jona would also be able to access his IECR and the information on it, as well as being able to record information on his record and upload information from personal devices. Services would only need verbal consent from Jona to upload or access information in the record. The GP says that the record could include Jona's medication record, housing history, consultation notes, test results, and referral letters. Jona's GP asks him if he would be happy to agree to have an IECR.

Riley

Recently, Riley was told by her psychiatrist that an "Integrated Electronic Care Record" (IECR) was being implemented and that she would receive one unless she chose to "opt-out." The record would allow all her service providers to view her health record and share information electronically. It would also allow Riley to access her IECR and the information on it. Riley would also be able to record information on her record and upload information from personal devices. The psychiatrist says that the record could include Riley's medication record, consultation notes, test results, and referral letters.

Textbox 2. Summary of the vignettes.

Story 1: Jona

- Opt-in integrated electronic care record (IECR)
- Lives in an urban area
- History of living interstate
- Diagnosed first with schizophrenia and then with borderline personality disorder (BPD)
- Experience of homelessness
- Accesses welfare payments
- No family support and limited social network
- Involuntarily admitted to an inpatient psychiatric ward
- Accesses the National Disability Insurance Scheme

Story 2: Riley

- Opt-out IECR
- Lives in a rural area
- Diagnosis of BPD
- Close family support
- Comorbidity of type 1 diabetes
- Voluntarily admitted to an inpatient psychiatric ward
- Experience of substance use issues

Recruitment and Participants

Our primary population of interest was people with mental health conditions that require them to access a range of health care, mental health care, and social and community care services. This framing may appear broad, but we wanted to avoid specifying a set of diagnoses that we may assume correlate with complexity (eg, so-called severe mental illness) but that people may not identify with and may risk alienating participants. Instead, we chose to focus on the experience of accessing multiple services as it is this experience that an IECR would seek to improve.

Participants were recruited through 2 approaches. First, service users who had participated in our previous research and had consented to be contacted about future research were emailed with details of the study. Second, the study details were circulated to mental health care organizations that included service user advisory groups. The reason for inviting previous participants and service users with experience in advisory roles was due to the effort required to read and respond to the vignettes and to minimize the risk of distress among participants sharing their experiences.

We planned to recruit and analyze data iteratively until we reached data saturation, where similar concepts were reoccurring in the data analysis. We expected that we would reach saturation with fewer participants using the chosen methodology than using other qualitative methods given that all participants responded to the same vignettes. Through our iterative analysis of the interviews, we used an online whiteboard to cluster the codes and concepts from each interview. We determined that

XSL•FO
RenderX

saturation had been reached when no new unique clusters of codes were identified.

Ten participants expressed an interest in taking part in this study, and all were recruited to participate. Of those 10 participants, 7 provided written answers to the vignettes before taking part in an interview, whereas 3 provided verbal answers to the vignettes during their interviews. The interviews with the participants who did not complete the prewritten activity were generally longer as the interviewer had to explain the scenarios and the questions. We chose not to collect demographic details of our participants given that our research did not intend to consider how demographics might relate to the qualitative themes. The participants all had a mental health condition and experience accessing a range of care services.

Analysis

All interviews were transcribed with the support of automated transcription software [40]. We used the inductive interpretative phenomenological analysis methodology from Smith et al [41] to analyze the data from the interviews and written responses. Interpretative phenomenological analysis is a methodology useful in understanding how people's lived experience shapes their experiences of situations [42]. The first author read each transcript and the associated written response and performed in-line coding using the comment function within a word processor. The research team each coded a subset of the transcripts and discussed their coding decisions to determine the breadth of potential codes. These codes were compiled and organized to identify common clusters of codes within each transcript. Codes and clusters from each participant were uploaded to an online whiteboard and clustered into common groups. These groups were compared with the coding and clusters developed for each participant and discussed among the research team to ensure that each participant's data were appropriately reflected in the groupings. The research team discussed these clusters until they reached a consensus on how to determine the appropriate delineation and naming of themes and subthemes.

Results

Thematic Results

The analysis led to the development of 5 major themes and 15 subthemes, which are outlined in Table 1. These themes were framed based on the participants' attitudes toward how an IECR *should* be used in their care. However, at the same time, the substance of each theme also reflects how participants expected an IECR *would* be used, based on their experience within the mental health care system. Further illustrative quotes are provided in Multimedia Appendix 2.

Table 1. Outline of themes and subthemes.

Theme	Subthemes
Service users have agency and control over their IECR[a] (theme 1).	• Care professionals minimize the use of the IECR during inpatient stays (subtheme 1.1). • Service users can establish a trusting relationship with care professionals before their IECR is used (subtheme 1.2). • Service users can see how their IECR is accessed and used (subtheme 1.3). • Service users have control, through informed consent, over who can access their IECR (subtheme 1.4). • Service users have control over what information in the IECR is available to different care professionals (subtheme 1.5).
Service users' perspectives, needs, and voice are included in what is documented in the IECR (theme 2).	• Stigmatizing or discriminatory information is not documented in the IECR (subtheme 2.1). • Information in the IECR supports rather than overrides the service user's needs (subtheme 2.2). • Service users can contribute and shape the information in their IECR (subtheme 2.3).
The IECR brings together an accurate record of relevant information about the service user (theme 3).	• Care professionals document information in the IECR that balances the need for care and the risk to service users' privacy (subtheme 3.1). • The IECR is a reliable and accurate record according to the service user (subtheme 3.2).
Service users are empowered to confidently use their IECR (theme 4).	• Service users receive detailed information about their IECR (subtheme 4.1). • Service users are supported to use their IECR (subtheme 4.2).
Care professionals use the IECR to proactively support and coordinate care across all services (theme 5).	• The IECR supports collaborative and integrated care across all services (subtheme 5.1). • The IECR supports more proactive care and feedback loops between services (subtheme 5.2). • The IECR supports service users in retelling their story (subtheme 5.3).

[a]IECR: integrated electronic care record.

XSL•FO
RenderX

Theme 1: Service Users Have Agency and Control Over Their IECR

Overview

Participants thought that service users should be able to manage who can access their IECR and what information they can view and that this required well-designed consent options that provided service users with explicit control over their IECR. The issue of consent was complicated when considering inpatient admissions and the level of agency that service users maintained during periods of acute symptoms. Participants thought that access to the IECR should be based on a trusting relationship between the service user and the care professional. However, in a time- and resource-limited care system, there may be limited opportunities to develop this trust before care professionals need access to a service user's IECR. In reflecting on how service user autonomy could already be circumvented in the mental health care system, some participants were concerned with how an IECR may be used in such situations. For example, one participant reflected on the fact that, in some circumstances, people with a diagnosis of schizophrenia could lose agency over their finances.

Subtheme 1.1: Care Professionals Minimize the Use of the IECR During Inpatient Stays

A question in both vignettes prompted participants to consider how the IECR should be managed in voluntary and involuntary inpatient care scenarios. Five participants thought that access to the IECR should be limited during inpatient care to reduce any distress that service users may experience knowing that their IECR is being accessed, especially without their consent. Participants acknowledged that the information in the IECR could benefit service users' inpatient care. However, they thought that it should only be accessed with informed consent from the service user or a trusted family member or carer.

> *Because they were involuntarily hospitalised, because they did not have access to their records, so they couldn't check their record and see that they were happy with it, that there was right information on there. If they're not allowed to access their own information, no one should be because that's just—it feels like a human rights violation to me. Like they should be able to access their record whether they're well or not. Either with or without a family member present. But that's their own record and for doctors to be accessing and adding things while that person can't even see what's going on, on that record, that's a big no-no. Talk about trust issues, that's...you can imagine being unwell, having schizophrenia. Having your voices screaming at you from outside of you. Like "they're putting down the wrong medications, they're trying to kill you."...Yeah, like I couldn't imagine how I'd be feeling when other people...could access my records but I was not allowed to. That just—just seems really wrong.* [P3011]

Some participants assumed that, during a voluntary admission, the service user would have access to their IECR, whereas in an involuntary admission, they would not. Participants thought that, if the service user cannot access and manage their IECR during an inpatient stay, which participants assumed would be the case, then no information should be uploaded to their IECR until after they are discharged and with their consent. Some participants considered that information could still be uploaded to the IECR during an inpatient stay but flagged for review by the service user before being made available for other care professionals to view after the admission.

Two participants thought that the record should be accessed and kept up-to-date during inpatient stays to inform the service user's treatment.

Subtheme 1.2: Service Users Can Establish a Trusting Relationship With Care Professionals Before Their IECR Is Used

All participants discussed the role of trust in shaping how service users share information with care professionals, which would also shape service users' perceptions of the IECR. Participants thought that service users would need to meet the care professionals first to ensure that they can establish a rapport and trust before providing them with access to their IECR. An element of building trust related to theme 2 was that care professionals should get to know the service user rather than just making assumptions about them based on their IECR. The need to establish a trusting relationship was contextualized with comments that Jona and Riley from the vignettes might feel frightened and isolated if they moved locations and saw a new care professional. Participants also questioned whether access to the IECR could be revoked if Jona or Riley found that they could not establish trust or rapport with the care professional.

> *It depends who you let see it. I'd really have to trust someone...for instance if you go to a psychologist or psychiatrist, I'd have to have a couple of session with them before I knew that I could trust them. Because you have to build that rapport with them before you can let them and trust them with your information.* [P3030]

Five participants raised the broader issue that service users might not trust the mental health care system or might have developed trust issues from previous life experiences, which may factor into whether they trust the use of an IECR.

Subtheme 1.3: Service Users Can See How Their IECR Is Accessed and Used

Five participants discussed the need for transparency over who accessed their IECR, what organization they were from, and what information they accessed or uploaded. Some participants discussed the current lack of transparency over what information is shared between care professionals. Transparency was also viewed as important for managing their symptoms, such as paranoia over who might be accessing their record. Some participants also thought that there needed to be transparency within care encounters as to whether the care professional had read the record and sensitivity regarding how information in the IECR was raised with the service user.

> *Without them absolutely blurting out, "well I know da-da-da," maybe...their introduction to you should*

XSL•FO
RenderX

be, "I have read your record, is there anything you'd like to talk about?" [P3090]

Subtheme 1.4: Service Users Have Control, Through Informed Consent, Over Who Can Access Their IECR

All participants thought that service users should have control over who can access the IECR and that providing access should be based on informed consent. Participants also questioned whether consent should be continuous (consent is provided for each care professional until the service user revokes it) or episodic (care professionals would have to seek consent each time they wanted to access a service user's IECR). Participants outlined how Jona and Riley should only consider providing consent to care professionals with whom they have a current and ongoing trusting relationship. One participant recommended that the default IECR setting should be to remove access for care professionals whom they have not seen in a while. There were also questions about how nuanced the consent options would be and whether service users could reveal only parts of their record to certain care professionals. The vignettes explicitly stated that verbal consent would be sought from service users for a care professional to access their record. Two participants questioned how their consent would be documented so they had evidence that they had given it. Some participants questioned whether care professionals could share information in the IECR with other care professionals without service user consent.

> *...how could we show whether or not I provided consent if I'm not signing anything?...my concerns are around, like Jona has a couple of diagnoses and experiences that are really quite stigmatised and wanting to make sure that Jona is able to protect himself around—like if he wants to access a service but doesn't want to reveal parts of that...like can I say, my pharmacist can access my scripts, and my mediations, but not my housing information.* [P3020]

In addition to having a thorough and informed consent process, participants thought that consent preferences should be visible to service users so that they can be confident that they are being followed. Participants identified that a potential barrier to informed consent is when service users are unwell or experiencing symptoms that may impact their ability to consider the benefits and risks of providing care professionals with access to their IECR.

Five participants raised queries about family involvement in the IECR, including how much control service users had over family members accessing their IECR. One participant identified that there may be circumstances in which a family member or another support person might need to access Riley's record to support them. Conversely, another participant, in reflecting on Riley's story, considered that, if Riley had a negative relationship with her parents, she might not want to provide access to her family members.

> *If Riley later has children or a violent partner or a toxic employer or family carer or workers compensation claim, how will you ensure her legal rights, privacy, + confidentiality are protected?* [P2050]

Subtheme 1.5: Service Users Have Control Over What Information in the IECR Is Available to Different Care Professionals

In addition to deciding who can access the IECR, 6 participants thought that service users should have control over what information different care professionals can view. One participant outlined how the onus should be on the care professional to justify to the service users the information they need to access in the IECR. Some participants framed this as ensuring that care professionals can only access what is relevant to their care and information that they will use in providing care. Participants also identified factors that service users might consider when determining what information to allow care professionals to access, including whether the information is accurate and up-to-date, whether they are comfortable sharing it with a new care professional, whether it is relevant for that care professional, and the current reason they are accessing care. Some participants also acknowledged that the IECR may include information from difficult periods in a service user's life, which they may not want current care professionals to access.

> *...is there a way for me to block that information...from another service, if I've just had a bad day and yelled at someone because I've been sleeping on the street for three weeks?...if I move out of this difficult period of my life to where I'm flourishing more, does my new pharmacist need to know that I was also accessing homelessness services?* [P3020]

The concept of "relevance" was pervasive across several answers that participants provided as to who should be able to access their IECR and what information they should be able to view. These 2 issues intersected in that relevant information may depend on who is accessing it and in what circumstances. For example, one participant thought that, if Jona gave the NDIS access to their IECR, it should only be for information relevant to supporting their application. This issue of relevance is further explored in theme 3.

Theme 2: Service Users' Perspectives, Needs, and Voice Are Included in What Is Documented in the IECR

Overview

Seven participants were concerned that the IECR would be used as the key source of information in providing care and would override service users' voice and needs. Underlying this concern was the risk that the IECR may only reflect care professionals' view of the service user, which may be outdated, include only negative information, and possibly include stigmatizing or judgmental information. However, 2 participants thought that it would be valuable for their care professional to review the IECR before a session so that they have the most up-to-date information. The risk that the information in the IECR will be prioritized over service users' voice could be managed by including service users' views and needs in the record (subtheme 2.2) and by ensuring the relevance, accuracy, and quality of the information in the IECR (theme 3).

XSL•FO
RenderX

Subtheme 2.1: Stigmatizing or Discriminatory Information Is Not Documented in the IECR

Nine participants raised the risk that an IECR might entrench service users' experiences of stigma, judgment, and discrimination both inside and outside the mental health care system. Participants were concerned that an IECR would allow for a greater reach and permanency of information that might negatively impact the care they receive, including their ability to access care. Several participants were concerned that information in the IECR might "leak" outside the health care system, such as to employers, and would lead to stigma and discrimination in other areas of life. There were also concerns about how certain information in the IECR could lead to the experience of stigma and discrimination within the health care system. For example, some participants were concerned that certain diagnoses being stigmatized, such as borderline personality disorder and also the label "mentally ill," may automatically lead to someone being treated differently by certain care professionals. Some participants discussed how they had opted out of My Health Record due to the risk of their diagnosiare.

> *I purposely was, in some of my answers, pushing the boundaries back of, well, really...why would this be good for Jona or whoever, you know, the person with the condition who's got disadvantage and discrimination happening? Why would this be good for them? I guess I got a flavour from...the scenarios that perhaps certain people and agencies would think an electronic record is a really good idea and that it wouldn't disadvantage...the service user at all. As long as we can maintain security, privacy, confidentiality...they won't be disadvantaged and I think it's a really strong underpinning for me about power and language and, you know...the electronic record is just neutral, right, it could be good or it could be bad for somebody but unless we address the actual disadvantage of Jona having a mental health diagnosis and all the other issues that he was facing...I suspect that an electronic record will disadvantage him...because of the underlying inequity he is facing.* [P3050]

Four participants were concerned that historical information from previous admissions, such as diagnoses and treatments irrelevant to their current care, might lead care professionals to prejudge or overlook their current issues or might impact their access to care. For example, one participant outlined how much of the information documented about them was from when they were at their worst, so future clinicians who access the IECR will only see the negative information that has followed them. This situation may inform a deficit-based rather than a strengths-based approach to care—especially if their strengths and achievements are not documented in the IECR. Another participant shared how their previous eating disorder diagnosis still impacted the care they received today even though they had recovered and no longer met the criteria for an eating disorder diagnosis.

> *Yeah, so I chose not to opt into the My Health Record, because of my history of BPD...after I stopped meeting criteria for borderline disorder, I just straight up don't have that issue anymore, I went to ED because of some intense anxiety...they read borderline, and then I was treated that way, instead of treated for what I was actually presenting for, and that was just in my hospital record. I didn't need other services, like, I don't think my pharmacist needs to know that I used to have a history of borderline.* [P2020]

Participants were also concerned that information relevant in one care context could be perceived negatively or be stigmatizing in another context, especially by care professionals with less knowledge of mental health. For example, one participant discussed how their previous drug use may negatively affect their access to mental health care even though it was a historical issue that they had overcome. This issue relates to whether information is relevant to care professionals, as discussed previously and further in theme 3. Participants suggested that care professionals needed to document information in their IECR in a way that was respectful and balanced, with consideration to how the service user may view the information.

Subtheme 2.2: Information in the IECR Supports Rather Than Overrides the Service User's Needs

Six participants were concerned that care professionals who accessed the IECR would focus on information from other care professionals and not on the service user's perspective. The risk of having information precede service users and shape their care before they can discuss their needs was viewed as entrenching a biomedical model of care in which service users' individual needs are not recognized or are viewed through a diagnostic lens. Furthermore, participants identified a risk that care professionals may not capture the service users' perspectives or voice in the IECR, further amplifying the care professionals' perceptions, ideas, and judgments. Even if the service user could contribute to the IECR, participants were concerned that clinical knowledge would be privileged in the IECR and in how the IECR is used. There were also concerns that the IECR may lead to some health issues, especially physical health issues, being overshadowed by the mental health issues documented in the IECR. Some participants thought that it was important for the service user to be able to tell their story before the care professional accessed their IECR as what is written in the IECR may be framed differently.

> *He would have the very real problem of clinicians not listening to where he is at and what is happening for him, because they are only going on what others have put in his record.* [P3011]

Subtheme 2.3 Service Users Can Contribute and Shape the Information in Their IECR

Although a number of participants thought that it was important for a service user perspective to be included in the IECR, there was less consideration of whether service users should directly add information to their IECR. One participant, when initially asked about the potential for a service user to contribute to their

XSL•FO
RenderX

IECR, thought that it was not necessary or valuable. However, later in the interview, they revisited their response and suggested that it could be valuable to have a service user write up their story. There was also consideration given to the potential for service users to add notes to care professionals' records that put information in their own words or to identify areas in which they disagreed with their care professionals. One participant thought that there was a risk that service users might change their IECR when unwell, which could negatively impact their care.

> *Yeah, because then you've got more input into it. You could say whether you disagree or agree with the doctor. Yeah, I think it'd be good actually. Sometimes doctors are not—like I just said, they don't understand [laughs] that they've said the wrong thing. So, yeah. If you could put little notes there to say I do not understand—I don't agree with the way he's described me, or this was—I don't see it this way or something. That'll be good.* [P3030]

Theme 3: The IECR Brings Together an Accurate Record of Relevant Information About the Service User

Beyond wanting the IECR to recognize service users' perspectives and needs, participants also discussed what information care professionals should include in the IECR. The concept of relevance was central to participants' views on what information an IECR should contain, and it appeared to capture both the need for privacy over certain information and the recognition that information could contribute positively to the care that service users receive.

Subtheme 3.1: Care Professionals Document Information in the IECR That Balances the Need for Care and the Risk to Service Users' Privacy

There was an assumption in the vignettes that the IECR would collate all information about a service user. However, participants were generally supportive of a summary of information being included in the IECR and thought that there should be a standard template or guidance for what should be documented. Participants thought that the information documented in the IECR should be relevant to their care and support future treatment, such as their diagnosis, medication, care plan, evaluation of previous treatment, family medical history, presenting problems, the types of services being accessed, and what participants do to manage their condition. One participant thought that the IECR should not include the personal "chit chat" that might also be shared during the clinical encounter. Participants also discussed that service users would need to determine what to disclose to care professionals that might be uploaded to an IECR and the risks posed by this information being shared. One participant outlined the balance of providing enough information to receive appropriate care but not so much as to create a risk of that information being used against them. For example, it may be appropriate to have information about alcohol and drug counseling in their IECR, but depending on how that information is presented, it could be interpreted in a certain way that does not represent their current needs or presentation.

> *I think it is important to have things like the diagnosis and the types of medication. Maybe just a little bit of what they do outside that helps them with their condition, especially if they have chronic pain and stuff, is there anything they do to help that. Keep it relatively minimal but succinct at the same time, because I just think that clinicians are honestly just—they're so overworked that they don't have time to look through everything. So just keeping it short and sweet and relevant.* [P3080]

Some participants were concerned that incomplete information could create an inaccurate picture of the service user. These participants were not necessarily in favor of everything being documented in the IECR, with one participant, who had concerns with gaps in their IECR, also stating that only relevant information to support treatment and not personal information should be uploaded. Participants also had questions about what would happen to their information if they opted out of the IECR for a period and then opted back in. In general, participants did not consider that the IECR should be a comprehensive record of all the information from the various services they accessed but that the IECR needed to present an accurate picture of the person's needs.

> *...there was another question that I answered stating that if a person opts out and then after six months opts back in, will that record that he had previous be put back on? (Interviewer: Is that important), Oh, yeah, I think so. I think any record is important.* [P2010]

The issue of sensitive information was only explicitly raised by 3 participants and, generally, was considered as not appropriate to document in an IECR. One participant classed their sexuality as potentially sensitive information, whereas another classed their experiences of hallucinations and delusions as sensitive information.

Subtheme 3.2: The IECR Is a Reliable and Accurate Record According to the Service User

One of the scenarios in the case studies was of a care professional watering down information uploaded to the IECR. Three participants were concerned that such a scenario may negatively impact the service user if the IECR does not reflect their care and condition. It was acknowledged that watering down information might be done for a valid reason, such as where information may be triggering for the service user. Participants considered that reducing the level of detail documented should be done in conversation with the service user and for their benefit and that information could be reframed to be shared on the IECR. Watering down information may also impact service users' ability to access other services, such as the NDIS, if those services rely on the IECR to assess eligibility for access to care. One participant outlined that, in such cases, service users should be able to annotate their IECR if information has been omitted, or the care professional should identify when information has been diluted.

XSL•FO
RenderX

> *So, something like that, watering that down...no history of being suicidal there, is there? So that automatically puts my life at risk. Just that one scenario...and there can be a gazillion things that watered down, is a safety hazard for the person in question...* [P3011]

Six participants raised concerns and questions about the management of inaccurate information in the IECR, with some sharing experiences of having inaccurate information recorded in their health record. Participants asked how Jona and Riley could receive support if inaccurate information was uploaded to the IECR and who would be responsible for ensuring that the information was accurate. There were also questions about whether service users could edit inaccurate information or whether care professionals would be required to confirm the accuracy of the IECR with the service user. One participant contrasted the IECR with a referral letter, asking "what's wrong with a referral letter that you give to the patient, and they read and say, oh, yeah, that sounds right but you missed this, or could you write it like this?" (P3050). Participants were also concerned with care professionals introducing their own subjective judgment into the IECR.

> *Also, because...it's done quick and rapid, the chances of an inaccuracy occurring can be high...obviously it impacts their health, it could damage—it could do harm to the client.* [P3010]

Participants thought that the accuracy and relevance of the IECR should be reviewed to ensure that historical information that is not directly relevant to their current care is not available on the IECR. Participants also thought that care professionals should discuss the accuracy and veracity of the record with the service user to identify information from previous encounters that may not present the service user's perspective or needs (theme 3). One participant who had a challenging experience of seeking to have incorrect information in their health record updated thought that service users would lack the time and resources to engage with their IECR to address such issues.

Theme 4: Service Users Are Empowered to Confidently Use Their IECR

Overview

Most participants had limited experience with EHRs. During the interviews, 8 participants identified that they had heard of an EHR, mainly Australia's My Health Record. Of these 8 participants, 1 opted out due to the risk of stigma, 1 noted that they had limited knowledge of My Health Record, and 1 shared that their general practitioner did not upload information to their My Health Record.

Four participants noted that being able to view the IECR could benefit service users by acting as a reference point for their condition, supporting their memory, and facilitating discussions with care professionals. Participants thought that seeing what their care professionals had written would help them engage in conversations about things that they agreed with and areas where they disagreed. There was also an acknowledgment that the digital nature of the IECR could benefit some service users, especially those experiencing homelessness, as they would not have to carry paper documents with them. Some participants thought that the IECR provided an opportunity to check that what was being uploaded to the IECR was correct and would allow them to have conversations with their care professionals about issues that they may not be focusing on or to see what their care professionals thought about them.

> *...if Jona is sleeping rough...Having something electronically, means that you—if it is cloud based, I don't have to keep it with me. So, I don't have to be worried about if it is stolen, and I don't have to be worried about if my bag gets wet when it rains. Like my scripts aren't potentially going to be destroyed, or even if a paper script is destroyed, I can be like, no, really, I have been diagnosed—like I have been prescribed these things and pointing to an electronic option.* [P3020]

Four participants thought that service users might require support when reading their IECR as the content could be distressing and the clinical terminology might be perceived negatively. For example, one participant thought that service users may have an experience of thinking, "is that how they really see me" (P3030).

> *...before the service provider jots information on the record, knowing that the patient will read it, it's important that whatever he jots down as a record, he notifies the patient of, if it's something that may cause fright. For example, a diagnosis of cancer, right, you don't just put it on someone's record unless you've had discussion with that person about it and is informed about it.* [P3010]

Subtheme 4.1: Service Users Receive Detailed Information About Their IECR

Participants actively engaged with the vignettes and spent time considering the benefits and risks of each scenario. Many of the written answers were framed as questions about the IECR. Participants actively considered the trade-offs of different decisions that the vignettes posed, such as whether to opt in or opt out of the IECR. Although some participants were more supportive of or more against the IECR, most saw reasons why someone might opt in or out.

> *Can he trust the benefits outweigh his fears and mistrust? Does he feel more confident to tell medical staff himself or would this be easier? Why can't I or a family member simply tell the doctors? What makes this a better option?* [P3011]

One way in which the case studies differed was whether the IECR had an opt-in or opt-out model. Six participants thought that it was important that service users be actively supported to make an informed choice as to whether to have an IECR. Some participants considered that service users may not have the opportunity to make an informed choice under an opt-out model, especially if they are unwell when they are required to decide whether to opt out. Participants questioned whether service users can opt in or out whenever they want and what happens to their records during periods in which they opt out.

XSL•FO
RenderX

> *Yeah, so one of my questions would be, can I opt out, after I've opted in? Can I—how do I withdraw consent for someone to access it? Those two things would be pretty key for me.* [P2020]

Participants raised broad concerns regarding the privacy, confidentiality, and security of the IECR. Some participants considered that there were many unknown risks of adopting an IECR because it is hard to foresee risks that may arise in the future. Participants raised various comments and questions about the security of the IECR and what would happen in the event of a security breach, referencing that there has been a lot of online information theft recently in Australia. Participants wanted to know what support would be available to service users in the case of a security breach. There were also concerns, which were identified in other themes, of potential breaches of privacy and confidentiality through inappropriate use of and access to the IECR by care professionals. Participants considered that service users would need assurances as to the privacy and security of their IECR so that they can confidently use it without worrying about the potential risks of their data being inappropriately accessed.

> *A breach in the security of IECR could mean serious harm to Riley's health or current employment or her perspective employment.* [P2011]

Some participants thought that service users would require someone such as an advocate to explain the IECR and help them make an informed choice about how it is used. A verbal explanation was considered important as written information could be overwhelming. However, such conversations may not be appropriate for care professionals to provide given the time constraints placed on them to provide such information.

Subtheme 4.2: Service Users Are Supported to Use Their IECR

All participants identified barriers that service users might face when using their IECR. These barriers included the skills needed to manage IECR settings, the resources needed to access the IECR, and the knowledge needed to understand the IECR and the information documented in it. The lack of access to appropriate information technology may limit services users' ability to use their IECR. Participants questioned whether training would be provided to support service users to utilise their IECR. Participants also suggested that the IECR should be easy to use. For example, password management should be simple because service users may struggle to remember passwords. Several participants questioned what support would be provided alongside the IECR to ensure that service users can use it and manage any issues arising from the IECR, such as inappropriate use by care professionals.

> *Firstly the "patient log-in password" should be one easy to remember by the patient and hard to decipher by anyone else foreign to the patient...It should not be shared by anyone.* [P3010]

A couple of participants considered that service users' symptoms may act as a barrier to using and making informed decisions about their IECR and that this would need to be considered in the design of the IECR and the support available to service users. A couple of participants considered that service users may negatively react to what is written in their IECR but that this should be managed by the care professional notifying the service user before uploading information to the IECR.

Although participants considered privacy settings an important component of the IECR, 3 questioned whether all service users would have the skills and knowledge required to use these settings. Participants thought that in-depth information and support would be required to ensure that Jona and Riley could use and understand the implications of the privacy settings of their IECR. There were questions about who Jona and Riley could contact for support and whether they could access free legal advice if there were issues or breaches with their IECR. Participants acknowledged that, in the vignette, Jona used a public computer to access his IECR, which could raise privacy risks for him.

> *I would be very selective with my...privacy...whereas in this situation of the two people in the stories, I don't know if they had enough knowledge and ability to perhaps do that, to work out what amount of privacy they would need.* [P3090]

Theme 5: Care Professionals Use the IECR to Proactively Support and Coordinate Care Across All Services

Overview

Participants discussed how the IECR could support more collaborative and integrated care across various services. Integrating various sources of information in the IECR may also enable more proactive care by providing care professionals with a more holistic picture of service users' needs. One participant thought that the IECR might help them prove their eligibility for other services. However, some participants questioned whether care professionals would use the record or whether they would still have to repeat their information when accessing a service.

Subtheme 5.1: The IECR Supports Collaborative and Integrated Care Across Relevant Services

Six participants considered that the IECR may support more collaborative care by linking the different care professionals supporting service users. It was acknowledged that the IECR may benefit services that are not usually kept informed, such as pharmacists and the NDIS.

> *Having One Record...One File...Electronically kept...and shared by everyone Jona agrees to doing with...is better than having many records scattered everywhere among service providers...better collaboration can occur...an easier / more precise healthcare can be administered.* [P3010]

Although some participants saw benefits in integrating their information via the IECR, 8 were also concerned about the IECR being accessed or information in the IECR being shared with too broad a range of organizations. This concern included whether noncare services such as employers, other government agencies, and the police could access the IECR. Participants also raised the concern that, depending on the policies of

XSL•FO
RenderX

different organizations, providing consent for an individual might allow others within that organization to view their IECR. Different participants usually identified a different list of organizations that they were concerned would access their IECR. One participant framed organizations that should not have access as those that did not have the service user's health as their primary focus. However, one participant considered the NDIS as an inappropriate service to be provided with access to their IECR.

Subtheme 5.2: The IECR Supports More Proactive Care and Feedback Loops Between Services

Four participants thought that care professionals might be more informed about the current needs of service users, including their social needs, by having more services involved in the IECR. For example, one participant thought that, in Jona's story, the IECR may help care professionals identify a risk of social isolation when he moved to a new suburb. Identifying this risk to Jona could prompt care professionals to support Jona in settling into his new community. Including social and community care services was viewed as important by participants because these services tend to have a long-term recovery focus and might see more of the service user over their recovery journey. Participants also identified that bringing together different services on the IECR could support the identification of inconsistencies, inadequacies, or overlaps in care that could, in turn, improve the effectiveness and adequacy of care. Some participants also thought that the IECR might help care professionals link the dots between different pieces of information to identify patterns or other factors, such as socioeconomic factors, that might contribute to their mental health.

> *IECR also might pick up on Jonas "pattern of unwellness," noting that Jona tends to have particular problems at certain times of the year so preventative measures and extra supports could be put in place ahead of time.* [P3011]

Providing a broader range of care professionals with access to the IECR was also viewed as supporting holistic care. For example, one participant thought that having their housing risk assessment and diabetes information in the IECR could better inform other care professionals of their needs.

Subtheme 5.3: The IECR Supports Service Users in Retelling Their Story

Nine participants discussed how the IECR could help bring service users' story together in one place to minimize the need to unnecessarily retell it when accessing new services. Participants thought that the IECR may also make transitions between services easier and provide care professionals with a picture of service users' current needs. Some participants noted that service users need to share a lot of information just to be prioritized when accessing a service, but at the same time, some of this information can be challenging to share. With the appropriate controls in place, the IECR could support service users in sharing their story, and as one participant put it, make sure that it is "translated to clinical speak." The IECR could also act as proof for the service user when sharing information with new care professionals. Participants discussed that, when they are acutely unwell, it can be challenging to remember information and put it in words that care professionals will understand. However, as was outlined in previous themes, there is a balance between the benefits of not having to retell the story and having the IECR override the service user's voice. Some participants were also concerned that care professionals would not read the IECR and they would still be required to retell their story.

> *Yeah, it can get depressive, it can get frustrating, it can get upsetting because you're talking about the past and no one wants to go to the past particularly when it's been related to an unfortunate experience.* [P3010]

Discussion

Principal Findings

Overview

This study sought to explore mental health service users' perspectives on an IECR. The results suggest that service users want to feel empowered to shape the content of their IECR and how it is used. However, participants were concerned that the IECR would likely be used to privilege the perspectives of care professionals, especially if service users were not supported to use their IECR. Participants thought that an IECR could bring together a comprehensive picture of their needs and support more collaborative and proactive care. However, there was also the risk that inaccurate and out-of-date information would overshadow the actual needs of service users or that care professionals would prejudge them based on the information in their IECR. The concept of relevance, including relevant care professionals accessing the IECR and relevant information being uploaded to the IECR, was central to participants' views on how the IECR should be used. The findings of this study provide insights into how IECRs and EHRs should be designed for use in the mental health care context.

There were some contradictions in the findings of this study. For example, participants wanted the IECR to minimize the need for them to retell their story while also not wanting to lose control of how their story is told. Similarly, participants only wanted relevant information in the IECR but were concerned about gaps in their record. One way to understand these contradictions is in the context of Australia's mental health care system, where there is an entrenched power imbalance between service users and the mental health care system that contributes to the disadvantage and marginalization of people with mental health conditions [43,44]. Our findings suggest that participants are concerned that an IECR might entrench many of these existing issues in the mental health care system. In the ideal care system, service users might feel confident relying on an IECR as a complete record of their story. However, in the current mental health care system, the risk of judgment, stigma, poor treatment, and a lack of service user control over their care may underpin a lack of trust in how an IECR would be used.

XSL•FO
RenderX

Risk of Care Professionals Prejudging Service Users Based on Their IECR

Participants were concerned that the IECR would entrench experiences of stigma and discrimination. This finding is not unexpected given the evidence that people with mental health diagnoses experience stigma and discrimination across various health care settings [45,46]. Stigma operates at different levels in the mental health care system, including the structural (eg, discriminatory policy and social structures), interpersonal (eg, prejudice and misinformation), and intrapersonal (eg, negative beliefs about the self) levels [45,47]. Henderson et al [45], in reviewing the evidence on stigma in mental health care settings, found that research has focused on interpersonal stigma, with less consideration being given to how structural stigma may shape interpersonal stigma. There could be an opportunity in the design of EHRs to manage structural stigma by shaping how organizations collect and manage stigmatizing information, which contributes to interpersonal stigma. Addressing stigma is important as it can act as a barrier to help seeking [48]. Grando et al [49] found that stigma was a key reason mental health service users might not consent for care professionals to access their EHR. Service users also anticipate stigma based on their past experiences, which may shape how they interact with care professionals and the information they disclose [46,50]. Some participants in this study anticipated, based on their previous experiences, that the IECR could further entrench stigma and discrimination and that stigmatizing information may follow them via their IECR.

Relevant and Sensitive Information

Participants did not support the IECR being a comprehensive record but rather valued a record that could provide relevant information to relevant care professionals to support their current care needs. This focus on relevance was framed as ensuring that the information available could be used by care professionals to improve their care. This finding supports previous research by Shen et al [3], who, in interviewing mental health service users about their privacy perspectives, found that they were supportive of health information exchange when it would contribute to better care. This finding also reflects modern theories of privacy, such as the theory of privacy as contextual integrity by Nissenbaum [51], which situates people's experiences of privacy within specific contexts. Nissenbaum [51] frames privacy as the *appropriate flow of information in a specific context*. Thus, some information may not raise privacy concerns when shared in some care contexts, but in others, it may be seen as inappropriate. Thus, the context in which the IECR is used will shape what service users may define as relevant to be shared.

These findings also challenge the purpose of the health record. Historically, the health record was a record of the care that someone received, usually within one specific health care setting [9]. Although EHRs are regularly framed as "digitizing" the health care record [52], EHRs introduce fundamentally different information-sharing practices compared to paper health records [25,53]. Currently, if information is shared between services, it is done via a letter, phone call, specific shared care plan, or the service user. In all these cases, the information shared is curated for a specific point in time, for a specific receiver, and usually as an outcome of the service user engaging with a service [53]. This approach to information sharing has been described as "pushing information" to other services [53,54]. In the case of the IECR or Australia's My Health Record, information is "pulled" out of a repository with limited curation by another care professional or the service user for that specific receiver [53,54]. There is a risk that an IECR would become unwieldy due to the amount of information stored in it, which risks becoming quickly out-of-date or irrelevant. It may be more appropriate for an IECR to operate similarly to a shared care plan, which is designed to be used in team-based care for a particular condition and include information relevant to the team and the care they are providing [55].

A comprehensive IECR may also breach modern privacy principles such as data minimization and privacy by design. Privacy by design asserts that the minimum necessary information should be collected for a specific purpose [56]. The challenge with IECRs, as articulated in this study, is defining what is useful or relevant at the point of collection in a complex care system in which the next step in someone's care journey is not always clear. The risk of an IECR is that it goes in the opposite direction of data minimization toward data maximization, which poses practical issues for care professionals trying to find relevant information and privacy issues for service users. Even when EHRs allow service users to place access controls on parts of their record, this may not be feasible when there are large amounts of content in the record.

Managing Sensitive Information

Only some participants in this study raised the issue of how sensitive information is managed. Other studies have found more explicit views on the management of sensitive information. Soni et al [57], in a mixed methods study with behavioral health patients, found that most (76%) participants considered mental health information sensitive and 24% feared stigma and discrimination in relation to their mental health. Participants also reported wanting to restrict the sharing of mental health information in the EHR. Similarly, a survey study by Soni et al [58] found that participants were less willing to share information that they perceived as sensitive. Mental health information was considered the most sensitive, and many participants wanted to restrict access to some or all of this information by care professionals. This study does highlight that service users consider information collected about them during involuntary inpatient treatment as requiring careful consideration before it is made available to other care professionals.

Service User Control and Consent

Consent was a key issue raised by participants, who thought it was important for informed consent to be required before care professionals can access their IECR. However, there are questions as to how consent is managed in cases of involuntary treatment, where service users are deemed to lack the capacity to make decisions about their care. Participants were concerned with how an IECR would be used in such cases and generally were against the IECR being used in involuntary inpatient care. There is growing research on the use of dynamic consent

XSL•FO
RenderX

mechanisms and psychiatric advance care plans that would provide service users with the ability to predetermine their preferences for care when they may be assessed to lack capacity [59]. However, research on psychiatric advance care plans has found low completion rates due to barriers such as service users not understanding the advance care plan, the complexity of completing the forms, and skepticism about their benefit [60,61]. Similarly, care professionals report barriers to using advance care plans due to a lack of access to and time to review documents in a crisis and a lack of training [61]. Research on advance care planning has questioned their ability to improve care when the processes required to establish and use an advance care plan rarely align with the realities of clinical practice [62]. There is a broader question as to whether service users should lose their ability to make decisions about their IECR in inpatient settings. There is recent evidence suggesting that most service users with psychiatric conditions in inpatient care have the capacity to make complex and important decisions about their care [63].

Participants also wanted control over what information certain care professionals could access. Given the findings of this study and others [64], it appears that service users would likely want to hide information that they perceive as sensitive or irrelevant to their care. However, Schwartz et al [65], in a study of how service users manage the privacy functions of their EHR, found that most service users who chose to limit access to their EHR chose to limit access to the entire EHR. This finding may be due to the effort required to restrict access to certain types of information [65]. Further research is required to understand how service users make decisions to use privacy controls and approaches to supporting them in managing their IECR. One approach to addressing this issue is through identifying sensitive information upfront when information is documented and allowing service users to preset conditions for when sensitive information can be accessed. For example, Chivilgina et al [66] found in a qualitative study with psychiatric service users that they wanted care professionals to obtain purpose-related informed consent when documenting sensitive information in their EHR.

Service User Contributions to the IECR

Participants thought that it was important that service users' perspectives were captured in the IECR. However, there were concerns that service users may not have the resources and time to independently add information to their IECR. Approaches such as collaborative documentation may facilitate care professionals working with service users to agree on what should be documented in the IECR [67]. However, the design of EHRs may also actively limit care professionals' ability to capture service users' stories and perspectives. One of the proposed benefits of EHRs is that they improve data quality and enable the collection of structured and standardized data that can be used for other purposes, such as research. Our previous research [25] and that by Varpio et al [68] have found that EHRs that require structured data entry can limit the capturing of narrative information, which may include service user perspectives. Furthermore, Rathert et al [26], in reviewing the literature on EHRs, found that they may limit the documentation of psychosocial and emotional information. Finding ways to capture, share, and use narrative data appears key to ensuring that service users' voices are considered in care encounters when using an IECR.

Participants questioned the level of support that service users would be provided with to access and manage their IECR. There were concerns that service users, including the fictional characters in the vignettes, would lack the skills and knowledge to make informed choices about their IECR. Ensuring the usability of EHRs is an ongoing issue in Australia, with research identifying gaps in the usability of My Health Record, including the educational resources available for service users, which may negatively impact those with low health literacy [69-71]. A notable finding in this study was the importance that participants placed on having support to engage with the privacy functions of the IECR. While existing literature has focused on the availability of privacy functions in EHRs [58,72], participants in this study highlighted the importance of having skills and capabilities to manage these functions, as well as support pathways outside the IECR to address privacy issues.

Inclusion of Social and Community Services

In presenting participants with the concept of an IECR, we purposefully expanded the potential array of care services that could contribute to the health record, which in turn may expand the types of information available. There is growing research on the inclusion of social and behavioral data in health records, with some researchers positing that such information provides broader context to tailor interventions and clinical decisions [73,74]. One of the challenges that has been identified in collecting such information is that service users may perceive it as sensitive and, therefore, not disclose it [75]. Where care professionals record this information, there is a risk that service users may perceive this negatively, especially if the information is viewed as a pejorative assessment of them, such as assessments of their income. What this study found is that service users perceive such information as enabling more proactive care but are concerned as to how broadly their IECR might be shared. This aligns with suggestions in the literature that service users should be engaged as partners in the process of collecting such information, with transparency over how it will be collected and shared [75].

Use of Qualitative Vignettes

The findings suggest that qualitative vignettes are a feasible approach to exploring service users' perspectives on digital health technologies that they have not yet experienced. One potential avenue for future research using this methodology includes exploring story completion methods alongside vignettes to encourage participants to explore ways in which the vignettes might evolve based on different responses to the scenarios [76].

Limitations

This study is limited by the breadth of our recruitment strategy. Due to the novel nature of the research topic, we determined that our recruitment strategy would focus on people with a specific experience (accessing multiple services for their mental health) rather than a targeted demographic of service users. Future research could include specific groups of service users, such as those with certain diagnoses, to determine how

XSL•FO
RenderX

perspectives on an IECR differ across various groups of service users. The sample is also not representative of all people who access the mental health care system. Those with the most acute presentations were likely not represented in this study due to the approach to recruitment and the resources required to participate. However, some participants did share that they had previous experiences of acute illness, including inpatient admissions.

Conclusions

This study found that mental health service users see two alternative ways in which an IECR might impact their care. The first is one in which the IECR entrenches issues that service users experience in the mental health care system and adds a new, burdensome system for care professionals to try to use. The alternative is an IECR that contributes to care professionals having access to relevant information that supports collaborative and proactive care and service users having control over and being able to see how their information is managed. Although an IECR will not solve the systemic issues present in Australia's mental health care system, it could help improve the coordination and proactiveness of care, amplifying service users' needs and supporting service users as active participants in their care. For an IECR to have a positive contribution to broader mental health care reforms, the design and implementation of such a record should consider how service users and care professionals will be supported in using the record, issues of service user consent, what information is necessary to support coordinated and proactive care, and how service users' self-defined needs can be captured and acted upon in an IECR.

Abstract

Background: Electronic health records (EHRs) provide valuable insights to address clinical and epidemiological research concerning HIV, including the disproportionate impact of the COVID-19 pandemic on people living with HIV. To identify this population, most studies using EHR or claims databases start with diagnostic codes, which can result in misclassification without further refinement using drug or laboratory data. Furthermore, given that antiretrovirals now have indications for both HIV and COVID-19 (ie, ritonavir in nirmatrelvir/ritonavir), new phenotyping methods are needed to better capture people living with HIV. Therefore, we created a generalizable and innovative method to robustly identify people living with HIV, preexposure prophylaxis

XSL•FO
RenderX

(PrEP) users, postexposure prophylaxis (PEP) users, and people not living with HIV using granular clinical data after the emergence of COVID-19.

Objective: The primary aim of this study was to use computational phenotyping in EHR data to identify people living with HIV (cohort 1), PrEP users (cohort 2), PEP users (cohort 3), or "none of the above" (people not living with HIV; cohort 4) and describe COVID-19–related characteristics among these cohorts.

Methods: We used diagnostic and laboratory measurements and drug concepts in the National Clinical Cohort Collaborative to create a computational phenotype for the 4 cohorts with confidence levels. For robustness, we conducted a randomly sampled, blinded clinician annotation to assess precision. We calculated the distribution of demographics, comorbidities, and COVID-19 variables among the 4 cohorts.

Results: We identified 132,664 people living with HIV with a high level of confidence, 36,088 PrEP users, 4120 PEP users, and 20,639,675 people not living with HIV. Most people living with HIV were identified by a combination of medical conditions, laboratory measurements, and drug exposures (74,809/132,664, 56.4%), followed by laboratory measurements and drug exposures (15,241/132,664, 11.5%) and then by medical conditions and drug exposures (14,595/132,664, 11%). A higher proportion of people living with HIV experienced COVID-19–related hospitalization (4650,132,664, 3.5%) or mortality (828/132,664, 0.6%) and all-cause mortality (2083/132,664, 1.6%) compared to other cohorts.

Conclusions: Using an extensive phenotyping algorithm leveraging granular data in an EHR repository, we have identified people living with HIV, people not living with HIV, PrEP users, and PEP users. Our findings offer transferable lessons to optimize future EHR phenotyping for these cohorts.

Introduction

Background

In the United States, there are an estimated 1.2 million people living with HIV, with 32,100 new cases diagnosed in 2021 [1]. The COVID-19 pandemic has disproportionately impacted people living with HIV, who have a 4-fold higher likelihood of contracting COVID-19 and experiencing severe outcomes, such as increased disease severity, higher hospitalization rates, and elevated mortality [2-4]. Initially, the COVID-19 pandemic introduced challenges to optimal HIV management, including a substantial reduction in HIV testing, resulting in underdiagnosis and barriers to necessary treatment [5-8]. Beyond its effects on people living with HIV, the COVID-19 pandemic also disrupted preexposure prophylaxis (PrEP) use and availability, potentially increasing the vulnerability of those at risk of acquiring HIV [9]. For example, PrEP users experienced a 6% to 11.5% decline in medication coverage early in the pandemic [5,9,10]. Disparities related to social determinants of health that have historically affected minoritized (ie, racial, ethnic, gender, rural, and socioeconomic) communities with HIV became more apparent since the onset of the COVID-19 pandemic [11-15]. The pronounced impact of COVID-19 on people living with HIV and those at risk for HIV underscores the urgent need for focused research within this population for better preparedness for the next public health crisis that may affect an already vulnerable population.

Electronic health records (EHRs) provide valuable insights to address specific clinical and epidemiological research concerning HIV, including the disproportionate impact of the COVID-19 pandemic on this population [2,13-15]. The National Clinical Cohort Collaborative (N3C) is a nationally sampled EHR repository in the United States with granular, individual-level clinical data from >98 data partner sites and houses >32 billion rows of data for >22 million individuals [16]. These rich EHR data have allowed investigation of questions related to the COVID-19 pandemic and HIV, including identification of an elevated risk of poor COVID-19 outcomes in people living with HIV with a low cluster of differentiation 4 (CD4) count (<200 cells/µL) and racial disparities with COVID-19 positivity among people living with HIV, in addition to both individual and area-level social determinants of health with COVID-19 outcomes [2,13-15]. The N3C Enclave not only provides a large sample size for answering research questions but also contains granular individual-level information, such as social determinants of health [17], visit and prescription frequencies, and geographic information to better identify health disparities during the COVID-19 pandemic [18,19].

Nonetheless, identifying potential people living with HIV, PrEP users, or postexposure prophylaxis (PEP) users in any EHR dataset necessitates indirectly inferring data from source information. Most studies using EHR or claims databases start with diagnostic codes, which can result in misclassification without further refinement using drug or laboratory data [20-22]. While these previous studies have performed computational phenotyping of HIV on smaller cohorts, with data or validation often limited to a single institution or health system, one study [23], conducted with All of Us data, has included additional complexity such as self-reporting of medical conditions, which is not always feasible with large datasets [22-26]. While each approach has strengths, they also suffer from limitations, such as (1) variation in the availability of EHR data among individuals that potentially leads to differential misclassification, (2) use of nonstandardized codes specific to a single health system preventing interoperability across health systems, (3) inability to distinguish between individuals with high- or low-confidence designations, (4) additional misclassification

XSL•FO
RenderX

with increased uptake of PrEP or PEP, and (5) the use of antiretrovirals that now have indications for both HIV and COVID-19 treatment (ie, ritonavir in nirmatrelvir/ritonavir) resulting in misclassification.

Objectives

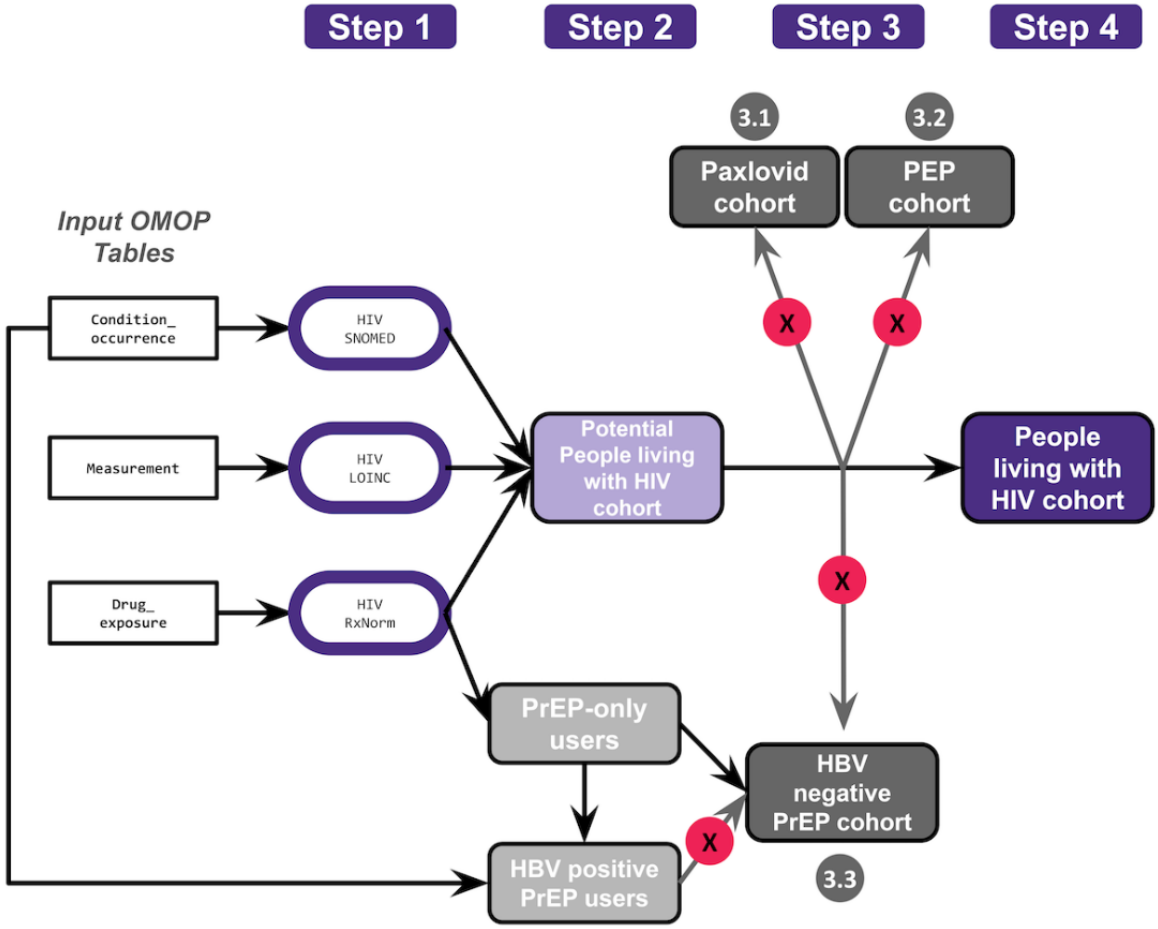
Our objective was to use an innovative approach after the emergence of COVID-19 to robustly identify people living with HIV, PrEP users, PEP users, and people not living with HIV using granular clinical data in N3C, augmented by clinician annotation without chart abstraction of source data. We used the standardized Observational Medical Outcomes Partnership (OMOP) Common Data Model to create 4 cohorts or "phenotypes," including people living with HIV (cohort 1), PrEP users (cohort 2), PEP users (cohort 3), and people not living with HIV (cohort 4), based on medical conditions, laboratory measurements, and drug data available in N3C. We conducted a clinician-curated annotation to reduce and describe misclassification. In addition, we introduced confidence levels to classify individuals into categories of low, medium, or high confidence in their status as people living with HIV, allowing researchers to tailor the cohorts to their specific research needs. These cohorts will serve as a framework for future research to address questions related to HIV within N3C, and our methods inform more generalizable approaches to phenotyping HIV in EHR data.

Methods

Study Population

The N3C Enclave contains EHR data from clinical sites and represents the largest limited dataset of COVID-19 cases and controls in the United States. N3C contains harmonized EHR data for individuals who tested positive and negative for COVID-19 from January 1, 2020, to present through routine weekly updates to incorporate near real-time clinical encounters and procedures, in addition to historical data dating back to January 1, 2018. Data include individuals who tested positive for COVID-19 matched with 2 controls who tested negative for COVID-19 based on a maximum of 4 sociodemographic variables (age, sex, race, and ethnicity) whenever available by data partner site. Our cohorts of people living with HIV, PrEP users, PEP users, and people not living with HIV were defined based on the N3C Enclave data release as of November 2, 2023 (version 148; from 93 data partner sites) using a limited dataset.

Procedures



HIV Phenotyping Overview Scheme

Our cohorts were identified in the N3C Enclave through the use of OMOP concepts, where concept IDs, concept set names, and our phenotyping pipeline can be searched in our public-facing GitHub repository for transferable methods in and out of N3C [27]. These standardized concepts correspond to three major sources of data: (1) Systematized Medical Nomenclature for Medicine Clinical Terminology (SNOMED CT) codes and *International Classification of Diseases, Tenth Revision* (*ICD-10*) mapped to SNOMED CT codes for HIV diagnosis from the HIV-related condition occurrence table; (2) Logical Observation Identifiers Names and Codes for HIV measurements from the measurement table; and (3) HIV medication exposures from the drug exposure table in RxNorm [28]. The selection of OMOP concepts across these 3 domains was carried out using the Observational Health Data Sciences and Informatics Atlas tool [29,30], in collaboration with HIV clinicians, to identify and include all relevant HIV-related OMOP concept IDs.

Conceptually, our approach identified possible people living with HIV, followed by subtyping PrEP and PEP users and removing people using HIV drugs for only chronic hepatitis B virus (HBV) or COVID-19 infection (Figure 1). From the potential cohort of people living with HIV, using the table of individuals prescribed HIV-related drugs, we phenotyped PrEP users using concept IDs in the *(immunosuppressed or compromised) PrEP concept set* and excluding individuals with an HIV diagnostic code or positive laboratory measurement (eg, antibody and antigen, viral load [VL] ≥50 copies/mL, or CD4 ≤200 cells/μL) [27]. The final cohort of PrEP users was created by excluding individuals with HBV infection to avoid potential misclassification (as tenofovir disoproxil fumarate [TDF] alone is often used for HBV treatment and avoided for PrEP to reduce the risk of acute hepatitis flare upon discontinuation of TDF for PrEP). From the potential cohort of people living with HIV, identified earlier by drug exposures (after excluding PrEP users), PEP users were identified using the concepts in the *PEP concept set* [27]. Individuals with ritonavir-only exposure (ie, those with no other antiretroviral exposure for HIV treatment, no medical conditions, and no laboratory measurements), were categorized as "uncertain classification," given the overlap of ritonavir use for COVID-19 treatment in nirmatrelvir/ritonavir using concepts listed in *Ritonavir concept set* and *Paxlovid concept set* [27]. In addition to our "ritonavir only" group, we identified those with uncertain classification status for whom, despite our best efforts, we could not adjudicate with precision which cohort they belonged to and therefore excluded these individuals from all cohorts. For instance, some individuals had repeat HIV VL testing without any results or other HIV-related laboratory measurements, drug exposures, or medical conditions, where the repeat testing could represent monitoring not only HIV treatment but also HIV screening. We considered this uncertain classification to be of low confidence, with high concern for misclassification. Given the risk of additional misclassification that assigning such individuals to one of the 4 specific cohorts would cause, we chose to remove them from the 4 specific cohorts altogether. Thus, the final cohort of people living with HIV was created by including individuals positive for HIV by medical conditions, laboratory measurements, or drug exposures and excluding any individuals listed in the final PrEP, PEP, and "ritonavir-only" cohorts (Figure 1).

XSL•FO
RenderX

Figure 1. A schematic detailing the process of creating our people living with HIV cohort. Individuals were included in the HIV cohort by a combination of medical conditions, laboratory measurements, or drug exposures (step 1) to create a potential cohort of people living with HIV (step 2). Individuals taking nirmatrelvir/ritonavir (step 3.1), postexposure prophylaxis (PEP) users (step 3.2), and pre-exposure prophylaxis (PrEP) users (step 3.3) were excluded from the intermediate cohort (step 3), which is depicted by "X" in the red circle, to create a final cohort of people living with HIV (step 4). HBV: hepatitis B virus; LOINC: Logical Observation Identifiers Names and Codes; OMOP: Observational Medical Outcomes Partnership; SNOMED: Systematized Medical Nomenclature for Medicine.

Data Preprocessing

Laboratory measurements, such as absolute CD4 cell count and percentage and VL measures, are crucial to research among people living with HIV. To extract meaningful data related to CD4 and VL measurements, we first identified concept IDs for CD4 and VL measurements seen in the *CD4 Cell Count (Absolute)* and the *HIV Viral Load (version 3) concept sets* [27]. CD4 and VL phenotyping were performed on all individuals in N3C using the measurement table.

Applying Levels of Confidence to the Cohort of People Living With HIV

To determine, with varying levels of confidence, who within the cohort were people living with HIV, we assigned a confidence level between 1 and 3 (with 1 indicating the highest confidence) per individual to reflect the degree of certainty in their status as someone living with HIV. Briefly, confidence level 1 included individuals with positive HIV laboratory results; confidence level 2 comprised individuals identified through a combination of medical conditions, the presence of laboratory measurements, and HIV medication exposures but without available laboratory results; and confidence level 3 consisted of individuals identified solely based on HIV drug exposures or only 1 record of an HIV diagnosis. More details are provided in the applying levels of confidence to the cohort of people living with HIV section in Multimedia Appendix 1 [16,31-33].

PrEP Phenotyping

In order to identify PrEP users, we first identified those using PrEP drugs (emtricitabine and tenofovir) from the possible HIV cohort who were identified by drug exposures only (ie, excluding individuals with an HIV diagnostic code or positive laboratory measurement, such as antibody and antigen, VL ≥50 copies/mL, or CD4 ≤200 cells/μL). Due to low numbers, cabotegravir for PrEP was not included. Among these, as noted earlier, individuals with likely chronic HBV infection were excluded based on concept IDs listed in the *HBV concept set* [27]. Further details about PrEP phenotyping and assigning confidence levels for PrEP users are provided in Multimedia Appendix 1.

PEP Phenotyping

PEP phenotyping was performed using the potential cohort of people living with HIV identified by drug exposures after excluding those in the PrEP cohort. We then filtered individuals based on the following criteria: (1) had a record of emtricitabine/TDF and dolutegravir or emtricitabine/TDF and

XSL•FO
RenderX

raltegravir use on the same date, (2) had a supply of <30 days (or the supply information was null), and (3) only had one row of data (indicating they were not receiving an HIV treatment regimen repeatedly, which would otherwise be more indicative of an HIV-infection–related treatment). Given that our phenotyping approach was dependent on accounting for all data available over time, it was not possible to distinguish, with confidence, PEP users who later acquired HIV. Concepts used in this workflow are available in the *PEP concept set* [27]. Given the overall small size of the PEP cohort, we chose not to pursue confidence level typing of this group.

Ritonavir-Only Phenotyping

We recognized that several individuals may have been prescribed ritonavir as part of nirmatrelvir/ritonavir (ie, Paxlovid) or another off-label regimen as a COVID-19 therapeutic. Therefore, those entering our cohort of people living with HIV by drug exposures only and who had only been prescribed ritonavir (without any other antiretrovirals used for HIV treatment documented) after January 1, 2020, were categorized separately for further evaluation using concepts described earlier [27]. We then identified those taking ritonavir as part of nirmatrelvir/ritonavir via concepts and drug source values. Individuals who only used ritonavir as part of nirmatrelvir/ritonavir were subsequently excluded. Given that there were no other laboratory tests, medical conditions, or drug exposures consistent with HIV, we suspected this group reflected people not living with HIV; however, due to the uncertainty of the indication for the ritonavir prescription, we categorized them in an uncertain classification.

Clinician Annotation Activity

To ensure the robustness of our cohorts of people living with HIV, PrEP users, and PEP users, clinicians experienced in treating HIV conducted a blinded annotation activity. Briefly, clinician annotation involving 120 randomly selected individuals (n=90, 75% people living with HIV; n=10, 8.3% PrEP users; n=10, 8.3% PEP users; and n=10, 8.3% individuals not living with HIV) was performed. Three clinicians with experience of treating HIV, blinded to the study procedures, reviewed row-level HIV EHR data (including medical conditions, laboratory measurements, and drug exposures) and classified each individual as person living with HIV, PrEP user, PEP user, or person not living with HIV based on the available data for each individual. For each clinician, we generated a confusion matrix and calculated sensitivity, specificity, positive predictive value, negative predictive value, precision, recall, and F_1-score. Multimedia Appendix 1 provides further details about this process.

Demographics and Comorbidity Definitions

Demographics and comorbidities of individuals were defined using standardized N3C-wide definitions. The set of comorbidities selected included those in the Charlson Comorbidity Index. Concept sets were created for each medical condition listed using the primary conditions listed in the SNOMED CT hierarchy, including all descendants. Specific details for each concept set can be found in the N3C concept set browser and are described in the data dictionary [16,34].

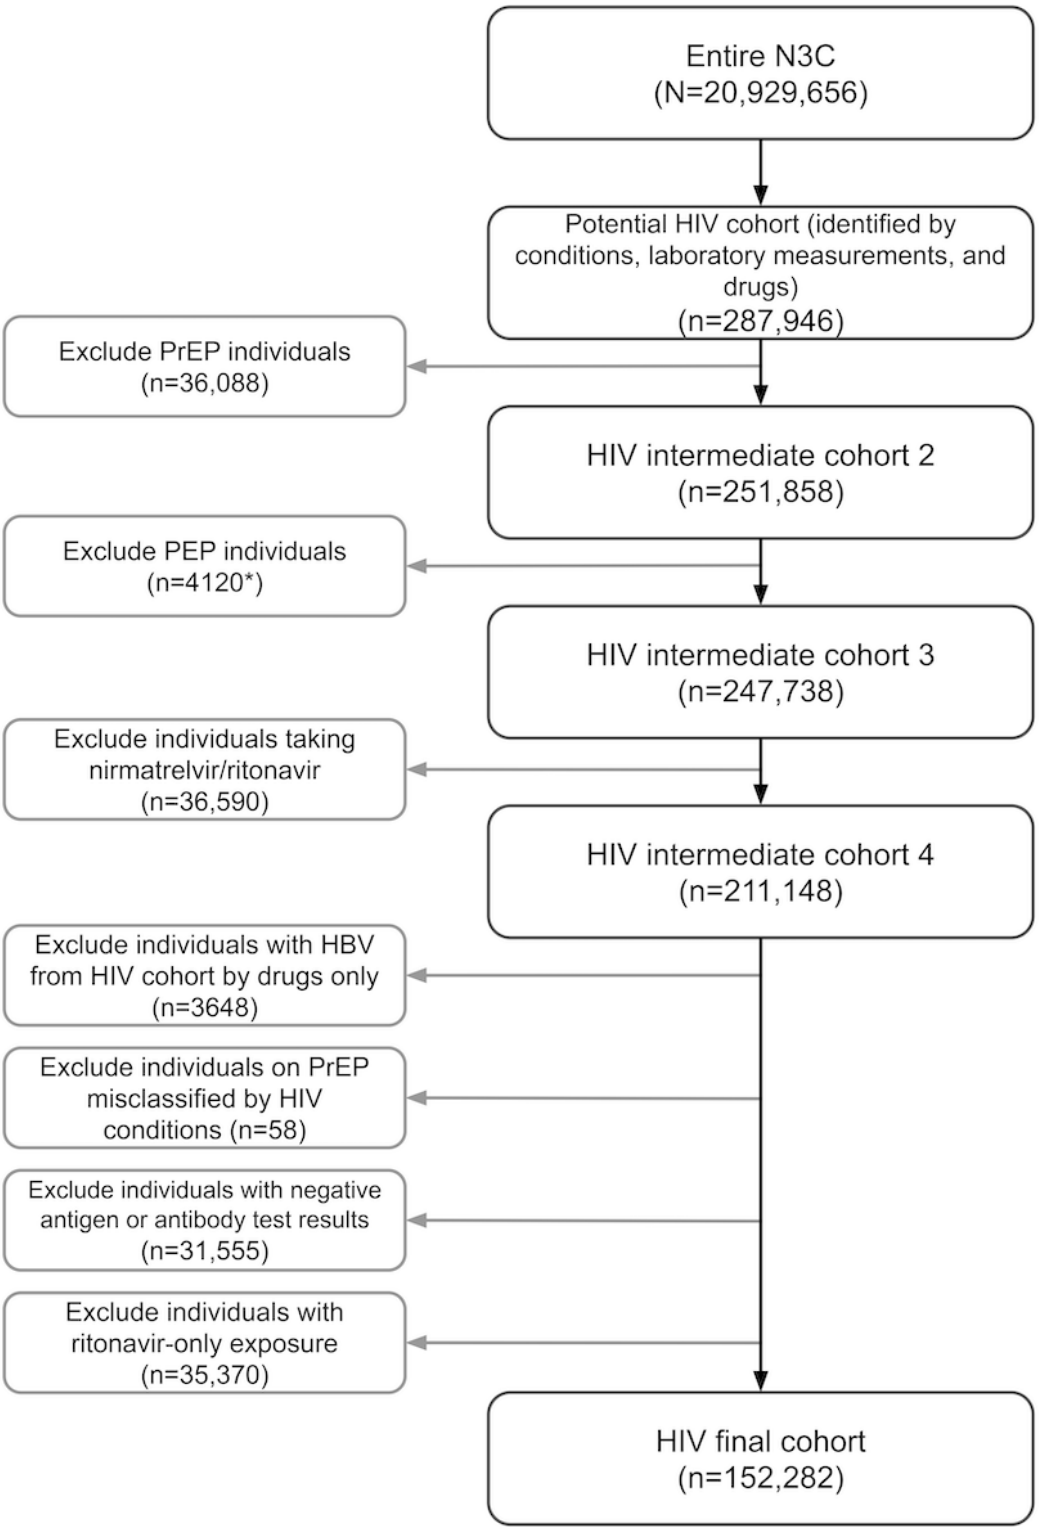
COVID-19 Outcome Definitions

The COVID-19 severity and outcomes for individuals were defined using N3C-wide definitions. In this analysis, COVID-19 positivity was defined by (1) a set of a priori–defined SARS-CoV-2 laboratory tests (that included polymerase chain reaction or antigen positivity but not antibody positivity) or (2) a "strong positive" diagnostic code (this cohort code is available on GitHub) [35,36].

Ethical Considerations

Direct patient consent was not obtained for this repository of deidentified data per N3C policies. The N3C received a waiver of consent from the National Institutes of Health (NIH) Institutional Review Board (IRB), and NIH takes care to ensure the highest privacy and security requirements are met and adhered to for housing and protecting these data in the NIH-managed N3C Enclave. More details can be found in N3C resources [37].

The N3C Enclave is approved through the NIH IRB. Each individual data partner site maintains its own IRB-approved data transfer agreement or joins under a Johns Hopkins University Reliance Protocol (IRB00249128). Each investigator accessing the N3C Enclave receives local IRB approval from their respective institutions. The N3C Data Access Committee approved this project (RP-CA3365).



Results

Identifying People Living With HIV, PrEP Users, and PEP Users in N3C

Using a computational phenotype through a combination of medical conditions, laboratory measurements, and medication data, we identified 152,282 (0.7%) individuals as people living with HIV from a total population of 20,928,656 (Figure 2). Among these cases, many were recognized through the combination of medical conditions, laboratory measurements, and drug exposures (n=74,809, 49.1%), followed by medical conditions alone (n=15,617, 10.3%), and then by laboratory measurements and drug exposures (n=15,241, 10%; Figure 3). When categorizing people living with HIV based on confidence levels, we found that most individuals fell into confidence level 1 (n=108,068, 71%), followed by level 2 (n=24,596, 16.2%), and then level 3 (n=19,618, 12.9%; Table 1). Our phenotyping process also identified 36,088 PrEP users (after excluding 303 individuals for HBV monoinfection), 4120 PEP users (the total number of PEP users is presented as an estimate due to N3C governance rules to obfuscate counts <20), and 96,491 individuals with uncertain classification (Table 2). In terms of our confidence levels for each PrEP user, most individuals were categorized as level 1 (20,742/36,088, 57.5%), followed by level 3 (11,560/36,088, 32%) and then level 2 (3786/36,088, 10.5%; Table 3). We did observe a small number of individuals from the people living with HIV cohort (24/152,282, 0%) with possible PrEP exposure before a diagnosis of HIV.

Verification of Cohort of People Living With HIV, PrEP Users, and PEP Users via a Clinician Annotation Activity

To enhance the reliability of our methods, we conducted a clinician annotation process aimed at assessing the accuracy of our phenotyping methods for people living with HIV, PrEP users, and PEP users. Our results demonstrated excellent sensitivity (range 0.90-1), specificity (range 0.97-1), positive predictive value (range 0.77-1), negative predictive value (range 0.88-1), precision (range 0.77-1), recall (range 0.90-1), and F_1-score (range 0.87-1; Multimedia Appendix 2). Similarly, the κ values exhibited high levels of interrater reliability (range 0.91-0.98; Multimedia Appendix 2).

Characteristics of People Living With HIV, PrEP Users, and PEP Users in N3C

To obtain a more comprehensive understanding of the individuals within our various cohorts, we described their sociodemographic characteristics. Within the cohort of people living with HIV in the highest 2 confidence levels (132,664/152,282, 87.1% of all potential people living with HIV identified), the highest proportion of non-Hispanic Black individuals is in the people living with HIV cohort (49,769/132,664, 37.5%), followed by PEP users (784/4120, 19%), people not living with HIV (2,909,443/20,639,675, 14.1%), and finally among PrEP users (4534/36,088, 12.6%; Table 4). Notably, PrEP users contained the highest proportion of Hispanic or Latinx individuals (5829/36,088, 16.2%) of any race and ethnicity compared to other cohorts (people living with HIV: 20,925/132,664, 15.8%; PEP users: 403/4120, 9.8%; people not living with HIV: 2,628,308/20,639,675, 12.7%; Table 4). Male individuals constituted a higher proportion of people living with HIV (90,496/132,664, 68.2%) and PrEP users (31,722/36,088, 87.9%), which was notably higher than the proportion of male individuals among PEP cohorts (1399/4120, 34%) and people not living with HIV (9,044,853/20,639,675, 43.8%; Table 4). The median ages of people living with HIV, PrEP users, PEP users, and people not living with HIV were 51 (IQR 38-61), 36 (IQR 30-46), 35 (IQR 28-44), and 44 (IQR 26-63) years, respectively, demonstrating that PrEP and PEP users were generally younger than people living with HIV and people living without HIV (Table 4). We also examined comorbidities among people living with HIV compared to other cohorts and found that people living with HIV experienced chronic lung disease, liver disease, hypertension, kidney disease, and diabetes more often compared to PrEP users, PEP users, and people not living with HIV (Table 4).

XSL•FO
RenderX

Table 4. Descriptive statistics of people living with HIV, preexposure prophylaxis (PrEP) users, postexposure prophylaxis (PEP) users, and people not living with HIV cohorts.

Characteristics	People living with HIV (n=132,664; confidence level 1-2)	People living with HIV (n=152,282; confidence level 1-3)	PrEP users (n=36,088)	PEP users (n=4120)[a]	People not living with HIV (n=20,639,675)
Race or ethnicity, n (%)					
Hispanic or Latinx, any race	20,925 (15.8)	23,346 (15.3)	5829 (16.2)	403 (9.8)	2,628,308 (12.7)

[a]The PEP cohort is estimated to obfuscate any groups with counts <20 to follow National Clinical Cohort Collaborative governance rules. This will also cause percentages not to sum to 100 in this group.

[b]Includes individuals with race and ethnicity variable values that do not include Hispanic, White, Black or African American, Asian, American Indian or Alaska Native, and Native Hawaiian or Other Pacific Islander.

[c]Includes individuals with sex variable values that do not include male or female.

HIV-Related Characteristics Among People Living With HIV in N3C

Of the 132,664 people living with HIV in the highest 2 confidence levels, 86,148 (64.9%) had at least 1 VL measurement, and 69,704 (52.5%) had at least 1 CD4 count recorded. The median number of VL and CD4 count laboratory tests was 5 (IQR 2-9) and 4 (IQR 2-8), respectively, per individual (Table 5). Of those with recorded VL and CD4 count measurements, 76,456 (57.6%) had VL and 69,254 (52.2%) had CD4 count results available for analysis (Table 5). Of those who had results, 41,923 (31.6%) had ≥1 detectable VLs (defined as VL >50 copies/mL) and 51,707 (39%) had ≥1 CD4 count <200 cells/µL (Table 5).

COVID-19 Outcomes in People Living With HIV, PrEP Users, and PEP Users in N3C

We examined the distribution of COVID-19–related variables within the cohorts of people living with HIV, PrEP users, and PEP users in comparison to people not living with HIV. The number of individuals who were tested for COVID-19, regardless of the results, was 104,903 (79.1%) among 132,664 people living with HIV (confidence levels 1 and 2), 30,799 (85.3%) for 36,008 PrEP users, 3704 (89.9%) for 4120 PEP users, and 17,756,497 (86%) in 20,639,675 people not living with HIV (Table 6). The proportions who tested positive for COVID-19 were similar between the cohorts; there were 34.4% (45,609/132,664) people living with HIV, 33.6% (12,121/36,088) PrEP users, 37% (1525/4120) PEP users, and 38.6% (7,970,336/20,639,675) people not living with HIV who tested positive for COVID-19 (Table 6). When categorizing individuals based on the severity of COVID-19, a higher

XSL•FO
RenderX

proportion of people living with HIV experienced a COVID-19–related hospitalization (4650/132,664, 3.5%), COVID-19–related mortality (828/132,664, 0.6%), and all-cause mortality (2083/132,664, 1.6%) outcomes compared to people not living with HIV who had a lower proportion of COVID-19–related hospitalization (407,894/20,639,675, 2%), COVID-19–related mortality (95,421/20,639,675, 0.5%), and all-cause mortality (192,519/20,639,675, 0.9%; Table 6). With regard to receipt of COVID-19 vaccinations, people living with HIV exhibited a lower proportion of full primary (ie, completing 2 doses when applicable) vaccination documentation (15,387/132,664, 11.6%) compared to PrEP users (5414/36,088, 15%), although it was higher compared to PEP users (441/4120, 10.7%) and similar to people not living with HIV (2,327,522/20,639,675, 11.3%; Table 6). The booster vaccination documentation displayed a lower proportion of people living with HIV receiving any booster vaccination (28,520/132,664, 21.5%) compared to PrEP users (12,547/36,088, 34.8%) but higher than PEP users (559/4120, 13.6%) and people not living with HIV (2,521,638/20,639,675, 12.2%; Table 6).

Table 6. COVID-19–related characteristics of the people living with HIV, preexposure prophylaxis (PrEP) user, postexposure prophylaxis (PEP) user, and people not living with HIV cohorts.

Discussion

Principal Findings

Using an extensive phenotyping algorithm that leverages granular data for medical conditions, laboratory measurements, and drug exposures available in an EHR repository, we have identified people living with HIV, PrEP users, and PEP users, augmented by confidence levels to provide flexibility in cohort selection to address potential misclassification. Our algorithm was refined using an iterative process with multiple reviews by clinicians with HIV experience to reduce misclassification. Our work allows for rapid identification of people living with HIV in large datasets originating from multiple health systems, with reduced misclassification among PrEP or PEP users, those with HBV infection only, or those prescribed ritonavir only for COVID-19 treatment. Our computational phenotyping approach allows for greater transferability to other EHR data sources, accounts for nuances after the emergence of COVID-19, and is applicable for optimizing future research. Our approach lays the groundwork for large epidemiological investigations among people living with HIV and those at risk of acquiring HIV [13,14,38-41], noting that analyses to date that use this phenotyping have influenced guidance for COVID-19 vaccination prioritization for people living with HIV and can inform interventions, ranging from addressing clinical to social needs.

We have identified one of the largest cohorts of people living with HIV in the United States, leveraging a nationally sampled EHR repository. The overall distribution of sociodemographic, comorbidity, and COVID-19 findings of our cohorts is consistent with available literature. We identified a higher proportion of diabetes, hypertension, and chronic lung disease in people living with HIV than in people not living with HIV, which reflects the epidemiology of comorbidity burden for HIV in the United States [1,42]. Similarly, where laboratory results were available, our proportion of people living with HIV with undetectable VL

XSL•FO
RenderX

(34,533/132,664, 26%) reflects the HIV care continuum for the United States [1]. In addition, the demographics for PrEP users are also consistent with what has been previously reported in the United States. Similarly, with regard to COVID-19, we saw increased COVID-19–related hospitalizations, mortality, and all-cause mortality in people living with HIV than in people not living with HIV, which has been previously reported in other cohorts of people living with HIV [43-46]. Nonetheless, appreciating the nuanced similarities and differences between our N3C cohorts and others helps articulate places of generalizability to the HIV or PrEP populations in the United States.

One key element of our computational phenotype, with clinician annotation, aimed to minimize potential misclassification. For instance, in the entire N3C, we identified 121,099 individuals with a condition for HIV, but 16,185 (13.4%) of them had tested negative for HIV, suggesting these individuals may be misclassified if we used medical conditions alone. In our experience, it also appeared that medical conditions were occasionally applied inappropriately for those who were being screened for HIV or receiving prescriptions for PrEP or PEP. Many of the published HIV case-finding algorithms, with specificity frequently >90%, were validated before approval of and more expanded access to PrEP or nonoccupational PEP [47,48]. Thus, the potential for misclassification is greater now than ever.

Our computational phenotyping approach parallels other recent work, although arguably, it adds nuances that help reduce potential misclassification. Yang et al [23] conducted a study involving computational phenotyping of people living with HIV and PrEP users within the All of Us research program. They used a hybrid approach, with both EHR and self-reported survey data, to identify people living with HIV. Notably, their findings indicated that the identification of people living with HIV was most prevalent through a combination of drug exposures and medical conditions (n=3324 individuals, constituting 43.4% as opposed to our study with 14,595/152,282, 9.6%) as well as drug exposure alone (n=2191 individuals, accounting for 28.6% as opposed to our study with 11,510/152,282, 7.6%), with 19.9% (43,419/216,971) of the individuals with drug exposure only to ritonavir [23]. Similarly, in the HIV-Phen algorithm, May et al [24] identified misclassification with *ICD-10* codes alone, including roughly 6.5% of individuals who only had a screening test. Within the Veterans Health Administration, using a single *ICD-10* code alone provided a positive predictive value of only 69% [25]. Notably, among our cohort of people not living with HIV, 6065 individuals had inappropriate HIV-related conditions assigned despite their data suggesting they are not living with HIV, and 4159 (68.6%) of them had only a single medical condition; 58 of the PrEP users in our PrEP cohort had a condition for HIV inappropriately assigned. This misclassification was relatively small for the people not living with HIV cohort (6065/20,639,675, 0.03%); however, it would make up 4% of our people living with HIV cohort if they were included. This underscores the fallibility of relying on diagnostic codes alone, and our work can provide estimates of misclassification for researchers who may not have access to additional clinical data (ie, those limited to claims data). To help address the low specificity of medical conditions alone, we used a comprehensive approach evaluating not only positive or negative laboratory results to identify our cohorts but also repeated laboratory measurements over time. For example, an instance of an individual with one row of medical condition data followed by multiple negative HIV antigen or antibody tests is more consistent with an HIV-related condition assigned incorrectly. In contrast, an instance of an individual with one row of medical condition data followed by repeated VL and CD4 laboratory measurements is more consistent with an HIV-related condition being assigned correctly. We estimate that using medical conditions alone in other published algorithms, approximately 13.4% of probable people living with HIV were potentially misclassified according to the methods developed by Yang et al [23]. Adding an algorithm to identify PEP users also allows for reduced misclassification, as these individuals were identified by drug exposures only and would be classified as people living with HIV if not properly removed.

Another novel element of our computational phenotyping is the ability to identify individuals at risk for HIV through both PrEP and PEP exposures. Unfortunately, due to low numbers of people with exposure to long-acting injectables (cabotegravir and lenacapavir) in N3C, these were not included in our phenotyping; however, this work is currently in progress as the use of these agents expands. Among the aforementioned studies, only one [23] conducts computational phenotyping to identify PrEP or PEP users, with the latter being a group of people exposed to HIV drugs but only for a short time and, thus, embodying an element of temporality that is only available in longitudinal datasets. This provides the benefit of reducing potential misclassification between these 3 cohorts with antiretroviral drug exposure for differing reasons and provides additional comparator groups at risk of acquiring HIV for analyses. Nonetheless, readers should consider that our overall approach lacks source validation, as N3C prohibits reidentification of individuals with site data. While our clinician annotation provided measures of high consistency, we are unable to assess accuracy. Thus, we are limited in adjudicating further these reductions in potential misclassification without source validation.

With the emergence of COVID-19 and one of its primary treatments (ie, oral nirmatrelvir/ritonavir), which includes an antiretroviral also used for HIV treatment, using a single antiretroviral alone after COVID-19 can result in misclassification. Out of the entire N3C population, we identified 0.21% (43,149/20,832,144) of the individuals with only ritonavir exposure and 0.03% (6586/20,832,144) with ritonavir exposure and an HIV laboratory measurement. From this point forward, in the post–COVID-19 era, additional steps need to be implemented to reduce misclassification of people not living with HIV as people living with HIV when isolated ritonavir exposures exist. Yang et al [23] identified 2191 individuals (accounting for 28.6% of people living with HIV) by drug exposure alone; 19.9% (43,149/216,971) of our study's drug-only population had ritonavir-only exposures, underscoring the point that, after the emergence of COVID-19, potential misclassification based on drug alone may be a significant issue [23].

XSL•FO
RenderX

A clinician-annotated approach to computational phenotyping of a cohort involving individuals with HIV is desirable from several points of view, engendering, for example, the use of clinically relevant data and insights. However, such efforts are less reproducible and repeatable over time. Thus, future work in automation, for example, through machine learning, could provide unique insights into how such a cohort can more readily be derived in any EHR dataset. Future research can assess various performance characteristics of clinician-annotated or curated approaches to automation approaches, as we acknowledge that our clinician-annotated approach was time consuming and may face challenges in transferability to other EHR repositories, despite our best efforts in making our phenotyping approach and code as transparent as possible.

Strengths and Limitations

While our work has several strengths, including identifying one of the largest cohorts of people living with HIV in the United States, demonstrating high consistency with our phenotyping using clinician annotation, and identifying PrEP and PEP users, it also faces several challenges. First, as already noted, the lack of source validation or any external validation limits our ability to assess the accuracy of the phenotypes. That being said, given our use of highly specific HIV laboratory data and repeated measures over time, we are extremely confident in our identification of people living with HIV in our confidence levels 1 and 2. Second, our dataset contains a significant amount of noninformative data. For example, there are instances where we can ascertain that an HIV screening test was performed, but the result is not available in an interpretable form, or a CD4 count is available, but the units are missing. This is likely a by-product of data ingestion and harmonization across multiple different health systems; while major strides have been made in EHR interoperability, more work needs to be done to meaningfully use all available data in the various EHRs and improve the quality of data ingestion processes. Third, while the N3C Enclave cohort is inclusive of multiple health systems across the United States, it is still only inclusive of individuals with encounters with the health care system, hence various characteristics, including COVID-19 outcomes, may not be fully generalizable to those affected by HIV with limited or no access to care, who are often the most vulnerable of the vulnerable.

Conclusions

Using an extensive phenotyping algorithm leveraging granular data in an EHR repository for medical conditions, laboratory measurements, and drug exposures, we have identified people living with HIV, PrEP users, and PEP users with high precision in the post–COVID-19 era. Our approach offers flexibility to select cohorts with confidence levels that best fit the needs of the research question under investigation, with regard to potential misclassification. We offer transferable lessons to optimize future EHR phenotyping for these cohorts. Our approach lays the groundwork for large epidemiological investigations among people living with HIV and those at risk for acquiring HIV and can inform interventions addressing clinical and social needs.

Acknowledgments

The authors would like to especially thank patients whose data are used in this analysis and the various National Clinical Cohort Collaborative (N3C) team members, whose work enables this and other research.

ChatGPT (GPT-3.5; OpenAI) and Claude (Anthropic) were used to edit pieces of the manuscript, including language, grammar, and synonyms. All edits by ChatGPT and Claude were reviewed by the authors and were not used for idea or content creation.

The overall work was supported by the National Institutes of Health (NIH; National Institute of Mental Health [NIMH]) R01131542; PI RCP and the National Institute of Diabetes and Digestive and Kidney Diseases Office of the Director; KJW). The funding sources or study sponsors had no role in study design; in the collection, analysis, and interpretation of data; in the writing of the report; and in the decision to submit the paper for publication.

The N3C Publication committee confirmed that this manuscript (MSID:2139.561) is in accordance with N3C data use and attribution policies; however, this content is solely the responsibility of the authors and does not necessarily represent the official views of the NIH or the N3C program.

The N3C data transfer to NCATS is performed under a Johns Hopkins University Reliance Protocol (IRB00249128) or individual site agreements with NIH. The N3C Data Enclave is managed under the authority of the NIH; information can be found at the NCATS website [53].

Data Availability

The National Clinical Cohort Collaborative (N3C) data transfer to the National Center for Advancing Translational Sciences is performed under a Johns Hopkins University Reliance Protocol (IRB00249128) or individual site agreements with the National Institutes of Health (NIH). The N3C Data Enclave is managed under the authority of the NIH; information can be found [54]. N3C Enclave data are protected and can be accessed for COVID-19–related research with an NIH-approved (1) IRB protocol

XSL•FO

and (2) institutional Data Use Request (DUR ID: RP-CA3365). A detailed accounting of data protections and access tiers is found at the NCATS website [54]. N3C Enclave and data access instructions can be found at the N3C website [55]; all codes used to produce the analyses in this manuscript are available within the N3C Enclave to users with valid log-in credentials to support reproducibility.

Authors' Contributions

EH and CDV take responsibility for the whole manuscript. RCP, EH, CDV, VM, and ALO were responsible for conceptualization. RCP, CDV, EH, KJW, and AJA were responsible for methodology. RCP, CDV, EH, AJA, VM, and ALO were responsible for phenotype development. RCP, CDV, EH, NF, JS, LEJ, and DV were responsible for phenotype validation. EH was responsible for software validation and data curation. Formal analysis was conducted by EH, KJW, DL, and SES. Investigation was performed by RCP, CDV, and EH. RCP and MAH were responsible for resources. CDV, EH, and RCP were responsible for the original manuscript draft preparation. AJA, VM, ALO, JS, DV, NF, JYI, LEJ, KJW, ZB-D, DL, SES, JAM, PM, TW, SAH, and MAH were responsible for reviewing and editing the manuscript. EH and JAM were responsible for visualization. RCP was responsible for supervision. RCP, SAH, TW, and PM were involved in project administration. RCP and MAH were responsible for funding acquisition.

Conflicts of Interest

None declared.

Multimedia Appendix 1
Supplementary methods for applying confidence levels to people living with HIV, pre-exposure prophylaxis users, the clinician annotation activity, demographic and comorbidity definitions, and COVID-19 outcomes definitions.

Abstract

Background: Hepatitis C virus (HCV) remains a significant public health concern in China, particularly in Shandong Province, where detailed molecular epidemiological data are limited. HCV exhibits substantial genetic diversity, and understanding its genotype distribution and transmission dynamics is critical for developing effective control strategies.

Objective: This study aimed to investigate the genetic diversity, geographic dissemination, and evolutionary history of HCV genotypes in Shandong Province, China, using molecular techniques and phylogenetic methods.

Methods: A total of 320 HCV-positive serum samples were collected from multiple hospitals across Shandong Province between 2013 and 2021. HCV RNA was extracted and amplified targeting the 5′ untranslated region (UTR), Core, and NS5B regions. Sequencing was conducted, and genotypes were determined using the National Center for Biotechnology Information's Basic Local Alignment Search Tool (NCBI BLAST). Phylogenetic trees were constructed using maximum likelihood methods with the general time reversible with Gamma-distributed rate variation among sites [(GTR)+Gamma model]. The temporal and geographic evolution of the major subtypes (1b and 2a) was analyzed using Bayesian Markov chain Monte Carlo (MCMC) methods implemented in Bayesian Evolutionary Analysis Sampling Trees (BEAST). The Bayesian skyline plot (BSP) was used to infer population dynamics and estimate the time to the most recent common ancestor (tMRCA).

Results: Genotypes 1b (n=165) and 2a (n=131) were identified as the predominant subtypes, with a small number of genotypes 3b, 6a, 6k, and potential recombinant strains also detected. Phylogenetic analysis revealed distinct evolutionary clustering of 1b and 2a strains, suggesting multiple diffusion events within the province. The tMRCA of subtypes 1b and 2a were estimated to be 1957 and 1979, respectively. Bayesian skyline analysis showed that both subtypes experienced long-term population stability, followed by a rapid expansion period between 2014 and 2019 (1b) and 2014 to 2016 (2a), respectively. The analysis also identified key transmission hubs such as Jinan, Liaocheng, Tai'an, and Dezhou, indicating city-level variations in HCV spread.

Conclusions: This study provides data-supported insights into the genotypic landscape and evolutionary patterns of HCV in Shandong Province. The identification of dominant subtypes, potential recombinant strains, and regional transmission pathways enhances our understanding of local HCV epidemiology. These findings have implications for public health policy, resource allocation, and targeted treatment strategies. The integration of molecular epidemiology and phylogenetics offers a valuable model for infectious disease surveillance and control in similar settings.

Introduction

Hepatitis C virus (HCV) is an enveloped virus containing a single-stranded positive RNA genome approximately 9.6 kilobases in length, belonging to the Flaviviridae family, *Hepacivirus* genus [1]. It can lead to acute and chronic hepatitis, and if not treated promptly and effectively, may progress to cirrhosis and hepatocellular carcinoma [2]. HCV infection

XSL•FO
RenderX

remains a global health burden, with an estimated 58 million chronic cases, 1.5 million new infections, and 290,000 deaths annually [3]. China is one of the most severely affected countries, with the highest number of HCV infections globally [4].

In recent years, the global epidemic trend of HCV has garnered significant attention [5]. Hepatitis C is primarily transmitted through blood contact and is associated with severe complications, including cirrhosis and liver cancer [6]. The prevalence and distribution of various HCV genotypes vary across different regions [7]. These disparities are influenced by factors such as geography, population mobility, and sanitation conditions [8].

Molecular epidemiological research is a critical tool for comprehending the dynamics of virus dissemination, transmission, and evolution [9]. The sequencing of viral RNA offers a more precise understanding of the viral genotype and its genetic variations [10]. Moreover, conducting phylogenetic tree analysis using viral sequence data can yield valuable insights into the virus's origins, transmission routes, and evolutionary pathways [11]. The 5′ untranslated region (UTR), NS5B region, and C region are recognized as core components of HCV, and variations in their sequences are closely linked to the virus's biological characteristics and epidemiological attributes [12]. Yang et al [13], found that HCV in Guizhou Province is mainly divided into six subtypes: 1a, 1b, 3a, 3b, 6a, and 6n, with subtype 6a being the dominant strain. In the coastal area of Putian, China, subtype 1b dominates, followed by 2a and 1a [4], while in Yunnan Province, subtype 3b is predominant, followed by 3a and 6n [14]. However, the prevalence of HCV in Shandong Province remains insufficiently studied, leaving a significant research gap in this field.

With the rapid advancements in modern bioinformatics technology, machine learning algorithms have found extensive applications in various biomedical domains [15]. In the context of HCV research, machine learning can expedite the classification of extensive viral sequence data and enhance the ability to predict epidemic trends and migration patterns of the virus [16,17]. For example, the Phylogenetic Maximum Likelihood (PhyML) method calculates branch probabilities based on the general time reversible (GTR)+Gamma model and determines the optimal topological structure, which is used to classify the evolutionary relationships of viral subtypes. The Bayesian Markov chain Monte Carlo (MCMC; Bayesian Evolutionary Analysis Sampling Trees [BEAST]) method reconstructs population history using the skyline model and generates posterior distribution trees (maximum clade credibility [MCC] trees) through MCMC sampling to infer the origins and transmission paths of viral subtypes. The exponential clock model uses sample collection time to calibrate the evolutionary tree and estimates the time to the most recent common ancestor (tMRCA) using Bayesian inference, providing estimates of viral divergence times. Although this study did not use traditional supervised learning models (eg, random forests and SVM), it integrates Bayesian statistical inference and maximum likelihood estimation to solve the evolutionary classification, spatiotemporal transmission inference, and divergence time estimation issues of HCV subtypes. These methods enable dynamic analysis of viral evolutionary history through probabilistic modeling and parameter optimization.

Given its economic significance and large population, Shandong Province holds a pivotal role in China. Therefore, conducting comprehensive research on the prevalence of HCV in the province carries significant public health importance [18]. Understanding the trends in prevalence, distribution of primary genotypes, and patterns of HCV transmission in Shandong Province can provide a scientific foundation for disease prevention and control in the region. Furthermore, it can serve as a valuable reference for comprehending the HCV epidemic in other areas of China and globally [19]. Therefore, the goal of this study is to conduct a molecular epidemiology and systematic geography crossover study of HCV isolates from various cities in Shandong using machine learning algorithms. It integrates viral genomics, bioinformatics modeling, and public health policy analysis, aiming to reveal the evolutionary history, transmission networks, and interactions with socioeconomic factors of HCV within the region. This multidimensional integrated analysis provides a scientific basis for regional infectious disease prevention and control.

Methods

Subjects

This study collected a total of 320 plasma samples from patients with hepatitis C. The samples were obtained from outpatient and inpatient settings in various hospitals in Shandong Province between 2013 and 2021. The main hospitals include Xintai People's Hospital, Tai'an Central Hospital, and Dongping People's Hospital, among others. A total of 38 hospitals participated in sample collection, with further details available in Table S1 in Multimedia Appendix 1. After centrifugation at 3000 rpm for 10 minutes, the obtained plasma samples are divided into 2 tubes and stored at −80 °C. All patients tested positive for anti-HCV antibodies and HCV RNA, with HCV RNA quantification ranging from 1.62×10^3 to 7.22×10^7 copies/mL. Serum samples were collected from healthy individuals who tested negative for anti-HCV and were allocated to the negative control group. Serum samples were collected from individuals in the positive control group who were confirmed to have HCV genotypes through sequencing and HCV RNA quantification of $\geq10^5$ copies/mL.

Furthermore, the researchers collected baseline demographic information from all participants and evaluated risk factors for HCV infection using a thorough epidemiological questionnaire. The questionnaire covered aspects such as age at diagnosis, gender, occupation, and place of residence. The diagnostic criteria for HCV infection are established according to the 2022 edition of the Chinese Guidelines for the Prevention and Control of Hepatitis C. The study follows the Helsinki Declaration [13].

Exclusion Criteria

Patients who tested positive for antibodies against the hepatitis B virus, hepatitis D virus (HDV), and HIV were excluded from this study. In addition, patients with known alcohol abuse, drug issues, pregnancy, and those with Child-Pugh grade B or C liver function were not included in this study.

XSL•FO
RenderX

Patients with high-risk factors, such as a history of blood selling, blood transfusion, blood product usage, hemodialysis, intravenous injections, needlestick injuries, maternal infection, high-risk behaviors, or a history of dental treatments, were also excluded [13].

HCV RNA Extraction and Polymerase Chain Reaction Amplification

Quantitative Polymerase Chain Reaction (qPCR) was performed using the Artus HCV QS-RGQ kit (Qiagen) and the Quant Studio 5 system (Thermo Fisher Scientific). In brief, following the manufacturer's protocol, viral RNA was reverse transcribed into complementary DNA (cDNA) using the RT-master mixture. A 4-µL aliquot of cDNA was used as a template in a 50-µL PCR reaction mixture. The PCR conditions included an initial incubation at 95 °C for 15 minutes, followed by 50 amplification cycles: denaturation at 95 °C for 30 seconds, annealing at 50 °C for 1 minute, extension at 72 °C for 30 seconds, and a final extension of 5 minutes at 72 °C, followed by a holding step at 37 °C for 1 minute and storage at 4 °C [20]. The primer sequences for the 5′ UTR, Core region, and NS5B region can be found in Table S2 in Multimedia Appendix 1, while specific primer sets for each region are detailed in Tables S3-S5 in Multimedia Appendix 1.

The 5′ UTR, Core region, and NS5B region are helpful in distinguishing different subtypes of HCV [21]. The 5′ UTR refers to the nontranslated region of the viral genome. This region may contain specific sequence variations that can be used for differentiating genotypes. The Core region is the gene region encoding the viral core protein, and its sequence analysis can reveal differences between genotypes and subtypes. The NS5B region encodes the RNA-dependent RNA polymerase of HCV, which plays a critical role in the virus replication process. Sequence analysis of the NS5B region can aid in identifying different genotypes and subtypes [21].

Sequencing and Phylogenetic Tree Analysis

After separation and amplification of the products through agarose gel electrophoresis, the amplified products of joyous bands (approximately 311 bp in the 5′UTR, 392 bp in the NS5B region [22], and approximately 503 bp in the C region; Figure S1 in Multimedia Appendix 1) were sent to Qinko Biotechnology Co, Ltd for sequencing. The sequencing data were used for genotyping analysis with National Center for Biotechnology Information's Basic Local Alignment Search Tool (NCBI BLAST). The sequences obtained from the different primers were renamed based on the sequence information, integrating the original sequence name, sequencing primers, and subtyping information. For instance, the sequence derived from the PV01 primer in the 5′ UTR was renamed P283uPV01-1b. P283u is the original sequence name, PV01 represents the sequencing primer name, and 1b signifies the subtype information.

Subsequently, all sequences from each region were combined with 10 reference strain sequences and were used for evolutionary analysis. The reference strains of HCV include: HCV genotype 1a (M62321), HCV genotype 1b (D90208), HCV genotype 1c (D14853), HCV genotype 2a (D00944), HCV genotype 2b (D10988), HCV genotype 2c (D50409), HCV genotype 2k (AB031663), HCV genotype 3a (D17763), HCV genotype 3b (D49374), and HCV genotype 3k (D63821).

MUSCLE software (Multiple Sequence Comparison by Log-Expectation; version 5.1.linux64; Robert C Edgar) was used for sequence alignment of the 5′ UTR, NS5B, and C regions, applying default parameters. Conserved sequence positions were extracted using Gblocks software (version 0.91b) for further evolutionary analysis. To construct the phylogenetic tree, we applied the GTR+Gamma model and used PhyML software (Phylogenetic Maximum Likelihood; version PhyML 3.3.20190909) to create the maximum likelihood phylogenetic tree. A bootstrap test with 1000 replicates was conducted to validate the results. The tree diagram was visualized and enhanced using EvolView software [23].

Bayesian Markov Chain Monte Carlo Evolutionary Analysis

This study is based on classifying the major subtypes (1b and 2a) into 2 datasets, each representing a specific HCV subtype. We constructed a maximum likelihood tree using PhyML and imported it into TempEst (Temporal Signal Estimation; v1.5.3), using sample collection year as a covariate. A linear regression analysis was performed between the root-to-tip distance and sample collection time. We observed a correlation coefficient (R^2) >0.2, with a positive slope, indicating the presence of a temporal signal in the data that can be used for molecular clock analysis. Therefore, we used the BEAST software package [24]. In this study, we used the Bayesian MCMC algorithm to investigate the ancestral relationships and migration patterns of various HCV subtypes among patients in Shandong Province.

According to research, exponential models perform better than log-normal and strict molecular clock models in HCV sequence analysis [25]. The population model incorporates the Bayesian skyline coalescent model, which surpasses constant size, exponential growth, logistic growth, and expansive growth models [26]. To analyze different HCV genotypes, we used the exponential clock model in combination with the GTR+Gamma+I substitution model and the Bayesian skyline model. The MCMC chain iterates a total of the number of sequences squared multiplied by 3000 times. A tree is generated at intervals of 25,000 iterations.

Each dataset underwent 2 independent MCMC runs, and the effective sample size for each parameter was evaluated using Tracer v1.7.2 software to confirm convergence between chains. The initial generated tree should be aged by 10%, and an MCC tree should be created using TreeAnnotator v1.10.4 software. The resultant posterior tree could be viewed using FigTree v1.4.4 software. Furthermore, this study used the Tracer v1.7.2 software to reconstruct the Bayesian Skyline Plot (BSP) to trace the growth history of HCV in patients with hepatitis C from Shandong province. It also estimated the evolutionary rate and the time of the most recent common ancestor. The BSP is a general skyline graph derived from the target sequence dataset. The distribution of the general skyline graph is then sampled, and these skyline graphs are combined to obtain the posterior distribution of the effective population size over time. Software

packages are exclusively obtained from the official BEAST website [13].

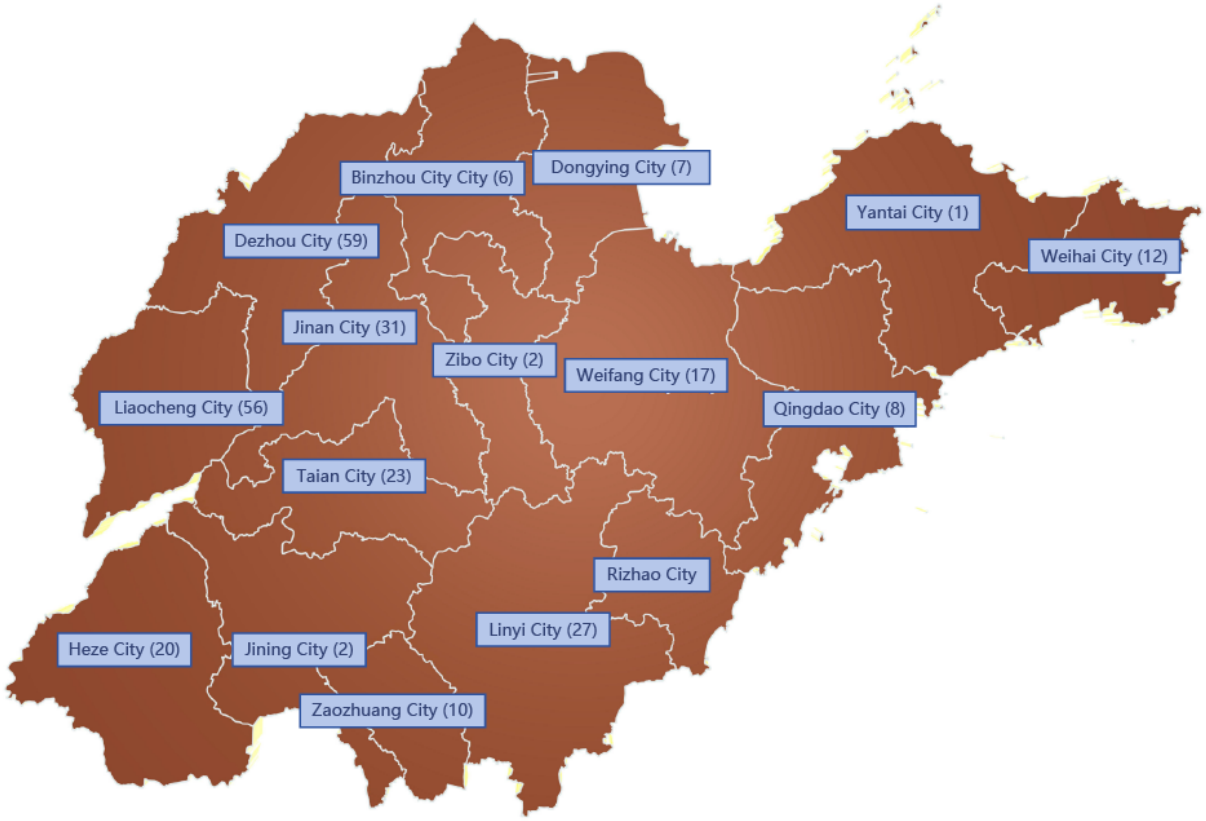
Ethical Considerations

This study was reviewed and approved by the Ethics Committee of Shandong Center for Disease Control and Prevention (institutional review board approval number: SDJK-2021-93-01). All study procedures involving human participants were performed in accordance with the ethical standards of the institutional and national research committees and with the principles of the Declaration of Helsinki (2013 version).

Written informed consent was obtained from all participants prior to the collection of blood samples and epidemiological data. For patients included through secondary data analysis, informed consent had been obtained during the original data collection. The protocol for secondary analysis was separately reviewed and approved by the same ethics committee, and a waiver of reconsent was granted in accordance with institutional policy and relevant regulations.

All data used in the study were fully deidentified prior to analysis to protect participant privacy and confidentiality. No identifiable personal information was collected, recorded, or stored. Data were managed and stored in compliance with institutional data protection policies, and access was restricted to authorized research personnel only.

Participants did not receive monetary or material compensation for participation. All samples and data were collected during routine clinical visits, and no additional interventions or burdens were imposed. The study did not involve vulnerable populations. No identifiable individual images or information are included in the manuscript or supplementary materials. All figures and data are anonymized, and individual identities cannot be inferred in any way.



Results

Demographic Characteristics and Age-Occupation Correlation of HCV Infections in the Shandong Region

A total of 320 blood samples from patients infected with HCV in different regions of Shandong, collected from 2013 to 2021, were included based on the established exclusion criteria. Excluding the few patients with incomplete identity information, the population's demographic characteristics are displayed in Figure 1 and Table 1. The data reveal 161 (50.3%) males and 121 (37.8%) females in the sample. The patients included in this study were HCV positive; their ages ranged from 7 to 80 years, with a mean age of 54.3 (14.3) years. The prevalence of HCV infection is approximately 7.8% in the age group under 30 years, 23.8% in the age group between 30 and 49 years, 54.9% in the age group between 50 and 69 years, and 13.5% in the age group 70 years and older. Analysis of the age-specific data clearly shows a higher frequency of HCV infection in the 50 - 69 years age group. Furthermore, when excluding patients who have not yet received a clinical diagnosis, it is observed that 97.6% of patients infected with HCV suffer from chronic hepatitis. This condition is particularly prevalent among farmers (75.2%), with homemakers and unemployed individuals at home exhibiting the next highest prevalence rates.

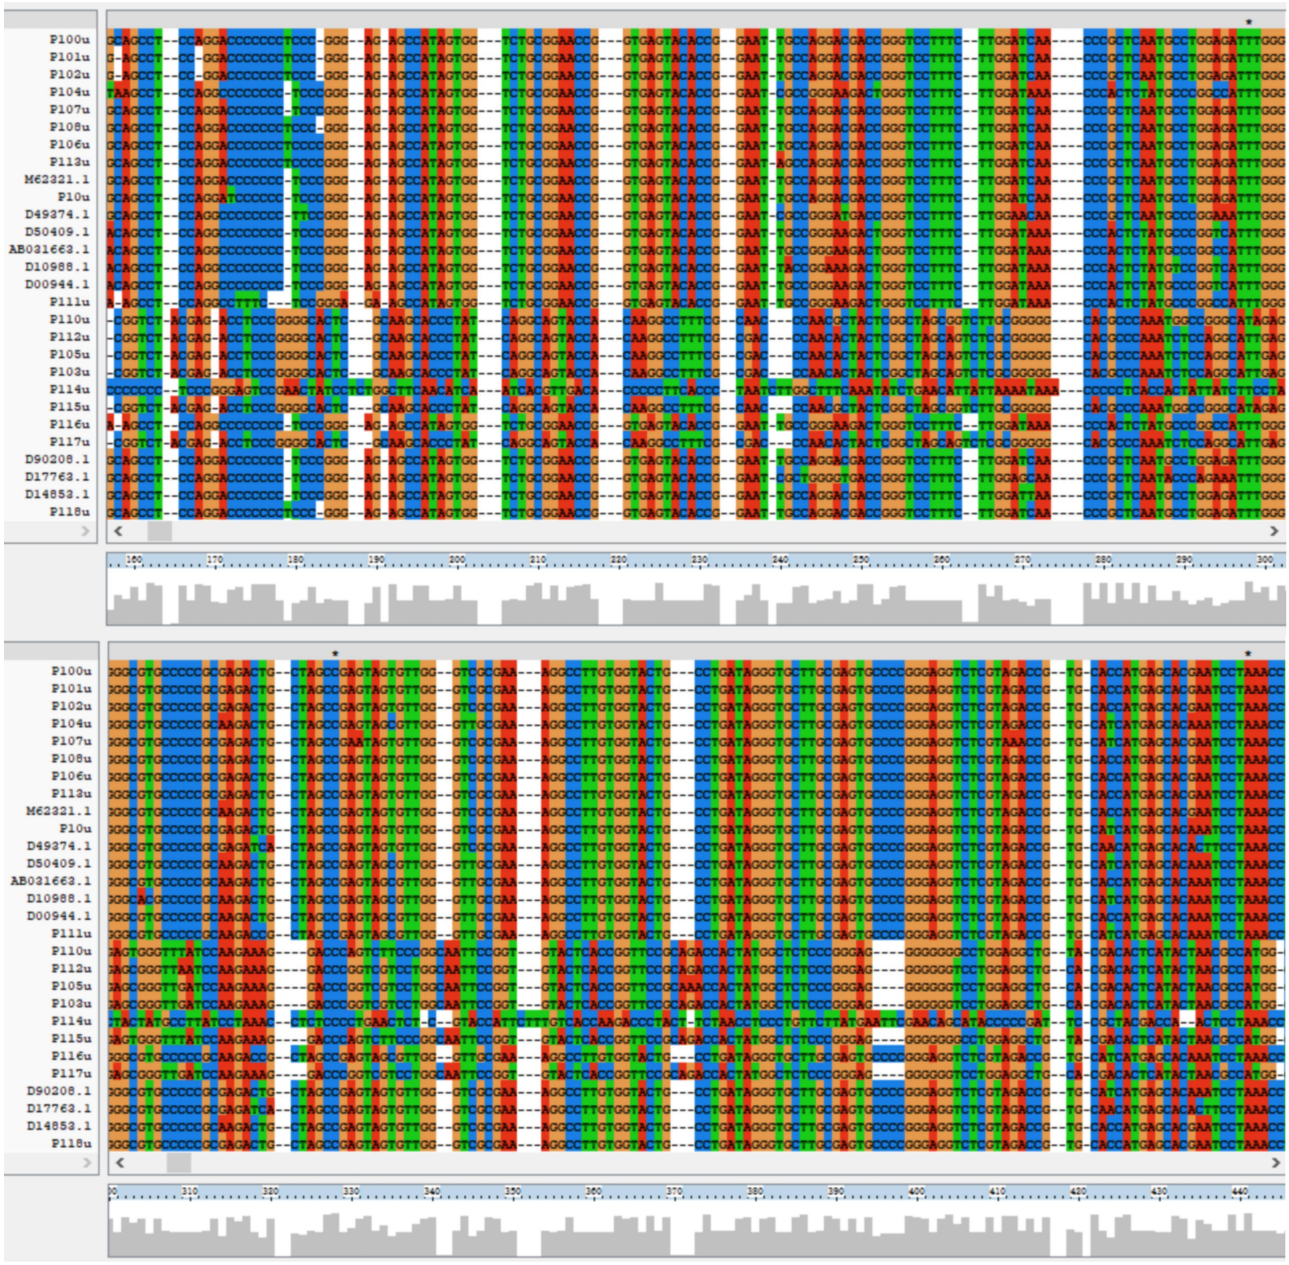
Methodology and Success Rates of HCV Genotyping in the 5′ UTR, Core Region, and NS5B Region With Sequence Variability Analysis

The genome of HCV comprises a 5′ UTR, which contains a highly conserved RNA structure. This region also includes a single open reading frame responsible for encoding structural proteins (Core, E1, and E2) and nonstructural proteins (p7, NS2, NS3, NS4A, NS4B, NS5A, and NS5B). A 3′ UTR is also present within the genome [27]. HCV's 5′ UTR is highly conserved, exhibiting minimal sequence variability. Hence, it is well-suited for the development of specific primers for amplification purposes. This region exhibits a high detection rate and is crucial in HCV RNA quantification and genotyping. However, several studies have identified limitations in using the 5′ UTR for distinguishing HCV genotypes, as the misclassification of 1a as 1b is quite prevalent [28]. Types 1, 2, 3, and 4 cannot be fully differentiated solely by their subtypes [29]. Certain 6-type sequences in the Southeast Asian region closely resemble the 1a and 1b sequences. As a result, it is not uncommon for 6-type sequences to be mistakenly classified as 1a and 1b [17]. In the species-specific region of the HCV genome, such as the C, E1, and NS5B regions, there is a high degree of heterogeneity between genotypes and subtypes, with gene sequences containing valuable information for genotyping. Therefore, sequence analysis based on this region can accurately differentiate HCV subtypes and even different isolates within the same subtype. Given the situation above, scholars have proposed a combined approach that uses 5′ UTR genotyping methods along with genotyping of the Core or NS5B region in recent years. This approach improves the detection rate and accurately distinguishes between HCV genotypes [30].



We primarily focused on sequencing the 5′ UTR. In addition, we used sequencing of the NS5B and Core regions as supplementary methods for genotyping analysis of 320 patients. A total of 320 gene fragments from the 5′ UTR were successfully amplified and sequenced, yielding a success rate of 98.8% (320/324). Similarly, 282 gene fragments from the Core region were successfully amplified and sequenced, resulting in a success rate of 89.5% (282/315). Furthermore, 233 gene fragments from the NS5B region were successfully amplified and sequenced, with a success rate of 77.7% (233/300). Consistent with previous studies, the amplification frequencies vary among the three regions, with the highest frequency observed in the 5′ UTR, followed by the Core region, and the lowest frequency observed in the NS5B region. A total of 104 cases of amplification failure may be attributed to low viral load and weak primer specificity.

After successful amplification, the resulting sequences were used as input for NCBI BLAST to search for the most likely similar sequences, thus determining the genotype of each region. Taking the P4u sequence from the 5′ UTR as an example, the BLAST analysis results (Table S6 in Multimedia Appendix 1) showed that the nucleotide homology (PNI) of the P4u sequence was 100%, with the highest score of 414. This 280 bp fragment showed 100% similarity to the HCV isolate QC156 (Accession: KJ439771.1) from nt32 to nt311, 100% similarity to the HCV

XSL•FO
RenderX

subtype 1b strain MD29 (Accession: AF207770.1) from nt85 to nt364, and 99.29% similarity to the HCV open reading frame gene (Accession: D90208.1) from nt85 to nt364. A multiple sequence alignment was performed on 307 partial gene sequences from the 5′ UTR using ClustalX2 software and compared to 10 reference strain sequences from the GenBank database. The nucleotide sequences of the 5′ UTR are considered highly conserved; however, as shown in Figure 2, there were some mutations and variations in the 5′ UTR of different HCV genotypes.

Figure 2. Comparison of 307 cases' 5' untranslated region nucleotide sequences with reference sequences in the GenBank database.

Distribution of HCV Genotypes, Potential Recombinants, and Correlation With Gender and Age

A total of 307 cases were genotyped for the 5′ UTR of the gene, 280 cases for the Core region, and 233 cases for the NS5B region. The typing results are presented in Table 2. It is evident that the 5′ UTR exhibits a high amplification frequency; however, distinguishing between many gene segments is challenging in the typing comparison. Conversely, while the amplification frequencies of the Core region and NS5B region are relatively low, they demonstrate superior capability in analyzing gene subtypes. The detection sensitivity was improved after conducting a combined analysis of the three. Four samples that did not amplify in the 5′ UTR could differentiate genotypes through successful amplification in the Core and NS5B regions. Moreover, gene fragments with ambiguous genotyping in the 5′ UTR could be further classified into subtypes.

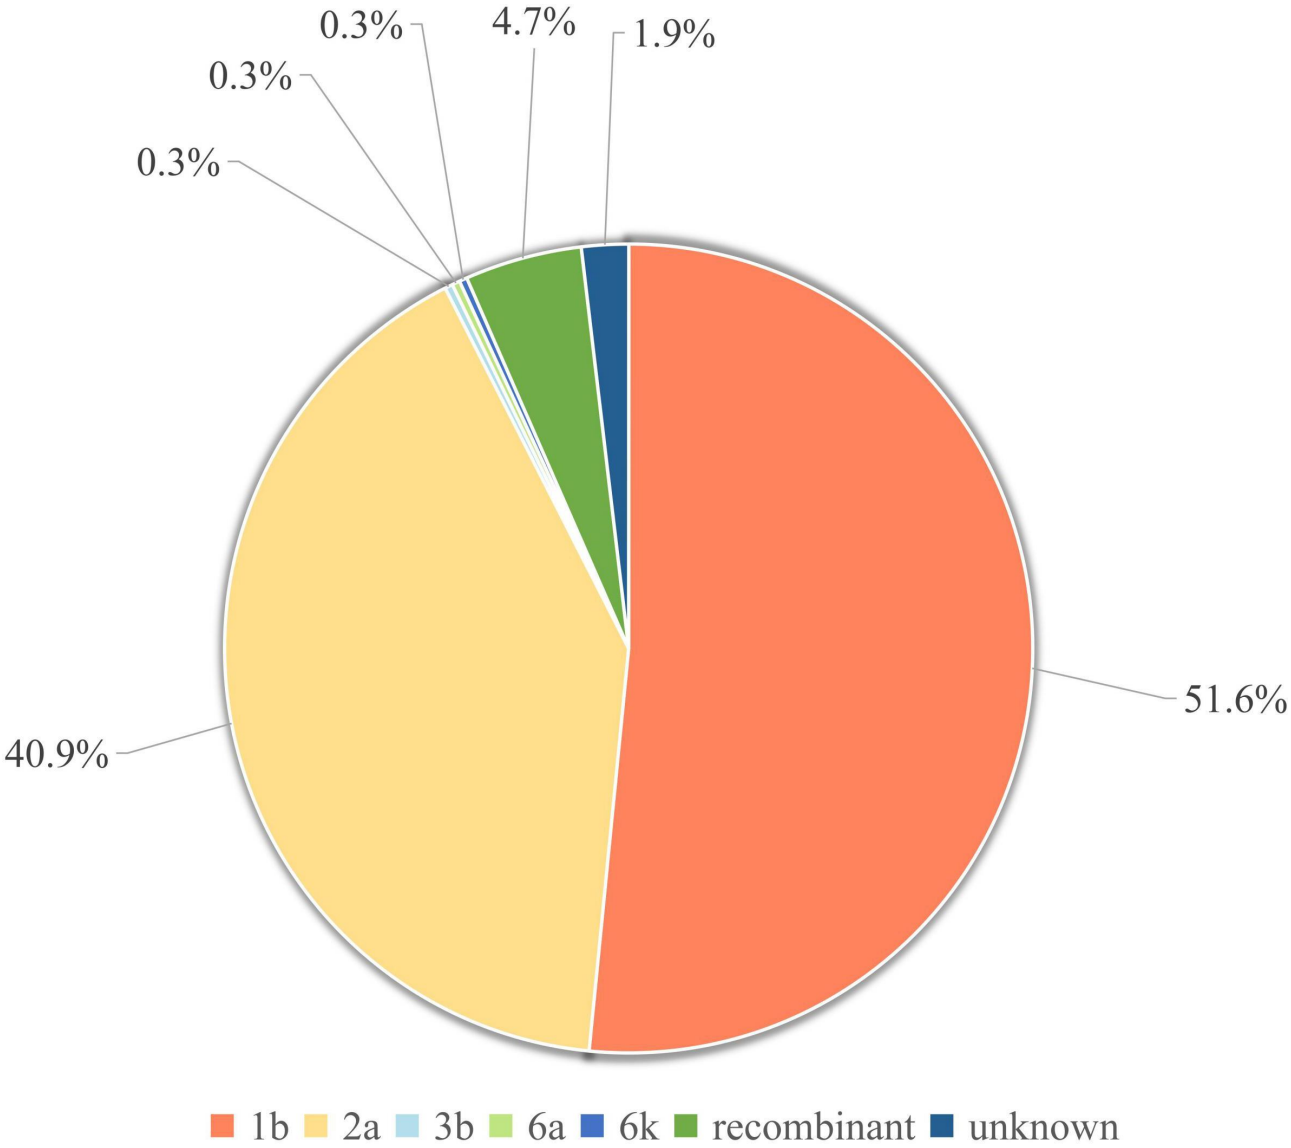
[a]HCV: Hepatitis C virus.

[b]Types 1, 2, and 6 all contain different numbers of recombinant cases, totaling 13 cases.



[c] *The number of cases indicates that this type cannot further differentiate subtypes.

[d]5′ UTR: 5′ untranslated region.

The main genotypes of HCV prevalent in most regions of our country are genotype 1b, followed by genotype 2a. These results are confirmed by our typing analysis (Figure 3). Among the 320 patients with hepatitis C analyzed, the most common HCV subtypes include 1b, 2a, 3b, 6a, and 6k. Of these subtypes, 1b (n=165) is the most dominant, followed by 2a (n=131), 3b (n=1), 6a (n=1), and 6k (n=1). Since 2002, Kalinina et al [31] reported the first case of the HCV natural recombinant 2k/1b in 2002, and several researchers have identified different recombinant strains through multiregion genotyping. This study found 13 cases with inconsistent genotyping in the 5′ UTR, Core region, and NS5B region, which are preliminarily considered potential recombinant strains of HCV, pending further confirmation in subsequent studies. In addition, there are 8 cases whose genotypes remain unclear.

Figure 3. Distribution of HCV genotypes in 320 hepatitis C patients with hepatitis C.

As demonstrated in Table 3, with the exclusion of a few patients with incomplete identity information, the HCV genotype ratio is higher in females compared to males. Out of the 148 patients diagnosed with genotype 1b, the average age was 54.7 (14.0) years. Among them, 86 were males (58.1%) and 62 were females (41.0%). One hundred eleven patients with genotype 2a were included in the study, with an average age of 54.9 (14.4) years. The patient population comprised 57 males (51.4%) and 54 females (48.6%). Based on statistical analysis, there was no difference in the average age of patients infected with genotypes 1b and 2a of HCV (P>.05).

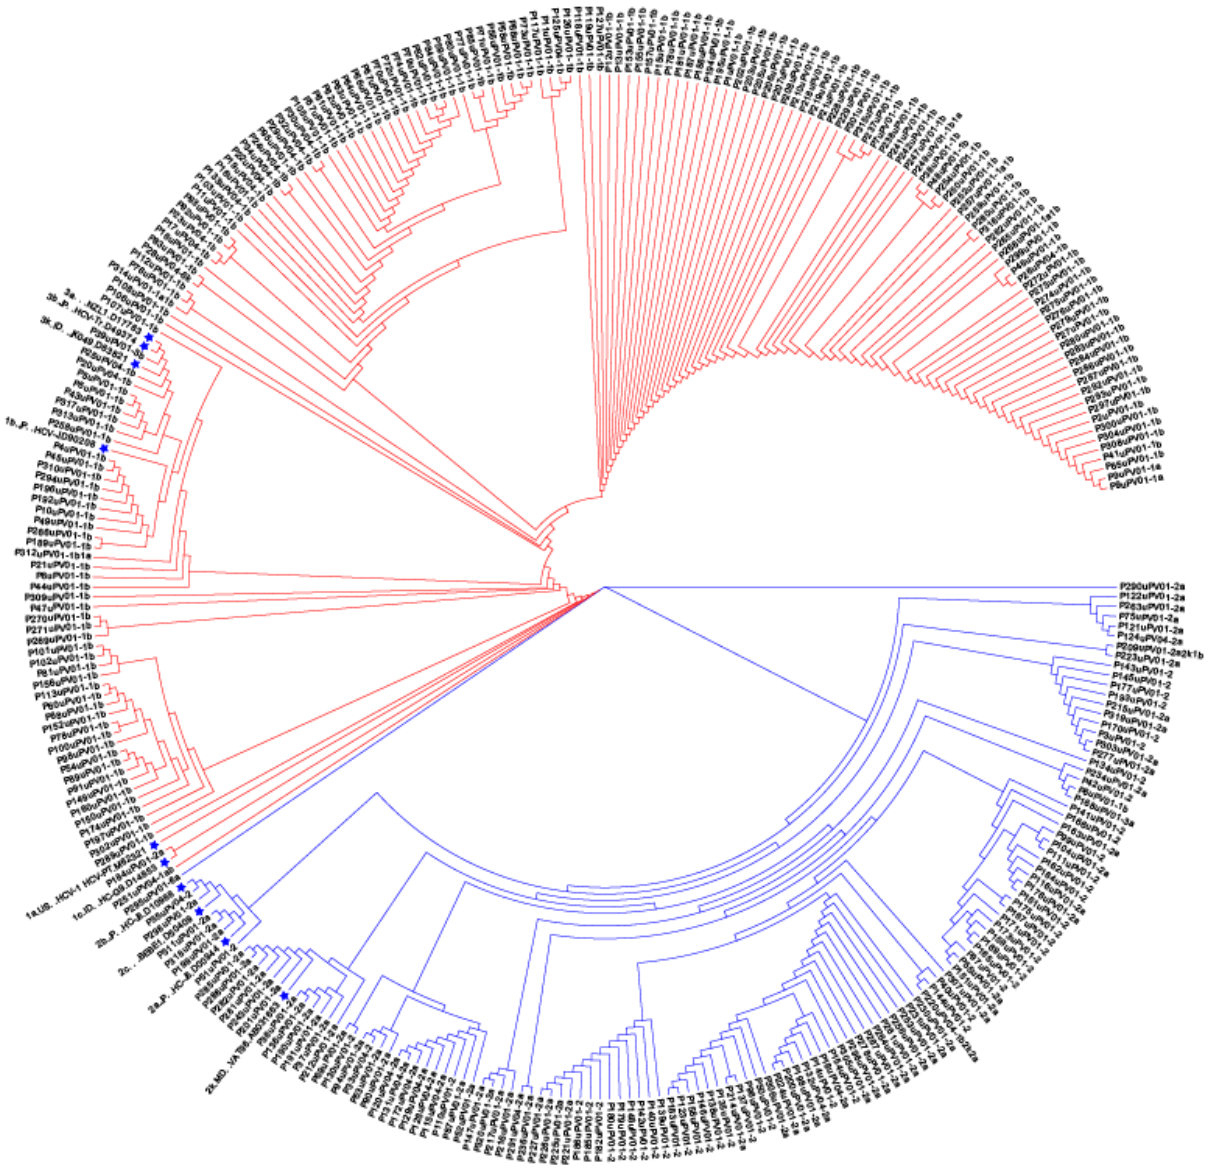
50 - 59	46 (31.1)	34 (30.6)	0	0	1	4
60 - 69	38 (25.7)	26 (23.4)	0	0	0	4
≥70	20 (13.5)	17 (15.3)	0	0	0	1
Age (years), mean (SD)	54.7 (14.0)	54.9 (14.4)				55.3 (12.8)
Total, mean (SD)	148 (54.0)	111 (40.5)	1 (0.4)	1 (0.4)	1 (0.4)	12 (5.8)

[a]HCV: hepatitis C virus.



The youngest patient diagnosed with hepatitis C is a 7-year-old girl with HCV genotype 1b, while the oldest patient is an 87-year-old woman with HCV genotype 1b. No deviation was observed in the age-specific incidence rates of the main HCV genotypes (1b, 2a) in this study. Most patients with hepatitis C are older than 50 years, with genotype 1b accounting for 70.3% and genotype 2a accounting for 69.3%. There is a lower prevalence in patients younger than 50 years, with 29.7% having genotype 1b and 30.7% having genotype 2a.

Phylogenetic Analysis of HCV Sequences Using Maximum Likelihood and Genotype Clustering Validation

We merged the 10 reference strain sequences obtained from the GenBank database with 307 5′ UTR sequences, 280 Core region sequences, and 233 NS5B region sequences. We selected the GTR+Gamma model and used the PhyML software to construct a maximum likelihood phylogenetic tree based on these sequences. We repeated the sequence alignment 1000 times using Bootstrap. The phylogenetic analysis of the 5′ UTR, Core region, and NS5B region circular system revealed substantial diversity among HCV isolates belonging to different genotypes, as demonstrated by Figure 4 and Figure S2-S3 in Multimedia Appendix 1. Furthermore, the clustering of genotypes 1b and 2a provided additional validation for the accuracy of the NCBI Blast results.

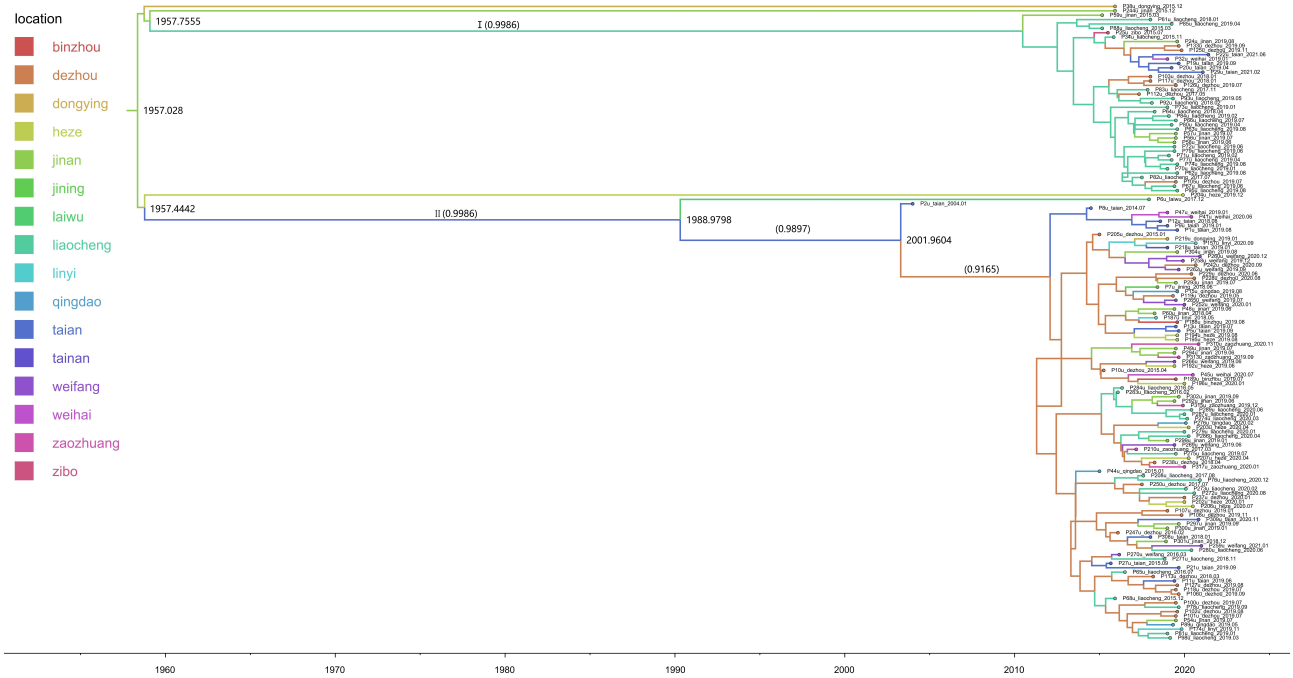
Figure 4. Evolutionary tree analysis of nucleotide sequences in the 5′ untranslated region. Sequences marked with asterisks represent reference strain sequences; branch lengths are proportional to the evolutionary distance and scale between sequences.

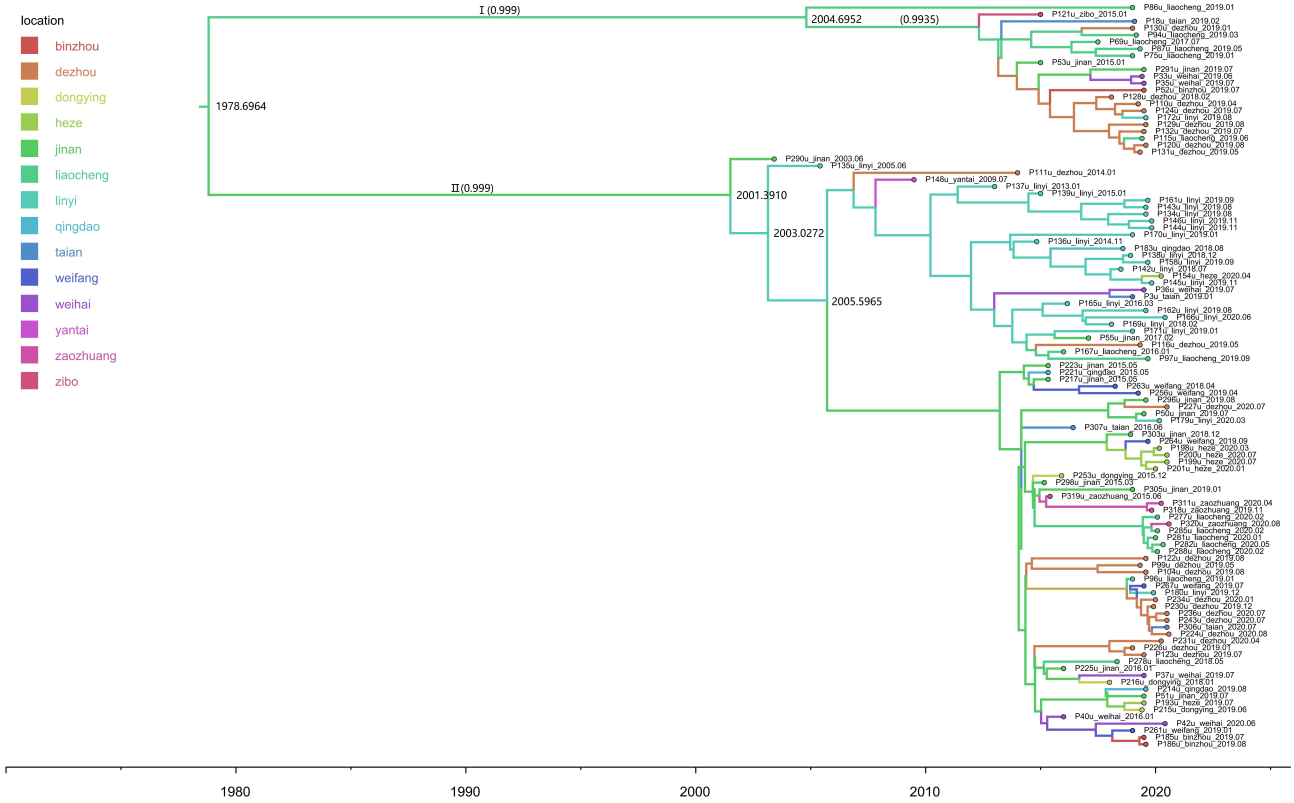
Geographical Dissemination, Estimation of the Most Recent Common Ancestor, and Population Dynamics of HCV Subtypes 1b and 2a in Shandong Province



To estimate the evolutionary relationship and emergence time of the 2 major HCV genotypes (1b and 2a) among patients with hepatitis C in different cities of Shandong Province, we conducted an evolutionary analysis using the highly conserved 5′ UTR sequences, taking into account their conservation in the region.

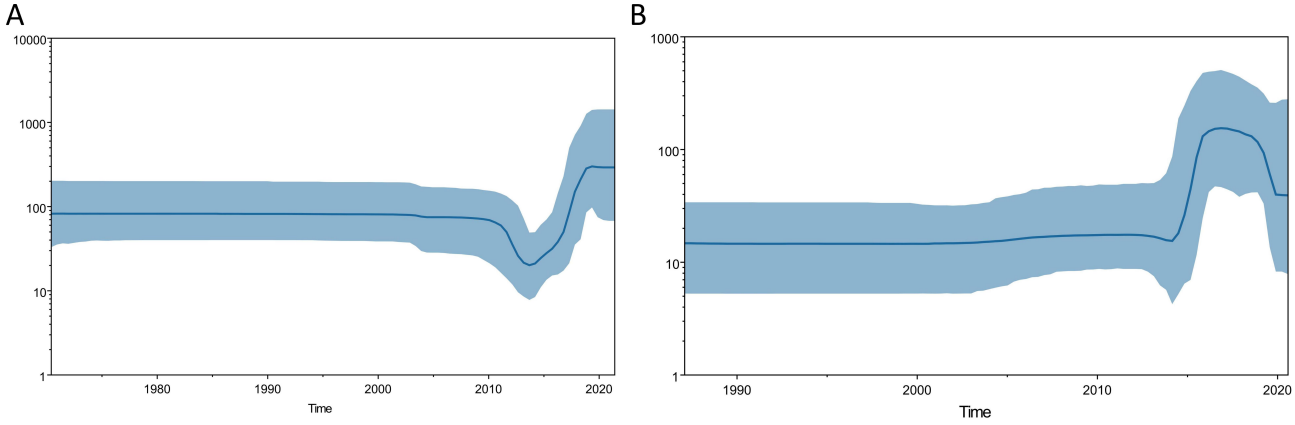
A systematic geographical analysis of the 1b subtype revealed a pronounced genetic relationship among 1b isolates from various cities in Shandong Province. Jinan may be the origin of the 1b subtype in Shandong, dating its divergence back to 1957 (Figure 5). The MCC tree of sequence 1b is roughly divided into 2 clusters, exhibiting a high posterior probability. The 2a subtypes of Cluster I primarily spread in the Licheng region, with a few cases extending to other urban areas. Regarding the transmission of the 2a subtypes in Cluster II, Taian and Dezhou have acted as conduits, enabling the successive spread of the 2a subtypes to surrounding cities.

In the phylogenetic analysis of subgenotype 2a (Figure 6), we divided the MCC tree of 2a sequences into two clusters, both exhibiting a high posterior probability. Both clusters suggest that Jinan and Liaocheng could have been bridge points in transmitting the 2a variant. The dissemination of the 2a variant to neighboring cities could be traced back to 1979.



XSL•FO
RenderX

Figure 5. Maximum clade credibility tree based on the 5' untranslated region of subtype 1b. The time scale on the x-axis represents years (1960 - 2020). The branches of the tree are colored based on the sampling city in Shandong Province (as shown in the legend). Only nodes with Bayesian posterior probabilities > 0.9 are shown, with posterior support values in parentheses. The phylogenetic tree can be roughly divided into two major clusters (Cluster I and Cluster II), each showing high geographic clustering and clear transmission paths. In Cluster I, the viral strains from the Liaocheng region show strong clustering, with a relatively limited transmission range. In Cluster II, viral strains from Tai'an and Dezhou are radially distributed, potentially playing a "bridge" role in the transmission of the 1b subtype. There is a noticeable temporal structure between the viral strains from multiple cities, reflecting the long-term dynamics of HCV transmission.



XSL•FO
RenderX

Figure 6. Maximum clade credibility tree based on the 5' untranslated region of subtype 2a. The time scale on the x-axis represents years (1980 - 2020), and the branches of the tree are colored based on the sampling cities in Shandong Province (as indicated in the legend). Only nodes with Bayesian posterior probabilities >0.9 are displayed, with posterior support values in parentheses. The tree structure can be roughly divided into two major clusters (Cluster I and Cluster II), each showing high confidence (posterior probability of 0.999). This suggests that the HCV subtypes in Shandong may have undergone at least 2 major diffusion events: Cluster I: Centered around the Liaocheng region, showing a certain degree of local transmission clustering. Cluster II: Exhibiting a multi-region mixed distribution, with Tai'an and Dezhou positioned as key nodes in the transmission network, potentially acting as "bridges" in the spread of the 2a subtype.

Subsequently, we performed a Bayesian skyline analysis to estimate the most recent common ancestor (tMRCA) time and the growth dynamics for these 2 prominent HCV subtypes (Figure 7). tMRCA for subtype 1b is estimated to be 1957 (95% CI 1943 - 1973), and for subtype 2a, it is estimated to be 1979 (95% CI 1967 - 1989). We used the Tracer software to generate a BSP to investigate the rapid expansion stage in the viral population. The rapid growth of phases 1b and 2a occurred from 2014 to 2019 and from 2014 to 2016, respectively. Before these rapid phases, the population sizes of 1b and 2a had remained relatively stable for the past 40 and 30 years. Furthermore, both population groups 1b and 2a underwent a decrease in size. The rapid decline stage of 1b (2010 - 2014) preceded the rapid growth stage, whereas the rapid decline stage of 2a (2018 - 2020) followed the rapid growth stage. Until now, there has been a relatively stable trend in the population sizes of 1b and 2a.

Figure 7. Bayesian skyline plot of the 2 major hepatitis C virus subtypes in Shandong. Graphs A and B represent HCV genotypes 1b and 2a, respectively. The horizontal ruler (x-axis) at the bottom displays years, while the vertical ruler (y-axis) on the left displays effective population size on a logarithmic scale. The black curve represents the median estimate of the changing effective population size over time. The blue curve with upper and lower areas defines the 95% highest posterior density confidence interval.

Discussion

Principal Findings

This study uses advanced phylogenetic and machine learning algorithms to perform genotype classification and evolutionary analysis of HCV isolates [32]. Previous research primarily relied on traditional molecular biology techniques, including nested PCR and gene sequencing [33]. By integrating machine learning algorithms, we enhance analysis accuracy, processing speed, and efficiency when dealing with complex data [34]. This technological innovation facilitates more precise migration and evolution tracking, providing robust data support for future disease control strategies [35].

We collected serum samples from 320 patients with hepatitis C in Shandong Province and successfully sequenced the 5 UTR from all 320 cases, the Core region from 282 cases, and the NS5B region from 233 cases. The predominant HCV subtypes in Shandong were 1b and 2a. The early spread of HCV 1b and 2a in Shandong occurred primarily in Jinan and Liaocheng, with population trends exhibiting stability, growth, and decline over time. Although the 1b subtype is globally widespread, other subtypes may be more common in regions such as Europe and North America [36]. This finding suggests that different geographical locations may have unique viral epidemic patterns, which is crucial for developing localized disease prevention strategies.

Comparison to Previous Work

While subtype 1b is widely distributed worldwide, certain regions, such as Europe and North America, may exhibit a higher prevalence of other subtypes [36]. This discovery underscores the significance of recognizing distinct geographical patterns in viral outbreaks, which is essential for developing localized disease prevention and control strategies. Using Bayesian phylogenetic inference, we estimated the tMRCA (time to the most recent common ancestor) for the 1b and 2a subtypes in Shandong Province to be 1957 and 1979, respectively. The spread of HCV 1b and 2a subtypes closely correlates with the socioeconomic development of Shandong. The origin of the 1b subtype in 1957 likely corresponds with the first systemic public health interventions post-1949 in China, during the “golden age” of public health system construction. During the late 1950s, China implemented large-scale vaccination, patriotic health campaigns, and grassroots health care network development, which increased the frequency of contact between medical institutions and populations, potentially elevating the risk of bloodborne pathogen transmission [37]. Conversely, the 1979 spread of the 2a subtype reflects the consequences of medical resource imbalance during China’s market-oriented reforms. The rapid urbanization and frequent population movement in Shandong, coupled with the concentration of medical resources in cities and limited rural health care facilities, may have increased the occurrence of high-risk behaviors, such as paid blood donations and unsafe injections, contributing to the spread of the virus [37]. Both Jinan and Liaocheng played pivotal roles in these diffusion events, highlighting the central role of major cities in pathogen transmission.

Limitations

First, the time span is limited, while the study covers samples collected from 2013 to 2021, this timeframe may not be sufficient to fully capture the long-term evolution of a chronic viral disease like HCV, which has a prolonged latency period and complex evolutionary history. Certain subtype introductions may have occurred earlier than the period observed, which could introduce uncertainty in the tMRCA estimation.

Second, there is a potential bias in the sample source: all samples were collected from patients attending medical institutions, which may introduce biases as individuals with mild symptoms, asymptomatic infections, or high-risk but undiagnosed individuals were likely excluded, potentially limiting the representativeness of the sample in terms of age, sex, and transmission route.

Third, there are limitations in the technical methods: although this study uses the BEAST Bayesian MCMC method and Bayesian skyline plots, these methods rely on certain assumptions (such as molecular clock assumptions, substitution model settings, and sample representativeness) and may introduce biases when facing uneven sequence distributions, weak time signals, or recombination events. In addition, machine learning and maximum likelihood methods for genotyping and phylogenetic tree construction may be limited by input data quality.

Fourth, the identification of recombinant strains remains uncertain: some samples identified as potential recombinants have not been validated by whole-genome sequencing or recombination detection algorithms, so the current conclusions should be interpreted cautiously.

Future Directions

Future research should aim to address several limitations identified in this study. First, expanding the temporal scope to include earlier samples would improve estimates of long-term viral evolution and help clarify the historical introduction of HCV subtypes in the region. In addition, community-based sampling—including asymptomatic individuals and high-risk populations not captured in hospital-based studies—would enhance the representativeness and generalizability of findings.

Incorporating whole-genome sequencing and advanced recombination detection tools would also enable more accurate identification of recombinant strains, particularly those with inconsistent genotyping results across genomic regions. Applying and comparing a broader range of machine learning algorithms may further enhance the efficiency and precision of genotypic classification and transmission modeling.

Moreover, future studies could explore the application of these approaches at a national scale by including data from other provinces in China. Such expansion would provide a more comprehensive understanding of HCV’s genetic and geographic diversity across the country. Finally, interdisciplinary collaboration among experts in virology, public health, clinical medicine, and bioinformatics will be essential to translate molecular epidemiological insights into targeted intervention

XSL•FO
RenderX

strategies, such as genotype-specific treatments and vaccine development.

Conclusions

This study investigated the genetic diversity and dissemination patterns of HCV in Shandong Province through sequencing and phylogenetic analysis. Genotypes 1b and 2a were identified as the predominant subtypes, with evidence of localized transmission and multiple diffusion events. Temporal and geographic reconstructions suggest distinct expansion phases for these subtypes, particularly between 2014 and 2019. The findings offer insights into regional HCV epidemiology that may support public health strategies in Shandong and similar settings. However, interpretations should be made in light of the study's methodological and temporal limitations.

Abstract

Background: Residents of facilities for older people are vulnerable to COVID-19 outbreaks. Nevertheless, timely recognition of outbreaks at facilities for older people at public health centers has been impossible in Japan since May 8, 2023, when the Japanese government discontinued aggressive countermeasures against COVID-19 because of the waning severity of the dominant Omicron strain. The Facility for Elderly Surveillance System (FESSy) has been developed to improve information collection.

Objective: This study examined FESSy experiences and effectiveness in two public health center jurisdictions in Japan.

Methods: This study assessed the use by public health centers of the detection mode of an automated AI detection system (ie, FESSy AI), as well as manual detection by the public health centers' staff (ie, FESSy staff) and direct reporting by facilities to the public health centers. We considered the following aspects: (1) diagnoses or symptoms, (2) numbers of patients as of their detection date, and (3) ultimate numbers of patients involved in incidents. Subsequently, effectiveness was assessed and compared based on detection modes. The study lasted from June 1, 2023, through January 2024.

Results: In both areas, this study examined 31 facilities at which 87 incidents were detected. FESSy (AI or staff) detected significantly fewer patients than non-FESSy methods, that is, direct reporting to the public health center of the detection date and ultimate number of patients.

Conclusions: FESSy was superior to direct reporting from facilities for the number of patients as of the detection date and for the ultimate outbreak size.

Introduction

Residents at facilities for older people have remained remarkably vulnerable to COVID-19 outbreaks [1]. Infection control at such facilities is expected to be the most important method to reduce the disease burden attributable to COVID-19 [2]. However, on May 8, 2023, infection control policies for COVID-19 in Japan were relaxed. For that reason, public health centers have become unable to recognize outbreak situations at facilities for older people unless the outbreak grows to include more than 10 cases [3]. To fill this information gap, the Facility for Elderly Surveillance System (FESSy) has been used [4] as a mode of syndromic surveillance that monitors symptoms and infectious diseases among facility residents. This web data exchange system transmits data entered from a smartphone or PC. Each facility inputs data on the number of residents or staff members with certain symptoms or who have been diagnosed as having infectious diseases in units where residents cohabitate and unit staff members manage them. Figure 1 presents the system concept. The targeted symptoms include fever, cough or difficulty breathing, vomiting, diarrhea, and eruption. The diagnosed infectious diseases include COVID-19, influenza,

XSL•FO
RenderX

infectious gastroenteritis, herpes zoster, and scabies. Data aberrations can be detected by the unit at each facility using artificial intelligence (AI). If an aberration is detected, this information is then delivered to the commissioned doctors, public health centers, medical associations, infection control nurses in the community, and local governments, who are allowed access to data entered at the facility, as shown on the right-hand side of Figure 1.

Figure 1. Concept of the Facility for Elderly Surveillance System (FESSy). Facilities enter data (shown on the left) on the number of patients with certain symptoms or infectious diseases; this is shared with stakeholders that include public health centers, local governments, infection control nurses, commissioned doctors, and the medical association (shown in the circle on the right). Moreover, the FESSy AI monitors the entered data to identify aberrations through comparison with past aberration data and patterns, as judged by the public health center staff or developers. When the AI finds an aberration, it sends an email to the stakeholders and FESSy facility correspondents.

Development of FESSy was begun in 2008 by a research group headed by Dr Yasushi Ohkusa of the National Institute of Infectious Diseases, with trials conducted at a few facilities. However, use of FESSy and the related research were then suspended for an extended period. Recently, an author of this study (JK) developed a smartphone version of FESSy and has renewed use of the system and related research. Currently, its copyright is held by a nonprofit organization that took over the project from the original research group and a private company (Milabo Co Ltd). It has been functioning in Ibaraki prefecture and Sumida City in Tokyo as part of research group activities headed by author NS.

Two public health centers operating FESSy in Sumida City in Tokyo and Tsuchiura in Ibaraki prefecture cooperated in this study. Sumida City, which is located in the center of metropolitan Tokyo, has approximately 280,000 residents. The Tsuchiura Public Health Center jurisdiction comprises 3 cities with a total population of 250,000. In Japan, most medical services are financed by national public health insurance. The same policies for older persons apply in all areas in Japan. In this sense, Sumida City and Tsuchiura present similar situations in terms of health care and welfare. Sumida City is a somewhat more urban area when compared with Tsuchiura. FESSy was activated in March 2023 in Sumida City. It was activated in September 2023 in Tsuchiura based on a request from the Ibaraki Prefectural University of Health Sciences. The Tsuchiura Public Health Center jurisdiction includes 31 long-term care facilities (special nursing homes for older people). There are 10 long-term care facilities in Sumida City.

Soon, FESSy is expected to be activated nationwide, where it can contribute to timely detection and rapid infection control at facilities. This study was conducted to summarize experiences of FESSy and to evaluate its effectiveness.

A system similar to FESSy has reportedly been operational in the Netherlands since April 2017 [5]. The Meldpunt voor Uitbraken van Infectieziekten en Bijzonder Resistente Micro-organismen (MUIZ) is a system for recording outbreaks at facilities and for the timely sharing of information, although it does not clearly define outbreaks for diseases other than COVID-19. All COVID-19 cases since March 2020 should have been recorded through the system, as it operated during the pandemic. However, it remains unknown how it has operated after the pandemic. It is noteworthy that the system does not function until an outbreak emerges. Therefore, unlike FESSy, MUIZ might not be suitable for early intervention and outbreak prevention for diseases other than COVID-19.

In Australia, the Aged Care National Antimicrobial Prescribing Survey and Victorian Healthcare Associated Infection Surveillance System operate at some facilities [6]. However, these facilities join voluntarily; like FESSy, participation is not

XSL•FO
RenderX

enforced by law. The Australian system is aimed at saving time used for data entry, which must also be considered in Japan [7].

Methods

Overview

This study was conducted at the Sumida City Public Health Center in Tokyo and at the Tsuchiura Public Health Center in Ibaraki prefecture. Study participants were limited to patients at facilities for older people in the jurisdictions of the 2 public health centers, as we particularly wanted to study long-term care facilities, specifically, special nursing homes for older people. The study period was from June 2023 to the end of January 2024. If a facility joined FESSy during the study period, data that the facility had accumulated before joining FESSy were ignored.

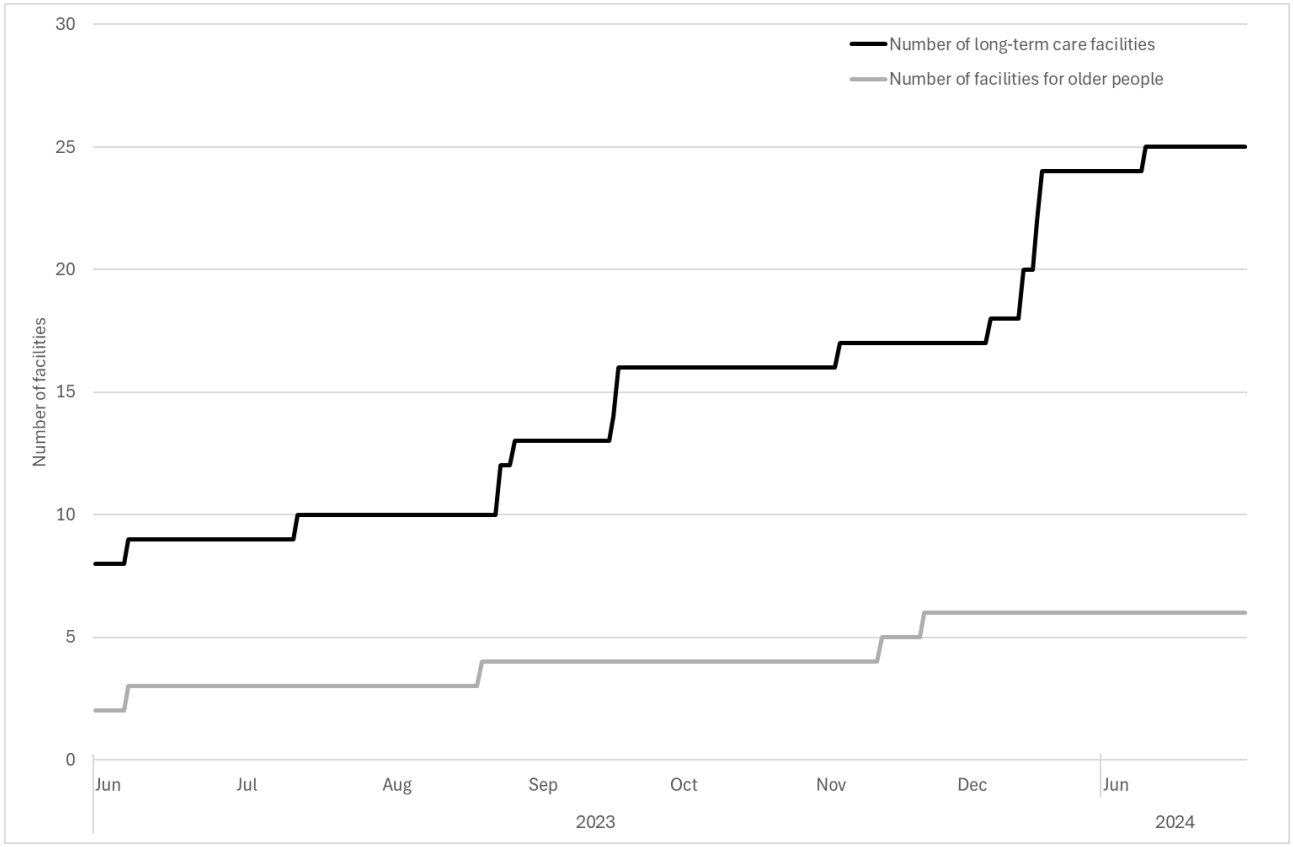
In each unit of the facility, FESSy detects aberrations using AI, based on the "C1-MILD" method of the Early Aberration Reporting System (EARS) [8], which includes symptoms and diagnoses. In EARS, C1-MILD defines a data aberration as being 3 times the standard deviation during the prior 7 days and higher than average in the same period. If the AI finds an aberration, then emails are sent automatically to facility managers or staff, public health centers, local governments, commissioned doctors, infection control nurses in the community, and medical associations. Hereafter, we refer to this AI detection mode in FESSy as "FESSy AI." Based on email notifications from FESSy AI, a public health center can activate a public health intervention at a facility. Of course, public health center staff can always monitor the situation at facilities using FESSy, even if they have not yet received an alert email from FESSy AI. Sometimes a very early-stage outbreak is identifiable by staff, facilitating a rapid public health response. We refer to this detection mode as "FESSy staff." Aside from FESSy AI and FESSy staff, a public health center sometimes receives a report from a facility directly, rather than via FESSy. We refer to that as a "direct report."

First, public health center operations can be generalized into 3 dimensions for all detection modes (FESSy AI, FESSy staff, and direct report): (1) diseases or symptoms, (2) number of patients as of the detection date, and (3) ultimate number of patients involved in the incident. Regarding (1), examination of diseases or symptoms can engender multiple answers.

We tested the overall FESSy effectiveness (sum of results for FESSy AI and FESSy staff) compared to the non-FESSy method, which can only operate based on direct reports from facilities. Moreover, we sought to ascertain, by testing, which was the more effective of the 2 FESSy communication modes: FESSy AI or FESSy staff. The effectiveness of each detection mode was measured as the number of patients as of the detection date or as of the end of the outbreak. The Wilcoxon rank-sum test was used to compare FESSy versus non-FESSy methods, as well as FESSy AI versus FESSy staff. We adopted 5% as the significance level and used software (Stata SE version 17.0; Stata Corp) for all statistical analyses.

Ethical Considerations

This study was approved by the Ethics Committee of Ibaraki Prefectural University of Health Sciences on August 21, 2023 (1103); the applicant was the corresponding author (JK). We obtained written informed consent from the two public health centers.



Results

As of the end of January 2024, 17 facilities had joined FESSy that were under the jurisdiction of the Tsuchiura Public Health Center: 16 were long-term care facilities (special nursing homes for older people) and 1 was a geriatric health services facility. In Sumida City, 14 facilities joined FESSy, of which 9 were long-term care facilities; others included geriatric health services facilities, low-cost homes for older people, and fee-based facilities. The proportion of long-term care facilities that joined FESSy was 53% (16/30 facilities) in the Tsuchiura Public Health Center and approximately 90% (9/10 facilities) in the Sumida City Public Health Center as of the end of January 2024. The increases in the number of facilities joining in the two areas are shown in Figure 2.

Figure 3 presents the proportion of data entry at FESSy facilities, which fluctuated between 50% and 80%. However, the average was almost 65%. In fact, some facilities that had joined never entered data into the FESSy system. In addition, facilities that immediately started to enter data into FESSy continued to enter data every day.

Figure 2. Number of facilities joining the Facility for Elderly Surveillance System (FESSy) in the Sumida City Public Health Center and the Tsuchiura Public Health Center from June 1, 2023, to January 31, 2024. The black line represents the number of long-term care facilities joining FESSy. The gray line represents the number of facilities for older people joining FESSy, other than long-term care facilities. In the Tsuchiura Public Health Center jurisdiction, FESSy started operation on September 1, 2023. Finally, 14 facilities had joined FESSy in the Sumida Public Health Center jurisdiction and 17 facilities had joined FESSy in the Tsuchiura Public Health Center jurisdiction as of the end of January 2024.

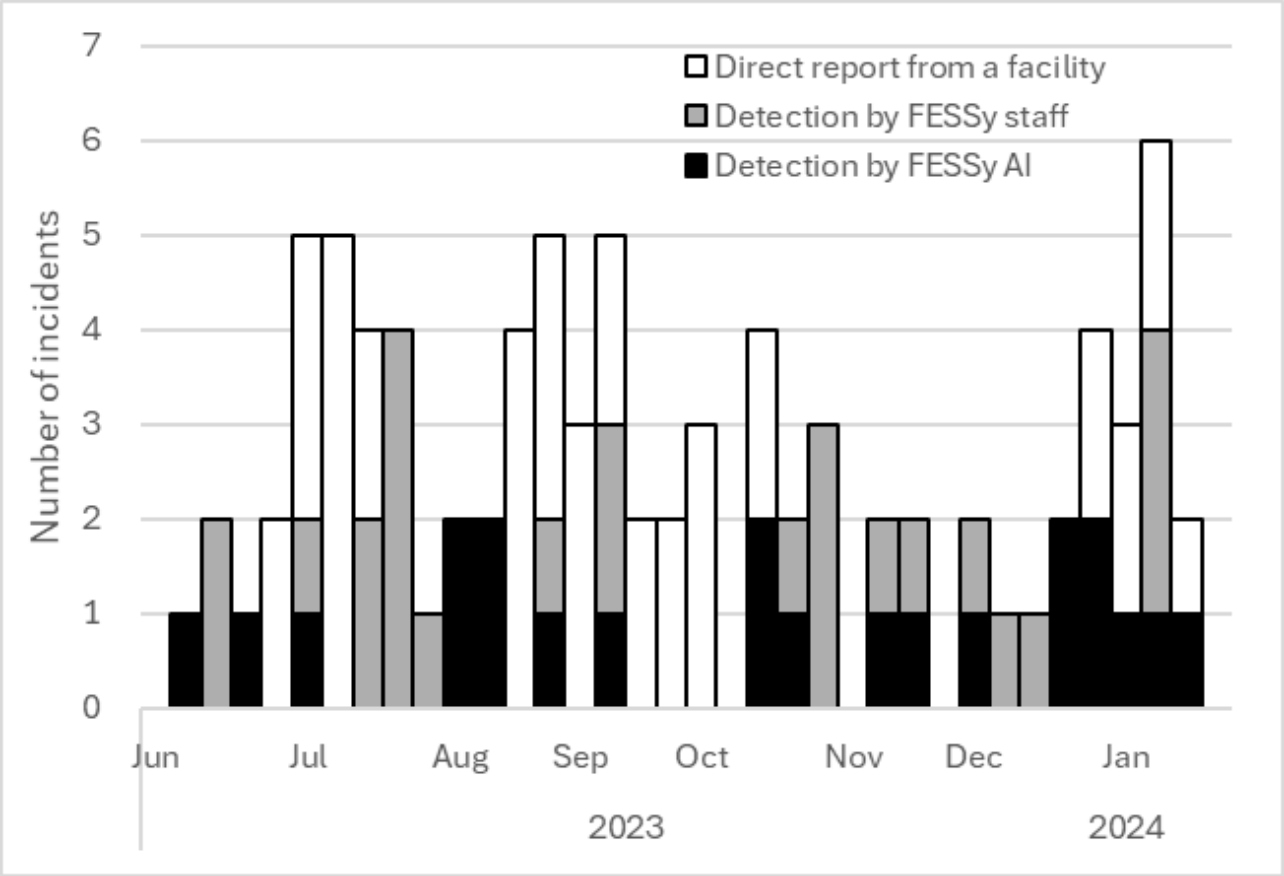
XSL•FO
RenderX

Figure 3. Proportion of facilities that entered data into the Facility for Elderly Surveillance System (FESSy) in the jurisdictions of the Sumida City Public Health Center and Tsuchiura Public Health Center from June 1, 2023, to January 31, 2024. Proportions for data entry were defined as the number of facilities that entered data in a day divided by the number of facilities that had joined FESSy as of the dates shown in Figure 2. A facility was defined as having entered data if it had entered information on symptoms, including an absence of patients with a certain symptom. Twelve facilities entered data every day, while another 10%-30% of facilities entered data but did not do so every day.

During the study period, 87 incidents were detected in both jurisdictions. Figure 4 presents the number of incidents by week and by detection mode. More than half of all incidents were detected through FESSy AI (n=21 incidents) and FESSy staff (n=26 incidents). Aside from those, 40 incidents were reported directly to the public health centers.

XSL•FO
RenderX

Figure 4. Number of incidents per week by detection mode for the Facility for Elderly Surveillance System (FESSy) at Sumida City Public Health Center and Tsuchiura Public Health Center from June 1, 2023, to January 31, 2024.



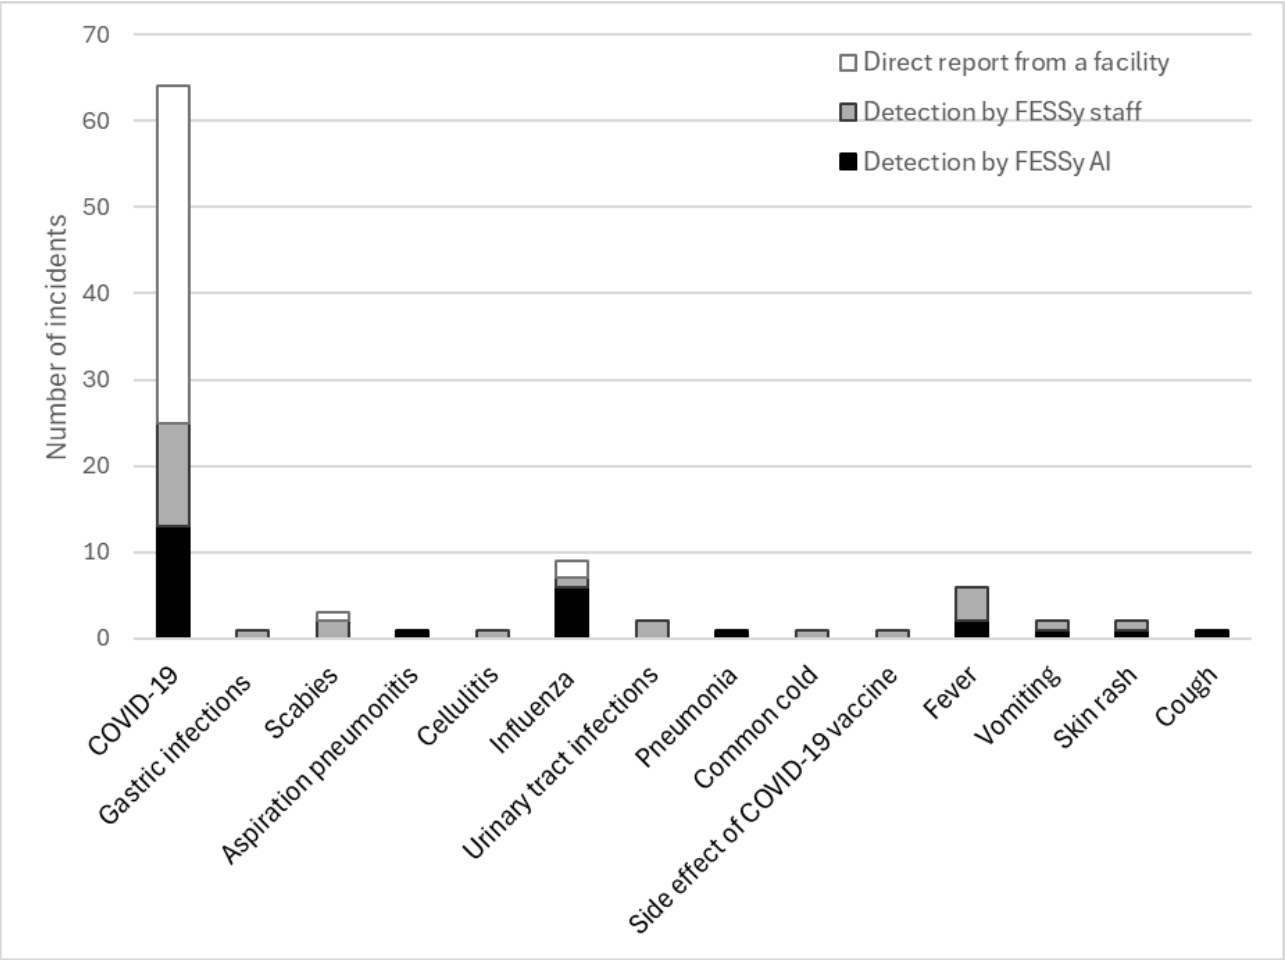


Figure 5 shows the distribution of diseases and symptoms by detection mode. The incidents caused by COVID-19 were the most numerous at 63. The next most frequent incidents were caused by influenza, with 8 incidents. Incidents detected by direct reports were limited mainly to COVID-19, with 2 incidents of influenza and 1 incident of scabies. Conversely, FESSy AI and FESSy staff found aberrations for diseases other than COVID-19, including symptoms such as fever, vomiting, and rash.

Figure 6 presents the distribution of the number of patients as of the detection date by detection mode. One reported incident did not include the number of patients. The mode for number of patients was 2. The largest number of patients was 26, which was attributable to a COVID-19 outbreak. Incidents with more than 11 patients were limited to detection by direct report. By detection mode, the average number of patients detected by FESSy AI was 4.29 (SD 2.80) for 21 incidents. For FESSy staff, the average number was 1.83 (SD 1.09) for 26 incidents. For direct reports, it was 6.55 (SD 6.18) for 40 incidents. The estimated *P* value of a rank-sum test comparison between FESSy and non-FESSy methods was .004. The *P* value was <.001 for a comparison of FESSy AI and FESSy staff.

Figure 7 shows a distribution of the ultimate number of patients involved in incidents by detection mode. Three incidents did not include this information because of the outbreak was ongoing at the end of the study period. The mode for number of patients was 1. The largest number of patients was 82, which was attributable to a COVID-19 outbreak. Incidents with more than 19 patients were limited to detection by direct report. By detection mode, the average number of patients detected by FESSy AI was 7.00(SD 3.60) for 21 incidents. For FESSy staff, the average number was 2.52 (SD 3.25) for 26 incidents. For direct report, it was 16.5 (SD 15.4 for 37 incidents. The estimated *P* value of a rank-sum test comparison of FESSy and non-FESSy methods was <.001. The P value was .001 for a comparison of FESSy AI and FESSy staff.

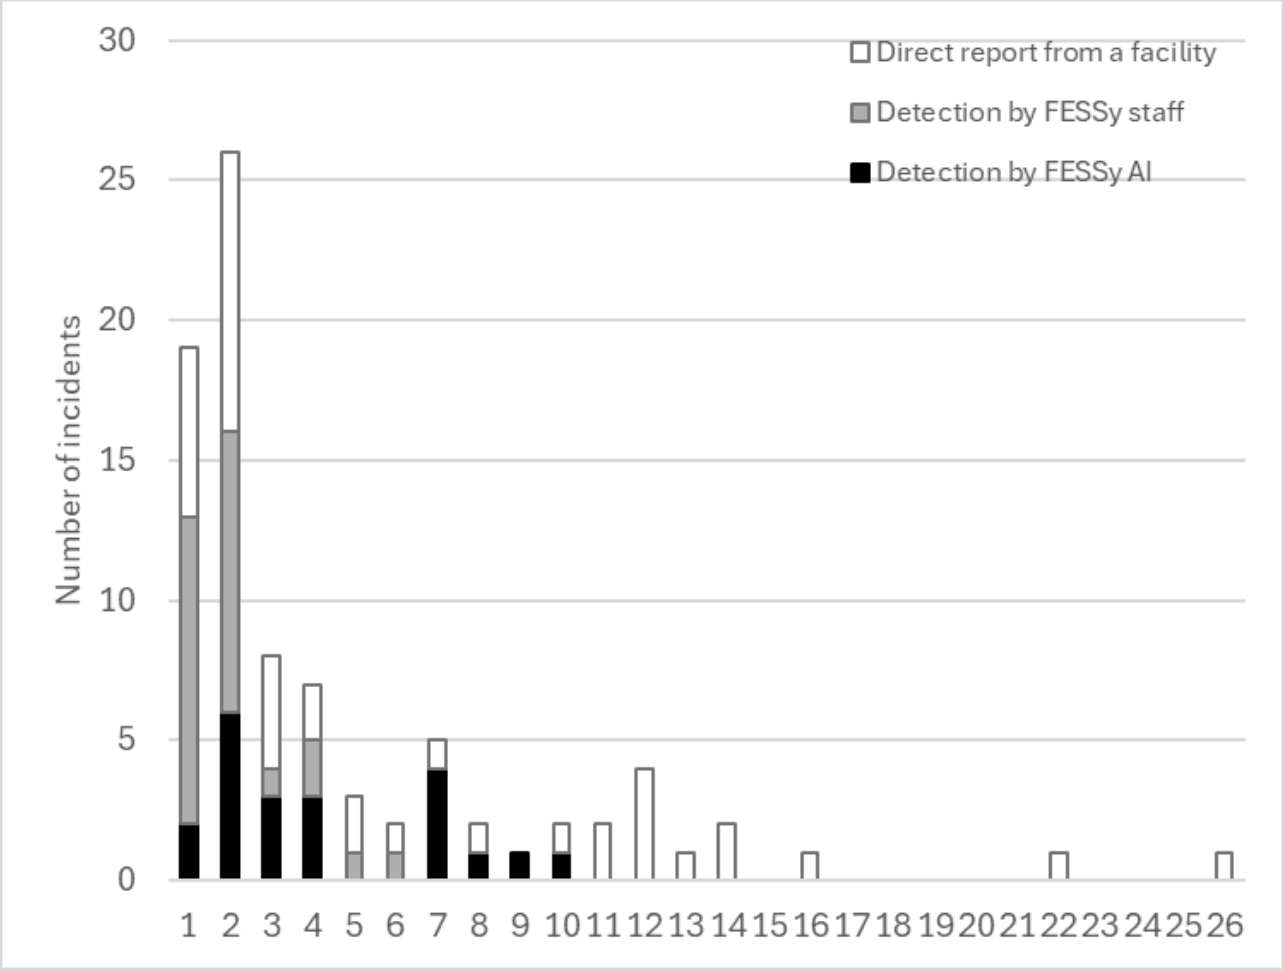
Figure 5. Numbers of incidents by disease or symptom and by detection and notification modes of the Facility for Elderly Surveillance System (FESSy) in Sumida City Public Health Center and Tsuchiura Public Health Center from June 1, 2023, to January 31, 2024. Terms from "COVID-19" through "side effect of COVID-19 vaccine" are diseases. Terms from "fever" through "cough" are symptoms. There were a total of 95 incidents with disease or symptoms (some incidents were caused by more than 1 disease or symptom).

XSL•FO
RenderX

Figure 6. Numbers of incidents by the number of patients as of the detection date and by detection mode of the Facility for Elderly Surveillance System (FESSy) in Sumida City Public Health Center and Tsuchiura Public Health Center from June 1, 2023, to January 31, 2024. One detected incident did not include the number of patients detected. The total number of incidents was 87.



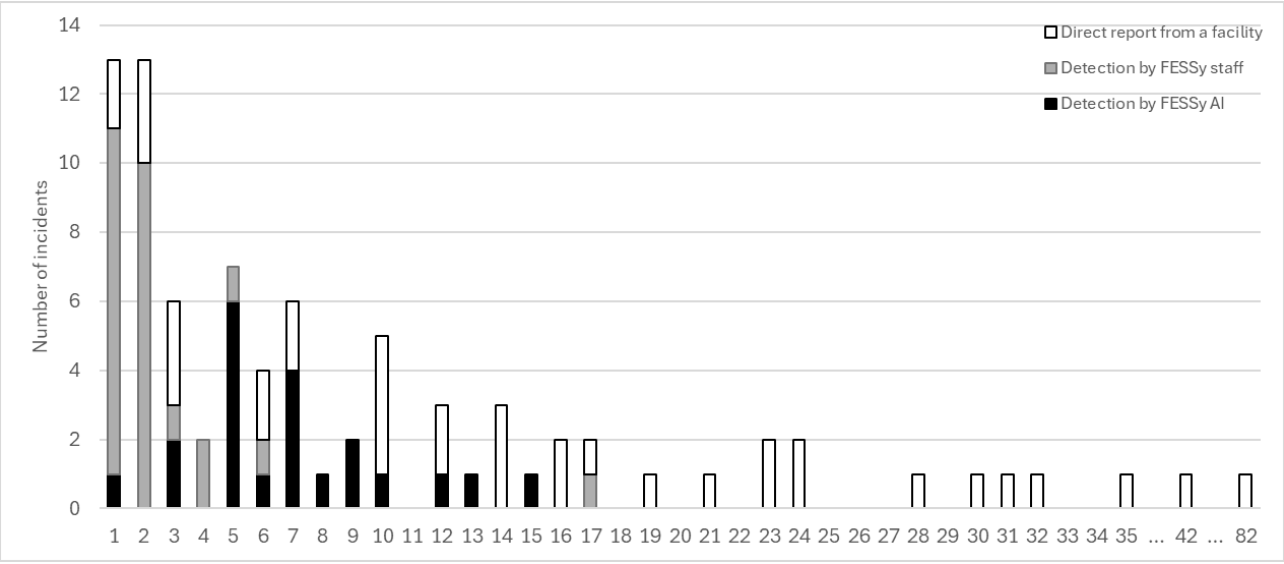


Figure 7. Number of incidents by ultimate number of patients and by detection mode of the Facility for Elderly Surveillance System (FESSy) in Sumida City and Tsuchiura from June 1, 2023, to January 31, 2024. The total number of incidents was 84. Three incidents were ongoing at the end of the study period; the ultimate number of patients was thus not available.

RenderX

Discussion

Principal Findings

Findings from statistical analysis indicate that FESSy detected outbreaks earlier than non-FESSy methods (eg, direct reporting). Notably, FESSy staff could detect an outbreak earlier than FESSy AI. Similarly, the ultimate number of patients was smaller for incidents detected by FESSy than by non-FESSy methods. Figure 5 shows that FESSy AI and FESSy staff detected aberrations for diseases other than COVID-19 and for certain symptoms. This finding suggests the usefulness of FESSy, for which detection is not limited to a particular disease, in contrast to MUIZ in the Netherlands, which is limited to COVID-19.

Comparison of the FESSy detection modes, FESSy AI and FESSy staff, showed that the latter was more timely than the former. FESSy staff sometimes detected an aberration with only 1 person. In this situation, AI usually inferred a nonaberration. In fact, the C1-MILD method was too sensitive: it produced many false positive results because it referred only to the prior 7 days. The use of AI reduced false positives by incorporating information from a longer period or that was obtained with other methods for aberration inference, including FESSy staff. Particularly, Figure 6 shows that, with few exceptions, AI did not recognize the initiation of an outbreak if the number of patients was merely 1. Therefore, a FESSy AI notification might be sent later than a FESSy staff notification. Regarding outcomes, the number of patients at the time of detection might be appropriate to evaluate timeliness. However, that measure does not include information about final outcomes, such as the outbreak size or whether mortality cases are included. In other words, the number of patients as of the time of detection can reflect timeliness or sensitivity, but might not reflect specificity for an aberration.

Evaluation of specificity not only for FESSy but also for syndromic surveillance in general was quite difficult because, unlike laboratory tests, no gold standard exists for surveillance. In the case of FESSy, specificity was defined as not detecting aberrations that would not develop into large outbreaks. Thus, to determine specificity for FESSy, one would have to know the proportion of aberrations found by FESSy that would not develop into a large outbreak if countermeasures were not taken. However, in the real world, FESSy immediately found aberrations, after which countermeasures at the facility or public health center were activated to reduce the probability of these aberrations developing into large outbreaks. Because FESSy was so effective, the high probability of an outbreak was removed. In other words, we could not observe a situation at a FESSy-affiliated facility in which FESSy detected no aberration. Moreover, at non-FESSy facilities, it was difficult to find aberrations that occurred with the same timing according to which FESSy usually detects an aberration. Public health centers sometimes recognize a situation at such facilities after an outbreak has already expanded. Because of these difficulties and paradoxical comparisons, we anticipate that evaluation of specificity will be a future challenge for the evaluation of FESSy.

On May 8, 2023, the government changed the criterion for reporting COVID-19 infections at facilities to a public health center: instead of reporting all cases, reporting was relaxed to the reporting of only clusters involving more than 10 cases. However, the modes for the number of patients detected by direct reports in this study were 2 and 1 at the two centers. This finding might indicate that the earlier criterion for reporting to a public health center (all cases) continued in facilities even after May 8, 2023, depending on spontaneous decisions at facilities, even though public health centers were never required to report all cases after May 8, 2023.

Before FESSy initiation in both areas, we were concerned about burdens imposed by data entry at the facilities. Nevertheless, no complaints have been made by facility staff members about data entry burdens. The data were entered regularly every day. To reduce the data entry burden at facilities joining FESSy, we developed a method for automatic data transfer from electronic care records at facilities [7], as suggested by the results of a study in Australia [6]. However, because the share of electronic care records including symptoms and diagnoses that could be transferred automatically as data was not very high, use of the method has been limited to a small number of facilities. We expect that other ideas to reduce the data entry burden will be necessary.

Moreover, information from FESSy has been shared with public health centers. That information has contributed to the detection of outbreaks of COVID-19 and other infectious diseases in a timely manner. Developing situations are followed up without additional effort. Infection control nurses in communities or at affiliated hospitals and public health nurses at public health centers in particular highly regarded its effectiveness at controlling outbreaks.

In Tsuchiura, the proportion of facilities joining FESSy remained at 51% (n=16 facilities), much lower than the corresponding proportion in Sumida City of 90% (n=9 facilities). However, the number of facilities joining FESSy was larger in Tsuchiura than in Sumida City. Therefore, this difference might reflect only the number of facilities covered by the public health center, irrespective of those participating in FESSy. We consider that there is no fundamental difference between them. Moreover, the program was introduced in Tsuchiura 3 months later than in Sumida City. Thus, we expect that the proportion of participating facilities in Tsuchiura will increase in the coming months. We will examine whether there are any difficulties associated with FESSy in Tsuchiura through surveys of facilities. If some particular difficulty is found, then a challenge for future research will be to solve it.

Study periods were insufficiently long: 8 months for Sumida City and 5 months for Tsuchiura. However, we found that FESSY had some degree of effectiveness. Earlier publication of this fact might have contributed to a more rapid spread of FESSy participation, even though we expect that ongoing verification of the robustness of our results will be necessary.

Finally, we used an AI system to detect aberrations. In FESSy, AI support for public health center staff awareness of situations can contribute to a reduced burden of monitoring the system. When the AI detects an aberration, the decision-making about

XSL•FO
RenderX

what actions to take as countermeasures and how to respond to the outbreak are made by public health center staff. Therefore, the AI itself can take no action after detecting an aberration other than sending email messages to an established list of recipients. Because the AI in our system only monitors data in FESSy, including the number of patients with certain symptoms and diagnoses, the AI never refers to the general internet outside of FESSy. Therefore, no ethical issues arose in relation to using AI in FESSy [9]. Moreover, the AI in FESSy has been learning about the criteria used for aberration detection by humans, public health center staff, facilities, and others to improve its own criteria. Therefore, the AI criteria will not deviate from the human criteria. If the number of participating facilities increases rapidly, then the AI criteria might converge to the human criteria in the near future.

Limitations

First, this study was an evaluation conducted at only 2 public health centers. The results might depend on the characteristics of the facilities or the public health centers. The findings' robustness must be verified through similar evaluations of FESSy conducted in other cities with other public health centers.

Second, the sample size of this study was too small for the AI to study and learn aberration patterns, especially those found by the FESSy staff. A longer period and a wider area can be expected to alleviate this limitation. In this sense, the results obtained from this study must be regarded as tentative, not final.

Third, data entry at participating FESSy facilities was based on free decisions made by the facility management. Therefore, facility participation in FESSy and data entry in FESSy might have been biased, reflecting especially strong concerns about infectious disease. That bias might have led to overestimation of FESSy's effectiveness. This is particularly the case in Tsuchiura because the proportion of facilities participating in FESSy was much smaller than in Sumida City, so the potential bias might be stronger. We cannot randomly assign participation in FESSy or data entry in FESSy, but an average treatment effect model might be able to resolve these issues. That is left as a challenge for a future study.

Conclusion

Our results show that FESSy was superior to direct reporting from facilities, which was the only method available in areas where FESSy had not been activated, not only for the number of patients as of the detection date but also the ultimate outbreak size. As a useful tool for public health centers, FESSy clearly improved the public health situations in both areas it was used.

Recently, special cities in Tokyo, including Sumida City, have been obligated to construct infection prevention plans based on a Japanese law, the Act on the Prevention of Infectious Diseases and Medical Care for Patients with Infectious Diseases. If FESSy were incorporated into the plan, it would support stable infection control measures before the emergence of outbreaks.

Acknowledgments

We acknowledge all staff and residents of the older-adult facilities in both areas. We received support from Project Research at the Ibaraki Prefectural University of Health Sciences in 2023 as part of a project titled "Construction of training course for infection control professional care givers" headed by NS, who is a professor at Ibaraki Prefectural University of Health Sciences.

Authors' Contributions

JK was responsible for the coordination of the study and developed FESSy. TS performed statistical analysis. MH, SY, Y Saito, AO, MS, AS, TH, AH, YK, YI, FI, and Y Sugishita jointly monitored FESSy and summarized activities at the public health centers. NS provided research funds and set the requirements for operating FESSy at the Sumida and Tsuchiura public health centers. All authors contributed to the writing of the final manuscript.

Abstract

Background: In Japan, research on the types of medical data requested by health care workers in health information exchanges (HIEs) is limited. Examining the number of views for each data type is important to quantify its benefits.

Objective: This study aimed to identify the types of medical data that are frequently viewed on demand using HIEs in Japan.

Methods: We analyzed audit log data from two HIEs, Choukai Net and PicaPicaLink, covering the period from April 1, 2017, to March 31, 2022. First, we calculated the cumulative monthly usage days of the HIEs by each institution for the financial year (FY) 2021/22. Second, we calculated the cumulative annual usage days of the HIEs by each user type for FY 2021/22. Third, we calculated the view rate for each output field and content within each HIE, using institution type or year as the aggregation unit. Fourth, we calculated the cumulative annual usage days of the HIEs for days with and without progress note viewing, and for days without any content viewing. Fifth, we calculated the cumulative number of viewed days for content scheduled to be included in the national HIE compared to that which was not.

Results: In 32.6% (47/144) of hospitals connected to Choukai Net and 2.3% (20/875) of hospitals connected to PicaPicaLink, cumulative monthly usage days exceeded 101. Additionally, in 32.4% (56/173) of visiting nursing stations connected to Choukai Net, cumulative monthly usage days were over 51. User types viewing HIEs were heavily biased toward institution types other than hospitals. The overall view rate for progress notes was highest among all content types, at 67.4% (83,476/123,915) for Choukai Net and 32.9% (26,159/79,612) for PicaPicaLink. In both HIEs, when comparing by institution type, the view rate for progress notes was highest for visiting nursing stations, reaching 91.8% (5553/6052) for Choukai Net and 65.3% (126/193) for PicaPicaLink. We also found that 17% (5417/31,944) of Choukai Net usage and 9.6% (1802/18,862) of PicaPicaLink usage involved referencing only progress notes in FY 2021/22. The view rate of content scheduled to be included in the national HIE was 45.6% (56,499/123,791) for Choukai Net and 47.7% (37,972/79,612) for PicaPicaLink. Conversely, the view rate for content not scheduled to be included in the national HIE was higher, at 80.2% (99,234/123,791) for Choukai Net and 56.6% (45,052/79,612) for PicaPicaLink.

Conclusions: In both HIEs analyzed in this study, progress notes were the most viewed content. As more health care organizations disclose the progress notes they manage to their HIEs, progress notes are likely to be viewed more frequently. The cost-benefit of disclosing progress notes to HIEs remains unclear, and both health care providers and patients have concerns about privacy risks. Future research is needed to quantify and maximize the benefits of disclosure while mitigating the associated privacy risks.

Introduction

Recently, health care delivery systems have undergone a profound global transformation catalyzed by advancements in information technology. Among the numerous innovations, the health information exchange (HIE) stands out as a remarkable tool for revolutionizing the health care sector by facilitating electronic data sharing among health care providers [1]. Currently, at least 200 HIEs are operating in Japan [2]. The most common feature of an HIE in Japan is on-demand viewing

XSL•FO
RenderX

or searching for medical data from other institutions [3,4], also known as a query-based exchange or query-based HIE [1,5,6]. In addition to already established regional HIEs, the Ministry of Health, Labour and Welfare (MHLW) is considering the establishment of a nationwide HIE. The MHLW intends to share 3 types of documents and 6 types of information (3D6I) [7] across this nationwide HIE, which is referred to as Clinical Information Sharing (CLINS) [8].

It is crucial to investigate the types of medical data required by health care workers using the HIE, as medical data, which are in high demand, may not always be disclosed to Japanese HIEs. In Japan, the types of medical data disclosed to HIEs vary among HIEs. For example, a 2023 questionnaire survey targeting 48 HIEs revealed that while prescription data and laboratory test data were disclosed in all HIEs, the disclosure rate of progress notes written by doctors was only 41% [9]. This variation in data disclosure is further complicated by the differences in the data types provided by each institution to the HIE. Sharing data incurs costs, making it crucial to assess the demand and value of each data type and share it selectively.

In Japan, research on the types of medical data in demand for HIEs is limited. The MHLW conducted at least 2 studies on the types of data that should be included in the CLINS [10,11]. However, both surveys were based on interviews or questionnaires with medical workers and did not incorporate data from regional HIEs. As noted above, not all data types are available in existing HIEs; however, analyzing the audit logs of HIEs to clarify the data types can provide valuable quantitative data.

To address these data type clarity limitations, this study aimed to determine the types of data frequently viewed on query-based exchanges in Japan by analyzing HIE audit logs. Considering our internal analysis of audit logs in a previous study [4], we suspected that there may be a large demand for progress notes written by doctors. Therefore, we analyzed audit logs of HIEs that share progress notes in this study.

Methods

HIE for Data Analysis

Selection of HIEs

We collected data on HIEs that met the following inclusion criteria: (1) they were included in the survey report "About the current situation of regional healthcare network" published by the MHLW, (2) the HIE was connected to more than 100 institutions and had more than 10,000 patients according to the report, and (3) progress notes from at least some of the connected institutions were shared in the HIE as of March 2022. The first two criteria were included in previous studies, while the third criterion was new to this study. We approached operators of HIEs that met these criteria to participate in the study and obtained consent from the operators of 2 HIEs, as described below.

Overview of Regions and HIEs

The first HIE, Choukai Net, operates in the Shonai medical area of Yamagata Prefecture [12]. The second HIE, PicaPicaLink, operates in Saga Prefecture [13].

These HIEs are operated by different regional health information organizations—the Shonai Medical Information Network Council and the Saga Prefecture Medical Information Regional Collaboration System Council, respectively. Both HIEs use the same commercial HIE, ID-Link [14], developed by SEC Co Ltd, with NEC Corporation as the service contact. ID-Link is a computer system that enables viewing patient data stored in other institutions using a query-based exchange. Institutions using ID-Link are categorized as either data disclosure institutions (DDIs), which disclose their patient data to the HIE, or data viewing institutions (DVIs), which only view the patient data. The DDIs can also view the patient data disclosed to the HIE. Table 1 presents the basic statistics for both HIEs and the regions in which they operate. Choukai Net collaborates with medical institutions from other HIEs; however, these institutions are not included in this analysis. The population in both regions is declining, with both regions experiencing a stronger trend of population decline than the national average and aging populations. In addition, the Shonai medical area, where Choukai Net operates, has a population density about one-third of the national average.

The type of disclosed patient data differed by DDI. Tables S1 and S2 in Multimedia Appendix 1 list the DDIs and the types of disclosed patient data. Additionally, there are restrictions on the types of jobs that use HIE. Choukai Net is available only to medical personnel and nursing care support specialists who are required by law or contracts (or labor contracts among DVI employees) to maintain confidentiality [15]. For employees who belong to DVIs other than nursing care institutions, occupations that can use PicaPicaLink are determined by the respective institution's manager. For DVI employees in nursing care institutions, the occupations that can use PicaPicaLink are limited to those with national qualifications that are legally required to maintain confidentiality [16].

Table . Basic information on regions and health information exchanges.

Characteristics	Choukai Net	PicaPicaLink
Estimated area population, n[a]	257,122	800,668
Population density of the area, people/km^2[b]	109.50	332.50
Proportion of population aged ≥65 years in the region[c], %	36.10	30.60
Regional population growth rate from 2015 to 2020[d], %	−5.76	−2.57
Number of participating patients, n[a]	55,131	559,650
Number of data viewing institutions, n [a]		
Hospital	12[e]	73
Medical clinic	78	154
Dental clinic	22	8
Pharmacy	25	125
Visiting nursing station	14	10
Nursing facilities	83	22
Number of data disclosure institutions, n[a]	7	15
Year in which the health information exchange started operation	2011	2010

[a]Aggregated values as of the end of March 2022.

[b]Census data from the Ministry of Internal Affairs and Communications in 2020. The national average is 338.2 people/km^2.

[c]Census data from the Ministry of Internal Affairs and Communications in 2020. The national average is 28.6%.

[d]Census data from the Ministry of Internal Affairs and Communications in 2015 and 2020. The national average is –0.75%.

[e]Yamagata University Hospital, Yamagata Prefectural Central Hospital, Yamagata Prefectural Shinjo Hospital, Okitama Public General Hospital, and Sanyudo Hospital are excluded from the tally.

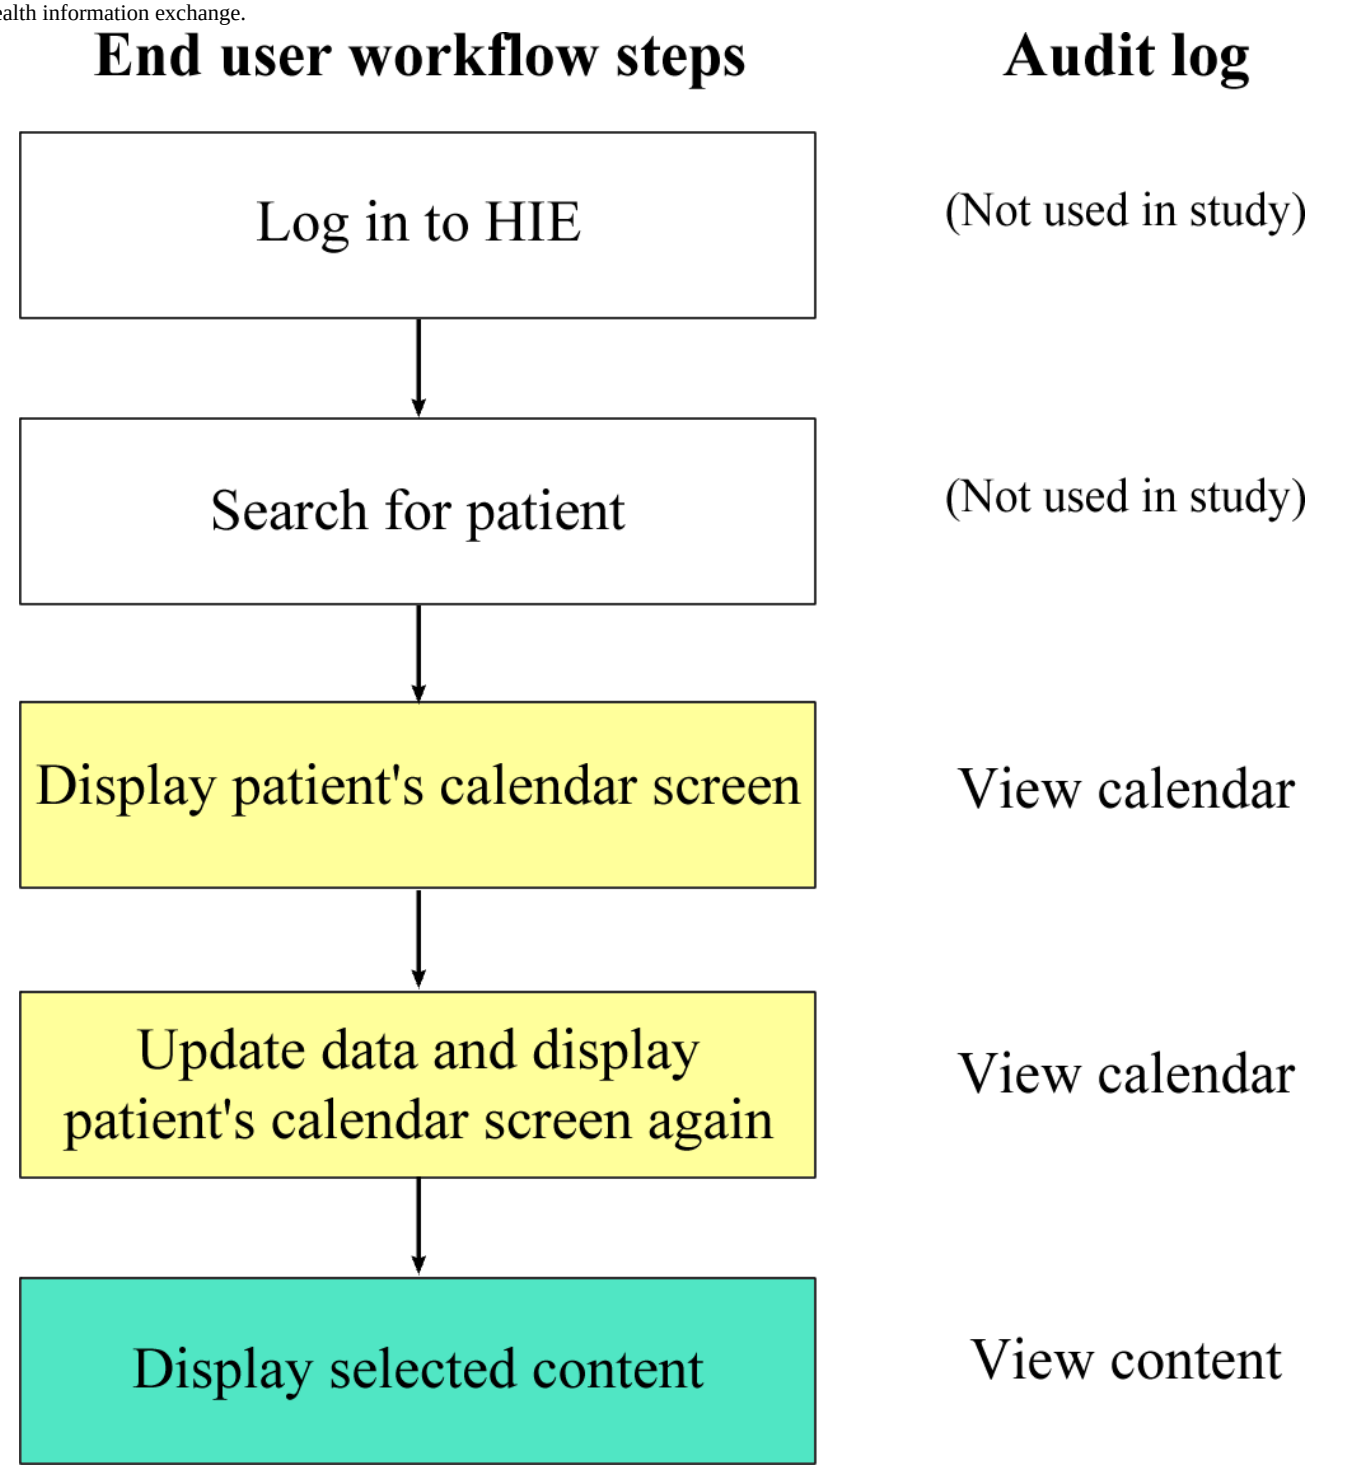
Patient Consent

Both HIEs require explicit patient consent before health care workers can use the HIE to view a patient's medical data [17,18]. If a DVI medical worker wants to use the HIE to refer to a certain patient's medical data stored in the DDI (eg, for treatment purposes), the medical worker must first explain the HIE to the patient. If the patient agrees to participate, they must complete a written consent form providing their demographic data, such as their name and date of birth. The DVI health care worker then adds the name of the DDI requesting disclosure of the patient's medical data and faxes the consent form. For Choukai Net, the consent form is sent to the HIE secretariat, and for PicaPicaLink, it is sent to the DDI requesting the disclosure. At the institution receiving the fax, an administrative worker releases the patient's medical data, as specified in the consent form, from the designated DDI to the fax sender's DVI. This process allows medical workers at the DVI to view the patient's medical data stored in the DDI using the HIE. Other DVIs cannot view the patient's medical data stored in the DDI. Once a patient consents to the disclosure of their medical data from the DDI to the DVI and the process is completed, the patient does not need to complete the consent form again for the same institution. When disclosing patient medical data from another DDI or to a new DVI, the patients must fill out an additional consent form.

However, there are some exceptions to the above operation. The first exception is when medical workers use the "emergency medical service" (EMS) [19]. The EMS is the default feature of ID-Link. Typically, DVI health care workers cannot view a patient's medical data unless the DDI actively discloses the patient's data. However, this feature allows DVI health care workers to view patient data without waiting for the DDI to take action. When DVI health care workers urgently need to view a patient's medical data stored in a DDI, they can do so by entering the patient's ID from the DDI into the HIE in a certain way. Medical workers can use the EMS in 2 main situations. The first situation is when emergency medical care is required, and the patient is unable to fill out a consent form. The second case is when medical data need to be accessed, but the DDI or HIE office is unable to perform operations for data disclosure.

The second exception is the "patient demographic data synchronization feature" (PDDSF) [20] and "name matching feature" (NMF) [21]. These features are available only in PicaPicaLink and are not available in Choukai Net. PDDSF allows for all basic patient data stored in DDIs to be uploaded to the ID-Link Data Center. These basic data include the name, date of birth, gender, address, telephone number, and insurance number of a patient. The NMF enumerates the IDs of the same patient in each DDI by comparing patient data collected using the PDDSF, thus enabling name matching. These features are used when DVI medical workers need to access a patient's medical data stored in a specific DDI using the EMS function but do not know the patient's ID in the DDI.

XSL•FO
RenderX



The third exception is an interagency data-sharing feature called "Sagan-Path Net" [22]. This feature is also available on PicaPicaLink and allows facilities to share summary data of stroke patients transferred from acute care hospitals to rehabilitation hospitals. To use this feature for a patient, the patient must also fill out a consent form, but they cannot specify the DVI details for each DDI. Instead, all DVIs with access to the patient's data through PicaPicaLink can view the shared summary data using Sagan-Path Net.

Flow of HIE Use

As explained in the previous section, both HIEs require explicit patient consent to view their data, except in emergencies by using the EMS functionality. A user logs in to the HIE with their ID and password. Subsequently, the user enters the name or registration ID of the patient whose information they want to view in the search field. Patients viewed within the past 14 days are displayed in a list, allowing the user to select from the list. When the desired patient appears in the list, the user clicks to select the patient option. The selected patient's medical information is then displayed in chronological order by item, known as the patient's calendar screen. When the user first opens the patient's calendar screen, the data remain unchanged from the last time they viewed the patient's page. Therefore, it is necessary to press the data-update button to obtain the most recent patient data. Once the data are updated, users can review the patient's calendar screen and select the contents displayed. This series of steps is illustrated in Figure 1.

XSL•FO
RenderX

Figure 1. Workflow when end users use ID-Link. We analyzed the usage data of users who had at least accessed the patient's calendar screen. HIE: health information exchange.

Ethical Considerations

This study was approved by the ethics committee of Kyoto University Graduate School and Faculty of Medicine (accession number R3266-7). The disclosure document outlining the research plan and data to be extracted were published on the Kyoto University Hospital website [23], ensuring that research subjects had the opportunity to opt out. Personal data obtained in the study were pseudonymized by the HIEs that provided the data. Research subjects did not receive compensation.

Data Collection

We collected profile and audit log data from health care workers enrolled in the 2 HIEs. The type of data collected was consistent with that from our previous study [4]. The data that were collected are presented in Textbox 1.

The data extraction period was from April 1, 2017, to March 31, 2022. We also obtained data on the number of participating institutions and patients per month for each HIE. The IDs of the patients accessed by medical workers were not extracted in this study.

XSL•FO

Textbox 1. Health information exchange user data collected in this study.

- Occupation Institution
- Anonymous identifier
- Date of account registration and account deletion in health information exchange
- Date and time of access to health information exchange
- Type of data accessed by the user
- Access details: calendar access or content access? If content access, what content?

Measures and Data Analyses

Overview

For each user, we counted records of "View calendar" or "View content" in the audit log, as shown in Figure 1, as a measure of HIE use. The aggregation unit used was days. When counting the number of views for a specific type of output field or content, we extracted only the relevant audit logs and counted them in the same way. As a unit for counting HIE use by group, 1 man-day was defined as HIE use on 1 day with 1 user account. The cumulative number of accesses to an institution was calculated as the total number of days of HIE use by each user associated with that institution.

We classified the institutions enrolled in HIE into 6 categories: hospitals, medical clinics, dental clinics, pharmacies, visiting nursing stations, and nursing facilities. Institutions that could not be classified into any of these categories were excluded from the analysis. For example, this study did not analyze public institutions, such as fire departments, public health centers, local medical associations, or HIE development vendors.

The financial year (FY) ran from April 1 of one year to March 31 of the following year. For example, FY 2021/22 started on April 1, 2021, and ended on March 31, 2022. R software (version 4.3.1; R Foundation for Statistical Computing) was used for the analysis.

Man-Days for Monthly HIE Use by Each Institution in FY 2021/22

We calculated the man-days for monthly HIE use by each institution and aggregated them by institution type. For each institution enrolled in both HIEs, the man-days for monthly HIE use in FY 2021/22 were aggregated. Subsequently, for each institution type, we tallied the number of months for each man-day group, which was divided into 5- or 10-day increments. Finally, the percentage of each man-day group was calculated for each institution type. This analytical method is consistent with that used in our previous study [4].

Man-Days for Annual HIE Use by User Type and Institution Type in FY 2021/22

We classified all user occupation data into 8 user types: "doctor," "nurse," "rehabilitation staff," "pharmacist," "dental profession," "nursing care staff," "other medical professions," and "type unknown." For each institution category, we aggregated the total number of man-days of HIE use by user type in FY 2021/22.

Man-Days and View Rate for Each Output Field and Content

For each HIE, we calculated the man-days and view rate for each output field and content. The aggregation units were FY and institution type. In the analysis using FY as the aggregation unit, all log data from the 5-year period were analyzed. In the analysis using institution type as the aggregation unit, only audit log data for FY 2021/22 were analyzed. The viewed output fields and content were listed for each man-day of HIE use. We then tallied the total number of man-days for HIE use, the number of man-days for views of each output field, and the content in each aggregation unit. Finally, we calculated the view rate for each output field and content in each aggregation unit. The view rates of the output field and content are defined as follows:

(Number of man-days viewing the output field and content in each aggregation unit / Total number of man-days of HIE use in each aggregation unit) × 100

In the analysis using FY as the aggregation unit, we presented the top 5 content views by man-days over the total data analysis period in bar graphs. In the analysis using institution type as the aggregation unit, we listed the man-days and view rates for each output field and content.

As a supplementary analysis, we divided all man-days into 2 categories: those that included audit logs of viewing any content and those that only included audit logs of viewing the patient's calendar screen (Figure 1). Man-days that included audit logs of viewing any content were further categorized as follows: man-days where (1) the only viewed content was progress notes, (2) the viewed content included both progress notes and other content, and (3) the viewed content did not include progress notes. This analysis was conducted to evaluate the impact of the disclosure of progress notes on usage man-days.

Man-Days of Views of Content That Corresponds to 3D6I and Content That Does Not Correspond to 3D6I

For each HIE and FY, we calculated the number of man-days spent viewing content that corresponded to 3D6I as well as content that did not correspond to 3D6I. The 3 types of documents in 3D6I were patient referral documents, discharge summaries, and health examination documents. The 6 data types in 3D6I are as follows: the name of the illness or injury; infectious disease; drug contraindications; allergies; laboratory test results and prescriptions written in the patient referral document; and discharge summary.

First, the total number of man-days for each HIE used in each FY was tallied. Subsequently, we sorted all content into categories corresponding to 3D6I and those that did not. The

XSL•FO
RenderX

results for each content type are listed in Table S3 in Multimedia Appendix 2. We then tallied the number of man-days during which any content corresponding to 3D6I was viewed for each FY or HIE. We also tallied the number of man-days spent viewing content that did not correspond to 3D6I for both FY and HIE. Finally, we calculated the percentage of man-days in which any content corresponding to 3D6I was viewed, as well as the percentage of man-days in which any content not corresponding to 3D6I was viewed.

Results

Man-Days for Monthly HIE Use by Each Institution in FY 2021/22

Table 2 presents man-days of monthly HIE use in hospitals. For hospitals, the percentage of man-days with monthly HIE use of 0 was 9% in this study, which is less than one-fifth of that of our previous study [4]. Similarly, the percentage of man-days with monthly HIE use of 101 or more was 32.6%, which is more than 10 times that in our previous study. PicaPicaLink usage closely aligned with that reported in our previous study.

Table 3 presents man-days of monthly HIE use in other institution types. Choukai Net was actively used in some visiting nursing stations. The percentage of man-days with monthly HIE use of 26 or more was 42.2%, which is approximately 6 times that of our previous study [4]. Such high frequency of usage by visiting nursing stations was not observed on PicaPicaLink. Overall, HIE use by dental clinics was low, consistent with our previous findings [4].

Table . Distribution of man-days for monthly health information exchange, use of hospitals in financial year 2021/22.

Man-days for monthly health information exchange, use per institution, n	Choukai Net, n (%)	PicaPicaLink, n (%)

Man-Days for Annual HIE Use by User Type and Institution Type in FY 2021/22

Table 4 presents man-days of annual HIE use by user type and institution type in both HIEs in FY 2021/22. In both HIEs, there are significant differences in the proportion of user types depending on the institution type. For hospitals, no single occupation accounts for half of the man-days. On the other hand, doctors at medical clinics, dentists at dental clinics, pharmacists at pharmacies, nurses at visiting nursing stations, and nursing care staff at nursing homes each account for more than half of the total man-days for their respective institution type. These distributions reflect the characteristics of each institution type.

XSL•FO

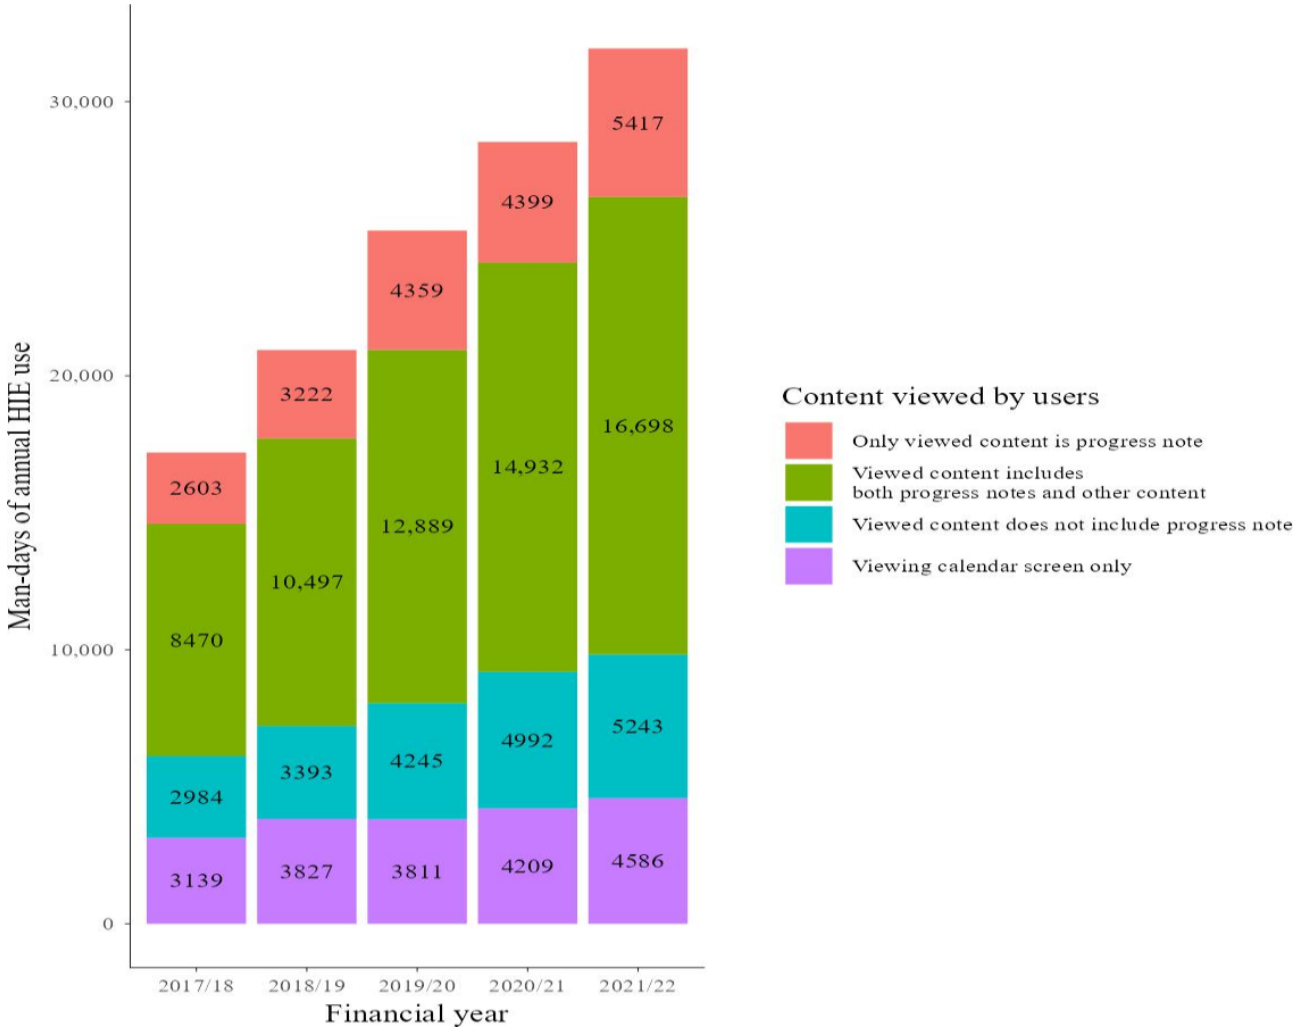
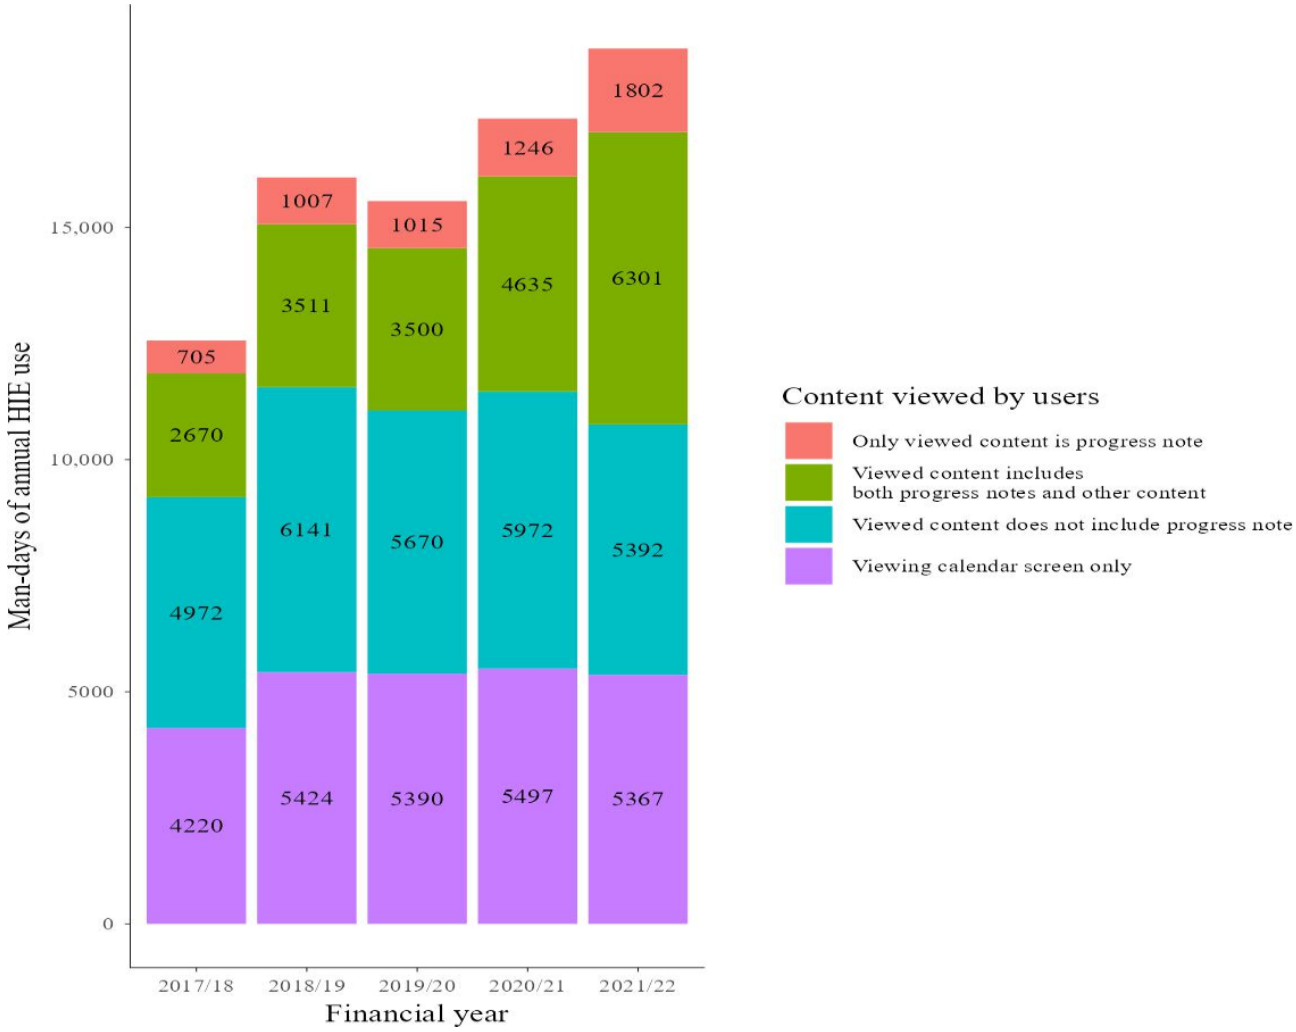
Man-Days and View Rate for Each Output Field and Content



Man-Days for Content View

In both HIEs analyzed, the most viewed data were progress notes. On Choukai Net, the overall number of man-days for progress notes was 83,476 and the overall view rate for progress notes was 67.4% (83,476/123,915). This was nearly 3 times higher than the overall man-days for patient summary, which was the second most viewed content. On PicaPicaLink, the number of overall man-days for progress notes was 26,159, and the overall view rate for progress notes was 32.9% (26,159/79,612).

We present the top 5 content views by man-days over the total data analysis period in Figures 2 and 3. Figure 2 presents the man-days on Choukai Net, and Figure 3 presents the man-days for PicaPicaLink. Man-days and the view rates including other types of content views, not just the top 5, are listed in Tables S4 and S5 in Multimedia Appendix 3. These supplementary tables include content with a total view rate of 1% or more.



XSL•FO
RenderX

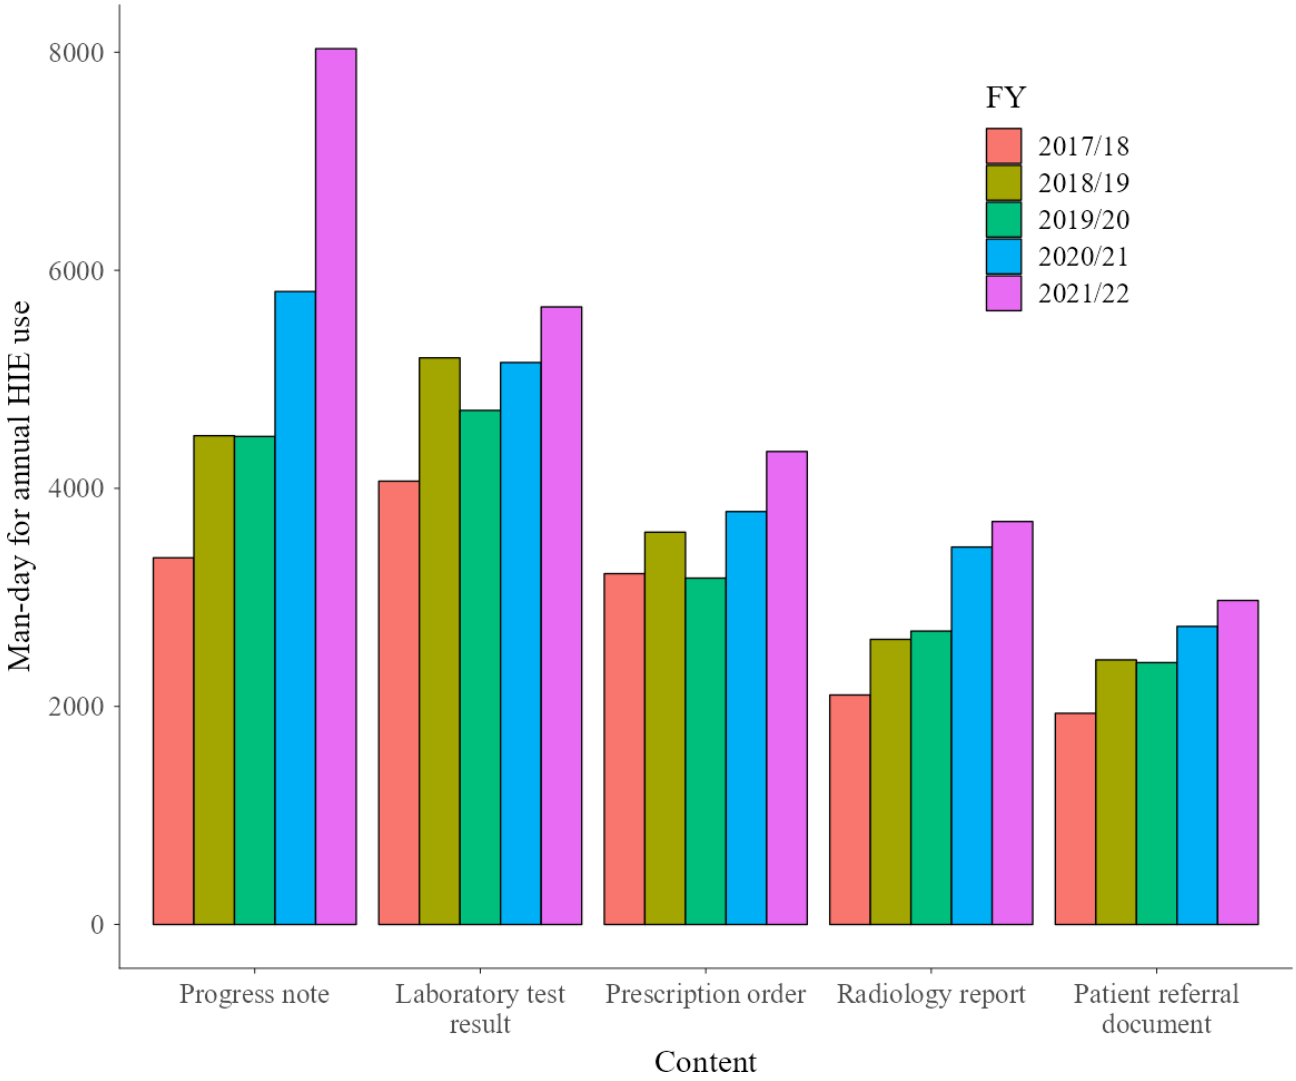
Progress notes are the most frequently viewed content at every institution type on both HIEs. When comparing the view rate of progress notes by institution type, visiting nursing stations had the highest rates, with 91.8% for Choukai Net and 65.3% for PicaPicaLink. On the other hand, the view rate of the Digital Imaging and Communications in Medicine (DICOM) image list was relatively low for most institution types. In both HIEs, the view rate of the DICOM image list was less than 5% in pharmacies, visiting nursing stations, and nursing facilities. The view rate for radiology reports was higher than for DICOM image lists in all these institution types. Even in medical clinics, the view rate for DICOM image lists was lower than the view ratio for radiology reports, indicating that many medical workers view the radiology reports written by radiologists rather than viewing the DICOM images. Hospitals were the only institution category where the view rate for DICOM image lists was higher than for radiology reports.

Man-Days of Viewing Content Out of the Total Man-Days of Viewing the Calendar and the Breakdown of Progress Note Views

The following presents the results of an analysis of content views and calendar views, and the percentage of progress note views among content views. The aggregated results are shown as bar graphs, with Choukai Net illustrated in Figure 4 and PicaPicaLink in Figure 5. On Choukai Net, the number of man-days in which progress notes were the only content viewed accounted for 17% (5417/31,944) of the total in FY 2021/22, a rate not significantly different from 15.1% (2603/17,196) in FY 2017/18. This may be because the medical institutions that disclose progress notes have remained unchanged from FY 2017/18 to FY 2021/22 (Table S1 in Multimedia Appendix 1).



In contrast, on PicaPicaLink, the disclosure of progress notes was implemented in stages over 5 years (Table S2 in Multimedia Appendix 1). At the beginning of FY 2017/18, only 2 of the 13 DDIs were disclosing progress notes. Over the 5 years analyzed, the DDIs of PicaPicaLink proceeded to disclose progress notes, and by March 2022, 8 of 15 DDIs had done so. Therefore, the proportion of viewing only progress notes on PicaPicaLink also increased from 5.6% (705/12,567) in FY 2017/18 to 9.6% (1802/18,862) in FY 2021/22.

Man-Days of Views of Content Corresponding to 3D6I and Non-3D6I Content

In Table 7, we present the man-days of total views, views of content corresponding to 3D6I, and views of content not corresponding to 3D6I by FY. The view rate of content corresponding to 3D6I was below 50%. On the other hand, the view rate of content not included in the 3D6I consistently exceeded 50%.

Discussion

Principal Findings

As mentioned in the Results section, the use of Choukai Net in hospitals and visiting nursing stations is more active than in previous studies (Tables 2 and 3). These findings suggest that the frequency of HIE use in Japan is not necessarily low and that certain factors may contribute to increased usage. To clarify these reasons, a survey of individual facilities using HIEs is needed rather than a survey of overall HIE usage. Although it is difficult to attribute the cause of active use to general statistical indicators of the region, low population density may have increased the need for medical coordination between institutions (Table 1). On the other hand, the population density of Saga Prefecture, where PicaPicaLink is operated, is roughly the same as the national average.

In both HIEs analyzed, the most viewed data were progress notes (Figures 2 and 3). In FY 2021/22, 17% of Choukai Net usage and 9.6% of PicaPicaLink usage involved referencing only progress notes (Figures 4 and 5). The overall view rate for progress notes was 67.4% for Choukai Net and 32.9% for PicaPicaLink. One reason for the more than 2-fold difference in view rate between the 2 HIEs is that each DDI has different progress note disclosure policies. On Choukai Net, 5 of the 7 DDIs had been disclosing progress notes since April 2017, and none changed their disclosure policies until March 2022 (Table S1 in Multimedia Appendix 1). In contrast, only 2 of the 13 DDIs of PicaPicaLink had disclosed progress notes as of April 2017 (Table S2 in Multimedia Appendix 1). As a result, the view rate of progress notes in FY 2017/18 was only 27%. However, in FY 2021/22, when 8 of 15 DDIs were disclosing progress notes, the view rate increased to 43%. The differences between the 2 HIEs and increase in progress note viewing rate on PicaPicaLink suggest that DDI data disclosure policies influence health care workers' data viewing behavior in HIEs. Previous studies have not necessarily examined the specific types of data disclosed by each DDI in HIEs, but this aspect is crucial for understanding HIE usage.

The results of these analyses do not necessarily align with those of previous studies. Laboratory results, medication data, and radiology data have been reported as the most frequently accessed types of data in HIEs [24-26]. This difference is partly because the number of views for progress notes was not aggregated in previous research. A recent study conducted in 2024 on Mame-Net, one of Japan's HIEs, found that medical records were the most frequently viewed, which is consistent with the findings of this study [27].

When comparing the view rate of progress notes by institution type, visiting nursing stations had the highest rates, with 91.8% for Choukai Net and 65.3% for PicaPicaLink (Tables 4 and 5). The distribution of occupations using HIEs is strongly influenced by institution type, and most users of HIE at visiting nursing stations are nurses (Table 4). It is understandable that the progress notes written by doctors are important for nurses who work based on doctors' instructions [28]. A similar trend has been observed in pharmacies, where pharmacies dispense medicines based on a doctor's prescription and therefore must check the doctor's notes to validate the prescription. However, the viewing rate of patient summaries, which are also written by physicians, is low across all institution types. Patient summaries or patient referral documents do not necessarily include detailed medical histories. Additionally, information is generally updated more frequently in progress notes. These factors may explain why progress notes are viewed more frequently. Further research, including qualitative studies, is needed to explore the benefits of disclosing progress notes and how they can be used in DVI.

XSL•FO
RenderX

Despite relatively high demand compared to other types of data, progress note disclosure is uncommon in Japanese HIEs. A survey conducted on HIEs in 2023 found that the disclosure rate of progress notes written by doctors was only 38.6% (81/210) [29]. The most common reason for not disclosing progress notes, cited by 48.6% (35/72) of HIEs, was the "lack of consent from DDIs to share progress notes." The fourth most common reason, cited by 15.3% (11/72) of HIEs, was that "it may limit doctors' entries in progress notes." These results suggest that concerns about violating patient and doctor privacy, owing to the sensitive information contained in progress notes, prevent their disclosure. On the other hand, the second most common reason, cited by 41.7% (30/72) of HIEs, was that "the system did not have a progress note sharing function". The third most common reason, given by 16.7% (12/72) of HIEs, was that "management organizations consider it unnecessary to disclose progress notes." These results indicate that the system would need modification to enable progress note sharing and this is not currently considered worth the cost in these HIEs. Past surveys have shown that the benefits of disclosing progress notes and reports include the ability to quickly share detailed medical information and improvements in the quality of progress notes [29]. However, these descriptions remain abstract, and the benefits are not quantified. Further research is needed to quantify the benefits of disclosure and evaluate whether they justify the additional costs and privacy risks. Moreover, efforts must be made to maximize the benefits relative to the costs of disclosure while minimizing privacy concerns.

The results of this study raise questions about the effectiveness of CLINS. Progress notes and radiology reports are not included in the 3D6I that CLINS plans to share. The discharge summary, a physician's record written in natural language, is included in 3D6I, but its view rate was less than 10% in this analysis. In the HIEs analyzed in this study, the view rate of 3D6I was less than 50%, which is lower than the view rate of data not included in 3D6I (Table 7). However, except for patient referral documents and discharge summaries, data shared via CLINS can be accessed by both patients and medical professionals. In contrast, most regional HIEs in Japan, including the 2 HIEs studied here, do not allow patients to view shared data using the HIE. Past surveys have shown that only 6.3% (14/224) of HIEs in Japan offer personal health record functionality [29]. Future evaluations of CLINS and regional HIEs should assess not only the types of data shared but also whether or not it is shared with patients.

It is necessary to consider whether the usefulness of the HIE analyzed in this study is worth the cost. There was no publicly available data on the costs of PicaPicaLink, making it difficult to estimate the cost-benefits. Regarding Choukai Net, some basic operational figures were presented at an academic conference in 2018 [30]. Excluding implementation cost, the annual maintenance costs are 3.89 million yen (US $27,020) for total data center usage, and 1.03 million yen (US $7020) for the HIE Management Council. The cost of replacing the systems at the 3 hospitals is 12.1 million yen (US $83,180). Assuming that the average system replacement cost for 1 facility is one-third of this amount, the cost of replacing the systems at all 7 DDI facilities can be roughly estimated to be 28.2 million yen (US $193,850). Assuming that system replacement occurs once every 5 years, the annual reserve required for system replacement of all DDIs of Choukai Net is 5.64 million yen (US $38,760). Therefore, the annual cost of data center usage fees, council operating fees, and annual reverse funds for system replacement of DDIs is about 10.6 million yen (US $72,850) per year. If we divide these annual costs by the number of man-days of Choukai Net usage in FY 2021/22, 31,918 person-days, we get an approximate cost of 331 yen (US $2.28) per 1 man-day of HIE use. Further research is needed to determine whether the health care workers' benefits per man-day of use are commensurate with these costs. On the other hand, from the perspective of benefits to patients, a randomized controlled trial on the benefits of HIEs to patients has been conducted in Japan [31]. However, the results were not necessarily clear, and analysis of HIE use or viewed data was not included. Further research is also needed to assess the benefits of HIEs for patients, including the associated costs and actual utilization.

As detailed in the "Patient consent" section under "Methods," patients must fill out a paper consent form each time to increase the number of sources or recipients of the patient medical information shared. This method takes privacy into consideration as patients have some control over whether or not their medical data are disclosed to specific medical institutions. This consent method is common in Japanese HIEs. Previous studies have shown that 87.8% (195/222) of HIEs in Japan require patients to complete a consent form when they first join the HIE. In addition, 58.5% (103/176) of HIEs require patients to complete additional consent forms when transferring patient medical information between new facilities [3]. However, the MHLW has notified that patient completion of a consent form is not necessarily required for them to participate in an HIE [32]. In addition, previous studies and reports have pointed out that opt-in consent policies not only impose an administrative burden on hospital medical staff, but also have the potential to lower consent rates and hinder the use of HIEs [33-35]. A future challenge for regional HIEs in Japan is how to reduce the effort of medical workers to obtain the consent required to use HIEs while respecting patient privacy. Recent research suggests that a hybrid combination of opt-in and opt-out policies can balance privacy considerations with the quality of consent [35]. As another approach, previous systematic reviews have noted that patients' perceptions of the benefits of HIEs may alleviate privacy concerns [36]. Another study also suggested that when patients are aware of an HIE's privacy policy and sharing procedures, and have trust in the HIE, they may be more likely to disclose their health information [37]. As we continue to study the benefits of HIEs and share these findings, it is possible that patients become less wary of HIEs and require simpler consent.

Limitations

This study had some limitations. The most significant limitation was that we analyzed data from only 2 HIEs. For example, the view rate of each item in HIEs that do not publish progress notes may differ significantly from the results of this study. As we have not been able to obtain audit log data, the detailed usage status of Sagan-Pass Net is unknown. In addition, because this

XSL•FO
RenderX

study was a quantitative analysis of audit logs, no questionnaires or interview surveys were conducted to directly ask medical workers about the factors influencing differences in utilization and content-viewing rates. A combination of audit log analysis and qualitative research will be necessary to identify in what situations medical data are being accessed during daily work and for what purposes.

Conclusions

In both HIEs analyzed in this study, progress notes were the most viewed content. As more health care organizations disclose the progress notes they manage to HIEs, their view rates are likely to increase. The cost-benefit of disclosing progress notes to HIEs remains unclear, and both health care providers and patients are concerned about privacy risks. Future research is needed to quantify and maximize the benefits of disclosure while minimizing privacy risks.

Acknowledgments

This work was supported by JST, CREST, and grant number JPMJCR21M1 from Japan. We would like to thank Tetsuya Otsubo, Naoki Ishizuka, Taichi Hatta, and Hiroshi Yamazaki for their helpful discussions. We also thank Editage for the English language editing.

Abstract

Background: Health data typically include patient-generated data and clinical medical data. Different types of data contribute to disease prevention, precision medicine, and the overall improvement of health care. With the introduction of regulations such as the Health Insurance Portability and Accountability Act (HIPAA), individuals play a key role in the sharing and application of personal health data.

Objective: This study aims to explore the impact of different types of health data on users' willingness to share. Additionally, it analyzes the effect of data control and delay discounting rate on this process.

Methods: The results of a web-based survey were analyzed to examine individuals' perceptions of sharing different types of health data and how data control and delay discounting rates influenced their decisions. We recruited participants for our study through the web-based platform "Wenjuanxing." After screening, we obtained 257 valid responses. Regression analysis was used to investigate the impact of data control, delayed discounting, and mental accounting on the public's willingness to share different types of health care data.

Results: Our findings indicate that the type of health data does not significantly affect the perceived benefits of data sharing. Instead, it negatively influences willingness to share by indirectly affecting data acquisition costs and perceived risks. Our results also show that data control reduces the perceived risks associated with sharing, while higher delay discounting rates lead to an overestimation of data acquisition costs and perceived risks.

Conclusions: Individuals' willingness to share data is primarily influenced by costs. To promote the acquisition and development of personal health data, stakeholders should strengthen individuals' control over their data or provide direct short-term incentives.

Introduction

Background

Health data encompass information related to medical diagnosis, treatment, prevention, and health risks [1,2]. This includes patient-generated data (PGD) and clinical medical data. PGD refer to health-related data created, recorded, or collected by patients [3,4] often through automatic tracking devices like smartphones and wearables as well as manual logs and surveys. Conversely, clinical medical data are derived from clinical research, medical diagnostic records, and health insurance company records. Using public health data can significantly reduce operational costs for health care providers and enhance the quality of services provided [5,6]. Sharing health data allows physicians to gain detailed insights into patients' conditions, facilitating the development of personalized treatment plans and enabling the exploration of new treatments for diseases such as cancer [7]. For the public, health data sharing and interaction offer substantial benefits, including the reduction of unnecessary hospitalizations, the avoidance of duplicate medical tests, and the prevention of adverse drug events [8,9]. Furthermore, the application of public health data aids policy makers in formulating equitable health care policies and improving public health management at a societal level [1,10]. The National Institutes of Health recently announced the "All of Us" initiative, aiming to collect data from 1 million or more patients, including electronic health records, medical imaging, sociobehavioral data, and environmental data.

XSL•FO
RenderX

Despite the potential advantages of data use, public willingness to share health data is shifting [11]. Sharing health data involves intertemporal decision-making, where individuals must balance benefits and costs over time [12,13]. The costs may include psychological, financial, or other nonfinancial costs, while the benefits relate to potential future advantages such as reduced disease incidence and improved personal health management. The public's delay discounting rate significantly impacts these intertemporal decisions. Individuals with a high delay discounting rate prefer immediate rewards, whereas those with a low rate prioritize long-term benefits [14,15]. Unlike other health behaviors, sharing health data involves both health benefits and the risk of privacy breaches. Different types of health data carry varying levels of benefits and risks. Clinical medical data, for example, present higher privacy concerns and greater application value compared to PGD. Health data contain vast amounts of sensitive personal information, and any breach can lead to significant social and economic losses for individuals, thus decreasing their willingness to share such data [16,17]. Additionally, social stigmatization is a significant barrier to sharing sensitive health data with numerous health care organizations [18-20]. For instance, a data breach in a health information exchange (HIE) could reveal genetic diseases, causing distress for affected families.

Simultaneously, the unique nature of health data has made the issue of related rights a significant topic of discussion within the health care industry and academia. A key factor contributing to the public's reluctance to share health data is their lack of control over it [19,21]. The public cannot ascertain how other organizations or individuals will use their health data once it is acquired nor can they know whether their data will be transmitted to third parties [20]. Many people fear that their personal medical information could be used for marketing purposes without their authorization, posing a significant privacy risk [20]. Reports indicate that many American adults are highly anxious about how their health information is accessed and used [22]. Currently, it is widely accepted that other institutions or individuals must obtain the data owner's consent before acquiring and using health data in accordance with relevant laws. For instance, the health care industry has established policies and regulations such as the Health Insurance Portability and Accountability Act (HIPAA) and the General Data Protection Regulation. Therefore, understanding public willingness to share health data is crucial for the future development of public health initiatives. Our study, based on the theory of mental accounting, explores how different types of health data impact the public's willingness to share their data through perceived benefits and costs. Additionally, it analyzes the mechanisms by which the public's delay discounting rate and health data control influence their willingness to share health data.

Related Work

With the increasing prevalence of patient-centered design (PCD), the role and authority of the public in the sharing and interaction of health data have garnered significant attention. Existing research has analyzed the factors influencing health data sharing from various perspectives. For example, van Panhuis et al [23] conducted a systematic review of potential barriers to public health data sharing, identifying 20 potential barriers and categorizing them into 6 types: technical, motivational, economic, political, legal, and ethical. Sun et al [24], from the perspective of satisfaction, analyzed the factors influencing users of web-based health communities in disclosing their health information. Demographic characteristics such as participant age, region of residence, country or region of residence, and education level have a certain impact on the willingness to share personal health data [11]. Additionally, the public's ability to access, understand, and use health data directly influences their willingness to share health data [7].

Moreover, the privacy of health data is a crucial concern for patients, and preferences vary depending on the type of health data and the characteristics of the patients involved [21,25]. Watson et al [19], through semistructured interviews with patients, identified data type as a significant factor influencing patients' willingness to share personal health data. Patients' preferences for sharing PGD vary: some consistently share their data to keep their clinicians informed [3], while others refuse to share due to privacy concerns or fear of judgment [18,26]. Some public limit sharing their PGD to only trusted clinicians [27]. Moreover, research indicates that the public tends to avoid sharing sensitive health data [28]. Kim et al [29] collected participants' exercise and sleep data through experiments and used questionnaires to analyze their views on sharing daily health data. Kirkham et al [18] used ordinal logistic regression to study the impact of demographic factors, clinical service experience, and primary mental illness on the willingness to share mental health data, comparing it with physical health data. Seltzer et al [30] analyzed patients' willingness to share different types of data. The results showed that 50% of patients agreed to share at least 1 type of digital data, and 78% agreed to donate at least 1 type of data posthumously, with the highest percentages for electronic medical record, wearable device data, and Google search histories. Kim et al [31] and Mello et al [32], respectively, analyzed the types of institutions to which participants are more inclined to share their medical records and biospecimens. However, there is limited research that focuses on the impact of both PGD and clinical medical data on the public's willingness to share data as well as the underlying mechanisms of these effects.

Existing research increasingly emphasizes the rights of patients regarding their health data. Scholars have studied patients' control over health data from ethical [33], legal [34,35], managerial [36], and other perspectives. Currently, the entire process of HIE is managed by health care institutions for the interaction. In this process, patients, as the owners and beneficiaries of health information, often have their rights overlooked [37]. According to Hunter [38], as the quantity and scope of collected personal health data increase, the greatest demand is for transparency in their use. Kish and Topol [39] point out that to fully realize the benefits of digital health care, we need not only to find a shared home for personal health data but also to empower individuals to own them. PCD increases patients' willingness to share health data with others [40]. Esmaeilzadeh [41], drawing on utility theory, explores the factors influencing patients' adoption of HIE from the perspectives of perceived value and perceived risk. The public

XSL•FO
RenderX

expects to know the purpose of sharing their health data and desires control over data circulation [28]. Karway et al [42] found in their research that patients prefer to share their health data when they can control it themselves. The majority (87%) also reported feeling more comfortable sharing their data when they know its purpose. Sanderson et al [43] examined the public's willingness to share their biological data under different consent scenarios. In contrast, our study focuses on the public's evaluation of the current situation and examines the interaction effect between delay discounting and data control.

While existing research has extensively studied the factors influencing the public's willingness to share health data, much of it has been conducted through structured interviews, literature analysis, and similar methods. The mechanisms through which types of health data and the public's control over data affect their willingness to share remain unclear. Additionally, as intertemporal decisions, the public's preference for delay discounting rate directly impacts their data-sharing behavior, but there has been no research analyzing its underlying mechanisms. Therefore, our study poses the following research questions: How do different types of health data affect the public's willingness to share through benefits and costs? What is the role of the public's control over their health data and delay discounting rate in health data sharing?

Research Model and Hypotheses

The benefits and costs inherent in different types of health data vary. Our study categorizes health data into PGD and clinical medical data. Compared to clinical medical data, PGD entail lower sensitivity and fewer legal compliance requirements. Clinical medical data, comprising medical diagnostic records, clinical research data, and health insurance company records, are highly sensitive and private, necessitating strict adherence to regulations such as HIPAA. Consequently, patients are more inclined to share PGD rather than clinical medical data due to the relatively less sensitive nature of PGD information. In contrast, clinical medical data involve highly sensitive personal health information, raising concerns about privacy breaches and data misuse. Furthermore, PGD acquisition costs are lower, as it is obtained through various wearable smart devices and the internet. However, the self-reporting nature and lower accuracy of PGD may diminish its value in medical research and clinical applications. In contrast, clinical medical data possess high precision and professional recording, making it directly applicable to medical research, clinical trials, and precision medicine, thus yielding higher sharing benefits. However, acquiring clinical medical data requires involvement from medical institutions or insurance companies, necessitating strict permission management and incurring potential costs and time expenses. Hence, we hypothesize the following:

- Hypothesis 1: The public exhibits a higher willingness to share PGD compared to clinical medical data.
- Hypothesis 2: The relationship between the type of health data and willingness to share data is mediated by perceived benefits (hypothesis 2a), perceived risks (hypothesis 2b), and data acquisition costs (hypothesis 2c).

The concept of mental accounting, introduced by Thaler [44], is a key area in behavioral decision-making. Tversky and Kahneman [45] further defined it as the cognitive processes of categorizing, encoding, evaluating, and budgeting outcomes. It essentially involves assessing gains and losses during decision-making [46]. Since its introduction, mental accounting theory has found extensive applications in behavioral economics, consumer behavior, and decision-making [47-49]. Additionally, Hossain [50] explored how individual cognition influences mental accounting and its application to different product types.

Moreover, mental accounting influences individuals' engagement in health data-sharing behavior. In the context of health data sharing, individuals tend to view the potential benefits of sharing as part of the "benefit account." The greater the perceived benefits, the more likely they are to share health data. Meanwhile, the potential risks of privacy leakage are classified under the "loss account." The stronger the perception of risk, the lower the individual's willingness to share data. Furthermore, the theory of mental accounting also highlights the impact of sunk costs—time and effort already invested are seen as irrecoverable losses, which, in turn, reduce the individual's willingness to continue sharing data. Hence, we propose the following hypotheses:

- Hypothesis 3: Perceived benefits positively affect the willingness to share health data.
- Hypothesis 4: Perceived risks negatively affect the willingness to share health data.
- Hypothesis 5: Data acquisition costs negatively affect the willingness to share health data.

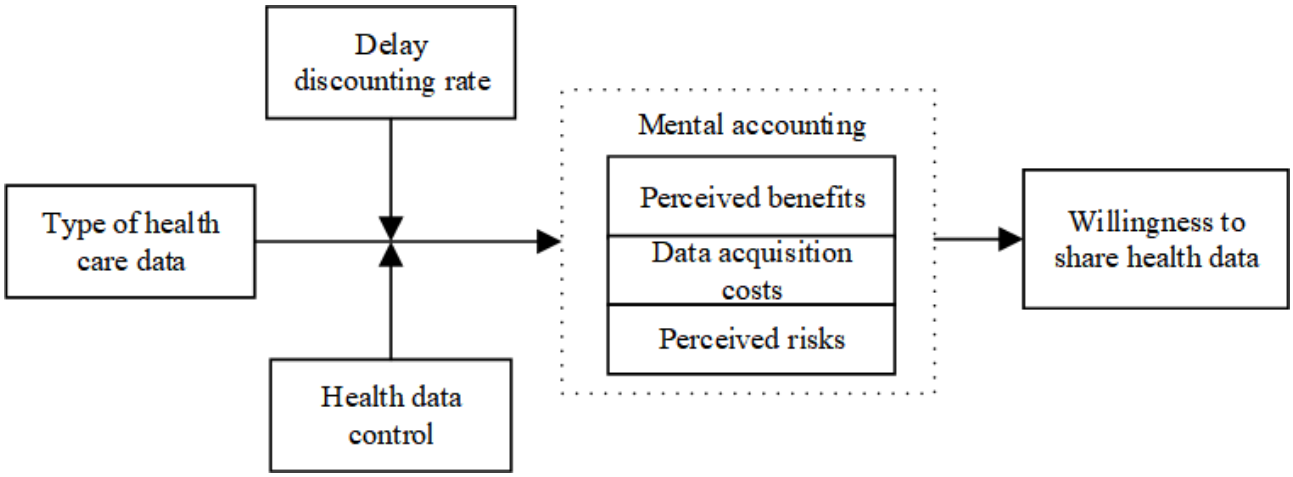
The notion of health data control pertains to individuals' rights to manage their health care information. Drawing from the theory of psychological ownership, individuals tend to perceive objects they own as extensions of themselves, influencing their attitudes, motivations, and behaviors [51]. Psychological ownership refers to the feeling individuals have that an object belongs to them, emphasizing their sense of possession [52]. In our study, health data serve as the focus of psychological ownership. Belanger and James [53] discovered that users prefer direct control over personal privacy compared to corporate control. Direct control enhances users' self-efficacy and willingness to disclose personal information.

Moreover, PCD significantly impacts patients' adoption of electronic health record systems. PCD ensures that all users within health care institutions can access patient health information with patient confirmation [54]. PCD increases patients' willingness to share health data [40] and empowers them to manage their information. Greater public control over health data reduces perceived privacy risks and enhances awareness of data-sharing benefits while downplaying associated costs. Thus, we propose the following hypothesis:

- Hypothesis 6: Health data control increases the perceived benefits (hypothesis 6a) and reduces the perceived risks (hypothesis 6b) in data sharing.

Intertemporal decision-making involves balancing and judging between time and gains or losses [55]. It includes choices like immediate gratification versus future enjoyment or the immediate pleasure of smoking versus future health concerns. This process, known as intertemporal choice, reflects the value

XSL•FO
RenderX



people assign to payoffs at different times [56]. Most decisions require trading off costs and benefits over time. Delay discounting rate and subjective value are key indicators of intertemporal choice; a higher discounting rate or lower subjective value suggests greater impulsivity and preference for immediate rewards over larger future gains [14,15].

Research has examined intertemporal decision-making in health care. Snider et al [57] studied how intertemporal preferences affect adverse health and financial behaviors using delay discounting rates. Tian et al [58] investigated the role of delay discounting rate in adolescent internet gaming addiction. Studies also show that altering intertemporal preferences can improve health behaviors. Interventions that reduce delay discounting rate or enhance future time orientation have been shown to promote better health behaviors [59]. Individuals with high delay discounting rates prioritize immediate gratification, undervaluing health data-sharing benefits and focusing on privacy risks. Conversely, those with lower rates prioritize long-term benefits, emphasizing data-sharing benefits and overlooking privacy risks and data acquisition costs. Therefore, we hypothesize the following:

- Hypothesis 7: Delay discounting rate reduces perceived benefit (hypothesis 7a), increasing perceived risk (hypothesis 7b) and data acquisition costs (hypothesis 7c).

Consequently, we propose a moderated mediation model (Figure 1) that is mediated by 3 factors in mental accounting, using health data control and delay discounting rate as moderators.

Figure 1. Theoretical model.

Methods

Participants and Procedure

This study was conducted through the web-based questionnaire platform "Wenjuanxing." After excluding invalid and incomplete questionnaires, a total of 257 valid responses were collected. To ensure the diversity and representativeness of the sample, recruitment information was posted on the platform. The recruitment notice clearly stated that participants must be between the ages of 20 and 69 years, with no specific educational background requirements, aiming to include individuals from various educational backgrounds. Prior to completing the questionnaire, participants were required to confirm their voluntary participation and understanding of all relevant research information, including the research objectives, expected time commitment, and potential risks involved.

At the beginning of the questionnaire, all participants were presented with a detailed informed consent form, which included a statement of voluntary participation, an explanation of data collection and use, a commitment to protecting personal privacy, and assurances of data anonymity. Participants were required to read this consent form carefully and check a consent box before proceeding with the questionnaire. All data collected were strictly for academic research purposes. Upon completion of the questionnaire, participants were rewarded with US $0.7 - $1.4 based on the completeness and quality of their responses. This incentive was designed to encourage careful and thoughtful participation. To ensure the reliability of the research results, all data were anonymized to prevent any personal identifying information (eg, names, contact information, and IP addresses) from being recorded.

The ages of participants ranged from 20 to 69 years. The majority of participants held undergraduate degrees (n=122, 47.5%), followed by master degree holders (n=70, 27.2%), individuals with college degrees or below (n=55, 21.4%), and doctoral students (n=10, 3.9%).

Ethical Considerations

This study has obtained ethics approval from the institutional review board of the School of Management, Zhengzhou University. In accordance with the regulations of the institutional review board, this research is deemed to meet ethical standards, and a series of measures have been implemented to ensure ethical compliance throughout the study process. Specifically, all participants' data have been anonymized to ensure the strict protection of their privacy. Throughout the research, no personal identifying information will be linked to the data, and all raw data will be restricted to use by the research team only. Furthermore, participants were fully informed of the research purpose, the manner in which their data would be used, and the commitment to privacy protection, and they voluntarily consented to participate.

XSL•FO
RenderX

Overview of the Scenarios

In our study, health data sharing refers to sharing one's own data with health care providers. Health care providers include hospitals, health insurance companies, and medical device companies. The questionnaire consisted of 3 parts. The first part used nominal scales to collect demographic information, including sex, age, and educational level. The second and third parts focused on variables related to the willingness to share PGD and clinical medical data, respectively. Participants respond using a 5-point Likert scale (1=strongly disagree and 5=strongly agree).

For data types, we classify them as PGD and clinical medical data. PGD include, but are not limited to, the following parts: data measured by wearable smart devices or home medical and health devices, data generated by daily activities, and internet health data. Clinical medical data are mainly electronic medical record data, medical image data, laboratory test data, etc. We divide mental accounts into perceived benefits, perceived risks, and data acquisition costs. Perceived benefits are people's self-perception of the benefits of sharing health care data based on their own expertise and experience. Perceived risk measures people's assessment of the risk of data leakage in the process of data sharing and the negative impact of data leakage on them. Data acquisition cost, on the other hand, refers to the effort people put into obtaining relevant health care before sharing health care data. The moderating variables in the paper are data control and delay discount, while data control refers to the degree of control people have over their own health care data. Delay discount rates were calculated using the 27-item Monetary Choice Questionnaire [14]. Each question contained an immediate reward option (eg, US $1.5 today) and a delayed reward option (eg, US $3 in 7 days). We simply replace the US dollar ($) with the Chinese yuan (¥) based on World Bank data. We still use Kirby's method to calculate the discount rate. In the Kirby task, the 27 trails were divided into 3 groups according to the magnitude of the delay reward, and the discount rates corresponding to the 9 trails in each group were ranked from smallest to largest (0.00016-0.250).

Results

Demographics

This study includes several demographic factors, such as sex (male and female) and education level among adolescents. Among the 257 participants, 40.9% (n=105) were male, and 59.1% (n=152) were female. Furthermore, among the respondents, 3.1% (n=8) were aged 20 years and younger, 48.6% (n=125) were aged 21 - 29 years, 16% (n=41) were aged 30 - 39 years, 13.6% (n=35) were aged 40 - 49 years, and 18.7% (n=48) were aged 49 years and older. Additionally, 21.4% (n=22) of individuals had education levels below an undergraduate degree, 47.5% (n=122) had undergraduate degrees, 27.2% (n=70) had master's degrees, and 3.9% (n=10) had doctoral degrees (Table 1).

Table . Demographic characteristics.

Variable	Values, n (%)
Sex	
Male	105 (40.9)
Female	152 (59.1)
Age (years)	
<20	8 (3.1)
21 - 29	125 (48.6)
30 - 39	41 (16)
40 - 49	35 (13.6)
>50	48 (18.7)
Education	
Below an undergraduate degree	22 (21.4)
Undergraduate degree	122 (47.5)
Master's degree	70 (27.2)
Doctoral degree	10 (3.9)

Preliminary Analyses

Table 2 presents the Pearson and point-biserial correlation coefficients of the variables. Data acquisition cost positively correlates with the data type. Perceived risk positively correlates with sex and data type. The delay discounting rate positively correlates with sex and negatively correlates with education. Health data control positively correlates with education and data type. Willingness to share health data negatively correlates with data type, data acquisition cost, perceived risk, and health data control and positively correlates with perceived benefits.

Hypotheses Testing

Table 3 shows the direct effects of each variable on the impact of health data sharing. The type of health data has a significant and direct effect on willingness to share (β=−0.28, SE=0.10; *P*<.001), supporting hypothesis 1. Perceived benefits positively influence the willingness to share (Table 2) health data (β=0.40, SE=0.06; *P*<.001), supporting hypothesis 3. Additionally, the data acquisition cost and perceived risk have significant negative direct effects on types of health data, supporting hypothesis 4 and hypothesis 5.

The results, as summarized in Table 4, indicate that there is no significant relationship between types of health data and perceived benefit (β=−0.06; P=.68; t_{249}=−0.92), suggesting that types of health data do not directly impact perceived benefit. However, it is noteworthy that in the moderated mediation model, participants' education level has a positive influence on perceived benefit (β=0.11; P=.02; t_{249}=2.24).

[a]DT: type of health care data.

[b]*P*<.001.

[c]DR: delay discounting rate.

[d]Not available.

[e]*P*<.05.

[f]*P*<.01.

[g]HC: health data control.

[h]DC: data acquisition cost.

[i]PR: perceived risk.

[j]PB: perceived benefit.

Furthermore, the results demonstrate that types of health data positively influence data acquisition costs (β=0.82; *P*<.001; t_{249}=11.78) and perceived risk (β=0.97; *P*<.001; t_{249}=11.73). Interestingly, sex also has a significant influence on perceived risk, with female participants perceiving higher risk in data sharing compared to male participants.

These findings suggest that while the types of health data themselves may not directly impact perceived benefit, they do influence both data acquisition cost and perceived risk. Additionally, participants' education level plays a role in shaping their perceptions of the benefits associated with sharing health data.

Table 5 shows the indirect effects of types of health data on the impact of health data sharing. Both data acquisition cost and perceived risk have significant mediating effects on the relationship between types of health data and willingness to share health data (β=−0.22, SE=0.05; odds ratio [OR] 0.80, 95% CI −0.33 to −0.12 and β=−0.17, SE=0.06; OR 0.84, 95% CI −0.28 to −0.07), supporting hypothesis 2b and hypothesis 2c. However, the mediating effect of perceived benefits on the relationship between types of health data and willingness to share health data is not significant (β=−0.03, SE=0.03; OR 0.97, 95% CI −0.08 to 0.03), hypothesis 2a was not supported.

XSL•FO
RenderX

Table . The indirect effect of the variable on health data sharing.

Discussion

Overview

With the advent of the digital age, the application and sharing of health data have garnered significant attention. However, issues such as privacy breaches and ambiguous ownership have emerged, resulting in individuals' reluctance to share their health care information. Scholars have increasingly focused on strategies to enhance public willingness to share or disclose their health data with institutions. Nonetheless, the influence of different data types on individuals and the moderating effects of delay discounting and health data control remain

XSL•FO
RenderX

underexplored. This study aims to analyze the impact of different types of health data on individual data sharing through the lens of psychological ownership theory and examine the moderating effects of delay discounting and health data control.

Principal Findings

Consistent with other studies, our study demonstrates that higher perceived benefits and lower perceived risks are associated with an increased willingness to share health data [24,41]. Building on this foundation, the study also explores the impact of the effort individuals invest in obtaining data on their willingness to share it. The findings indicate a correlation between lower data acquisition costs and a greater willingness to share data. When individuals expend considerable effort to obtain data, they develop a sense of psychological ownership, perceiving the data as something they have acquired at a cost and therefore value more highly. Due to this psychological ownership effect, they become more cautious and conservative about sharing the data, showing reluctance to share it easily with others. As indicated by Karway et al [42], the public is more inclined to share their health data when they can exercise control over it.

Types of health data may not only directly influence the willingness to share data but also indirectly affect it through mental accounting. Our mediation model revealed that types of health data negatively impact individuals' willingness to share data by increasing data acquisition costs and perceived risks. Obtaining clinical medical data requires more effort compared to everyday health data due to its complexity and sensitivity, which involves more permissions and privacy protection measures during the acquisition process. Additionally, clinical medical data contain more sensitive information, and its leakage may result in more severe consequences [28,30]. Consequently, the public perceives higher risks associated with sharing such data, resulting in a greater reluctance to share it.

However, contrary to our hypothesis, types of health data do not influence the public's perception of data-sharing benefits. Whether it is PGD or clinical medical data, the public may prioritize whether data sharing can improve the quality of health care services and enhance health management. However, the public cannot ascertain how their data will be used after sharing nor can they accurately perceive the benefits to themselves after data sharing [22,23]. For different types of health data, the differences in the perceived benefits of data sharing by the public may not be significant.

In the moderated mediation model, participants' educational level has a positive influence on perceived benefits. This indicates that individuals with higher education levels are more inclined to perceive higher benefits from data sharing. Individuals with higher education levels typically possess greater information literacy and understanding, enabling them to recognize better the potential benefits of data sharing in health management, disease prevention, and medical research. Therefore, they have a more positive perception of the benefits of data sharing. Similarly, sex has a positive influence on participants' perception of data-sharing risks, with female participants perceiving higher risks compared to male participants. This finding is consistent with existing literature, where female participants typically demonstrate higher sensitivity and caution regarding data privacy and security [60,61]. Female participants may exhibit greater sensitivity to data privacy issues due to societal processes emphasizing security concerns or experiences of insecurity in the use and management of health data.

The delay discounting rate has a positive moderating effect on the relationship between types of health data and the effort participants expend in obtaining data as well as their perceived risks. Individuals with a higher delay discounting rate tend to be more impulsive, with a lower valuation of future rewards. This leads them to rely more on immediate costs and benefits rather than long-term gains in decision-making [14,15]. This psychological characteristic may lead them to perceive the effort required to obtain data as part of the decision-making process. Additionally, compared to long-term health management and potential benefits, individuals with a higher delay discounting rate may prioritize immediate security and privacy protection. Consequently, they may overly focus on the immediate risks associated with sharing medical data, such as privacy breaches and data misuse, while overlooking the potential long-term health benefits and medical advancements that data sharing could bring about.

The relationship between types of health data and perceived data-sharing risks is negatively moderated by health data control rights. Individuals with higher health data control rights typically have more resources and means to simplify the data acquisition process, reduce the complexity and difficulty of obtaining data, and enhance their data protection capabilities, thereby mitigating the perceived risks associated with data sharing [42]. Additionally, granting the public more control over their health data increases their engagement in data sharing, thereby promoting it [40]. Enhancing transparency in the data-sharing process can further empower the public with greater control over their health data [38].

The following insights were gained: to enhance participation in data sharing, health care institutions and policy makers should simplify the data authorization and acquisition processes. By reducing complex authorization steps and clarifying the permissions involved in the sharing process, individuals' psychological burden and practical operational costs during data sharing can be significantly reduced. For example, adopting a unified user authorization platform or a "single consent" mechanism can simplify the public's decision-making process regarding data sharing. Additionally, users should be clearly informed about the context and purpose of data use, and options for data modification, deletion, and revocation of consent should be provided. During the data sharing process, a "transparent data use statement" should be made available to ensure that the public has a clearer understanding of the data's destination, use, and potential impact. Furthermore, the moderating role of delayed discounting on data-sharing decisions offers new perspectives for research. For individuals with a high delayed discounting rate, the immediate risks associated with data sharing may be overemphasized, potentially overshadowing the long-term health benefits. To address this issue, future data-sharing initiatives could focus on increasing public awareness of the long-term benefits of data sharing, emphasizing its potential in health management, disease prevention, and

XSL•FO
RenderX

medical research. This approach could help individuals balance short-term privacy protection with long-term benefits.

Limitations

There are some limitations in our study. First, we classified health data only into PGD and clinical medical data. Future research could categorize them in more detail. Second, although we included variables such as sex, age, and education in our questionnaire, we did not analyze other personal characteristics, such as history of illness. Additionally, our study did not provide a detailed categorization of the recipients of data sharing. Future studies could specify recipients more precisely, categorizing them as hospitals, insurance agencies, medical device companies, and so on.

Conclusions

Our study has revealed the multifaceted impacts of different types of health data on public willingness to data sharing and highlighted the significant roles of data acquisition costs, delay discounting rates, and health data control rights in this process. These findings not only contribute to a deeper understanding of public attitudes and behaviors regarding data sharing but also provide valuable insights for the development of effective data-sharing policies and privacy protection measures.

Abstract

Background: Health information exchange (HIE) supports clinical decision-making in emergency medicine settings. Despite evidence and policies that encourage the adoption of HIE, use by clinicians is limited. Moreover, few studies examine HIE use years after adoption by hospitals or clinics.

Objective: This study aims to examine the perceptions and use of a mature, operational HIE system by emergency department clinicians years after its implementation.

Methods: We interviewed 21 clinicians in various roles (eg, attending physician and nurse practitioner) across multiple health systems that participate in a statewide HIE network. We asked questions about their use of the HIE system and the factors that facilitate or inhibit use. Analysis of interview transcripts was guided by a theoretical framework derived from information systems theories describing individual perception of, and use behavior toward, HIE systems.

Results: A total of 26 factors across 6 domains were identified by respondents. All respondents recognized the value of HIE for medical decision-making in the emergency department, and access to information via the HIE system was preferred over traditional methods of telephoning other facilities or waiting for faxed records. Ease of use, particularly single sign-on functionality, was recognized as a key facilitator of routine use, enabling clinicians to access a patient's HIE record with a single click from within their electronic health record system. Access to integrated data and advanced search features supported clinical decision-making. Limited training and poor system usability were identified as barriers to use.

Conclusions: Achieving widespread adoption and use of HIE systems globally will require a focused effort to address multiple individual perception and behavioral factors. Researchers, leaders of HIE organizations, and policymakers alike should leverage these factors to achieve the goals of HIE and interoperability.

Introduction

Background

The adoption and use of health information exchange (HIE)—the electronic transfer of patient-level data or information across diverse and often competing health-related organizations [1]—offers a number of benefits, including reductions in inpatient readmissions, reduced duplicate laboratory and imaging studies, and decreased inpatient length of stay [2]. Multiple studies have demonstrated benefits especially to emergency department (ED) care [3-8]. Moreover, HIE facilitates intelligent communication, including clinical decision support [9], remote monitoring [2], and automated data integration [10]. As HIE is linked to better outcomes and efficiencies in care delivery processes, US health policies, including the Health Information Technology for Economic and Clinical Health Act [11] and the 21st Century Cures Act [12], have systematically encouraged adoption and use across myriad clinical settings [13].

As a result of multiple federal- and state-level policies, HIE availability—as well as the types of HIE systems available (eg, community based and vendor based)—has increased in many communities across the United States [13,14]. In 2021, according to the Office of the National Coordinator for Health Information Technology (ONC), 61% of hospitals reported using an HIE system to electronically query or find patient health information from external sources, suggesting that most clinicians use HIE routinely in care delivery [15]. Moreover, the ONC reported that in 2021, four out of 10 hospitals participated in more than one type of HIE, and most of these hospitals reported exchanging data with a community-based HIE network [15].

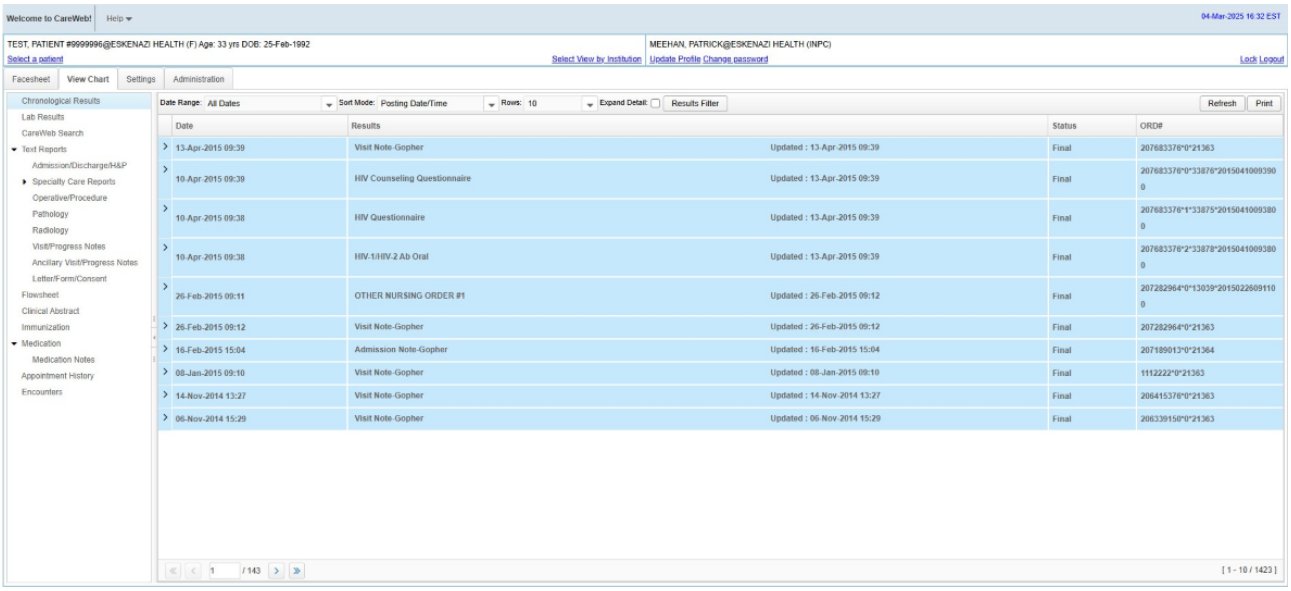
However, despite clear policy incentives, robust literature demonstrating impact, increasing organizational adoption, and evidence of more widespread availability, the actual state of individual HIE use in clinical practice seems to be limited; for example, using log data from a community-based HIE in operation for >15 years, we observed low rates of use among health care providers across inpatient, emergency, and outpatient settings despite overall increased adoption and use over time [16]. Other studies and reviews have reported relatively low use by clinicians [17]. As a further complication, much of the existing evidence on clinician use and perceptions was generated when HIE was a novel intervention or in the period shortly after implementation. These studies documented multiple barriers to implementation and use, including HIE system conflicts with workflow as well as usability challenges [18]. Clinicians may also be frustrated by the lack of information available (eg, in terms of breadth and depth) from smaller-scale exchange efforts [19]. While these earlier studies are critical, HIE has since evolved, electronic health record (EHR) systems and workflows have continued to change, and modern HIE is no longer an innovation but rather a routine capability.

A better understanding of actual use would support system improvements and identify additional, and potentially valuable, use cases. This is particularly true in the ED setting, where clinicians may not have a longitudinal relationship with patients, and access to prior information may be difficult [20]. Prior research involving ED clinicians before the implementation of technologies for accessing past medical history found that these clinicians desired better access to prior medical information [19,20]. Despite the value of HIE in the ED, reviews suggest that the ED is becoming a less-studied setting [21]. This study sought to elucidate ED users' perceptions and use of a mature and robust HIE system.

Purpose

As knowledge of HIE use by health care providers is limited, we conducted a qualitative study of ED clinicians to capture their perceptions and use of an operational HIE system many years after its introduction in the community. Our goal was to better understand when HIE is useful and the context of HIE use in ED care. We hypothesized that clinicians would perceive HIE to be useful and effective; yet, HIE would not be used for every patient, given the availability of information from a broad array of sources, including the patient, family, and intraorganizational EHR data.

Methods



Study Design and Setting

This study used qualitative methods to explore the antecedents of HIE use factors that act as facilitators or barriers to its adoption within ED settings. We recruited ED clinicians with access to the Indiana Network for Patient Care (INPC), a community-based HIE network operational since the late 1990s [22]. The INPC is managed by the Indiana Health Information Exchange, which has systematically expanded the service area and capabilities of the INPC, integrating longitudinal data from 38 health systems that encompass >100 hospitals with EDs [23,24]. The INPC is routinely used as a platform for research [25], including innovations in HIE [26-29] and interoperability [30,31].

Clinicians with access to the INPC interact with patient medical records via a web-based intelligent communication system known as CareWeb. Originally, CareWeb was developed using Java. The current version was redesigned in 2009 using ZK, an open-source Ajax web application framework written in Java for mobile and web apps. Users are managed by the Indiana Health Information Exchange, and updated user lists are provided regularly by each INPC organization. As depicted in Figure 1, the CareWeb system provides access to patients' integrated, longitudinal medical records. By default, recent notes and results are displayed in reverse chronological order. The left-hand menu provides access to specific types of information (eg, immunizations, radiology, and discharge summaries) as well as CareWeb Search, an intelligent search that enables clinicians to query patients' medical records. In the past, clinicians logged into CareWeb using an internet browser—outside of their EHR system (Multimedia Appendix 1). Currently, clinicians access CareWeb primarily via a button in their EHR system that launches a web browser and opens the same patient record that they have open in the EHR.

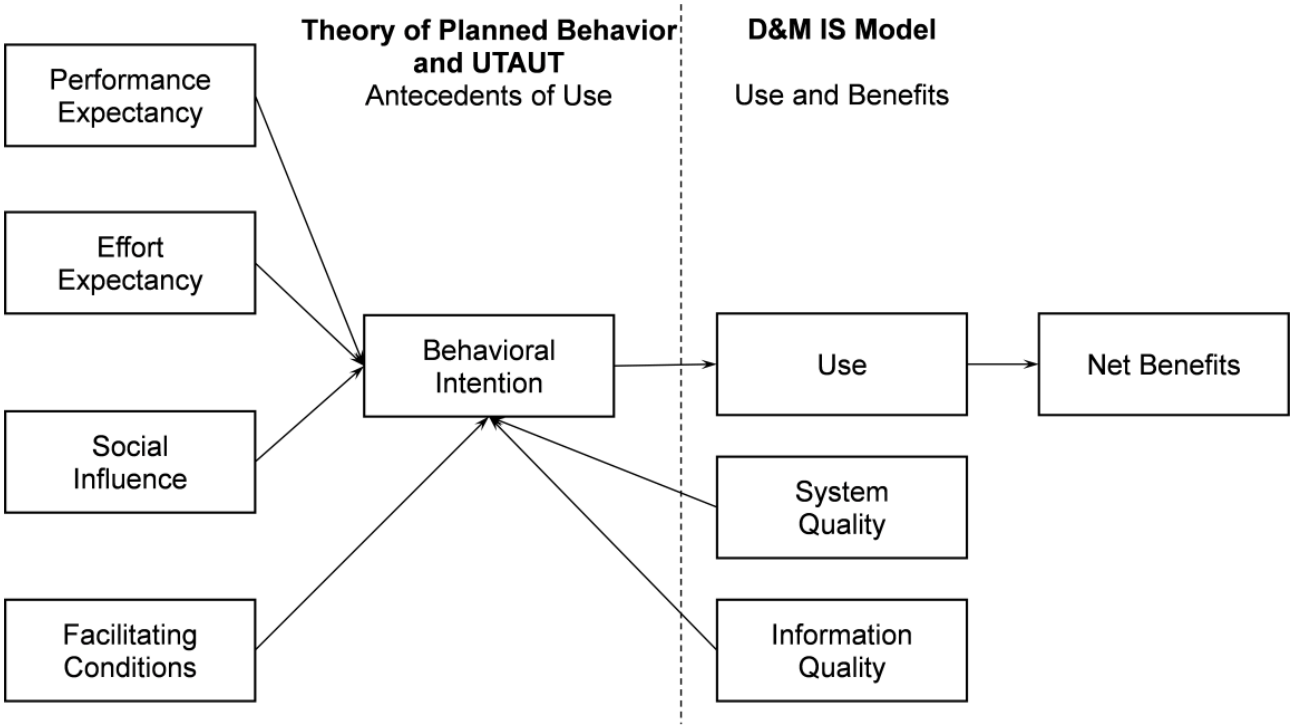
Figure 1. Screenshot of the CareWeb application that clinicians use to access patient medical records available in the Indiana Network for Patient Care.



Our target participants were ED clinicians practicing in central Indiana, a region with the longest-established use of the INPC that includes urban, suburban, and rural communities. We purposely sampled clinicians with a goal of 30 users, stratified by clinical role (eg, physician, nurse practitioner or physician assistant, and registered nurse). The target sample was further stratified by level of HIE use, observed from INPC log files that measure the number of log-ins to CareWeb. We purposely sought to include low users (eg, approximately 1-2 log-ins per mo or up to 26 log-ins per y), medium users (eg, approximately 1 log-in per wk or 27-51 log-ins per y), and high users (eg, ≥52 log-ins per y, representing an average of ≥1 log-in per wk). We recruited clinicians across these strata until thematic saturation was achieved after 21 interviews [32,33].

Theoretical Framework

Our research is grounded in a novel integration of 3 conceptual frameworks from the information sciences (Figure 2). These frameworks are compatible and complementary, given that each theory centers on the concept of information systems (IS) use and its antecedents. The combined model allows for an examination of the factors that influence behavioral intention (BI) and use, which in turn influence net benefits. In the context of HIE use within ED settings, which manage a substantial proportion of clinical conditions, the integrated theoretical model facilitates a comprehensive exploration of the factors influencing ED clinicians' intentions to use HIE as part of patient care. This exploration extends to understanding how these factors influence decision-making processes regarding individual care delivery and impact patient care outcomes. We hypothesized that a variety of factors, including system quality (eg, ease of use) and information quality (eg, data available in the INPC for patient care), would influence clinicians' engagement with the HIE platform.

XSL•FO
RenderX

Figure 2. Theoretical framework used to guide the research. The framework integrates concepts from the theory of planned behavior, the unified theory of acceptance and use of technology (UTAUT), and the DeLone and McLean information systems (D&M IS) success model.

The theory of planned behavior posits that human behavior follows BI, which is influenced by a number of factors, including subjective norms [34]. This theory has been widely used in many fields, including health care, to explain behaviors as well as the factors that influence behaviors, such as vaccination uptake [35] or the adoption of EHR systems [36,37].

The unified theory of acceptance and use of technology (UTAUT) is a model that enables the measurement and study of the acceptance and use of technology and has been used to examine the adoption and use of EHR systems [38-40]. The UTAUT identifies 3 primary constructs that influence BI: performance expectancy, effort expectancy, and social influence [38,41]. Performance expectancy refers to the degree to which an individual believes that using the system will improve their performance. Effort expectancy denotes the perceived ease of using the system. Social influence refers to the degree to which an individual perceives that important others (eg, a supervisor or an influential colleague) believe that they should use the new system. The UTAUT posits an additional construct—facilitating conditions—defined as the individual's belief that sufficient organizational and technical infrastructure is available to support the use of the system.

The DeLone and McLean IS success model is a multidimensional, interrelated framework for conceptualizing IS success [42,43]. The model involves 3 distinct but interrelated levels of success: technical, referring to system quality (eg, does the system perform as intended?); semantic, referring to information quality (eg, does the information convey the intended meaning?); and effectiveness, referring to the impact of the IS on the receiver (eg, user behavior, individual impact, and organizational impact). Success is defined in terms of net benefits to the user or the organization. The choice of "net benefits" is purposeful because there are always costs to implementing and using an IS. Furthermore, the model allows for an examination of the complex interrelationships between use and impact (eg, system use influences the products that in turn influence the individual user, which may in turn impact organizational outputs).

Data Collection

Semistructured interviews with ED providers were conducted from February 2019 through January 2020 via Zoom (Zoom Video Communications, Inc), Skype (Microsoft Corporation), or telephone. Several respondents preferred to participate from home on their day off. Each interview lasted approximately 45 minutes.

During each interview, one researcher facilitated discussion while another took detailed notes. The questions aimed to elicit clinicians' experiences of seeking information on patients from outside facilities; awareness and use of the INPC during ED encounters; perceptions of INPC tools, including the interface; and use of any other HIE tools, such as Care Everywhere. Probing questions were asked to dig deeper into clinicians' experiences with HIE, particularly when responses were vague or involved specific use cases. All interviews were audio recorded and transcribed verbatim. The interview guide is presented in Multimedia Appendix 2.

Data Analysis

We analyzed the interviews using a deductive approach. The initial codebook was developed by BED based on the theoretical framework and iteratively refined with input from the broader study team, including CB. Two coders (BR and MF) then analyzed the transcripts independently, meeting weekly throughout the process to review each other's coding, discuss and refine codes and subcodes, and draw codes into broader themes. Any disagreements between the coders were resolved

XSL•FO
RenderX

through discussion with BED. UG later independently reviewed and summarized these codes to ensure accuracy. Data were coded and analyzed using NVivo 12 (Lumivero) [44].

Ethical Considerations

This study was approved by the institutional review board of Indiana University (protocol number 1710653338). All interviews were anonymized to protect participant confidentiality. Participants received a $50 gift card as remuneration.

Results

Participant Characteristics

We interviewed 21 ED clinicians drawn from 7 distinct health systems (Table 1). Of these 21 clinicians, 11 (52%) were physicians, 5 (24%) were registered nurses, 3 (14%) were nurse practitioners, and 2 (10%) were physician assistants. Most of the respondents (14/21, 67%) reported being in practice for 5 years, while 7 (33%) of the 21 respondents reported being in practice for ≤2 years (average 11, SD 8 y; range: 1-23 y). Nearly one-third of the respondents (6/21, 29%) reported dedicating between 80% and 100% of their work time to clinical activities, while others balanced patient care and administrative roles such as division chief, medical director, or manager. Participants were drawn from both large health systems (11/21, 52%) and community hospitals (10/21, 48%).

Table 1. Participants by clinical role and site (N=21).

Participant role	Large health system (n=11), n (%)	Community hospital (n=10), n (%)
Physician	6 (55)	5 (50)
Registered nurse	1 (9)	4 (40)
Nurse practitioner	2 (18)	1 (10)
Physician assistant	2 (18)	0 (0)

Factors That Influence HIE Use

Overview

As summarized in Table 2, respondents identified an array of factors that influence their HIE use. A more complete synthesis of responses and example quotes from respondents is presented in Multimedia Appendix 1. In this subsection, we summarize some of the major themes from clinicians relevant to their use of HIE.

XSL•FO
RenderX

Table 2. Key factors, summarized by theoretical framework domain, that influence the use of health information exchange (HIE) by clinicians in emergency department (ED) settings.

Domains and factors	Illustrative quote
Performance expectancy	
Changes to decision-making	"I was able to pull up their imaging studies from a week ago which helped guide my decision." [R7; y in practice: 10]
Continuity of care	"The ability to see that they were just at the hospital twelve hours ago...keeps us from doing unnecessary tests." [R16; y in practice: 21]
Frequency of use	"I probably use it every day for a few of my patients to confirm what happened at other hospitals." [R5; y in practice: 15]
Information retrieval in workflow	"Right after the patient left, I went back to CareWeb to double-check and then it changed the approach we were taking." [R4; y in practice: 23]
Patient characterization	"By pulling in all their previous admissions, I had a clearer picture of their frequent ED visits and issues." [R9; y in practice: 7]
Efficient retrieval	"It takes a few minutes to get through all the records, but it's worth it when you're avoiding duplication." [R6; y in practice: 11]
Motivation for information retrieval	"Patients come from all over, and to give them the best care, we need to know what's been done at other hospitals." [R10; y in practice: 5]
Effort expectancy	
Desired features for ease of use	"I just think if I could make it so that I can stay logged in longer. So not constantly having to log in and log out." [R2; y in practice: 14]
Ease of use	"CareWeb is fairly self-explanatory, especially for information gathering rather than charting or placing orders." [R1; y in practice: 21]
Effort to retrieve information	"It took us a few minutes just to kind of read through, and they were all fairly much the same story." [R1; y in practice: 23]
Features that facilitate ease of use	"I like Care[Web]. I can often go into documents and copy and paste data directly into my notes." [R2; y in practice: 14]
Information display	"I think it may be organizing it differently...you can primarily organize by dates or something with tabs for labs, et cetera." [R3; y in practice: 1]
Speed of information retrieval	"It's fast compared to a lot of our systems." [R21; y in practice: 22]
Social influence	
Discussion of use	"I first learned about using CareWeb when my colleague mentioned it as a helpful tool during our shift." [R12; y in practice: 2]
Expectation of use	"It's pretty much expected now that we check the HIE before making any big decisions." [R14; y in practice: 4]
Resident use	"We always ask the residents to check CareWeb as part of their evaluation process." [R11; y in practice: 13]
Facilitating conditions	
Organizational support	"[A] patient came in saying they were just seen and had a test done...I asked the provider if I should contact the facility." [R17; y in practice: 2]
Team support	"Whenever someone has trouble accessing information, we work together to figure it out." [R19; y in practice: 1]
Training	"[A] colleague mentioned it as being useful. So that's kind of how I found out about it just working with coworkers." [R4; y in practice: 23]
Technical support	"We always reach out to IT if the system is slow or down, and they respond quickly." [R13; y in practice: 9]
Information quality	
Desired information	"I need to make sure that they haven't had seven CT scans already in 2020." [R2; y in practice: 14]
Missing information	"I've had this before where a patient was recently discharged but the actual discharge summary is not in the system yet." [R8; y in practice: 13]
Missing institutions	"The VA has no records online that I know of anywhere, so you always have to call and get records from there." [R1; y in practice: 21]

XSL•FO
RenderX

Domains and factors	Illustrative quote
Usability of information	"As long as we can get to it, that's super helpful." [R17; y in practice: 2]
System quality	
Network reliability	"[H]ospitals created that VPN connection, so I don't have a problem with that anymore." [R8; y in practice: 13]
System reliability	"If that link works...it's so much more useful and quicker." [R1; y in practice: 23]

Performance Expectancy

All respondents indicated that they knew about CareWeb and used it at least sometimes to look up information. Respondents reported that, overall, CareWeb enhances the retrieval of information for clinical decision-making. First, the HIE system provided access within "five to ten minutes" (R15; y in practice: 13), which was an improvement over waiting "fifteen to twenty minutes" (R19; y in practice: 1) or "up to an hour" (R13; y in practice: 4) to retrieve information from outside facilities. Moreover, one physician stated as follows:

> *A lot of times patients seem to fall apart in the evenings or at night when there's no office staff, and the on-call person doesn't want to or doesn't have the capabilities to fax or email me the patient information.* [R12; y in practice: 2]

Second, most respondents reported that accessing CareWeb fits well into clinical workflow. Respondents generally accessed CareWeb either before they went into the examination room to see the patient or right after examining the patient to "double-check" information they obtained from their conversation with the patient.

Clinicians further viewed accessing the HIE system as critical to making good clinical decisions, with most respondents reporting that information from CareWeb had changed a clinical decision. Providers noted as follows:

> *Looking at that information can change what needs to be done in the immediate emergent future.* [R2; y in practice: 14]

> *The ability to see that they were just at the hospital twelve hours ago across town and got whatever treatment plan was there...keeps us from doing unnecessary tests.* [R16; y in practice: 21]

Reduction in duplicate procedures and tests, especially imaging, was frequently cited by clinicians as a major reason for looking up information in the HIE system. Some also reported experiences where information in the HIE system likely saved their patient's life:

> *Had I not known how big it [tumor] had been before, he might have been discharged, and that could have had a poor outcome for him.* [R12; y in practice: 2]

Respondents also reported instances where the HIE system is unlikely to impact their performance as clinicians and therefore cases in which they do not feel that they need to use it. First, for patients whose care is immediate in nature, where past history might not make a difference in the care provided, some respondents indicated that using the HIE system would not be fruitful. Second, some clinicians were less likely to use it if patients reported that their prior care was delivered in the same health system. In these cases, health care providers used only the EHR to look up prior medical records.

Effort Expectancy

Respondents identified several effort expectancy factors that influence their use of HIE. With respect to factors that encouraged use, respondents highlighted ease of use, speed of access, comprehensiveness of data, SSO integration with the EHR, search capabilities, and features that allow information to be copied and pasted into their local notes. Factors that discouraged use included feeling overwhelmed by the volume of data in the HIE system and the system frequently logging out users.

Several aspects of the HIE system facilitated ease of use and supported clinicians' effort. Several respondents reported that the system is intuitive to use or "fairly self-explanatory" and requires minimal training for basic functions such as accessing patient information, which encourages them to use it during clinical encounters. A frequently cited feature was SSO, which allows clinicians to click a single button in their home EHR to easily bring up the same patient's records in CareWeb. Multiple respondents mentioned SSO as a key effort expectancy factor that encouraged HIE use. Clinicians who mentioned SSO functionality were generally those who had practiced for several years and compared accessing the HIE currently to a previous time when accessing it required a separate username and password:

> *Being able to click the button in Cerner that opens and goes directly to the patient's chart without me having to remember and enter another password...has dramatically increased how often I use CareWeb compared to the way it was ten years ago.* [R15; y in practice: 13]

Respondents who did not report SSO as a feature were practicing in smaller community hospitals that had not yet implemented this feature, and these respondents often suggested that a more efficient log-in process would encourage their use of the HIE system.

Similarly, a few respondents reported that the search capability, which enables clinicians to conduct a Google-like search of the records in the HIE system, was a major enabling factor for wading through the comprehensive data available:

> *If you want to look up someone's renal function or a CBC, you can just type in CBC in the box, and it'll pull up the most recent ones. These little things are*

XSL•FO
RenderX

> *helpful to the clinician on the front lines.* [R8; y in practice: 13]

Respondents who did not mention the search feature reported that they did not know about it and that it would be a useful, desired feature:

> *Especially the lab results, it can get tedious clicking through [multiple pages].* [R19; y in practice: 1]

Finally, some clinicians reported that easily copying and pasting information from the HIE system into their notes within their EHR system was an important factor encouraging their use of CareWeb:

> *I can often go into documents and see if they've had a CT scan or MRI, then copy and paste that directly into my note. So, I find it the easiest to use.* [R2; y in practice: 14]

A few clinicians mentioned challenges with the volume and organization of data within the HIE system. While the respondents noted that comprehensive data were available to them, they felt overwhelmed by the volume of data and the fact that, by default, it is organized in reverse chronological order. These clinicians expressed a desire for tools that allow users to better sort and organize or filter the data to enable streamlined views that facilitate clinical decision-making. Similarly, some clinicians reported getting logged out of the HIE system when interrupted or during an encounter:

> *I just think if I could make it so that I can stay logged in longer. So not constantly having to log in and log out.* [R2; y in practice: 14]

Clinicians suggested that longer log-out times or ways to prevent involuntary log out would be an improvement. Such features would encourage clinicians' use of the HIE system.

Social Influence

Respondents discussed several social influences on HIE use. Many respondents credited colleagues with introducing them to CareWeb:

> *A colleague mentioned it as being useful, so that's how I found out about it.* [R3; y in practice: 1]

Most respondents who trained in Indiana were introduced to it during residency. A clinician who supervises trainees stated as follows:

> *I often have to prompt my learners to look in CareWeb.* [R18; y in practice: 6]

Other clinicians made the following observations:

> *The residents encourage us to use CareWeb more than we encourage them.* [R19; y in practice: 1]

> *We all use it. It's extremely helpful.* [R1; y in practice: 21]

All these responses suggest that for most clinicians, at least those in training hospitals, there is broad use and a social contract to use it regularly.

Social influences were less clear in community hospital settings. A clinician practicing in a community hospital stated as follows:

> *I think some of [my colleagues] are still requesting records from the coordinator...not knowing what that kind of information exchange is.* [R7; y in practice: 10]

Therefore, social influence is not ubiquitous across Indiana despite the fact that the HIE system has existed for >25 years.

Facilitating Conditions

Health care providers discussed several organizational and technical factors that acted either as facilitators or barriers to use. Some respondents worked in organizations that actively promoted HIE use through experienced colleagues who encouraged their peers to use the system. A nurse practitioner stated as follows:

> *[A] patient came in saying they were just seen and had a test done...I asked the provider if I should contact the facility for records, and he showed me the CareWeb log-in.* [R17; y in practice: 2]

However, few respondents indicated that their organization embraced the HIE system. Rather, their colleagues showed them how to use it or encouraged their use:

> *It's never been encouraged, and I've worked at three different hospitals here in [city].* [R20; y in practice: 21]

> *[I] don't know if it's a cost issue or utilization, um, but I think not having an auto enrollment, um, especially for providers is a disadvantage just because it's not available.* [R17; y in practice: 2]

Therefore, organizational processes may not be set up to encourage HIE use.

A lack of organizational support for HIE was also evidenced in comments from multiple respondents who indicated that they learned how to access and use the HIE system from colleagues or on their own:

> *I just sort of started using it and figured it out myself.* [R11; y in practice: 13]

Another respondent stated as follows:

> *We don't really include it in our formal onboarding or training of physicians.* [R1: y in practice: 21]

Moreover, none of the respondents indicated that the HIE system or anyone from the clinical organization provided updated, refresher training on the system:

> *There was never like, um, information session on how it can be used in a different, different ways that you can navigate through it that might be more beneficial.* [R3; y in practice: 1]

However, respondents did suggest that they perceived sufficient technical support to use the system when things did not seem to work:

> *I don't feel as frustrated now because I know I can rely on 24/7 technical support—there's always someone available.* [R14; y in practice: 4]

XSL•FO
RenderX

Other respondents similarly stated that they could contact the HIE organization directly or their hospital IT team and receive technical assistance with access or use.

Information Quality

All respondents emphasized the critical importance of information quality in the ED. The dimensions of quality mentioned often included completeness and information timeliness. The respondents expressed a strong desire for access to detailed past medical records, specifically laboratory results, imaging reports, encounter notes, and discharge summaries:

> *I need to make sure that they haven't had seven CT scans already in 2020.* [R2; y in practice: 14]

Many respondents noted that the availability of timely information, such as recent diagnostic tests, was critical for swift decision-making in the ED.

Although most respondents said that the INPC generally possessed needed information, they also identified gaps. Some respondents reported incomplete access to records from specialized care settings, such as psychiatric facilities or smaller independent health care providers:

> *Most patients get cardiology care at XYZ, and I almost never find an EKG from them.* [R11; y in practice: 13]

A frequently mentioned institution was the Veterans Health Administration, from which clinicians strongly desired information on encounters but perceived it as obtainable only after first making a telephone call to request details by fax. In addition, respondents highlighted difficulty in accessing raw imaging data, with some relying solely on reports due to the time constraints inherent in ED workflows.

System Quality

Nearly all respondents indicated that the INPC was reliable, especially when accessed through the virtual private network (VPN) connection that most were using for their EHR system. Few clinicians reported technical challenges, apart from a provider who had difficulty with their VPN connection from home. An experienced provider who has accessed the INPC in multiple ways over the years noted that VPNs and other modern networking solutions have reduced technical barriers to accessing the INPC, thus motivating increased HIE use. System upgrades and downtime, when they occurred, were noted by clinicians as challenging. However, most respondents noted that these events occurred infrequently and were no more bothersome than when their EHR systems experienced downtime.

Summary of Findings

Most ED clinicians had practiced in Indiana for >10 years (11/21, 52%) and reported being frequent users of the Indiana HIE, although several were categorized as low users based on system log-in events (eg, approximately 1-2 log-ins per mo). Knowledge of HIE was generally acquired during residency or through informal peer support on the job. Some clinicians received information about the CareWeb system when joining Indiana-based health systems from out of state. Clinicians unanimously emphasized the critical role of CareWeb in accessing patient information for informed decision-making and improving continuity of care.

Most clinicians recognized the utility of the HIE system while identifying areas for improvement, particularly in accessing the most relevant subset of information for clinical decision-making. HIE use was constrained by data availability, with most clinicians estimating its use for approximately 20% of their patient population. Ease of use, particularly the SSO functionality, was recognized as a key facilitator, allowing access with a single click from the EHR system directly into the patient's CareWeb record. Although clinicians noted the usability of CareWeb for retrieving data from multiple institutions where their patients received care, they identified gaps in institutional participation within the HIE network.

The clinicians reported that the system was reliable and fast, and they appreciated the availability of support for troubleshooting when needed. Nevertheless, many were unfamiliar with advanced features such as the intelligent search function, which could enhance efficiency by streamlining information retrieval compared to manually scrolling through multiple encounter records. Persistent gaps in training and limitations in system usability were identified as significant barriers to HIE use.

Discussion

Principal Findings

This study of ED clinicians working in various health systems with access to a mature, statewide intelligent communications system highlights the complex, interrelated, and multifaceted factors influencing HIE use. Although purposely sampled to include clinicians who rarely used the HIE system and those who use it regularly (based on log data), respondents generally reported using CareWeb regularly. The HIE system was overwhelmingly viewed favorably by the clinicians, who unanimously preferred accessing information from other hospitals via the system rather than relying on telephone calls or waiting for faxed records. Multiple effort, performance, social, and organizational factors encouraged HIE use. These included the level of integration with their EHR (eg, SSO and an "easy button"), access to comprehensive information that influenced decision-making, and peers who encouraged and demonstrated HIE use. Nevertheless, several clinicians reported multiple effort, performance, and organizational factors that discouraged use. These included information missing from specific sources, information overload, and lack of training. The findings have implications for the advancement and adoption of HIE networks, including policies to encourage HIE use and strategies to enhance HIE operations.

Importance of Research on HIE Use and Study Contributions

This study makes several important contributions to existing literature on HIE. First, the study used theoretical frameworks from the information sciences. A recent scoping review by Lum et al [17] identified gaps in HIE implementation studies and specifically encouraged researchers to "employ theoretical

XSL•FO
RenderX

frameworks." Second, most existing HIE literature focuses on organizational adoption of HIE systems and technologies (eg, whether a hospital reports having the capability to exchange information with outside hospitals [45,46]). Other studies have surveyed or interviewed clinicians before or just after HIE implementation [47,48], with virtually no research examining clinician perceptions years after implementation [19]. Moreover, few studies have assessed the level of use by clinicians, and while the annual American Hospital Association IT Survey asks organizations to report how "frequently do providers" use health information received electronically "from outside providers or sources," it is unclear how hospitals distinguish responses such as "often," "sometimes," or "rarely" [49]. In this study, respondents characterized their frequency of use, with most reporting regular use and estimating HIE use for approximately 20% of their patient population. Third, respondent comments provide valuable context to prior work that examined the benefits of HIE [2,50], underscoring that data available through HIE networks indeed influence clinical decision-making, have benefited patient outcomes, and are perceived as highly valuable to clinicians. In other words, HIE systems are critical components of intelligent communications in health care, as evidenced by respondents reporting that HIE information enhanced their diagnostic reasoning, improved continuity of care, and led to a reduction in duplicate procedures and tests, often influencing clinical decisions and potentially improving patient outcomes.

Implications for Advancing Adoption and Use of HIE

Interoperability and HIE remain key areas of focus for the Assistant Secretary of Technology and Policy and a global priority as specified in many nations' digital health strategies. Achieving greater adoption and use of HIE will require attention to the factors described in this study; for example, existing studies suggest that hospitals with strong adoption of HIE functionality report higher levels of HIE use [51,52]. Therefore, many states and nations will need to continue to focus on performance expectancy factors, improving clinician perceptions of the value of HIE [46,53], enabling clinicians to apply HIE knowledge to clinical decision-making, and making the right thing to do the easy thing to do [54]. Approaches to support performance expectancy include asking clinicians to share why they use HIE, conducting quantitative assessments of HIE benefits, and performing mixed methods studies of clinician use cases. One example is a statewide survey of clinicians in Virginia [55]. Addressing challenges, such as the usability of HIE systems [56], seamless log-in mechanisms [57], and other effort expectancy factors, will also be critical to securing routine adoption and use. Seamless integration with EHR systems, search functionalities, and ways to optimize interaction with comprehensive patient data are additional effort expectancy strategies implied by this study to support clinician use.

Social and organizational factors are also critical to HIE adoption and use. A weakness of the INPC is the lack of training for newly hired clinicians. None of the respondents could recall learning about the HIE during onboarding or training by staff from the HIE organization. While training is often part of HIE implementation, ongoing training for both new and existing users years after implementation is important to sustain and expand use. HIE networks should help health systems incorporate training into onboarding of new clinicians, or the HIE organization should offer regular in situ training opportunities for new employees. Online, on-demand training might also be a strategy to deliver information to existing users about new features (eg, search functionality) or new data sources added to the HIE. Moreover, HIE networks should work with their health care facilities to establish a culture in which regular HIE use is expected, fostering resiliency that ensures use well beyond the implementation phase.

Finally, the findings from this study call into question existing metrics [58] of clinician HIE use. Respondents reported using the HIE system for between 5% and 30% of their patients. These data might help refine expectations around what constitutes frequent versus "sometimes" use. Moreover, they imply that there is a theoretical maximum proportion of patients for whom accessing the HIE yields value. Given that this study focused solely on the ED setting, a ballpark figure of 20% of patients might not be appropriate for every HIE use case. Still, these data suggest that work is necessary to refine metrics for clinician use, which may be lower than some stakeholders expect or promote. Regardless of the proportion, it is clear that clinicians value having information from HIE networks for those patients whose care and outcomes can be meaningfully impacted.

Limitations and Future Directions for HIE Research

This study has several limitations. First, the study involved perspectives from clinicians on a single HIE network that has been operational for many years, and the participants primarily worked in health systems with established EHR use. Therefore, the results may not generalize to all HIE networks despite our efforts to purposely sample clinicians in different roles and practicing at hospitals of varied sizes and in diverse locations. Second, respondents worked in the ED, and perspectives from other specialties may differ. Third, despite our best attempts to interview clinicians who do not use the HIE system regularly, all respondents indicated that they use it on a regular basis. This might bias the findings because clinicians who purposely avoid using or have never used the HIE system were not interviewed.

While this study provides meaningful insights into HIE use in the ED setting, more research is needed to measure HIE use in various clinical settings and establish better indices for clinician use. Longitudinal studies on HIE use in relation to clinical outcomes could more firmly establish the evidence base needed to guide policy and practice. Cost-effectiveness studies involving clinician use data from logs could better demonstrate the value and return on investment of HIE infrastructure. Future research should examine the role of emerging technologies in enhancing HIE functionality, such as artificial intelligence summaries of clinical documents or comprehensive records, and their impact on clinician use. In addition, future research could explore potential differences in HIE use and perceptions across clinical roles (eg, physicians, nurses, and advanced practice providers) using a larger sample size and a mixed methods analysis approach.

XSL•FO
RenderX

Conclusions

This study of ED clinicians' perspectives illuminated several factors that facilitate or inhibit HIE use. As policymakers and health systems develop strategies to implement nationwide HIE, noting and leveraging these factors could be useful in achieving the goals of universal HIE adoption and use. Supporting clinicians' performance and effort through advanced HIE technologies will be critical for adoption and for impacting care outcomes and costs.

Abstract

Background: Metabolic dysfunction–associated fatty liver disease (MAFLD) is a leading cause of chronic disease and can progress to liver fibrosis or hepatocellular carcinoma. Its subtypes—obese, diabetic, and lean—are associated with varying degrees of fibrotic burden and different complications, yet the existing analytics methods often overlook its multisystem nature, intraphenotype variability, and disease dynamics. These limitations hinder accurate risk stratification and restrict personalized intervention planning.

Objective: This study developed a novel, 2-stage, contrastive learning–based method to predict the phenotype of MAFLD among adults. This method leverages multiview contrastive learning; it models individual heterogeneities and important relationships in clinical and survey-based data to predict phenotypes among adults, thus supporting clinical decision-making and personalized care.

Methods: Demographic, clinical, lifestyle, and genetic family history data of 4408 adults revealed how capturing essential relationships in patient data from different sources can transform individual-level representations into multiple, complementary views. Evaluation of the predictive efficacy of the proposed method in comparison with 8 prevalent methods relied on recall, precision, F_1-score, and area under the curve values. Moreover, a Shapley additive explanation analysis was performed for interpretability.

Results: The proposed method consistently and significantly outperformed all benchmark methods. It attained the highest F_1-score, showing a 32.8% improvement for nondiabetic MAFLD (0.531 vs 0.400) and 30.4% improvement for diabetic MAFLD (0.519 vs 0.398) over the respective best-performing benchmark. The results underscore the clinical value and utility of integrating clinical and survey-based data in the prediction of MAFLD phenotypes among adults.

Conclusions: The proposed method is a viable approach for MAFLD phenotype prediction. It is more effective in identifying at-risk adults than many prevalent data-driven analytics methods and thereby can enhance clinical decision-making and support patient-centric care and management.

Introduction

Background

Metabolic dysfunction–associated fatty liver disease (MAFLD) is a leading cause of chronic liver disease, affecting more than one-third of the global population [1,2] and resulting in annual, direct medical costs of US $103 billion in the United States and €35 billion (US $40 billion) in Europe [3]. The relabeling of nonalcoholic fatty liver disease as MAFLD reflects a deeper understanding of fatty liver disease [4]. It also helps identify adults at risk of serious prognoses [5] such as liver cirrhosis and hepatocellular carcinoma, which account for most liver-related deaths [6,7]. The exacerbation of comorbid conditions due to MAFLD amplifies its clinical significance; patients with chronic liver diseases often develop severe infections, chronic cardiovascular or kidney disease, cancer, and death [8]. Yet, therapeutic options for devastating MAFLD-induced liver diseases are limited. Liver transplantation is the optimal treatment [9,10] but is greatly restricted by organ availability and financial costs [11].

A diagnosis of MAFLD requires hepatic steatosis in the presence of excessive weight, type 2 diabetes mellitus, or metabolic dysregulation, manifested in the obese, diabetic, and lean phenotypes (subtypes) of MAFLD, respectively [12]. These phenotypes have distinct prognostic values [5], fibrotic burden [13,14], and complications [15,16]. For example, the diabetic phenotype is characterized by severe insulin resistance and is associated with the highest risk of any-cause and disease-specific mortality [17]. The obese phenotype is related to lifestyle factors (eg, diet and physical inactivity) and can lead to systemic inflammation and metabolic dysfunction. The lean phenotype involves ectopic fat deposition and genetic predispositions to MAFLD, although without obesity [18]. Because of the differences between the MAFLD phenotypes, accurate phenotype prediction is crucial for clinical decision-making, personalized care planning, and efficient resource allocation [19]. With relevant insights into the underlying etiology and pathology [20], effective phenotype prediction can facilitate patient stratification and treatment planning for streamlining diagnostic procedures, optimizing the use of laboratory tests or imaging, and specifying necessary lifestyle changes, all of which have cost-containment implications [21-23].

Physicians usually rely on liver biopsies [24,25] or score-based methods [26,27] that require contemporaneous clinical data, impose substantial costs, and misidentify at-risk adults. These constraints favor the potential of data-driven analytics for supporting timely identification of at-risk adults such that clinicians can formulate actionable risk reduction measures and effective patient stratification and researchers can design more appropriate clinical trials and treatment plans [28]. Despite the promise, data-driven analytics for MAFLD phenotyping face several challenges. First, MAFLD is a multisystem disease [29] because clinical, family genetics, lifestyle, and socioeconomic factors can influence fatty liver development and progression [30]. Incorporating such heterogeneous data in analytics methods, which typically are gathered from different sources, is difficult. For example, surveys designed to gather genetic family history data or lifestyle data tend to have small samples and often suffer from data incompleteness. Second, due to the complex nature of MAFLD, people with the same MAFLD phenotype may exhibit intraphenotype variability in etiology or pathology, which also should be considered for phenotype predictions. Third, both disease classification hierarchy and manifestations of MAFLD involve temporal complexity at the individual level.

Objective

In an effort to design a data-driven method to predict MAFLD phenotypes more accurately, we developed a novel, 2-stage, contrastive learning–based method. This method leverages graph representation learning, in combination with interindividual similarity, to process integrated individual-level data pertaining to genetic family history or lifestyle, which then can inform downstream predictions by complementing (incomplete) survey-based data with clinical data or vice versa. In addition, the proposed method incorporates multiview, contrastive pretraining that captures intraphenotype variability on the basis of clinical, genetic family history, and lifestyle data. By linking important data from different sources, it constructs individual-level representations for downstream tasks and predictions. Finally, its 2-stage estimation design accounts for disease hierarchy and temporal complexity, such that the proposed method can predict phenotypes among adults more accurately and explicitly than the existing analytics methods.

To demonstrate the predictive efficacy of the proposed method, we used clinical and survey-based data of 4408 adults in Taiwan [31] and included 8 prevalent methods as benchmarks. The results indicated that the proposed method consistently and significantly outperformed all the benchmarks in both F_1-score and area under the curve (AUC). This novel method can predict phenotypes accurately and can potentially contribute to medical informatics research and support personalized care for at-risk adults.

MAFLD and Its Phenotypes

Clinically, MAFLD involves metabolic abnormalities [32], and its diagnosis requires hepatic steatosis, which can be determined by imaging, blood biomarker scores, or liver biopsies [20]. Adults diagnosed with MAFLD often differ in their phenotypes, prognoses, and complications [5], leading to distinct clinical manifestations and metabolic characteristics. For example, diabetic MAFLD is characterized by diabetes mellitus, independent of BMI, and exhibits a higher fibrotic burden than other phenotypes, with substantial risks of hepatocellular carcinoma [33] and cardiovascular disease (CVD) [15]. Both obese MAFLD and lean MAFLD are determined on the basis of BMI: ≥23 kg/m² and <23 kg/m², respectively. The former condition involves excess adiposity and is associated with insulin resistance, systemic inflammation, and increased risk of cardiovascular complications [34]. The latter, also known as metabolic dysregulation, is characterized by metabolic abnormalities, and individuals with this phenotype are at a greater risk of liver-related complications and mortality [21]. Because both obese MAFLD and lean MAFLD are determined

XSL•FO
RenderX

on the basis of BMI, they can be considered in combination for phenotype predictions. Phenotypic heterogeneity reflects the significant complexity of MAFLD and its varied pathophysiological mechanisms [35], which stem from demographic characteristics, clinical variables, lifestyle factors, and genetic predisposition [36].

In turn, the heterogeneity and complexity of MAFLD make timely, accurate phenotype prediction important but difficult. Notably, MAFLD is reversible in its early stages, with appropriate lifestyle changes and clinical interventions [35]. On the other hand, advanced stages can induce liver diseases and are associated with poor prognoses [37]. In general, accurate phenotype predictions are needed within a 1-year timeframe [38] because MAFLD often exhibits few or no directly observable symptoms until liver damage has occurred. By identifying at-risk adults in a timely manner, physicians can encourage lifestyle changes such as dietary alterations or reduced alcohol consumption [39,40] and plan for laboratory tests or imaging examinations (eg, abdominal ultrasound) [36].

Data-Driven Analytics Methods for Patient Risk and Outcome Predictions

Existing data-driven analytics for MAFLD phenotype predictions rely on regression-based [41-43], tree-based [44-46], neural network (NN)–based [47-49], or graph-based [50-52] methods. Regression-based methods, such as Cox regression–based risk estimation [42] and logistic regression models [43], use statistical modeling to predict patient risk and outcomes, support patient risk predictions, and identify important factors. However, these methods cannot deal with high-dimensional data or nonlinear relationships and often make strong data property assumptions. A tree-based method can model nonlinear relationships and derive predictions by applying variable values to split the data recursively, as exemplified by decision tree (DT) [44], random forest (RF) [45], and extreme gradient boosting (XGBoost) [46] methods. While intuitive and interpretable, tree-based methods struggle with overfitting in the presence of noise or data sparsity, and they cannot handle missing data or individual heterogeneity effectively [53]. The deep learning, NN-based methods are able to model complex relationships and nonlinear interactions [54]. For example, deep autoencoders [49] and multilayer perceptron (MLP) [48] methods are advantageous for representing multisource data with high-dimensional features. But they can be difficult to train and are prone to overfitting, especially with insufficient, incomplete, or low-quality data [55]. Finally, graph-based methods represent data as nodes and edges in a graph; they are designed to capture complex relationships and interactions among entities (eg, patients and medications) to inform downstream predictions. Representative methods include graph convolutional networks (GCNs) [56], graph attention networks (GATs) [57], and GraphSAGE [58]. Despite their general effectiveness, graph-based methods rely on predefined graph structures, which can restrict their ability to account for complex, multifaceted, individual feature interactions.

As summarized in Table 1, the existing analytics methods seem generally effective for estimating patient risk and outcome, but their direct use for MAFLD phenotype prediction is insufficient for several reasons. First, many methods depend on clinical data available in electronic health records, which prevents them from accounting for the multifactorial nature of MAFLD. For example, effective phenotype prediction needs to consider genetic family history and lifestyle data, but the incorporation of such data complicates the modeling and obscures patterns essential for accurate prediction, in addition to sample size and data incompleteness issues. Second, most of the prevalent methods do not capture intraphenotype variability, which is critical for downstream predictions. For example, semisupervised (eg, contrastive) learning can deal with complex representations [59-61], but its use requires data augmentation [62-65] and complementary views [66], in addition to the tabular data common in healthcare settings. Third, MAFLD phenotype prediction involves disease classification hierarchy and temporal dynamics. For instance, individuals are classified as those with and without MAFLD (MAFLD and non-MAFLD, respectively), and those with MAFLD need to be further classified into distinct phenotypes by a selective layer, which implies a priori knowledge to inform appropriate feature selection.

Methods

Materials

We used 2-year longitudinal data of 4408 adults, obtained from a major healthcare organization in Taiwan, to evaluate the proposed method in comparison with 8 prevalent methods. No adults in the sample had MAFLD in year 1. For each person, the data include 2 demographic variables, 36 clinical variables, 32 lifestyle variables, and 42 genetic family history–related variables. Multimedia Appendix 1 provides the description and coding of variables. With these data, we evaluated the ability of each method to predict whether a person would develop MAFLD in year 2 and, if so, of which phenotype.

Of the 4408 individuals in our sample, 2999 (68.1%) were women, and 1409 (31.9%) were men, with an average age of 58.18 (SD 12.94) years. The outcome class distribution was imbalanced: 85.0% non-MAFLD (3747/4408), 11.5% nondiabetic MAFLD (507/4408), and 3.5% diabetic MAFLD (154/4408). We used class weights during model training to address the imbalance issue. Prior to making phenotype predictions, we applied z score standardization to numeric variables and one-hot encoding to categorical variables to prepare the data.

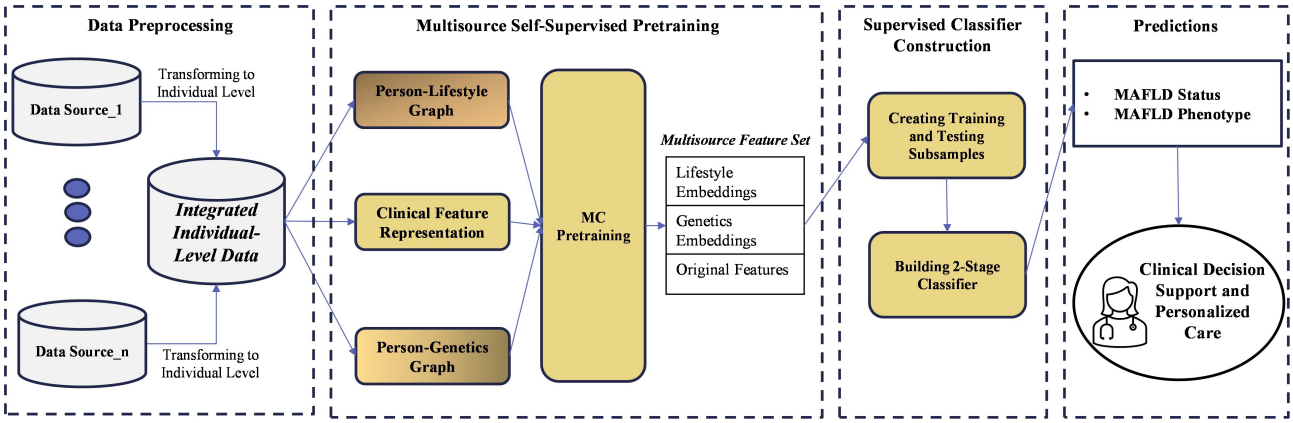
Ethical Considerations

This study was approved by the Chang Gung Medical Foundation Institutional Review Board (201800270B0). All procedures were performed in accordance with relevant guidelines and regulations. Written informed consent was obtained from all participants. All patient information was anonymized prior to analysis, and the study complied with ethical standards for research involving deidentified healthcare data. Participants were informed that their involvement was voluntary and that they could withdraw from the study at any time without penalty. No financial compensation was provided.

Proposed Method

Problem Definition

Let D be individual demographics, C represent clinical variables, S denote genetic family history–related and lifestyle data, and Y indicate distinct MAFLD outcomes. Phenotype prediction represents a multiclass classification task: given D, C, and S, the objective is to effectively process S based on the observed values, then integrate with D and C to predict whether an individual is likely to develop a specific MAFLD phenotype within a 1-year timeframe. By effectively processing S, it is possible to extract useful information from S, to better cope with the missingness that often arises among self-reported genetic family history data and lifestyle data for improved predictive efficacy. We considered 3 outcome classes for the multiclass classification task, Y=Y1,Y2,Y3, which correspond to the non-MAFLD, nondiabetic MAFLD, and diabetic MAFLD phenotypes, respectively. The combination of obese MAFLD and lean MAFLD phenotypes into a single outcome class (nondiabetic MAFLD) is justified because both phenotypes rely solely on BMI. It also simplifies the outcome class classification and allows for meaningful, accurate predictions, in that physicians can readily separate obese and lean MAFLD according to BMI values, which offers clinical practicality [33,72] and facilitates predictions [73,74].



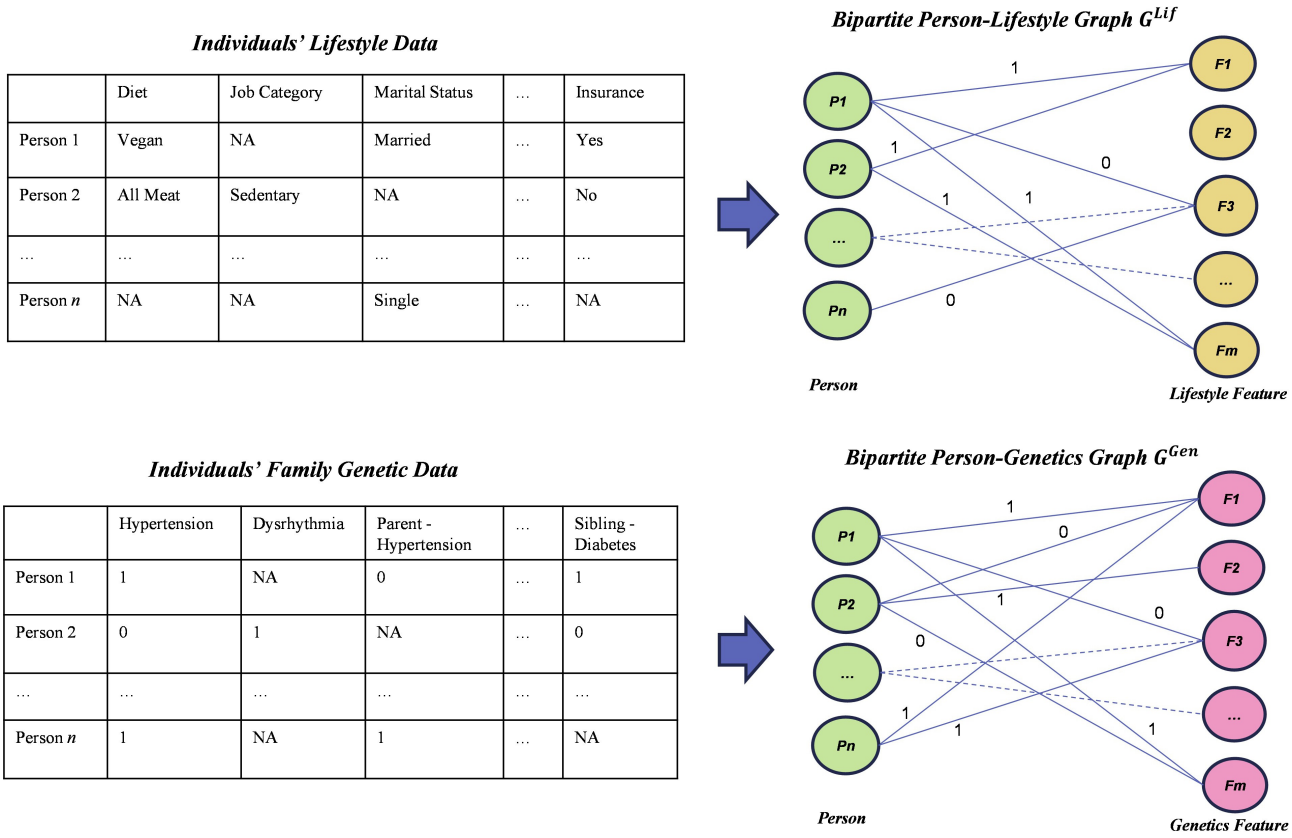
Architectural Framework

Figure 1 depicts the proposed method's architectural framework and highlights its 3 important components: graph representation learning, multiview contrastive pretraining, and 2-stage risk

XSL•FO
RenderX

estimation. With graph representation learning, the method uses sparse, incomplete survey data to build 2 individual-feature bipartite networks, a person-lifestyle graph and a person-genetics graph, which are used to learn graph representations. The multiview contrastive pretraining component then uses the individual graph representations as inputs to capture intraphenotype variability and create lifestyle and genetics embeddings. Finally, these embeddings are combined with demographic and clinical data in the 2-stage risk estimation process to predict the likelihood of each outcome class for an individual.

Figure 1. Architectural framework of the proposed method. MAFLD: metabolic dysfunction–associated fatty liver disease; MC: multiview contrastive.



Graph Representation Learning

We used lifestyle and genetic family history data to perform the novel graph representation learning and construct both person-lifestyle and person-genetics networks. The former captures relationships among individuals according to their lifestyle predispositions (eg, shared dietary habits and physical activities). The latter leverages genetic family history–related variables (eg, shared alleles and single nucleotide polymorphisms) that can influence individuals' biological or genetic predispositions. These 2 networks were constructed separately to enable the graph representation learning component to concentrate on unique structures and relationships intrinsic to each type of data, thereby capturing the interplay of lifestyle and family genetic variables.

Figure 2 illustrates the construction of 2 bipartite networks. For the person-lifestyle bipartite network, GLif={VPLif,VFLif,ELif}, VPLif={P1,P2,…,PN} refers to a set of individuals, VFLif={F11,F12,…Fij,…,FMJ} represents lifestyle features, and ELif denotes an edge set that links VPLif and VFLif. N and M denote the total number of individuals and lifestyle feature values, respectively. For each lifestyle feature, multiple nodes are used to indicate its plausible (coded) values. J denotes the number of distinct values or categories of FM; thus, Fij denotes the jth category of feature Fi. If person Pu has a value on lifestyle feature Fv of the jth category, there exists an undirected link eu,vj between nodes Pu and Fvj, and the edge weight reflects Pu's value on feature Fvj.

XSL•FO
RenderX

Figure 2. Graph representation learning component of the proposed method. NA: not applicable.

	Diet	Job Category	Marital Status	…	Insurance
Person 1	Vegan	NA	Married	…	Yes
Person 2	All Meat	Sedentary	NA	…	No
…	…	…	…	…	…
Person *n*	NA	NA	Single	…	NA

	Hypertension	Dysrhythmia	Parent - Hypertension	…	Sibling - Diabetes
Person 1	1	NA	0	…	1
Person 2	0	1	NA	…	0
…	…	…	…	…	…
Person *n*	1	NA	1	…	NA

For the person-lifestyle bipartite network, we used GraphSAGE [58] to learn representations for the nodes and edges. We relied on triplet loss to train the graph representation model, which involved an anchor node, a positive sample (neighboring nodes or the node itself if no neighbors existed), and a negative sample:

$$(1)L=\max(0,d(f(a),f(p)-f(a),f(n))+\alpha)$$

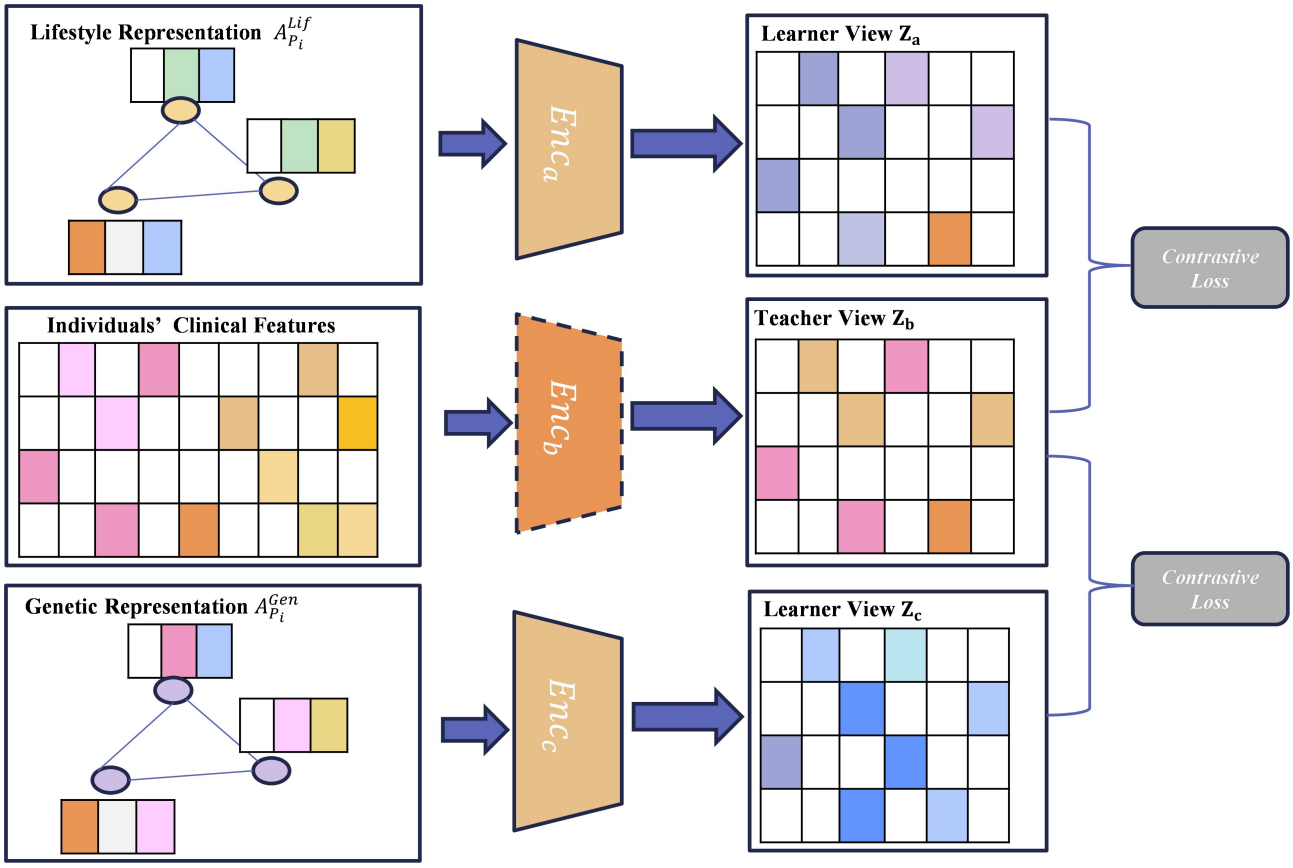
where a is the anchor node, p is the positive node, n is the negative sample, d(·) is the distance function, f(·) is the embedding function, and α is a margin parameter. APiLif represents the learned node embedding for each person Pi. Similarly, we built the person-genetics bipartite network, GGen={VPGen,VFGen,EGen}, to learn the genetic representation APiGen. The representations learned from these 2 networks provided the input for the contrastive pretraining component.

Multiview Contrastive Pretraining

Originally developed for computer vision tasks, contrastive learning leverages data augmentation and complementary views for effective representation learning [66]. Conventional, supervised learning faces multifaceted challenges, especially when dealing with high intraclass variance and imbalanced outcome class distribution. Contrastive learning offers a viable solution by learning data representations through instance discrimination. The core idea is intuitive: instead of solely relying on labeled examples, contrastive learning learns to distinguish among different patients while ensuring that similar patients have similar representations in the learned feature space. This self-supervised approach can learn robust features, particularly in scenarios involving limited or imbalanced labeled data. However, existing contrastive learning methods, such as MoCo [63] and SimCLR [65], rely heavily on data augmentation techniques such as cropping and rotation in images, which are not directly applicable to structured patient data.

We designed a novel multiview contrastive pretraining component that leverages multiple context-specific representations to capture intraphenotype variability. In the proposed method, multiview contrastive learning examines patients' clinical profiles from multiple perspectives and learns discriminative representations that better predict infrequent but important MAFLD subtypes while maintaining performance across different categories. For this task, an intuitive learning objective can be defined by the cosine similarity among individuals, according to the person-lifestyle representation APiLif, person-genetic representation APiGen, and clinical data C. The intent is to capture intraphenotype variability. We applied guided, collaborative training to steer the training process, for which we used clinical variables for the teacher view and survey-based, context-specific representations (APiLif and APiGen) for the learner views. The resulting model can integrate and align critical information from clinical and survey-based data.

Figure 3 depicts the contrastive pretraining component, in which 3 encoders (Enca, Encb, and Encc) process the representations of lifestyle data, clinical data, and genetic family history data, respectively. Thus, Encb is pretrained with an autoencoder to produce the teacher view that anchors the learning process. As learner views, Enca and Encc are trained according to Encb during the contrastive learning process. Both Enca and Encc adopt the same 3-layer MLP with nonlinear activation functions. The outputs of Enca, Encb, and Encc are represented by za, zb, and zc, which denote the embeddings of lifestyle, clinical, and



XSL•FO
RenderX

genetic family history data, respectively. For a person Pi, the objective is to align the cosine similarity of the embeddings of positive pairs {za(i),zb(i)} and {zc(i),zb(i)}, according to the infoNCEloss:

(2)Lcontrastive(za,zb)=−log⁡exp⁡(sim(za(i),zb(i))/τbatch)∑k=1nexp⁡(sim(za(i),zb(k))/τbatch)

where sim(·,·) is the similarity function, and τbatch is the temperature parameter.

Figure 3. Multiview contrastive learning component of the proposed method.

In contrastive learning, fixed temperature settings are generally ineffective for heterogeneous data distributions [75]. Therefore, we designed an adaptive temperature network (ATN) to adjust the temperature, τbatch, dynamically. As a lightweight NN, the ATN uses batch-level aggregated statistics as input and generates a single temperature value:

(3)Vbatch=1n∑inzb(i)

and

(4)τbatch=W·Relu(Vbatch)

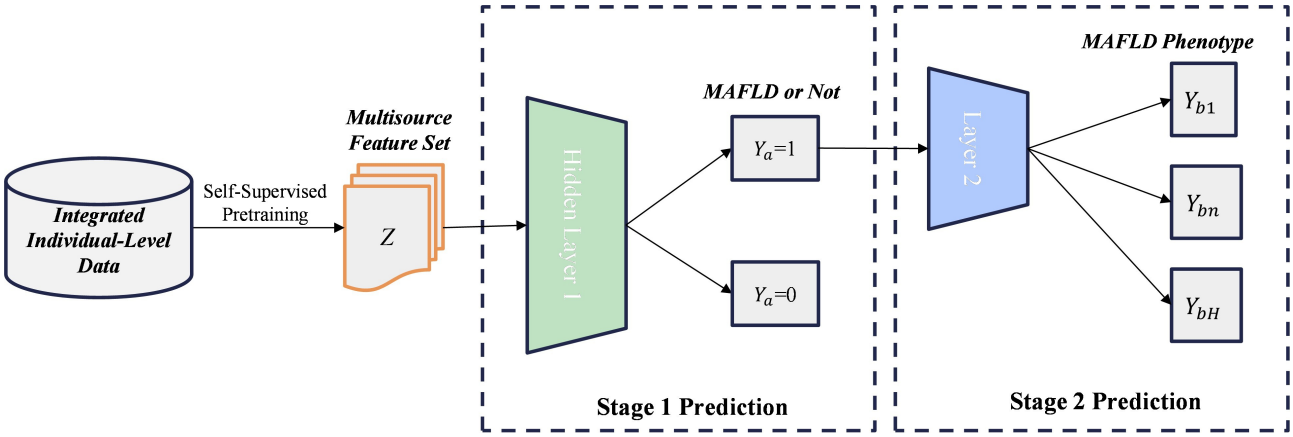
where n is the batch size; Vbatch is the aggregated feature representation, calculated as the batch average of clinical representations {Zb(i)}; and τbatch is the temperature value for each data batch.

Both Enca and Encc are trained with a cross-entropy loss:

(5)Ltotal=Lcontrastive(za,zb)+Lcontrastive(zc,zb)

where Lcontrastive(za,zb) and Lcontrastive(zc,zb) reflect the contrastive loss between za and zb and zb and zc, respectively.

Multiview contrastive learning ensures that the learned lifestyle and family genetics embeddings (learner view) align with the clinical embeddings (teacher view), which enhances representation quality.



Two-Stage Risk Estimation

Finally, the 2-stage deep NN component for MAFLD phenotype prediction targets important interphenotype relationships. As depicted in Figure 4, this component estimates whether a person is likely to develop MAFLD (Y^i,a=[Y^i,a1,Y^i,a2]), such that Y^i,a1=1 if there is an indication of any MAFLD phenotype and Y^i,a1=0 otherwise. In the former case, the component then estimates the likelihood of a specific phenotype and produces the probability distribution Y^i,b=[Y^i,b1,…,Y^i,bH], corresponding to distinct phenotypes, where H is the total number of phenotypes. This hierarchical estimation design enables the proposed method to capture general characteristics of MAFLD and distinct phenotypes for predictions. The overall probability distribution Y^i can be calculated as follows:

(6)Y^i=[1−Y^i,a1,Y^i,b1·Y^i,a1,Y^i,b2·Y^i,a1,Y^i,b3·Y^i,a1,…,Y^i,bH·Y^i,a1]

XSL•FO
RenderX

Figure 4. Two-stage phenotype prediction component of the proposed method, where Y_a represents the first-stage binary prediction, indicating the presence (Y_a=1) or absence (Y_a=0) of any MAFLD phenotype. Y_b represents the second-stage probability distribution over the H specific phenotypes, which is subsequently estimated if Y_a=1. Y_{b1}, Y_{bn}, and Y_{bH} denote the estimated probabilities for the first, -th, and -th (final) specific MAFLD phenotypes, respectively. MAFLD: metabolic dysfunction–associated fatty liver disease.

In the 2-stage estimation process, we also designed a loss function to train the proposed method:

(7)Ltotal=−∑i=1Nyi(n)log(y^i(n))+γ(−∑i=1Kyi,a(k)log(y^i,a(k)))+λ(−∑i=1Mbi(m)log(y^i,b(m)))

The first term of Ltotal is the negative log-likelihood loss, calculated according to the actual and predicted MAFLD phenotype. The second and third terms denote the losses in the first and second stages, respectively, and γ and are hyperparameters that control the trade-offs among these 3 terms. Specifically, y^i(n) indicates the overall predicted probability of the nth class for person i, y^i,a(k) is the estimated probability of MAFLD (binary, k=2), and y^i,b(m) denotes the estimated probability of the mth phenotype for individuals predicted to have MAFLD in stage 2. With Ltotal, our method learns interphenotype relationships for phenotype prediction.

Evaluations

Eight prevalent methods were included as benchmarks: DT [44], RF [45], XGBoost [46], MLP [48], autoencoder [49], GAT [57], GCN [56], and GraphSAGE [58]. These methods represent different analytics approaches and are frequently used for clinical prediction tasks; therefore, they are suitable for performance comparisons. Many of these benchmark methods are not designed to deal with incomplete data. Because the sample had missing values, we applied k-nearest neighbor (k=5) imputation [76-78] to the dataset and used one-hot encoding for categorical variables during data preprocessing to ensure consistency and comparability in the evaluations, that is, all methods used the same preprocessed data for fair comparisons. The only difference was that the proposed method also used the raw, nonimputed survey data (genetic family history and lifestyle data) as input for graph representation learning and contrastive learning, which are components capable of handling missing values. Moreover, we conducted an ablation study to examine the relative contribution of each key component to the proposed method's overall performance.

To examine the prediction performance of each method, we randomly split the sample 10 times, using different random seeds to ensure robustness. In each trial, we used 80% of the data for model training and the remaining 20% for testing [76]. We also conducted 5-fold cross-validation on the training data prior to the evaluations and performed a series of analyses to fine-tune the key parameters of each method. Multimedia Appendix 2 summarizes important parameter values of the respective methods. Performance assessments relied on precision, recall, F_1-score, and AUC values. We did not consider accuracy, as it could not reflect prediction performance due to the imbalanced distribution of the outcome classes [79]. Compared with precision or recall, the F_1-score and AUC are arguably better indicators of a method's efficacy of predicting MAFLD phenotypes. As reported by Docherty et al [80], we adopted a one-versus-rest strategy to assess each outcome class and compared the respective AUC values of all methods, which supports a fair, holistic analysis of their ability to predict MAFLD phenotypes.

Results

Overall Prediction Performance

Table 2 presents each method's prediction performance across 10 trials. The proposed method has a 2-stage estimation design—stage 1 estimates whether an individual will develop MAFLD, and stage 2 predicts the likelihood of each MAFLD phenotype. Therefore, we report the results for each stage separately. As Table 2 shows, the proposed method attained higher AUC values in both stages, indicating its ability to distinguish patients with different outcomes. In stage 1, it accurately identified adults likely to develop MAFLD, with few false alarms, as signified by the relatively high precision and recall values. In stage 2, the proposed method generated effective predictions by consolidating the stage 1 results. The multiclass prediction results in stage 2 also allowed for direct comparisons with the benchmark methods. As seen in Table 2, the proposed method outperformed all benchmarks on both F_1-score and AUC. It exhibited a 7.2% improvement in AUC over the best-performing benchmark (0.898 vs 0.838) and had a 16.6% higher F_1-score than the best-performing benchmark (0.652 vs 0.559). Paired two-tailed *t* tests performed to examine differences in AUC indicated that the observed improvements were statistically significant (P<.001).

XSL•FO
RenderX

Figure 5 presents the respective receiver operating characteristic curves of all methods. The proposed method's AUC curve was notably better than that of any benchmark method. This result further affirms its superior efficacy in estimating MAFLD phenotypes among adults compared with many prevalent methods.

Prediction Performance for Each Outcome Class

In addition to overall performance, we examined the respective methods' performance for each outcome class. As shown in Table 3, the proposed method achieved the highest F_1-score and AUC values for each outcome class, reaffirming its superior prediction ability. It attained a higher F_1-score (0.913) and AUC (0.859) for non-MAFLD than the respective best-performing benchmarks (DT: F_1-score=0.908; GraphSAGE: AUC=0.801). The performance improvements were especially prominent for the MAFLD phenotypes. For nondiabetic MAFLD, our method achieved an F_1-score of 0.531, much higher than that of the best-performing benchmark (MLP: F_1-score=0.400), exhibiting a 32.8% improvement. It also attained the highest AUC (0.878), higher than that of the best-performing benchmark (GraphSAGE: AUC=0.804). For diabetic MAFLD, the proposed method's F_1-score (0.519) was 30.4% higher than that of the best-performing benchmark (GraphSAGE: F_1-score=0.398). Moreover, its precision value was superior to that of other methods, suggesting that it can identify adults who are likely to develop diabetic MAFLD with fewer false alarms.

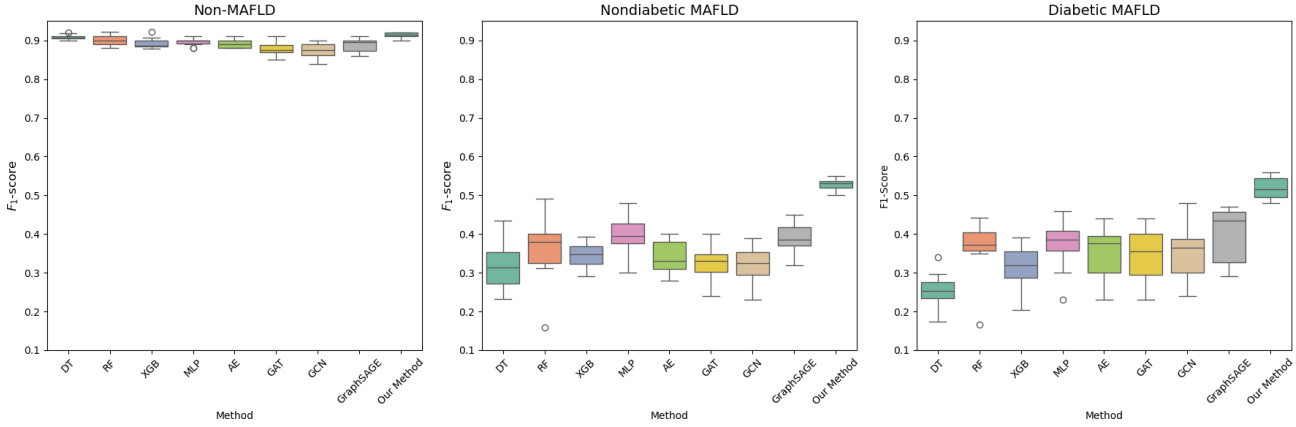
[a]MAFLD: metabolic dysfunction–associated fatty liver disease.

[b]XGBoost: extreme gradient boosting.

[c]MLP: multilayer perceptron.



[d]GAT: graph attention network.

[e]GCN: graph convolutional network.

The box plots in Figure 6 indicate the proposed method's robust performance for each outcome class across 10 trials. It attained high F_1-scores for each outcome class, especially nondiabetic MAFLD and diabetic MAFLD, while the benchmark methods exhibited notably greater variance and occasional outliers. Together, these plots provide further evidence of the proposed method's efficacy and value for clinical decision-making and patient management.

Figure 6. Box plots showing F_1-scores (median and IQR) of each method for different outcome classes. AE: autoencoder; DT: decision tree; GAT: graph attention network; GCN: graph convolutional network; MAFLD: metabolic dysfunction–associated fatty liver disease; MLP: multilayer perceptron; RF: random forest; XGBoost: extreme gradient boosting.

Ablation Study

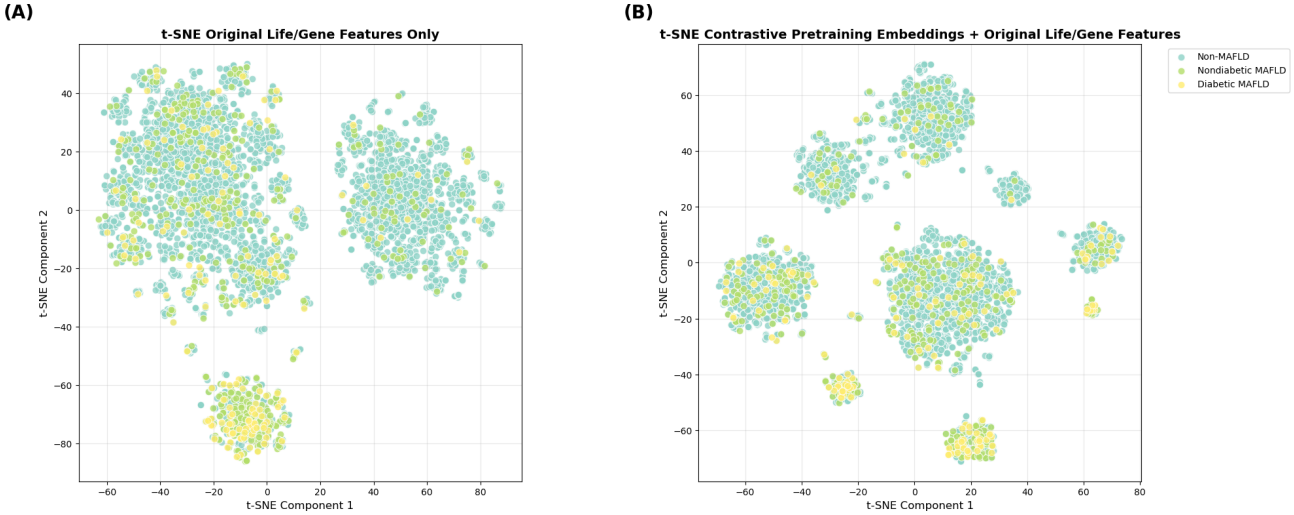
We also performed an ablation study to examine the relative contribution of each key component of the proposed method. We considered MLP, Graph, Graph + contrastive learning, and the (complete) proposed method. In essence, MLP serves as a baseline because it only uses the preprocessed data, without any key components of the proposed method. Graph builds on MLP and includes the graph representation learning of genetic family history and lifestyle data, together with the learned embeddings concatenated to the preprocessed dataset to train the MLP classifier. Graph + contrastive learning further extends Graph by incorporating contrastive learning after graph representation learning. The complete proposed method included all 3 key components. The results of the ablation study (Table 4) revealed how each component contributed to the method's performance. They jointly produced the best predictions, indicating that MAFLD phenotype prediction can benefit from graph representation, multiview contrastive pretraining, and 2-stage estimation design.

Table . Results of the ablation study.

Model	AUC[a]
MLP[b]	0.831 (0.002)
Graph	0.847 (0.004)
Graph + CL[c]	0.881 (0.001)
Complete proposed method	0.898 (0.003)

[a]AUC: area under the curve.

[b]MLP: multilayer perceptron.



[c]CL: contrastive learning.

Interpretability Analysis

To gain clinical insights into the proposed method's learned representations, we examined its interpretability by depicting the embeddings visually. Specifically, we applied t-distributed stochastic neighbor embedding (t-SNE) [81] to visualize the contrastive pretraining embeddings and performed a Shapley additive explanation (SHAP) analysis [82] to reveal feature importance. Figure 7A presents a visualization of the original lifestyle and genetic features, and Figure 7B provides a visualization of the features obtained by concatenating the contrastive pretraining embeddings with the original lifestyle and genetic features. The original lifestyle and genetic features exhibited a scattered distribution, without any clear patterns. With contrastive pretraining embeddings, more distinctive clusters emerged, suggesting that patients with similar characteristics tend to cluster more closely than those with dissimilar characteristics. While these visual plots are exploratory without formal proof of class separability, they still illustrate that incorporating contrastive pretraining embeddings can potentially create a more structured, distinguishable representation of patient outcomes for effective MAFLD phenotype prediction.

RenderX

Figure 7. T-distributed stochastic neighbor embedding (t-SNE) visualization of (A) original lifestyle and genetic (life/gene) features and (B) contrastive pretraining embeddings with lifestyle and genetic features. MAFLD: metabolic dysfunction–associated fatty liver disease.

We further examined the feature importance for each outcome class, as depicted by the SHAP summary plots in Figure 8. Because the proposed method adopted a 2-stage estimation (architecture) design, the model-agnostic explainer KernelSHAP was used with a background dataset of 100 training instances. For all test instances, SHAP values were computed on a representative model instance (ie, median test AUC across 10 trials). As seen in Figure 8, several metabolic indicators were important predictors consistently across different outcome classes. For example, BMI and waist circumference were highly influential. As Figure 8A shows, high BMI values (marked as red points) greatly reduced the likelihood of non-MAFLD predictions; particularly, high BMI and waist circumference values were associated with a greater likelihood of nondiabetic MAFLD or diabetic MAFLD, as shown in Figure 8B and C. Predictions of nondiabetic MAFLD were influenced by a combination of general metabolic indicators (eg, BMI and waist circumference) and lifestyle factors (eg, smoking and sleep disturbance). For diabetic MAFLD, definitive disease markers and factors related to disease consequence and management, such as self-care status and nutritional status (Mini Nutritional Assessment), appeared to be essential auxiliary predictors. These results align with clinical knowledge and reveal the proposed method's ability to capture phenotype-specific patterns from patient data, with desirable interpretability.

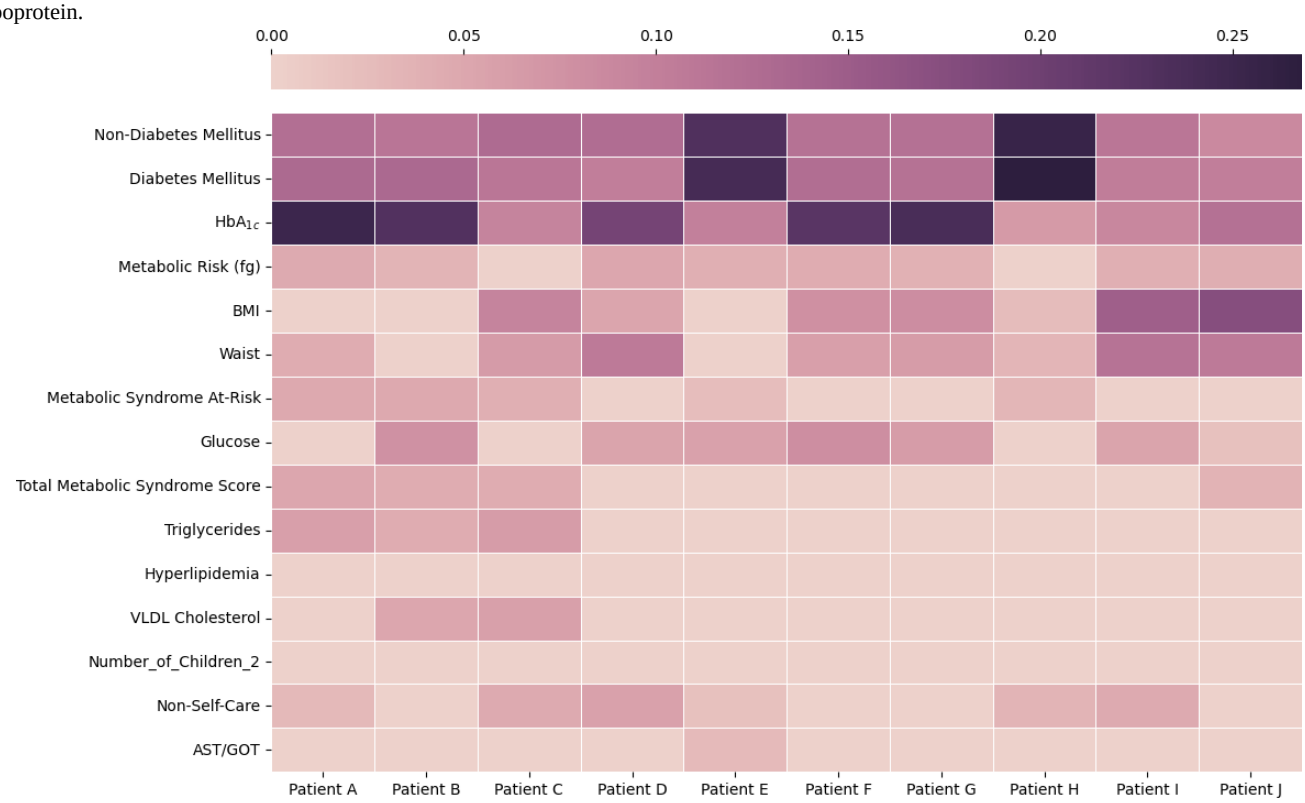

Figure 8. Summary plots of Shapley additive explanation (SHAP) values for (A) non–metabolic dysfunction–associated fatty liver disease (non-MAFLD), (B) nondiabetic MAFLD, and (C) diabetic MAFLD. ALT/GPT: alanine aminotransferase/glutamic-pyruvic transaminase; AST/GOT: aspartate aminotransferase/glutamic-oxaloacetic transaminase; CVD: cardiovascular disease; GGT: gamma-glutamyl transferase; HbA_{1c}: hemoglobin A_{1c}; MNA: Mini Nutritional Assessment.

Additionally, SHAP analyses allow for reasoning at the individual level. Figure 9 provides a visualization of SHAP values for 10 patients who were predicted to develop diabetic MAFLD. The heat map shows that diabetes mellitus and high hemoglobin A_{1c} diagnoses were consistently important predictors for most patients in this group, including patients B, G, and H. We also observed significant intraphenotype variability among patients. For example, the prediction for patient J was also significantly influenced by BMI and waist circumference, whereas triglycerides were a more important factor for patient C. The interpatient variability can help physicians better understand the impact of different factors at the individual level and thereby support personalized care and treatment planning.

XSL•FO
RenderX

Figure 9. Heat map of sample patients with the predicted phenotype diabetic metabolic dysfunction–associated fatty liver disease (diabetic MAFLD) and top 15 features. AST/GOT: aspartate aminotransferase/glutamic oxaloacetic transaminase; HbA_{1c}: hemoglobin A_{1c}; VLDL, very-low-density lipoprotein.

Discussion

Principal Findings

The proposed method leverages deep learning to estimate MAFLD phenotypes among adults, using graph representation learning and contrastive learning. It provides several methodological novelties that can advance medical informatics research and enhance clinical decision-making for improved patient management. The evaluation results establish its predictive efficacy, demonstrate the value of combining clinical and survey-based data, and underscore the importance of intraphenotype variability and disease dynamics for MAFLD phenotype prediction. Furthermore, this method is generalizable and can be applied to other prediction tasks in similar clinical scenarios (eg, gauging the risk of diabetes or CVD) that feature multisource data, individual heterogeneities, intraclass variance, and intervariable relationships.

Using the proposed method, physicians will be able to identify individuals at higher risk of fibrosis and generate timely alerts for effective patient-centric care [83], which can mitigate the likelihood of significant disease progression and serious patient outcomes. Accurate prediction of MAFLD phenotypes also helps reduce hepatic complications such as CVD, chronic kidney disease [16], hepatocellular carcinoma [6], osteoporosis, endocrine disorders, and cognitive impairment [84]. The proposed method is capable of distinguishing high-risk versus low-risk adults on the basis of pathogenesis, spanning lifestyle, genetic, and metabolic factors; as a result, the likelihood of fibrosis or cirrhosis can be reduced, with broad implications for precision medicine and drug development [85]. In a related sense, its ability to predict phenotypes in an accurate and timely manner also enables personalized surveillance, treatment choice assessments, lifestyle changes, and treatment planning.

Although the proposed method does not achieve an objectively high F_1-score for MAFLD phenotypes, it still offers meaningful improvements over prevalent methods, even in the presence of the inherent challenges created by highly imbalanced patient clinical data. In our sample, most adults were in the non-MAFLD category, and few had MAFLD phenotypes, which made model training difficult for every method we investigated. This challenge is common to many clinical settings and has been documented across different patient outcome or risk prediction tasks. For example, recent related studies report F_1-scores in the range between 0.10 and 0.51 for minority classes [86,87]. Despite this persistent difficulty, the proposed method consistently outperformed all the benchmarks on MAFLD phenotypes (minority classes), which are clinically important. Hence, the observed improvements with our method represent valuable advances [22,88].

We illustrate the clinical use of the proposed method as a proactive risk stratification approach for clinical decision support and patient management. In stage 1, it estimates the probability of a person developing MAFLD within 1 year. To flag individuals as high risk, a physician can use the probability to select a decision threshold for balancing the trade-off between precision (the proportion of flagged individuals who are truly at high risk) and recall (the proportion of all true positive individuals who are truly flagged as high risk). If the physician prefers high certainty, they can choose a high threshold value. For example, our post hoc analysis showed that by setting the

XSL•FO
RenderX

threshold to 0.60, the proposed method's precision increased to 0.777, that is, approximately 78% of flagged patients indeed developed MAFLD. By choosing an even higher threshold value of 0.70, its precision further increased to 0.820, although at the cost of reduced sensitivity (0.59 in recall). As a result, the physician can identify adults who should be monitored more closely (for example, a semiannual follow-up instead of an annual follow-up), need immediate lifestyle counseling, or require proactive baseline liver function tests to track changes over time.

Furthermore, the proposed method provides additional insights based on the stage 2 estimate, which can support personalized planning and care. In general, obtaining clinically meaningful precision requires a higher threshold value. For example, with a threshold value of 0.50, the proposed method's precision reached 0.506 for nondiabetic MAFLD and 0.500 for diabetic MAFLD. Emphasizing high-probability instances with a threshold value of 0.70 increased the precision to 0.762 and 0.778, respectively, which would allow physicians to tailor management strategies for adults whose phenotype can be predicted with higher confidence. Additionally, physicians can leverage the instance-level SHAP analysis, as depicted in Figure 9, to identify the specific factors that drive patient risk. While these insights do not directly indicate a definitive diagnosis, they can still guide physicians to engage in preventive care through patient risk stratification, while coping with the challenge of precise phenotype classification. Overall, physicians can adopt an appropriate threshold value to balance precision and recall while minimizing the likelihood of missing at-risk individuals for proactive stratification.

In summary, a multiview architecture leverages complementary information from lifestyle, genetic, and clinical data perspectives for richer representations that help distinguish infrequent yet clinically important MAFLD phenotypes, without sacrificing interpretability. The 2-stage design offers flexibility and additional utility. Accurate and robust estimates in stage 1 help physicians assess whether or not an individual is likely to develop MAFLD for initial screening purposes. In addition to that determination, even a moderate improvement in the F_1-score in stage 2 can facilitate physicians' decision-making by providing additional information and clinical insights. These valuable risk stratification capabilities enable physicians to identify high-risk adults who may need close monitoring or alternative treatments. The 2-stage design also offers beneficial flexibility. Physicians can adjust their focus across the first or second stage, depending on their objective (eg, early screening, risk stratification, or intervention planning). According to 2 experienced hepatologists (who wish to remain anonymous), "Early, better estimates of individuals' likelihood of MAFLD is valuable clinically," and "The use of data-driven analytics methods to predict MAFLD phenotypes can enhance clinical decision-making and personalized patient management" (September 2, 2025). These expert inputs affirm the clinical value and practicality of our proposed method.

Limitations and Research Directions

This study has several limitations, and it can be extended by further research. First, we used a sample from a single healthcare organization, which offered relatively limited diversity in terms of data sources and patient populations. In a related sense, our sample was imbalanced in the outcome class distribution, which constrained the prediction performance for minority classes, as reflected by the relatively low F_1-scores, which is in line with previous research [87]. Future studies should consider additional data sources and types such as image and text [89] to extend the proposed method, use different patient cohorts to affirm its efficacy, and apply synthetic data augmentation or multimodal foundation models to better address the issue of imbalanced outcome class distribution with cross-modal learning capabilities [62]. Second, because intraphenotype variability introduces complexity with regard to achieving compact clusters in the embedding space, a trade-off arises between variability and compactness, which could restrict the predictive utility for large datasets or different diseases. Therefore, we call for efforts to explore an optimal balance of variability and compactness for both accuracy and generalizability, such as clustering-based contrastive learning [90]. Third, the proposed 2-stage method provides some limited interpretability, through a feature attribution–based approach (ie, SHAP); its contrastive pretraining component deserves further exploration for greater transferability and interpretability. Ongoing efforts could facilitate and interpret embeddings in focal clinical contexts. Fourth, an international, multisociety Delphi process led to the proposal of metabolic dysfunction–associated steatotic liver disease (MASLD) in 2023 [91]. Although our findings might be extrapolated to adults with MASLD [92], the proposed method should be extended with research that tests for differences between MAFLD and MASLD and refines the proposed method to ensure robustness and prediction performance.

Conclusion

Predicting MAFLD phenotypes among adults is crucial, but existing analytic methods overlook its multisystem nature and phenotypic heterogeneity. As a solution, we developed a novel method that leverages graph representation learning, multiview contrastive pretraining, and a 2-stage estimation design to produce effective predictions that reflect phenotypic heterogeneity, complex relationships, and disease dynamics. It is effective in identifying at-risk adults and thus offers support for clinical decision-making and personalized care. This study reveals a promising pathway to advance health informatics research and clinical practice by leveraging rich, detailed clinical data in electronic health records and survey-based data to predict MAFLD phenotypes.

Abstract

Background: Missing data are a common challenge in electronic health record (EHR)–based prediction modeling. Traditional imputation methods may not suit prediction or machine learning models, and real-world use requires workflows that are implementable for both model development and real-time prediction.

Objective: We evaluated methods for handling missing data when using EHR data to build clinical prediction models for patients admitted to the pediatric intensive care unit (PICU).

Methods: Using EHR data containing missing values from an academic medical center PICU, we generated a synthetic complete dataset. From this, we created 300 datasets with missing data under varying mechanisms and proportions of missingness for the outcomes of (1) successful extubation (binary) and (2) blood pressure (continuous). We assessed strategies to address missing data including simple methods (eg, last observation carried forward [LOCF]), complex methods (eg, random forest multiple imputation), and native support for missing values in outcome prediction models.

Results: Across 886 patients and 1220 intubation events, 18.2% of original data were missing. LOCF had the lowest imputation error, followed by random forest imputation (average mean squared error [MSE] improvement over mean imputation: 0.41 [range: 0.30, 0.50] and 0.33 [0.21, 0.43], respectively). LOCF generally outperformed other imputation methods across outcome metrics and models (mean improvement: 1.28% [range: −0.07%, 7.2%]). Imputation methods showed more performance variability for the binary outcome (balanced accuracy coefficient of variation: 0.042) than the continuous outcome (mean squared error coefficient of variation: 0.001).

Conclusions: Traditional imputation methods for inferential statistics, such as multiple imputation, may not be optimal for prediction models. The amount of missingness influenced performance more than the missingness mechanism. In datasets with frequent measurements, LOCF and native support for missing values in machine learning models offer reasonable performance for handling missingness at minimal computational cost in predictive analyses.

Introduction

Background and Significance

Addressing missing data is necessary for developing a clinical prediction model. Electronic health record (EHR) data are a rich data source but present particular challenges. Missing data may result from lack of documentation or measurement [1]. EHR data are generated via clinical care, with values measured at irregular intervals.

Raw EHR data are often transformed into an analytic dataset by binning variables by time. Missing data arise if a variable is not measured within a time window [2]. Measurement frequency (and resultant missingness) is often linked to how abnormal the value is or is expected to be, such that missingness itself may be informative. Given many algorithms require complete data, a principled approach to address missingness is required.

Techniques for handling missing data for inferential models that seek to describe or causally explain are well established. Missingness is traditionally categorized into three mechanisms [3,4]:

1. Missing completely at random (MCAR)—probability of missingness does not depend on variables in the dataset or

XSL•FO
RenderX

depends only on observed values of covariates included in the model; for example, a laboratory technician forgets to record results for a patient, unrelated to any characteristics of that patient or their health [5].

2. Missing at random (MAR)—probability of missingness depends on observed values in the data, including the outcome; for example, height is not recorded for a patient but is related to weight and sex of the patient, which are present in the EHR.
3. Missing not at random (MNAR)—probability of missingness depends on unobserved values; for example, no lactate is measured on a patient because the clinician expects it to be normal.

Bias from MNAR can be intractable for inferential models [4]. Given EHR data are likely MNAR, this could be problematic if also true for clinical prediction models. For inferential models, simple strategies, such as complete case analysis, mean imputation, and last observation carried forward, are known to produce biased results [6,7]. Preferred strategies, such as multiple imputation, incorporate uncertainty into imputed values, thereby accurately characterizing uncertainty in parameter estimates.

Literature on handling missing data in prediction modeling is less developed. Unlike inferential models, which focus on bias and precision in parameter estimates, prediction models prioritize improving predictive accuracy and interpretability [4]. Classic statistical imputation methods may be complex to implement for prediction models [8] or less relevant, particularly as medicine advances toward ever more complex machine learning algorithms [4,9,10]. There is little guidance on best practices to address missing data for clinical prediction models [11]. Methods for handling missing data are rarely reported, and complete case analysis is the most common approach [11,12]. This may not only result in bias but also risk significant loss of data in high-dimensional EHR datasets [9]. Machine learning is increasingly being used to address missing data, both as imputation models (eg, random forests) [13] and by natively handling missing data in prediction models themselves, bypassing the need for imputation altogether. Tree-based methods [14] are particularly suited for this task [9]. Yet, few studies have compared classic imputation methods with such built-in strategies in EHR data [9,12].

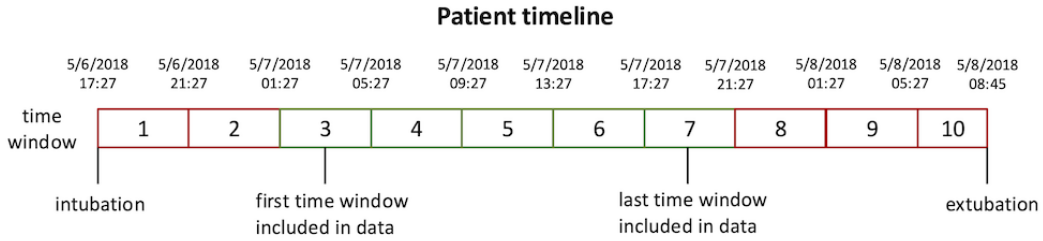
Real-world application of clinical prediction models presents additional challenges. Many risk models currently in practice require complete data or use imputation methods that may be overly simplistic, limiting their usefulness [15,16]. Implementing models prospectively requires data workflows that can be applied in the same way to both retrospective data to build the model and new data for real-time prediction for individuals [4,10,11,15]. There are no established techniques for managing missing data post-model development. Studies assessing methods for handling missing data in prospective applications on individual patients often used datasets containing only a few predictors [16,17]. These findings may not translate to datasets with more variables because some imputation methods may struggle to handle large numbers of correlated features and binary variables are more likely to be perfectly predicted, leading to overfitting. Furthermore, outcome prediction models after addressing missing data were often standard statistical methods such as logistic regression [15,17] or Cox proportional hazard models [16], when different methods for addressing missingness may be preferable for predictive machine learning models.

Objective

We used EHR data from a live use case (predicting extubation readiness of children in the pediatric intensive care unit [PICU]) to generate a synthetic complete dataset to evaluate multiple methods for imputation and their effects on predictive performance. We included methods that learn from training data and apply to new data. As the relative performance of methods varies by type of missingness (MAR, MCAR, and MNAR) and proportion of missing values [18], we varied both in our assessment.

Methods

Study Population



The study population was patients aged >30 days and <18 years old from the PICU at the University of California, San Francisco (UCSF) Benioff Children's Hospital intubated between January 1, 2013, and March 31, 2023. Patient encounters were eligible for the sample if the child was intubated for more than 24 hours. We excluded patients intubated for less than 24 hours as they were likely intubated for surgeries, procedures, or other indications and extubated quickly without complications. Children with repeated intubations were eligible for inclusion for each intubation event.

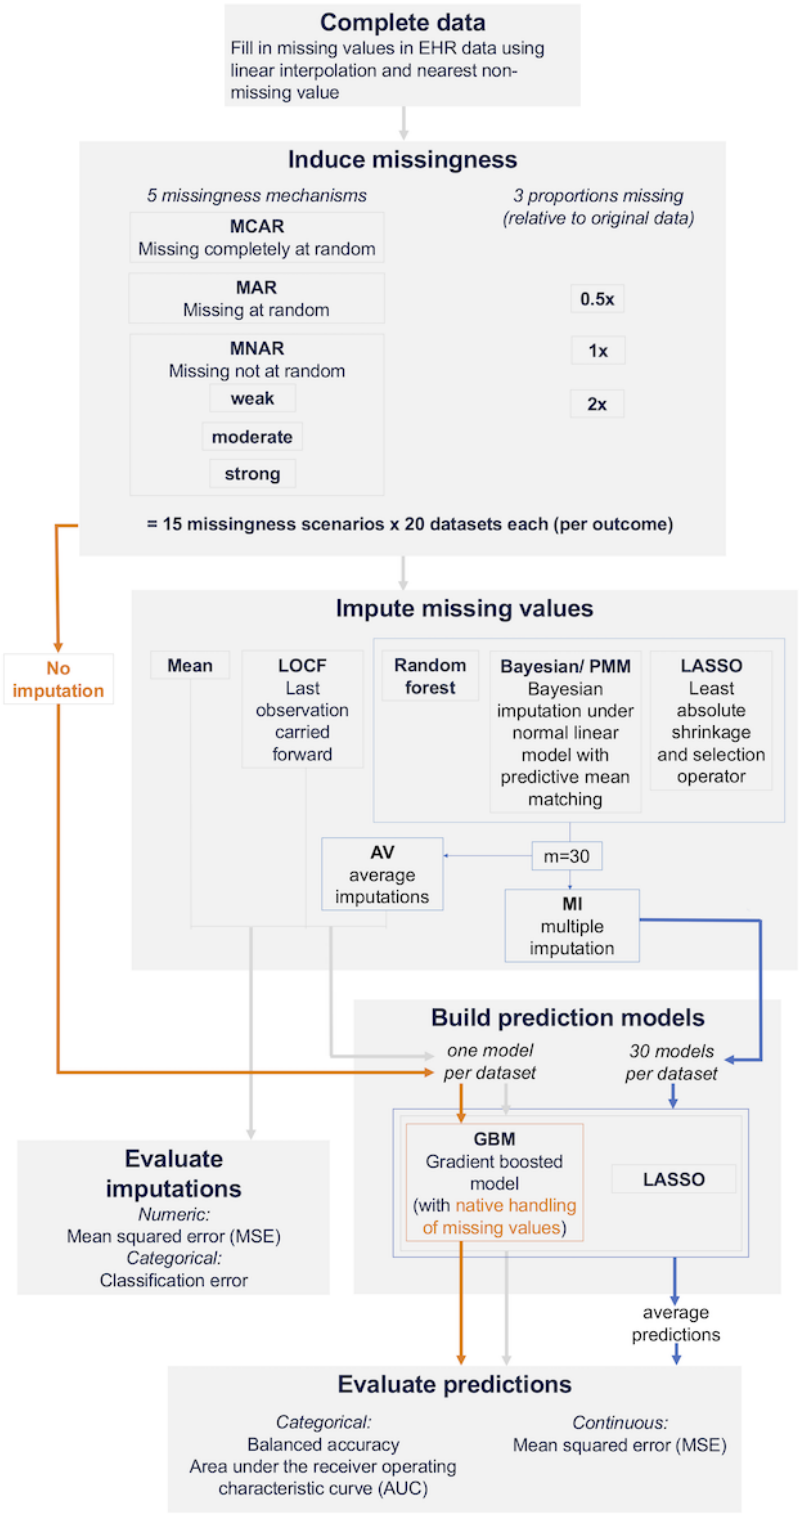
Data

We used EHR data extracted from the UCSF Clinical Data Warehouse (updated daily from the real-time EHR). Based on expert opinion, peer-reviewed literature, and group consensus of the UCSF Pediatric Critical Care Research Group, we selected a broad range of clinical, physiologic, and laboratory variables in the EHR that could be relevant to extubation readiness including: vital signs, ventilator settings, laboratory values, medications, neurological status, fluid balance, and other patient characteristics (Table S1 in Multimedia Appendix 1). Raw data were collapsed into 4-hour time windows [1] containing the mean of each numeric or binary variable and mode of each multi-level categorical variable, resulting in 99 variables. Collapsing variables into time windows made imputation more tractable as it increased the probability of at least 1 nonmissing value per time window and more computationally feasible by decreasing the number of observations on which we needed to impute. In practice, nursing assessments are completed at least every 4 hours (with some assessments in the ICU performed hourly); thus, the 4-hour interval is clinically meaningful. The first time window included in the model ended 12 hours after intubation (Figure 1).

XSL•FO
RenderX

Figure 1. Example patient timeline and resultant data. The example patient timeline depicts 4-hour time windows beginning at intubation and ending at extubation. The table in the figure demonstrates the data resulting from this patient that would be included in the model. This patient was intubated at 17:27 on 5/6/2018 and extubated at 08:45 on 5/8/2018. The first time window included as an observation in the model ended 12 hours after intubation at 05:27 on 5/7/2018. Time-varying data from the prior 2 time windows were included for each observation as lagged variables to capture the trajectory of the patient. The final time window included in the model for this patient is from 17:27 to 21:27 on 5/7/2018. The extubation outcome for each time window was the status 12 hours (or 3 time windows) later. The blood pressure outcome for each time window was the value 4 hours (or 1 time window) later.

Patient data



Row	Start time	End time	Time window	Lagged variables: Time windows	Outcome		Extubation status time
					Extubation status: Time window	Blood pressure: Time window	
1	5/6/2018 01:27	5/6/2018 05:27	3	1 and 2	6	4	5/7/2018 17:27

The binary outcome of successful extubation was defined as extubation that did not result in reintubation within 48 hours. The extubation outcome assigned to each time window indicated status 12 hours after the end of the time window (Figure 1; Multimedia Appendix 1), as we aimed to predict successful extubation prior to clinician actions indicating they already decided to extubate a patient. A secondary outcome of age-adjusted systolic blood pressure percentile [19] was added to ascertain whether findings were similar for a continuous outcome. The blood pressure outcome assigned to each time window was the value 4 hours after the end of the time window.

To generate a synthetic dataset with no missing values (Figure 2), we filled in missing numeric values with linear interpolation between last value observed and next value observed [20]. We filled in all remaining missing values with the nearest nonmissing value. For never observed variables (1.4% of cells), we made reasonable assumptions (eg, we used the standard endotracheal tube [ETT] size formula [age in years/4+4] for pediatrics to fill in missing ETT sizes [21]) and then filled in remaining missingness using the *missRanger* package [22], which implements random forest imputation with predictive mean matching and is optimized for speed and memory efficiency. Analyses were conducted in R version 4.3.2 [23].

Figure 2. Experimental methods flowchart. EHR: electronic health record.

Missingness Mechanisms

We induced missingness in the complete, synthetic dataset to simulate 5 missing data mechanisms:

1. MCAR
2. MAR
3. weak MNAR (twice as much weight given to observed compared with missing variables to determine missingness)
4. moderate MNAR (equal weight given to observed compared with missing variables to determine missingness)
5. strong MNAR (missingness solely based on missing variables)

For each, we created 3 scenarios varying the amount of missingness: approximately 0.5x, 1x, and 2x the percentage of missing cells in the original data, generating 15 total missingness scenarios. We divided variables into 5 groups (Table S1 in Multimedia Appendix 1) to create patterns of missing data. The

XSL•FO
RenderX

outcome was allowed to influence missingness in MAR and MNAR scenarios (Multimedia Appendix 1). Using the ampute command in the *mice* package [24], we induced missingness in 20 unique datasets (enough to have a distribution of results, but not exceed our computing power) for each of the 15 scenarios, resulting in 300 datasets per outcome. All datasets for both outcomes contained the same predictor variables.

Imputation Methods

To incorporate temporal patterns in the predictors, we added values of time-varying variables from the prior 2 lagged time windows to each row for a total of 265 features. These data were structured in wide format, such that each row included the current value and its 2 lags as separate variables. This allowed the imputation models to use all 3 time points to inform each other's missing values. For simplicity, we treated these repeated measurements as distinct variables in imputation models (rather than using a multilevel model). While some studies suggest this approach yields comparable performance [25], others have reported advantages of multilevel models [26]. Data were split into training (75% of intubations) and test (25% of intubations) sets ordered by date, with earlier intubations included in training and later ones in test. We ensured each patient was only in either the training or test set.

To simulate a real-time prediction workflow, imputation models were built using only training data and excluded the outcome [15]. In total, 6 methods to handle missingness were applied to each amputed dataset (Table 1, Multimedia Appendix 1):

1. Mean: Mean imputation is frequently used in practice [27]. We imputed test set values using the unconditional mean (numeric and binary) or mode (factor) in the training set.
2. Last observation carried forward (LOCF): This simple approach is recommended for imputation in time series data where data are available only before the missing value [20] (true in prospective implementation of clinical decision support). We allowed values to be carried forward indefinitely across time windows.
3. Random forest: Traditional statistical imputation relies on parametric assumptions. However, nonparametric methods, such as this, have been shown to outperform established methods (especially in settings with complex interactions and nonlinear relationships) [28]. *Mice* [29] imputes missing values by building a random forest for each variable, identifying observations in the same terminal node, and sampling a donor value from one of these observations.
4. Bayesian imputation under the normal linear model with predictive mean matching (Bayesian/PMM): PMM is a hot deck method where missing values are imputed from cases with observed values matched according to predictions of the imputation model (here, Bayesian imputation under the normal linear model in *mice* [29]). PMM is robust against model misspecification and ensures imputed values are constrained to the range of observed data [7].
5. Least absolute shrinkage and selection operator (LASSO): Regularized models, such as LASSO, are beneficial to handle multicollinearity and prevent overfitting in high-dimensional data. We used *mice* [29] to fit LASSO-penalized regression models on bootstrap samples of observed data and drew imputed values from the resulting distributions.
6. Native support for missing data in prediction model (no imputation required): Some machine learning algorithms can handle missing values directly, without dropping cases or requiring separate imputation. We used gradient boosted trees for our primary prediction model [30]. The LightGBM package [31] allocates missing values to the bins that optimally minimize loss.

RenderX

Table . Methods for handling missing data.

Method	Assumptions	Computational complexity	Limitations	Benefits
Mean imputation	• Assumes missing values are similar to the mean	Negligible	• Artificially reduces variance • Disturbs relationships between variables	• Simple to implement • Constant imputation creates patterns that machine learning can exploit
Last observation carried forward	• Assumes stability over time	Negligible	• Data remain missing if no prior measurement exists • May not reflect true patient progression • Can introduce bias if trends are not stable over time	• Simple to implement • Reflects how clinicians practice for many variables (assume no changes or re-measure if important)
Random forest	• MCAR[a] or MAR[b]	High computational cost	• Requires significant computational resources • May not perform well in small datasets • Dearth of packages that allow models to impute on new data	• Nonparametric method handles complex interactions and nonlinear relationships well • Works with mixed data types (categorical and continuous)
Bayesian imputation under the normal linear model with predictive mean matching (Bayesian/PMM)	• MCAR or MAR • Assumes normality for underlying distribution	High computational cost	• Works best with large samples • Dearth of packages that allow models to impute on new data	• Robust against model misspecification • Ensures imputed values are within the range of observed data
Least absolute shrinkage and selection operator (LASSO)	• MCAR or MAR	High computational cost	• May not capture nonlinear relationships well • Dearth of packages that allow models to impute on new data	• Handles multicollinearity well • Prevents overfitting in high-dimensional data
Native support for missing data in prediction models	• Varies by model • Methods [12] include surrogate splits and allocating missing values to bins that optimally minimize loss	None for imputation	• This capability is not available in all machine learning algorithms • Performance depends on algorithm's internal handling of missing values	• No need for explicit imputation

[a]MCAR: missing completely at random.

[b]MAR: missing at random.

We used available software for imputation to avoid the need to develop custom software and enable our findings to be more readily applicable to practitioners. We did not include deep-learning methods in our experiment as they were impractical with our relatively small sample size. We generated 30 imputations per dataset using the *mice* package [29] for methods 3 - 5. Models built with the training data were then used to impute on the test set. We tested the imputations 2 ways. *Mice* purposefully incorporates uncertainty into imputations because it is advantageous for inferential analysis. First, we averaged the imputations to get a more stable estimate of each missing value to use in a single outcome model. Second, we implemented multiple imputation by estimating 30 outcome models and averaging the predicted probabilities for a final prediction.

Prediction Model

For the outcome prediction model, we used gradient boosted trees [30]. It is one of the best-performing algorithms in structured data in general and within biomedical datasets [32] and uses all cases in training data, even if they are incomplete. To assess whether imputation method performance was consistent across outcome models, we also compared a LASSO outcome model. However, linear models like LASSO cannot accommodate missing values, so this was only performed on imputed datasets. Outcome models were implemented using the rtemis package [33] with LightGBM [34] and glmnet [35].

XSL•FO
RenderX

We used 5-fold cross-validation in the training set to tune hyperparameters and inverse frequency weighting to upweight the minority class given the data were unbalanced.

Analysis of Imputation Accuracy

It is established that in imputation for statistical inference, focusing on improving accuracy of the imputations at the cost of correctly incorporating true uncertainty leads to biased and invalid results [7]. However, the relationship between imputation accuracy and prediction model performance is less well-studied. We compared the accuracy of imputations by calculating mean squared error (MSE) for numeric variables and classification error for categorical variables in each dataset and creating box plots. Before calculating MSE, we standardized the variables by dividing by their standard deviations in the complete dataset. To calculate MSE for random forest, Bayesian/PMM, and LASSO, we compared the average of the 30 imputations to the true value. We also assessed whether temporal autocorrelation of each variable was associated with imputation performance across all methods descriptively using scatterplots and quantified using correlation coefficients (Multimedia Appendix 1). In addition, we conducted a sensitivity analysis stratifying imputation error by whether a variable's values had been missing in the original data (and filled in to create the synthetic complete dataset) versus not originally missing, to evaluate whether this initial filling step influenced the apparent performance of the imputation methods.

To assess the accuracy of imputation for different categories of variables, we built linear models for MSE and classification error. Each observation's outcome was the error value for a given variable in a given dataset. Each model included imputation type, missingness type, proportion missing data (0.5x, 1x, and 2x original), and variable group (Multimedia Appendix 1). We included all 3-way and 2-way interactions and completed a backward stepwise elimination procedure based on *P* values (included $P<.05$) to determine the final models.

Analysis of Outcome Model Performance

We assessed the performance of outcome prediction models for extubation with 2 primary metrics: balanced accuracy [36] and area under the receiver operating characteristic curve (AUC) [37]. We present secondary results for sensitivity, specificity, positive predictive value, negative predictive value, and F1 [38]. We assessed the performance of the outcome prediction models for blood pressure with the primary metric of MSE. Secondary results are presented for mean absolute error, root MSE, and R^2 [39]. We compared these graphically to the performance of a model built with the complete data and calculated the coefficient of variation (CV) to assess variability.

Ethical Considerations

We received ethical approval from the University of California, San Francisco Institutional Review Board (study #17 - 23751), which granted a waiver of informed consent. No financial incentives were provided to patients. Patient privacy and confidentiality were protected through secure data storage, restricted access to authorized study personnel, and compliance with institutional and regulatory requirements.

Results

Data

The data contained 886 patients and 1220 intubations, 929 (76.1%) of which ended in successful extubation (Table 2). The median duration of intubation in the PICU was 4.4 (IQR 2.2-8.5) days, leading to 50,187 four-hour time windows in the analytic dataset.

XSL•FO
RenderX

Table . Description of sample[a].

Variable	Value
Patients	
Total, n	886
Female patients, n (%)	405 (45.7)
Race or ethnicity, n (%)	
Asian	117 (13.9)
Black	67 (8)
Latinx	340 (40.4)
Other	88 (10.5)
White	229 (27.2)
Intubations	
Total, n	1220
Age at intubation (years), median (IQR)	4.3 (1-12.1)
Outcome, n (%)	
Extubation success	929 (76.1)
Extubation failure	100 (8.2)
Death	96 (7.9)
Tracheostomy	36 (3)
Transfer to another unit	25 (2)
ETT[b] change	34 (2.8)
Duration of intubation (days), median (IQR)	4.4 (2.2-8.5)

[a]Patients intubated multiple times during the study period may have multiple intubation events included in the sample. The binary outcome of successful extubation for the model collapsed all other outcome categories. Here, extubation failure is defined as reintubation within 48 hours, death is death before or within 48 hours of extubation, and ETT change is an extubation that was immediately and purposefully replaced by another ETT (eg, to change the size).

[b]ETT: endotracheal tube.

Missingness for each variable in the original data (collapsed into 4 h time windows) varied from 0% (0/56,287; eg, sex, age) to 77% (43,077/56,287; white blood cells) (Table 3; Table S2 in Multimedia Appendix 1). Overall, 18.2% of cells (1,012,668/5,561,767) were missing (Table S3 in Multimedia Appendix 1). After simulating missingness, datasets approximating 0.5x, 1x, and 2x missingness of the original data averaged 9.6%, 18.1%, and 35.9% missing cells, respectively.

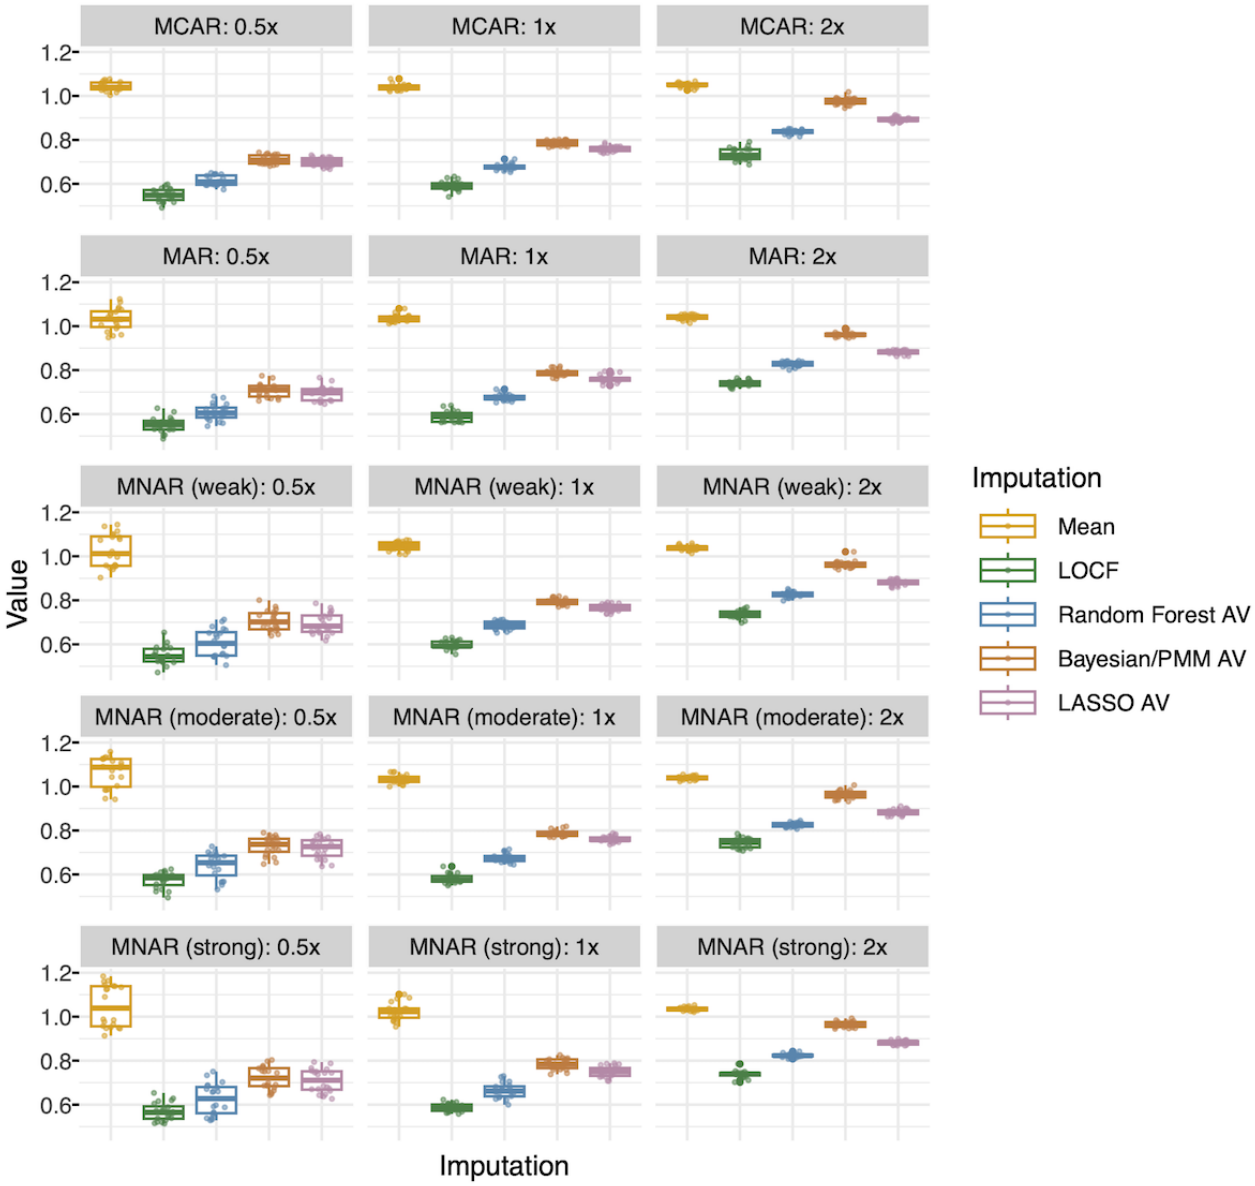
XSL•FO
RenderX

Table . Missingness in original data[a].

Variable	Number of 4-hour time windows missing variable	Percent of 4-hour time windows missing variable
Age at time of intubation (in days)	0	0.0
Medication: total oral morphine equivalents (mg kg^{-1})	0	0.0
Sex	0	0.0
Intake or output total milliliter over the prior 12 hours kg^{-1}	167	0.3
Pulse	420	0.7
Respiratory rate (recorded in vital signs)	1179	2.1
ETT[b] size	6179	11.0
Respiratory pattern: tachypneic	7290	13.0
PEEP[d]	8975	15.9
Exhaled tidal volume kg^{-1}	10,274	18.3
State behavioral scale	15,888	28.2
Secretion amount (categories: none, scant, small, moderate, large, copious)	16,325	29.0
Glasgow coma scale score	25,751	45.7
pH	25,804	45.8
Upper extremity motor response	28,839	51.2
Cough: present	35,254	62.6
White blood cell count	43,077	76.5

[a]Example variables display the range of proportion of missingness in the original data (N=56,287 4-h time windows; these data include more time windows than the final analytic dataset because they were compiled before excluding time windows that were constructed solely for creating lagged variables). Detailed data for all variables are available in Table S2 in Multimedia Appendix 1.

[b]EET: endotracheal tube.



[c]PEEP: positive end-expiratory pressure.

Imputation Performance

Across 300 datasets with induced missingness per outcome, the same 176 numeric and 6 categorical variables were imputed. Figure 3 presents MSE for datasets for the outcome of extubation.

XSL•FO
RenderX

Figure 3. Imputation test performance metrics (extubation): mean squared error. Each point represents mean squared error calculated for 176 numeric variables for 1 of 300 datasets created for the outcome of extubation. There are 20 datasets per missingness scenario and imputation type represented in each box plot. AV: average (average of 30 imputations); Bayesian/PMM: Bayesian imputation under the normal linear model with predictive mean matching; LASSO: least absolute shrinkage and selection operator; LOCF: last observation carried forward; MAR: missing at random; MCAR: missing completely at random; MNAR: missing not at random.

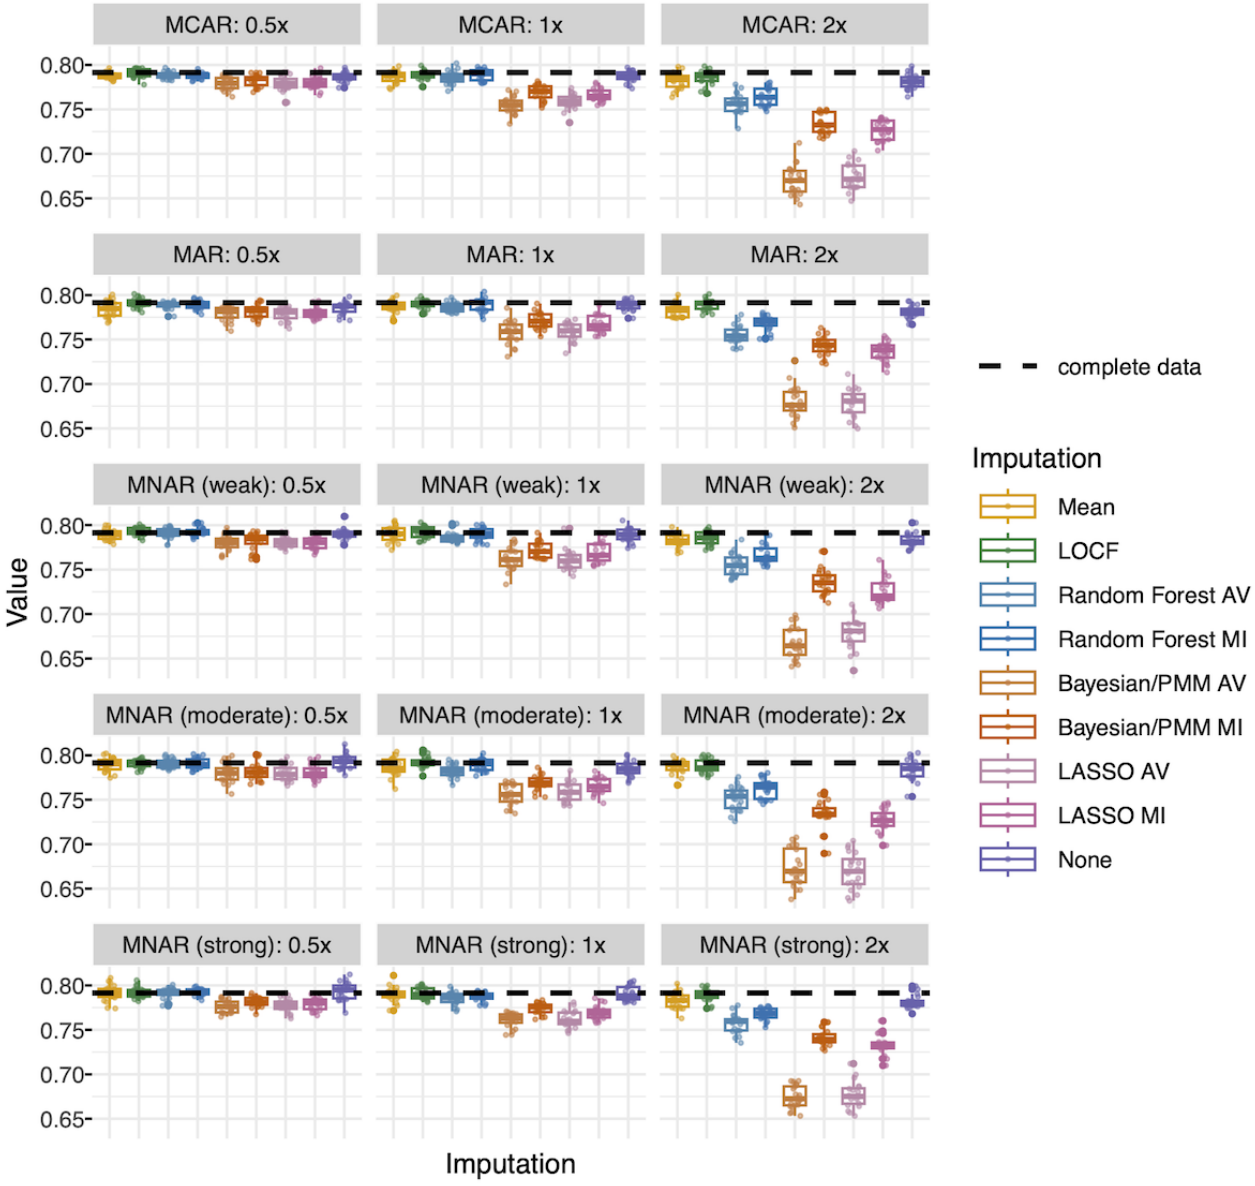
The results for the outcome of blood pressure (which imputed the same variables) were virtually identical (Multimedia Appendix 2). Performance in the test sets showed that LOCF had the lowest MSE on average in all missingness scenarios for numeric variables (average improvement of MSE compared with mean imputation was 0.41 for the outcome of extubation [range: 0.30, 0.50]). Random forest imputation was consistently second best (0.33 [0.21, 0.43]), followed by LASSO (0.26 [0.15, 0.35]), Bayesian/PMM (0.22 [0.07, 0.34]), and finally, mean imputation (Reference). Performance overall degraded as the proportion of missing data increased, with proportion missing having a greater effect than missingness mechanism. Classification error displayed similar patterns overall for categorical variables (Multimedia Appendix 3). While LOCF and mean imputation did not generally overfit in the training data compared with the test set, all model-based imputation methods overfit the training data, with random forest doing so the least (Multimedia Appendices 4 and 5). Temporal autocorrelation was negatively associated with imputation error for all methods except mean imputation, which showed little association (r=–0.13; Multimedia Appendix 6). The association was strongest for LOCF (r=–0.92), followed by random forest (r=–0.74). For these, error decreased almost monotonically with increasing autocorrelation, indicating substantially better accuracy for more temporally stable variables.

In a sensitivity analysis, we examined whether the initial filling of originally missing values influenced subsequent comparisons of imputation performance. Overall, MSE was lower for values that were missing in the original data and filled in to create the synthetic complete dataset, especially for LOCF and random forest imputation (2 methods used to fill in the original missingness). Still, both LOCF and random forest continued to

XSL•FO
RenderX

achieve the best performance when imputing values not missing in the original data (Multimedia Appendix 7).

In models for mean squared error, a significant 3-way interaction existed between imputation method, proportion missing, and variable group (Tables S4 and S5 in Multimedia Appendix 1) due to the fact that (1) all methods except mean imputation degraded with increased missingness and (2) variables with a response of "select all that apply" were more poorly predicted (Multimedia Appendix 8). There was no interaction between missingness mechanism and (1) imputation method or (2) variable group.



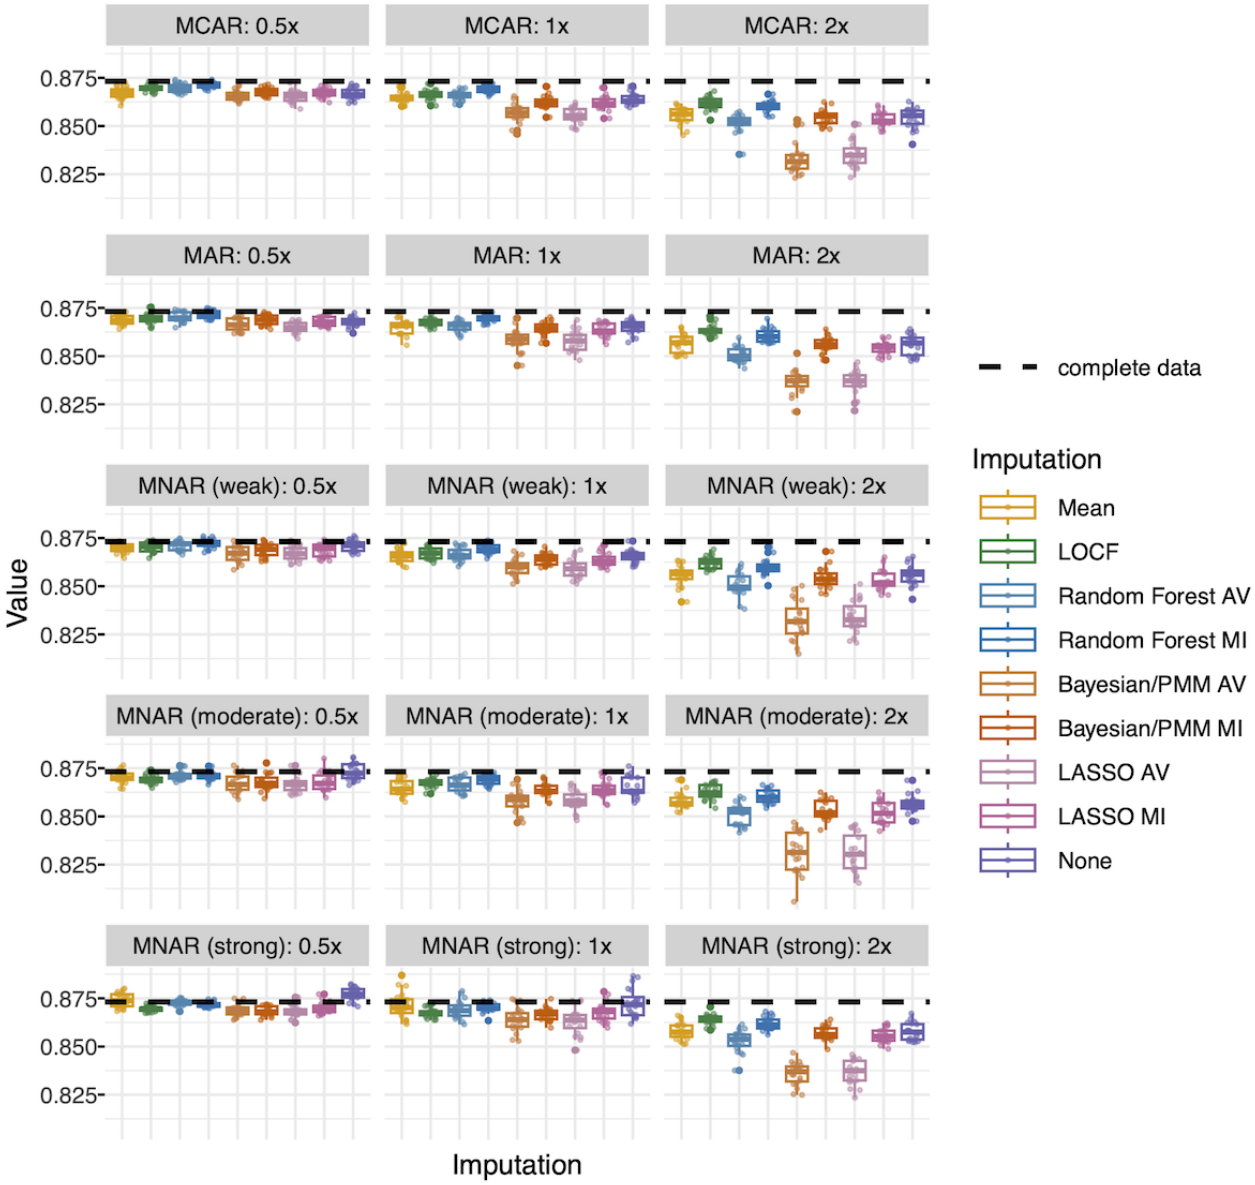
Prediction Model Performance

Gradient Boosted Models

Extubation: Balanced accuracy

For the outcome of extubation using gradient boosted models, balanced accuracy was the highest for LOCF (Figure 4). Mean imputation and no imputation (native support for missing values) performed almost as well. Random forest (both averaged and multiple imputation) also performed well at 0.5x and 1x missingness, but its performance degraded at 2x missingness. The amount of missingness was more influential than the missingness mechanism (Table S6 in Multimedia Appendix 1).

Figure 4. Gradient boosted model test performance (extubation): balanced accuracy. Each point represents balanced accuracy for 1 dataset. There are 20 datasets per missingness scenario and imputation type represented in each box plot. Balanced accuracy in the complete dataset is represented by a dashed line. AV, average (average of 30 imputations); Bayesian/PMM: Bayesian imputation under the normal linear model with predictive mean matching; LASSO: least absolute shrinkage and selection operator; LOCF: last observation carried forward; MAR, missing at random; MCAR: missing completely at random; MI: multiple imputation; MNAR: missing not at random.



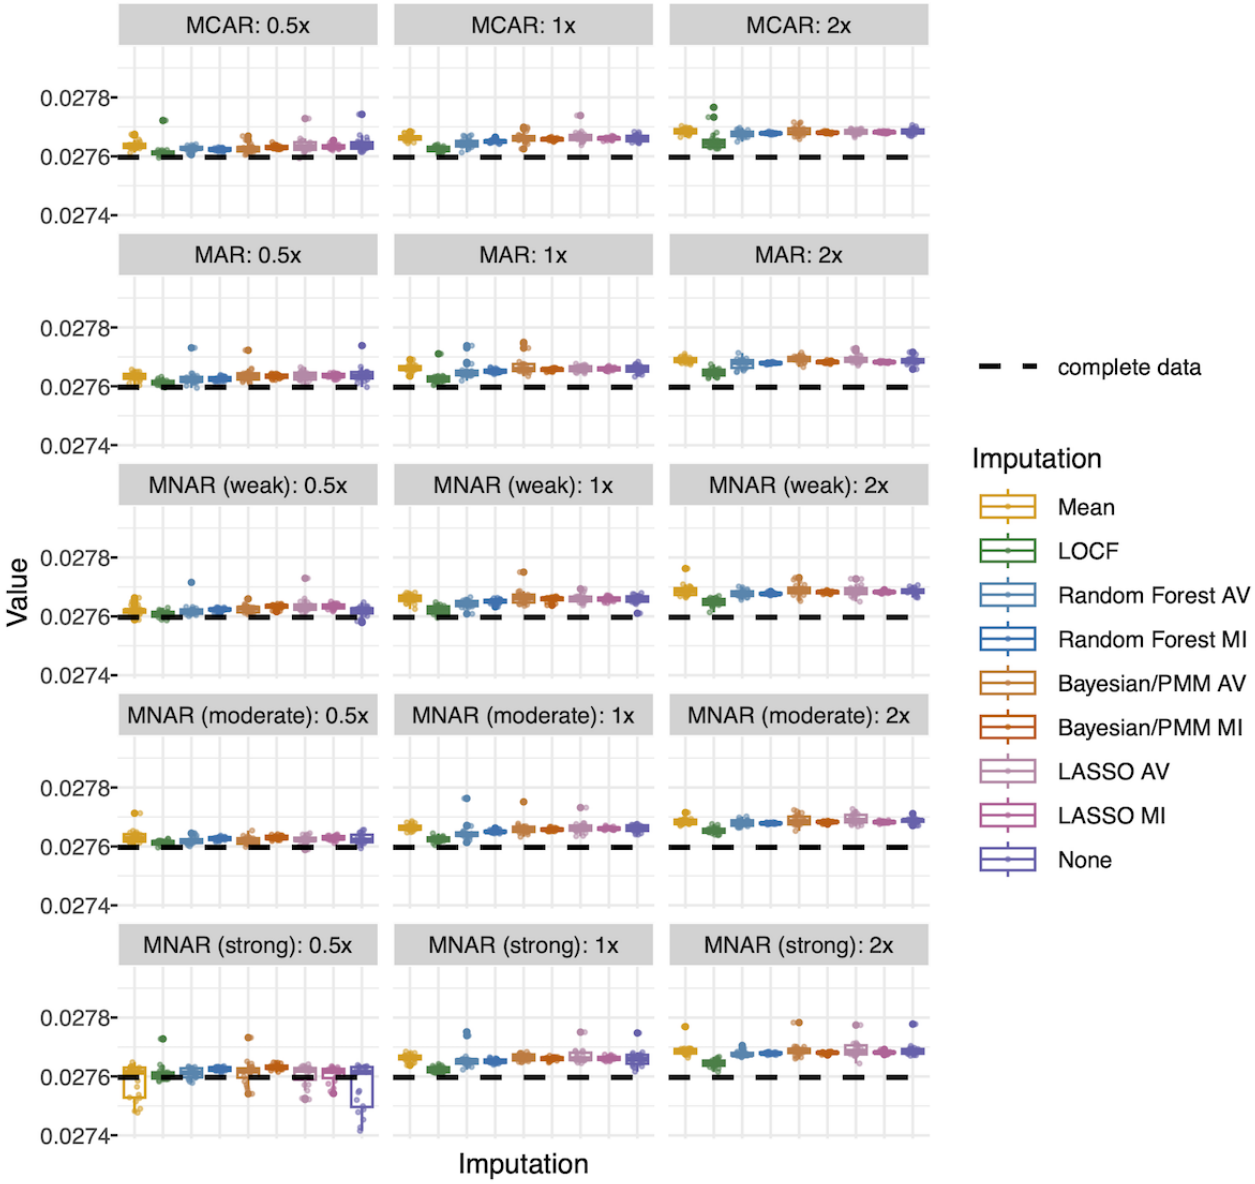
Extubation: AUC

Random forest multiple imputation had the highest AUC for gradient boosted models for 0.5x and 1x missingness, while LOCF did for 2x missingness (Figure 5). Random forest averaged, mean imputation, and no imputation had reasonable performance but degraded at 2x missingness. The amount of

XSL•FO
RenderX

missingness continued to have a greater effect on performance than the missingness mechanism.

Figure 5. Gradient boosted model test performance (extubation): AUC. Each point represents AUC for 1 dataset. There are 20 datasets per missingness scenario and imputation type represented in each box plot. AUC in the complete dataset is represented by a dashed line. Other performance outcome metrics (sensitivity, specificity, positive predictive value [PPV], negative predictive value [NPV], and F1) are presented in Multimedia Appendix 9. AV, average (average of 30 imputations); Bayesian/PMM: Bayesian imputation under the normal linear model with predictive mean matching; LASSO: least absolute shrinkage and selection operator; LOCF: last observation carried forward; MAR, missing at random; MCAR: missing completely at random; MI: multiple imputation; MNAR: missing not at random.



Blood Pressure: MSE

LOCF had the lowest overall MSE (Figure 6). Random forest (both averaged and multiple imputation) generally had the next lowest MSE. Unlike in extubation models, mean imputation and no imputation did not perform substantially better than other methods. Performance was again more sensitive to amount of missingness than to missingness mechanism; overall, MSE increased in a stepwise fashion as missingness increased. However, there was less overall variability (CV=0.001) between models than for balanced accuracy (CV=0.042) and AUC (CV=0.012).

XSL•FO
RenderX

Figure 6. Gradient boosted model test performance (blood pressure): mean squared error (MSE). Each point represents MSE for 1 dataset. There are 20 datasets per missingness scenario and imputation type represented in each box plot. MSE in the complete dataset is represented by a dashed line. Other performance outcome metrics (mean absolute error [MAE], root MSE, and R^2) are presented in Multimedia Appendix 10. AV, average (average of 30 imputations); Bayesian/PMM: Bayesian imputation under the normal linear model with predictive mean matching; LASSO: least absolute shrinkage and selection operator; LOCF: last observation carried forward; MAR, missing at random; MCAR: missing completely at random; MI: multiple imputation; MNAR: missing not at random.

LASSO Models

Extubation: Balanced Accuracy

For the LASSO outcome model, performance and patterns were similar to the gradient boosted model for balanced accuracy, with LOCF demonstrating top performance (Table S7 in Multimedia Appendix 1; Multimedia Appendix 11). Mean imputation did not perform as well in LASSO models. Interestingly, imputation methods that performed worst—Bayesian/PMM and LASSO—yielded better results in LASSO models than in gradient boosted models, with less variation in performance across methods (CV=0.029).

Extubation: AUC

AUC followed similar patterns to balanced accuracy for LASSO. LOCF had the best performance. Mean imputation again performed worse comparatively, and there was a smaller performance gap between the best and worst imputation methods relative to gradient boosted models (CV=0.011; Table S7 in Multimedia Appendix 1; Multimedia Appendix 11).

Blood Pressure: MSE

LOCF had the lowest overall MSE (Multimedia Appendix 12). MSE again increased as missingness increased. MSE of LASSO models for all imputation methods was higher than gradient boosted models, although LASSO MSE was consistently closer to the MSE for complete data. The range between the best and

XSL•FO
RenderX

worst imputation methods was narrower than for gradient boosted models (CV=0.0008).

Overfitting to training data: Both models

Extubation: Balanced Accuracy and AUC

Overfitting to the training data (Multimedia Appendices 13 and 14) increased as proportion of missingness increased. It was greatest for the worst-performing imputation methods (Bayesian/PMM and LASSO) in both gradient-boosted and LASSO outcome models. It was higher overall for gradient boosted models than for LASSO outcome models.

Blood Pressure: MSE

Gradient boosted models exhibited more overfitting overall and higher variability in overfitting than LASSO models (Multimedia Appendices 15 and 16).

Discussion

Overview

EHR data present challenges in how to handle missing data when developing clinical prediction models. It is critical to use methods that are transferable to new data when generating real-time predictions for use cases like clinical decision support tools. In a realistic EHR dataset, we compared imputation methods based on (1) imputation accuracy and (2) outcome prediction.

Imputation Performance

LOCF and random forest multiple imputation consistently had the lowest MSE and classification error. LOCF has performed well in health survey and cohort datasets [18,20]. In our data, per-variable LOCF imputation error decreased monotonically with first-order autocorrelation, indicating better performance for more temporally stable variables. Random forest, while not explicitly designed for longitudinal data, was informed by lagged variables in our implementation and therefore also showed some gains for more temporally stable variables, though the association was weaker than for LOCF. By contrast, mean imputation does not account for correlation across repeated measures, and accordingly showed no relationship between autocorrelation and error. In the PICU, where many measurements are recorded frequently and less frequent measurements often indicate presumed stability over time, LOCF may be particularly suitable, while random forest may provide added value when temporal patterns are weaker.

As expected, imputation performance degraded as the proportion of missingness increased. Jäger et al [13] also found imputation performance generally worsened when difficulty (eg, higher missingness fraction and MNAR) increased. We found that missingness proportion affected imputation quality more than missingness mechanism. Although the imputation methods we employed are only theoretically valid in MCAR and MAR settings, performance in MNAR data was fairly similar, possibly due to the availability of repeated measurements over time, which may have captured underlying patterns. This is fortunate, given that EHR data are often likely MNAR [9].

Prediction Model Performance

Many studies do not report imputation performance [9,15,16], focusing instead on prediction performance. In our experiment, LOCF generally yielded the highest prediction performance across outcome types and models. We evaluated whether LOCF's strong performance was influenced by how we constructed the synthetic, complete dataset. Although it may have been somewhat inflated, sensitivity analyses confirmed that LOCF remained a top performer. Its accuracy was greatest for variables with higher first-order autocorrelation, which may help explain its strong performance in this setting. While criticized in inferential statistics for causing bias and low standard errors [6,40], here it outperformed many multiple imputation methods.

Random forest multiple imputation was the best performing multiple imputation model. Jaeger et al [27] also found it led to the best predictive performance across 12 imputation strategies with 2 different outcome models in a registry dataset. Perez-Lebel et al [9] attributed multiple imputation's improved performance to ensembling (averaging multiple predictors) rather than accurately capturing the distribution of the missing values (the theoretical basis for its use in inferential statistics).

Native support for missing values (no imputation) yielded high balanced accuracy for gradient boosted models and reasonable performance for other metrics. Perez-Lebel et al [9] concluded that it had the best predictive performance in real-world EHR data, with the lowest computational cost. LOCF (which they did not test) also has very little computational cost but may be less broadly applicable.

As with imputation performance, missingness mechanism had less impact on prediction performance than proportion of missingness. Performance degraded substantially as missingness fraction increased, consistent with prior findings [13]. Interestingly, performance was similar across MAR, MCAR, and MNAR scenarios. Some studies suggest explicitly adding indicator variables for missingness to outcome models improves prediction in MNAR settings [9,10,41]. However, others argue against them because they are fragile to operational and practice changes and may not generalize well to other settings [11,12,42]. We therefore did not include such indicators, and performance in MNAR scenarios was comparable to MAR and MCAR scenarios. Machine learning models with native support for missing data may exploit missingness patterns for prediction. If no imputation is employed, missingness patterns should be closely monitored for drift and its effect on predictive performance [42].

Variability between imputation methods differed by model type and performance metric. LASSO outcome models showed less variability than gradient boosted models. In our experiment, imputation method appeared to have a greater impact on the binary outcome than the continuous outcome. Balanced accuracy had the highest variability between methods, followed by AUC; MSE exhibited substantially less variability than either. All imputation methods had lower MSE for gradient boosted models than LASSO models, indicating choice of outcome model mattered more than choice of imputation method.

XSL•FO
RenderX

Relationship Between Imputation and Prediction Performance

The best performing methods for imputation—LOCF and random forest multiple imputation—also performed well in prediction. Thus, our main results for imputation and prediction performance were largely concordant. Mean imputation had the worst MSE but performed relatively well in gradient boosted models, possibly because constant imputation creates patterns that machine learning can exploit [9,43]. Its performance dropped in LASSO models. Others have noted that more accurate imputation methods do not always yield better predictions [9,27], especially when features are weakly correlated [9].

Overfitting in imputation models reduced imputation accuracy, which subsequently impacted the accuracy of outcome models. Outcome metrics that overfit more (eg, balanced accuracy in gradient boosted models) also showed greater variability between imputation methods in patterns that reflected differences in imputation accuracy.

Imputation and Interpretability

For clinical decision support, it is important to assess how missing data handling affects interpretability. The full promise of artificial intelligence will not be realized if it is not deemed trustworthy and transparent by humans [44,45]. Mean imputation, the most common method of imputation in machine learning clinical prediction models [12], may reduce interpretability for clinicians trying to understand predictions for individual patients, as the mean is not meaningful at the individual level. Native support by algorithms may improve interpretability by relying only on recorded values. LOCF is simple to implement and aligns with clinical reasoning—if a measurement is expected to change and that change is important, it will be remeasured if possible. Finally, if complex methods like random forests (while less interpretable themselves) generate accurate imputations that reflect a biological or clinical relationship between the predictor and outcome, this could lead to more interpretable outcome models that are also more robust over time and across populations [9].

Limitations

The primary limitation of this experiment is its reliance on both a single dataset and a single method for generating the complete dataset on which the analysis is based. However, a key strength is the high fidelity of the data, with detailed, frequent measurements typical of the intensive care unit. This contrasts with EHR data from settings like primary care, where visits may be months or years apart. Although we predicted both a binary and continuous outcome, our dataset was limited to a single PICU at one academic medical center. Raw data were transformed into a structured format with time windows and summary variables, a common approach for EHR data [2,46]. Thus, our findings may not generalize to other settings or data structures.

We restricted imputation methods in our experiment to those with readily available packages in R that allowed model training on 1 dataset and subsequent imputation in new data. Deep learning methods were not included, nor were novel approaches [47-49] that may outperform tested methods but are more complex to implement for applied practitioners. Performance could also theoretically be improved by combining imputation approaches (eg, a SuperLearner [50]).

Most existing imputation packages do not allow users to save model parameters to apply on new data, limiting the methods available [15]. Some have proposed workarounds, such as stacking data from a new patient with all training data and rerunning multiple imputation models [15,17]. However, this was computationally infeasible in a dataset of our size. Privacy concerns may also prevent access to training data in deployment. Even packages like *mice* that allow imputation on single new cases have limitations—each call refits an iteration of the model, making real-time imputation for new patients infeasible due to speed. The lack of scalable imputation tools remains a barrier to progress to deploying real-time clinical prediction models.

Conclusion

When using EHR data with frequent measurements to build a prediction model, LOCF offers reasonable performance with simple implementation. Native support for missing data in machine learning models, such as gradient boosted trees, is the least computationally intensive approach, with decent performance and potentially broader applicability than LOCF. While multiple imputation is the gold standard for inferential models, it is extremely computationally intensive, may not be optimal for prediction models, and may not be feasible in real time. As clinical prediction models continue to integrate into real-time patient care, addressing missing data appropriately remains essential.

Multimedia Appendix 2
Imputation test performance metrics (blood pressure): mean squared error. Each point represents mean squared error calculated for 176 numeric variables for 1 of 300 datasets created for the outcome of blood pressure. There are 20 datasets per missingness scenario and imputation type represented in each box plot. AV: average (average of 30 imputations); Bayesian/PMM: Bayesian imputation under the normal linear model with predictive mean matching; LASSO: least absolute shrinkage and selection operator; LOCF: last observation carried forward.
[PDF File, 126 KB - medinform_v13i1e79307_app2.pdf]

Multimedia Appendix 3
Imputation test performance metrics (extubation and blood pressure): classification error. Each point represents classification error calculated for 6 categorical variables for 1 dataset (of 300 created for the outcome of extubation and 300 created for the outcome of blood pressure). There are 20 datasets per missingness scenario and imputation type represented in each box plot. The mice implementation of LASSO cannot accommodate multiclass categorical outcomes; thus, we used a simple classification tree. AV: average (average of 30 imputations); Bayesian/PMM: Bayesian imputation under the normal linear model with predictive mean matching; LASSO: least absolute shrinkage and selection operator; LOCF: last observation carried forward.
[PDF File, 249 KB - medinform_v13i1e79307_app3.pdf]

Multimedia Appendix 4
Imputation performance difference between train and test (extubation and blood pressure): mean squared error. Each point represents the difference in mean squared error between training and test sets calculated for 176 numeric variables for 1 dataset (of 300 created for the outcome of extubation and 300 created for the outcome of blood pressure). There are 20 datasets per missingness scenario and imputation type represented in each box plot. AV: average (average of 30 imputations); Bayesian/PMM: Bayesian imputation under the normal linear model with predictive mean matching; LASSO: least absolute shrinkage and selection operator; LOCF: last observation carried forward.
[PDF File, 256 KB - medinform_v13i1e79307_app4.pdf]

Multimedia Appendix 5
Imputation performance difference between train and test (extubation and blood pressure): classification error. Each point represents the difference in mean squared error between training and test sets calculated for 6 categorical variables for 1 dataset (of 300 created for the outcome of extubation and 300 created for the outcome of blood pressure). There are 20 datasets per missingness scenario and imputation type represented in each box plot. The mice implementation of LASSO cannot accommodate multiclass categorical outcomes; thus, we used a simple classification tree. AV: average (average of 30 imputations); Bayesian/PMM: Bayesian imputation under the normal linear model with predictive mean matching; LASSO: least absolute shrinkage and selection operator; LOCF: last observation carried forward.

Multimedia Appendix 6
Autocorrelation versus imputation error by method (extubation). Scatterplot of per-variable temporal autocorrelation (AR(1) coefficient, *x*-axis) versus imputation error (*y*-axis; mean squared error (MSE) for numeric variables, classification error for categorical) using 4-hour windows. Each point represents 1 predictor; higher persistence corresponds to lower error for last observation carried forward (LOCF).
[PDF File, 22 KB - medinform_v13i1e79307_app6.pdf]

Multimedia Appendix 7
Imputation test performance metrics by missingness in original data (extubation and blood pressure): mean squared error. Each point represents mean squared error calculated for 176 numeric variables for 1 dataset stratified by whether the value was missing in the original data (of 300 created for the outcome of extubation and 300 created for the outcome of blood pressure). There are 20 datasets per missingness scenario and imputation type represented in each box plot. AV: average (average of 30 imputations); Bayesian/PMM: Bayesian imputation under the normal linear model with predictive mean matching; LASSO: least absolute shrinkage and selection operator; LOCF: last observation carried forward.
[PDF File, 768 KB - medinform_v13i1e79307_app7.pdf]

Multimedia Appendix 8
Marginal means for interaction between imputation method, proportion missing, and variable group (extubation and blood pressure). We calculated marginal means for interaction from linear models of mean squared error comparing imputed values to complete dataset (for each outcome: 1 observation [n=264,000] per 176 variables per 300 datasets per 5 imputation methods). We calculated marginal means for interaction from linear models of classification error comparing imputed values to complete dataset (for each outcome: 1 observation [n=9000] per 6 variables per 300 datasets per 5 imputation methods) with random intercepts for each of the 1500 datasets. We included all 3-way and 2-way interactions and completed a backward stepwise elimination procedure (included $P<.05$) to determine the final model. Variable group 4, unlike other variable groups, included mostly indicator variables constructed from “select all that apply” responses in the electronic health record (EHR) (see Table S1). Bayesian/PMM: Bayesian imputation under the normal linear model with predictive mean matching; LASSO: least absolute shrinkage and selection operator; LOCF: last observation carried forward.
[PDF File, 76 KB - medinform_v13i1e79307_app8.pdf]

Multimedia Appendix 9
Gradient-boosted model test performance (extubation): other metrics. Each point represents performance for 1 dataset. There are 20 datasets per missingness scenario and imputation type represented in each box plot. Performance in the complete dataset is represented by a dashed line. AV: average (average of 30 imputations); Bayesian/PMM: Bayesian imputation under the normal linear model with predictive mean matching; LASSO: least absolute shrinkage and selection operator; LOCF: last observation carried forward; MI: multiple imputation; NPV: negative predictive value; PPV: positive predictive value.
[PDF File, 1010 KB - medinform_v13i1e79307_app9.pdf]

Multimedia Appendix 10
Gradient boosted model test performance (blood pressure): other metrics. Each point represents performance for 1 dataset. There are 20 datasets per missingness scenario and imputation type represented in each box plot. Performance in the complete dataset is represented by a dashed line. AV: average (average of 30 imputations); Bayesian/PMM: Bayesian imputation under the normal linear model with predictive mean matching; LASSO: least absolute shrinkage and selection operator; LOCF: last observation carried forward; MAE: mean absolute error; MI: multiple imputation; NPV: negative predictive value; PPV: positive predictive value; RMSE: root mean squared error.
[PDF File, 617 KB - medinform_v13i1e79307_app10.pdf]

Multimedia Appendix 11
LASSO test performance (extubation): all metrics. Each point represents performance for 1 dataset. There are 20 datasets per missingness scenario and imputation type represented in each box plot. Performance in the complete dataset is represented by a dashed line. AV: average (average of 30 imputations); Bayesian/PMM: Bayesian imputation under the normal linear model with predictive mean matching; LASSO: least absolute shrinkage and selection operator; LOCF: last observation carried forward; MAE: mean absolute error; MI: multiple imputation; NPV: negative predictive value; PPV: positive predictive value; RMSE: root mean squared error.

Abstract

Background: Concerns have been expressed about the abundance of new clinical prediction models (CPMs) proposed in the literature. However, the extent of this proliferation in prediction research remains unclear.

Objective: This study aimed to estimate the total and annual number of CPM development-related publications available across all medical fields.

Methods: Using a validated search strategy, we conducted a systematic search of literature for prediction model studies published in Pubmed and Embase between 1995 and the end of 2020. By taking random samples for each year, we identified eligible studies that developed a multivariable model (ie, diagnostic or prognostic) for individual-level prediction of a health outcome across all medical fields. Exclusion criteria included development of models with a single predictor, studies not involving humans, methodological studies, conference abstracts, articles with unavailable full text, and those not available in English. We estimated the total and annual number of published regression-based multivariable CPM development articles, based on the total number of publications, proportion of included articles, and the search sensitivity. Furthermore, we used an adjusted Poisson regression to extrapolate our results to the period 1950 - 2024. Additionally, we estimated the number of articles that developed CPMs using techniques other than regression (eg, machine learning).

Results: From a random sample of 10,660 articles published between 1995 and 2020, 109 regression-based CPM development articles were included. We estimated that 82,772 (95% CI 65,313 - 100,231) CPM development articles using regression were published, with an acceleration in model development from 2010 onward. With the addition of articles that developed non-regression-based CPMs, the number increased to 147,714 (95% CI 125,201-170,226). After extrapolation to the years 1950 - 2024, the number of articles increased to 156,673 and 248,431 for regression-based models and total CPMs, respectively.

Conclusions: Based on a representative sample of publications from the literature, we estimated that nearly 250,000 articles reporting the development of CPMs across all medical fields were published until 2024. CPM development–related publications continue to increase in number. To prevent research waste and close the gap between research and clinical practice, focus should shift away from developing new CPMs to facilitating model validation and impact assessment of the plethora of existing CPMs. Limitations of this study include restriction of search to articles available in English and development of the validated search strategy prior to the popularity of artificial intelligence and machine learning models.

Introduction

Concerns have been expressed about the abundance of new clinical prediction models (CPMs) proposed in the literature and their limited application in clinical practice, pointing to a high level of research waste [1,2]. Despite efforts to regulate model development and shift focus to model evaluation and implementation, new models appear to be developed at an ever increasing rate [3-5]. Although the number of published CPMs has been reported for specific medical fields or target groups [6-8], a comprehensive overview of the publication of CPM development studies across the spectrum of health care practice does not currently exist. In this study, we estimated the total and annual number of CPM development articles available across all medical fields.

Methods

Study design

This study is a bibliometric analysis of a previously published protocol [9], registered on the Open Science Framework Registries platform [10]. We conducted a systematic search of prediction model articles published between January 1, 1995, and December 31, 2020, in PubMed and Embase, using a validated search strategy for retrieval of clinical prediction modeling studies [sensitivity: 98.2% (91.5% - 99.9%) and specificity: 86.1% (85.4% - 86.7%)] (see Textbox 1) [11-15]. Publication records including titles and abstracts from the searched online databases were stored separately based on each publication year.

Textbox 1. Search terms for prediction models developed and validated by Ingui and Rogers

‘(Validat$ OR Predict$.ti. OR Rule$) OR (Predict$ AND (Outcome$ OR Risk$ OR Model$)) OR ((History OR Variable$ OR Criteria OR Scor$ OR Characteristic$ OR Finding$ OR Factor$) AND (Predict$ OR Model$ OR Decision$ OR Identif$ OR Prognos$)) OR (Decision$ AND (Model$ OR Clinical$ OR Logistic Models/)) OR (Prognostic AND (History OR Variable$ OR Criteria OR Scor$ OR Characteristic$ OR Finding$ OR Factor$ OR Model$))’

This study has been prepared in accordance with the reporting bibliometric reviews of the biomedical literature (BIBLIO) guideline [16]. The PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) [17] elements have been incorporated into the description of the systematic search.

Random Sampling

We aimed to obtain an unbiased stratified sample of at least 100 published CPM articles. Based on published search string metrics, positive predictive value 3.5% (95% CI 2.7% - 4.6%), we calculated that 2860 records needed screening; therefore, 110 records were randomly selected per publication year. As the target sample size of 100 articles—with a minimum of one development article per year— was not reached after the screening process, we increased the sample size in increments of 30 articles per year until at least 100 articles were included. Details about the sample size calculation and random selection of records are provided in Multimedia Appendix 1 and the published protocol [9].

Eligibility, Screening Process and Data Extraction

Articles were eligible for inclusion in this study if they described the development or external validation of a multivariable model [18]. Studies that described development of a regression-based multivariable prediction model for a health outcome were the focus of the current analysis. Studies that reported development of a prediction model without using logistic, proportional hazards, or linear regression were designated as non-regression–based development articles (eg, machine learning models or scoring rules based on multiple unadjusted bivariate associations). Studies updating existing models were also categorized as development articles.

Articles that externally validated a CPM in a different population or in a different time period were designated as validation articles. Of note, an article could be of more than one type (eg, CPM development and external validation article). A random train-test split was not considered external validation. Finally, decision curve analysis (net benefit) was regarded as a method of validation.

We excluded articles that did not present any developed prediction models or external validation in the main results sections (eg, etiologic studies, risk factor assessments, reviews). Articles were also excluded if they were based on a single predictor; reported development or validation of a diagnostic questionnaire (eg, for diagnosis of depression); presented models that were neither diagnostic nor prognostic; did not yield individual-level predictions; did not involve humans; or if they were methodological studies. Articles that were not available in English; conference abstracts; and those without available full texts were also excluded.

Six reviewers (BA, ER, KR, LC, LS, and LW) independently screened titles and abstracts, in pairs. After selection of potential eligible articles, two independent researchers (BA and ER) reviewed the full text articles for eligibility and extracted data. Disagreements were discussed among the reviewers and unresolved conflicts were solved during team consensus meetings. Extracted data included medical domain (based on outcome or target population, or both); publishing journal; publication year; country; study design; study setting; data sources; study population; sample size; outcomes; number of models; model type (diagnostic or prognostic); internal or external validation; performance measures (eg, discrimination, calibration); and model presentation (model equation, nomogram, sum score, etc.).

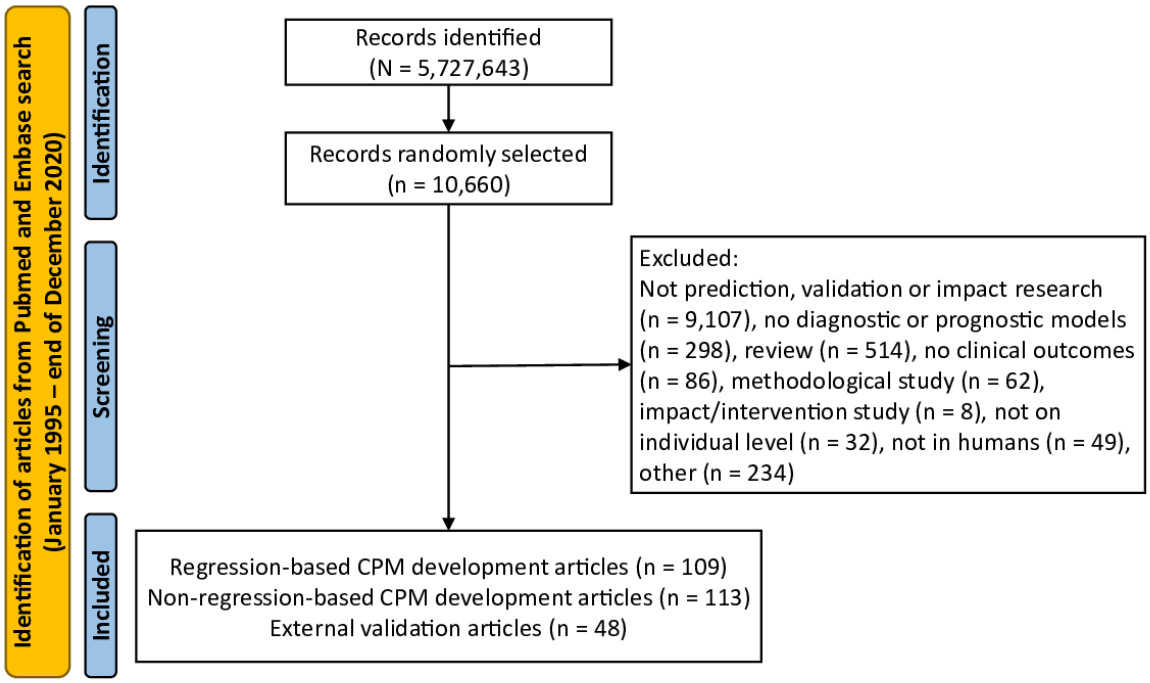
Data Analysis

Characteristics of eligible regression-based CPM development articles were described using frequencies (n) and percentages (%) for categorical data. We categorized articles by medical field, geographical origin, model type (diagnostic or prognostic), and other characteristics. Next, we estimated the annual number of CPM development articles using the following formula:

XSL•FO
RenderX

To estimate the overall number of articles, we used the weighted average of year-specific proportions of CPM development articles, weighted by the number of hits per year using a conventional estimator of proportion based on a stratified sample [19]. Further details, including calculation of 95% CI is shown in Multimedia Appendix 1. As the search string was developed for identification of regression-based CPMs, we focused primarily on these models for our primary analysis. Additionally, we extrapolated our estimates to 1950 - 2024 using Poisson regression adjusted for publication year. We compared the fit of models with a quadratic term and a linear term for publication year, which showed no apparent difference between the two models (P=.82). Therefore, a linear term was used for the publication year.

In additional analyses, we estimated the total and annual number of articles that reported development of non-regression–based CPMs and external validation articles using the above-mentioned formula, and calculated their respective 95% CIs. For sensitivity analyses, we recalculated our estimations using search sensitivity reported in a validation study by Geersing et al [15].



Ethical Considerations

This study was deemed as conforming to the ethics standards of Maastricht University by the ethics committee (case number: FHML-REC/2023/066).

Results

Our search yielded 5,727,643 publications, from which a random sample of 10,660 (410 articles per year) were screened. A total of 222 CPM development articles were identified. including 109 reporting on regression-based models and 113 on non-regression–based models (Figure 1). Characteristics of the regression-based articles are shown in Table 1. Most articles were from North America 41 (37.6%), Europe 37 (33.9%), and Asia 25 (22.9%). The most common medical fields for models development were cardiovascular medicine 22 (20.1%), gynecology and obstetrics 16 (14.7%), and gastroenterology 14 (12.8%). Across all medical fields, 38 (34.9%) of the articles were related to oncology (Table S1 in Multimedia Appendix 1). In addition, 67 (61.5%) of articles described prognostic models while 42 (38.5%) described diagnostic models. Model calibration and discrimination were reported in 31 (28%) and 87 (80%) of the articles, respectively; only 37 (33.9%) of the articles presented their final model.

[a]Other fields: Infectious disease: 4 (3.7%); Endocrinology: 3 (2.7%); Hematology: 3 (2.7%); Dermatology: 2 (1.8%); Critical care: 2 (1.8%); Orthopedic surgery: 2 (1.8); Ophthalmology: 1 (0.9%); Emergency medicine: 1 (0.9%).

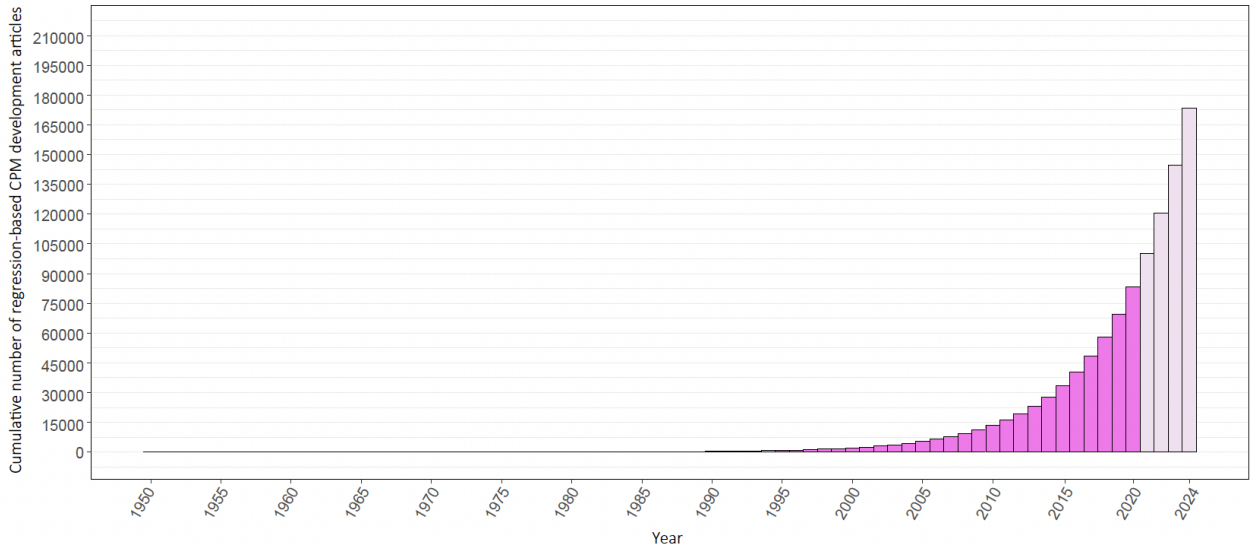
The estimated number of published regression-based CPM development articles from 1995 to 2020 was 82,772 (95% CI 65,313 - 100,231), with the number of these articles rapidly increasing from 2010 onward (Figure 2, darker area). The number of regression-based CPM development articles that were published increased to 156,673 after extrapolating the findings to 1950 - 2024 (Figure 2, lighter area). Furthermore, an estimated 64,942 (95% CI 50,484 - 79,400) non-regression–based development articles were published between 1995 and 2020 (Figure 3, darker area), increasing the estimated total number of CPM development articles during this period to 147,714 (95% CI 125,201 - 170,226). When

XSL•FO
RenderX

expanded to 1950 - 2024, this number increased to 248,431 (Figure 3, lighter area).

In additional analysis, the estimated number of CPM external validation articles (n=48) published between 1995 and 2020 was 36,394 (95% CI 24,837 - 47,952) (Figure S1 in Multimedia Appendix 1). The estimated number of articles based on search sensitivity reported by Geersing et al [15] are presented in Multimedia Appendix 1.

Figure 2. Cumulative estimated number of regression-based CPM development articles published between 1950 and 2024.



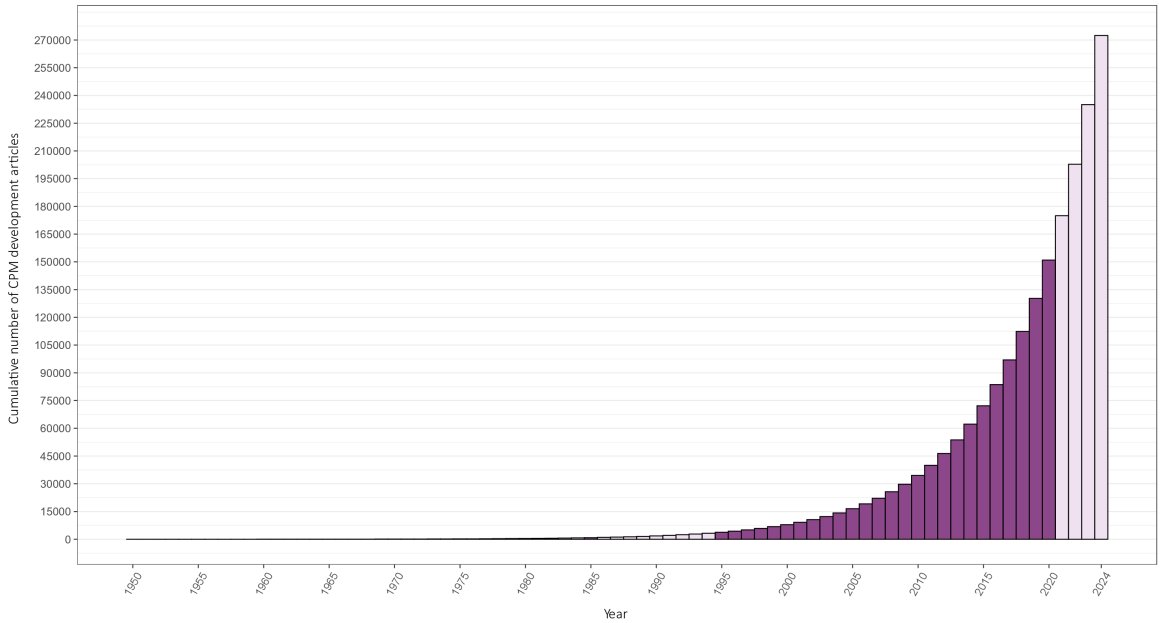


Figure 3. Cumulative estimated number of regression and non-regression–based CPM development articles between 1950 and 2024.

Discussion

Summary

More than 150,000 articles reporting new regression-based CPMs have been published in the medical literature up to 2024, with the number increasing rapidly in recent years—about 10,000 per year. After the addition of non-regression models, the current total approaches 250,000 articles.

Trends in the numbers of model development studies had not been systematically assessed across different medical fields to date. Previously, CPM development for cardiovascular outcomes showed a three-fold increase between 2005-2014, compared to 1995 - 2004 [5]. Further, a sharp increase was observed in the number of models developed using electronic health record data between 2009 - 2019 [3]. Our study shows that despite all regulatory efforts, the growth in model development is ever increasing and is not limited to a specific field [11]. This surge in model development publication has been attributed to the growing accessibility to data and analytical tools [12,20]. However, the excessive model development may obscure decent models and hinder their evaluation [2]. Without further

XSL•FO
RenderX

evaluation such as external validation, these models are unlikely to be fit for adoption in clinical practice.

The proportion of CPMs that undergo external validation remains the topic of ongoing research [9,21]. Among 127 selected CPMs developed before 2010, the probability of external validation within 5 years was only 16% [21]. At such rates, the current surge in model development is bound to produce excess research waste. Adequate methodology and transparent reporting may increase the chances of validation [5,22]. In our study, two-thirds of the development articles did not report the final model. With such an omission, the likelihood that a model will be further evaluated is limited.

Our study benefits from a long time span across more than two decades, assessment of a random sample, and a validated search strategy. However, certain limitations should be acknowledged. Our search was restricted to articles available in English. In addition, the validated strategy that we used was developed prior to the rise in popularity of machine learning and artificial intelligence models. Therefore, our estimates may be considered a lower bound of the actual abundance of CPM development. Despite this, our findings underscore the implications for the current enthusiasm and rapid growth of machine learning and artificial intelligence models. Given the emphasis on retraining, we reiterate that these models also need to undergo rigorous evaluation [7,23,24]. The lack of interpretability of these complex models poses additional challenges; when it is difficult to understand how a model arrives at its predictions, rigorous validation is all the more important.

Implication for Researchers and Stakeholders

To enhance efficiency, prediction research must shift from developing new CPMs to evaluating existing ones [1]. Targeted validation and impact assessment of current CPMs, along with active dissemination and implementation of prediction model-based innovations are crucial steps in minimizing research waste and bridging the gap between research and clinical practice [25]. The responsibility for advancing model evaluation beyond development falls on researchers, clinicians, funding agencies, and other stakeholders. Future validation efforts may depend on both pre-development factors (eg, a clearly defined clinical need, clinician, or public demand) and post-development considerations (eg, model complexity, feasibility of use or the absence of a dissemination or implementation plan) [5]. Additionally, the emphasis on novelty by funding agencies may inadvertently discourage evaluation of existing models. We also advocate for greater transparency in reporting (including presentation of model equations), alongside adherence to contemporary methodological standards by researchers.

Conclusion

Based on a random sample of publications from a validated search strategy, we estimate that nearly 250,000 articles reporting the development of clinical prediction models were published in the literature until 2024. The proliferation of model development, regardless of medical field has accelerated at an unprecedented rate in recent years. It is critical to shift focus from model development to model validation and assessing impact on health care.

Abstract

Background: The field of digital health solutions (DHS) has grown tremendously over the past years. DHS include tools for self-management, which support individuals to take charge of their own health. The usability of DHS, as experienced by patients, is pivotal to adoption. However, well-known questionnaires that evaluate usability and satisfaction use complex terminology derived from human-computer interaction and are therefore not well suited to assess experienced usability of patients using DHS in a home setting.

Objective: This study aimed to develop, validate, and assess an instrument that measures experienced usability and satisfaction of patients using DHS in a home setting.

Methods: The development of the "Experienced Usability and Satisfaction with Self-monitoring in the Home Setting" (GEMS) questionnaire followed several steps. Step I consisted of assessing the content validity, by conducting a literature review on current usability and satisfaction questionnaires, collecting statements and discussing these in an expert meeting, and translating each statement and adjusting it to the language level of the general population. This phase resulted in a draft version of the GEMS. Step II comprised assessing its face validity by pilot testing with Amsterdam University Medical Center's patient panel. In step III, psychometric analysis was conducted and the GEMS was assessed for reliability.

Results: A total of 14 items were included for psychometric analysis and resulted in 4 reliable scales: convenience of use, perceived value, efficiency of use, and satisfaction.

Conclusions: Overall, the GEMS questionnaire demonstrated its reliability and validity in assessing experienced usability and satisfaction of DHS in a home setting. Further refinement of the instrument is necessary to confirm its applicability in other patient populations in order to promote the development of a steering mechanism that can be applied longitudinally throughout implementation, and can be used as a benchmarking instrument.

Introduction

The number of digital health solutions (DHS) has increased rapidly, with the potential to significantly enhance the way health care is delivered [1]. DHS include, among others, tools for self-management of clinical data such as blood pressure measurements, for medication adherence, and for education on health-related behaviours such as diet, smoking, and exercise [2]. These tools present the opportunity to increase access to health care and optimize disease management, and they ultimately aim to alleviate health care expenditure [3]. Self-management, as per the World Health Organization, encompasses the capacity of individuals to support and sustain their own health, prevent diseases, and cope with illness and disability, whether independently or with the assistance of a health care professional (HCP) [4,5]. The use of DHS serves a dual purpose in patient self-management: (1) facilitating proactive engagement of individuals in their health journey to optimize treatment outcomes and (2) enhancing prevention of negative health outcomes [6,7]. Consequently, ensuring accessibility and adoption of DHS among target users is crucial for effective implementation [8]. The experienced usability of DHS is pivotal to their adoption, especially for individuals with disabilities or those living with chronic diseases who need to make frequent use of a DHS within their care journey [9-11]. Measuring DHS usability and patient satisfaction is crucial to understand and improve accessibility and use of DHS, thereby fostering patient engagement.

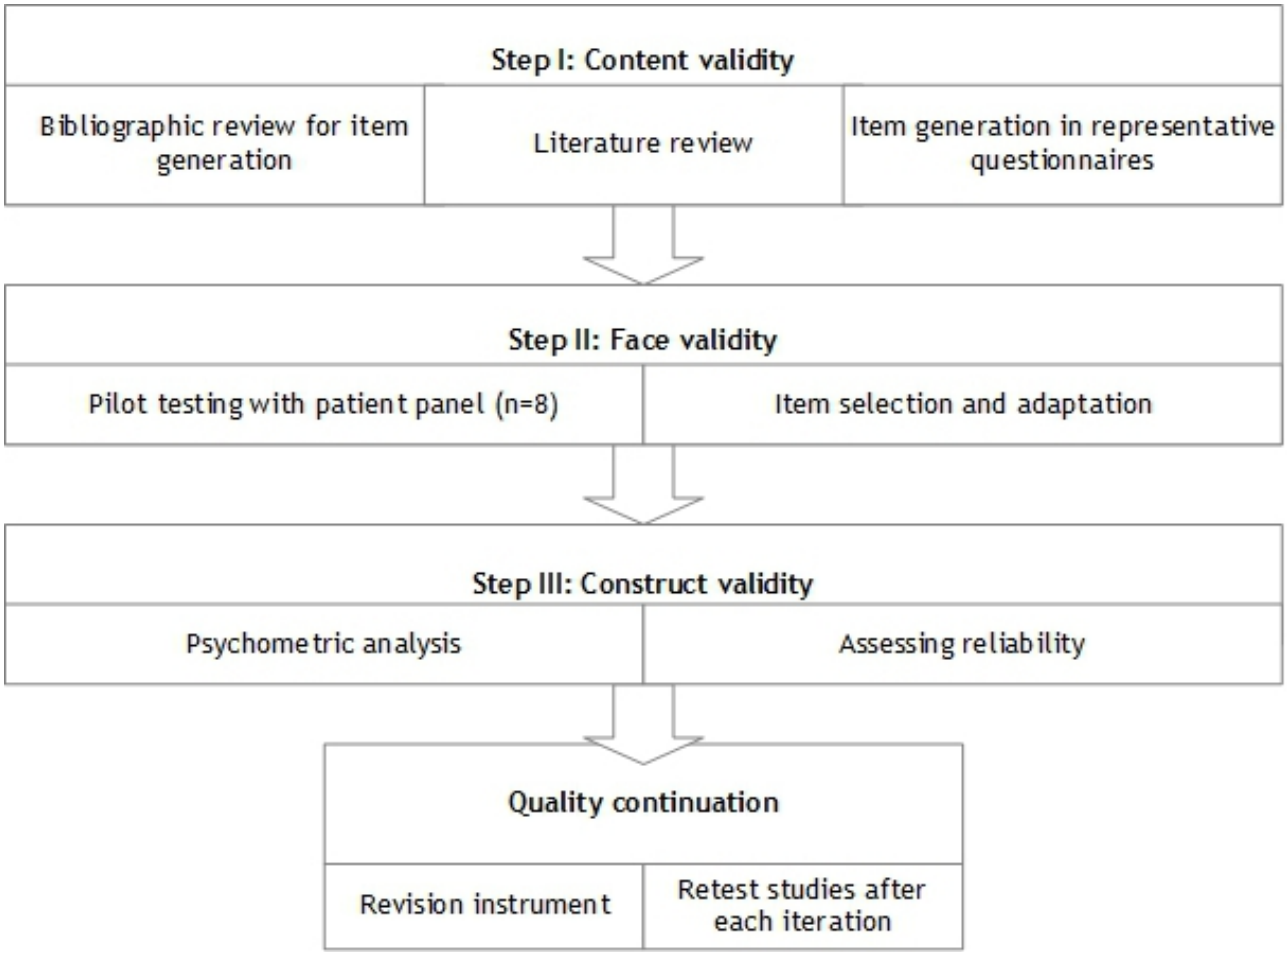
The international organization for standardization defines usability, as comprising effectiveness, efficiency, and satisfaction, given a specific user in a context [12]. In the context of DHS, effectiveness refers to the capacity for thorough and accurate task completion, such as logging into a patient portal or setting personal preferences for medication reminders. Efficiency, on the other hand, involves accomplishing these tasks with minimal effort. Finally, satisfaction is expressed as the comfort and acceptability experienced by patients when using a DHS tool. Usability is often measured by (validated) usability and satisfaction questionnaires, as they allow efficient collection and structured assessment of data from a large number of individual users [13,14]. Usability questionnaires originate from the field of human-computer interaction and user-centered design and have emerged as a means to evaluate the effectiveness, efficiency, and satisfaction of interactive systems, particularly software and digital interfaces from the perspective of end users [15]. Therefore, existing well-known and applied usability questionnaires, such as the System Usability Scale (SUS) and mHealth App Usability Questionnaire (MAUQ) apply software terminology such as the "*various functions* in this system," or "*navigation* between screens" [16-18]. These statements are difficult to interpret for individuals lacking familiarity with software terminology, particularly for patients with low levels of digital literacy [19]. These statements are therefore not suited to measure the usability of self-management tools in healthcare practice by all users.

In addition, introducing DHS in a self-management care journey may increase disparities, as it requires particular skills to use it that comprise both health and digital literacy [20]. In terms of patient characteristics, patients with high health literacy, a higher educational level, and patients who are familiar with DHS find it easier to use these tools [21]. Variability in digital literacy skills among patients are well-recognized, posing challenges in its utilization [22]. Comprehensive research on the specific patient groups for which DHS is relevant, and our understanding of usability in this domain are still in the nascent stages. Disparities arising within groups due to the utilization of technology might lead to one group adopting the technology, while the other group opts not to use it. With the increasing availability and reliance on DHS [26], these tools should be usable for the majority of the patient population. Evaluations of patient experiences with DHS should therefore also be accessible to diverse groups of patients. Thus, to optimize health outcomes and to deliver high quality care, evaluating patients' experienced DHS usability and satisfaction in a home setting is imperative for health care organizations and HCPs [1,23]. In order to ensure patient inclusivity, a general and accessible instrument is needed, which can be applied as a steering mechanism, deployed at multiple points in time to measure usability and satisfaction of DHS in a home setting.

The aim of this study is to develop, validate, and assess the reliability of an instrument that measures experienced usability of and satisfaction with DHS use, taking digital (language) literacy into account. When developing the Experienced Usability and Satisfaction with Self-monitoring in the Home Setting (GEMS) questionnaire, our goal is to find a middle ground between innovation and familiarity, drawing from established statements and questionnaires while tailoring them to be able to evaluate patients experiences with DHS from an inclusive perspective. In doing so, we aim to advance DHS implementation and expand our understanding of end users' needs, for efficient, effective and satisfied DHS use.

Methods

Ethical Considerations



The Medical Ethical Committee of Amsterdam University Medical Center (Academic Medical Center) declared that this study was not subject to the Medical Research Involving Human Subject Act and that further approval was not required (W22 291 # 22.352).

GEMS Questionnaire Development

To develop and validate the questionnaire "Gebruiksvriendelijkheid en Ervaring met Monitoren in de ThuisSetting," translated as Experienced Usability and Satisfaction with self-monitoring in the Home Setting, we followed several steps, as depicted in Figure 1.

XSL•FO
RenderX

Figure 1. Flowchart of the development of experienced usability and satisfaction with digital health solutions in a home setting.

Step I: Content Validity - Collecting User Experience Statements

To design the GEMS questionnaire, we first searched for published literature on user experience questionnaires in the context of DHS in PubMed using the keywords “Digital Health Solutions,” “Digital Health Technologies,” “Self-Management tools,” “Digital health apps,” “mHealth apps,” AND (“Usability” OR “Satisfaction”) [24]. We searched for questionnaires that measured end-user experiences, and restricted our search to studies published in the last 5 years due to the rapidly evolving nature of the field.

After the literature review, an expert meeting was held, for which we invited several usability experts in the field. We went through the domains and statements from the validated questionnaires retrieved from the literature search. The outcome of this meeting was a list of requirements for domains with items that should be included in the GEMS questionnaire. This is in line with the 6 domains of usability, according to the general guidelines for usability assessment [12,25]: “Effectiveness,” “Efficiency,” “Satisfaction,” “Learnability,” “Perceived value,” and “Privacy and Security Issues.”

After the selection of the items during the expert meeting, we translated the items that were only available in English into Dutch. We applied a forward-backward translation (English to Dutch) procedure for each item. This procedure was executed by 2 people who were native proficiency speakers of both Dutch and English (DPN and Stephanie Medlock). A formal assessment of each item’s linguistic complexity using the Common European Framework of Reference for Language was conducted, including translating items as required to B1 level, by an expert that had experience in making patient instructions accessible (Marieke van Maanen) [26,27]. Items from 6 individual (validated) questionnaires were collected (Table S1 in Multimedia Appendix 1). In addition, insights from the article of the authors Berkman and Karahoca [28] were integrated into the process, as they describe that the change in sensitivity of a scale varies due to the responses, while in human-computer interaction, a scale is expected to be sensitive to the differences between systems instead of people. This insight enriched the questionnaire development with current research findings and best practices in usability metrics. We therefore maintained the item scores consistent with the current scoring methodology across responses. This has resulted in sufficient differentiation at the system level; however, further refinement is required to optimize the scoring of the GEMS.

Step II: Face Validity - Pilot Testing, Item Selection, and Adaptation

We recruited participants to take part in the evaluation of (1) the questionnaire itself, and (2) the evaluation of DHS using the draft GEMS instrument (Figure S1 in Multimedia Appendix 1). Round I consisted of an appreciative inquiry, to get feedback from stakeholders, to ensure that the instrument reflected their perspectives and values and that questions were understandable

XSL•FO
RenderX

[29]. We presented the questionnaire to the patient panel from the Amsterdam University Medical Center (n=8; Table S2 in Multimedia Appendix 1). After this round, an expert meeting including all authors (and Thomas Engelsma) was held to make adjustments to the language and wording of the questions.

Step III: Construct Validity - Psychometric Analysis

Round II consisted of the validation of the questionnaire by applying it with users of two self-management tools within the Amsterdam University Medical Center patient portal, which are available from the electronic health record for patients under the nephrology department: (1) entering home measurements of kidney transplant patients' vital statistics such as blood pressure, pulse, and temperature and (2) medication reminders. Patients were included when they participated in home measurements, or in the use of medication reminders, could read and understand the Dutch language, and downloaded the app from the patient portal in order to use one of these functionalities. Patients were invited to participate in this study by their HCP (physician or nurse practitioner). Informed consent of the participants was provided online (e-consent). Patients who agreed to participate were contacted by a researcher (SJO or a supportive researcher) to administer the GEMS questionnaire by email. Data were collected using Castor EDC [30]. Patients who did not return the questionnaire or did not fully complete the questionnaire received a reminder after 2 weeks, and, if necessary, a phone call after 4 weeks. After psychometric analysis, an expert meeting was held to discuss the findings, and if necessary, adjustments were made to the instrument.

Assessing Acceptability

The data from the questionnaire were analyzed using SPSS statistics (version 28.0.1.1, IBM) [31]. Respondents who missed more than one item of the GEMS were removed from the data set. Records missing other data, such as demographics, that were not part of the core of the GEMS questionnaire were not excluded. All items were recoded so that "1" was the most negative value on the Likert scale. In order to be able to perform factor analysis, the questions with scales ranging from "1-10" were recoded to "1 - 5" (1 and 2 were recoded to 1, 3 and 4 recoded to 2, and so on). The question with a Likert scale from "1-7" was recoded to "1 - 5," where the extremes are taken together (1 and 2 were recoded to 1; 6 and 7 were recoded to 5).

The Single Ease Questions (SEQ) is a single-item measure that assesses the complexity of a task for a user, such as entering home blood pressure measurements into the patient portal [32,33]. The SEQ aligns with the main features available in the system [33]. The different tasks that patients have to fulfil for the two separate DHS are difficult to compare, as logging into the system is the only task that is consistent across our analyses. Consequently, in psychometric evaluations, only the question regarding the ease or difficulty of "logging into the system" was included for both DHS assessments. For items where the nonresponse rate reached or exceeded 90%, it was inferred that patients chose not to answer the respective question. Consequently, the item in question was deemed unnecessary and was subsequently removed from the GEMS questionnaire [34]. With regard to the distribution of item scores, a skewness of 90% was considered to indicate redundancy for inclusion of the item in the GEMS questionnaire [34].

Assessing Construct Validity

An item correlation analysis was performed using the Spearman rank-order correlation coefficient. All items were compared with each other to find inter-item overlap, with a score of r_s>0.70 meaning that there could be singularity. Prior to performing a factor analysis, we tested whether the data set was suitable by assessing the Kaiser-Meyer-Olkin test of sampling adequacy (>0.60), and Bartlett test of sphericity (α<.05) [35,36]. A principal component analysis (PCA) with direct Oblimin rotation was used for factor analysis (FA). In addition, a scree plot was made of the PCA results. The number of values above the scree plateau were taken as the number of factors the items contributed to. In case of no clear scree plateau, a threshold of 1.0 was used.

Assessing Reliability and Internal Consistency

For all factors, extracted with PCA, the reliability and internal consistency were assessed by using the Cronbach α (>0.70) and item-total correlations (>0.40). Per factor, the items were dropped one by one to see whether items had to be removed to increase the Cronbach α to the threshold of 0.70. Finally, the items were scrutinised in an expert meeting (SJO, LWDP, DPN, SAN, HJM, and EMAS) using the results of the aforementioned analyses to determine which items were to be dropped and which should remain. In addition, we assigned labels to the constructs.

Results

Step I: Content Validity

In evaluations of DHS, researchers readily access numerous validated questionnaires from the literature, using them as tools for assessing usability and satisfaction in order to improve the product or system. Drawing from our literature review, the SUS is the most widely used usability evaluation instrument in the digital health industry [10,11]. For a long time, it has been a standard procedure to evaluate the usability of digital technology using general benchmarking tools, which has led to the adoption of generic tools like the SUS [11]. However, this questionnaire was developed in the early stages of the human-computer interaction field, at a time when digital health did not yet exist [16,37]. Newer questionnaires in the field such as the MAUQ and eHealth UsaBility Benchmarking Instrument try to be more specific within their domain; however, these questionnaires are still extensive, not easy to deploy, and using terminology derived from human-computer interaction [11,18]. In addition, as questionnaires such as SUS and Usability Metric for User Experience (UMUX) are primarily designed for software development, they use complex software-related terminology, such as functionalities of a system, that is often not understood by the general population [11].

We excluded statements regarding software interaction due to their complexity, which could potentially hinder understanding. We collected 14 unique statements from the identified questionnaires [12,25]. We chose to incorporate the 4-item UMUX (with Likert scale 1 - 5), along with SEQ (Likert scale 1 - 7). To include learnability, we added a question from the

XSL•FO
RenderX

SUS on whether patients had to learn a lot about the specific DHS before they could use it (Likert scale 1 - 5). Regarding perceived value, we added 2 questions from the MAUQ on whether the DHS contributed to the patient's health, and whether patients had the feeling that the DHS improved health care (both Likert scale 1 - 7). Finally, for perceived value, we added a question from Timmermans et al [38] on whether using the DHS reminded patients of being sick (Likert scale 1 - 5). To assess privacy and security, we added a question from Timmermans et al [38] (Likert scale 1 - 5). Regarding satisfaction, we opted to include the Net Promoter Score (NPS; Likert scale 1 - 10), the Customer Satisfaction Score (CSAT; Likert scale 1 - 5), and continued use, as we aimed to investigate whether satisfaction had an influence on continued use and vice versa (Likert scale 1 - 10). We added demographics such as gender, age, educational level, and health literacy [39,40]. At a later stage, we also added one question on digital literacy. The final GEMS questionnaire for validation consisted of 14 items (Table S4 in Multimedia Appendix 1).

Step II: Face Validity

In total, 92 patients participated in the validation: 65.2% (n=58) were male, 38% (n=35) were aged between 40 and 59 years, and 32.6% (n=30) had a higher professional education (Table S3 in Multimedia Appendix 1). A total of 92 patients were included for the psychometric analysis. All items presented to patients had a response rate of over 95%. For item skewness, no score was answered more than 90% for any of the answered questions. In the distribution of scores, we noticed that the highest value not applicable was entered with 10.9% on Q5 (question 5; "Q#" represents the questions involved in this study). The highest missing value with 17.4% was on Q13. No items of the GEMS were removed. Not all patients completed the question about digital literacy as this question was added to the demographics later (n=43). Patients' remarks and suggestions for improvement mainly focused on Q5, with some patients being unfamiliar with the nondigital method of filling in home measurements on paper. Therefore, some patients were unable to fill in this question. In addition, with Q8, patients indicated that the disease process is much more intense for some people than others, and that this question is difficult to answer in the home setting (Table 1).

Table . Description of each measurement instrument found in explorative literature search.

Measurement instrument	Abbreviation	Author	Items, n	Population validated	Scale	Reference where questionnaire has been used in health care context
Usability						
Questionnaire for User Interaction Satisfaction	QUIS	Chin et al [41]	27	150 users	1 - 9	[42,43]
System Usability Scale	SUS	Brooke [16]	10	184, aimed to include a diverse range of participants	1 - 5	[44-46]
mHealth App Usability Questionnaire	MAUQ	Zhou et al [18]	20	128, majority included were students with a bachelor's degree	1 - 7	[47,48]
The Usability Metric for User Experience	UMUX	Finstad [49]	4	255, not extensively described	1 - 7	[50]
Poststudy System Usability Questionnaire	PSSUQ	Lewis [37] Lewis [51]	16	48, and 210 in second validation study	1 - 7	[44,52]
Technology Acceptance Model questionnaire	TAM	Davis [53]	12	107 users	1 - 7	[54]
User version of the Mobile App Rating Scale	uMARS	Stoyanov et al [55]	20	164 young people	1 - 5	[56,57]
Mobile app rating scale	MARS	Terhorst et al [58]	23	1299 mobile health apps	1 - 5	[59]
eHealth Usability Benchmarking Instrument	HUBBI	Broekhuis et al [11]	18	148 persons	1 - 5	[60]
Satisfaction						
Net Promoter Score	NPS	Reichheld [61] Mekonnen [62]	1	Not described	1 - 10	[63,64]
Client Satisfaction Questionnaire	CSQ-8	Larsen et al [65]	8	Different populations, also in health care setting	1 - 4	[66]
Patient satisfaction questionnaire III	PSQ-III	Ware et al [67]	50	Various populations, in individuals with various medical conditions	1 - 5	[68]
Other						
Single Ease Questionnaire	SEQ	Nielsen and Molich [25]	1	Not described	1 - 7	[69]

Step III: Construct Validity

Spearman's rank correlation coefficient indicated Q8 as redundant as it showed a negative correlation on almost all items. The calculated UMUX score was also taken into consideration but did not show a significant correlation with items other than its own questions (Q1-Q4). None of the items was extremely skewed. Since none of the items were completed by less than 95% of the respondents, all items were included for psychometric analyses. The data set consisted of 14 items that were used for psychometric analysis (Table S4 in Multimedia Appendix 1 presents the Dutch original items). Kaiser-Meyer-Olkin was 0.72, and Bartlett Test of Sphericity was $P<.01$. PCA suggested a 5-factor solution. However, the fifth factor had an eigenvalue of 1.05, and we, therefore, decided to not include this factor. Q1 did not load to any factor. Common factor analysis using 4 factors with a factor loading threshold of 0.40 resulted in Q1 and Q5 not loading to any factors. Q7 cross loaded into factors 3 and 4. Q7 was dropped from factor 4 because this lowered the Cronbach α. Q8, Q10, and Q13 were

XSL•FO
RenderX

also dropped because these items lowered the Cronbach α for the respective factor. As shown in Table 2, item-total correlation was considered sufficient (>0.40) for all items. Factors 1 and 3 had the lowest Cronbach α (0.66 and 0.67, respectively) and factors 2 and 4 the highest (0.77 and 0.78, respectively).

XSL•FO

[g]DHS: Digital Health Solution.

[h]Original English item from questionnaire.

[i]Not applicable.

After PCA, a collaborate expert meeting was held to determine the most appropriate labels for these factors based on existing usability terminology: convenience of use, perceived value, efficiency of use, and satisfaction. These constructs are known in the field of human-computer interaction. A more complete definition of the 4 factors applied to the home setting are shown in Textbox 1. The final constructs of the GEMS are outlined in Figure 2.

Textbox 1. Textbox 1. Description of the constructs of the GEMS questionnaire.

Constructs and their explanations

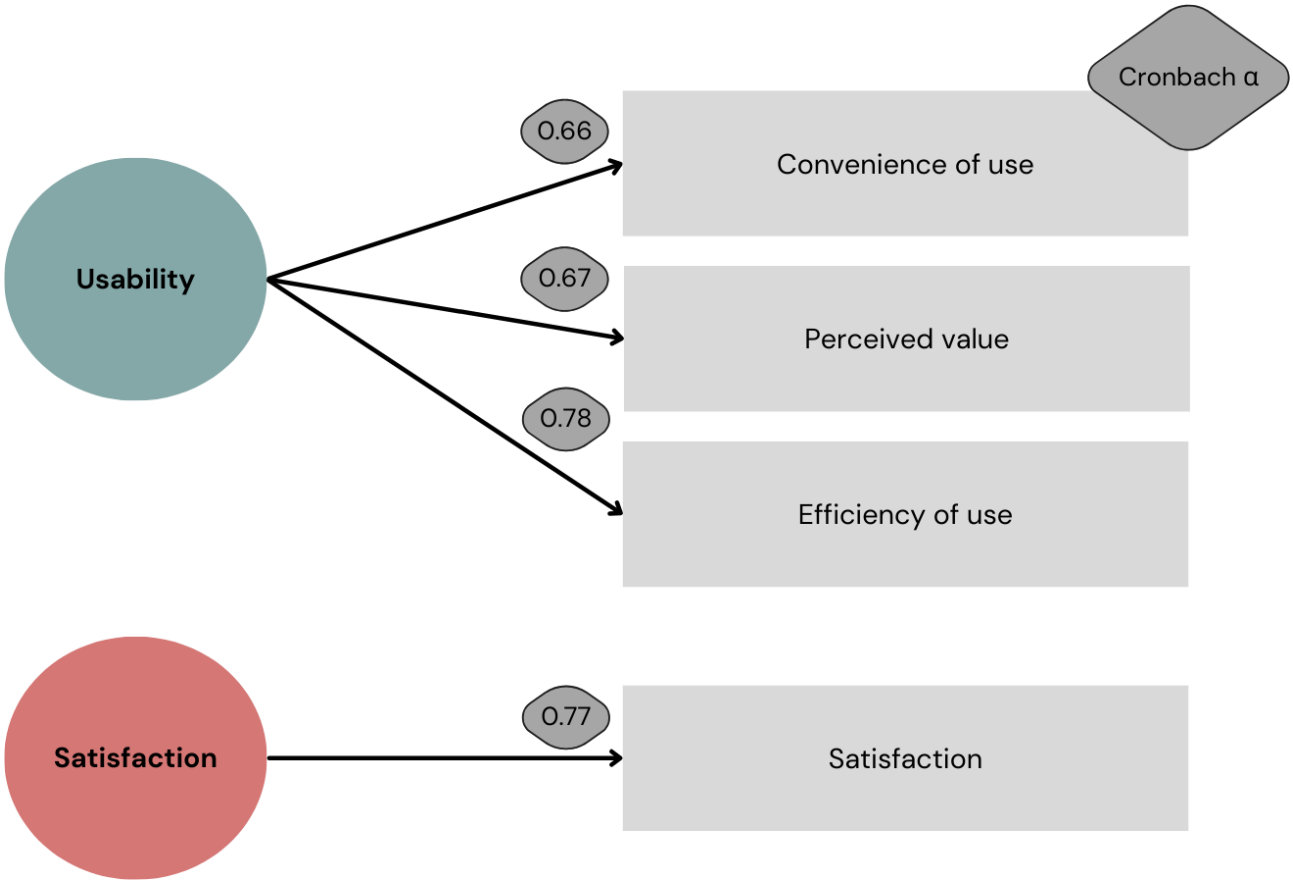
Convenience of use

This highlights the ease and comfort with which users can interact with the digital health solutions at home. Convenience of use is a component of usability, emphasizing aspects that contribute to making the user experience more convenient, pleasant, and smooth [70]. This means tailoring it to fit to patient preferences and expectations for self-management at home.

Perceived value

Perceived value refers to the extent to which a system or product fulfills users' needs and goals, addressing the pragmatic utility it offers to its intended users [70]. It encompasses the relevance and value of the digital health solutions features and functionalities in addressing user requirements in a home setting. In a health care setting, perceived value ultimately determines the practical utility and adoption of the digital health solutions by patients [71,72].

Efficiency of use



In a home setting, efficiency of use highlights how quickly users can perform tasks in a digital health solutions once they are familiar with it. Efficiency of use is influenced by factors such as learnability, memorability, and error prevention, as it pertains to how quickly and effortlessly users can achieve their goals when using a self-management tool in a home setting [12].

Satisfaction

According to International Organization for Standardization 9241, satisfaction is referred to as the degree to which users experience comfort and have positive attitudes toward using the product [12]. For self-management tools, satisfaction goes beyond mere functionality and usability, extending to factors such as efficacy, empowerment, and emotional well-being [73].

RenderX

Figure 2. Visual abstract of final results and named constructs of Experienced Usability and Satisfaction With Self-Monitoring in the Home Setting Questionnaire.

Discussion

Principal Findings

Our aim, was to develop a steering instrument that enables the measurement of usability and satisfaction at various stages of adoption, with constructs that are relevant for a home setting, adapted to the language proficiency of the general population, and which might serve as a benchmarking instrument for usability and satisfaction with DHS. Following the initial translation phase of this study, it became evident that the items of the GEMS were easy to understand for patients. Although we designed the questionnaire for a broad population, our evaluation revealed that the majority of study participants had a higher level of education. In research, it is a known challenge to reach those with lower health and digital literacy levels for evaluation [74]. The applicability of the DHS varies depending on the specific needs and characteristics of different users. The GEMS questionnaire has been tailored to a B1 language proficiency level, which enhances its accessibility. However, there is a risk of obtaining biased outcomes of the GEMS depending on the demographic profile (eg, age, education, digital literacy, and health literacy) of the respondents. Therefore, collecting these demographic data are essential to understand if DHS users with different profiles assess the experienced usability and satisfaction differently. Gaining these insights may help in ensuring tailorization of the DHS to the user needs based on GEMS outcomes. This necessitates further refinement of the DHS to ensure its suitability across diverse populations.

Internal consistency of the GEMS was sufficient and factor analysis confirmed 4 factors, to which we have assigned the following labels: convenience of use, perceived value, efficiency of use, and satisfaction. Internal consistency of the GEMS, as measured with the Cronbach α, was slightly lower compared with the minimum value of 0.7 [75]. A possible explanation could lie, in our sample characteristics, as several participants also used similar applications, such as smartwatches that provided reminders. This dual usage could have influenced their responses, leading to expressed preferences or aversions towards the usage of medication reminders.

Given that the NPS was integrated into our satisfaction metric within the GEMS questionnaire, we opted to use the raw NPS as a component within our scoring scale. This approach involves incorporating the absolute values of promoters, passives, and detractors, rather than calculating the traditional NPS by subtracting the percentage of detractors from the percentage of promoters [76]. In a manner similar to the SUS questionnaire, we reversed the scales in our questionnaire to enhance reliability and validity. This approach serves several key purposes: (1) mitigating response bias, (2) maintaining participant attention and engagement, (3) ensuring balance and consistency within the questionnaire, and (4) detecting random responses on the questions by participants [16]. For the factors and questions derived from the factor analysis, we carefully examined whether reversed scaling was still present in the questionnaire. We concluded that reversed scaling was still present in 2 out of the 4 constructs.

XSL•FO
RenderX

For the statements in the GEMS questionnaire, we decided to adopt, translate, and adapt the statements from the UMUX and adjust them to using DHS in a home setting. However, in some cases, we have labeled the factors differently from those in the UMUX. Specifically, the statement "It is frustrating to use this digital tool" is classified under "Convenience of use" in the GEMS questionnaire, while it is categorized under "Satisfaction" in the UMUX. The interrelationship with the other questions in GEMS aligns more closely with the definition of convenience. We decided to address the experiences related to the context in which the DHS are used, specifically the deployment of DHS in a home setting. First, the difficulty in using the technology due to lack of digital literacy or misunderstanding of terminology. Second, ease of use, as the primary concern in a home setting is how conveniently the DHS can be integrated into daily routines. In addition, we translated and modified the UMUX question "I spend too much time correcting things with this system" to make it applicable at a higher conceptual level. The revised question no longer concerns the correction of things (errors), but instead evaluates whether the DHS is usable within its intended context [28].

Closing the feedback loop between patients and HCP through the utilization of DHS represents a pivotal strategy in enhancing health care delivery with DHS. By enabling self-management of patients through communication and data exchange, digital tools foster a collaborative environment where patients can actively participate in their care and providers can make informed decisions [77]. Incorporating the GEMS questionnaire as part of a comprehensive evaluation of DHS may enhance usability and satisfaction, contributing to adoption and the overall effectiveness of the DHS in improving health outcomes. The GEMS is therefore of relevance and value to HCPs, decision makers, health insurance companies, and public health institutions. The outcomes of the GEMS can assist these stakeholders to identify important issues as perceived by patients, and to develop strategies to address these issues and improve the quality of their DHS.

Strengths and Limitations

The strength of the GEMS questionnaire lies in the convergence of the four factors: convenience of use, perceived value, efficiency of use, and satisfaction, its concise questionnaire format, its adaptation to the language proficiency of the general population, and its utility as a steering tool as it can be used longitudinally in DHS implementation. The main strength of this study is that we applied a 4-step structured methodology to develop the GEMS questionnaire, consisting of both qualitative and quantitative evaluation phases. We also included 2 functionalities of our electronic health records in our evaluation in order to assure that the GEMS is applicable to a range of self-management tools. One of the limitations of this study is that a subset of patients may have been unable to participate in these (digital) evaluations due to requirements such as internet access, concentration, self-confidence, and proficient reading skills. We recognize that these evaluations cannot be used without considering potential issues of inequality [78]. According to the literature, this can be due to several reasons. First, the DHS may currently not be usable enough, for instance, by not involving the users during the design phase [79]. Second, health care professionals might be unfamiliar with the technology and not offering these tools to all patients [80]. Third, patients may feel having inadequate knowledge to use these tools [81], or have low (digital) literacy and therefore unable to use the tool [82]. Hence, we recommend further evaluating and refining the GEMS questionnaire in populations characterized by low (digital) literacy. Currently, we are conducting such a validation study within a demographic comprising individuals with low socioeconomic status and chronic obstructive pulmonary disease using a self-management tool. For these groups, we will conduct the evaluation on paper, using concept cards and translating the questions to graphics that visually support the questions [83]. By adopting this method, we aim to facilitate a comprehensive understanding of usability and satisfaction tailored to the needs and preferences of this specific population.

Because we used statements from various questionnaires, during the initial validation phase of the GEMS, some questions had different Likert scales. In order to ensure consistency in the analysis, the scales were converted. As a result, this might impact the interpretation of results, as the participants may interpret and respond to the items differently due to an expanded or contracted range of options [84,85]. Literature supports rescaling of 5- and 7-point scales for comparison, although it is noted that these scales may produce higher mean scores compared with a 10-point scale [84]. Finally, If the GEMS is used in another cultural setting, correct linguistic and cultural translation is needed to ensure content validity [86]. In order to facilitate this, an ongoing study is being conducted to assess a German translation of the GEMS questionnaire.

Conclusion

The GEMS questionnaire, comprising 9 items, has demonstrated its reliability and validity in assessing the usability and satisfaction of DHS within a home environment. It offers valuable insights into patient experiences with self-management tools, covering aspects of convenience of use, perceived value, efficiency of use and satisfaction. This development and validation study has been conducted with patient populations using medication reminders and home measurements. Further refinement is necessary in order to confirm the efficacy and applicability of the GEMS questionnaire in patient populations with low digital literacy. Using the GEMS questionnaire as a steering metric reflects a dedication to improving usability and satisfaction within DHS. In conclusion, the GEMS may promote development of a robust DHS , which enriches experienced usability and satisfaction and augments the efficacy of the DHS, thereby fostering positive health outcomes.

Acknowledgments

The authors would like to thank all experts who participated in the development rounds of the GEMS; Marieke van Maanen for her expertise on the adjustment of the items to the language proficiency of patients; Dr. Stephanie Medlock for contributing to the translation of the items; Hugo van Mens for his expertise on the Usability Metric for User Experience; Thomas Engelsma for the final expert meeting and questionnaire development process; and Ro Glasius for questionnaire support.

Conflicts of Interest

None declared.

Multimedia Appendix 1
Flowchart of the inclusion process, original English or Dutch items and final version of translated Dutch version of GEMS, original GEMS, and demographics of included sample for validation (n=92).

Abstract

Background: Missing data in electronic health records are highly prevalent and result in analytical concerns such as heterogeneous sources of bias and loss of statistical power. One simple analytic method for addressing missing or unknown covariate values is to treat missingness for a particular variable as a category onto itself, which we refer to as the missing indicator method. For cross-sectional analyses, recent work suggested that there was minimal benefit to the missing indicator method; however, it is unclear how this approach performs in the setting of longitudinal data, in which correlation among clustered repeated measures may be leveraged for potentially improved model performance.

Objectives: This study aims to conduct a simulation study to evaluate whether the missing indicator method improved model performance and imputation accuracy for longitudinal data mimicking an application of developing a clinical prediction model for falls in older adults based on electronic health record data.

Methods: We simulated a longitudinal binary outcome using mixed effects logistic regression that emulated a falls assessment at annual follow-up visits. Using multivariate imputation by chained equations, we simulated time-invariant predictors such as sex and medical history, as well as dynamic predictors such as physical function, BMI, and medication use. We induced missing data in predictors under scenarios that had both random (missing at random) and dependent missingness (missing not at random). We evaluated aggregate performance using the area under the receiver operating characteristic curve (AUROC) for models with and with no missing indicators as predictors, as well as complete case analysis, across simulation replicates. We evaluated imputation quality using normalized root-mean-square error for continuous variables and percent falsely classified for categorical variables.

Results: Independent of the mechanism used to simulate missing data (missing at random or missing not at random), overall model performance via AUROC was similar regardless of whether missing indicators were included in the model. The root-mean-square error and percent falsely classified measures were similar for models including missing indicators versus those with no missing indicators. Model performance and imputation quality were similar regardless of whether the outcome was related to missingness. Imputation with or with no missing indicators had similar mean values of AUROC compared with complete case analysis, although complete case analysis had the largest range of values.

Conclusions: The results of this study suggest that the inclusion of missing indicators in longitudinal data modeling neither improves nor worsens overall performance or imputation accuracy. Future research is needed to address whether the inclusion of missing indicators is useful in prediction modeling with longitudinal data in different settings, such as high dimensional data analysis.

Introduction

Electronic health record (EHR) data have many analytic uses, including patient monitoring, clinical decision support, quality improvement projects, and research initiatives [1]. However, missing data are pervasive in EHRs because these systems were largely designed for the purposes of billing and because of the fragmented nature of health care in the United States where

XSL•FO
RenderX

patients often use multiple health systems with disparate EHR systems. The incomplete nature of the EHR creates significant potential for bias for research studies leveraging real-world data [2]. Statistically, missing data may be considered ignorable when they are missing completely at random (MCAR) or missing at random (MAR). A recent study illustrated that more than 1 missing mechanism may be present for EHR data, and the assumption that all missing data are MAR is generally not plausible [3]. Recent work by Hu et al [4] indicated that clinical EHR data were consistent with a mixture of random and nonrandom mechanisms. For example, a white blood cell count test was less likely to be ordered for patients who were clinically doing well (eg, lack of collection).

Current approaches to handle missing data include complete case analysis, imputation, and nonimputation approaches such as the use of missing indicators. These approaches vary in terms of their appropriateness depending on untestable assumptions about the mechanisms generating missing values. A detailed discussion of statistical approaches to handling missing data can be found in the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) checklist [5,6]. Complete case analysis is a common method in which observations with missing values in any of the analysis variables are listwise deleted. If data are MCAR, complete case analysis may be appropriate, but if data are MAR or missing not at random (MNAR), complete case analysis can result in biased estimates. Independent of the missingness mechanism, complete case analysis results in a loss of statistical power by reducing the number of available observations [7,8].

Imputation is another commonly used method for handling missing data and involves using observed data to estimate and fill in values that are missing, typically through regression approaches that model the variable with missingness as the outcome with the other variables in the dataset as predictors. While this method retains all observations in the dataset and reduces bias when data are MAR, regression imputation underestimates the SE of the model parameters and therefore overestimates precision [8,9]. Multiple imputation overcomes the limitations of regression imputation by generating multiple imputed values for each missing value. By separately analyzing each dataset and combining the outputs to obtain an overall point estimate and corresponding SE, variability estimates are more accurate and the analysis accounts for the uncertainty caused by missingness [9,10]. However, the appropriate imputation strategy may depend on both the type of missingness and the objective of the analysis. One recent study has shown that regression imputation performs as well as multiple imputation when the ultimate goal is prediction rather than statistical inference or model interpretation [11]. Another study found that for logistic regression, regression imputation was comparable with multiple imputation in terms of model performance with a low percentage of missingness [12]. However, none of the imputation methods are unbiased or recommended for nonignorable missing data.

A third approach is the missing indicator method, which adds a binary predictor to the model that takes the value of 1 if the value of a certain variable is missing and zero if the value is not missing, therefore, taking advantage of the information contained in missingness itself [13]. The use of missing indicators has been introduced as a method when missingness in informative, or when the presence or absence of missingness adds prognostic information to a model. Although this is a simple method for potentially leveraging information about missingness, it increases the number of predictor variables to be included, which may not be ideal for high-dimensional datasets, datasets with many predictors, or situations where significant model flexibility is desired (ie, semiparametric models that use basis functions or splines to flexibly model continuous predictors such as vital signs or laboratory values).

There is still a lack of consensus on the appropriateness of the missing indicator method for handling missing data for clinical prediction modeling [14]. One concern is the creation of a negative feedback loop between the model and the providers using the model for decision support. When an individual knows that taking or not taking a certain measurement is informative, their decision to take the measurement could hypothetically be impacted [13,15], or the model may simply reiterate a clinical suspicion or decision that has already occurred, such as a recent prediction model for the early detection of sepsis [16]. An example for this is the decision to order certain specialized laboratory tests. In addition, prediction models that use the missing indicator method must be consistently monitored and revised due to how quickly patient medical data and factors that affect physician decision-making change [15]. However, other work has found that the missing indicator method could improve predictive performance [14,17]. One study found that the addition of missing indicators, which signaled the presence or absence of a laboratory test result, to observed measurements improved area under the receiver operating characteristic curve (AUROC) when predicting clinical outcomes [17]. Missing indicators have been shown to increase predictive performance when missingness is informative, with the effectiveness of the method increasing as the informativeness of missingness increased [14]. The same study found that the missing indicator method did not harm predictive performance when missingness was uninformative. This is an important distinction, as it is not possible to empirically test whether missingness is informative [18].

There is currently a gap in knowledge regarding the effectiveness of including missing indicators in longitudinal data modeling, specifically whether missing indicators improve model performance and the quality of model-based imputations. The setting of longitudinal repeated measures and clustered data is an important context for the missing indicator method because the correlation within clusters may be leveraged to increase the imputation accuracy and model performance, particularly in the case of data that are MNAR. However, we are not aware of work that has investigated the missing indicator method in this setting.

We aimed to assess the missing indicator method for longitudinal, repeated-measures data using a simulation study mimicking real-world EHR data. In section 2, we detail the methods we used to generate the synthetic longitudinal data, including fixed and repeated measures of predictors for MAR and MNAR missing data patterns, and we define outcome metrics used to assess performance and imputation quality. In

XSL•FO
RenderX

section 3, we present results aggregated across the simulation runs for models with and with no missing indicator variables. In section 4, we discuss the results and implications of the study, compare our study with prior studies, and consider the strengths and limitations of this work.

Methods

Study Design

This study is a simulation study in which missing indicator variables in imputation and modeling were evaluated under different missing data mechanisms (MAR and MNAR). We follow the simulation study guidelines suggested by Morris and colleagues [19]. Analyses were performed with R (version 4.2.1; The R Project for Statistical Computing). All code is available on our GitHub repository [20]. We use the following R packages in our analysis: *bindata* [21], *MASS* [22], *tidyverse* [23], *lme4* [24], *lmerTest* [25], *naniar* [26], *mice* [27], *broom.mixed* [28], *pROC* [29], *DescTools* [30], *missForest* [31], *table1* [32], *flextable* [32], *skimr* [32], *sjPlot* [33], *gridExtra* [34], *grid* [35], and *car* [36].

Data-Generating Mechanisms

This study focuses on a mixed effects logistic regression model that uses a binary outcome simulated to represent whether or not patients experienced a fall since their last visit. A total of 250 patients were simulated, each with 5 visits. Medical history variables, demographic variables, fall-specific variables, and variables intended to add noise to the model were simulated. We simulated the data to represent EHR data that may be used to develop models for falls in older adults. Predictors of falls were simulated based on previous research [37] and represent a combination of fixed, patient-level variables and visit-level variables that are collected repeatedly. The fixed variables included sex and comorbidities (diabetes, dementia, hypertension, and urinary incontinence), all of which may be related to falls in older adults. The visit-level variables included BMI, gait speed, single-leg balance, and use of medications (pain or depression), again representing variables that could be associated will falls in older adults. Table 1 lists all variables in the dataset and describes how they were simulated. We include summaries of the variables for one of the simulated datasets in Multimedia Appendix 1. For more details, including parameter values, see the code on GitHub.

Table . Variable list and description.

Variables	Data generation and description
Patient-level variables	
Birth sex, diabetes, dementia, hypertension, and urinary incontinence	Binary random variables simulated with the bindata R package
Age	Continuous with mean dependent on number of chronic conditions (ie, number of the following conditions: diabetes, dementia, hypertension, and urinary incontinence)
Visit-level variables	
Visit	Discrete, 5 visits for each patient.
BMI	Continuous, simulated with a linear mixed effects model with age, diabetes, hypertension, and birth sex as predictors. Random intercept for patient ID and random error included.
Gait speed	Continuous, simulated with a linear mixed effects model with age, BMI, diabetes, and birth sex as predictors. Random intercept for patient ID and random error included.
Single-leg balance	Continuous, simulated with a linear mixed effects model with age, BMI, diabetes, dementia, and birth sex as predictors. Random intercept for patient ID and random error included.
Pain medication	Binary, probability simulated with expit function with age, sex, and diabetes as predictors in the model. A random intercept for patient was included in the model. The probability was then used to simulate a Bernoulli random variable where: 0=did not take pain medication since last visit 1=took pain medication since last visit
Depression medication	Binary, probability simulated with expit function with age, sex, and dementia as predictors in the model. A random intercept for patient ID was included in the model. The probability was then used to simulate a Bernoulli random variable where: 0 = did not take depression medication since last visit 1 = took depression medication since last visit
Junk 1 - 5	Continuous random variables with means and SDs chosen at random.
Y	Binary outcome variable, probability simulated with expit function with all variables except the junk variables and visit as predictors. A random intercept for patient ID was also included in the model. The probability was simulated with and with no missing indicators included in the model. The probability was then used to simulate a Bernoulli random variable where: 0 = did not fall since last visit 1 = fall since last visit

The probability of the binary outcome was simulated in 2 different ways using the expit function. For both versions, the model included a random intercept for patient, and all variables except the junk variables, patient ID, and visit were included as predictors. The first version included missing indicator variables as predictors in the model, while the second did not. The outcome was a random Bernoulli variable with the probability of being one equal to the calculated probability for each visit. A total of 250 iterations were run, so 250 different datasets were created.

Missingness was induced for the visit-level continuous variables gait speed and single-leg balance, and for the binary variables pain medication and depression medication. Overall missing data percentages of 20% and 50% were simulated. Under the assumption of MAR, the probability that gait speed, single-leg balance, pain medication, and depression medication were missing for a specific visit was dependent on age, BMI, diabetes, and urinary incontinence. Specifically, the probability each variable was missing was simulated with the expit function where age, BMI, diabetes, and urinary incontinence were included as predictors. The intercept was changed to achieve different percentages of missing data. The probability was higher for older patients, patients with a larger BMI, and patients with diabetes or urinary incontinence. Missing indicators were created by defining Bernoulli random variables with the probability of being one equal to the probability of being missing, and indicator variables were created for each of the 4 variables. If the missing indicator was 1, the value of the corresponding variable was set to missing. Therefore, although all 4 variables had the same probability of being missing for each visit, different combinations of variables could be missing at each visit.

XSL•FO
RenderX

Under the MNAR missingness mechanism, the probability that gait speed, single-leg balance, pain medication, and depression medication were missing for a specific visit was dependent on the value of the variable itself. For gait speed and single-leg balance, if the value of the variable at a visit was less than the 25th percentile, the probability of the value being set to missing was .7 to target an overall missing percentage of 50% and .3 to target an overall missing percentage of 20%. Otherwise, the probability was zero. For pain medication and depression medication, if the value of the variable was 1 at a visit (indicating that the patient was taking the medication), the probability the value was set to missing was .4 to target an overall missing percentage of 50% and .1 to target an overall missing percentage of 20%. Otherwise, the probability was zero. Therefore, lower values of gait speed and single-leg balance were more likely to be missing. Similarly, if patients were taking pain medication or depression medication, these values were more likely to be missing. For all of the simulated scenarios, the outcome, all patient-level variables, and the remaining visit-level variable (BMI) were fully observed.

Missing Data-Handling Strategies

Multivariate imputation via chained equations was performed using the *mice* package in R [27]. Regression imputation was performed using single imputation (ie, multiple imputation was not used because the purpose of the model is prediction). All variables in the dataset were included in the imputation model, including the outcome variable. The 2-level structure of the dataset was specified in the imputation model by denoting patient as the clustering variable. To impute gait speed and single-leg balance, a 2-level normal model was used. Values below zero were capped at zero. To impute pain and depression medication, a 2-level logistic model was used. When imputing a variable, the indicator for that variable was not included in the imputation model because in imputation only present data are used and the value of the indicator is 1 for all present data. The indicators for the other variables were included in the imputation model.

The outcome was calculated with a mixed effects logistic regression for both analyses that included and did not include missing indicator variables. All variables except visit were included in the model as predictors, and a random intercept for patient was also included in the model. Missing indicators were included in the model when they had also been included in the imputation model. The junk variables were included with the expectation that they would not be significant in the model. Complete case analysis was performed by deleting all observations with missing values prior to running the model. A summary of the different scenarios and models run is shown in Table 2.

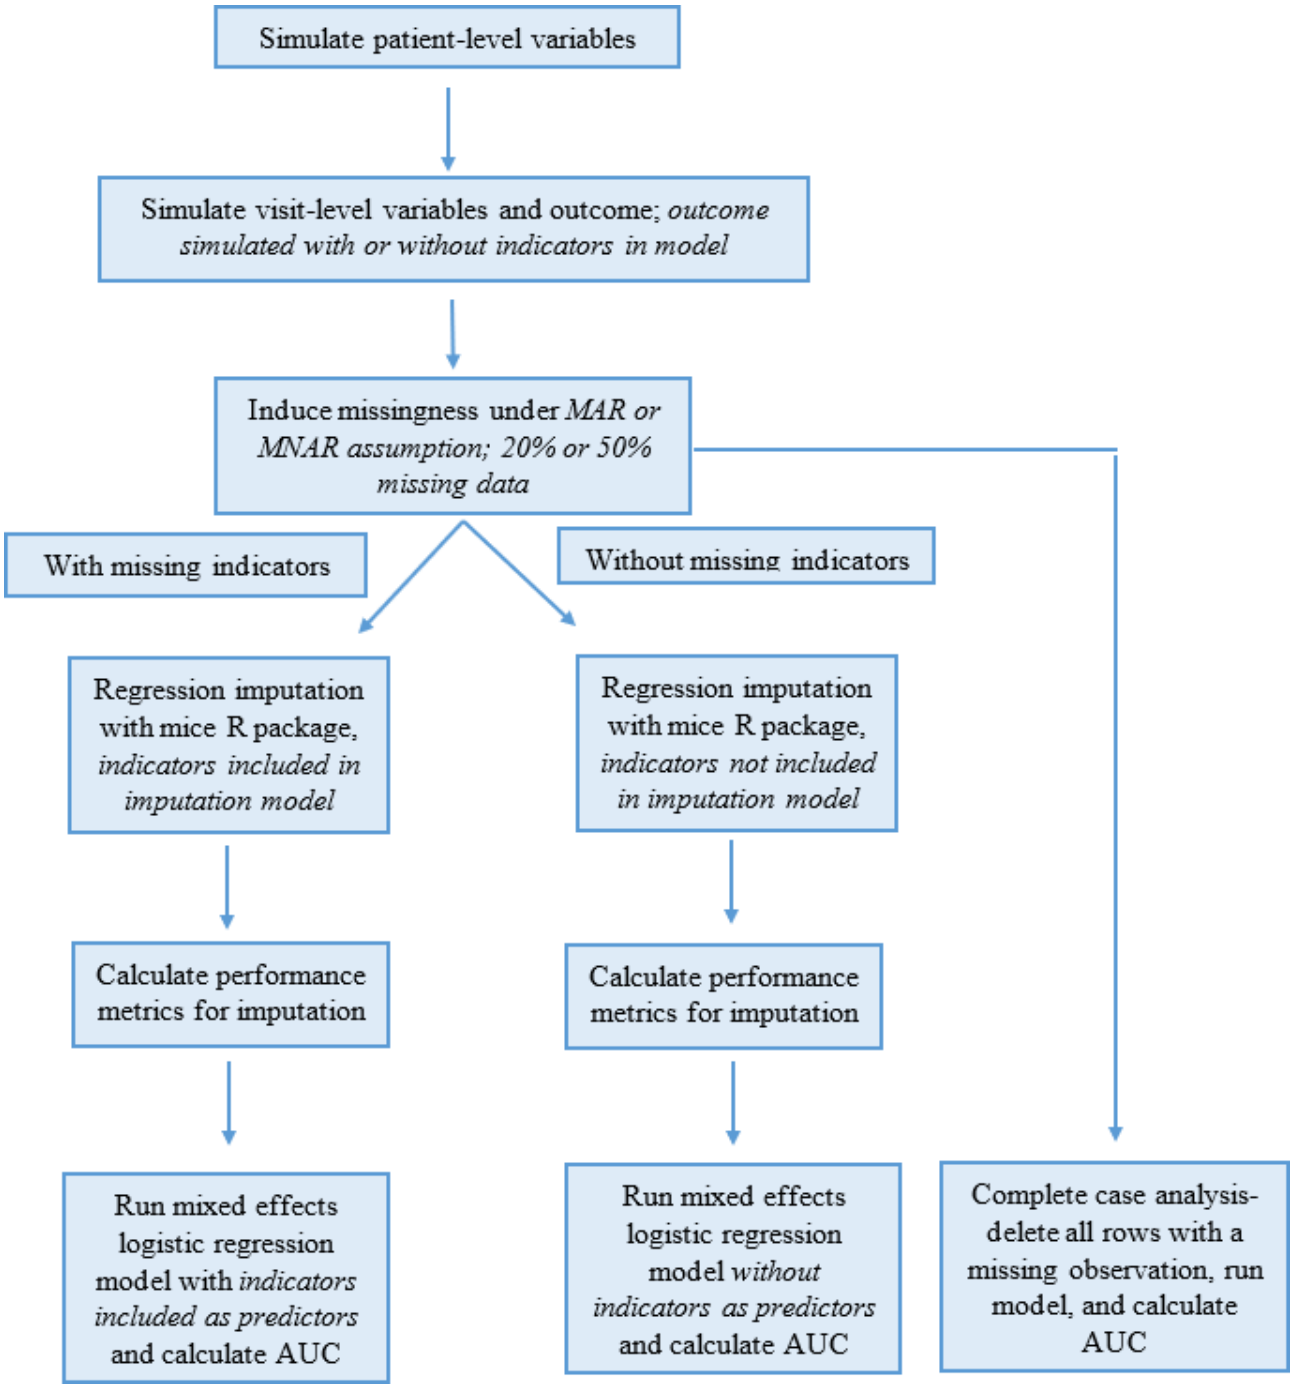
[a]MAR: missing at random.

[b]MNAR: missing not at random.

Performance Metrics



We assessed models in terms of performance and imputation quality. To assess model performance, AUROC was calculated. To assess imputation quality for binary variables, the proportion of falsely classified imputations (PFC) was calculated [38], defined as the number of incorrect binary imputed values divided by the total number of imputed values. Lower proportions indicate better quality of imputations. To assess imputation quality for continuous variables, the normalized root-mean-square error (NRMSE) between the imputed values and the observed values was calculated. The root-mean-square error is normalized by dividing by the SD of the observed values (from the study by Stekhoven and Bühlmann [38]). Lower NRSME indicates better imputation quality. For each iteration and scenario, the PFC, NRMSE, and AUROC were stored and the average values were calculated across the simulation runs.

RenderX

Simulation Study Analysis Pipeline

Figure 1 provides an overview of the simulation and analysis performed in this study. The first key step is data generation, with patient-level variables generated first, then visit-level variables, and finally the outcome under the 2 underlined scenarios. Missingness is then induced under different mechanisms and at different percentages, and imputation occurs with and without the missing indicators in the imputation model. After the calculation of evaluation metrics, models were run with and without the missing indicators as predictors in the model—along with complete-case analysis—and the AUROC of each model was extracted. For models using imputation, NRMSE was calculated for continuous variables and PFC was calculated for binary variables. Results for each run of the simulation were aggregated, and averages of the performance metrics are presented.

Figure 1. Data pipeline flowchart. AUC: area under the receiver operating characteristic curve; MAR: missing at random; MNAR: missing not at random.

Results

Table 3 shows the average overall percentage of missing data and the SD for each scenario under the different missing mechanisms and data-generating mechanisms. For all scenarios, the actual missing percentage of data was slightly higher than the targeted amount.

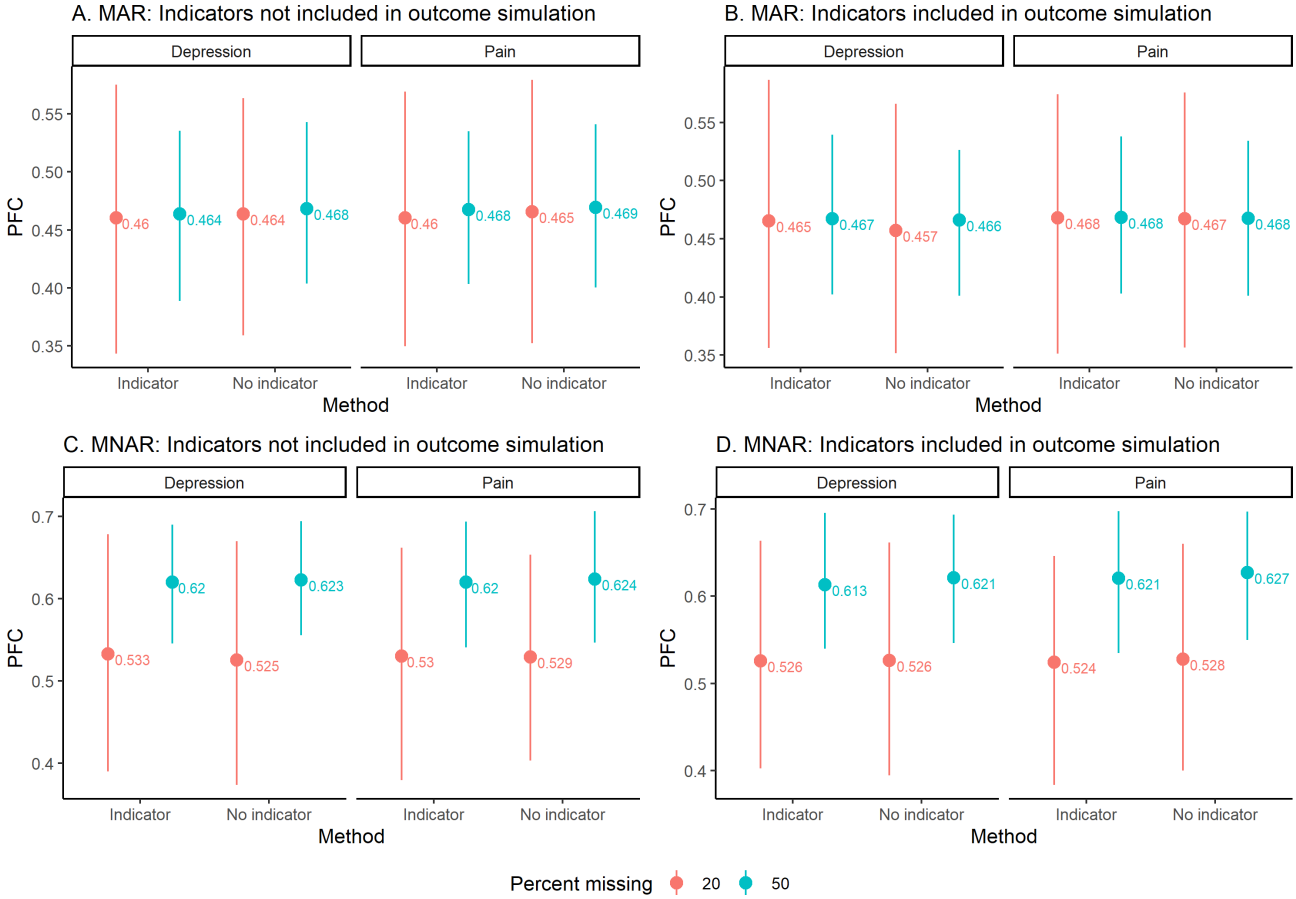
MNAR	20	22.35 (1.07)
MNAR	50	54.29 (1.33)

[a]MAR: missing at random.



[b]MNAR: missing not at random.

Imputation Quality

First, we present results related to imputation quality. We begin by assessing the PFC for the binary variables (Figure 2), in which higher PFC indicates a higher misclassification rate and therefore worse imputation quality. For MAR scenarios (Figure 2A and B), the PFC was about 46% - 47% for both pain and depression medication, regardless of whether indicators were used to simulate the outcome. There was little difference between the PFC at 20% of missing data compared with 50% of missing data. For MNAR scenarios (Figure 2C and D), the PFC was about 61% - 63% for both pain and depression medication at 50% of missing data and about 52% - 53% for 20% of missing data. PFCs comparing including missing indicators versus not including missing indicators were similar. The PFCs were higher for MNAR data than for MAR data.

XSL•FO
RenderX

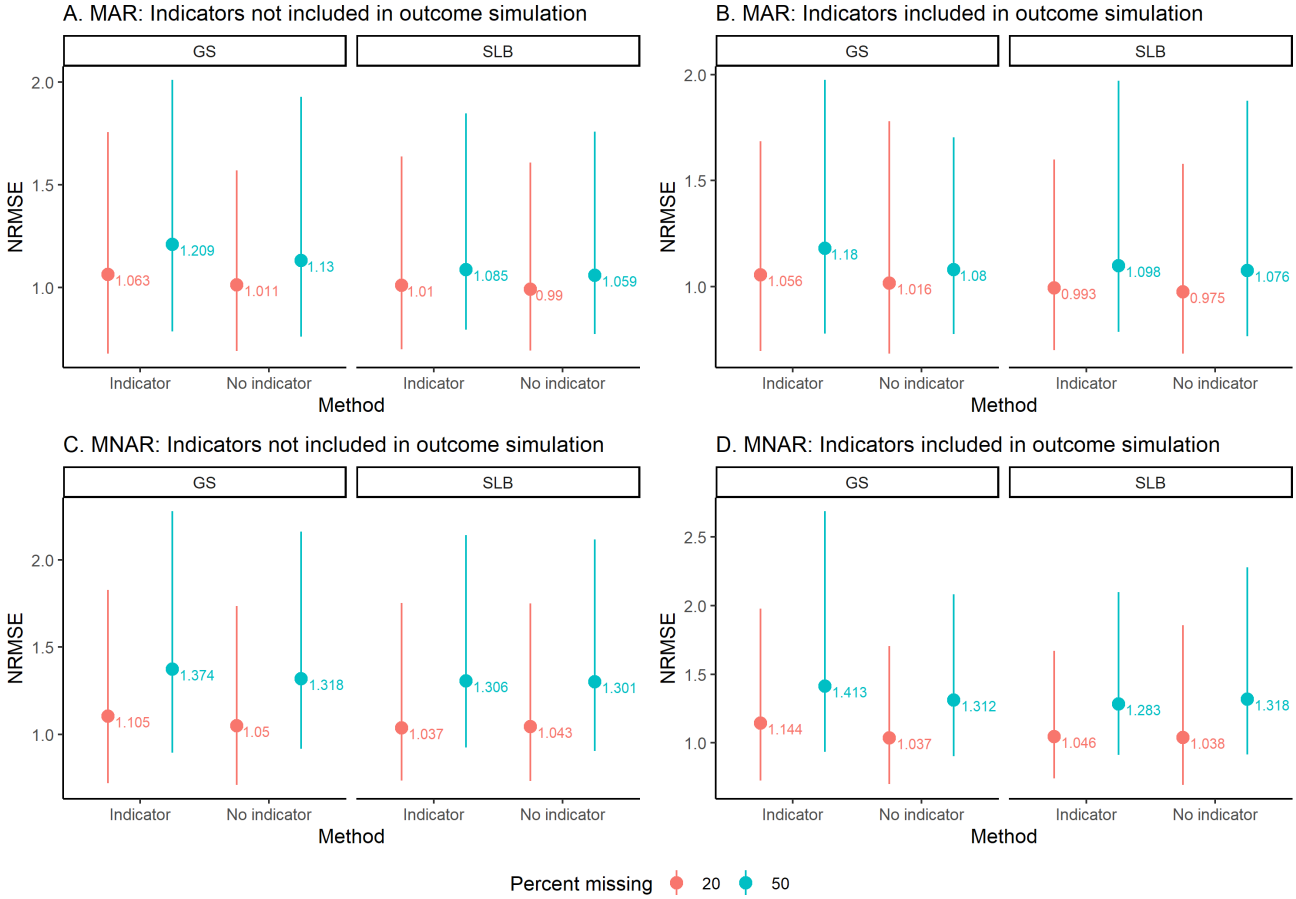


Figure 2. Average proportion of falsely classified imputations (PFC) for binary variables across iterations. The average value is indicated with a point, and the lines go to the 2.5th percentile and 97.5th quantiles. Panels A and B are for MAR data, when indicators are not included in the outcome simulation and when indicators are included in the outcome simulation. Panels C and D are for MNAR data, when indicators are not included in the outcome simulation and when indicators are included in the outcome simulation. MAR: missing at random; MNAR: missing not at random.

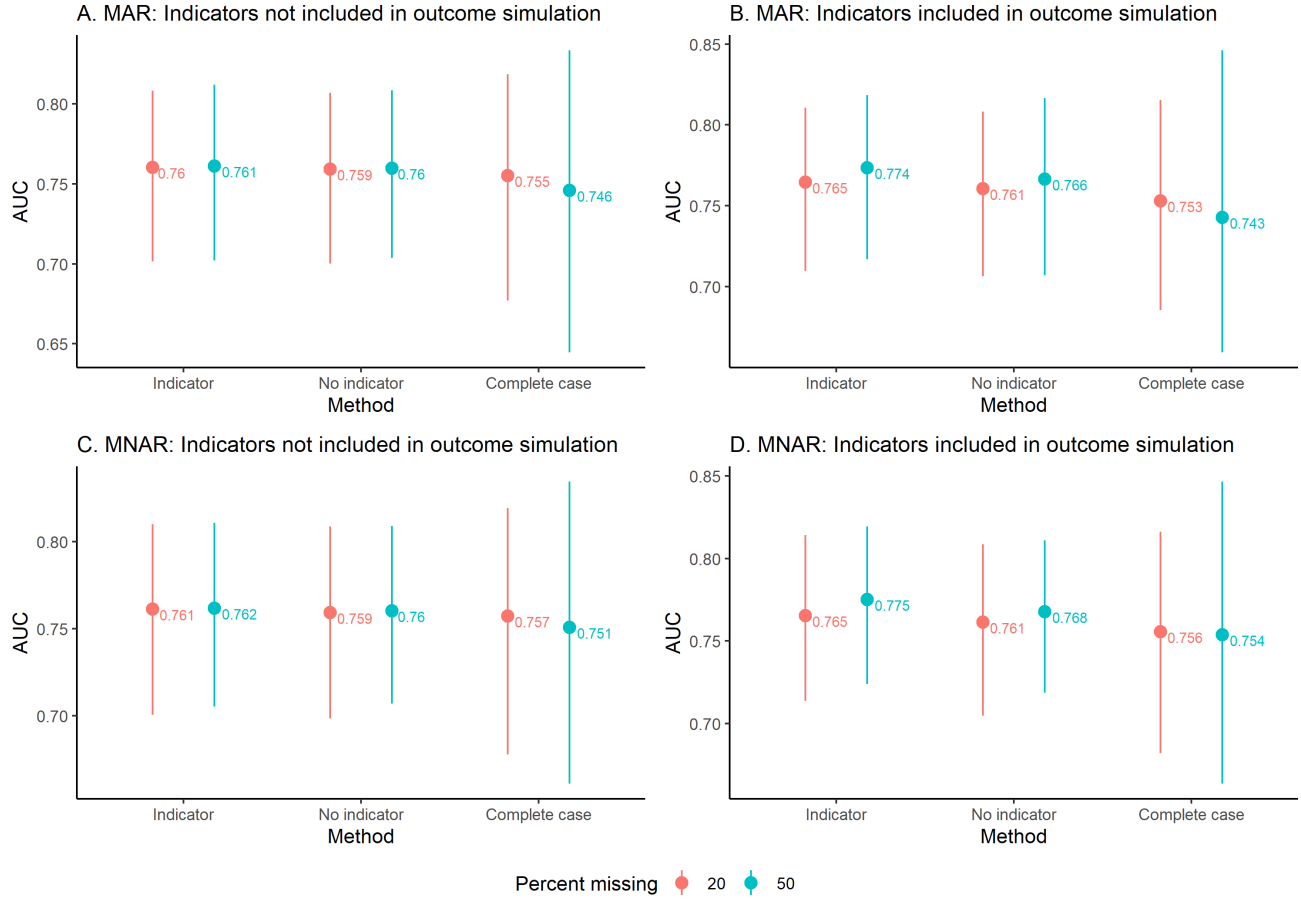
Next, we assess NRMSE for continuous variables (Figure 3A-D), in which higher NRMSE indicates worse imputation quality. In general, the NRMSE of single-leg balance was lower than that of gait speed. For the variables gait speed and single-leg balance, NRMSE was higher when there was 50% of missing data compared with 20% of missing. NRMSE was higher in MNAR scenarios compared with MAR scenarios. Whether or not indicators were included when simulating the outcome resulted in similar NRMSE for the variables. The NRMSE for the imputation of gait speed was slightly larger when indicators were included for all scenarios, but for single-leg balance there was no clear pattern.

XSL•FO
RenderX

Figure 3. Average normalized root-mean-square error (NRMSE) for continuous variables across iterations. The average value is indicated with a point, and the lines go to the 2.5th percentile and 97.5th quantiles. Panels A and B are for MAR data, when indicators are not included in the outcome simulation and when indicators are included in the outcome simulation. Panels C and D are for MNAR data, when indicators are not included in the outcome simulation and when indicators are included in the outcome simulation. GS: gait speed; MAR: missing at random; MNAR: missing not at random.



Performance Evaluation

We compare AUROC values for complete case analysis with the imputation methods (indicators included vs not included) in Figure 4A-D. AUROCs for the methods within a simulated scenario were generally similar and close to 0.75. The complete case analysis had the largest spread of AUROC values, whereas imputation with or with no missing indicators had similar spread of AUROC values. The amount of missing data (20% or 50%) and the missing data assumption (MAR and MNAR) did not substantially impact the AUROC values, which were similar across these groups. Comparing models using missing indicators with those with no missing indicators, we observed overlap in the AUROC intervals.

XSL•FO
RenderX

Figure 4. Average AUC comparison across iterations. The average value is indicated with a point, and the lines go to the 2.5th percentile and 97.5th quantiles. Panels A and B are for MAR data, when indicators are not included in the outcome simulation and when indicators are included in the outcome simulation. Panels C and D are for MNAR data, when indicators are not included in the outcome simulation and when indicators are included in the outcome simulation. AUC: area under the receiver operating characteristic curve; MAR: missing at random; MNAR: missing not at random.

Discussion

This study investigated the performance of the missing indicator method in terms of imputation quality and model performance for longitudinal data under MAR and MNAR mechanisms and different amounts of missing data. The imputation quality was worse under MNAR, as the PFC was about 15% higher under MNAR and the NRMSE for continuous values were higher under MNAR. When data were MAR and MNAR, the inclusion of missing indicators in the imputation and outcome models had a minimal effect on AUROC, regardless of whether the indicators were included as inputs when simulating the outcome. Therefore, the results from our simulation of longitudinal data mimicking data from the EHR suggest that the missing indicator method may not improve imputation quality or model performance, even when data are MNAR. However, it does not seem that including missing indicators harms imputation quality or model performance either.

In all scenarios, AUROC from complete case analysis was similar to AUROC from the other models, but the range of values was largest. While complete case analysis had similar AUROC values to imputation, we would not generally advocate for the use of complete case analysis. The increased variability associated with complete case analysis compared with imputation approaches can result in loss of power. In addition, while this study is focused on prediction and does not report model parameter estimates, complete case analysis may result in biased model coefficient estimates when data are MAR or MNAR. If model interpretation is of interest, complete case analysis will likely result in bias in settings such as EHR data, where missingness is often informative.

It was somewhat surprising that the imputations for the simulated binary variables were poor, as demonstrated by the high rates of PFC in Figure 2. We were not expecting such high errors in the imputed values. We hypothesize that some of the error may be attributed to rounding to force the imputed values to be binary, as many imputation methods provide a probability for binary variables which then must be handled in the analysis. Although the accuracy of the binary variable imputations was poor in our simulations, our main focus was on whether or not missing indicators may be beneficial for imputation and modeling. Future work may investigate the accuracy of imputation methods for multilevel data, especially when the predictors contain a mix of binary and continuous variables.

Previous studies on the missing indicator method have shown conflicting results. Van Ness et al [14] found that when missingness is informative, the missing indicator method increases predictive performance of linear models and neural networks with mean imputation and other imputation methods. The authors simulated data using an informativeness parameter, which differs from our study. The only situation where the method harmed predictive performance was in high-dimensional

XSL•FO
RenderX

data, where the addition of uninformative indicators led to overfitting. Sperrin and Martin [39] found that the method improves causal effect estimation when missingness is informative when combined with multiple imputation. Sisk et al [11] investigated the use of the missing indicator method in addition to both regression and multiple imputation to deal with nonignorable missing data in prediction modeling. Similar to Van Ness et al [14], Sisk et al [11] showed that the missing indicator method corrected bias but requires the assumption that the missing mechanism remains constant throughout the clinical prediction model pipeline, which may not be plausible because of how the likelihood of collection differs across providers.

The results of our study contribute to the growing body of literature aiming to provide guidance regarding the missing indicator method. Our simulation based on EHR data of falls in older adults using a longitudinal, repeated-measures setup suggested that the missing indicator method may not be beneficial in terms of imputation quality or model performance, but it also did not seem to cause harm. None of the previously described papers used longitudinal data when investigating the missing indicator method with a focus on prediction modeling, which may be a reason why the results of this paper differ from findings of the other papers mentioned. There is clearly debate as to the potential benefit and harm of the missing indicator method, and this paper provides guidance for longitudinal, repeated-measures data.

Our study should be considered within the context of its strengths and limitations. We used a simulation framework, which has multiple advantages that allow for the evaluation of statistical methods. A major strength of this study is the ability to define and control the missing mechanism. In practice, investigators can make assumptions regarding why data are missing, but there is no statistical test to decide whether data are MAR or MNAR. In this study, because the truth regarding the missing mechanism for each variable is known, no assumptions are made. The effectiveness of the missing indicator method can be evaluated and compared between the 2 mechanisms. In addition, because the true value of all variables is known, the imputations themselves can be evaluated for quality.

Despite the many strengths of our study, there are some limitations. One limitation of this study was the quality of imputations for the binary variables. With 45% - 60% of values being incorrectly classified, the imputation performed only slightly better than random guessing. This may have impacted how beneficial the missing indicators were in modeling. A future study could investigate how to boost imputation performance in longitudinal data, perhaps using machine learning imputation methods. Another limitation of the study is that time-dependent covariates were not considered. Future work may investigate the missing indicator method in this setting. Other limitations are related to the nature of simulation studies. Assumptions about the relationships between variables must be made, and these relationships are often oversimplified. The results may be sensitive to the parameter values chosen for the study; however, we completed a rigorous study based on a real-world scenario of falls in older adults. Future studies could evaluate how the addition of more visits, missed visits, dropout, and other missing patterns common in EHR data impacts results. In addition, a future simulation study could use an informativeness missing parameter such as that imposed in Van Ness' analysis for MNAR scenarios.

The results of this study suggest that the inclusion of missing indicators in longitudinal data modeling does not seem to be beneficial for overall performance or imputation accuracy, as neither metric improved. However, inclusion of missing indicators does not appear to cause harm in terms of performance or imputation accuracy, as neither metric worsened. Future research may address whether the inclusion of missing indicators is useful in prediction modeling with longitudinal data in different settings, such as high-dimensional data analysis.

Abstract

Background: Many tools have been developed to predict the risk of diabetes in a population without diabetes; however, these tools have shortcomings that include the omission of race, inclusion of variables that are not readily available to patients, and low sensitivity or specificity.

Objective: We aimed to develop and validate an easy, systematic index for predicting diabetes risk in the Asian population.

Methods: We collected the data from the NAGALA (NAfld [nonalcoholic fatty liver disease] in the Gifu Area, Longitudinal Analysis) database. The least absolute shrinkage and selection operator model was used to select potentially relevant features. Multiple Cox proportional hazard analysis was used to develop a model based on the training set.

Results: The final study population of 15464 participants had a mean age of 42 (range 18-79) years; 54.5% (8430) were men. The mean follow-up duration was 6.05 (SD 3.78) years. A total of 373 (2.41%) participants showed progression to diabetes during the follow-up period. Then, we established a novel parameter (the FHTHWA index), to evaluate the incidence of diabetes in a population without diabetes, comprising 6 parameters based on the training set. After multivariable adjustment, individuals in tertile 3 had a significantly higher rate of diabetes compared with those in tertile 1 (hazard ratio 32.141, 95% CI 11.545 - 89.476). Time receiver operating characteristic curve analyses showed that the FHTHWA index had high accuracy, with the area under the curve value being around 0.9 during the more than 12 years of follow-up.

Conclusions: This research successfully developed a diabetes risk assessment index tailored for the Japanese population by utilizing an extensive dataset and a wide range of indices. By categorizing the diabetes risk levels among Japanese individuals, this study offers a novel predictive tool for identifying potential patients, while also delivering valuable insights into diabetes prevention strategies for the healthy Japanese populace.

KEYWORDS

prediction; diabetes; risk; index; population without diabetes

Introduction

The increasing number of patients with diabetes mellitus represents an escalating challenge worldwide [1,2]. Based on the recently published International Diabetes Federation (IDF) Diabetes Atlas, the recorded worldwide incidence of diabetes among the adult population (20 - 79 years) in 2021 was 10.5%, while the prevalence in Southeast Asia was 8.7% [3]. It is estimated that by the year 2045, the global prevalence of individuals living with diabetes will increase to an estimated 783 million, corresponding to a prevalence rate of approximately 12.2% [3], which indicates the urgent need for global diabetes prevention and control. Given the significant prevalence of patients with impaired fasting glucose or undiagnosed diabetes, it is imperative to prioritize the early screening and detection in these patients to mitigate the morbidity associated with diabetes, minimize healthcare expenditures, and prevent a decline in the quality of life [2,4].

Diabetes mellitus is a metabolic disorder, affecting both glucose and lipid metabolism [5,6]. Recent studies have investigated the correlation between glucose and lipid-related indexes and the prevalence of diabetes, including the triglyceride-glucose (TyG) index, metabolic score for insulin resistance (METS-IR), triglyceride to high-density lipoprotein cholesterol ratio

XSL•FO
RenderX

(TG/HDL-C), and total cholesterol to high-density lipoprotein cholesterol ratio (TC/HDL-C) [7-9]. However, the accuracy of these indexes remains limited, and better prognostication indexes need to be found. Meanwhile, certain researchers have redirected their attention towards employing computational methods in order to predict diabetes at an early stage with greater precision [10-14]. The diabetes risk test created by the American Diabetes Association (ADA) serves as a screening tool designed to categorize individuals at a heightened risk within the community to enhance awareness regarding modifiable risk factors and promote the adoption of a healthy lifestyle [15]. Bang et al [16] developed a new screening score using the National Health and Nutrition Examination Survey (NHANES) and a combined cohort of two community studies However, the utilization of diabetes prediction and risk assessment models has been limited due to their predominantly designed focus on White populations. Specifically, there is a scarcity of scoring systems tailored to Japanese populations.

Therefore, in this study, we aimed to develop and validate an easy, systematic index for predicting the diabetes risk in the Asian population using glucose and lipid metabolism parameters and anthropometric parameters, which will enable the clinician or lay persons to assess their own risk of undiagnosed diabetes.

Methods

Study Population

The study participants were selected from the NAGALA (NAfld [nonalcoholic fatty liver disease] in the Gifu Area, Longitudinal Analysis) database—a human dock that serves as a repository for detecting chronic diseases and their linked risk factors, with the aim of advancing public health initiatives. The cohort has been comprehensively delineated in a prior investigation undertaken by Okamura et al [17]. The NAGALA cohort was initiated in 1994, encompassing individuals who underwent health examinations at Murakami Memorial Hospital. As a significant portion of the hospital's screening participants, approximately 60%, return for annual or biennial check-ups, the NAGALA team implemented an extended follow-up study to monitor the emergence of diabetes and nonalcoholic fatty liver disease in this population over time. Furthermore, the available dataset relevant to the investigation cohort has been made accessible on the Dryad public database [18] to facilitate the sharing of data.

The present study incorporated the data of 20,944 individuals who were enrolled in the NAGALA cohort between 1994 and 2016. After the further exclusion of participants who were diagnosed with diabetes, impaired fasting glucose, liver disease, excessive drinking, missing data on potential covariates, baseline medication, and unexplained withdrawal from the survey, a total of 15,464 participants were included as the analytical sample.

Ethical Considerations

The data used in this study were obtained from publicly available online databases. As these databases consist of deidentified and aggregated data, they do not involve human subjects or animals. All data were collected from publicly available sources; therefore, ethical approval was not required. Therefore, ethical review and approval were not required for this study in accordance with the ethical standards of the institutional and national research committees, as well as with the 1964 Helsinki Declaration and its later amendments or comparable ethical standards.

Measurement

Demographic data, examination and laboratory test results, medical history, and prescription medication information were used from the NAGALA data. The laboratory test levels included alanine aminotransferase (ALT), aspartate aminotransferase (AST), gamma-glutamyl transferase (GGT), total cholesterol (TC), triglyceride (TG), fasting plasma glucose (FPG), high-density lipoprotein cholesterol (HDL-C), and low-density lipoprotein cholesterol (LDL-C). The examination and laboratory tests included the evaluation of the BMI, systolic blood pressure (SBP), diastolic blood pressure (DBP), and waist circumference (WC). Regarding exercise behaviors, the participants' frequency of engaging in physical exercise per week was evaluated, with the criterion for the habit of exercise being defined as more than once per week. Alcohol consumption was categorized as heavy, moderate, light, and none, in line with the quantity and nature of participants' weekly alcohol intake over the course of the preceding month [19]. Smoking status was categorized as current smoker, past smoker, and never smoker.

TyG index was calculated as follows: TyG index = Ln [fasting TGs (mg/dL) × fasting glucose (mg/dL) / 2] [20].

TG/HDL-C was calculated as follows: TG/HDL-C ratio = TG/HDL-C [21].

METS-IR was calculated as follows: METS-IR = Ln ((2 × FPG) + TG) × BMI) / (Ln (HDL-C)) [22].

Gastroenterologists made a diagnosis of fatty liver by evaluating specific characteristics observed on abdominal Doppler ultrasonography; these characteristics included vascular blurring, deep attenuation, liver brightness, and hepatorenal echo contrast [23].

The diagnosis of diabetes mellitus was established using the criteria set forth by the ADA. Participants were deemed to have diabetes if their HbA_{1c} measurements were ≥6.5% or if their FPG levels were ≥7 mmol/L during the follow-up period. Furthermore, the analysis incorporated the participant's self-reported diabetes diagnosis during the follow-up period.

Statistical Analysis

If the continuous variables followed a normal distribution, they were represented as the mean and the standard deviation. The variables exhibiting nonnormal distribution were presented as medians accompanied by their respective minimum and maximum values. To evaluate variations between the two groups, the statistical analysis employed the Pearson chi-square test for categorical variables, while the Mann-Whitney *U* test or Student *t*-test was utilized for continuous variables. One-way ANOVA was used to compare several groups of data that followed a normal distribution, while the Kruskal-Wallis test

XSL•FO
RenderX

was used to analyze data that did not conform to a normal distribution.

A total of 15464 participants were randomly assigned to the training (n=9280, 60%) and internal validation (n=6184, 40%) sets. To establish the index for predicting the incidence of diabetes, univariate Cox regression was applied to detect the variables related to diabetes in the training set. Subsequently, the Cox regression model incorporating the least absolute shrinkage and selection operator (LASSO) was employed to ascertain the coefficients for constructing the model by utilizing an optimal log λ value. The index was established with the following formula: risk score = value of factor 1 × β1+ value of factor 2 × β2+…value of factor n × βn (β was the weighted coefficient of each factor).

Furthermore, an analysis of the receiver operating characteristic (ROC) curve was conducted, and areas under the curve (AUCs) were carried out to assess the predictive value of fasting stress hyperglycemia ratio, FPG, and HbA_{1c} in relation to the risk of diabetes.

The patients were divided into three groups (tertile 1: <33rd percentile, tertile 2: ≥33rd to 67th percentile, and tertile 3: ≥67th percentile) according to the novel index tertiles. Cox proportional hazards regression models were employed to assess the link between the index and the incidence of diabetes. The models included several covariates, namely sex, alcohol consumption, smoking status, habit of exercise, BMI, fatty liver, ALT, AST, GGT, TC, SBP, DBP, TyG, TG/HDL-C ratio, and METS-IR.

The statistical analyses were conducted using SPSS version 23.0 (SPSS Inc.) and R version 3.6.0 (R Foundation for Statistical Computing). A two-sided *P*-value <.05 was deemed to be statistically significant.

Results

Study Population

The current investigation encompassed 15,464 diabetes-free participants, with a mean age of 42 (range 18-79) years, 8430 (54.5%) men and 7034 (45.5%) women, and a mean follow-up of 6.05 (SD 3.7) years. A 6-to-4 ratio was used to randomly allocate patients into the training (n=9280) and validation (n=6184) sets. Table S1 in Multimedia Appendix 1 displays the variations in baseline characteristics of the study population in both the training set and validation set.

Establishment of the Diabetes Incidence Index

A univariate analysis was conducted on the training dataset in order to ascertain the variables that were correlated with the occurrence of diabetes. Eight significant variables, namely age, BMI, WC, HDL-C, TC, TG, HbA_{1c}, and FPG, were employed as predictive factors for progressing diabetes (*P*<.05; see Table S2 in Multimedia Appendix 1). The 8 clinical features were subsequently included in the LASSO regression analysis, which was performed for 1000 bootstrap iterations. From this analysis, 4 features were identified with nonzero coefficients and a minimum lambda value (Figure S1 in Multimedia Appendix 1). The findings of multivariate Cox regression analysis indicate that age, WC, HDL-C, TG, HbA_{1c}, and FPG were identified as independent risk factors (Table S3 in Multimedia Appendix 1).

To develop a risk index, we constructed a clinical feature-based risk signature derived from the results of a multivariate Cox regression analysis. The risk score was calculated as follows:

$$[(FPG) \times 1.525] - [(HDL\text{-}C) \times 0.454] + [(TG) \times 0.216] + [(HbA_{1c}) \times 3.298] + [(WC) \times 0.044] + [(age) \times 0.016].$$

We defined this new parameter combined with FPG, HDL-C, TG, HbA_{1c}, WC, and age as the FHTHWA index based on the initial letter of each variable.

Baseline Characteristics

The baseline characteristics of participants were examined based on the FHTHWA index in both the training and validation sets.

For the training set, patients with increased FHTHWA index levels tended to be of advanced age and displayed characteristics indicative of fatty liver, with higher BMI, WC, ALT, AST, body weight, GGT, TC, TG, HbA_{1c}, FPG, SBP, DBP, alcohol consumption, smoking, TG/HDLC ratio, TyG index, and METS-IR, as well as low HDL-C levels (Table 1; all *P*<.01).

[a]TG/HDL-C: triglyceride to high-density lipoprotein cholesterol.

For the validation set, patients with increased FHTHWA index levels tended to be of advanced age and displayed characteristics indicative of fatty liver, with higher BMI, WC, ALT, AST, body weight, GGT, TC, TG, HbA_{1c}, FPG, SBP, DBP, alcohol consumption, smoking, TG/HDLC ratio, TyG index, and METS-IR, as well as low HDL-C levels (Table S4 in Multimedia Appendix 1; all $P<.05$).

Predictive Value of the FHTHWA Index

Time-dependent ROC curves were utilized in order to assess the predictive efficacy of the FHTHWA index, as well as other newly proposed predictive parameters such as TG/HDL-C, the TyG index, and METS-IR, in relation to the risk of developing diabetes in the future. Figure 1A shows the AUC of the FHTHWA index and other novel predictive parameters over time for the training set. Overall, the baseline FHTHWA index demonstrated strong predictive capabilities for future diabetes occurrence at various time intervals. The AUCs of the FHTHWA index were higher compared with the AUCs of the TG/HDL-C, TyG index, and METS-IR during the 12-year follow-up. Figure 1B shows the AUC of the FHTHWA index and other novel predictive parameters over time for the validation set. Overall, the baseline FHTHWA index demonstrated strong predictive capability for future diabetes occurrence at various time intervals. Furthermore, the FHTHWA index exhibited greater AUC values compared to the TG/HDL-C, TyG index, and METS-IR at all time points.

Figure 1. Time-dependent receiver operator characteristic curves of the FHTHWA index vary with time to predict the future risk of diabetes. (**A**) Area under the curve (AUC) comparison of the FHTHWA index, TG/HDL-C ratio, TyG index, and METS-IR in the training set. (**B**) AUC comparison of the FHTHWA index, TG/HDL-C ratio, TyG index, and METS-IR in the validation set. METS-IR: metabolic score for insulin resistance; TG/HDL-C: triglyceride to high-density lipoprotein cholesterol ratio; TyG index: triglyceride-glucose index.

Relationship of the FHTHWA Index With Diabetes Risk

In the training set, 213 (1.38%) cases progressed to diabetes during the follow-up period. From quartile 1 to quartile 3 of the FHTHWA index, the diabetes rate increased gradually from 0.04% to 2.05% (Table 1). After multivariate adjustment, including sex, consumption of alcohol, smoking status, habit of exercise, BMI, fatty liver, ALT, AST, and GGT, an elevated FHTHWA index was markedly correlated with diabetes risk (Table 2). Multivariate adjusted hazard ratios and 95% CIs from the lowest to the highest FHTHWA index categories (tertile 1, tertile 2, and tertile 3) were 1.00 (reference), 4.509 (1.520 - 13.373), and 32.141 (11.545 - 89.476), respectively, for the incidence of diabetes ($P<.001$). The analysis of weighted Kaplan-Meier curves demonstrated significant dose-response patterns within the FHTHWA index strata in relation to the incidence of diabetes. These trends persisted even after a 12-year follow-up period. Furthermore, the risk of developing diabetes across the FHTHWA index strata displayed a noticeable divergence over time (Figure 2A).

RenderX

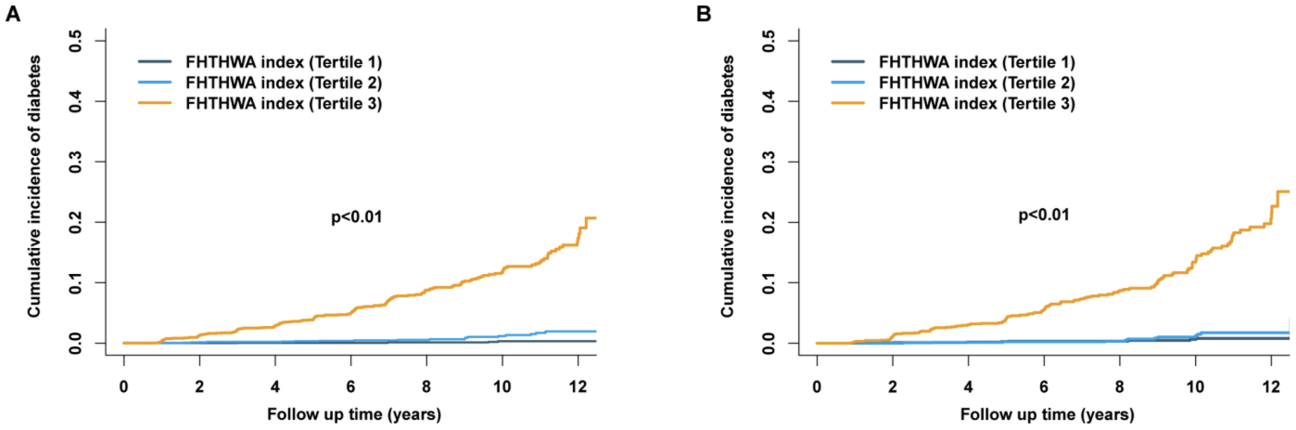

Table . Hazard ratios and corresponding 95% CIs for diabetes incidence according to the FHTHWA index among the population without diabetes in the training set.

	FHTHWA index			*P* trend	Per unit increment in the FHTHWA index
	Tertile 1	Tertile 2	Tertile 3		
Number of cases of diabetes mellitus/total	4/3093	19/3093	190/3094		
Crude	1.000 (ref.)	5.846 (1.988 - 17.158)	66.098 (24.542 - 178.020)	<.001	1.019 (1.018 - 1.021)
Model 1[a]	1.000 (ref.)	5.720 (1.914 - 16.856)	64.129 (23.679 - 173.677)	<.001	1.020 (1.018 - 1.022)
Model 2[b]	1.000 (ref.)	4.975 (1.684 - 14.695)	39.714 (14.459 - 109.084)	<.001	1.017 (1.015 - 1.019)

[a]Model 1: adjusted for sex, alcohol consumption, smoking status, and habit of exercise.

[b]Model 2: further adjusted (from Model 1) for BMI, fatty liver, ALT, AST, and GGT.

Figure 2. Weighted Kaplan-Meier curves for diabetes incidence by the baseline FHTHWA index strata. (**A**) Diabetes risk across the FHTHWA index strata in the training set exhibited divergence over time. (**B**) Diabetes risk across the FHTHWA index strata in the validation set exhibited divergence over time.

In the validation set, 160 (2.59%) cases progressed to diabetes during the follow-up period. From quartile 1 to quartile 3 of the FHTHWA index, the diabetes rate increased gradually from 0.16% to 2.25% (Table S4 in Multimedia Appendix 1). After multivariate adjustment, including sex, consumption of alcohol, smoking status, habit of exercise, BMI, fatty liver, ALT, AST, GGT, TC, TG, SBP, DBP, TyG, TG/HDL-C ratio, and METS-IR, an elevated FHTHWA index was markedly correlated with diabetes risk (Table S5 in Multimedia Appendix 1). Multivariate adjusted hazard ratios and 95% CIs from the lowest to the highest FHTHWA index categories (tertile 1, tertile 2, and tertile 3) were 1.00 (reference), 1.010 (0.419 - 2.435), and 9.924 (4.830 - 20.392), respectively, for the incidence of diabetes (*P*<.001). The utilization of weighted Kaplan-Meier curves demonstrated significant dose-response patterns across different strata of the FHTHWA index in relation to the incidence of diabetes, even after a follow-up period of 12 years. Moreover, the risk of developing diabetes across the FHTHWA index strata exhibited a noticeable divergence over time (Figure 2B).

Stratification Analyses

In the stratified analyses of the dose-response association between FHTHWA index levels and diabetes risk, participants were stratified by sex (male or female), habit of exercise (yes or no), BMI (<25 kg/m^2 or ≥25 kg/m^2), current smoker (yes or no), and current alcohol use (yes or no). In the training set, we discovered that a high FHTHWA index was linked with a higher diabetes risk, contrasted with the reference group in all subgroups (Table 3). In the validation set, the results were the same as our main results (Table S6 in Multimedia Appendix 1).

[a]Hazard ratios (95% CIs) were assessed using weighted Cox proportional regression that was fully adjusted except for the stratification factor.

Discussion

Study Findings and Comparison With Previous Works

Diabetes mellitus can lead to a range of complications that result in significant psychological and physical distress for individuals who carry the disease. Moreover, this places a substantial strain on the healthcare systems [24,25]. Nevertheless, the early detection of this condition is often hindered due to the absence of distinct symptoms and a limited focus on public healthcare. Early identification of the population with high risk for diabetes might help prevent the onset of diabetes or delay its progression [26]. In this study, we developed and validated a robust parameter, named the FHTHWA index, to forecast the development of the future diabetes likelihood depending on a comprehensive longitudinal cohort study of the Japanese physical examination population. Our results revealed that the higher the FHTHWA index, the higher the risk of developing diabetes. The correlation exhibited independence from conventional risk factors, such as sex, alcohol consumption, smoking status, habit of exercise, BMI, fatty liver, SBP, DBP, TyG, TG/HDL-C ratio, and laboratory parameters.

The early identification of individuals at high risk for diabetes is crucial for implementing preventive strategies and mitigating the burden of this disease. A growth of risk assessment tools for type 2 diabetes mellitus has been observed on a global scale, such as the ADA risk score [16], the Canadian Diabetes Risk Score (CANRISK) [27], the Finnish Diabetes Risk Score (FINDRISC) [15], the Indian Diabetes Risk Score (IDRS) [28], and Indonesian Undiagnosed Diabetes Mellitus (UDDM) scoring system [29]. Both the ADA and CANRISK tools have demonstrated efficacy in identifying individuals at risk within their respective communities; nevertheless, these products were specifically created to cater to the diverse populations residing in the United States and Canada, respectively. The validation of the IDRS took place in a low- to middle-income country. The IDRS is a valuable screening tool specifically for the mono-ethnic Indian population [28]. The scoring system originated in Indonesia. However, its accuracy has not been assessed through prospective evaluation [29]. Most of the predictive indices are genetic, demographic characteristics, and clinical parameters. With the intensive study of the pathogenesis of diabetes, many studies have begun to identify the genetic associations associated with the onset of diabetes. These studies not only reveal the genetic basis of diabetes but also provide new perspectives for understanding its pathogenesis. For example, recent genome-wide association studies identified multiple genetic variants associated with type 2 diabetes that may affect insulin secretion and islet β-cell function [30]. Furthermore, studies show that certain genetic variants are strongly associated with the age of onset of diabetes, and younger patients with the onset of diabetes often face a higher risk of cardiovascular disease and all-cause mortality [31]. The effects of genetic variation also vary in different populations. For example, studies in East Asian populations found that certain genetic variants associated with type 2 diabetes mellitus showed different effects in this population, underscoring the importance of genetic studies in different ethnic groups [32]. Moreover, studies targeting monogenic diabetes have also revealed genetic mechanisms associated with autoimmunity that may play an important role in polygenic diabetes [33]. It is very important to consider incorporating genes into predictors in future studies.

XSL•FO
RenderX

Moreover, most tools are based on the general population in defined regions and may not be generalizable to populations from different regions [34,35]. Currently, there is still a lack of widely used diabetes risk tools for the Japanese population [36]. The participants in this study were selected from a longitudinal cohort study that specifically targeted those undergoing health check-ups. This study commenced in 1994 and involved the continuous recruitment of individuals who underwent health examinations at Murakami Memorial Hospital. Thus, the study population typically included Japanese or Eastern Asian populations. The genetic constitution and lifestyle of Asian populations are different from those of European or American populations. Thus, the FHTHWA index might be suitable for the Japanese general population and other East Asian populations.

Insulin resistance (IR) is a medical condition characterized by reduced cellular responsiveness to insulin, independent of hyperinsulinemia [37]. IR serves as the primary pathophysiological mechanism underlying the developing type 2 diabetes mellitus, and it has the potential to manifest in individuals up to 2 decades prior to the diagnosis [38]. IR serves as a pivotal indicator of the imminent onset of diabetes. Evidence indicates that visceral adiposity indexes, such as BMI and WC, possess the capacity to effectively detect IR [39,40]. Moreover, evidence supports the effectiveness of classic lipid indices, including TC, TG, HDL-C, and LDL-C, in diagnosing IR [41,42]. However, the predictive capacities of these factors are limited [8]. Recently, the TyG index and TG/HDL-C have been recommended as diabetes risk indicators, both of which have better performance than traditional indicators (BMI, WC, TC, TG, HDL-C, and LDL-C) [43,44]. In this study, we performed a comparison of AUC values by time-dependent ROC analyses between the FHTHWA index, TyG index, TG/HDL-C, and METS-IR. It was found that the FHTHWA index had high accuracy, with the AUC value greater than 0.9 during the more than 12 years of follow-up. However, the AUC values of the TyG index, TG/HDL-C, and METS-IR mostly ranged from 0.7 to 0.8. Thus, the novel index has a higher prediction accuracy than the traditional parameters.

Study Strengths

This study's primary strengths include the large sample size of 15464 individuals ranging from 18 - 79 years of age, who underwent thorough examination and were subsequently monitored over an extended duration of up to 13 years. This sample was representative of the entire nation, enabling the findings to be extrapolated to the broader Japanese or East Asian populations.

Study Limitations

The present study has certain limitations. First, the primary focus of this study was the onset of diabetes as the outcome of interest. Nevertheless, it is important to acknowledge that the diagnostic criteria utilized in this investigation did not include the participants' 2-hour postprandial blood glucose level. This has the potential to result in an underestimation of the incidence of diabetes. Second, due to the utilization of the NAGALA database, it was impossible to eliminate self-reported characteristics, resulting in a potential reporting bias. Consequently, the findings of this study can only be generalized to the Japanese or East Asian population. It is crucial to determine the degree to which these findings can be extrapolated to heterogeneous populations. Third, it is important to note that the primary outcome measure of this study is the occurrence of new-onset diabetes events. However, it is noteworthy to emphasize that the dataset utilized in this study does not include information on death events that may have occurred during the follow-up period. This limitation introduces a potential competing risk that could impact the findings of the current research.

Conclusion

The research has successfully developed the FHTHWA index, which demonstrates a high degree of accuracy in predicting the future risk of diabetes within the Japanese population without diabetes. This index is particularly valuable for clinical practitioners in Japan, as it is recommended for regular use in assessing the risk of diabetes and monitoring therapeutic progress among the Japanese population.

Acknowledgments

We would like to thank Prof. Okamura Takuro and his team at Kyoto Prefectural University of Medicine for sharing their data. This study was supported by grants from the Jiangxi Provincial Key R&D Plan (no. 20201BBG71006), the Natural Science Foundation of Jiangxi Province (no. 20224BAB216009), and Technology Plan of Jiangxi Health Planning Committee (no. 202210484).

Data Availability

All the data used in this study were obtained from the Dryad Digital Repository database (https://datadryad.org/stash/dataset/doi:10.5061/dryad.8q0p192).

Abstract

Background: Despite the Coronary Artery Reporting and Data System (CAD-RADS) providing a standardized approach, radiologists continue to favor free-text reports. This preference creates significant challenges for data extraction and analysis in longitudinal studies, potentially limiting large-scale research and quality assessment initiatives.

Objective: To evaluate the ability of the generative pre-trained transformer (GPT)-4o model to convert real-world coronary computed tomography angiography (CCTA) free-text reports into structured data and automatically identify CAD-RADS categories and P categories.

Methods: This retrospective study analyzed CCTA reports from January 2024 and July 2024. A subset of 25 reports was used for prompt engineering to instruct the large language models (LLMs) in extracting CAD-RADS categories, P categories, and the presence of myocardial bridges and noncalcified plaques. Reports were processed using the GPT-4o API (application programming interface) and custom Python scripts. The ground truth was established by radiologists based on the CAD-RADS 2.0 guidelines. Model performance was assessed using accuracy, sensitivity, specificity, and F_1-score. Intrarater reliability was assessed using Cohen κ coefficient.

Results: Among 999 patients (median age 66 y, range 58 - 74; 650 males), CAD-RADS categorization showed accuracy of 0.98 - 1.00 (95% CI 0.9730 - 1.0000), sensitivity of 0.95 - 1.00 (95% CI 0.9191 - 1.0000), specificity of 0.98 - 1.00 (95% CI 0.9669 - 1.0000), and F_1-score of 0.96 - 1.00 (95% CI 0.9253 - 1.0000). P categories demonstrated accuracy of 0.97 - 1.00 (95% CI 0.9569 - 0.9990), sensitivity from 0.90 to 1.00 (95% CI 0.8085 - 1.0000), specificity from 0.97 to 1.00 (95% CI 0.9533 - 1.0000), and F_1-score from 0.91 to 0.99 (95% CI 0.8377 - 0.9967). Myocardial bridge detection achieved an accuracy of 0.98 (95% CI 0.9680 - 0.9870), and noncalcified coronary plaques detection showed an accuracy of 0.98 (95% CI 0.9680 - 0.9870). Cohen κ values for all classifications exceeded 0.98.

Conclusions: The GPT-4o model efficiently and accurately converts CCTA free-text reports into structured data, excelling in CAD-RADS classification, plaque burden assessment, and detection of myocardial bridges and calcified plaques.

KEYWORDS

GPT-4o; radiology report; CAD-RADS; coronary computed tomography angiography (CCTA); free-text reports

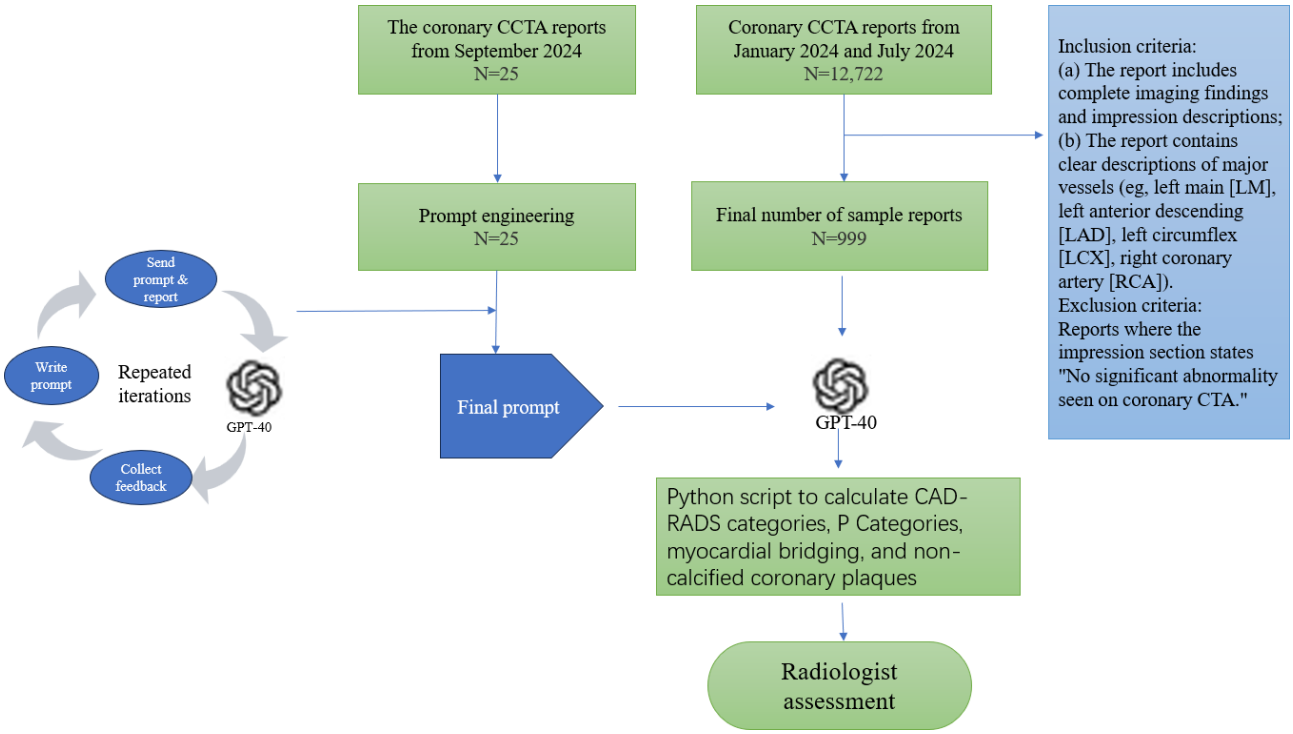
Introduction

The Coronary Artery Reporting and Data System (CAD-RADS), developed with support from the American College of Radiology and the American College of Cardiology, provides a standardized imaging approach for the screening, diagnosis, and treatment evaluation of coronary artery disease. CAD-RADS has been widely adopted and has had a significant impact on coronary artery disease management [1-5]. Despite the standardized approach of CAD-RADS, radiologists continue to favor free-text reports in practice. These reports often vary in style and structure, which can result in the omission of critical clinical information. This inconsistency complicates data extraction for longitudinal studies on coronary artery disease [6,7]. The issue is further exacerbated by the rapid advancements in medical technology and the increasing volume of coronary computed tomography angiography (CCTA) exams. Hospitals are now overwhelmed with unstructured reports, and manual

XSL•FO
RenderX

data extraction is both time-consuming and prone to errors. Therefore, there is an urgent need for automated methods to process these reports and enhance the efficiency and accuracy of information extraction.

Traditionally, medical natural language processing (NLP) techniques have been used to extract structured data elements from medical records, particularly in the field of radiology reports [8,9]. For instance, to bridge the gap between unstructured coronary artery reports and structured data, studies have successfully used deep learning and NLP techniques to predict coronary CAD-RADS scores [10]. However, a key challenge of traditional NLP algorithms is the scarcity of high-quality annotated datasets and the high cost associated with acquiring new annotated data [11]. Even with meticulously labeled ground truth data, the relatively small size of the corpus often leads to poor model generalization or makes generalization assessments impossible. For decades, traditional artificial intelligence (AI) systems (both symbolic and neural networks) have lacked general knowledge and common-sense reasoning.



With the development of large language models (LLMs) [12,13], especially generative pre-trained transformer (GPT) models like ChatGPT, these models exhibit unique capabilities such as zero-shot and few-shot learning. Such abilities enable them to learn from prompt-based examples and perform diverse tasks [14-16]. As a result, LLMs show significant potential across multiple industries. In healthcare, LLMs, with their powerful NLP capabilities, have been used to facilitate communication between patients and clinicians [17]. In the past year, there has been a surge in the exploration of LLMs in the field of radiology reports, which has garnered increasing attention. Research has shown that LLMs can assist radiologists in tasks such as diagnosis, generating radiology reports, data extraction, error detection, incidental findings, classifying reports and data systems for various diseases, and converting unstructured free-text reports into structured formats [18-23]. Some studies have also demonstrated that LLMs excel at extracting realistic, complex, and multilingual clinical information from radiology reports, such as LI-RADS features [22,24]. However, current studies mostly rely on web-based reports and texts, with small sample sizes. Prompt engineering often involves manually created virtual reports. As a result, research on how to leverage LLMs to automatically extract structured data from vast, real-world unstructured reports and build high-quality radiology medical databases remains scarce.

This study aims to evaluate the ability of the GPT-4o model to convert real-world free-text CCTA reports into structured data and automatically identify CAD-RADS categories and Plaque Burden categories (P categories). We hypothesize that the GPT-4o model, when applied through a systematic prompt engineering approach, will demonstrate robust performance in extracting and categorizing data from CCTA reports with accuracy comparable to human experts.

Methods

The overall study workflow is shown in Figure 1. The reports used for prompt engineering and the study cohort are authentic radiological reports with all sensitive information removed. This retrospective study was approved by the ethics committee of the Third Affiliated Hospital of Sun Yat-sen University (2023-042-01). All source code used in this study is publicly available in GitHub [25].

LLM Selection

The GPT-4o model used in this study is based on the GPT-4o model released by OpenAI in May 2024 and is implemented through official API interface calls. This model is based on general domain pre-training and does not undergo institution-specific fine-tuning. The "o" in "GPT-4o" stands for "omni," a step towards more natural human-computer interaction. It accepts any combination of text, audio, images, and video as input and generates any combination of text, audio, and image output. Compared with previous LLMs such as GPT-4, it has significant improvements on text in non-English languages and is also faster in the API and 50% cheaper. Compared with existing models, GPT-4o is particularly good at visual and auditory understanding.

Study Sample

Reports from CCTA examinations conducted between January 2024 and July 2024 were retrieved from the Picture Archiving and Communication System (PACS) database of the Third Affiliated Hospital of Sun Yat-sen University. A total of 12,722 CCTA reports from this period were initially included. All reports were written by committee-certified radiologists and were in Chinese. Inclusion criteria were as follows: (1) reports containing complete imaging findings and impression descriptions, and (2) clear descriptions of major coronary vessels such as the left main, left anterior descending, left circumflex (LCX), and right coronary artery. Exclusion criteria involved reports where the impression stated, "no significant abnormalities detected in coronary CTA." After applying the inclusion and exclusion criteria, 999 reports remained for analysis (sample 1). In addition, 25 CCTA reports from September 2024 (sample 2) were included for prompt engineering.

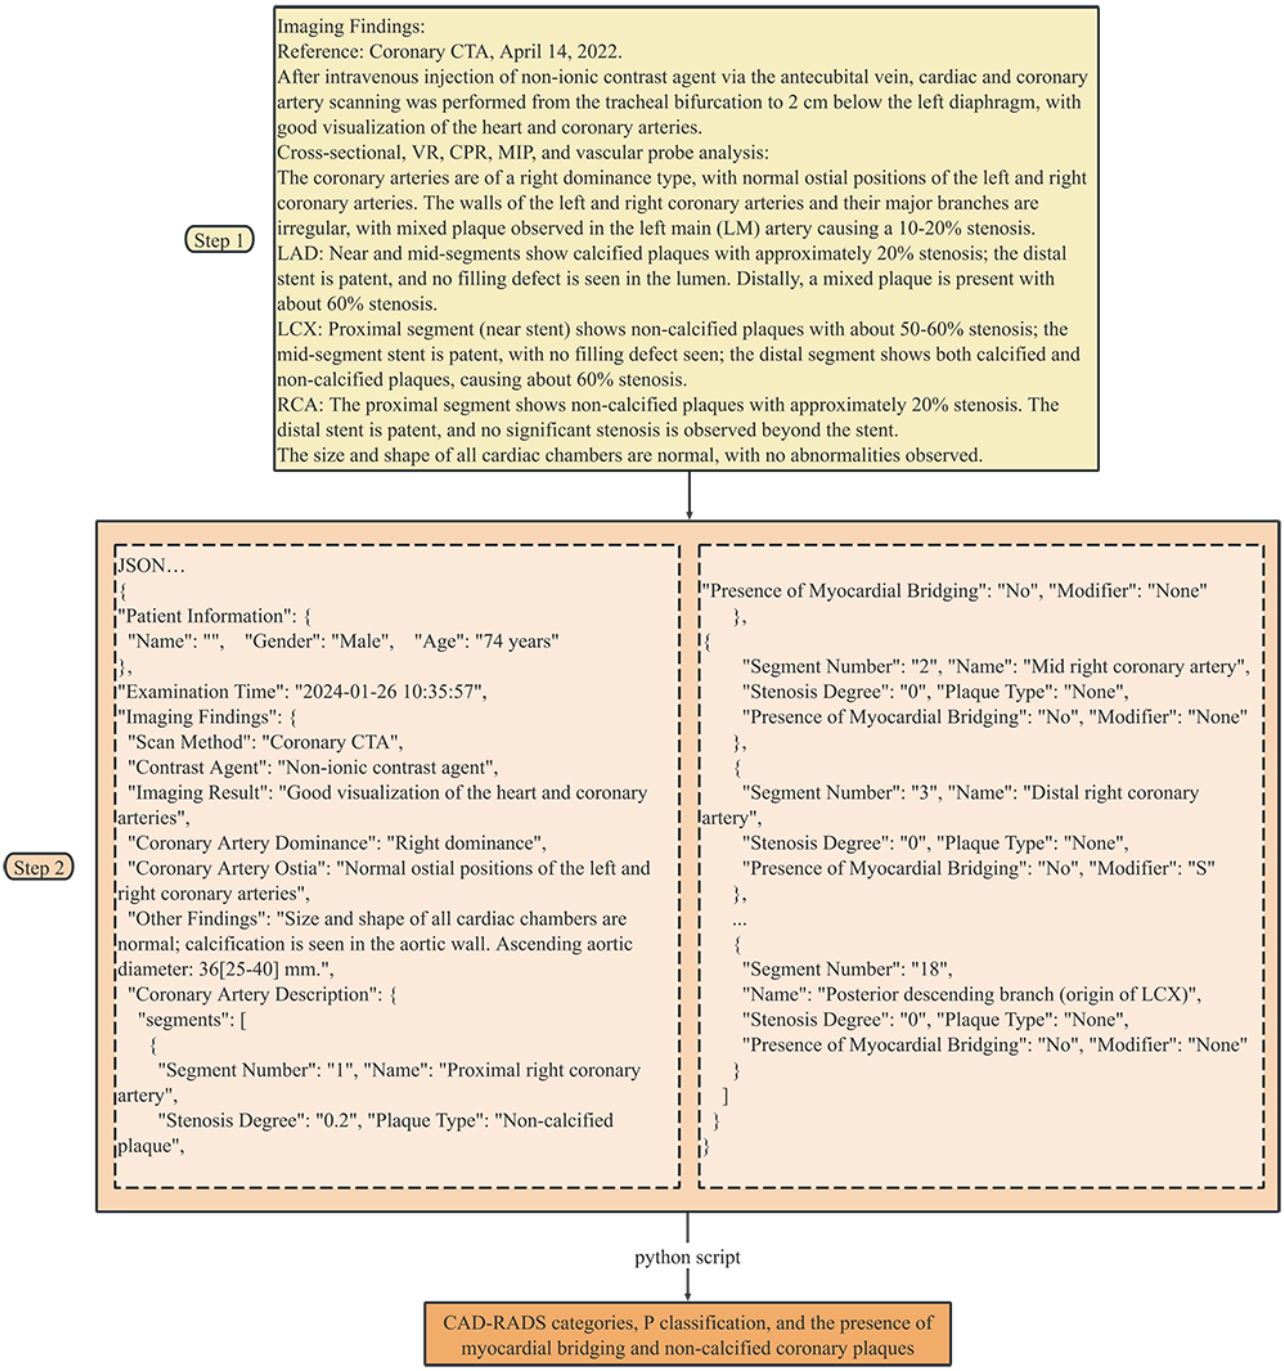
Data Processing

The selected reports were exported to an Excel spreadsheet (Microsoft), and the author, YC, evaluated these reports, removing sensitive information such as registration numbers and names while retaining relevant details such as gender, age, imaging findings, impression descriptions, and examination dates. Except for minor typographical errors, no changes were made to the content of the reports.

Creation of the Ground Truth

The ground truth labels for each report were established by a radiologist (YC with 3 y of experience) who evaluated all reports according to the CAD-RADS (version 2.0) guidelines [1] published in 2022, with data manually extracted into CSV format. The labeling process incorporated CAD-RADS categories, P categories, as well as the identification of myocardial bridging and noncalcified coronary plaques. In instances where YC encountered challenges in labeling, expert consultations were sought from JQ, who possesses 24 years of professional experience. To assess intrarater reliability, 200 reports were randomly selected and re-evaluated after a 15-day washout period, with agreement measured using Cohen κ coefficient.

Prompt Engineering



The creation of prompts strictly follows the CAD-RADS 2.0 guidelines and the 18-segment coronary artery method, aiming to extract coronary artery disease-related data through simplified steps. The task of GPT-4o is to convert the free-text CCTA report into a structured format and output the data in JSON format. The initial prompt used simple instructions, such as: "Please construct the following coronary artery CTA report and output it in JSON format." Sample 2 was used for prompt engineering, and corresponding feedback was collected. When it was found that the model output was not good or errors occurred, the instructions were modified again, such as "Please read the following report carefully, summarize it according to the CAD-RADS 2.0 guidelines, and output it in a structured form, in JSON format." The prompt was optimized through multiple iterations until the model output the best results, and the final prompt was obtained and no longer changed. The final prompt consisted of a single step: generating structured data in JSON format based on the original report, containing the current examination date, examination technique, coronary origin, dominant vessel, and key features of each coronary artery (such as stenosis degree, plaque type, presence of myocardial bridges, presence of stents, etc.). The Chinese version of the prompt is provided in Multimedia Appendix 1. GPT-4o was instructed to generate a CSV file with process details for each report.

Batch Feature Extraction and Classification

The final prompt was used to process the reports from the study cohort (Sample 1). A Python script containing the final prompt was written for batch processing of all reports. This script interacted with the GPT-4o API, sending prompts to the model one by one, with the model automatically processing the reports and converting them into CSV tables with relevant details. The characteristics of myocardial bridging and noncalcified coronary plaques were directly extracted from the model's responses, while the CAD-RADS and P categories were programmatically determined using custom Python functions based on the CAD-RADS and P categories algorithms. An example of a report and its downstream processing is depicted in Figure 2.

XSL•FO
RenderX

Figure 2. A representative example showing how GPT-4o processes and structures a coronary computed tomography angiography radiology report. The system uses a specialized prompt to transform the free-text report into a standardized JSON format, comprising 18 distinct sections (sections 1 - 18, with intermediate sections abbreviated for brevity). The structured output is subsequently analyzed by a Python script to identify the Coronary Artery Reporting and Data System categories, P categories, myocardial bridge, and noncalcified plaque.

The detailed calculation process of CAD-RADS and P categories algorithms can be viewed in GitHub [25].

Error Analysis

YC conducted a review of cases with errors in the extraction of key features, specifically the CAD-RADS category and P categories. The original report, the outputs from the structured reporting process, and the final results computed using Python were jointly examined to identify the source of the errors.

Model Performance Evaluation

The accuracy, specificity, sensitivity, and F_1-score are used to evaluate the performance of the model in extracting and classifying the 4 features. The formula is as follows:

Accuracy=TP+TNTP+TN+FP+FN

Sensitivity=TPTP+FN

Specificity=TNTN+FP

F1=2×Precision×SensitivityPrecision+Sensitivity,Precision=TPTP+FP

XSL•FO
RenderX

Statistical Analysis

In this study, baseline characteristics of the sample were described using the median and interquartile range (Q1, Q3) for continuous variables (eg, age) and frequency (n) and percentage (%) for categorical variables (eg, gender, CAD-RADS categories, P categories, and the presence of myocardial bridging and noncalcified coronary plaques). Intrarater agreement was assessed using Cohen κ statistics.

For the model-extracted features (eg, presence of myocardial bridges) and the CAD-RADS 0 - 5 classification and P 0 - 4 Categories, accuracy, specificity, sensitivity, and F_1-score were calculated. According to the CAD-RADS 2.0 guidelines, CAD-RADS 0 indicates the absence of plaque or stenosis, and P0 is not included in the Categories. However, to evaluate the performance of the LLM in patients without plaque or stenosis, patients without plaque or stenosis were treated as P0 level in the statistical analysis.

This study was conducted using Python (version 3.8.16) as the primary programming environment and the OpenAI API (version 1.33.0) for LLM interactions. The temperature parameter mainly affects the diversity and randomness of the output of the LLM. Generally speaking, the higher the temperature, the greater the diversity and randomness of the model output, and the more unpredictable the results. To minimize model variability and ensure reproducibility, the temperature parameter was consistently set to 1E-10 across all model configurations [26,27]. Statistical analyses were performed using Python's scikit-learn library (version 1.3.2) and SPSS statistical software (version 27; IBM Corporation).

Results

Study Sample

Figure 1 shows the inclusion and exclusion process for patients, while Table 1 summarizes the baseline characteristics of patients based on CAD-RADS categories and Plaque Burden categories (P categories), among other features. Initially, 12,722 coronary CTA free-text reports were screened, with 8465 reports excluded due to "no significant abnormality detected in coronary CTA," as these patients showed no obvious coronary artery disease. An additional 3258 reports were excluded due to missing comprehensive imaging results, insufficient descriptions of findings, and the absence of clear identification of the major coronary arteries. Ultimately, 999 reports were included for analysis (median age 66 y; age range 57 - 73, of whom 650 were male). All reports were successfully processed into structured data using GPT-4o, and the corresponding CAD-RADS and P categories were generated for each report.

Table . Characteristics of included patients. Unless otherwise indicated, data are numerators and data in parentheses are percentages.

Characteristics	Patients (N=999)
Gender, n (%)	
Male	650 (65.1)
Female	349 (34.9)
Age (years), median (IQR)	66 (57 - 73)

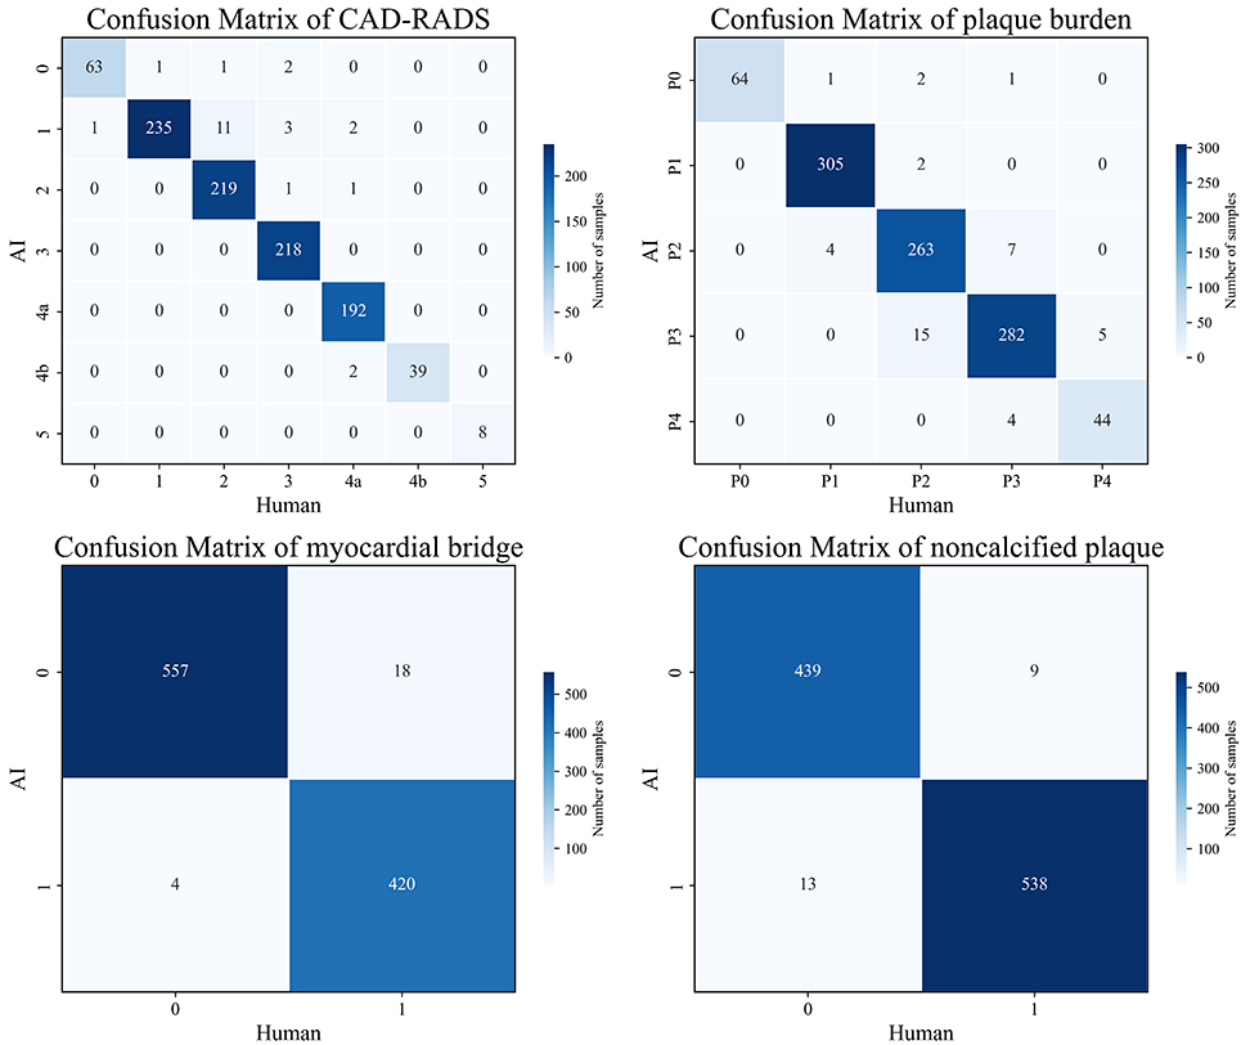
RenderX



Intrarater Reliability

The κ values were 0.99 for CAD-RADS categories, 0.98 for P categories, 0.99 for myocardial bridging, and 0.98 for noncalcified plaque, indicating excellent intrarater reliability.

Model Performance Evaluation

The confusion matrix for each CAD-RADS category, P categories, and related features from the study cohort is shown in Figure 3. The X-axis represents the number calculated by human doctors (gold standard), and the Y-axis represents the number predicted by GPT-4o. Table 2 lists the accuracy, specificity, sensitivity, and F_1-score for each feature. For CAD-RADS classification (from class 0 to 5), the accuracy ranged from 0.98 to 1.00 (0.9730 - 1.0000), sensitivity from 0.95 to 1.00 (0.9191 - 1.0000), specificity from 0.98 to 1.00 (0.9669 - 1.0000), and F_1-score from 0.96 to 1.00 (95% CI 0.9253 - 1.0000). For Plaque Burden P categories (P0 to P4), the accuracy ranged from 0.97 to 1.00 (95% CI 0.9569 - 0.9990), sensitivity from 0.90 to 1.00 (95% CI 0.8085 - 1.0000), specificity from 0.97 to 1.00 (95% CI 0.9533 - 1.0000), and F_1-score from 0.91 to 0.99 (95% CI 0.8377 - 0.9967). For the presence of myocardial bridges in the coronary arteries, the accuracy was 0.98 (95% CI 0.9680 - 0.9870), sensitivity 0.96 (95% CI 0.9376 - 0.9764), specificity 0.99 (95% CI 0.9852 - 0.9983), and F_1-score 0.97 (95% CI 0.9630 - 0.9844). For the presence of noncalcified coronary plaques, the accuracy was 0.98 (95% CI 0.9680 - 0.9870), sensitivity 0.98 (95% CI 0.9710 - 0.9929), specificity 0.97 (95% CI 0.9533 - 0.9862), and F_1-score of 0.98 (95% CI 0.9709 - 0.9880). See details in Figures 4 and 5.

Figure 3. Confusion matrix of GPT-4o performance in Coronary Artery Reporting and Data System (CAD-RADS) categories and Plaque Burden categories. The confusion matrix can intuitively show the number of correct or incorrect model outputs. For example, in CAD-RADS 3 categories, the model has 218 correct answers and 6 incorrect answers.

[b]CAD-RADS: Coronary Artery Disease-Reporting and Data System.

Figure 4. Performance metrics of generative pre-trained transformer (GPT)-4o in identifying Coronary Artery Reporting and Data System (CAD-RADS) categories and Plaque Burden categories (P categories). The radar chart can intuitively show that the model has a very high accuracy in various tasks in the CAD-RADS categories and P categories.

RenderX

Figure 5. Performance metrics of generative pre-trained transformer (GPT)-4o in identifying myocardial bridge and noncalcified plaque.

Error Analysis

This study performed an error analysis for CAD-RADS categories and P categories, involving 1998 features, with 57 errors identified, resulting in an overall error rate of 2.9%. The errors were classified into 3 main types: model output termination errors, feature extraction errors, and ambiguities in the original report descriptions, as shown in Table 3.

XSL•FO
RenderX

Table . Error analysis. In the 18-segment coronary artery model, the left circumflex is divided into proximal and distal segments with no midsegment. When "midsegment" is mentioned in the report, it is defined as the proximal segment in our system settings for the prompt engineering.

Error type	Frequency	Explanation
CAD-RADS[a] categories		
Model output termination error	2	The model failed to output complete structured data due to unknown reasons, resulting in classification errors (n=2).
Feature extraction error	20	Although the model output the report completely, errors occurred during the feature extraction phase when converting free text to structured data, leading to classification errors (n=20). For example, in the original report, the coronary arteries had no plaques or stenosis, and the most severe stenosis was 0%. However, the model output a 10% - 20% stenosis level, misclassifying it from class 0 to class 1.
Ambiguity i then original report	0	The original report contained ambiguous or unclear descriptions, leading to erroneous structured outputs, which impacted the final classification (n=0).
Plaque Burden categories		
Model output termination error	4	The model failed to output complete structured data due to unknown reasons, resulting in classification errors (n=4).
Feature extraction error	25	Although the model output the report completely, errors occurred during the structured data conversion, particularly in recognizing coronary segment involvement, leading to classification errors (n=25). This included incorrectly identifying one or more segments as affected (n=13) or missing one or more segments (n=12), ultimately causing misclassification.
Ambiguity i then original report	6	The original report contained ambiguous or unclear descriptions, leading to erroneous structured outputs and affecting final classification (n=6). For instance, the report contained an ambiguous description of the mid-proximal segment, which was incorrectly identified as 2 separate segments during the structured output phase (n=6), resulting in misclassification.

[a]CAD-RADS: Coronary Artery Disease Reporting and Data System.

For CAD-RADS categories, there were 2 instances of model output termination errors, 20 instances of feature extraction errors, and no instances of ambiguities in the original report descriptions.

For overall plaque burden subclassification, there were 4 instances of model output termination errors, 25 instances of feature extraction errors, and 6 instances of ambiguities in the original report descriptions.

Discussion

This study aimed to evaluate the capability of GPT-4o in converting unstructured coronary CTA reports into standardized formats and automatically identifying CAD-RADS categories and P categories. Our results demonstrated exceptional performance, with accuracy rates exceeding 0.97 for CAD-RADS classification and P classification. These findings suggest that LLMs could not only automate the structuring of free-text reports to enhance radiological workflow efficiency but also facilitate the extraction of valuable structured information for database construction and subsequent clinical research.

Our findings align with previous studies showing that LLMs can effectively extract structured information from medical reports. Recent research has demonstrated similar success in extracting features for various standardized reporting systems, including LI-RADS and BI-RADS [24,28]. However, our study extends beyond previous work by using a larger dataset of real-world clinical reports rather than simulated data, providing more robust evidence of GPT-4o's clinical applicability. The model's high performance across different classification tasks suggests its potential for broader implementation in clinical radiology workflows, particularly in standardizing reporting practices and facilitating data collection for research.

XSL•FO
RenderX

Our study further confirms LLMs' exceptional performance in extracting clinically relevant data. For instance, GPT-4 demonstrated a 96% accuracy rate in extracting lesion information from lung cancer CT reports [29], and also showed high accuracy in emergency department CT reports [30]. In our study, GPT-4o successfully identified and classified coronary artery disease, particularly in the CAD-RADS and P classification tasks, with remarkable accuracy. These findings further support LLMs' efficiency in handling complex medical tasks, especially where traditional manual extraction methods may be prone to errors due to task complexity [31].

While LLM models have shown strong capabilities in medical data extraction, hallucinations and randomness remain inherent challenges [27,32]. To reduce accuracy loss caused by hallucinations, we implemented 2 key measures. First, we set the model's temperature to 1E-10 [27], which helps reduce variability in the model's outputs, thus controlling randomness. Second, for the CAD-RADS and P classification tasks, we did not rely solely on the model's output; instead, we used custom Python scripts to perform further calculations based on its structured responses. This approach ensured accuracy and validated the feasibility of our study through high performance.

Although we achieved promising results, our study still contained a small number of erroneous cases, with an overall error rate of 2.9%. Most of these errors occurred during the feature extraction phase, particularly in the CAD-RADS classification (20 out of 22 errors occurred in this phase) and P classification (25 out of 35 errors were related to segment involvement scoring). Among them, 6 errors were due to ambiguity in the original report. This error was caused by the fact that when radiologists wrote coronary CTA reports, they referred to inconsistent literature on the segmentation of coronary arteries. The descriptions of the LCX segment included the proximal LCX segment, the middle LCX segment, and the distal LCX segment. However, this study adopted the internationally accepted segmentation method of 18 coronary arteries, and the LCX only had the proximal and distal segments. For the handling of ambiguous reports, we provided the large model with relevant literature knowledge when prompt engineering and clearly informed the model that ambiguous reports generally needed to be carefully identified. After manual review and repeated iterations, the accuracy of the model for ambiguous reports was greatly improved. This shows that by giving the model specific knowledge and rules, the model can adapt to the complex clinical environment in the real world.

Due to the black-box nature of LLMs [33], we cannot directly explore the root causes of errors, but we can reasonably speculate on their sources. First, the model's inherent hallucinations [32] may cause misleading outputs during the reasoning process of structured data. Although the temperature adjustment reduced randomness to some extent, hallucinations still influenced the reasoning process. Second, external factors such as API stability, network conditions, or computational resource limitations could also impact the model's output. Additionally, ambiguities or inconsistencies in the original reports contributed to the occurrence of errors.

These issues highlight the need for professional oversight and intervention when using LLMs for large-scale data extraction [34] to ensure the accuracy and consistency of the extracted results. Regarding hallucinations, while we have taken measures to mitigate their impact, future research should further explore strategies to reduce hallucination phenomena, especially in clinical data extraction tasks. Furthermore, ambiguities in the original reports may arise from subtle differences in guidelines referenced by medical professionals when writing reports. To minimize this impact, radiologists should strive to adhere to internationally accepted segmentation methods, and the model should be further trained to enhance its understanding of medical knowledge, particularly the differences between various guidelines for the same disease. With these improvements, the accuracy and reliability of the model could be further enhanced.

The implementation of GPT-4o in clinical practice appears feasible given its high accuracy and efficiency. In addition, in terms of operating costs, based on OpenAI's official pricing, the input and output of a single report in this study is approximately 2052 (SD 15) tokens, with a cost of approximately US $0.03. Batch processing of 1000 reports a day only costs US $30.80, which has the potential to be applied in clinical practice. In the RIS (Radiology Information System) of the radiology department, there is a port that can be connected to the GPT-4o API. This may require the government, hospitals, and other relevant departments to sign a patient data privacy confidentiality agreement with OpenAI. In the future, GPT-4o will have the opportunity to be applied in the radiology workflow. However, several critical considerations must be addressed before widespread adoption. Patient privacy protection remains the foremost ethical priority, requiring robust safeguards implemented in our study through a multilayered approach: beyond foundational IRB compliance, all coronary CTA reports underwent rigorous deidentification (removing Health Insurance Portability and Accountability Act–defined Protected Health Information) prior to LLM API interaction; data transmission was secured via TLS 1.2+ encryption with explicit configuration to disable third-party data retention; and access was restricted to authorized personnel through institutional role-based controls. Crucially, future clinical deployments must enforce equally stringent, auditable protocols within existing health care IT infrastructure (eg, RIS or PACS or EHR (electronic health record). Additionally, model outputs necessitate validation by qualified radiologists—particularly for high-risk cases—to ensure clinical accountability, while regular updates to the model's knowledge base are essential to maintain alignment with evolving guidelines.

Our study has several limitations. First, all reports came from a single institution, potentially limiting the generalizability of our findings. Second, the retrospective nature of this study may have introduced selection bias, and this study used Chinese as the research subjects, mainly middle-aged and older males, so the research data may be biased, and the performance of groups in other countries may be different. Third, we only evaluated one version of GPT-4o, and performance may vary with different model versions or other LLMs. Finally, the study period was relatively short, and longer-term evaluation would be valuable for assessing the model's consistency over time.

XSL•FO
RenderX

In conclusion, GPT-4o demonstrates remarkable capability in converting unstructured coronary CTA reports from our institution into standardized formats, suggesting significant potential for LLMs to improve radiological workflow efficiency and data standardization. If integrated with clinical decision support systems in the future, it will greatly improve the accuracy of radiologists' diagnosis of coronary artery disease, facilitate the management of coronary artery disease, and reduce the time required to generate reports on coronary artery findings. However, the limitations outlined earlier, particularly concerning generalizability across diverse health care settings and report formats, must be rigorously addressed. Future research should prioritize multicenter validation to rigorously assess robustness and adaptability, investigate seamless integration with existing health care systems (RIS or PACS or EHR), and critically evaluate the model's impact on downstream clinical outcomes and decision-making.

Acknowledgments

I would like to express my sincere gratitude to my supervisor, Professor Qin Jie, and Dr. Li Chao for their invaluable guidance and support throughout this research. This research was supported by the Hospital National Natural Science Foundation Cultivation Project (2021GZRPYM06), the Five-Five Project of the Third Affiliated Hospital of Sun Yat-sen University (2023WW605), and the National Natural Science Foundation of China grant (82202129, to CL).

Abstract

Background: Millions of people affected with complex medical conditions with diverse symptoms often turn to online discourse to share their experiences. While some studies have explored natural language processing methods and medical information extraction tools, these typically focus on generic symptoms in clinical notes and struggle to identify patient-reported, disease-specific, subtle symptoms from online health discourse.

Objective: We aimed to extract patient-reported, disease-specific symptoms shared on social media reflecting the lived experiences of thousands of affected individuals and explore the characteristics, prevalence, and occurrence patterns of the symptoms.

Methods: We propose a lexicon-based symptom extraction (LSE) method to identify a diverse list of disease-specific, patient-reported symptoms. We initially used a large language model to accelerate the extraction of symptom-related key phrases that formed the lexicon. We evaluated the effectiveness of lexicon extraction against human annotation using a Jaccard index score. We then leveraged BERT-Base, BioBERT, and Phrase-BERT–based embeddings to learn representations of these symptom-related key phrases and cluster similar symptoms using k-means and hierarchical density-based spatial clustering of applications with noise (HDBSCAN). Among the different options explored in our experiments, BioBERT-based k-means clustering was found to be the most effective. Finally, we applied symptom normalization to eliminate duplicate and redundant entries in the comprehensive symptom list.

Results: In a real-world polycystic ovary syndrome (PCOS) subreddit dataset, we found that LSE significantly outperformed state-of-the-art baselines, achieving at least 41% and 20% higher F_1-scores (mean 86.10) than automatic medical extraction tools and large language models, respectively. Notably, the comprehensive list of 64 PCOS symptoms generated via LSE ensured extensive coverage of symptoms reported in 7 reputable eHealth forums. Analyzing PCOS symptomatology revealed 28 potentially emerging symptoms and 8 self-reported comorbidities co-occurring with PCOS.

Conclusions: The comprehensive patient-reported, disease-specific symptom list can help patients and health practitioners resolve uncertainties surrounding the disease, eliminating the variability of PCOS symptoms prevailing in the community. Analyzing PCOS symptomatology across varied dimensions provides valuable insights for public health research.

Introduction

Background

The rise of health 2.0 has significantly increased the consumption of health-related information on social media in recent years. Worldwide, 34.7% of adult internet users frequently search for health-related information online, with approximately 58.5% of adults in the United States specifically engaging in such searches as of 2023 [1,2]. Analyzing online discourse on health-related topics offers valuable insights into the lived experiences and perspectives of affected individuals [3-5]. The critical findings of these analyses are particularly significant for understanding complex medical conditions, such as different types of cancer, cognitive and mental health conditions, autoimmune disorders, and metabolic and endocrinological conditions. These medical conditions often manifest with diverse symptoms that vary significantly among patients [6-8]. Furthermore, there is often no consensus among established medical sources regarding the full range of possible symptoms for such conditions [9,10]. This variability poses challenges for patients, health care providers, and researchers seeking a comprehensive understanding of these symptoms and their characteristics. Thus, the study and analysis of symptoms associated with a disease, referred to as *symptomatology*, is crucial for understanding complex diseases [11]. We argue that a robust approach to extracting disease-specific symptoms from individuals' lived experiences shared on social media can address uncertainties surrounding complex medical conditions. This approach would also allow for the identification of symptoms that patients associate with a condition (eg, brain fog with post–COVID-19 condition), prevalence of symptom co-occurrence (eg, unexplained weight loss and pain with cancer), and how symptoms vary based on patients' comorbidities and preexisting conditions.

Recent advancements in natural language processing (NLP) have enabled public health researchers to explore medical information extraction tools [12-15] and develop novel techniques [16-18] for analyzing online health discourse, including patient-reported data from social media. However, off-the-shelf medical information extraction tools primarily excel in extracting well-known medical entities (eg, diseases, drugs, and basic symptoms). Their limitations become evident with granular, patient-centric details (eg, unusual symptom descriptions, implicit context, or subtle adverse events), which often require specialized rules or retrained models for accurate detection [19-22]. Modern transformer-based models used with medical named entity recognition have shown promising results in symptom extraction [23,24]. However, these models typically require large amounts of domain-specific data and are mostly trained on clinical notes (electronic health records), which limits their effectiveness when dealing with colloquial health discourse generated by patients [7,23-25]. A family of bidirectional encoder representations from transformers (BERT)–based models fine-tuned on colloquial data markedly improves symptom recognition in informal texts; nevertheless, their error analysis indicates that the best-trained models still capture only approximately 25% to 50% of lengthy, figurative symptom phrases and continue to misclassify many subtle or previously unseen expressions (eg, "mild difficulty taking deep breaths" or "chest again felt a little tight") [26]. A recent NLP pipeline [27] used to extract symptoms from patient narratives on social media proposed a dual-corpus symptom lexicon containing keywords (eg, *fever* and *cough*) and related modifiers (eg, *mild* or *severe*) followed by applying a rule-based postprocessing step to merge the 2. However, this fixed rule-based approach may struggle to report symptoms whenever people describe them implicitly, with spelling noise, or in new phrasing that never entered the seed lists (eg, "can't breathe properly" or "my lungs felt on fire").

While the existing lexicon-based approaches have successfully used predefined resources and deep learning frameworks for broad public health surveillance, their reliance on explicit wording limits their ability to capture the full range of informal expressions. On the other hand, large language models (LLMs) have significantly accelerated medical NLP research, especially in the field of information extraction [16,17,21,28]. While some studies have demonstrated the potential of LLMs for health information extraction from social media [29,30], they face challenges when extracting specific contexts such as health advice and disease-specific treatment [12,16].

Objectives

To overcome the aforementioned limitations of symptom extraction from social media discourse, we propose a novel NLP pipeline that systematically combines the capabilities of LLMs and other NLP methods with feedback from domain experts, resulting in a scalable and practical solution to the problem of symptom extraction from patient-reported social media discourse.

While the proposed pipeline can be applied to explore a plethora of medical conditions for which there is an abundance of patient-reported online discourse, we focused on a common chronic condition with significant uncertainty, namely, polycystic ovary syndrome (PCOS), as a use case in this paper. According to the World Health Organization [31], an estimated 116 million women (3.4% of reproductive-age women) worldwide are affected by PCOS, and its prevalence is on the rise. Despite its widespread impact, the full spectrum of PCOS remains insufficiently explored [32]. Patients report a diverse range of symptoms that vary in severity depending on previous medical history and their effect on daily life. The combination of varied symptoms, insufficient treatment guidelines, and instances of medical gaslighting often leads to psychological distress, prompting many individuals to seek support and share experiences on social media platforms [33], including Reddit. Existing research leveraging social media data to study PCOS is still underdeveloped [4,34-36]. This creates a unique opportunity to systematically identify self-reported symptoms

XSL•FO
RenderX

and related symptomatology based on the lived experiences of thousands of individuals and, thereby, inform the clinical understanding of this complex medical condition. We make 3 primary contributions. First, we developed a novel lexicon-based symptom extraction (LSE) method to identify diverse disease-specific symptoms from individuals' experiences shared on social media. This method can effectively detect even subtle symptoms mentioned in user discourse. We applied our LSE method to a novel PCOS subreddit dataset, achieving statistically significant improvements over state-of-the-art medical NLP baselines.

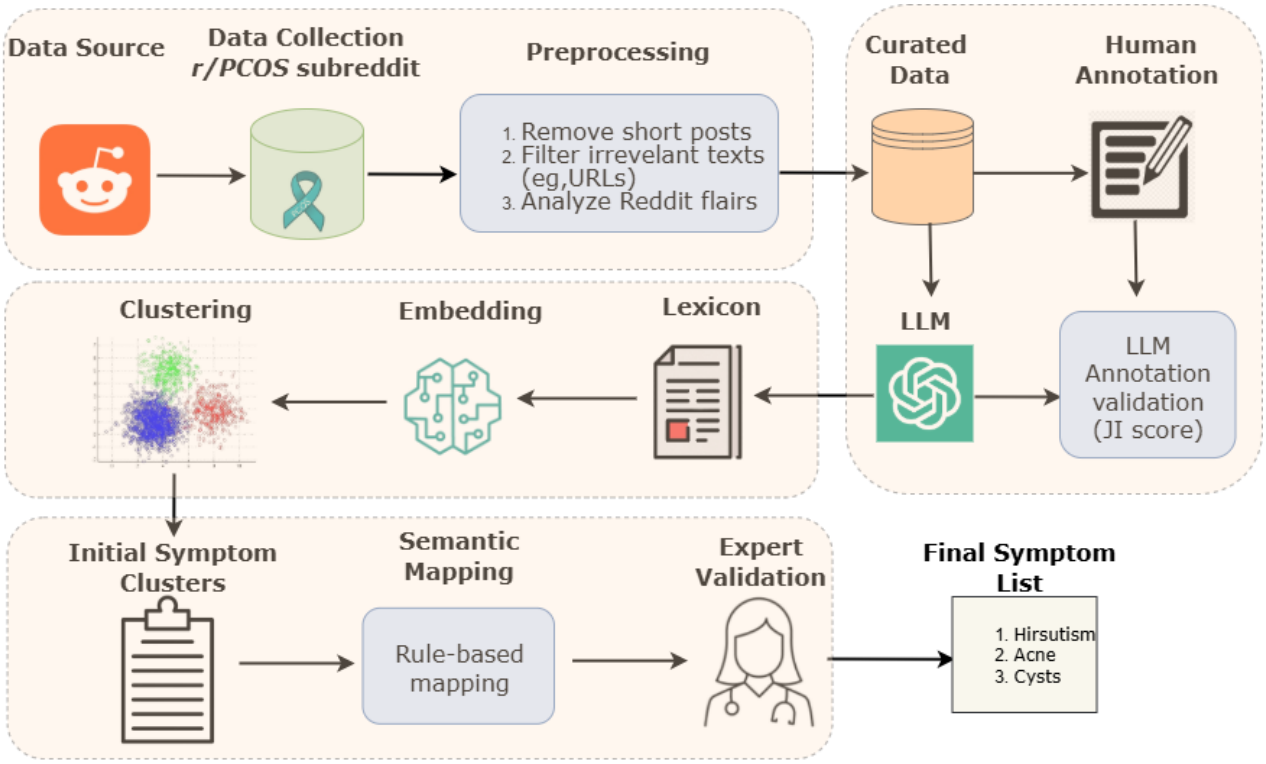
Second, we conducted an in-depth analysis of peer discussion threads on the extracted PCOS symptoms to reveal a set of lesser-known yet prevalent symptoms that individuals associate with PCOS and associated co-occurring symptoms and comorbidities. These findings can contribute to clinical research and public health research in a community-informed way.

Third, we curated a novel Reddit dataset containing 59,962 and 641,441 relevant posts and comments, respectively. This dataset captures self-reported PCOS symptoms and their context from 68,010 affected individuals. In addition, we curated a human-annotated, labeled dataset of 1000 posts of patient-reported symptoms related to PCOS based on guidance from domain experts and patient input. We release these resources in a public domain. These unique, rich resources can enable medical NLP and computational health researchers to further investigate the symptomatology of complex medical conditions identified and analyzed online.

Methods

Data Collection and Preprocessing

We selected Reddit as a source of data because of its anonymous nature. It encourages users to share personal experiences on stigmatized topics [4,37]. The data collection process began with the identification of the r/PCOS subreddit by considering the group posts' availability and popularity among 153,000 members engaging in discussions on PCOS. We systematically collected data from this subreddit using the *Python Reddit API Wrapper* package (Python Software Foundation) and the Pushshift application programming interface (API) [38,39]. We obtained all the posts and comments from the r/PCOS subreddit from August 4, 2010, to December 31, 2022. This timeline was chosen to ensure a comprehensive capture of recent as well as previous discussions. For each post, we retained the date, flair name, unique post ID, post title, post content, score, upvotes, and comments due to their utility and relevance.



During preprocessing, we discarded entries with deleted posts or those in which the post content had <5 words as the brevity poses challenges to deriving meaningful insights from posts. We also removed posts containing irrelevant text (eg, polls, survey links only, or URLs). The URL-heavy posts were classified using a rule-based heuristic combining personal pronoun frequency and URL-to-text ratio. We provide a summary of the steps to remove irrelevant text from social media data in Table S1 in Multimedia Appendix 1. This filtering process enabled us to focus on patient-authored, experience-rich discussions. Finally, we obtained a primary dataset comprising 59,962 posts and 641,441 comments by 68,010 active unique users. Identifying task-relevant data is crucial for data-driven approaches [12] as it significantly impacts the efficiency of downstream tasks. We leveraged Reddit's post "flair" option to filter relevant data. On Reddit, a post flair is a customizable text or icon that appears next to a post title to provide additional context or categorization, similar to hashtags available on other platforms. We reviewed 30 randomly selected posts from several flairs of the PCOS subreddit. We identified that, among all the flairs, posts in the "General/Advice" flair were more likely to share knowledge and seek advice on symptoms. Further investigation on the most frequent unigrams of these flairs supported our qualitative analysis, where the presence of symptom-related unigrams such as "period," "symptom," "doctor," "birth," "control," and "diagnosed" was predominantly observed in the "General/Advice" flair. The distribution of frequent unigrams in the "General/Advice" flair is shown in Figure S1 in Multimedia Appendix 1. On the basis of these findings, we chose the "General/Advice" flair for extracting a wide range of symptoms. In addition, the "General/Advice" flair is more popular in the community as it contains the highest number of posts, as shown in Table S2 in Multimedia Appendix 1. This selection ensured a broad range of symptoms and valuable insights. Finally, we developed a corpus of 10,500 posts for the symptom identification task, randomly selected from the posts with the "General/Advice" flair.

Our Method: LSE

We propose an LSE method to analyze self-reported symptoms of a complex medical condition using social media discourse. Our proposed method consists of three main steps: (1) symptom-related lexicon extraction, (2) symptom identification, and (3) symptom normalization, as illustrated in Figure 1.

XSL•FO
RenderX

Figure 1. Steps of the lexicon-based symptom extraction method. JI: Jaccard index; LLM: large language model.

Symptom-Related Lexicon Extraction

We leveraged symptom-related key phrases for lexicon extraction as it helped distill the most relevant terms and phrases associated with physical manifestations from user narratives. We focused on extracting the key symptom-related phrases instead of the symptoms as the latter results in extracting (1) phrases that are not relevant and (2) repetitive mentions of the same symptoms, rendering the subsequent analysis challenging. Compared to the tedious and time-intensive task of manual extraction, LLMs emerge as a more economical choice, offering consistency in their responses, especially when the temperature setting is near 0 [40,41]. We used the OpenAI API *gpt-3.5-turbo-16k* [42] to annotate 10,500 user posts. To ensure precision in identifying the physical manifestation of the condition, we emphasized physical symptoms while excluding psychological aspects in our base prompt using a zero-shot prompting strategy (Figure S2 in Multimedia Appendix 1). The API responses were stored in a JSON line format containing key phrases and corresponding posts. This process yielded a lexicon of 30,370 symptom-related key phrases that we used in the subsequent steps.

We resorted to human annotation to validate the extraction conducted by ChatGPT (OpenAI). We employed 2 graduate students in the science, technology, engineering, and mathematics field particularly active in women's health–related social media forums. Before annotation, they underwent multiple training sessions led by a domain expert specializing in computational health. These sessions were designed to refine their understanding on key phrase extraction and promote annotation consistency. On a sample set of 30 posts, the interannotator agreement reached 92% in a relaxed match. Finally, we randomly selected 500 entries from 10,500 user posts. We recognize that many social media and health NLP studies use larger annotated sets, often containing 2000 to 4000 messages, and few drop below 1000 annotations [12,43-45]. However, those datasets are typically used to validate end-to-end model performance, whereas our 500-post sample supported a specific component of our pipeline. We deliberately divided tasks between the LLM and human experts to balance coverage and precision while remaining practical as (1) the cost in terms of time and resources was significant (eg, annotating just 500 entries required 4 training sessions × 3 hours = 12 hours, 35 hours for literature study and documentation, and 208.3 hours approximately for annotation per post; 500 posts × 25 minutes), making larger samples prohibitively expensive; (2) we observed a significant drop in new symptom-related key phrase discoveries after the first 200 posts, mirroring the classic "diminishing returns" shown in Table S3 in Multimedia Appendix 1, also evident in social media symptom mining and related tasks [46]; and (3) during manual inspection, we observed minimal disagreement as the annotation task was primarily syntactic rather than interpretive. Taking into consideration the above 3 points, we assigned 250 unique posts to each annotator to minimize bias and enhance the quality of our annotated set.

We choose the Jaccard index (JI) to measure the similarity between key phrases extracted by ChatGPT and the human annotators [12]. This required normalizing the extracted key phrases (eg, changing "pressure in pelvic area" to "pelvic pressure") to maintain homogeneity in both lists. We computed the JI similarity for each post in the sample using exact key phrase match. Table 1 shows 3 posts from our sample set with extracted key phrases and their corresponding JI scores. The average JI score was 74%, indicating moderate lexical similarity between the key phrases extracted by ChatGPT and the human

XSL•FO
RenderX

annotators considering the complexity of the task [47]. Our manual investigation of all missed or incorrectly extracted key phrases by the LLM revealed 5 distinct error categories, as outlined in Table S4 in Multimedia Appendix 1. For instance, in row 1 of Table 1, the LLM missed "absence of period" as it was implicitly mentioned in the post as "haven't had a period since December." Similarly, in row 3, "insulin resistance" is an ambiguous expression to be accepted as a symptom. However, a deeper analysis revealed 3 findings supporting the acceptability of the lexicon.

First, post-level JI analysis; our manual investigation showed that 12.6% (63/500) of the posts had a JI score of 0, which substantially affected the average JI. We found that most of these JIs with a value of 0 resulted from very short posts (eg, "Does anyone know if weightloss in PCOS helps or throws off hormones?") and were annotated as *no symptom* by humans, whereas the LLM incorrectly extracted the key phrases *weightloss* and *hormones*. The median JI score across all posts was 1.0 (IQR 0.5-1.0), indicating strong agreement between the LLM and human annotations in most cases.

Second, lexicon-level robustness; we observed that the LLM missed a key phrase in a post, resulting in a mismatch, but extracted the same key phrase in another post. Similar cases were found for human annotation, resulting in incorrect extraction for the LLM. We identified such cases for 61% (104/172) of the total missed or incorrectly extracted key phrases, which affected the average JI. As the final lexicon aggregates key phrases across all posts, these disagreements at the post level did not propagate to the lexicon level. When comparing the LLM-derived lexicon with the human-annotated lexicon, we observed a JI of 0.89, demonstrating strong alignment between the 2. This high agreement confirmed that discrepancies in per-post extraction had minimal impact on the final lexicon's accuracy and coverage.

Third, downstream impact on symptom list; the frequency of unique incorrectly extracted key phrases in the lexicon was very low (maximum of 3). Consequently, their influence on the cluster centroids was negligible. Because our symptom list was derived by selecting the most frequent phrases within each cluster, the effect of noisy or rare phrases was minimized. Such key phrases either formed microclusters (eg, *ultrasound*) that were discarded during the normalization step or were absorbed into broader, validated symptom cluster categories.

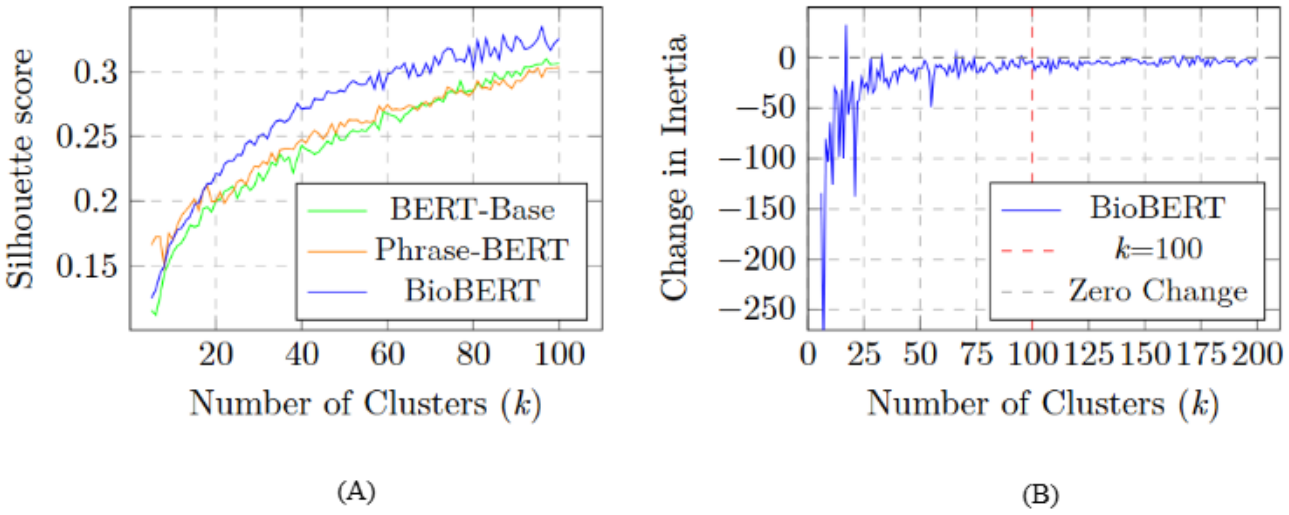
Table 1. Sample excerpts of human and ChatGPT annotations of posts. The Jaccard index (JI) was calculated for the similarity between the 2 annotations based on the extracted key phrases.

Post	Human annotation	ChatGPT annotation	JI score
"I haven't had a period since December, however in the past week I keep getting really bad cramping with sharp pains (almost feels like my ovaries), but no period...has anyone else experienced this? Is this normal?"	"Absence of period," "cramping," and "sharp pains"	"Cramping" and "sharp pains"	0.67
"I'm 22, F and over the years, I have gained 50 pounds. Recently, my acne is getting worse and I feel pressure in my pelvic area. I am trying to lose weight and thereby started working out but the scale is still not budging."	"Weight gain," "acne," and "pelvic pressure"	"Weight gain," "acne," and "pelvic pressure"	1.0
"Due to PCOS and insulin resistance, Does anyone else get symptoms like they're getting their period (sore breasts, crampy feeling) and just overall malaise when you're 'due' for your period you don't actually get?"	"Insulin resistance," "sore breasts," and "crampy feeling"	"Sore breasts," "crampy feeling," and "malaise"	0.5

In summary, while there were post-level discrepancies, the high lexicon-level JI (0.89) and the robustness of frequency-based clustering ensured that the final symptom list remained accurate and representative of human annotation without prohibitive annotation burden.

Symptom Identification

Overview



In this step, we identified a distinct set of disease symptoms using the symptom-related lexicon. As the key phrases in the lexicon were captured exactly as mentioned in users' posts, many were semantically similar with different phrasing. For example, key phrases such as *cystic ovary*, *ovarian cysts*, and *multiple cysts in ovaries* have the same semantic meaning with different surface forms. Thus, we used clustering to categorize the semantically similar key phrases and identify such categories as unique symptoms. To ensure accurate clustering, it is crucial to generate meaningful representations of symptom-related key phrases that effectively capture their semantic meaning. To achieve this, we used embeddings, which convert words into numeric representations in lower dimensions that preserve their contexts. The process of embedding and clustering the key phrases is described in the following sections.

Choosing the Right Embedding

We explored and evaluated widely used transformer models such as BERT-Base [48], Phrase-BERT [49], and BioBERT [50] to generate embeddings of symptom-related key phrases. We observed the performance of these embeddings by applying various clustering methods. For k-means clustering, we analyzed the silhouette score for each BERT-based embedding. The silhouette score considers both within-cluster and intercluster variances to determine cluster quality [51]. We plotted silhouette scores of different embedding approaches, shown in Figure 2A. The curves for BERT-Base and Phrase-BERT show a general increase but noticeable fluctuation, representing inconsistency in the results. In contrast, BioBERT shows a consistent and uniform ascent compared to the other 2 in the silhouette curve. Furthermore, applying L2 normalization during embedding improved the uniqueness of the clusters [48]. The consistent superiority of BioBERT across all clustering approaches steered our decision to adopt BioBERT as our embedding method.

XSL•FO
RenderX

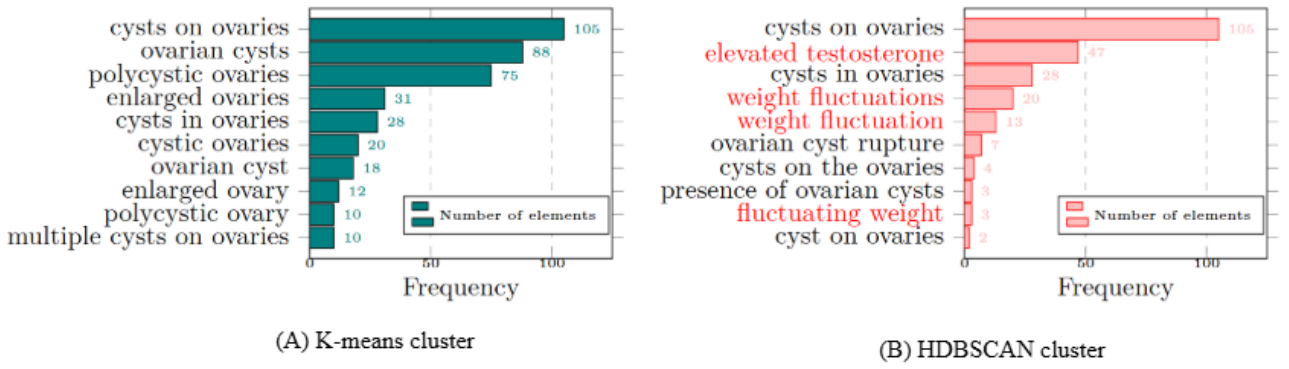


Figure 2. Characteristic analysis of embedding methods for selecting optimal clustering methods—(A) silhouette score analysis of different embeddings on k-means and (B) rate of change in inertia (within-cluster sum of the squares) decreasing as the number of clusters increases. BERT: bidirectional encoder representations from transformers.

Selecting the Optimal Clustering Method

We exploited k-means and hierarchical density-based spatial clustering of applications with noise (HDBSCAN) with BioBERT embeddings for clustering symptom-related key phrases. Comparing k-means and HDBSCAN is fairly tricky as their hyperparameters (number of clusters vs density thresholds) are fundamentally different. Although it is widely known that HDBSCAN performs better for noisy social media data as it filters out “low-density” points as noise, the choice of clustering method depends on the downstream task and the performance on specific data. In Table S5 in Multimedia Appendix 1, we report the performance of HDBSCAN under a grid of *min_cluster_size* and *min_samples* settings with the observations of cluster numbers, density-based clustering validation (DBCV) score, and noise. The DBCV score measures how dense and well separated core clusters are in a density-based clustering method [52]. Thus, HDBSCAN with lower *minimum_cluster_size* increases in DBCV scores indicates compactness of the clusters but may generate spurious microclusters. Manual observation shows that HDBSCAN with lower *minimum_cluster_size* provides better intracluster coherence but reduce intercluster separation and generate more semantically similar clusters, such as *increased testosterone* and *elevated level of testosterone*. In contrast, an increasing *minimum_cluster_size* results in lower DBCV scores. As a result, the number of clusters decreases, which may contribute to losing meaningful clusters by being too strict on cluster size. For such instances, elements of the *cysts on ovaries* cluster represents less coherence and semantic similarity in HDBSCAN compared to k-means shown in (Figure 3). In our use case, HDBSCAN labeled 31% to 56% of the points as noise across settings. This affected the downstream task as our goal was to maximize symptom coverage. On the other hand, k-means has no noise filtering, which ensures maximum coverage of symptoms. In addition, we implemented k-means using the cosine distance to improve the cluster uniqueness with fewer duplicates compared to using the Euclidean distance [53].

Figure 3. Comparison of elements within the cluster "cysts on ovaries" between 2 clustering methods: (A) k-means, containing semantically similar key phrases that are evenly distributed, and (B) hierarchical density-based spatial clustering of applications with noise, containing key phrases conflicting with the cluster name, highlighted in red, and showing more uneven distribution.

XSL•FO
RenderX

Sensitivity and Stability Analysis in Choosing the *k* Value

We varied the number of clusters (*k*) to determine the optimal number based on the silhouette score (in Figure 2A) and rate of change in inertia (in Figure 2B). In our PCOS use case, we identified that, after *k*=100, the change in inertia became flat and the rate of increment in silhouette score was also negligible. Therefore, we set *k* to range from 10 to 100, and at *k*=96, we observed an optimal silhouette score. In addition, we explored a –10 to +10 window for *k*=96 to verify the sensitivity of the resulting clusters. Across *k*=86 to 106, the silhouette score remained within approximately –0.01 to +0.01 of its value at *k*=96, and the inertia curve showed minimal change, confirming that the choice of *k* sat in the middle of a stable region. In addition, we report the bootstrap stability results for 3 representative choices between *k*=86 and 96. All 3 settings yielded high median Adjusted Rand Index (ARI) values (≥0.75) and narrow 95% CIs, demonstrating that cluster assignments are largely consistent when up to 20% of the data are held out. We provide a summary of the sensitivity and stability analysis of the choice of *k* in k-means in Table S6 in Multimedia Appendix 1.

Symptom Normalization

Overview

Each of the obtained clusters represented a symptom as the elements of the clusters were semantically similar. We considered the most frequent element of the cluster as the key symptom. The justification for selecting the most frequent element as the key symptom was 2-fold. First, its occurrences were significantly higher than those of other elements within the cluster. For instance, occurrences of *cysts on ovaries* compared to other elements within the cluster in Figure 3A were negligible. Second, all elements within a cluster consistently pointed toward the same physical condition as the key symptom. In the k-means cluster in Figure 3A, all the cluster elements referred to ovarian cysts. However, there were repetitions of symptoms in the obtained list. Therefore, we conducted symptom normalization by applying semantic mapping and validation by experts, as outlined in the following sections.

Applying Semantic Mapping

We applied semantic mapping of clusters, a manual process that involves merging symptoms with similar meanings and concepts using Unified Medical Language System Metathesaurus synonyms to avoid repetition. Through progressive discussions with our medical specialist, we formalized 4 semantic mapping rules suitable for this task. For instance, *irregular bleeding*, *irregular menstrual cycles*, and *irregular cycles* were mapped to *irregular periods* using rule 1, “synonym merging.” Applying these rules, we consolidated 11 such mappings from the initial 96 PCOS symptoms to 68 unique symptoms. The complete rule set is provided in Table S7 in Multimedia Appendix 1 to ensure reproducibility.

Validation by an Expert

We further refined the symptom list by validating the relevance of the lived experiences of patients to the disease. One of our coauthors, a gynecologist with >10 years of experience in treating PCOS, conducted this validation step. The expert’s role was to discard symptoms that were not related to the disease and resolve ambiguities between similar symptoms. For instance, the medical specialist discarded 4 irrelevant symptoms—*ultrasound*, *birth control*, *low-carb diet*, and *neck*—by manually investigating the cluster elements, resulting in a comprehensive list of 64 unique PCOS symptoms.

Ethical Considerations

We acknowledge that the research on symptom extraction from social media has multifaceted ethical concerns and requires careful attention to privacy, consent, and the responsible use of data and technology. The research was approved by Bangladesh University of Engineering and Technology's Institutional Review Board. Although Reddit is an anonymous platform, we ensured that no personally identifiable information was inadvertently revealed during data collection, analysis, or publication. All Reddit posts and comments cited as examples in this paper were paraphrased to protect user privacy. We also recognize that the demographic composition of Reddit users might not be fully representative of the broader population with PCOS, potentially limiting generalizability. Therefore, findings derived from Reddit discourse should be generalized cautiously to other populations or settings. In addition, we recognize that any biases in the dataset and the proposed model are unintentional. As the outcomes of this work are based on social media content, we emphasize the superiority of medical evidence–based facts in cases of conflict, particularly concerning direct clinical practice and medical diagnosis. We strongly encourage the use of the model for research and exploratory purposes, serving as a foundation for further developments in computational health research.

Results

Test Data Curation and Ground Truth Annotation

We initially separated 1000 sample posts of various lengths from our dataset for results evaluation. Considering the influence of post length on symptom identification, we categorized the posts into three groups: (1) short posts of <100 words, (2) medium-length posts of between 100 and 300 words, and (3) long posts of >300 words. Post length distribution in the dataset revealed that 45% (450/1000) of the posts belonged to the medium-length category (Table S8 in Multimedia Appendix 1). To ensure a balance across all categories, we selected 500 posts from the medium-length category and 250 posts from each of the short and long post categories for curating test data.

We recruited a medical graduate with domain knowledge and a patient with PCOS lived experience to perform annotation. Before annotation, both annotators participated in progressive training sessions and interactive discussions with medical specialists to refine their understanding and improve annotation consistency. During this phase, the medical specialist primarily identified 3 potential disagreements between the annotators. These observed disagreements were instances in which (1) the medical graduate often used clinical terminology (eg, “amenorrhea”) whereas the patient used informal language (eg, “no period for months”); (2) the patient included self-reported experiences (eg, “hypothyroidism”) that lacked clinical validation whereas the clinician strictly adhered to established

XSL•FO
RenderX

PCOS diagnostic criteria; and (3) the medical graduate inferred implicit symptoms (eg, laboratory test results) from domain knowledge, which was lacking in the patient annotation. Given our goal to prioritize the capture of patient-experienced symptoms, medical specialists suggested resolving these discrepancies by (1) avoiding overly technical clinical terms unless they were explicitly mentioned, (2) retaining self-reported experiences unless they were clinically invalid, and (3) including implicit symptoms as long as they were related to PCOS. Following these guidelines, both annotators extracted symptoms independently. We adopted the combination of both annotators' symptom lists per post to maximize coverage and ensure the consistency and reliability of the ground truth dataset.

In our ground truth annotation, annotators were not restricted to predefined symptom lists. They identified any symptoms that they perceived as PCOS related, resulting in free-text labels. Moreover, each post included multiple symptoms, making the traditional Cohen κ not suitable. Instead, we evaluated interannotator agreement using relaxed-match F_1-score due to the generative nature of our annotation [16,54,55]. We used BioBERT-based semantic similarity with the medical graduate's annotation as a reference. We achieved an F_1-score of 0.82, with a recall of 0.84 at a similarity threshold of 0.6, indicating substantial agreement considering the realistic complexity inherent in patient-derived, generative-nature symptom annotation.

Symptom Comparison: LSE With eHealth Forums

LSE resulted in a comprehensive list of 64 unique PCOS symptoms (Table 2) from 10,500 user posts. We also determined the unique users reporting each symptom in our primary dataset, with counts ranging from 31 to 16,001. This confirmed that LSE captures widely experienced symptoms, whereas less common symptoms are not ignored. In addition, this list provides a wide range of coverage as we cross-checked it with 7 evidence-based consumer health websites: the World Health Organization [31]; the Mayo Clinic [56]; WebMD [57]; the *International Classification of Diseases, 10th Revision* [58]; Johns Hopkins Medicine [59]; the National Health Service [60]; and the Centers for Disease Control and Prevention [61]. All symptoms mentioned in these sources were included in our list except for 4: sleep apnea, high blood pressure, low progesterone, and dandruff. Upon examining the clusters, we found that these 4 symptoms were represented within their respective key clusters—*insomnia*, *high cholesterol*, *low estrogen*, and *high DHEA*—due to their close medical relevance. Furthermore, all the forums recognized the 10 most frequently reported symptoms in our dataset (Table S9 in Multimedia Appendix 1). On the other hand, we identified 28 symptoms not acknowledged by any of the eHealth forums that we mention as potentially emerging symptoms in the Discussion section. Thus, our comprehensive symptom list reflects the diversity of self-reported PCOS lived experience symptoms and aligns closely with authoritative medical sources, helping standardize the variability in the symptom descriptions.

Baseline Comparisons

Overview

We compared the performance of LSE with leading baselines, including 2 popular off-the-shelf models—Amazon Comprehend Medical (ACM) [62] and Google Healthcare Natural Language API (GHNLP) [63]—in their default configuration. In addition, we evaluated both open-source and closed-source LLMs, namely, Llama 3.1 (8B) and GPT-4o in a zero-shot, near-0 temperature (0.25) setting. We identified symptoms in each post of the test dataset using all the baselines for comparison with the ground truth. For LSE, we used GPT-4o to identify symptoms guided by the comprehensive symptom list obtained through our method. Therefore, it was not strictly zero-shot but, rather, a form of lexicon-guided prompting. The model's task was to match symptoms in the text against the LSE-provided symptom lexicon. To ensure reproducibility, we included the LLM prompt templates used for the baseline comparisons (GPT-4o and Llama 3.1), shown in Figure S3 in Multimedia Appendix 1, and LSE evaluation using GPT-4o, as detailed in Figure S4 in Multimedia Appendix 1. We evaluated competitive models using standard performance metrics—precision, recall, and F_1-score. To measure the similarity between symptoms, we used BioBERT-based semantic similarity as it performs optimally with medical data. Given the nuanced nature of symptom expressions, we set the different semantic similarity thresholds at 0.4, 0.6, and 0.8 for match acceptance, and the corresponding performance results are reported in Table 3. Experimental results show that LSE outperformed all baselines significantly across all metrics at every threshold level. As expected, increasing the similarity threshold imposed stricter matching criteria, resulting in fewer accepted symptom matches. Consequently, the performance of all baseline models dropped significantly with higher thresholds. In contrast, the performance of LSE decreased only marginally, highlighting the stability and robustness of our framework. For all subsequent analyses in this study, we adopted a semantic similarity threshold of 0.6 as the default setting. Several additional useful insights from the results are discussed in the following sections.

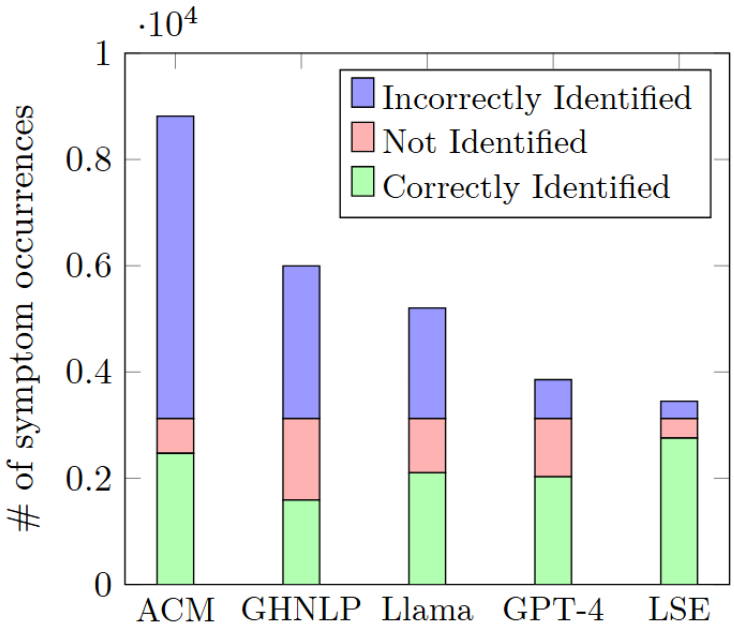
[c]GHNLP: Google Healthcare Natural Language Application Programming Interface.



[d]For these values, the LSE obtained the highest F_1-scores among all models in all the threshold-settings.

Off-the-Shelf Models Tend to Overpredict

The GHNLP and ACM models largely extracted generic symptoms that were not disease specific, such as *pregnancy*, *cold*, *sick*, *illness*, and *discomfort*. In addition, they extracted mental conditions such as *anxiety*, *overwhelmed*, and *feeling bad* as PCOS symptoms. As a result, they identified more symptoms (4.84 and 9.05 per post by GHNLP and ACM on average, respectively) compared to the ground truth (mean 2.76, SD 1.90 per post). Moreover, they struggled to comprehend the context of the post content, often extracting medical jargon such as *side effect*, *lab report*, and *medication* as symptoms. Substantially, GHNLP and ACM extracted 64% (2874/4463) and 70% (5691/8161) incorrect symptoms, respectively, of the total symptoms identified (Figure 4). Longer posts aggravated these issues as the presence of more jargon further reduced the precision and F_1-scores of these models (Table 3). However, both models achieved better recall than precision due to overprediction.

XSL•FO
RenderX

Figure 4. Performance comparison of different models in identifying symptom occurrences from 1000 sample posts. Each bar represents the number of correctly identified, not identified, and incorrectly identified symptoms stacked on top of each other. ACM: Amazon Comprehend Medical; GHNLP: Google Healthcare Natural Language Application Programming Interface; LSE: lexicon-based symptom extraction.

Baselines Struggle to Capture Nuanced Symptoms

All the baselines struggled to detect subtle symptoms, specifically when they were stated in informal language. As a result, GHNLP correctly identified only 50% (1589/3124) of the ground truth symptoms, whereas the LLMs showed better performance with approximately 65% (4133/6248) correct matches (Figure 4). Although ACM achieved a 79% (2470/3124) match with the ground truth, its overall performance was hindered by significant overpredictions. For instance, a PCOS symptom, *high testosterone*, was mentioned informally in the following post, but only LSE and none of the baselines could identify it:

> *I had two sets of blood tests taken last year, which showed that my hormones (especially testosterone) were all over the place. My GP said that my test results were enough to confirm PCOS diagnosis.*

LSE Outperformed State-of-the-Art LLMs

Figure 4 shows that, while LLMs significantly reduced the number of incorrectly identified symptoms, they still missed a notable number of symptoms. Leveraging the symptom list generated by LSE in the base prompt for generative pretrained transformers increased the number of correctly identified symptoms, enhancing overall performance. The high values for LSE across all metrics in Table 3 indicate that the comprehensive symptom list effectively covered all PCOS lived experience symptoms while filtering out generic ones.

Statistical Significance

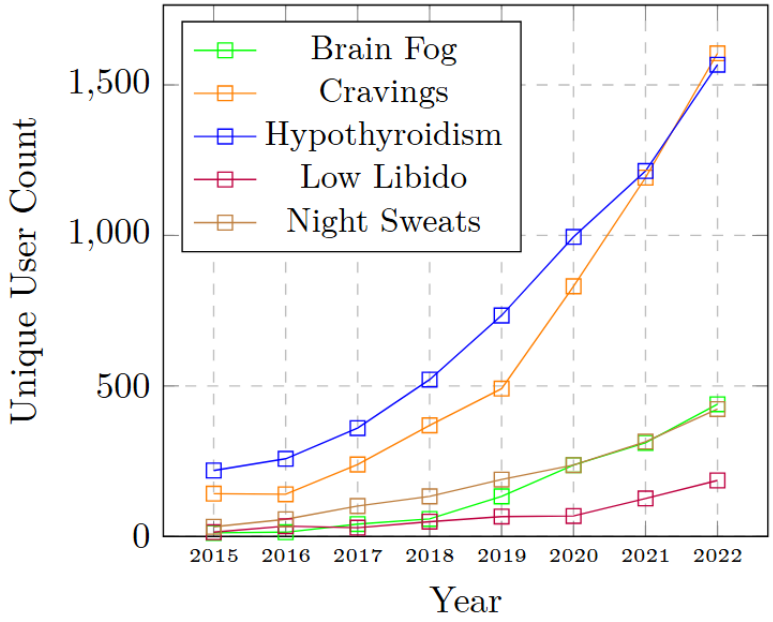
We also compared the F_1-score of LSE with those of the baselines using the approximated randomization test [28] with a similarity threshold of 0.6 to determine whether the results were statistically significant. As this test does not require specific distributional assumptions, it is particularly suitable for complex metrics such as the F_1-score [64]. We conducted pairwise comparisons between symptoms extracted from a post via LSE and each of the baselines. The number of occurrences in the sample set of 1000 posts in which LSE significantly outperformed the baselines at 95% (P<.05) and 90% (P<.10) confidence levels. The observed results suggest that, in terms of the F_1-score, LSE significantly outperformed all the other baselines shown in Table S10 in Multimedia Appendix 1.

Discussion

Analysis of PCOS Symptomatology

Overview

Our study was motivated by the limitations of existing information extraction methods in identifying symptom expressions from colloquial patient narratives. We propose an LSE method incorporating LLMs into the pipeline to capture disease-specific symptoms from social media discourse. We focused on PCOS as a representative case given its highly variable and often underdocumented symptomatology. We evaluated LSE against multiple strong baselines across a manually annotated Reddit dataset, and it demonstrated substantial improvements in precision, recall, and F_1-score.



We conducted an in-depth study of PCOS symptomatology to evaluate the characteristics, prevalence, and occurrence patterns of the symptoms, capturing implicit insights from patient-generated data. We also highlighted how capturing symptoms in patient-centric language can bridge gaps between patient experiences and clinical practice, potentially enhancing health care provider communication and guiding clinical decision-making.

XSL•FO
RenderX

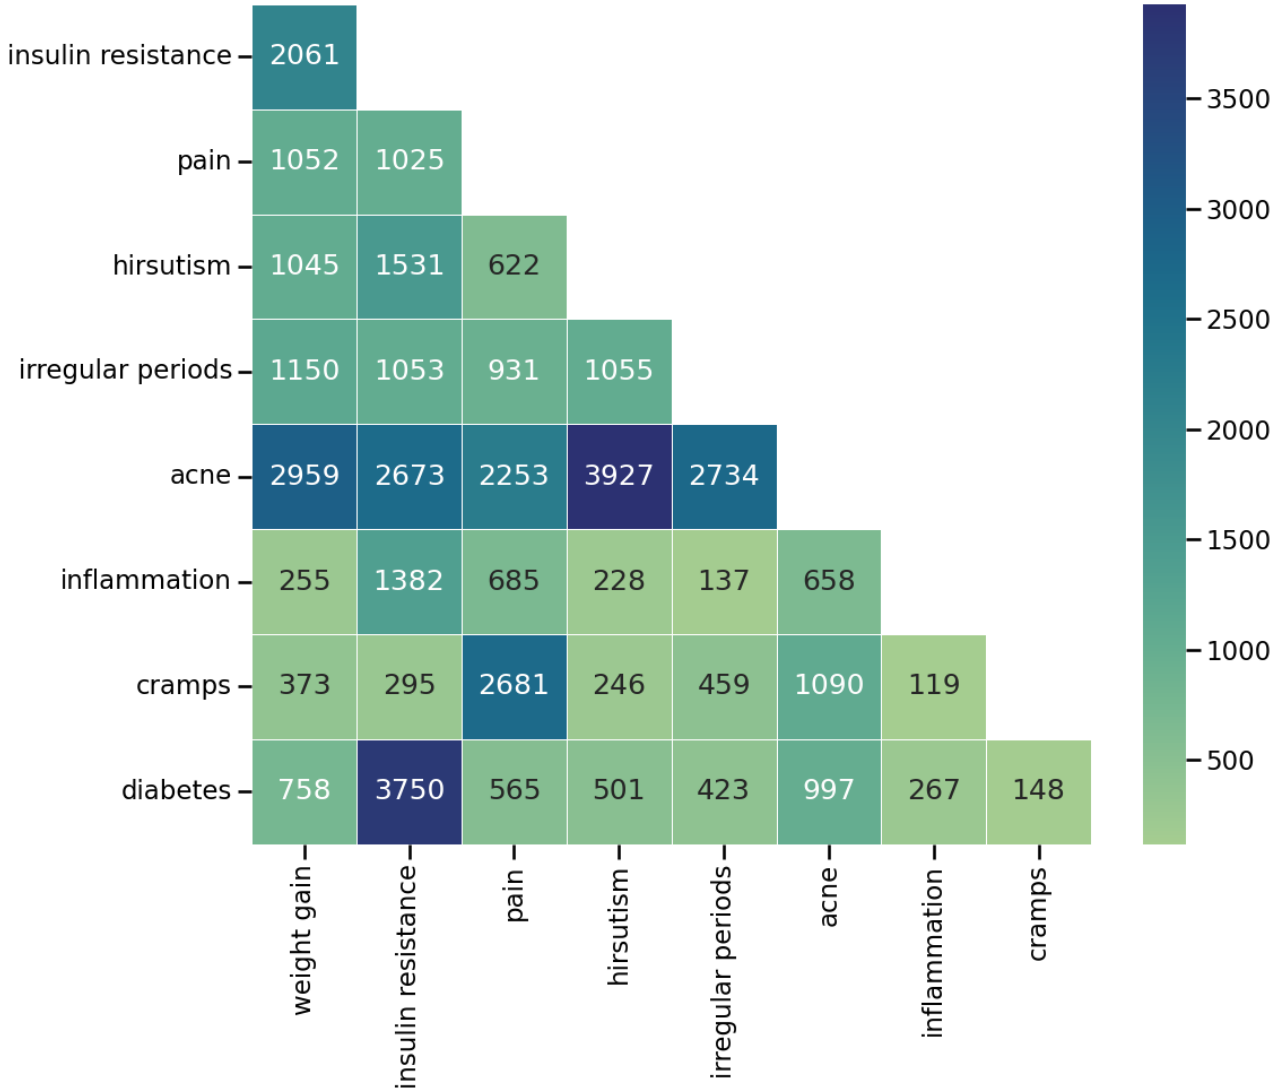
Potentially Emerging Symptoms

We identified 28 distinct symptoms from our comprehensive symptom list prominently reported by patients yet currently underrepresented or insufficiently explored in established medical literature and not acknowledged by existing eHealth sources (highlighted in italics in Table 2). Although many of these symptoms currently lack robust clinical evidence linking them directly to PCOS, their frequent occurrence in patient-generated data suggests that patients often experience and associate these symptoms with PCOS. As illustrated in Figure 5, the number of unique users reporting some of these symptoms, such as hypothyroidism and brain fog, demonstrate a consistent upward reporting trend over time. Moreover, some recent studies have provided medical evidence supporting the connection between some of these symptoms and PCOS, such as brain fog, thyroid disorder, low libido, digestive issues, and cravings [65-69]. Therefore, we marked them as potentially emerging symptoms. However, while frequently reported by patients, it is important to recognize that these symptoms might not represent entirely novel manifestations of PCOS. Instead, they may reflect less common but known clinical symptoms, secondary manifestations of the primary disease, or symptoms associated with frequently co-occurring conditions. For example, hypothyroidism, reported by 5366 users, reflects a well-established thyroid-PCOS comorbidity [66], underscoring potential shared pathophysiological mechanisms rather than indicating a novel PCOS symptom. In addition, nausea and cravings, although frequently reported by patients, advocate for a broader and patient-inclusive diagnostic perspective rather than confirming direct causality. These emerging findings reinforce the credibility of patient-reported underdocumented symptoms and underscore the necessity for rigorous clinical investigation to determine their prevalence, pathophysiological connections, and implications for diagnosis and treatment protocols.

Figure 5. Instances of potentially emerging symptoms mentioned by users in the primary dataset, showing notable upward trends over time.

Capturing Symptoms in Patient-Centric Language

LSE captured the lived experience symptoms as expressed by the patients. This approach makes the symptoms more accessible to laypersons compared to clinical terminology and jargon. Some symptoms with unorthodox clinical terms require complex medical tests to diagnose, whereas their effects are often evident in lived experiences, and hence, these symptoms are included in the symptom list. For instance, hyperandrogenism is a symptom that may not be familiar to all users and requires laboratory tests, whereas hirsutism, acne, or hair loss are visible outcomes of the condition that are easily recognized and commonly reported by users, as shown in Table 2.



Identifying Co-Occurrence of Symptoms

We constructed a symptom co-occurrence matrix in which multiple symptoms mentioned by an individual in a single post or comment were considered as co-occurring. Figure 6 illustrates a segment of the matrix highlighting the most frequently mentioned symptom pairs with their number of co-occurrences. The eHealth forums further complemented these co-occurrences. Understanding these co-occurring symptoms raises awareness among the community and helps individuals better cope with their condition. In addition, such analysis can assist health care providers and patients in proactively diagnosing and managing symptoms such as hirsutism, oily skin, and acne, as observed in the following comment:

> *The best natural remedy I've tried is spearmint supplement. I'm a thin cysterbut have most of the other symptoms and it has been the only thing I've foundso far that helps with hirsutism, oily skin, acne.*

XSL•FO
RenderX

Figure 6. A segment of the symptom co-occurrence matrix, where hirsutism and acne appear as one of the most frequently mentioned symptom pairs.

Association With Chronic Diseases and Comorbidity

We identified 8 chronic diseases from the list of PCOS symptoms that were distinct medical conditions in their own right. For example, chronic conditions such as hypothyroidism and endometriosis were mentioned by 5366 and 2303 unique users, respectively (Table 2). The association with chronic diseases and comorbidity increases the complexity of the disease and its management and significantly impacts social determinants of health, as shown in the following example:

> *I went to the ER...but they found cysts on my ovaries and mentioned PCOS with possibly Endometriosis. Now, I have no insurance and I'm struggling to find the care. My husband and I want to start a family, but I feel like our chances are slipping away because I can't afford the help I need. Any advice on where to get financial or medical support would be greatly appreciated.*

The financial strain from frequent physician visits and prolonged medications impacts patients' overall health outcomes. This emphasizes the need for clinical and public health research to find ways to reduce the burden on patients, such as overprescription and cost. This may also involve policy reforms to ensure comprehensive coverage for chronic conditions associated with PCOS.

Enhancing Patient–Health Care Provider Communication

The comprehensive symptom list generated by our lexicon-based approach, encompassing both widely recognized and emerging patient-reported symptoms, provides clinicians with a deeper insight into how patients perceive and articulate their condition. For example, terms such as *brain fog*, *pelvic pressure*, and *fatigue* are not only clinically relevant but also capture the nuanced ways in which patients describe their daily experiences with PCOS. Studies also show that using patient-generated health-related terminology during visits deepens shared understanding and decision-making [70]. Therefore, clinicians can leverage this enriched vocabulary to enhance patient–health care provider communication, promoting empathy, validating patient experiences, and facilitating more targeted and personalized clinical interviews.

XSL•FO
RenderX

Guide to Clinical Decision-Making

The patient-derived symptom list (Table 2) can serve as a preliminary checklist during consultations to identify overlooked or underdiscussed symptoms that patients might hesitate to share spontaneously due to stigma or uncertainty. Documenting co-occurrence patterns further empowers clinicians to anticipate linked symptoms. A patient presenting with hirsutism, for instance, could be screened for insulin resistance or acne, enabling early intervention and holistic management. To scale these benefits, the symptom list can be integrated into electronic health record systems. This integration allows for auto-completion prompts that reflect patient language while supporting consistent clinical documentation. Such structured integration enhances clinical decision-making through automated reminders and promotes interoperability for population-level research. Acknowledging patient-reported symptoms does not undermine established clinical evidence; rather, it complements traditional clinical frameworks by incorporating patient perspectives into evidence-based medicine.

Limitations

Despite the promising results, this study has several limitations. First, our study focused on a single health condition and a single social media platform, which may introduce platform-specific biases and limit generalizability. Second, both the lexicon and the evaluation sample sizes are relatively small for broader conclusions. Third, our findings are exploratory and hypothesis generating and not yet clinically validated.

We also acknowledge specific implementation limitations. Although the LSE pipeline is designed for modularity and adaptability, applying it to other complex health conditions may require empirical adjustments. Determining optimal clusters for symptom identification and establishing semantic mapping rules for symptom normalization would require condition-specific customization. In this study, we used silhouette scores and inertia analysis to determine the optimal cluster metrics, such as the number of clusters (k). However, we recognize the limitation of distance-based metrics due to the curse of dimensionality, which may not fully capture cluster shape or density nuances. Despite this, our bootstrap stability analysis demonstrated consistently high Adjusted Rand Index (ARI) values across various k settings, indicating that our symptom clusters were robust to moderate changes in the number of clusters and to the random removal of data points. The performance of this framework may vary depending on the extracted lexicon due to linguistic variability and the nature of symptom discourse. Future work should focus on validating this method across diverse conditions, platforms, and languages. In addition, we plan to conduct online surveys and focus groups involving both patients and practitioners to assess the clinical relevance of our findings.

Conclusions

This work focused on extracting and analyzing disease-specific symptoms from individuals' lived experiences with an application to the PCOS use case. The uniqueness of our work lies in several key aspects. The extraction of a symptom-related lexicon ensures the capture of subtle mentions without overlooking informal expressions on social media. We generated disease-specific symptoms by integrating LLMs into the NLP pipeline rather than relying on traditional NLP methods, which often obtain generic symptoms. In addition, analyzing PCOS symptomatology across varied dimensions revealed unique findings, such as emerging new symptoms expressed in patient-centric language, symptom co-occurrence patterns, and associated comorbidities. The outcomes of this work may help eliminate uncertainties surrounding complex medical conditions and contribute to clinical research and public health policies in a community-informed way.

Acknowledgments

This work was partially supported by the Information and Communication Technology Division of Bangladesh under a postgraduate research fellowship grant. The funding body had no involvement in the study design; data collection, analysis, or experimentation; writing of the report; or decision to submit the paper for publication.

Data Availability

We have publicly released our curated Reddit dataset and human-annotated labeled dataset. To support reproducibility, all source code and resources used in this study have also been made available. The datasets and related materials can be accessed through our GitHub repository [71].

Authors' Contributions

BH conceptualized the study, curated the data, designed the methodology, and organized this study; analyzed the results; and wrote, reviewed, and revised the manuscript. SMP and MEA contributed to conceptualization; supervision; validation of the results; and writing, review, and revision of the manuscript. MFR analyzed the results and contributed to writing, reviewing, and revising the manuscript. RA conceptualized the study, validated the results, and reviewed and revised the manuscript.

Abstract

Background: Diabetic nephropathy (DN), a severe complication of diabetes, is characterized by proteinuria, hypertension, and progressive renal function decline, potentially leading to end-stage renal disease. The International Diabetes Federation projects that by 2045, 783 million people will have diabetes, with 30% - 40% of them developing DN. Current diagnostic approaches lack sufficient sensitivity and specificity for early detection and diagnosis, underscoring the need for an accurate, interpretable predictive model to enable timely intervention, reduce cardiovascular risks, and optimize health care costs.

Objective: This study aimed to develop and validate a machine learning–based predictive model for DN in patients with type 2 diabetes, with a focus on achieving high predictive accuracy while ensuring transparency and interpretability through explainable artificial intelligence techniques, thereby supporting early diagnosis, risk assessment, and personalized clinical decision-making.

Methods: Our retrospective cohort study investigated 1000 patients with type 2 diabetes using data from electronic medical records collected between 2015 and 2020. The study design incorporated a sample of 444 patients with DN and 556 without, focusing on demographics, clinical metrics such as blood pressure and glucose levels, and renal function markers. Data collection relied on electronic records, with missing values handled via multiple imputation and dataset balance achieved using Synthetic Minority Oversampling Technique (SMOTE). In this study, advanced machine learning algorithms, namely Extreme Gradient Boosting (XGBoost), CatBoost, and Light Gradient-Boosting Machine (LightGBM), were used due to their robustness in handling complex datasets. Key metrics, including accuracy, precision, recall, F_1-score, specificity, and area under the curve, were used to provide a comprehensive assessment of model performance. In addition, explainable machine learning techniques, such as Local Interpretable Model-Agnostic Explanations (LIME) and Shapley Additive Explanations (SHAP), were applied to enhance the transparency and interpretability of the models, offering valuable insights into their decision-making processes.

Results: XGBoost and LightGBM demonstrated superior performance, with XGBoost achieving the highest accuracy of 86.87%, a precision of 88.90%, a recall of 84.40%, an F_1-score of 86.44%, and a specificity of 89.12%. LIME and SHAP analyses provided insights into the contribution of individual features to elucidate the decision-making processes of these models, identifying serum creatinine, albumin, and lipoproteins as significant predictors.

Conclusions: The developed machine learning model not only provides a robust predictive tool for early diagnosis and risk assessment of DN but also ensures transparency and interpretability, crucial for clinical integration. By enabling early intervention and personalized treatment strategies, this model has the potential to improve patient outcomes and optimize health care resource usage.

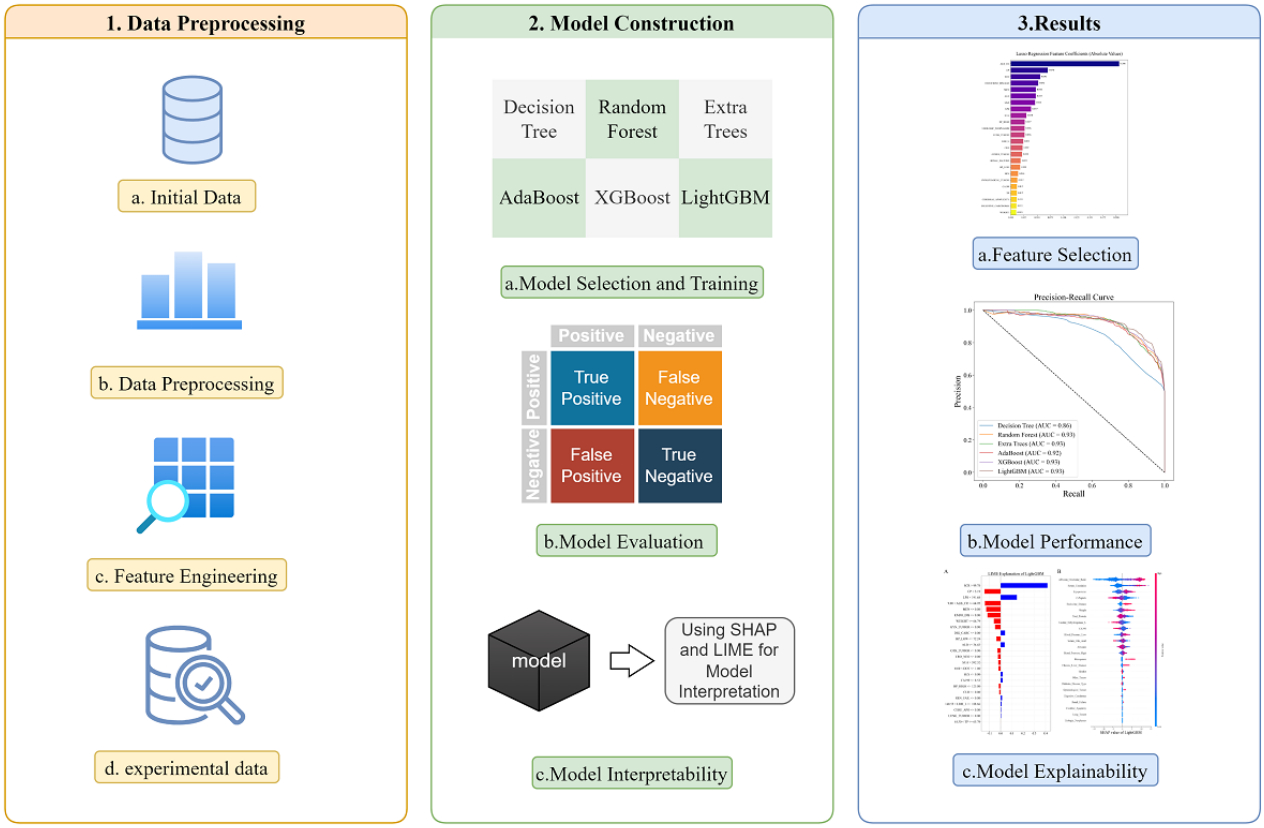
Introduction

Background

Diabetic nephropathy (DN), severe microvascular complications of diabetes, primarily manifests as proteinuria, hypertension, and a progressive decline in renal function, potentially leading to end-stage renal disease. The pathogenesis of DN is attributed to a high-glucose milieu, oxidative stress, inflammation, and fibrosis, collectively contributing to substantial morphological changes in kidneys including thickening of glomerular basement membrane, glomerulosclerosis, tubular atrophy, interstitial inflammation, and renal fibrosis [1]. The prevalence of diabetes and diabetic kidney disease has been increasing, and the International Diabetes Federation projected that the number of patients with diabetes would rise to 783 million by 2045. Notably, approximately 30%‐40% of these patients are expected to develop DN [2], with a mortality rate 30 times higher than that of diabetic patients without kidney disease [3]. Hence, the importance of early detection cannot be overstated in managing DN. Early diagnosis not only significantly reduces the reliance on costly medical resources such as dialysis and transplantation but also alleviates the economic burden on patients [4]. By intervening in the early stages of DN, clinicians can effectively preserve renal function and slow disease progression, thereby enhancing the quality of life and reducing the risk of cardiovascular complications, a major cause of death among patients with diabetes. Moreover, from a perspective of health economics, early detection is crucial as it reduces the need for intensive later-stage treatments, allowing for the reallocation of medical resources to other pressing needs [5]. Consequently, investing in the early detection of DN not only benefits patients but also enhances the efficiency of health care resource usage across society.



Machine learning (ML), as a significant branch of artificial intelligence (AI), has revolutionized the field of medical research by analyzing complex datasets to discover models and make predictions. Particularly in disease prediction and classification, ML algorithms can handle vast amounts of clinical and biological data, identify risk factors, predict disease onset, and accurately classify disease subtypes [6]. In contrast, traditional statistical methods often perform poorly when dealing with the high dimensionality and nonlinearity of biomedical data, whereas ML algorithms, such as decision trees, random forests, support vector machines, and neural networks, exhibit advantages that traditional statistical methods cannot match [7]. ML algorithms have been widely applied in clinical research and shown outstanding performance in various fields. For example, they have achieved significant results in the early prediction of acute kidney injury [8], malaria prediction [9], and cervical cancer survival prediction [10]. Despite the tremendous potential of ML models in predictive analysis, their application in clinical environments is often hindered by the "black box" nature of many algorithms. This opacity limits clinicians' understanding, trust, and effective use of ML predictions. To address this issue, explainable machine learning (XML) techniques have emerged, aiming to enhance the transparency and interpretability of models [11]. By using techniques such as Shapley Additive Explanations (SHAP) and Local Interpretable Model-Agnostic Explanations (LIME), XML can elucidate the contribution of individual features to prediction outcomes, thereby increasing the model's transparency and interpretability [12]. This interpretability is crucial for integrating ML into clinical workflows, as it allows health care providers to validate model outputs based on clinical knowledge, explain decisions to patients, and comply with regulatory standards [13]. Ultimately, XML holds the promise of bridging the gap between advanced analytics and clinical applications, fostering more informed and more confident decision-making in patient care.

Objective

In the clinical management of DN, early diagnosis and precise treatment are crucial for improving patient outcomes. However, traditional diagnostic methods often fall short in predicting the complex progression of the disease, necessitating new tools to enhance predictive accuracy and reliability. This study aims to develop and validate an ML-based model for predicting DN, emphasizing both high predictive accuracy and model interpretability to meet clinicians' needs for transparency. By addressing the gap in both predictive performance and interpretability, this model provides a more holistic approach to managing DN. By creating a new predictive tool, we aim to provide clinicians with a deep understanding of the model's predictive logic, thereby enhancing trust and application of the predictions. We meticulously designed and integrated various ML algorithms, including decision trees, random forests, extra trees, Adaptive Boosting (AdaBoost), Extreme Gradient Boosting (XGBoost), and Light Gradient-Boosting Machine (LightGBM), to build a model with significant predictive accuracy. Concurrently, we used LIME and SHAP methods for in-depth analysis of the model's interpretability, ensuring transparency and fairness in the prediction process. The core contribution of this study lies in enhancing model interpretability, thereby increasing its credibility and practicality in real medical applications. This model not only provides a scientifically transparent decision support system for early diagnosis, risk assessment, and personalized treatment of DN but also aids doctors in devising more precise intervention strategies to improve patient outcomes. We believe that the generalizability and effectiveness of these methods will lay a solid foundation for the broader application of ML technologies in various medical scenarios and open new avenues for medical research. We outline the overall approach of our study as shown in Figure 1.

Related Work

XML has been introduced to enhance model transparency and reliability, helping clinicians better understand the predictions made by these models. Several studies have successfully demonstrated how interpretability techniques can improve the transparency of clinical decision-making. Chadaga et al [14] used SHAP and LIME to predict COVID-19 prognosis using clinical markers, aiming to identify high-risk patients early and provide appropriate treatments to prevent severe outcomes, while also making AI predictions interpretable and trustworthy for medical professionals. Khanna et al [15] built a decision support system using SHAP and LIME to predict osteoporosis risk, aiming to enhance early diagnosis and treatment while making ML models interpretable and reliable for medical professionals. Guan et al [16] used SHAP to interpret venous thromboembolism risks in patients who are critically ill, with the goal of improving early risk identification, enabling timely interventions, and fostering transparency and trust in the decision-making process. Zhong et al [17] introduced SHAP to significantly improve the accuracy of blood oxygen saturation estimation based on neck photoplethysmography, thereby enhancing the reliability of noninvasive oxygen monitoring. Suh et al [18] used LIME to analyze a deep learning model for osteoporosis risk screening, identifying and ranking critical features that contribute to risk prediction. This approach enhances the interpretability of ML models, facilitating personalized health care and aiding clinicians in understanding the decision-making process. In the domain of XML, SHAP and LIME are among the most commonly used methods; however, other approaches, such as partial dependence plot (PDP), are also available. Bernard et al [19] used PDP to visualize the influence of individual features on the model's output by isolating their effects while averaging over all other features. Zhang et al [20] used PDP to analyze the marginal effect of individual features on the model's predictions by averaging their impacts while keeping other features constant. This method helps reveal how changes in a particular feature influence the predicted outcomes, providing clinicians with interpretable insights into feature significance and supporting informed decision-making in personalized health care.

Methods

Data Source

The dataset for this study originated from the National Population Health Data Center's "Diabetes Complications Dataset" and comprised detailed records of 1000 patients with type 2 diabetes. The complete dataset of 1000 patients was used for our analysis without applying any additional inclusion or exclusion criteria, as the dataset had already undergone an initial selection and screening process before public release by the data provider. The dataset covers 87 features, including patients' basic demographic information such as age, gender, ethnicity, and marital status, biochemical test results such as blood glucose

XSL•FO
RenderX

levels, lipid analysis, renal function indicators, and other relevant hematological parameters, and comorbidities such as kidney disease, cardiovascular diseases, fatty liver, and many other chronic conditions. The dataset contained information on 444 patients with DN and 556 patients without nephropathy, providing a rich empirical basis for the study of DN risk prediction.

Data Preprocessing

In this study, features with a data missing proportion exceeding 75% (750/1000) were excluded due to their severely limited informational content and minimal impact on the research outcomes. For features with a data missing proportion less than 75% (750/1000), multiple imputation was used. This method, based on multivariate regression models and iterative algorithms, is well-suited for handling clinical data with diverse feature types due to its ability to preserve interfeature correlations and prevent the disruption of internal data relationships, which is typical for singular imputation methods. The fundamental approach involves initially filling each feature containing missing values with simple methods such as the mean to provide initial values, followed by the use of current filled values from other features to predict and update missing values through regression models. This process iterates until the imputation converges or the predefined maximum number of iterations is reached. In addition, we noted that the ratio of patients with DN to those without is 444:556, close to 4:5. Although this imbalance is not particularly severe, we used the Synthetic Minority Oversampling Technique (SMOTE) to enhance the accuracy and reliability of our model predictions. SMOTE generates new synthetic samples by randomly interpolating between minority class samples and their nearest neighbors. This method not only increases the number of minority class samples but also maintains intraclass diversity, thereby avoiding the potential overfitting issues associated with simple sample replication. Through this approach, SMOTE has effectively addressed the issue of data imbalance, laying a solid foundation for the development of a more robust and more accurate predictive model.

Statistical Analysis

This study used Python version 3.9.5, originally developed by Guido van Rossum and currently maintained by the Python Software Foundation, for data analysis. In the statistical data analysis, the Shapiro-Wilk test was first conducted on continuous variables to determine whether they follow a normal distribution. If these variables did not follow a normal distribution, the Mann-Whitney *U* test was used to explore their associations with DN. The Mann-Whitney *U* test helped examine whether there are significant statistical differences between the patient and nonpatient groups, making it an effective nonparametric testing method. If these variables followed a normal distribution, the Student *t* test was used to analyze their associations with DN. This parametric testing method assessed the significance of differences in the means of 2 samples, aiding in the identification of key indicators related to the risk of DN. For categorical variables, chi-square tests were used to analyze their associations with DN, detecting distribution differences of categorical variables across different disease states. Through these tests, we gained a more comprehensive understanding of how different types of data characteristics influence the risk of DN. Statistical significance was defined as $P<.001$.

Feature Selection

Given the limited sample size and large number of features in the data involved in this study, we adopted the least absolute shrinkage and selection operator (lasso) method for feature selection to ensure the efficiency of the analysis and the accuracy of the results. Lasso introduces the L1 paradigm as a penalty term in regression analysis, making it widely used in high-dimensional data processing [21]. Its objective function is:

$$\min\beta\{12n\sum i=0n(yi-\sum j=1pxij\beta j)2+\lambda\sum j=0p\beta j\}$$

where, yi is the response variable of the ith observation, xij is the jth feature of the ith observation, βj is the regression coefficient of the jth feature, λ is the regularization parameter used to control the complexity of the model, n is the number of samples, and p is the number of features.

By adjusting the regularization parameter λ, lasso achieves a balance between model complexity and fitting accuracy. The core mechanism is to drive some of the regression coefficients to zero through the L1 paradigm penalty, enabling variable selection and feature downscaling. This capability gives lasso a significant advantage when dealing with clinical data, as it is able to automatically screen out important variables and eliminate redundant or irrelevant features, making it particularly suitable for high-dimensional data with a large number of features. Through this regularization, lasso enhances the stability and predictive power of the model, preventing overfitting and ensuring more robust model performance on test sets. In addition, by retaining only the most predictive features, lasso significantly improves the accuracy of the model's predictions.

Model Construction

In this study, we used a series of powerful ensemble learning algorithms, including random forests, extra trees, AdaBoost, XGBoost, and LightGBM. These algorithms are widely used in a variety of ML applications due to their excellent predictive performance and efficient processing speed.

Decision tree is a fundamental ML algorithm used for classification and regression [22]. The data are split into different subsets based on a series of conditions, ultimately forming a tree structure. Each node represents a feature, each branch represents one possible value of the feature, and each leaf node represents a category or regression value.

Random forest is an ensemble learning method that enhances prediction accuracy and stability by constructing multiple decision trees [23]. The core idea is to train multiple decision trees using different subsets of data and features, and obtain the final result by voting or averaging the predictions of all trees. This approach effectively reduces overfitting and improves the model's generalization ability.

Extra trees, or extremely randomized trees, is an improved random forest method that constructs decision trees by randomly selecting features and split points [24]. Unlike random forests, extra trees randomly selects multiple split points at each node,

XSL•FO
RenderX

from which the best split point is chosen. This completely random strategy reduces the variance of the model and improves generalization while retaining the interpretability and training speed of the decision tree model.

AdaBoost is a boosting method based on an additive model that improves overall classification performance by progressively weighting the training of multiple weak classifiers [25]. In each round of training, misclassified samples are given higher weights, prompting subsequent classifiers to focus more on these difficult-to-classify samples. The final model is a weighted sum of multiple weak classifiers, which gradually reduces error and significantly enhances performance.

XGBoost is an efficient gradient-boosting decision tree algorithm that combines parallel processing and regularization techniques to improve the speed and performance of the model [26]. Key features include the use of second-order derivative information, the ability to handle missing values, and pruning operations on the decision tree. These features enable XGBoost to perform well when dealing with large-scale and high-dimensional data.

LightGBM is an efficient gradient-boosting framework that improves training speed and memory usage through a histogram-based decision tree learning algorithm [27]. Its features include support for categorical features, a depth-first strategy using leaf-count limitation, and efficient parallel processing. These characteristics allow LightGBM to have a significant advantage in handling large-scale data.

Model Evaluation

To comprehensively evaluate the model's performance, this study used multiple evaluation metrics, including accuracy, precision, recall, F_1-score, specificity, and area under the curve (AUC). These metrics reflect various aspects of the model's performance, ensuring an objective and thorough assessment.

Accuracy refers to the ratio of correctly predicted samples to the total number of samples and reflects the overall prediction accuracy of the model. The formula for accuracy is:

$$\text{Accuracy}=\frac{TP+TN}{TP+TN+FP+FN}$$

where, TP is true positives, TN is true negatives, FP is false positives, and FN is false negatives.

A higher accuracy indicates that the model makes correct predictions in most cases.

Precision represents the proportion of true positives among all samples predicted as positive. It primarily measures the accuracy of the model's positive predictions. The formula for precision is:

$$\text{Precision}=\frac{TP}{TP+FP}$$

Recall, also known as sensitivity, is the proportion of true positives among all actual positive samples. A higher recall indicates fewer false negatives and a better ability of the model to identify positive samples. The formula for recall is:

$$\text{Recall}=\frac{TP}{TP+FN}$$

F_1-score means the harmonic mean of precision and recall, and is used to evaluate the balance between these 2 metrics. It is suitable for datasets with class imbalance. The formula for F_1-score is:

$$\text{F1Score}=2\times\frac{\text{Precision}\times\text{Recall}}{\text{Precision}+\text{Recall}}$$

A higher F_1-score indicates better performance in both precision and recall.

Specificity represents the proportion of true negatives among all actual negative samples. It measures the model's ability to identify negative samples. The formula for specificity is:

$$\text{Specificity}=\frac{TN}{TN+FP}$$

The AUC of the receiver operating characteristic (ROC) curve is used to evaluate the overall performance of the model. The ROC curve reflects the trade-off between the true-positive rate and false-positive rate at different thresholds. A higher AUC indicates better discrimination ability of the model, balancing the true-positive rate and false-positive rate more effectively. AUC is especially useful for comparing the performance of different models, providing a global perspective on evaluation.

By comprehensively assessing these metrics, we can understand the models' performance in various aspects, identify their strengths and weaknesses, and provide a solid basis for further optimization and improvement. This multiangle, multidimensional evaluation approach ensures a more accurate and comprehensive evaluation of the model's performance, enhancing its reliability and effectiveness in practical applications.

Model Interpretability

For the interpretability of ML models, we primarily used 2 widely recognized methods, LIME [28] and SHAP [29]. LIME approximates complex ML models by fitting an interpretable linear model within a local neighborhood of the target prediction point. This approach provides individualized feature importance interpretations for each instance, thus elucidating the logic behind specific model predictions. Unlike LIME, which focuses on local interpretation, SHAP quantifies the global contribution of each feature to the model prediction based on the Shapley value from game theory. The SHAP value ensures that the contribution of each feature is consistent and fair across all possible feature combinations. By calculating the SHAP value for each feature, SHAP reveals the interactions and dependencies between features and model predictions. Both methods have their respective strengths. SHAP offers a more comprehensive and in-depth interpretation, while LIME is more intuitive and flexible for instance-specific explanations. Combining the local interpretability of LIME with the global analysis of SHAP provides a more thorough and detailed interpretative support for ML models in clinical data. This combination is crucial for enhancing the transparency of the models, increasing the trust of health care professionals, and optimizing the clinical decision-making process.

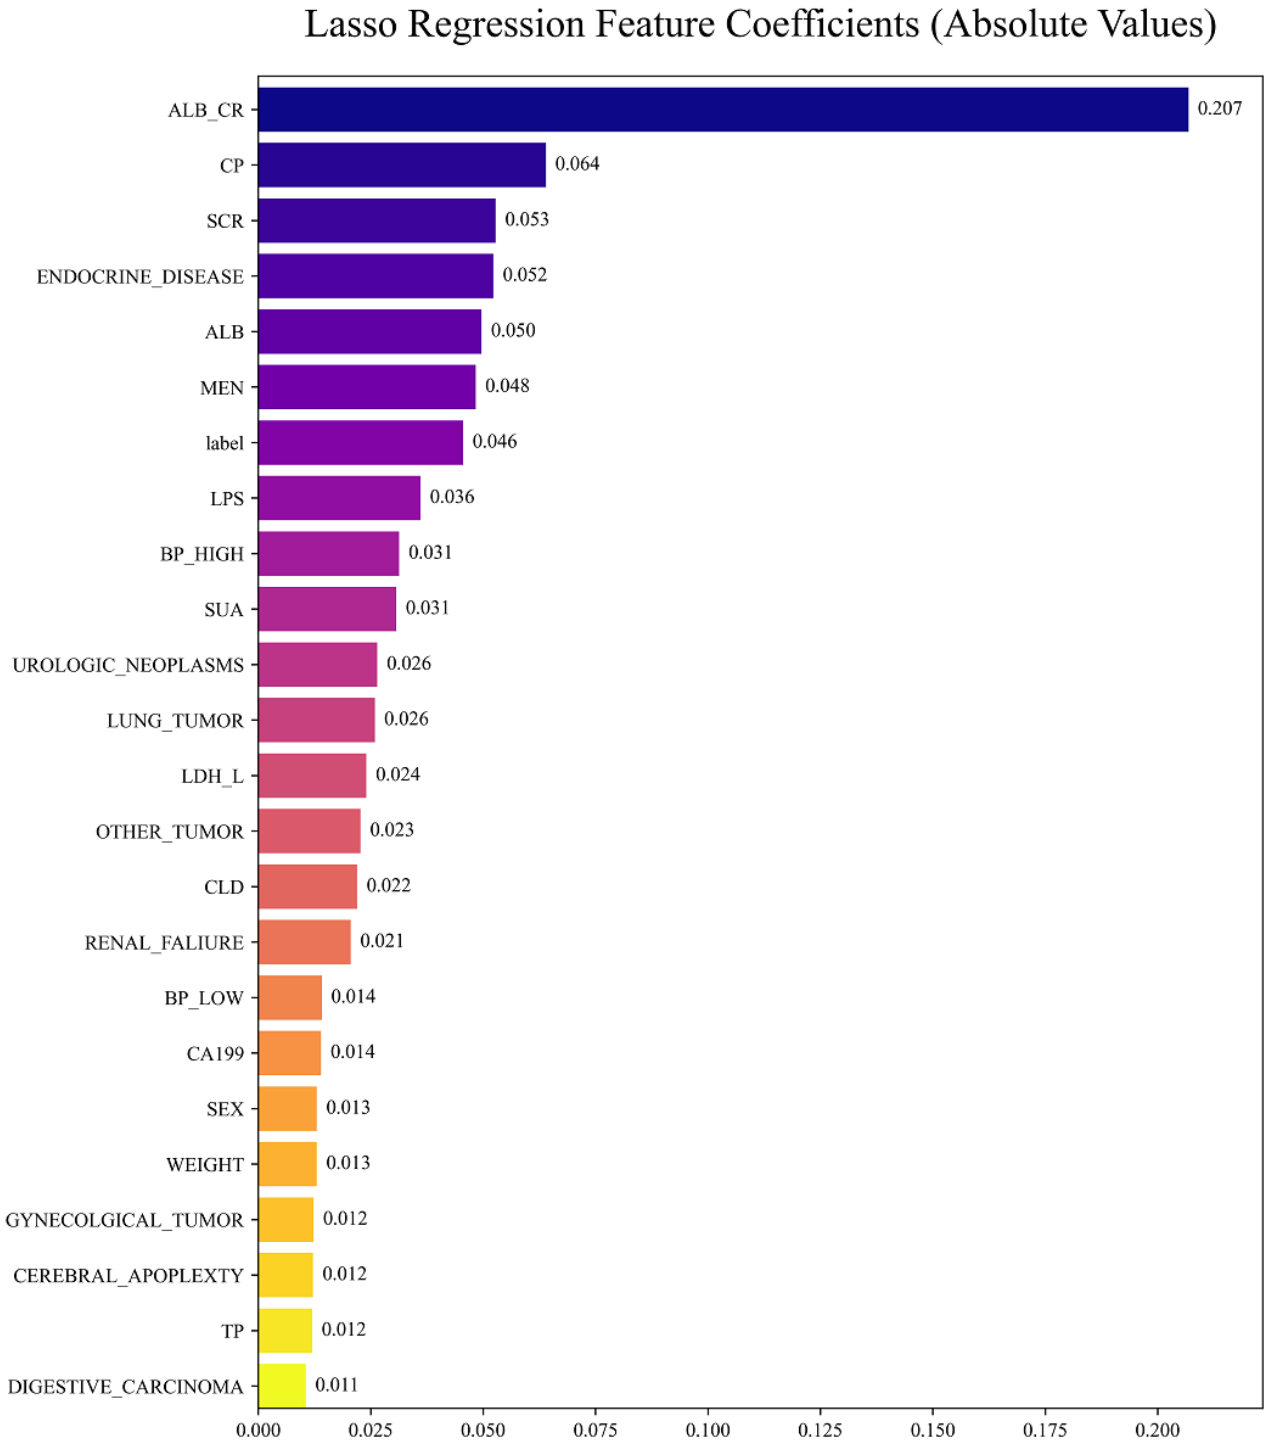
Ethical Considerations

This study conducted a secondary analysis using the publicly available Diabetes Complications Dataset [30] from the National Population Health Data Center. As this study exclusively used anonymized secondary data without direct human participant involvement, it is exempt from additional institutional ethics

XSL•FO
RenderX

review. The original data collection by the National Population Health Data Center complies with the "Regulations on the Management of Human Genetic Resources of the People's Republic of China" and relevant ethical guidelines. All data are completely deidentified with no personally identifiable information included, and formal data access approval was obtained from the data provider following their established protocols. The original informed consent permits secondary analysis of the deidentified data for research purposes.

Results



Feature Selection

As illustrated in Figures 2 and 3, lasso regression effectively filters and optimizes the variables in the model by adjusting the regularization parameter λ (Log Lambda). Each curve represents the coefficients of a feature. It can be observed that as λ increases, most coefficients gradually approach zero (Figure 3A). This phenomenon demonstrates the unique feature selection capability of lasso regression, to reduce the coefficients of unimportant features by increasing λ, and thereby simplify the model. Simultaneously, it can be seen that the mean squared error remains low when λ is small (Figure 3B), indicating that the model has a good fitting performance. However, as λ continues to increase, the mean squared error value starts to rise significantly after a relatively stable period. This trend indicates that excessive regularization will result in an overly simplified model, impairing its predictive ability. Through lasso regression, we eventually selected the 24 features, including 14 numerical features and 10 categorical ones.

Table 1 summarizes the differences in features between the DN group and the non-DN group. The statistical data reveal significant disparities between the two groups across various biochemical indicators and health conditions. Specifically, the albumin level is significantly higher in the non-DN group (mean 41.9, range 39.7-44.3) than that in the DN group (mean 38.2, range 32.4-41.4), with a *P* value of less than .001. Similar trends are observed for albumin creatinine ratio, blood pressure high, and blood pressure low. For instance, the albumin creatinine ratio is significantly lower in the non-DN group (mean 12.0, range 4.0-60.2) than that in the DN group (mean 272.7, range 79.0-472.1), with a *P* value of less than .001. Blood pressure high and blood pressure low are also lower in the non-DN group with means of 130.0 (range 120.0-142.0) and 80.0 (range 70.0-86.0) compared to the DN group with means of 142.0 (range 130.0-160.0) and 80.0 (range 75.0-90.0), respectively, both with *P* values less than .001. The levels of CA199, lactate dehydrogenase L, and lipoproteins indicate more severe renal impairment in the DN group compared to the non-DN group. For example, the CA199 level is significantly higher in the DN group (mean 16.5, range 9.5-26.3) than that in the non-DN group (mean 13.0, range 7.8-21.9), with a *P* value of less than .001. Similarly, the lactate dehydrogenase L level is higher in the DN group (mean 169.8, range 142.5-203.2) than that in the non-DN group (mean 153.2, range 135.6-176.6), with a *P* value of less than .001. Furthermore, patients with DN exhibit a higher incidence of certain clinical conditions compared to those without DN. For instance, the incidence of digestive carcinoma in the DN group is 18.33%, whereas it is 46.06% in the non-DN group, with a *P* value of less than .001. Similar significant differences are observed for other conditions such as rheumatic immunity disease, other tumors, cerebral apoplexy, and hypertension. Table 1 provides a detailed comparison of these features between the DN and non-DN groups, highlighting significant health disparities and emphasizing the need for targeted clinical interventions. Table 2 lists the variables and their corresponding abbreviations used throughout the analysis, providing a clear reference for understanding the various health indicators assessed in this study.

Model Performance

In this study, we used various ML algorithms to construct predictive models, including decision tree, random forest, extra trees, AdaBoost, XGBoost, and LightGBM. In order to determine the optimal model parameters, we used ten-fold cross-validation and grid search strategies, ensuring thorough and accurate model tuning. The final results, presented in Table 3, show that XGBoost and LightGBM exhibited superior performance across multiple evaluation metrics, including accuracy, precision, recall, F_1-score, and specificity. In particular, XGBoost achieved the highest accuracy of 86.87%, with a precision of 88.90%, a recall of 84.40%, an F_1-score of 86.44%, and a specificity of 89.12%. LightGBM followed closely with an accuracy of 86.78%, a precision of 88.72%, a recall of 84.37%, an F_1-score of 86.35%, and a specificity of 88.88%. These results highlight the exceptional capability of both XGBoost and LightGBM in handling complex datasets, making them ideal for predictive modeling in this context. The other effective models, however, did not match the overall performance of XGBoost and LightGBM.

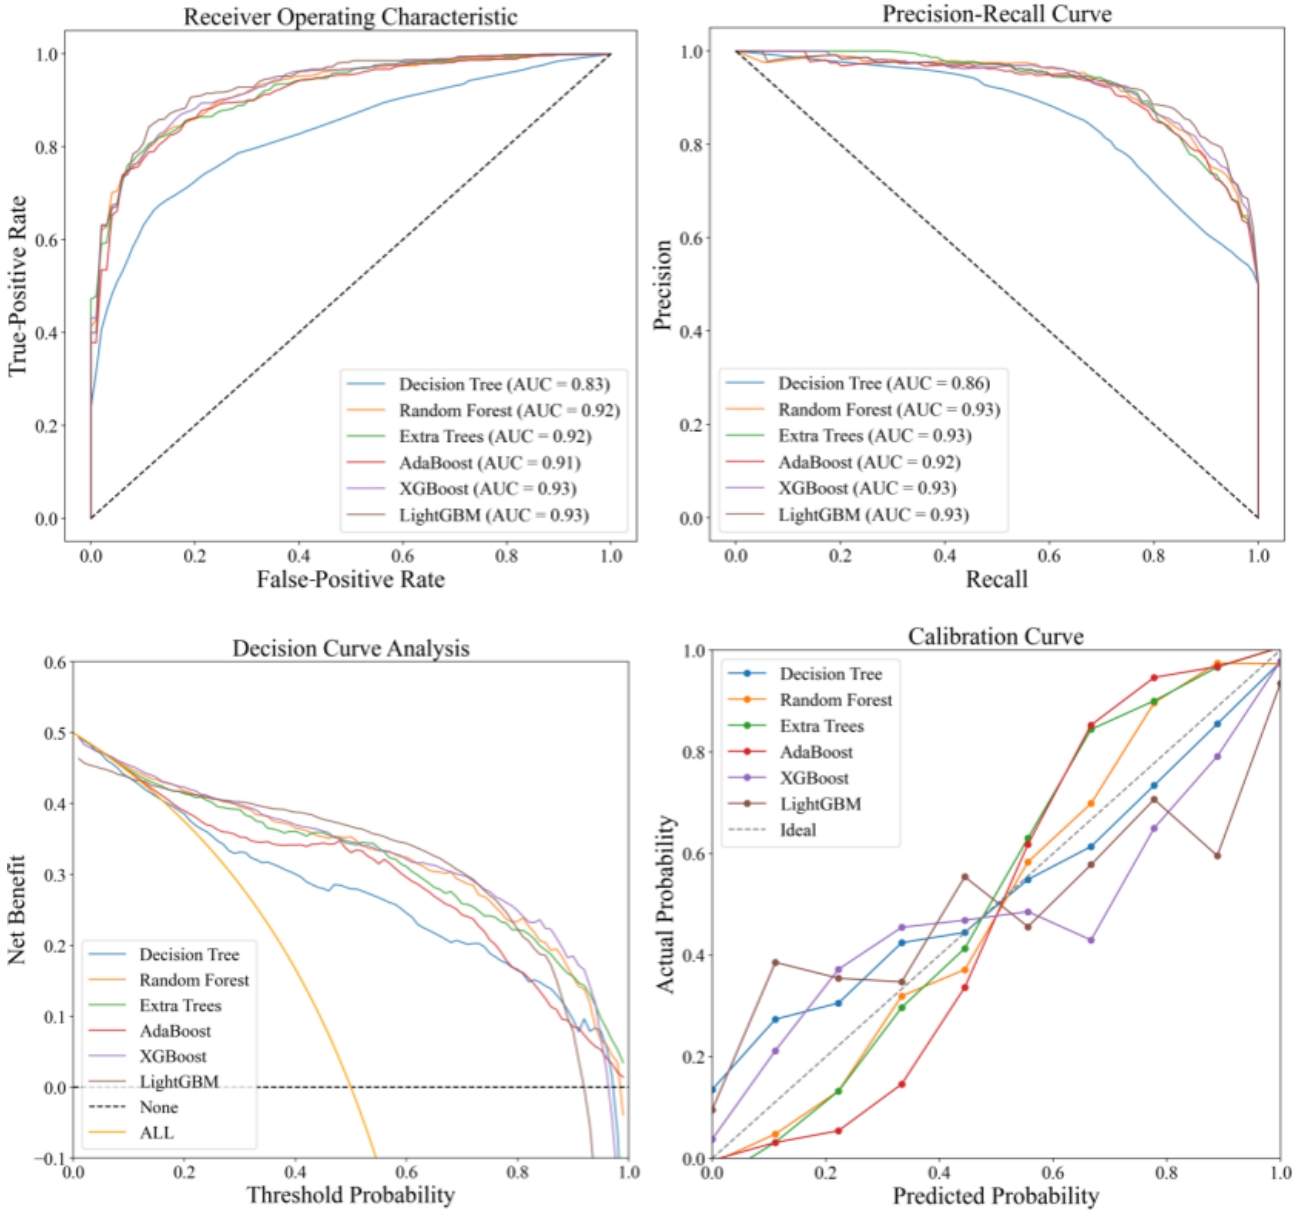
AdaBoost[a]	83.10	85.44	79.77	82.29	86.31
XGBoost[b]	86.87	88.90	84.40	86.44	89.12
LightGBM[c]	86.78	88.72	84.37	86.35	88.88

[a]AdaBoost: Adaptive Boosting.



[b]XGBoost: Extreme Gradient Boosting.

[c]LightGBM: Light Gradient-Boosting Machine.

As shown in Figure 4, through a comprehensive performance evaluation that included ROC curves, precision-recall curves, decision curve analysis, and calibration curves, we found that LightGBM and XGBoost performed exceptionally well. Both models demonstrated strong discriminative abilities with an AUC of 0.93, indicating their effectiveness at distinguishing between positive and negative classes. The precision-recall curves, particularly valuable for imbalanced datasets, also showed an AUC of 0.93 for both models, reflecting their capability to maintain high precision and recall, which minimizes false positives and negatives. In the decision curve analysis, XGBoost provided the highest net benefit, highlighting its robustness and wide applicability across various clinical decision thresholds. This indicates that XGBoost can be particularly useful in diverse clinical scenarios, offering reliable support for decision-making processes. The calibration curves further confirmed the reliability of the predicted probabilities from both models, showing that their predictions closely matched the actual outcomes, especially in the high probability prediction range. This means that when the models predict a high probability for an event, the prediction is likely to be accurate, which is essential for building trust in model predictions. In summary, LightGBM and XGBoost excelled across all evaluated metrics, demonstrating superior performance and robustness. Their high AUC values, significant net benefit, and accurate probability predictions collectively underscore their effectiveness in handling complex clinical datasets, making them highly suitable for predictive modeling in health care where accurate and reliable predictions are critical for effective patient management and treatment planning.

RenderX

Figure 4. Comprehensive evaluation of model performance. (A) Receiver operating characteristic (ROC) curves demonstrate discriminative ability, with LightGBM achieving the highest AUC (0.93) [6,10]. (B) Precision-recall curves highlight performance in imbalanced datasets, where XGBoost and LightGBM maintain high precision across recall ranges. (C) Decision curve analysis reveals net clinical benefit, indicating LightGBM's superiority over alternative models at most threshold probabilities. (D) Calibration curves assess predictive accuracy, showing LightGBM aligns closest to the ideal calibration line. AdaBoost: Adaptive Boosting; AUC: area under the curve; LightGBM: Light Gradient-Boosting Machine; XGBoost: Extreme Gradient Boosting.

Model Explainability

In the analysis of the LIME diagram, we identified a series of key biomarkers and clinical indicators closely associated with the occurrence and progression of DN. As depicted in Figure 5A, the values next to each feature represent the contribution of that feature to the model's prediction outcomes, denoted as the importance score. Blue indicates a positive correlation between the feature value and the model's prediction outcomes, meaning that as the feature value increases, the likelihood of the model predicting the positive class also increases. Conversely, red indicates a negative correlation, suggesting that as the feature value increases, the likelihood of the model predicting the negative class increases. LIME technology provides an intuitive explanation of the factors influencing model predictions by constructing local surrogate models around the model's predictions in the form of linear models, approximating the original complex model. Specifically, the level of serum creatinine was identified as a significant positive predictive factor, with a threshold exceeding 99.78 µmol/L associated with an increased risk of DN. This finding aligns with the clinical understanding that elevated creatinine levels typically indicate decreased kidney filtration capacity. Albumin levels within the range of 9.00 to 64.95 g/L were also associated with the risk of DN. As the main protein in plasma, abnormal albumin levels may indicate malnutrition or an inflammatory state, both of which can impact kidney health. The lipopolysaccharide level exceeding 191.68 mg/dL was identified as another positive predictive factor. As an inflammatory mediator, elevated lipopolysaccharide levels may be linked to the inflammatory processes in DN. The level of serum uric acid

XSL•FO
RenderX

exceeding 392.32 µmol/L was also identified as a positive predictive factor. Hyperuricemia is associated with various kidney diseases and may increase the risk of DN through mechanisms such as promoting inflammation and oxidative stress. Blood pressure indicators, including diastolic blood pressure (BP_LOW) at 72.24 mmHg and systolic blood pressure (BP_HIGH) not exceeding 125.00 mmHg, were also considered to be significant in the LIME analysis. Effective blood pressure control is crucial for slowing the progression of DN. In addition, the levels of total protein within the range of 61.30 to 65.70 g/L and lactate dehydrogenase within the range of 160.55 to 188.66 U/L played a role in the model's predictions. Abnormalities in these indicators may reflect systemic metabolic disorders or tissue damage, both of which are related to the risk of DN. The presence of other medical conditions such as gynecological tumors, endocrine diseases, and lung tumors also showed a negative correlation with the risk of DN, suggesting that these factors may have a protective or neutralizing effect in this specific dataset. Through this detailed analysis, LIME technology provided a comprehensive and intuitive explanation of the key factors influencing model predictions, thereby enhancing our understanding of the biomarkers and clinical indicators associated with DN.

Figure 5. Feature importance analysis of the LightGBM model. (A) LIME explanation highlights individual feature contributions, where blue/red bars indicate positive/negative impacts on predictions. (B) SHAP values reveal global feature influence, with ALB_CR and SCR exhibiting the strongest associations (purple/blue gradient reflects feature magnitude). ALB: albumin; ALB_CR: albumin creatinine ratio; BP_HIGH: blood pressure high; BP_LOW: blood pressure low; CLD: chronic liver disease; CP: C-reactive protein; LDL_L: lactate dehydrogenase L; LightGBM: Light Gradient-Boosting Machine; LIME: Local Interpretable Model-Agnostic Explanations; LPS: lipoproteins; MEN: endocrine gland tumors; SCR: serum creatinine; SHAP: Shapley Additive Explanations; SUA: serum uric acid; TP: total protein.

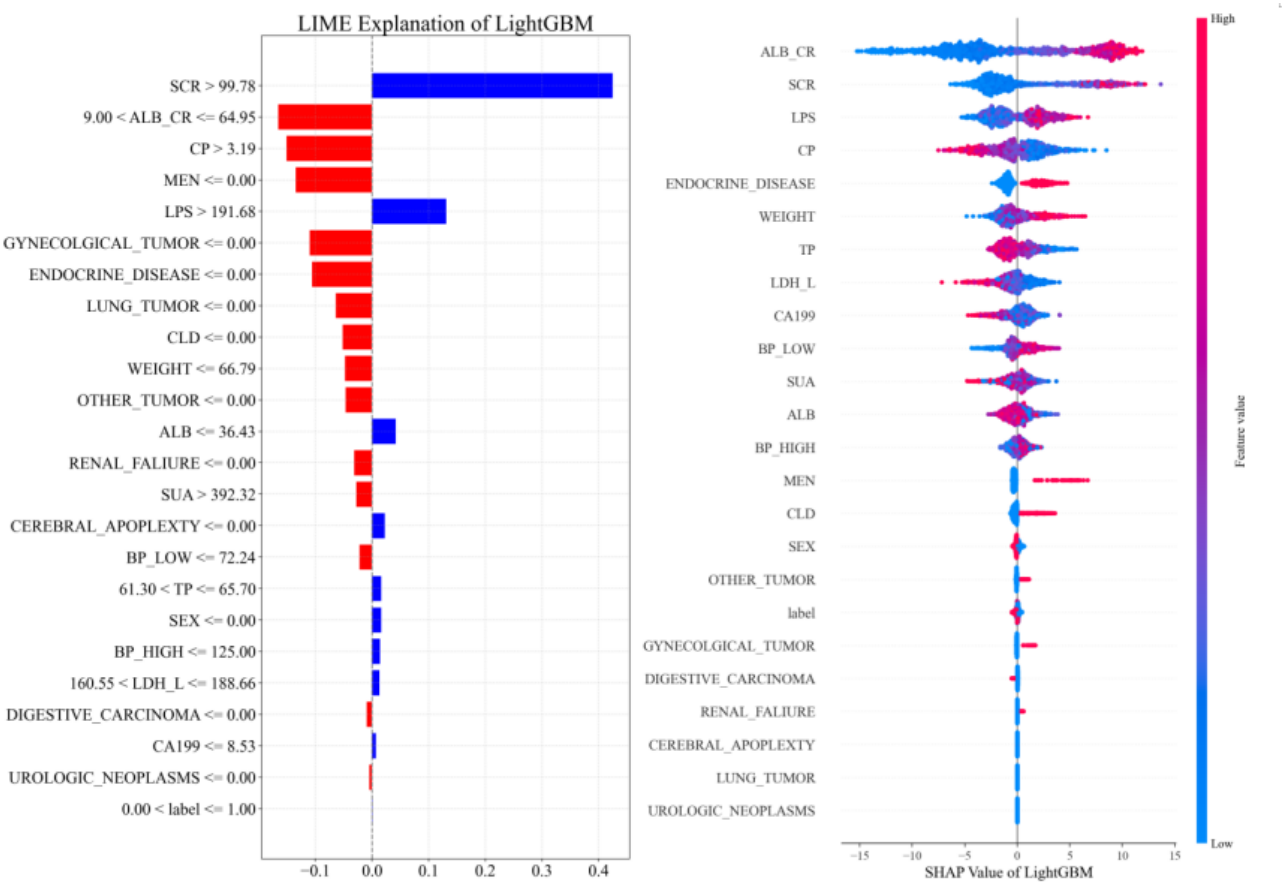

Figure 5B illustrates the SHAP importance of features within the LightGBM model, identifying primary factors such as lipoprotein A, serum creatinine, C-reactive protein, albumin, and blood pressure high as crucial ones in evaluating DN. These features are pivotal across models, underscoring their integral role in disease assessment. Lipoprotein_A and other lipoproteins serve as critical lipid markers, essential for gauging the cardiovascular risks and progression of kidney disease in patients with diabetes. Abnormal lipid metabolism is intimately linked with the onset of DN, highlighting a potential need for enhanced lipid management strategies to thwart disease advancement. Furthermore, Serum_Creatinine and Blood_Urea nitrogen are paramount biochemical indicators for renal function assessment. Elevated concentrations of these markers generally denote diminished kidney filtration ability, serving as significant indicators of DN progression. Regular monitoring of these parameters is vital for the early detection of renal impairment and timely medical intervention. Albumin serves as a sensitive biomarker for early DN. The abnormal rate of urinary albumin excretion reflects the extent of renal damage. Early detection and continual monitoring of urinary albumin levels enable physicians to assess disease progression and the efficacy of their treatment protocols, thereby facilitating the development of customized therapeutic strategies aimed at decelerating disease progression. Hypertension significantly accelerates DN development; thus, effective blood pressure management is

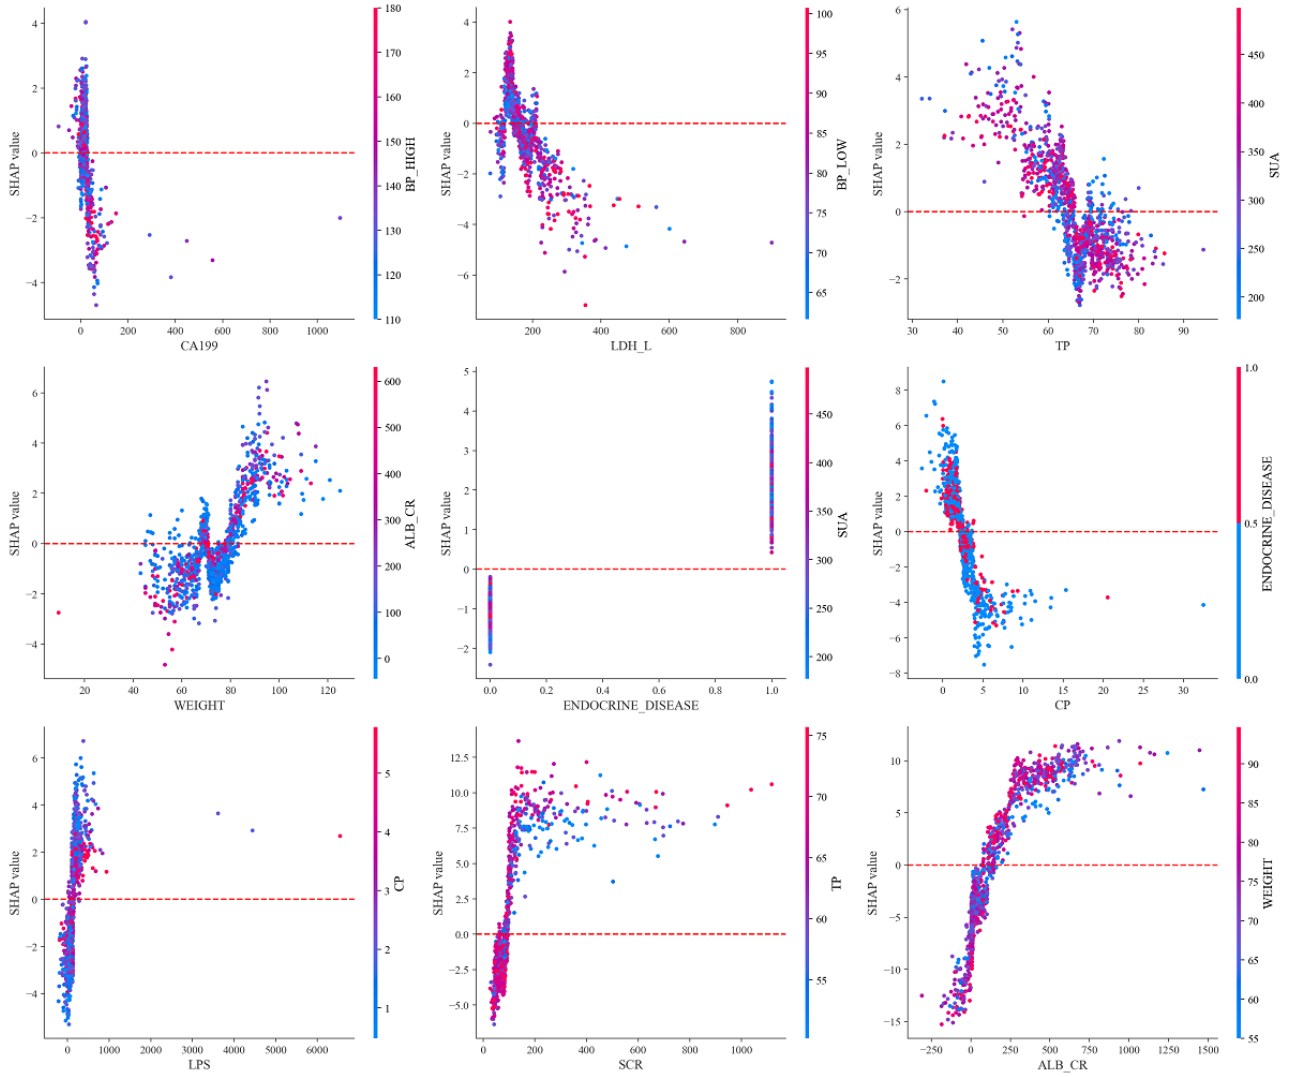
XSL•FO
RenderX



imperative for delaying or preventing disease progression. Optimal control of hypertension not only preserves renal function but also mitigates the risk of cardiovascular incidents. The collective significance of these features underscores their pivotal role in DN assessment. Through a comprehensive analysis of these factors, physicians can obtain a deeper understanding of the disease's complexity, and develop more effective monitoring and treatment modalities that enhance patients' management and prognosis.

Figure 6 delineates the correlation between various biochemical indicators and their SHAP values in interpretable ML models designed for predicting and evaluating the risk of DN. An in-depth analysis of these biochemical markers furnishes critical scientific insights into their influence on DN risk predictions, thereby informing clinical intervention strategies. The analysis reveals a pronounced negative correlation between the levels of blood urea nitrogen (blood urea) and the model's predictive accuracy. As blood urea nitrogen levels increase, the associated SHAP values decline markedly, signifying an augmented risk of DN. This trend underscores the prognostic importance of blood urea nitrogen in the early detection of renal dysfunction, establishing it as an essential indicator for kidney disease risk assessments. Similarly, fluctuations in albumin levels are critical for forecasting DN. The presented data indicate that rising albumin levels correlate with decreasing SHAP values, underscoring albumin's predictive utility, particularly in detecting microalbuminuria—an early manifestation of kidney damage. Elevated levels of C-reactive protein, a marker of systemic inflammation, also correspond with reduced SHAP values, suggesting that high concentrations of this protein are linked to an increased risk of DN. This relationship may stem from chronic inflammatory states that foster the progression of DN. The findings concerning serum creatinine demonstrate that increased creatinine levels are indicative of reduced kidney filtration capabilities, mirrored by a decline in SHAP values. This reinforces the value of serum creatinine as a crucial indicator of renal insufficiency and a metric for assessing the risk of DN. The analysis also highlights the significant negative impact of elevated lipoprotein markers on the model's predictions, emphasizing the imperative role of lipid management in the prevention and treatment of DN. The perturbations in these indicators not only relate to cardiovascular diseases but also pose a substantial risk factor for DN. Furthermore, the notable SHAP values for endocrine disease and diabetes type underscore the critical role of these conditions in assessing DN risk, indicating that they are significant contributors to the disease's development. By synthesizing these data, we can enhance our comprehension of the risk factors associated with DN. This integration aids medical professionals in more accurately identifying patients at high risk, thereby facilitating the development of more effective treatment strategies and management practices to improve the renal health of patients with diabetes.

For the purpose of evaluating the predictive models for DN, the SHAP value plots for three distinct samples (Figure 7) offer a nuanced understanding of the contribution of various biochemical and physiological indicators to disease risks prediction. These comprehensive data enable insights into how different indicators, either individually or synergistically, influence disease risk assessment, thereby furnishing a scientific foundation for clinical decision-making. The analysis of the first sample elucidates that elevated levels of serum creatinine and C-reactive protein markedly enhance disease risks. Serum creatinine, a key marker of renal function impairment, signals a significant reduction in kidney function, which is particularly crucial in DN where renal lesions often correlate with prolonged suboptimal diabetes control. C-reactive protein, indicative of the body's inflammatory response, suggests the presence of an inflammatory state that is instrumental in accelerating renal damage. Furthermore, hypertension is a significant risk factor for DN, and the notably increased low blood pressure might suggest inadequate blood pressure management in this sample, exacerbating the renal burden. Conversely, higher levels of serum uric acid and albumin are generally viewed as protective in the first sample. Although elevated serum uric acid levels are linked to other conditions like gout, they may indicate preserved renal excretion function to a degree. Albumin, a crucial component of plasma proteins, with maintained levels suggests a favorable nutritional state and some preservation of kidney filtration function. The analysis of the second sample, with its positive prediction value indicating disease absence, highlights the critical role of lipoprotein A in increasing disease risks. Lipoprotein A, an independent risk factor for cardiovascular diseases, underscores a possible link between cardiovascular and renal health in the context of DN. Moreover, an elevated level of serum lipase (lipopolysaccharides) contributes to lowering disease risks in this sample, possibly due to its role in modulating immune responses and inflammation. The third sample's negative prediction value signals a heightened disease risk. In this context, increased serum creatinine and high blood pressure significantly elevate disease risks, emphasizing the importance of vigilant monitoring and control of these indicators. Although blood urea contributes less significantly to the prediction value, its elevation is typically associated with renal insufficiency and warrants clinical attention. Through this meticulous SHAP value–based analysis, we unveil not only the specific contributions of each biochemical indicator to disease risks but also the intricate interplay and connections among these indicators. This profound understanding provides invaluable information for medical professionals in the early diagnosis, risk assessment, and therapeutic decision-making of DN, facilitating personalized medicine and enhancing treatment outcomes of patients.

Figure 6. SHAP value distributions for key biochemical indicators in nephropathy risk prediction. Each subplot illustrates the relationship between feature values (x-axis) and SHAP values (y-axis), with color gradients indicating feature magnitude. Red dashed lines denote baseline thresholds, where features above/below these thresholds significantly influence model predictions. Notably, ALB_CR and SCR exhibit the strongest associations with nephropathy risk due to their wide SHAP value ranges and distinct clustering patterns. Detailed subfigures are available in Multimedia Appendices 1-9. ALB_CR: albumin creatinine ratio; BP_HIGH: blood pressure high; CP: C-reactive protein; LDL_L: lactate dehydrogenase L; SCR: serum creatinine; SHAP: Shapley Additive Explanations; SUA: serum uric acid; TP: total protein.

XSL•FO
RenderX

Figure 7. Comparative analysis of Shapley Additive Explanations (SHAP) values across three patient samples for diabetic nephropathy prediction. Each waterfall plot illustrates individual feature contributions to the final prediction score, where red/blue segments indicate positive/negative impacts on diabetic nephropathy risk. The base value represents the average model output without feature effects, while the final f(x) reflects personalized risk assessment. Notably, SUA and ALB exhibit consistent positive associations in high-risk samples (first/second), whereas MEN and HTN dominate negative contributions in low-risk cases (third). ALB: albumin; BP_HIGH: blood pressure high; BP_LOW: blood pressure low; BU: albumin creatinine ratio; CP: C-peptide; CRP: C-reactive protein; LP_A: lysophosphatidic acid; LPS: lipoproteins; DC: digestive carcinoma; HTN: hypertension; LPS: lipoproteins; MEN: endocrine gland tumors; OT: other tumor; PL: phospholipid; SCR: serum creatinine; SUA: serum uric acid.

Discussion

Principal Findings

In this study, we focused on developing a predictive model for DN risks and conducted an extensive feature analysis, aiming to identify patients at risk of progressing to severe kidney disease in a clinical setting. To achieve this goal, we thoroughly analyzed a range of biomarkers and clinical indicators and evaluated several popular ML algorithms. Among these various algorithms tested, we found that the gradient-boosting–based algorithms, XGBoost and LightGBM, performed exceptionally well on our dataset. The models not only demonstrated significant advantages in training speed and handling large datasets but also exhibited superior predictive performance across key metrics such as accuracy, precision, recall, and AUC, showcasing their outstanding predictive capabilities. Our study also found that serum creatinine, the albumin-creatinine ratio (ACR), abnormal levels of lipoproteins, C-peptide, and hypertension were the most relevant factors associated with DN, aligning with findings from clinical research on the key risk factors for DN progression.

Comparison With Prior Work

Serum creatinine is a key biomarker for evaluating DN and core indicator of kidney function, and its elevated levels are often closely associated with kidney damage. In patients with diabetes, even a slight increase in serum creatinine levels is sufficient to indicate early kidney function impairment [31]. As serum creatinine levels rise, the risk of kidney damage also increases; thus, it is recommended to closely monitor serum creatinine levels in diabetes management [32]. Serum creatinine levels have independent predictive value in the progression of DN. Regular monitoring of serum creatinine levels helps the early identification of potential kidney disease risks and the taking of appropriate preventive measures [33]. By optimizing medical management for patients with diabetes and regularly assessing serum creatinine levels, clinicians can detect and address kidney function damage earlier, thereby reducing the progression risk of DN.

The ACR is an important method for detecting microalbuminuria, used to evaluate early changes in kidney disease in patients with diabetes. An increase in ACR is closely related to the progression of DN, and even a slight elevation in ACR should be considered as a warning signal for the development of DN [34]. Elevated ACR is an independent predictor for the progression of DN, and regular monitoring of ACR levels helps the early identification of potential kidney disease risks, aiding clinicians in assessing disease progression and treatment response [35]. Moreover, a reduction in ACR is associated with a slowdown in the progression of DN and a decrease in cardiovascular event rates. By optimizing medical management for patients with diabetes and regularly monitoring ACR levels, clinicians can detect and address kidney function damage earlier, thus reducing the risk of progression of DN [36].

Abnormal levels of lipoproteins, particularly elevated low-density lipoprotein (LDL) and very low–density lipoprotein (VLDL), are significant risk factors in the development of diabetic kidney disease. These lipid particles damage vascular

XSL•FO
RenderX

endothelium, thereby accelerating the progression of diabetic kidney disease. Research indicates that changes in the size and number of LDL particles in patients with diabetes are significantly correlated with renal function impairment [37]. Elevated LDL levels not only lead to atherosclerosis but also directly harm renal function by promoting inflammation and oxidative stress. This damage mechanism is primarily manifested by the thickening of the glomerular basement membrane and glomerulosclerosis, which may ultimately result in renal failure [38]. Similarly, elevated VLDL levels are closely associated with the progression of kidney disease. VLDL carries a large amount of triglycerides and can be absorbed by renal tubular cells, causing cytotoxic reactions that further exacerbate tubular damage and accelerate the progression of kidney disease [39]. Even after other comorbid factors are controlled, high LDL levels remain significantly associated with the progression of kidney disease. Multiple studies have also shown that high LDL levels are closely related to increased urinary protein excretion and decreased renal function [40,41]. Therefore, managing lipoprotein levels is crucial to slowing the progression of diabetic kidney disease. Dietary adjustments, medication treatments such as statins, and lifestyle changes can effectively lower LDL and VLDL levels, thus protecting renal function.

C-peptide is an important marker for evaluating β-cell function in the pancreas, with its levels closely associated with metabolic control in diabetes. Low C-peptide levels are linked to an increased risk of DN, possibly due to metabolic disorders caused by insufficient insulin secretion. In contrast, high C-peptide levels are associated with a reduced risk of renal function deterioration in patients with type 2 diabetes. Research indicates that patients with higher C-peptide levels would experience slower declines in renal function and less increase in albuminuria [42]. Moreover, C-peptide shows potential in the treatment of DN. C-peptide replacement therapy can reduce glomerular hyperfiltration, decrease albumin excretion, and prevent glomerular and renal hypertrophy [43]. Supporting this view, another study demonstrates that C-peptide at physiological concentrations can improve glomerular filtration rate and increase renal plasma flow, and effect further validation in clinical trials [44]. C-peptide levels play a crucial role in the progression and management of DN. Monitoring and potentially modulating these levels through therapeutic interventions can provide significant benefits for the prevention and treatment of DN.

Hypertension is a major risk factor for the development and progression of DN. Persistent hypertension can lead to structural and functional changes in the renal vasculature, accelerating the decline in renal function. Patients with hypertension experience faster progression of kidney damage and thus require earlier intervention to prevent further deterioration of renal function [45]. In the context of hypertension, a sustained high pressure load on the renal blood vessels results in the thickening and hardening of the vessel walls. These structural changes weaken the kidney's filtration function and accelerate glomerulosclerosis and renal fibrosis [34]. Effective hypertension management typically includes the use of angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, which not only lower blood pressure but also provide renal protection [46]. On the other hand, although hypotension is less common in patients with diabetes, it can have negative effects on renal function in certain situations. In severe circulatory failure or shock, hypotension can lead to inadequate renal perfusion, reducing blood flow to the kidneys and exacerbating renal damage. In clinical practice, the management strategies for hypertension and hypotension need to be individualized. For patients with hypertension, the goal is to reduce blood pressure to recommended levels while avoiding excessive hypotension. For patients at risk of hypotension, particularly older adults, close monitoring of blood pressure fluctuations is essential to prevent inadequate renal perfusion. Overall, blood pressure management plays a crucial role in the prevention and treatment of DN. Appropriate pharmacological treatment and lifestyle interventions can control blood pressure effectively, protect renal function, and delay the progression of DN.

Limitations

This study has made notable progress in predicting DN; however, certain limitations remain. First, the data used in the study were sourced from a single medical institution. Although the model performed well on this dataset, validation with data from other institutions is needed to assess its effectiveness and generalizability. Additionally, the model has not yet undergone comprehensive clinical validation, and some features selected by the algorithm may lack diagnostic significance, while commonly used clinical indicators might not have been included.

Future Directions

Future research should focus on the following improvements: collecting data from multiple institutions to validate the model's robustness, strengthening collaboration with clinical experts to optimize feature selection based on clinical knowledge, and investigating potential nonlinear relationships among features. Developing a user-friendly online platform and a simplified scoring system would make the model more intuitive and accessible for clinical use. Furthermore, incorporating multimodal data, such as imaging and genomic information, could enhance the model's predictive performance and clinical value, providing robust support for the early diagnosis and personalized treatment of DN.

Conclusion

In this study, we developed a robust predictive model for DN using various ML techniques. Among the models tested, XGBoost and LightGBM demonstrated superior performance, achieving notable metrics across other performance indicators. The integration of XML techniques, such as LIME and SHAP, provided valuable insights into the contribution of individual features, enhancing the model's transparency and interpretability, which is crucial for clinical application. Our analysis identified several significant risk factors for DN, including serum creatinine, C-peptide, albumin, and lipoproteins. These findings are well-supported by extensive literature, reinforcing the reliability and relevance of our predictive model. The ability to accurately predict DN and understand the underlying risk factors allows for early intervention and

XSL•FO
RenderX

personalized treatment strategies, ultimately improving patients' outcomes and optimizing health care resource usage.

Acknowledgments

The authors would like to thank the Population Health Data Archive for providing the Diabetes Complications Dataset, which was instrumental in this research. This work is supported by the Innovation Engineering project "Construction of a Digital Resource System for Biomedical Literature" (grant 24C0001-1).

Data Availability

The data used in this study are publicly available from the National Population Health Data Center under the title "Diabetes Complications Dataset" (DOI: 10.12213/11.A0005.201905.000282). The dataset can be accessed at [46]. This study was conducted with formal approval from the data provider following submission of a data access request through the National Population Health Data Center platform. All data have been deidentified and privacy-protected by the data provider, with assurance that no personally identifiable information or other sensitive data are included in the deposited dataset. Researchers interested in accessing this dataset should submit a formal request through the National Population Health Data Center platform according to their data-sharing policies. Further details regarding the dataset and its structure are provided in Multimedia Appendix 10.

Abstract

Background: Medical crowdfunding has emerged as a critical tool to alleviate the financial burden of health care costs, particularly in regions where economic disparities limit access to medical treatment. Despite its potential, the success rates of medical crowdfunding projects remain low, with only 9% achieving their fundraising goals in China. Previous research has examined isolated factors influencing success, but a holistic understanding of how multimodal affordances—narrativity, visibility, and progress—collectively impact donor behavior and project outcomes is lacking.

Objective: This study aims to investigate how medical crowdfunding affordances, as an integrated system, influence the success of charitable crowdfunding projects. Specifically, it explores the roles of narrativity (textual elements), visibility (visual elements), and progress (dynamic updates) affordances, and how these interact with patient demographics to shape donor engagement and fundraising outcomes.

Methods: A multimodal analysis was conducted using 1261 medical crowdfunding projects from the Shuidichou platform in China. Machine learning techniques (eg, sentiment analysis via SnowNLP) and regression models were used to examine textual content, visual elements, and progress updates. Control variables included patient age, gender, and beneficiary type. Hypotheses were tested using both continuous (success ratio) and binary (success indicator) measures of project success. In total, 6 models were constructed to examine the influences of affordances.

Results: The study found that narrativity affordances—longer titles (model 1a: P=.04; model 3a: P=.03) and detailed surplus fund descriptions (P=.03)—boosted success, while overly lengthy surplus fund explanations had diminishing returns (P=.005). Disease mentions in titles increased donations (model 1a: P=.01; model 3a: P=.003). A neutral tone in the project plan also improved success (P<.001). For visibility affordances, a moderate number of progress photos maximized project success, while excessive visuals reduced impact (P<.001). Progress affordances followed a similar pattern, with a moderate number of updates enhancing success (P<.001). Critically, when all affordances were considered, only progress update frequency retained a strong inverted U-shaped effect on success (P<.001). Demographics, particularly age, also influenced donations: patients at both ends of the age spectrum received greater support , while middle-aged individuals received less (model 1b: P=.02; model 2b: P=.005; model 3b: P=.02).

Conclusions: This study advances medical crowdfunding affordance theory by demonstrating the interconnected effects of narrativity, visibility, and progress affordances on project success. Practically, results highlight the importance of strategically crafted titles, targeted demographic disclosures, and balanced progress updates—with moderate update frequency being crucial

XSL•FO
RenderX

when controlling all affordances—to enhance donor engagement. Platform designers and project organizers can apply these insights to optimize fundraising outcomes and effectively address health care inequalities. Future research should further investigate visual content analysis and donor psychology to refine engagement strategies.

medical crowdfunding; multimodal approach; information affordance; donor behavior; machine learning

Introduction

Background and Research Aim

By 2030, the economic burden of chronic diseases is projected to reach approximately 343 trillion CNY (US $47 trillion) [1]. In China, the average direct medical expenditure for a case of lung cancer was 39,015 CNY (US $6041) in 2011, with an annual growth rate of 7.55% [2]. Meanwhile, Statista's 2024 data reported that the average annual disposable income per capita in 2015 was just 21,966 CNY (US $3404)—showing how severe illnesses could push average-income families into poverty.

In light of these financial challenges, crowdfunding has emerged as a key charitable tool, enabling widespread, low-cost support for individuals facing medical expenses without expectation of reciprocation [3]. In China, platforms such as Shuidichou (also called Waterdrop) and Qingsongchou have been developed and supported more than 5 million patients from September 2014 to the end of 2021, raising more than 80 billion CNY (US $12.03 billion) [4]. However, medical crowdfunding projects on these platforms have low success rates: Only 9% of the projects reach their fundraising goals, while 70% achieve just 10% of their target [5]. This underscores the urgent need for research to improve crowdfunding success.

Previous medical crowdfunding research has largely examined success factors in isolation. These factors include cultural proximity [6], social media outreach [7], gender dynamics [8], socioeconomic status [9], linguistic style and structure [10,11], and donor-recipient relationships [3]. More recently, research has begun to explore the properties of information, extending to textual [12-17], visual [12,14,15,18,19], and progress-related [12,13,15,17,20] features of crowdfunding projects.

Most previous studies have focused on GoFundMe [13,14,16,21], which hosts a wide range of projects and primarily serves Western populations, leaving donor behavior in Asian contexts less understood. The majority of Chinese relevant research in China has been conducted using data from Qingsongchou [12,19,22,23] and Tencent Charity platform [15,20]. In contrast, Shuidichou, China's largest medical crowdfunding platform, is dedicated exclusively to health care projects and remains understudied despite its relevance to Chinese users. While prior research has examined individual informational features, few studies have explored how different cues interact to shape outcomes. To address these gaps, this study applies Gibson's affordance theory [24], which emphasizes how environments provide actionable information that guides behavior. In the context of medical crowdfunding platforms, the platform serves as the environment, and crowdfunding projects act as information offered to potential donors. Overall, this study aims to address key gaps in prior research [12-17,19,25-29], which has often focused on Western populations and overlooked the interplay among affordances.

Guided by this framework, our study explores: (1) how narrativity affordances (text length, patient demographics, sentiment) influence project success; (2) how visibility affordances (number and type of images) shape donor engagement; (3) how progress affordances (update frequency and sentiment) impact project outcomes; (4) how different types of information—narrativity, visibility, and progress affordances—shape success when controlling for other affordances within the same environment; and 5) how these affordances interact with demographic and contextual factors to shape crowdfunding success.

Building on prior studies, this research responds to Zhang et al [11] by extending the analysis of narrativity affordances beyond project titles to include project descriptions and all textual content. It expands visibility affordances by drawing on Karahanna et al [30] and Zhang et al [31] to examine the number of images across projects. Inspired by Thies et al [32], it investigates progress affordances—particularly update frequency—and incorporates update sentiment, following Zhang et al [3], for a more nuanced content analysis. Additionally, building on findings by Zhou [33], it includes demographic and project characteristics as control variables to assess how affordance effects vary across contexts. By synthesizing insights across modalities, this study constructs a comprehensive multimodal framework encompassing narrativity, visibility, and progress affordances.

Literature Review

Affordance, as an ecological and psychological concept, has been developed and extended for decades. It was initially proposed by Gibson [24], defining it as the information offered by the environment with references to the abilities of animals to act, mainly in the field of visual perception. Post-Gibson stream researchers [34-36] extend Gibson's theories and summarize affordance as the property of the environment. Debates and discussions led to further development of Gibson's theories. Norman [37] was among the earliest to link affordance with human-computer interaction, laying the groundwork for a future extended definition of interaction-oriented affordance. He stresses that users are important because they can perceive and interpret affordances that are built into the design of computers and systems. Later, Jiao et al [38] apply affordances to technologies. He denies and criticizes technological determinism and stresses that affordances are embedded in interactions among users, objects, and technologies. Through

XSL•FO
RenderX

perceiving and understanding technologies, users can achieve different goals and outcomes. Heft [34] emphasizes that users can take corresponding actions based on the provided information. Meanwhile, these actions influence information effectiveness.

The rapid rise of the internet and digital technologies has made social media platforms an integral part of daily life, supporting a wide range of activities such as self-promotion, marketing, entertainment, political engagement, and crowdfunding. In recent years, a growing body of academic research has explored the influence of platform affordances on user behavior. For instance, Karahanna et al [30] proposed that individuals use social media to fulfill both psychological and emotional needs, with platform affordances—particularly IT-enabled ones—helping to meet these objectives. Several studies further highlight how platform affordances shape web-based behavior. Zhou [33] finds that changes in social media affordances can causally affect communication among users. Theocharis et al [39] examine how platform features and user interaction reshape political participation. Scharlach and Hallinan [40] argue that IT-enabled affordances transform abstract social values into measurable actions on the web, guiding users' decisions. In the context of medical crowdfunding, Choy and Schlagwein [41] used the Earthship Kapita case to illustrate how IT affordances on crowdfunding platforms satisfy donors' psychological needs and motivations, making web-based charity models more effective than traditional offline approaches. Jiao et al [38] deliver a web-based survey and prove that IT affordances effectively influence donors' perceptions and, therefore, donors' donation decisions. Collectively, these studies emphasize the central role of affordances in shaping user behavior on the web.

Medical crowdfunding has emerged as a trending method for financing high-cost medical treatments. Severe diseases, exemplified by the far-reaching impact of the COVID-19 pandemic over the past few years, typically put significant economic pressures on patients and their families. Consequently, many resort to medical crowdfunding as a source of economic assistance. To better understand the mechanism of the practice and to optimize the chances of the success of crowdfunding projects, we frame medical crowdfunding as a multimodal information system facilitating the complex interaction between the three central stakeholders: (1) project initiator (organizer or patient), (2) the platform's technology and information infrastructure, and (3) prospective donors. We maintain that when information relevant to the project is properly presented and creates interaction between these actors, the chances of project success can be greatly improved.

Table 1 [12-17,19,20,22,23,42] displays related works and research data of medical crowdfunding platforms over the past several years. Based on the table, the primary studied medical crowdfunding platform includes GoFundMe, Tencent Charity, and Qingsongchou, while the primary methodologies used in related works are text analysis and linear regression. Independent and dependent variables are also acquired as seen in Table 2 [12-17,19,20,22,23,42]. Although various variables are chosen, related works only analyze the impact of the chosen variables on the project success in isolation.

Our study uses data from the Shuidichou platform, which serves a Chinese demographic, to examine both the individual effects of variables and the interaction. In contrast to prior research mentioned that has predominantly relied on data from GoFundMe—a platform primarily used in the United States—our approach expands the demographic scope by focusing on the Chinese context. As the largest crowdfunding platform in China, Shuidichou specializes in health care–related projects, offering a reliable and relevant data source for studying medical crowdfunding. While Qingsongchou is another Chinese platform with comparable functions, it presents a critical limitation: project organizers can alter fundraising goals during a project, potentially introducing bias and compromising data consistency. Therefore, Shuidichou provides a more targeted and stable foundation for our research. In addition to these, while each affordance may individually influence project success, their interactions must also be considered. Beyond studies using field data from platforms like GoFundMe that analyze affordances in isolation, previous experimental research—such as Jiao et al [38]—has used surveys to manipulate specific features and examine their effects. In contrast, our study uses objective field data from Shuidichou and considers affordances simultaneously, capturing how they function together in real-world settings. This integrated approach provides a more realistic and comprehensive understanding of crowdfunding dynamics and offers actionable insights on optimizing information presentation to enhance project effectiveness. In addition, clear explanations on how information presentation can be managed to enhance crowdfunding success are provided, along with examples.

Table 1. Medical crowdfunding affordance-related literature in the past 5 years.

Platform	Obs number	Method	Findings	Source
GoFundMe	997	Visual analytics approach	Social media plays a crucial role in boosting medical crowdfunding success.	Ren et al [14]
Qingsongchou	1010	Convolutional neural networks	Emotional-related and credible-related photos increase the donation amount, while rational-related ones decrease it.	Wang et al [19]
Tencent Charity	1891	Linear regression	Project with health-related and disease-related keywords are more likely to succeed	Ba et al [20]
Tencent Le Donation	29,700	Textual analysis	Persuasive language significantly influences donor willingness and trust.	Wu et al [15]
Shuidichou	50,000	Linear regression	Projects with positive expressions achieve higher success rates.	Zheng and Jiang [17]
Qingsongchou	754	Linear regression	Funding goals and project duration can help to predict crowdfunding project performances.	Chen et al [12]
GoFundMe	1830	Univariate, multivariate analysis	The success rate of the project heavily depends on the cancer type and the donor's social networks.	Holler et al [13]
GoFundMe	92,753	Textual analysis	Hard-to-treat, high-mortality cancers attract more donors. Projects with strong sentiment words and female beneficiaries are more likely to succeed.	Zhang et al [16]
GoFundMe	243,795	Topic model	Images featuring younger individuals, more people, and more smiles significantly improve the success of projects.	Wang et al [42]
Qinsongchou	116,282	Linear regression	Air pollution negatively impacts donations for critical illness, increasing negative emotions.	Hua et al [22]
Qingsongchou	84,712	Linear regression	Key factors such as patient age, disease type, geographical location, and donation target, influence the success of projects.	Zhang et al [23]

Hypothesis Development

Drawing on affordance theory [24], we conceptualize the crowdfunding platform as an environment in which textual, visual, and progress-related elements function as informational affordances. Similarly, signaling theory states the presence of information asymmetry between sender and receiver [43]. In web-based medical crowdfunding (Figure 1), we have the sender as the crowdfunding project organizer, while the receivers are potential donors online. Senders use affordances to make information signals efficiently to influence receivers, and receivers make informed decisions based on the signals. All interactions among receivers and senders and the information presented on the platform exert a significant influence on donor behavior, ultimately shaping the success rate of crowdfunding projects.

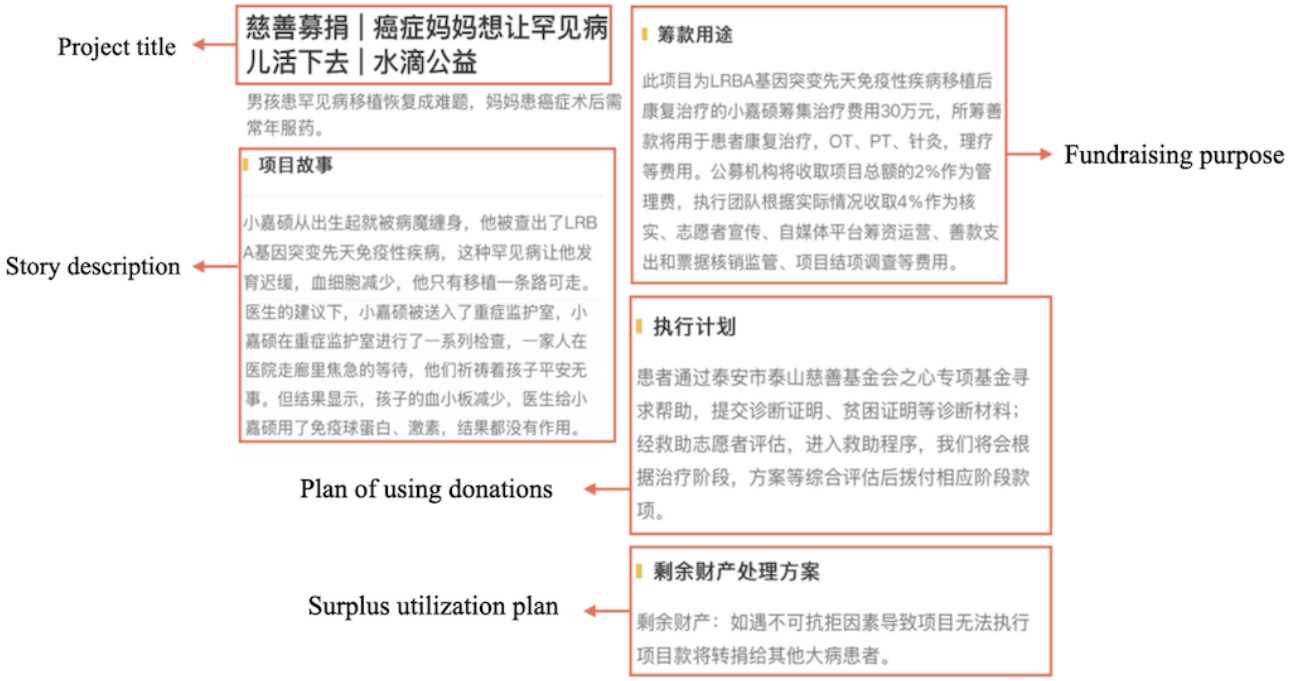
XSL•FO
RenderX

Figure 1. Interaction between project organizers or patients, potential donors, and the platform.

To quantitatively evaluate a project's success, the most frequently applied metric is the project's success rate, although its definition is not uniform across earlier studies. For example, Ba et al [20] use a variable termed *Goal_Pro*, where the percentage of raised funds compared with the target donation is used. Likewise, Zhang et al [44] follow the same benchmark. By way of contrast, Zheng and Jiang [17] gauge success by measuring the number of donations received and the donation amount. A lesser-used measure is binary success—whether a project is a success. For example, Parhankangas and Renko [45] create a dummy variable where 1 represents a goal achieved and 0 represents failure. Both continuous and binary measures are used by our study for the dependent variables, providing a richer assessment of project results. Based on these theoretical underpinnings and earlier results (Tables 1 and 2), the following hypotheses are proposed.

We define narrativity affordance as the action possibilities offered by textual elements written by project organizers. On Shuidichou, these include the project title, project description, fundraising purpose, donation plans, and surplus fund use (Figure 2). To capture donor attention, patients and platform managers must craft descriptions using effective language. Multiple indicators, including text length and sentiment analysis, are selected to evaluate narrativity affordance.

The text lengths of titles and project descriptions have been widely studied, yet findings remain inconsistent. Hou et al [18] and Chen et al [12] claim that a longer text length, especially the length of the story, can attract more attention. However, Zhang et al [44] conclude that there is an inverted U-shaped relationship between story length and the success of a project, meaning that a project with a medium-length description is more likely to succeed. Similarly, Ren et al [14] conclude that the optimal length of a successful project title should be 6 to 11 words. Zhang et al [44] claim that statistically, the length of the title is not significant, and a shorter project description positively influences the success of the project. We develop our first hypothesis as follows.



> *Text length has an inverted U-shaped relationship with the success of a project.* [H1a]

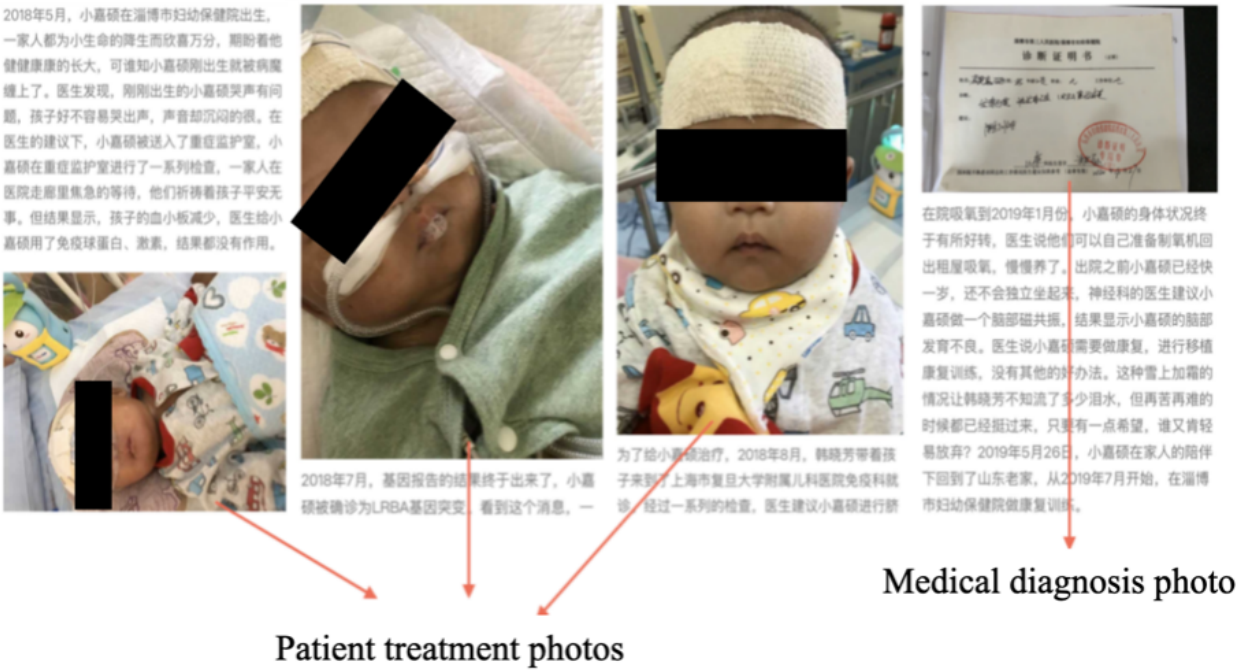
Studies also discussed whether project titles or project descriptions should contain disease type, gender, and age in order to improve the success of the project. Chen et al [12], Hou et al [18], and Peng et al [46] all conclude that projects for younger patients, especially children, are more likely to succeed. Zhang et al [44] confirm that if the project title includes disease type, the success rate of the project increases. No past research has directly proved that gender information included in the title and description can impact the success rate of a project. However, Holler et al [13] conclude that female patients are more willing to initiate crowdfunding projects. We develop our second hypothesis as follows.

> *Disease type, gender, and age in the project title and the project description positively influence the success of a project.* [H1b]

XSL•FO
RenderX

Figure 2. Screenshots of narrativity affordances.

The sentiments in the title and the project description also influence the success of a project. Researchers apply various methods to capture sentiments. Kim et al [47] designed questionnaires and divided project sentiments into 3 types: responsibility, guilt, and urgency. In the experiment of Wang et al [48], sentiments are measured using scales that include pride and guilt. Although questionnaires and experiments can measure sentiments more precisely, their limitation lies in the need for fully qualified participants; otherwise, accuracy may be compromised. Current techniques can be divided into 2 groups: Lexicon-based and machine learning methods. Agarwal et al [49] construct a domain-specific ontology with ConceptNet and WordNet, extract wordings with natural language processing (NLP), and convert them into a contextual polarity lexicon, classifying sentiments into positive, negative, and neutral ones. Similar lexicon-based methods are used by multiple research works [50-53]. Machine learning techniques are commonly used by extracting and crawling keywords, followed by classification. With such techniques, it is possible to analyze a relatively larger volume of texts and quantify the sentiments in them [54-56].



Previous studies report various findings on sentiments in titles and project descriptions. Zhang et al [57] conclude that the negative sentiments in project titles decrease the success rate, but if these words are in project descriptions, the success rate increases. Hou et al [18] and Zheng and Jiang [17] confirm that if the project description narratives are more positive, the project tends to succeed. We propose a hypothesis as follows.

> *Positive or negative sentiments of the project title and project descriptions significantly influence the success of a project.* [H1c]

We define visibility affordance (Figure 3) as the action possibilities through design and graphical elements, specifically referring to the number of photos in different sections (main page and progress updates). Studies have proven that photos and videos on social media are effective tools for establishing web-based identification and attracting the attention of online users [58,59]. Similarly, posting photos for medical crowdfunding projects can provide potential donors with more direct information, and photo types, such as the current status of patients and ID verification, can influence donor motivation and donor trust [14]. Wang et al [19] list the influence of different types of photos on the success of a project. They point out that photos related to the current health status and treatment status positively influence the success of a project, while those presenting treatment expenses negatively influence the success of a project. Thies et al [32] and Wu et al [15] conclude that the number of photos included positively influences the success of a project. Therefore, our hypothesis is as follows.

XSL•FO
RenderX

Figure 3. Screenshots of visibility affordances.

The number of photos included in a project positively influences the success of a project. [H2]

We define progress visibility (Figure 4) as the action possibilities offered by progress updates, including elements such as patient treatments, donation cash flows, etc. The progress updates of a project can be crucial for the following reasons. First, regularly posting updates establishes the credibility of the project organizer [15], because this shows that the project is transparent and that donors can track their donations. Second, platform managers can structure textual descriptions and use words that convey positive or negative sentiments to evoke donor empathy. Some prior academic research has already highlighted the impact of progress updates. Parhankangas and Renko [45] claim that a higher frequency of progress updates improves donor engagement, thereby enhancing the project's success. Ren et al [14] and Wu and Peng [60] have similar conclusions. Zhang et al [44] conclude that a high frequency of progress updates with negative sentiment words can significantly increase the success rate of a project. Wu and Peng [60] propose that sentiments in progress updates significantly influence donation amounts. Previous studies also suggest an inverted U-shaped relationship between progress update frequencies and project success. Thies et al [32] and Wu et al [15] mention that when the frequency is too high, donors can be negatively influenced by information overload. We develop 2 hypotheses as follows.

The frequency of progress updates has an inverted U-shaped relationship with the success of a project. [H3a]

Positive or negative sentiments in progress updates significantly influence the success of a project. [H3b]

XSL•FO
RenderX

Figure 4. Screenshots of progress affordances.

Methods

Ethical Considerations

This study did not require ethics board review because it did not involve direct interaction with human participants nor the collection of any private or identifiable information. All analyses were conducted on aggregated, anonymized data from public sources. This rationale is consistent with prevailing ethical research standards and common institutional practices for studies of this nature.

Overview

All data were extracted from disease-related crowdfunding projects on the Shuidichou platform. This study did not involve any surveys or experimental interventions; thus, no RCT registration number is applicable. Launched in July 2016, Shuidichou is China's leading platform for medical crowdfunding. By the end of 2020, the Shuidichou platform had facilitated over 37 billion RMB (approximately US $5.1 billion) in donations from more than 340 million contributors across 1.7 million medical aid projects, according to its publicly reported data.

According to company profile summaries on Tracxn.com, while GoFundMe remains the leading crowdfunding platform [31], Shuidichou specializes in health care, making it China's top platform and the world's third-largest. Backed by US $251 million from major investors like Tencent and IDG Capital, its scale and user base offer a strong basis for analyzing information affordances in crowdfunding success.

On Shuidichou, project pages follow a standardized format. Information—such as the project title, target amount, funds raised, timeline, beneficiary, initiating organization, project leader, and donation recipient—is shown on the right side. On the left, donors can navigate three sections: (1) Project Details, which outlines the patient's story, fundraising purpose, fund allocation, execution plan, and surplus handling; (2) Project Progress, which provides updates on the patient's condition and fund use; and (3) Donation Status, which tracks contributions from donors.

To ensure representative results, this study uses a sample of 1261 crowdfunding projects initiated between May 11, 2018, and September 5, 2024. Due to platform restrictions requiring additional authorization for long-expired projects, we extracted data from all publicly available projects as of November 11, 2024, without applying additional selection criteria. As such, we consider the dataset broadly representative of various disease types, while acknowledging that its demographic scope is limited to the Chinese population and that some projects may have been overlooked due to limitations in platform visibility. Among these projects, 1228 out of 1261 (97.38%) have already closed. Given that this study aims to understand how the platform's information management capabilities influence whether a project reaches its funding goal, and recognizing that projects may meet their objectives before the intended end dates, we chose not to exclude any projects based on their completion status.

Data Extraction

The Shuidichou platform restricts the direct extraction of comprehensive project data. To address this, research assistants manually collected project links to include all available projects for individuals with various diseases. Software engineers then used Python to scrape donor-visible data. Since patient gender,

XSL•FO
RenderX

age, and name are not explicitly displayed in a dedicated section, these variables were manually coded.

After removing duplicates, we conducted a comprehensive textual analysis to examine how affordances influence donation behavior across project titles, project descriptions, progress updates, fund purposes, fund use plans, and surplus fund use. All text elements were evaluated for length and sentiment using SnowNLP. Titles and project descriptions were the primary focus, as they conveyed crucial information to donors. We measured text length excluding spaces and punctuation to assess information density and generated dummy variables for age, gender, and disease presence using Python-based text-matching methods.

For sentiment analysis, we preprocessed text using the Jieba Chinese segmentation tool and generated sentiment scores with SnowNLP, which assigns values from 0 (negative) to 1 (positive). SnowNLP is a widely used tool for Chinese sentiment analysis, particularly effective for processing user-generated content such as social media and crowdfunding texts. Prior studies have successfully applied SnowNLP for sentiment analysis in Chinese platforms, demonstrating its suitability for this context [61]. We further analyzed the frequency of positive, negative, and degree words using the Hownet Chinese dictionary [62].

Variables and Models

Dependent Variables

The success of crowdfunding projects is measured in two ways: (1) success ratio: the ratio of the donations received to the funding goal. (2) success indicator: a binary indicator of whether the project met or exceeded its goal. Only 39 projects have fully reached their funding targets. Given the limited number of successful cases, we conducted bootstrap robustness tests for each model using *success_ind* as the dependent variable. Only models that passed the robustness test—indicating low bias and stable results—were considered.

Independent Variables

The main independent variable in this study is information affordance, comprising three components: (1) narrativity affordance, which examines how textual elements influence donation behavior through factors such as text length, word frequency, and sentiment scores; (2) visibility affordance, which explores the role of visual information, particularly the number of images in project descriptions and progress updates, in shaping donor engagement; and (3) progress affordance, which analyzes how the frequency and content of patient progress update impact donation patterns over time.

Control Variables

The control variables in this study are patient age, patient gender, and an indicator of whether the beneficiary is an individual or a group of recipients.

The multivariable models assess how narrativity, visibility, and progress affordances influence crowdfunding success. Each model is tested with both the success indicator and success ratio using regression analysis and U-tests. Given that each affordance includes distinct elements—such as textual length, which may be reflected in title length, story length, or other components—that may influence donor decisions differently, we analyze them separately to test for differential effects. Models 1-5 assess the individual impact of specific affordance elements on the success ratio, while model 6 takes a holistic approach to examine how narrativity, visibility, and progress affordances collectively influence success.

Models 1 to 3 focus on narrativity affordance, leveraging the textual richness of titles and project descriptions. Model 1 examines titles, model 2 analyzes project stories, and model 3 combines both, along with additional elements such as purpose statements, plans, and surplus fund use, to assess the impact of narrative elements on donation behavior. Model 4 captures visibility affordance by measuring the effect of image counts in project descriptions and progress updates. Model 5 addresses progress affordance by incorporating patient progress updates' frequency, length, and sentiment to explore how updates shape donation behavior.

Model 6 integrates the 3 affordances into a comprehensive framework. To assess the effect of each affordance type while controlling for the others, we aggregated related variables within each category. Narrative length is calculated by summing all relevant text fields. Demographic information—patient age, gender, and disease type—is combined into a composite index, with higher values indicating more demographic content. Wording valence is derived by subtracting total negative word counts from total positive word counts. Additionally, degree words and their intensity scores from both the title and project descriptions are summed to capture overall linguistic intensity.

Results

Descriptive Statistics

Overview

Only 39 out of 1261 projects (3%) successfully reached their funding goals. On average, the projects achieved only 18% of their target. To validate our success measures, we examined their correlations with key outcomes. Both the number of donations (R=0.5512 and 0.2359) and the amount received (R=0.5455 and 0.2167) show strong, significant correlations with success ratio and success indicator (all P<.001). Descriptive statistics are provided in Tables S2 and S3 in Multimedia Appendix 1.

Robustness Test

To ensure the statistical validity of our results, we conducted robustness tests for both the success ratio and success indicator models. Given the small number of fully successful projects, these tests help confirm that our findings are stable and not driven by random variation. Specifically, we used nonparametric bootstrapping with 1000 replications for models 1 to 6 using both dependent variables.

For the success ratio models, bootstrap analyses demonstrated generally stable coefficient estimates across models 1 to 6, with low bias (< ±0.05) and moderate standard errors (<0.10). However, in model 2, the sentiment score calculated using the

XSL•FO
RenderX

SnowNLP algorithm exhibited substantially inflated standard errors (up to 30) and high bias, indicating instability for this predictor. Similarly, in model 3, the indicator for whether the project beneficiary is an individual showed large standard errors (up to 1464.41) and considerable bias, likely due to model complexity and multicollinearity among narrative-related features. These unstable predictors were excluded from interpretation, while the remaining estimates across models 1 to 6 demonstrate solid robustness in explaining the success ratio.

In the success indicator models, bootstrapping with 1000 resamples for models 1 to 3 (focused on narrative affordances) revealed substantial statistical instability. Several predictors showed significant bias (eg, exceeding ±1.0 in model 1 and reaching up to $\pm 1.78\times10^{13}$ in model 3) and substantial standard errors (up to 4.65×10^{14}). Consequently, estimates from these models are excluded from further interpretation. In contrast, bootstrap analyses for models 4 to 6, which examine visual, progress, and combined affordances, produced substantially more stable results. Most key predictors in these models exhibited minimal bias (< ±0.05) and moderate standard errors (<0.10), supporting the reliability of these estimates. Therefore, models 4 to 6 are retained for interpretation, given their demonstrated stability.

Collectively, these analyses demonstrate that the majority of models in this study produce stable and reliable estimates, with specific unstable predictors identified and excluded from interpretation. To further assess the robustness of the success ratio models, we conducted a sensitivity analysis by re-estimating the models after excluding projects that fully met or exceeded their fundraising goals. This approach tested whether these extreme cases disproportionately influenced the results. The findings remained consistent, with similar coefficient magnitudes and significance levels, and only minor fluctuations were observed. All results based on the filtered dataset are reported for transparency (Tables S4-S6 in Multimedia Appendix 1). Together, the bootstrap and sensitivity analyses provide a comprehensive assessment of model reliability, while acknowledged limitations ensure cautious, evidence-based interpretation.

Regression Results

Overall, we present 6 models using the success ratio (Tables 3-5) and success indicator (Tables 5 and 6). U-shaped relationships are visualized in Figures 5-7.

XSL•FO
RenderX

Table 3. Regression results for success ratio (models 1-3). This table presents regression results for narrative affordance models (models 1-3) with success ratio as the dependent variable. Model (a) shows main effects; model (b) adds U-tests for significant predictors.

[a]Not applicable.

Table 3 presents the regression analyses for the narrativity affordance models (models 1-3), using success ratio as the dependent variable. T-values are reported with *P* values in parentheses. Story sentiment (model 2) and the beneficiary indicator (model 3) are marked as "N/A" to reflect their exclusion from interpretation due to substantial bias found in robustness tests. Model (a) shows the main effects, while model (b) includes U-tests for variables significant in model (a). U-tests (quadratic terms) are only estimated for continuous predictors. For binary variables, quadratic terms are perfectly collinear with the original variable and therefore omitted from the models.

For H1a, our findings reveal that the impact of text length on success varies by text type, providing partial support for H1a. Surplus use length shows a significant inverted U-shaped impact on the success ratio (*P*=.005), but not for other texts (Figure 5). The main effects suggest that longer text generally leads to greater success. Longer titles (model 1a: *P*=.04; model 3a: *P*=.03) and more detailed surplus fund explanations (*P*=.03) improve the success ratio, while longer fund purpose descriptions (*P*=.006) reduce it.

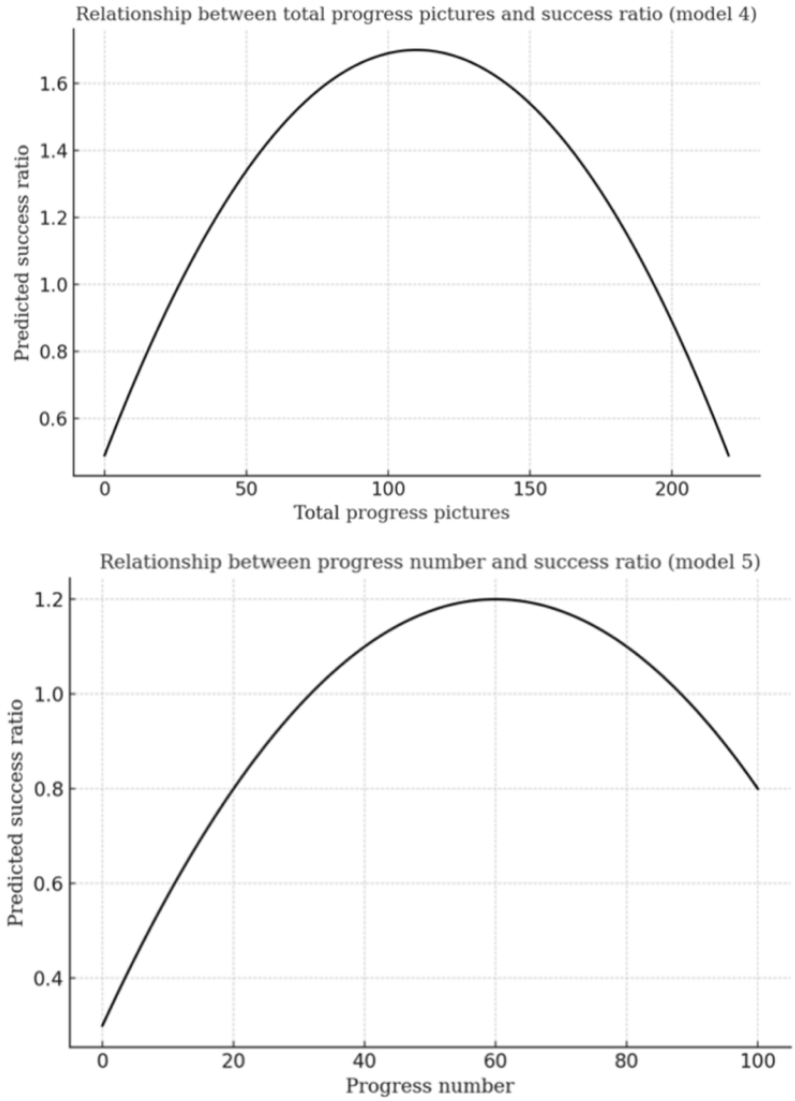
Figure 5. U-test results for model 3.



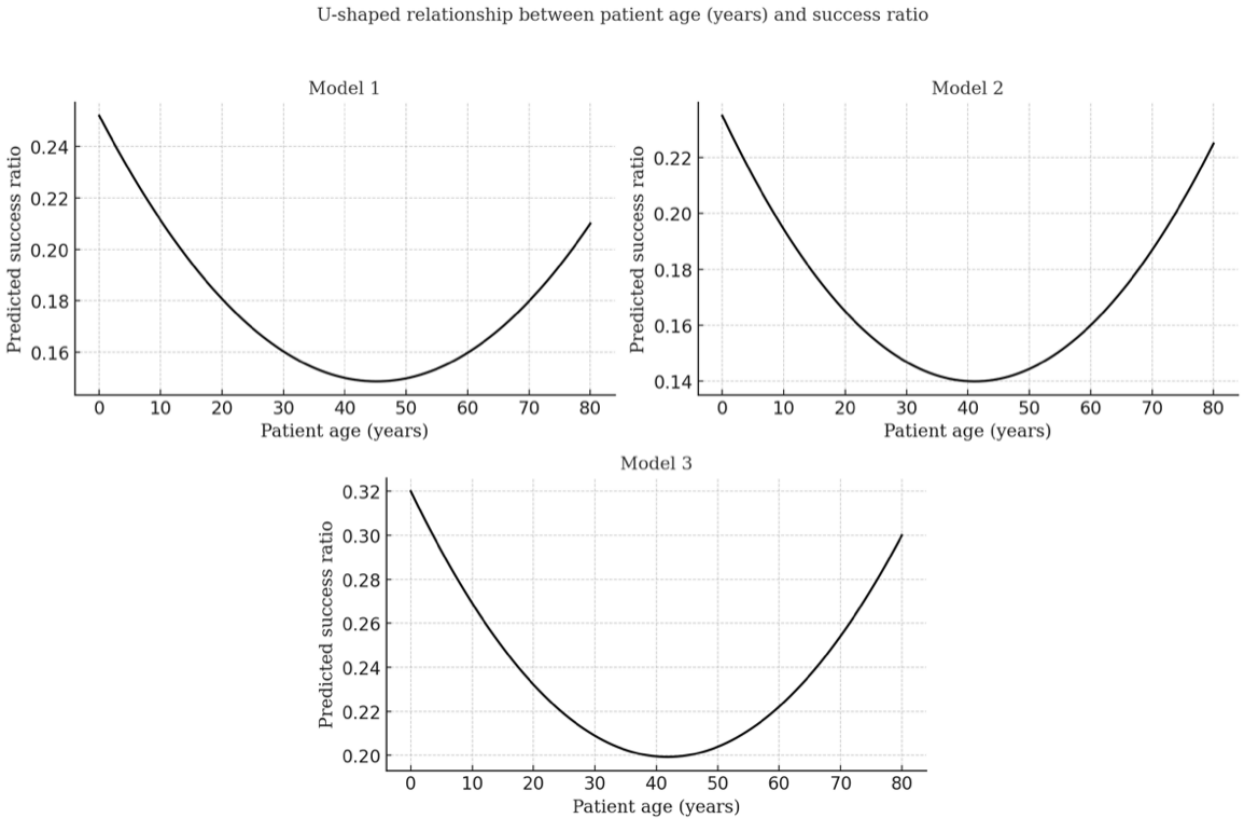
Including demographic information does not consistently enhance project success; only when the title includes a disease (model 1a: *P*=.01; model 3a: *P*=.003) does it show a significant positive effect, offering partial support for H1b. H1c is largely supported. A more positive-phrased fund use plan (*P*<.001) significantly improves the success ratio, with a U-shaped pattern (*P*<.001) suggesting moderate sentiment is more effective than extremes (Figure 5). In contrast, greater positivity in titles (*P*=.02) reduces the success ratio.

The results support H2, showing that a higher number of progress update images (*P*<.001) is associated with greater success across both outcome measures, though this relationship follows an inverted U-shaped pattern. Progress-related models confirm an inverted U-shaped relationship between update frequency (*P*<.001) and project success, supporting H3a (Figure 6). Although frequent updates enhance both the success ratio and the likelihood of success, the effect diminishes at higher frequencies. H3b is not supported, as progress update sentiment shows no significant effect on project success.

We conducted interaction analyses only when the corresponding main effects were significant to avoid testing interactions without meaningful baseline effects (Tables S7 and S8 in Multimedia Appendix 1). The success ratio, including gender in the title (*P*=.03), positively affects success, but this effect weakens when the patient is male (*P*=.01). The positive effect of story length is reduced when age is mentioned in the title (*P*=.01), and the negative effect of negative words in the story also diminishes under the same condition (*P*=.02). Moreover, positive sentiment in the story description (*P*=.04) amplifies the positive effect of story length and mitigates the negative effect of negative words. Degree words in the story (*P*=.03) also moderate the impact of negative language, reducing its negative effect when more degree words are present, but enhancing it when the intensity of degree words is higher (*P*=.03).

XSL•FO
RenderX

Figure 6. U-test results for models 4 and 5.



Additionally, for success ratio, interaction analysis for model 4 reveals a marginally significant positive effect of total progress pictures (P=.05). This positive effect weakens for older patients (P=.045) but strengthens when the project supports multiple beneficiaries compared with a single patient (P<.001). Model 5, focusing on progress updates, shows no significant effect on the success ratio but does influence the likelihood of success. Negative sentiment in progress updates (P=.01) reduces success likelihood, especially in single-beneficiary projects (P=.03) though more updates mitigate this effect (P<.001).

Beyond hypothesis testing and interaction analysis, control variables show consistent effects. Projects with older patients (models 1-6) and individual beneficiaries (models 1 and 2) tend to have lower success ratios. Quadratic tests reveal a U-shaped relationship for patient age across affordances (models 1-3), indicating that both younger and older patients see higher success than middle-aged ones (Figure 7).

The final model integrates all affordances into a cohesive framework. When controlling for all factors, the inclusion of demographic information in narrative text marginally improves the success ratio (P=.09). A higher number of progress updates (P<.001) significantly enhances both the success ratio and the likelihood of success, with an inverted U-shaped pattern indicating diminishing returns at higher frequencies—consistent with earlier models. Patient age remains significant (P=.003), with younger patients more likely to succeed. The success indicator further suggests that more project description images are associated with lower success.

Additional Analysis

The XGBoost (extreme gradient boosting) models were implemented for both dependent variables to capture complex relationships between predictors. The regression model demonstrated strong predictive performance, with a root mean square error of 0.00083, indicating a close alignment between predicted and actual donation outcomes. The classification model achieved 91% accuracy, effectively distinguishing successful projects from unsuccessful ones.

To interpret the contributions of individual features to success predictions, we conducted SHAP (Shapley additive explanations) analysis for the success ratio. The analysis identified donation frequency and donation amounts as the most influential predictors, with mean absolute SHAP values of 0.287 and 0.025, respectively. This aligns with expectations, as a higher number of contributions and greater total donations naturally increase the likelihood of success. Beyond these factors, patient age emerged as the second most significant predictor (0.084) (Table 7), highlighting a demographic bias where younger patients tend to receive stronger donor support.

Table 7. Shapley additive explanations (SHAP) analysis results.

Variable	Mean absolute
Patient age	0.0841
Title gender	0.0180
Title length	0.0092
Patient gender	0.0007
Progress picture numbers	0.0006
All other variables	0

Discussion

Primary Findings

Key findings reveal nuanced effects of textual content: longer, informative titles boost success, while the impact of story length varies by context. Moderate detail in surplus fund explanations and explicit demographic cues, particularly disease and gender (female), enhance appeal. This finding directly contradicts the finding of Wang et al [42] regarding the negative impact of female gender on the success of crowdfunding projects. Emotional framing with negative titles and moderately positive fund use plans engages donors effectively. Visual and progress updates predict success through positive inverted U-shaped relationships. Critically, when controlling for all affordances simultaneously, only the frequency of progress updates

XSL•FO
RenderX

maintains a robust, inverted U-shaped positive effect. Finally, patient demographics, especially age extremes, significantly improve success, underscoring the importance of multimodal analysis in understanding crowdfunding outcomes.

This study analyzes 1261 health-related crowdfunding projects from Shuidichou to examine how narrativity, visibility, and progress affordances collectively influence project success. After removing models 1 to 3 for the success indicator due to failed robustness tests, we found highly consistent outcomes between the 2 success measures for the visual, progress, and combined affordance models.

Narrativity plays a critical role in crowdfunding outcomes. While prior research suggests an inverted U-shaped relationship between text length and success [14,16,44], our findings show no such pattern for title or story length, instead indicating a more nuanced effect. Specifically, longer titles consistently improve project success, suggesting that donors favor more informative titles. Given their generally short length (max 13 characters), even small increases may have a noticeable impact. The influence of story length appears context-dependent. Its positive effect weakens when age appears in the title, suggesting informational redundancy may lessen effectiveness. Conversely, a more positive tone in the story strengthens the effect, implying that longer narratives are more impactful when framed optimistically. This may be because a positive tone helps sustain engagement in longer texts by reducing emotional fatigue. In emotionally charged contexts like medical crowdfunding, optimistic framing can also convey resilience and hope, making the project appear more credible and worth supporting.

Beyond the title and main description, the length of surplus fund explanations matters—donors appear to value how extra funds will be used. Moderate detail can build trust and encourage donations [63]. Extending prior research, we find that overly long fund purpose descriptions negatively impact success, possibly because donors assume funds will support severe cases or due to reduced patience with lengthy text [64]. Regarding demographic information in textual content, our findings partially align with prior research. Titles mentioning disease positively influence success [44], likely because they clearly communicate the medical issue, drawing attention and encouraging users to click and engage with the project. However, the inclusion of other demographic details showed no significant effect, failing to replicate findings from previous studies [12,13,18,44,46].

The emotional tone of textual content significantly shapes project success [17,18,57]. Consistent with prior research, a negative tone in titles is effective in increasing donations [44], while positive sentiment in fund use plans enhances success. A U-shaped relationship between plan sentiment and success further suggests that moderate emotional tone may be more persuasive than extreme positivity or negativity. This may indicate that overly cheerful language in serious medical funding explanations may come across as insincere or discordant, whereas a moderately positive tone can convey hope and resilience without downplaying the gravity of the situation. Striking this balance may foster empathy and trust, highlighting the importance of context-appropriate emotional framing. Although overall story sentiment was removed from the robustness test due to potential bias, a higher number of negative words still reduces success. This effect is mitigated by age references in titles or the presence of positive and intensifying language in the story, though a stronger degree of intensity slightly amplifies it. Interestingly, while donors may respond to a negatively framed title, they seem less receptive to a high concentration of negative words in the story. This contrast may stem from donors being drawn in by urgency in titles but feeling overwhelmed by negative narratives in the main story.

Although prior research suggests images may have a stronger impact than text [18], we find no such effect for project description images. In contrast, more images in progress updates enhance project success, though their effectiveness declines when used excessively. The relationship also varies by context, with stronger effects in projects for individual beneficiaries and weaker effects when the patient is older. This may suggest that while donors value helping more people, moderate image use is effective when focused on a single recipient, as it may evoke stronger, individually oriented empathy. In contrast, for older patients, donor preferences may favor younger individuals, making additional images less impactful. Similarly, the number of progress updates supports project success, with an inverted U-shaped pattern—while frequent updates generally encourage greater donations [65], excessive updates may reduce their effectiveness. This highlights the importance of both visual and textual progress affordances, though their impact diminishes when overused.

Departing from prior work that isolates individual factors, our study provides a multimodal analysis of how narrativity, visibility, and progress affordances jointly influence crowdfunding success, capturing the complex dynamics of donor behavior. Although a large body of prior work highlights the significant role of narrativity affordances [12-17,20], our findings differ. After accounting for visual and progress-related cues, most narrative effects become insignificant. Only the inclusion of demographic information shows a marginal positive impact. Similarly, we find no significant effect from visual elements. Notably, progress cues remain strong predictors of project success, with an inverted U-shaped relationship observed. This suggests that in the context of similarly structured crowdfunding projects, donors may rely most on progress updates to guide their decisions. Frequent updates likely signal transparency and build trust, enhancing donor motivation, while excessive updates may lead to fatigue or reduced engagement.

The final research question integrates patient demographic characteristics into the discussion. Building on prior research, this study validates and extends the findings of Ba et al [20] and Zhang et al [23], which found that projects featuring younger patients attract more donations and better meet funding goals across affordance types. Similar to Zhang et al [23], we find that older patients also receive higher donations than middle-aged ones. This pattern underscores the preference for supporting beneficiaries at the extremes of the age spectrum. Furthermore, this study builds on Ba et al's findings [20] by using advanced techniques, including XGBoost and SHAP models, to examine the nuanced role of patient age. These models consistently identify age as a key predictor of success

XSL•FO
RenderX

across all 3 affordance dimensions, reinforcing the importance of demographics in crowdfunding outcomes. Additionally, projects supporting individual beneficiaries appear to weaken the influence of narrative and visual features, suggesting these affordances are more effective in projects aiding multiple recipients.

Practical Implications

Our findings provide practical guidance for patients and platform managers on structuring crowdfunding projects to maximize donations and funding success. First, our multimodal analysis shows that projects featuring younger or older patients and those supporting multiple beneficiaries attract more donations. Therefore, project descriptions should emphasize these demographic factors. For example, a project supporting patients with blood-related diseases shares the story of both a child and a 29-year-old mother. Focusing on the child's story could attract more donations, so the project might prioritize highlighting children over detailing the mother's story, thereby maximizing benefits for all beneficiaries.

Then, for projects benefiting individual patients, platform managers might consider grouping similar cases to improve visibility and broaden appeal. For example, a patient aged 53 years with Parkinson disease may struggle individually but could gain enhanced visibility and attract more donors by being grouped with other Parkinson patients, increasing the likelihood of meeting fundraising targets.

Beyond demographic insights, projects should use longer titles that specify the disease and convey urgency in a negative tone, omitting age details. Generic titles like "Partnering with the Very Sick to Get Through Difficult Times" lack specificity and urgency. Instead, platforms could guide projects to include the specific disease, rather than vague terms such as "very sick." Moreover, replacing optimistic wording, such as "partnering," with more urgent language can emphasize the severity. For example, titles such as "A Female with Cancer Needs Urgent Help," which reached its funding goal of 80,154 CNY (US $11,694), or "Boy's Leukemia relapsed twice, restarting the fight of survival," which achieved its funding goal with 800,000 CNY (US $114,555). Well-framed titles can more effectively emphasize the urgency of the need and drive greater engagement.
