The interaction suggests that the effectiveness of a title depends on demographic factors such as gender and beneficiary type. Titles with gender details generally have a positive impact, but are less effective for male patients or individual beneficiary projects. To compensate, these projects could emphasize visual updates or progress-related details to enhance engagement. Similarly, including patient age in titles weakens the positive effect of narrative length, especially for male patients. To maintain donor interest, projects should omit age details and focus on emotionally compelling or progress-oriented narratives. Platforms should also ensure surplus fund use plans are clear, while avoiding overly lengthy or repetitive explanations. Tailoring strategies to patient characteristics and optimizing key narrative elements can maximize donor response and crowdfunding success. Importantly, active and transparent treatment updates are crucial, but should not be overly frequent. Our findings show that, when all types of information are available, donors rely most on progress updates. Project managers should therefore encourage patients to maintain regular updates while avoiding excess that could dilute donor attention.

Our findings are meaningful and applicable across diverse crowdfunding platforms. Although some might argue that Shuidichou's results are limited to a Chinese context, we emphasize that the types of information examined (textual narratives, visual elements, and progress updates) are universally present across platforms. Crucially, our analysis demonstrates that when all affordances are considered simultaneously, the impact of narrative elements diminishes, while the strong positive effect of progress updates persists. This result underscores the importance of examining information integratively, as donors typically encounter all these elements together. Unlike previous studies, our findings distinctly show that dynamic elements (eg, update frequency) have a stronger influence on donor decisions compared with static narrative elements, highlighting a vital direction for future crowdfunding research.

Overall, all findings offer practical guidance for both patients and platform managers. In general, patients should openly share details to build trust, while platform managers should be informed about new research related to crowdfunding practices. Our findings highlight the importance of collaboration between these 2 parties in improving the effectiveness of crowdfunding. The strategic application of affordances can help projects optimize donor engagement and increase the probability of success.

Limitations and Future Research

While this study provides valuable information on the multimodal impact of information affordance on donations, several limitations should be noted. Due to time constraints and limited access to the data of the Shuidichou platform, we could not extract all health-related projects automatically. Instead, project selection required manual link extraction, potentially leading to omissions within the selected timeframe. To mitigate this, multiple research assistants manually extracted links by navigating from the top to the bottom of the platform pages. Nonetheless, we acknowledge the possibility of omitted cases. Additionally, during extraction, we observed that the platform predominantly features severe illnesses such as cancer or trauma from events like fires, while chronic conditions (eg, vision impairment) are rarely represented. This suggests our results may not fully generalize to chronic disease projects.

Although the initial aim was to extract patients' names and their relationship with the project creators, these details were not accessible through Python-based methods, limiting our analysis of these personal connections. Additionally, we retained model 2 and model 3 despite each containing one variable with moderate bias to preserve the integrity of the simultaneous information environment that donors encounter on crowdfunding platforms. These variables were excluded from interpretation to mitigate potential bias, and an additional sensitivity analysis was conducted to verify the overall stability of the results. Nonetheless, we acknowledge this as a potential limitation.

XSL•FO
RenderX

Beyond these limitations, this study opens several avenues for future research. While our multimodal approach incorporates visual information through numeric counts, deeper analysis of image content—such as facial expressions or the number of people—could provide richer insights. Further investigation is also needed to understand why donors respond to specific cues, such as disease references in titles or gender mentions in descriptions. Survey-based or scenario-driven experiments may help identify psychological mechanisms that mediate these effects. Importantly, we find that progress updates exert the most consistent influence on project success, even after controlling for other affordances. Future research could explore which types of progress updates (eg, medical and emotional) are most effective in engaging donors.

This study highlights the complexity of crowdfunding dynamics, showing that text length and emotional tone can have contrasting effects depending on context. Studying elements in isolation is insufficient. Future work should adopt a holistic approach, examining how donors interact with the overall platform environment to understand what drives donations and how platform design shapes donor behavior.

Abstract

Background: Coherence across sites in multicenter datasets is one substantial data quality dimension for reliable health data reuse, as unexpected heterogeneity in data can lead to biases in data analyses and suboptimal generalization of results.

Objective: This work aims to characterize and label the data coherence across sites in the first European multicenter dataset for cancer prevention in people and early detection among the homeless population in Europe: coadapting and implementing the health navigator model. This dataset emerged to enable research to address disparities in health challenges and health care access due to barriers such as unstable housing, limited resources, and social stigma in people experiencing homelessness.

Methods: The dataset comprises 652 cases: 142 from Austria, 158 from Greece, 197 from Spain, and 155 from the United Kingdom. All participants fit classifications from the European Typology of Homelessness and Housing Exclusion. This longitudinal study collected questionnaires at baseline, after 4 weeks, and at the end of the intervention. The 180-question survey covered sociodemographic data, overall health, mental health, empowerment, and interpersonal communication. Data variability was assessed using information theory and geometric methods to analyze discrepancies in distributions and completeness across the dataset.

Results: Substantial variability was observed among the 4 pilot countries, both in the overall analysis and within specific domains. In particular, measures of health care empowerment, quality of life, and interpersonal communication demonstrated the greatest discrepancies among pilot sites, with the exception of the health domain. Notably, Spain exhibited the most pronounced differences, characterized by a high number of missing values related to interpersonal communication and the use of health care services.

Conclusions: Health data may be comparable across the 4 countries; however, substantial differences were observed in the other questionnaires, requiring independent, country-specific analyses. This study underscores the heterogeneity among people experiencing homelessness and the critical need for data quality assessments to inform future research and policymaking in this field.

Introduction

Homelessness is a complex and multifaceted phenomenon, encompassing more than the mere absence of a physical dwelling. It signifies a state of profound vulnerability and social exclusion, characterized by a lack of stable, safe, or adequate housing [1-3]. The experience of homelessness is deeply intertwined with a range of social, economic, and individual factors, including poverty, unemployment, mental health challenges, substance use, and domestic violence. People experiencing homelessness constitute a highly heterogeneous group with varying backgrounds, needs, and challenges, encompassing socioeconomic, cultural, physical, and mental health aspects, as well as historical and geographical contexts [4,5]. This inherent diversity within the group of people experiencing homelessness, coupled with inconsistent definitions and methodological variations in data collection across countries, makes it exceedingly challenging to accurately estimate the true prevalence of homelessness. Despite these complexities, it is estimated that at least 895,000 individuals in Europe are experiencing homelessness on any given night, living rough or in temporary or emergency accommodations [6].

Research consistently demonstrates substantial health disparities between people experiencing homelessness and the housed population. Homelessness is associated with poorer health outcomes, including premature mortality, partly due to barriers to accessing health care [7-9]. Furthermore, people experiencing homelessness experience higher cancer morbidity, lower cancer screening rates, later-stage cancer diagnoses, and poorer cancer-specific health outcomes compared to the housed population [10], with cancer being the second most common cause of death among people experiencing homelessness [11]. Among the most relevant factors, people experiencing homelessness usually report low health literacy, especially regarding cancer [12], and they tend to experience barriers to accessing fragmented cancer prevention and community health services [13].

Research interest in improving the health status and cancer prevention efforts for people experiencing homelessness is growing, leading to the implementation and piloting of innovative health care strategies, such as the patient navigation model and the patient empowerment model [14,15]. In the patient navigation model, patient navigators, defined as health care professionals or peers specializing in care coordination, case management, and reducing barriers to care, play a crucial role in guiding individuals to overcome obstacles and access health care services in a timely manner [16]. This includes facilitating access to preventive care and health promotion programs, which have been shown to improve their users' health outcomes and care satisfaction [17]. The patient empowerment model focuses on equipping individuals with the knowledge, skills, and confidence to take an active role in managing their health and navigating the health care system [18,19]. This approach emphasizes self-efficacy and shared decision-making, empowering patients to make informed choices about their health care and advocate for their needs.

Within the CANCERLESS project, a multicenter study funded by the European Union, critical components of the patient navigation and patient empowerment models have converged into the novel health navigator model. This model was co-designed with input from both people experiencing homelessness and health and social care professionals working with them as well as those working in primary care settings. The project piloted this model in 4 European countries to assess its effectiveness in connecting people experiencing homelessness with cancer prevention services. To the authors' knowledge, CANCERLESS is the first multicenter study involving people experiencing homelessness from different countries, marking substantial progress in research within this field. However, challenges such as data variability, missing data (missing completely at random and missing not at random), and fragmented in care may introduce biases in the results [20,21].

Building on the premise that various studies have highlighted the inherent heterogeneity within this population [22,23], this diversity becomes even more pronounced when research conducted in different geographical and cultural contexts is considered. While such variability is evident, it should not be regarded solely as an intrinsic characteristic of the data but must be systematically quantified. This necessity arises because a portion of this heterogeneity may stem from biases introduced either by differences among the population subgroups studied or by external factors unrelated to the participants, such as variations in the conditions under which the interventions were conducted. If left unaddressed, this heterogeneity could lead to erroneous interpretations of the results and, consequently, to inaccurate conclusions that undermine the validity of the analysis [24-26]. Several techniques aim to detect variability among samples and approach the data quality (DQ) of datasets [27]. Among them, spatial DQ techniques [28] have been developed to evaluate the differences between the probability distribution function from multiple sources, and these techniques have been demonstrated to deal with sets of heterogeneous data, including multivariate and multitype. Additionally, these are valuable tools for dealing with DQ issues, such as missing values among the datasets, which provide metrics that quantify this heterogeneity and outliers.

Given the above considerations, an exhaustive DQ analysis is needed for several reasons. First, this is key to extracting information about the participants' characteristic distribution for each pilot site. Second, to examine the differences between these distributions and obtain knowledge about the status of homelessness in different European countries. Finally, these analyses allow us to understand if the information gathered can be used as a different pilot-specific dataset. Thus, this work aims to examine the heterogeneity between the people experiencing homelessness data in 4 different European countries and provide quality metadata while delivering a

XSL•FO
RenderX

curated CANCERLESS dataset to extract common knowledge and conclusions.

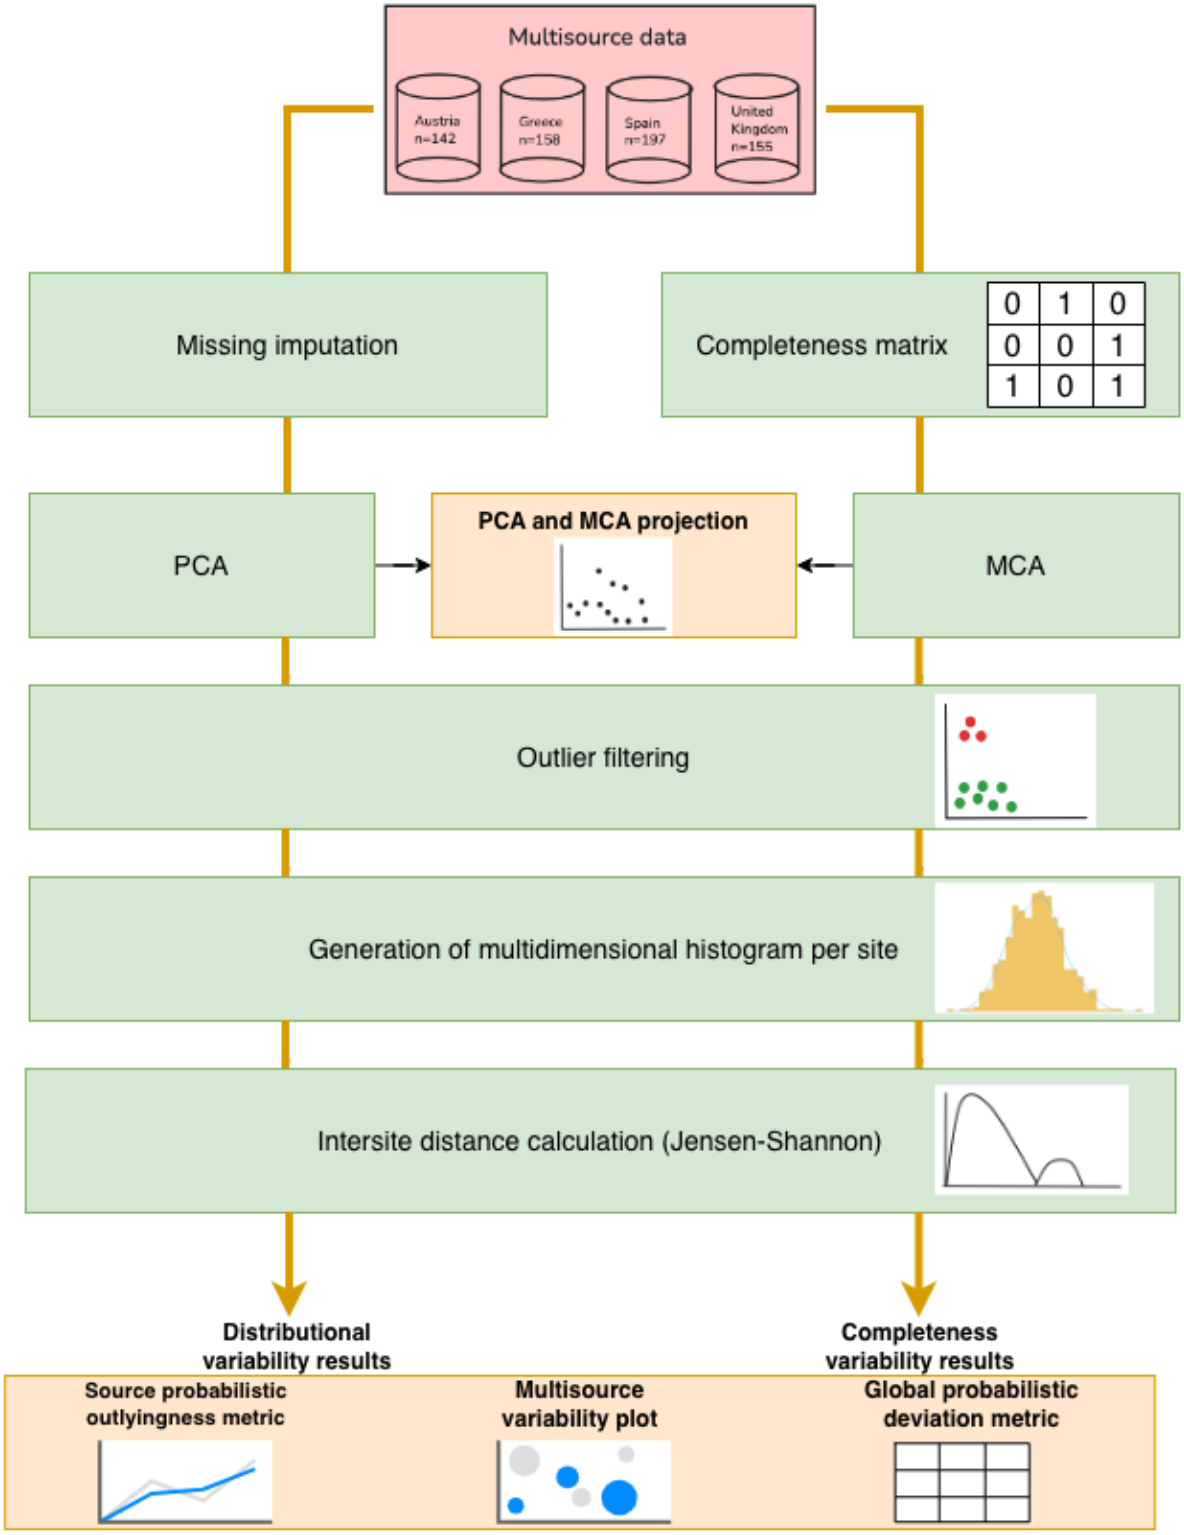
Methods

Dataset Conformation

Data collection was carried out between June 2022 and November 2023. A total sample of 652 people experiencing homelessness was collected: 142 from Austria, 158 from Greece, 197 from Spain, and 155 from the United Kingdom. Participants were included if they were at least 18 years of age and experiencing homelessness, fitting any classification of the European Typology of Homelessness and Housing Exclusion [29]. Participants were excluded if they could not provide informed consent, had difficulties interpreting the aim of the research, did not accept to participate in the study, if they had a known cancer diagnosis or have had cancer previously, and the intervention or study would harm them.

Data used in this study were collected as part of the CANCERLESS project. The study followed a pre- and postdesign, but in this specific analysis, we present only data collected at baseline (T0), that is, before each individual started the intervention. This approach allows us to see the characteristics of each pilot at the beginning of the intervention and, subsequently, to observe the initial differences that will serve to perform a correct analysis of the data.

The questionnaires included in the database were the following: EQ-5D-5L to measure self-reported health-related quality of life [30], Health Care Empowerment Questionnaire (HCEQ) to assess users' empowerment related to health care [31], Brief Symptom Inventory-18 to measure psychological distress [32], and the Person-Centered Coordinated Care Experience Questionnaire to evaluate several domains of person-centered coordinated care from the perspective of the user [33]. Additionally, specific-purpose questions were included regarding the following information: sociodemographics, health literacy, active diagnosis, medication taken, risk behaviors, healthy lifestyles, and previous use of health care services. Multimedia Appendix 1 provides the complete list of the T0 questionnaires.



The T0 questionnaire was administered to all pilot participants. A coordinator at each pilot site recorded the responses. Later, the information was uploaded by the research team of each pilot to a digital platform created by this research consortium called CANCERLESS Interventions Data Management Application, which stores the data in a digital format. This platform also provides feedback to the coordinator through metrics and aggregated information.

Methods—Data Quality Workflow

Figure 1 shows the methodology followed in this study. The workflow is divided into 2 blocks for assessing the intersite coherence, one across the information captured in the questionnaires and the other across their completeness patterns. The main difference lies in the preprocessing step: for the questionnaire, imputation is performed, whereas for completeness, a matrix of fault categories is used. Subsequently, a dimensional reduction technique was applied according to the analysis performed—see the specific details in the following subsections. The following steps were common to both analyses: calculating outlier filtering, histogram application to represent the probability density function of the dataset, followed by flattening, normalization, and column stacking, to be used as input for the information theory–based DQ metrics. The technique for evaluating DQ and response variability across the pilot studies involved transforming each dataset into a probability distribution, then applying comparative metrics to measure similarity and identify missing information and therefore the level of nonoverlapping between them. The technique relies on the calculus of a simplex, multidimensional generalization of a triangle, conserving the intersite dissimilarity where the centroid represents an informed average distribution of the sources. Subsequently, 2 metrics were computed, constrained to the Jensen-Shannon distance: the source probabilistic outlyingness (SPO), measuring the dissimilarity of each source to the average distribution; and the global probabilistic deviation (GPD), gauging the degree of global variability among the sources [34,35]. The derived metrics, that is, GPD and SPO, are bounded between 0 and 1, so 0 means equal distributions and 1 means nonoverlapping. For the SPO, a value of 0 denotes the closest possible approach to the centroid, while for the GPD, it indicates the least data variability. Finally, visual plots of these metrics are shown to compare the variability results in a visual form between the different pilots. All these steps were later used to extract GPD, SPO, and multisource variability (MSV) for the global dataset and each section inside the questionnaire.

XSL•FO
RenderX

Figure 1. Overview of the methodology to obtain data quality metrics for the CANCERLESS dataset. Two types of analysis are conducted, with shared steps. For the complete dataset, missing values are imputed using iterative imputation techniques. In the missing data analysis, a matrix is built with values indicating 0=ordinary, 1=dependent, or 2=nonmissing. Dimensionality reduction is applied: PCA for complete data and MCA for missing data. After preprocessing, histograms for each country are normalized and combined to calculate distances from the centroid, yielding global probabilistic deviation, source probabilistic outlyingness, and multisource variability values. For specific dataset sections, the same process is applied to each subset. MCA: multiple correspondence analysis; PCA: principal component analysis.

Questionnaire Information

This approach has been used following a top-down methodology analyzing multivariate to univariate data, that is, to compare the whole T0 questionnaire and its sections. We excluded textual and multiple-choice options from the analysis since there was a high number of missing data and a much smaller number of category selections per question than the total number of choices, implying minimal variability with no final effect on the analysis. First, we preprocessed the data to transform

XSL•FO
RenderX

categorical text into numerical variables along with an iterative imputation method [36,37]. This method performs multivariate imputation through chained equations. Initially, all missing values are filled with simple univariate estimates (eg, the feature's mean). Thereafter, each incomplete variable is regressed on the other features using a Bayesian ridge estimator to predict its missing entries. Predicted values replace the initial estimates, and this process cycles through all variables for a predefined number of iterations or until convergence of the imputed values is reached.

Subsequently, to obtain a multivariate representation, we applied principal component analysis (PCA) [38] to reduce the dimensionality of the original 130-variable space to 3 dimensions and select the top 20 variables with the highest explained variance. Following this, we segregated the data by pilot source and conducted outlier filtering using the local outlier factor method [39], removing outliers specific to each pilot site. Finally, we computed a 3D histogram for each pilot, using 10 bins for each dimension, which were then used as the input in the method.

Completeness Patterns

Regarding the comparison of patterns related to blank responses or missing data, the T0 questionnaire comprises questions with varying levels of branching—specific queries are intended to be answered only if certain conditions from prior responses are met (eg, the question about the number of cigarettes smoked daily is only relevant if the participant declares themselves as a smoker in the preceding questions). Consequently, we distinguished between "not applicable missing" and ordinary missing data, which was applied using a predefined rule set. Once the rule was defined, it was applied to the dataset, obtaining a missing matrix and transforming the values into one of these categories. After the transformation, we applied the multiple correspondence analysis (MCA) [40] technique to reduce the dimensionality of the data and select the top 20 variables with the highest explained variance, thus identifying the most influential questionnaires since MCA is a specific technique to reduce dimensionality for categorical values. Next, the local outlier factor methodology was applied to remove outliers over the data on the reduced space. Finally, the multidimensional histogram that was flattened and normalized to be used as GPD's input was created.

Exploratory Analyses

The exploratory analyses of the study are presented using the following methods. First, biplots with 2 dimensions are generated after the original data undergo dimensionality reduction either using PCA or MCA. Additionally, the GDP methodology incorporates the MSV plot [35], where the 2 or 3 components with the highest variances are projected using multidimensional scaling. In the MSV plot, sources are represented as circles or spheres, and the distance between them indicates the distance between their distributions, based on the Jensen-Shannon distance, with the circle's radius representing the number of cases.

To conduct this analysis, we used the Python 3 programming language [41] and the NumPy, pandas, scikit-learn, and prince libraries [42-45]. The experimentation notebooks, including a Python version of the MSV metrics and visualizations, are available on GitHub [46].

Ethical Considerations

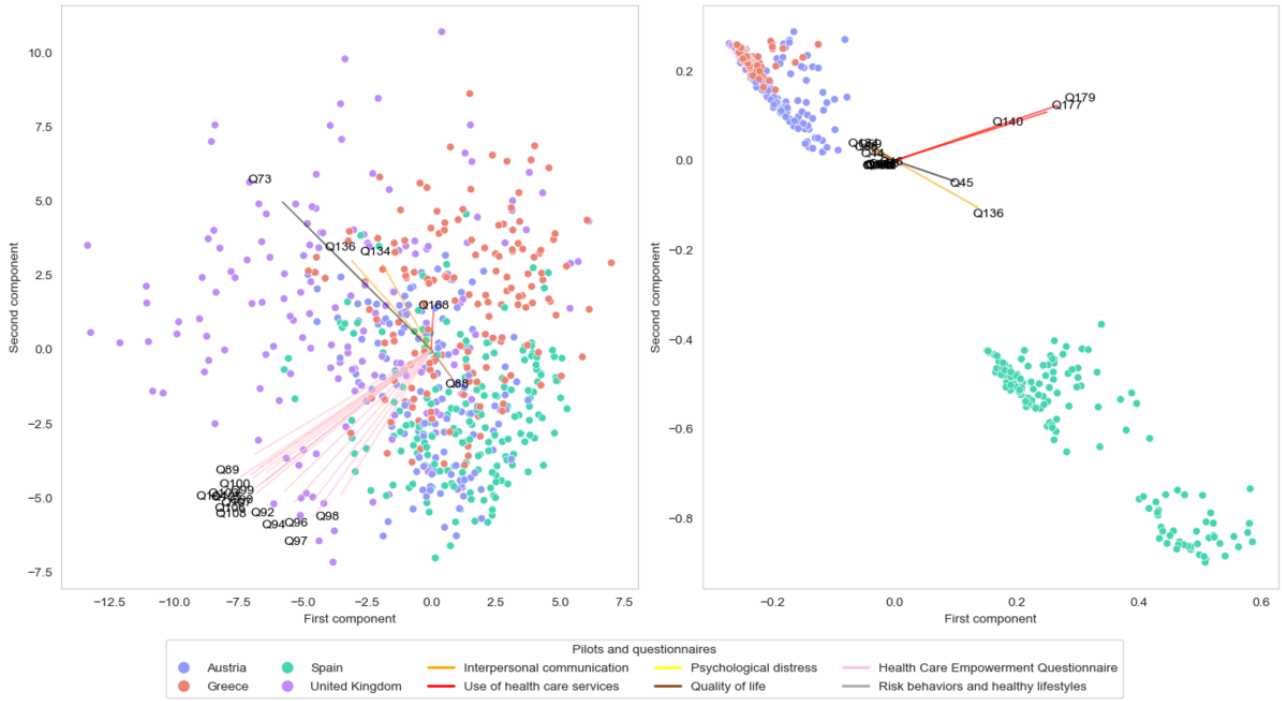
The study was approved by the ethics committee of the Medical University of Vienna (1702/2021), which served as the lead ethics committee for the project. Additionally, each pilot site in the 4 countries secured approval from their respective ethical review boards or institutions before commencing data collection, and Universitat Politècnica de València also obtained approval from an ethics committee, specifically for the management of participants' personal data. Prior to conducting any data collection, participants were given an information leaflet detailing the study's purpose and were allowed to ask questions to help them decide on their participation. It was emphasized to all participants that their involvement was entirely voluntary, and they could opt out of answering any questions that made them uncomfortable. Participants were explicitly reassured that declining participation would not negatively impact their access to health and social care services. Informed consent was obtained from all participants through signed forms, which were also verbally confirmed at the beginning of the data collection sessions. All collected data have been securely stored in accordance with data protection regulations. CANCERLESS Interventions Data Management Application platform securely stores data in agreement with the General Data Protection Regulation, following strict guidelines for collecting, processing, storing, and transferring personal data in the European Union and the European Economic Area. Participants did not receive any financial compensation for taking part in the project.

Results

Overview

Data used in this study comprehend the whole T0 set of responses, whose demographic distribution is presented in Table 1.

Table 1. Demographic distribution among the different pilots.



Pilot	Values, n (%)	Age (years), mean (SD)	Male, n (%)	Female, n (%)	Nonbinary, n (%)	Other, n (%)	Do not want to disclose sex, n (%)
Austria	142 (21.8)	45.28 (12.83)	60 (42.3)	82 (57.7)	0 (0)	0 (0)	0 (0)
Greece	158 (24.2)	51.57 (13.53)	121 (76.6)	34 (21.5)	0 (0)	2 (1.3)	1 (0.6)
Spain	198 (30.3)	48.94 (14.82)	110 (55.6)	87 (43.9)	0 (0)	0 (0)	0 (0)
United Kingdom	155 (23.8)	42.91 (12.04)	127 (81.9)	27 (17.4)	1 (0.6)	0 (0)	0 (0)
Total	652 (100)	47.87 (13.06)	418 (64.1)	230 (35.3)	1 (0.2)	2 (0.3)	1 (0.2)

Questionnaire Data Analysis

The left side of Figure 2 shows the scatter plot of the 2 first PCA components of the complete dataset for the entire questionnaire. The UK pilot shows a larger variance in comparison to the others. In addition, substantial differences in position and sparsity can be appreciated between the different pilot sites. The PCA loadings in the figure show the most critical variables that have influenced the PCA, which are divided into sections. The HCEQ, which is the one with the greatest dispersion, is also the most influential, as it is the questionnaire with the highest contribution to the PCA with questions Q89, Q90, Q92, Q94, Q96, Q97, Q98, Q99, Q100, Q103, Q104, Q105, Q106, Q107, and Q10, followed by the interpersonal communication questionnaire with Q134 and Q136, afterward use of health care services with Q168, quality of life with Q88, and psychological distress with Q73. Table S1 in Multimedia Appendix 2 provides detailed information regarding the questions corresponding to the selected numbering.

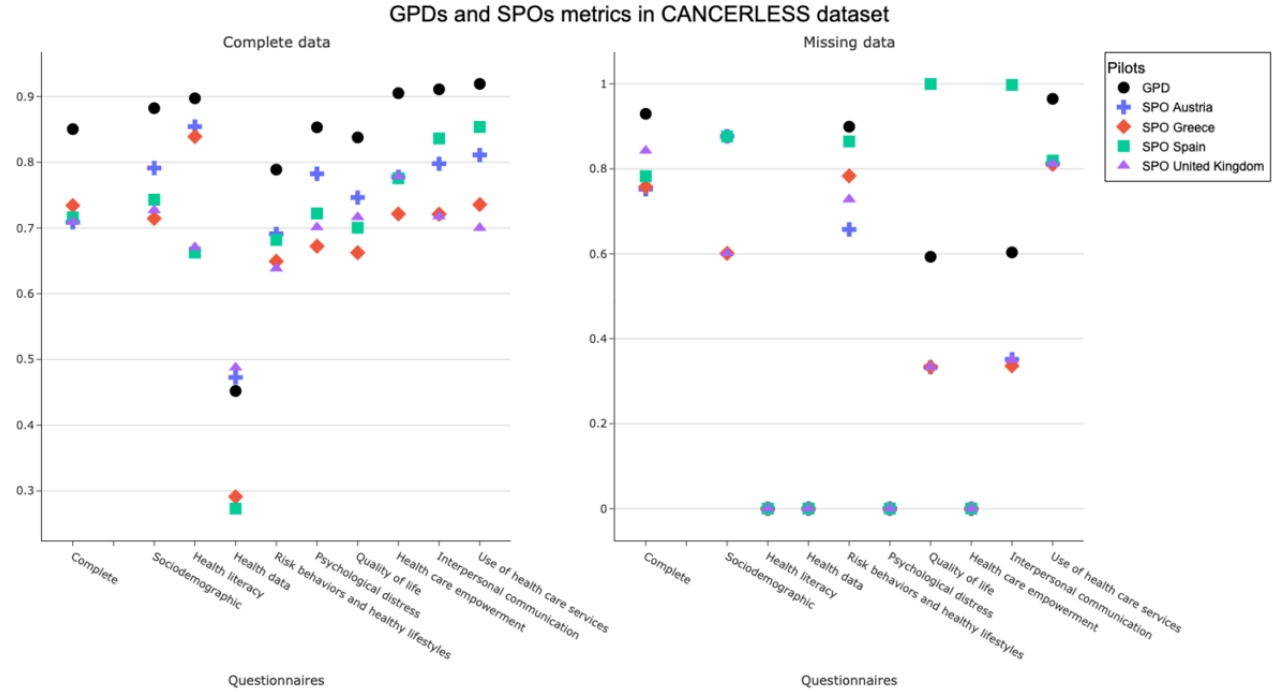

Figure 2. Scatter plot of data along the 2 principal components elicited from the principal component analysis and the multiple correspondence analysis, respectively. Each point is colorized depending on its pilot precedence. Most contributed questions for the principal component analysis calculation have been shown with arrows, depending on the questionnaire they belong to. Tables S1 and S2 in Multimedia Appendix 2 present a detailed table of both, indicating the specific questions and their associated questionnaires. For the global analysis, the principal component analysis indicates a central point where most of the samples are concentrated, with the UK pilot showing the greatest dispersion relative to the others. There is a substantial difference between the UK and Spanish pilot samples. In contrast, Austria and Greece pilots show a wider distribution of their samples. In the completeness case, the figure clearly shows 2 different parts, being the pilots from the United Kingdom, Greece, and Austria quite similar compared to Spain, where it presents an entirely different type of missing from the other pilots, being interpersonal communication and use of health care services sections the most relevant in the calculation of the multiple correspondence analysis. Q: question.

The left side of Figure 3 shows the resultant DQ metrics, which generally present a wide dispersion between pilots for the overall questionnaire and most of the questionnaires. Noteworthy, the health data questionnaire shows metrics less than 0.5 observed, in contrast to those in the other questionnaires with values exceeding 0.8, indicating a clear difference for each pilot. For health care services, interpersonal communication, and health care empowerment, the GPD value exceeds 0.9, highlighting the divergence shown in Figure 2. However, several imputations have been performed for the case of Spain in the interpersonal communication and use of health care services sections.

XSL•FO
RenderX

Figure 3. Results from the GDP and SPO multicentric analysis were applied to both the complete dataset (left side) and the completeness (right side) from the dataset composed of the T0 interviews in Austria, Greece, Spain, and the United Kingdom. The SPO indicates the distance of that pilot from the latent central tendency; the GPD can be understood as the mean of the variability of each pilot; a value close to 0 means less variability. In our case, a value of 0 indicates no missings for these questionnaires. Generally, a large variability is observed, especially in the Spanish pilot. GPD: global probabilistic deviation; SPO: source probabilistic outlyingness.

The overall analysis of the questionnaire reveals 3 types of variability patterns. First, we found questionnaires with very different distributions between pilots. Still, there are no decisive questions within the questionnaire, as they do not appear on the left side of Figure 2 as the most relevant in the PCA, such as sociodemographic data, health literacy, and risk behaviors and healthy lifestyles. Second, questions related to health data showed fewer differences concerning the pilots compared to the other questionnaires, which had a GPD of 0.452. Finally, questionnaires such as psychological distress, quality of life, HCEQ, interpersonal communication (Person-Centered Coordinated Care Experience Questionnaire), and the items related to the use of health care services, apart from diverging between the different pilots according to the metrics applied, present some questions that are determinant and differentiable by country.

Missing Patterns Analysis

From the 652 participants analyzed and the 130 questions collected at T0, a total of 84,760 values were obtained. Of these, 70,384 of 84,760 (83%) values are complete and valid, 6260 of 84,760 (7.4%) values are not applicable missing, and 8116 of 84,760 (9.6%) values are ordinary missing.

The right side of Figure 2 shows the MCA projection of the missing profiles to 2 dimensions, where a cluster of Austria, Greece, and the United Kingdom can be observed at the top-left side of the plot. Mainly, Spain samples can be observed at the bottom-right of the figure, denoting that Spain is very different from the other sites in terms of the missing pattern. In this instance, the questionnaire with the highest number of questions was the use of health care services, comprising Q155, Q158, Q167, Q161, Q152, Q180, Q176, Q179, and Q178. This was followed by the interpersonal communication questionnaire, which included Q138, Q142, Q140, Q136, and Q134. Next was risk behaviors and healthy lifestyle, encompassing Q45, Q46, Q44, and Q59, and quality of life with Q88. Table S2 in Multimedia Appendix 2 provides detailed information regarding the questions corresponding to the selected numbering.

The right side of Figure 3 offers both a global and section-by-section view of missing-data behavior after applying the GPD and SPO metrics. Overall variability is high; yet, 3 distinct patterns emerge. First, several sections—health literacy, health data, psychological distress, and health care empowerment—show virtually no disparity across pilots because they contain no missing values, so their GPD and SPO scores sit near 0. Second, marked differences appear in sociodemographic data, risk behaviors, healthy lifestyles, and use of health care services, where some pilots contribute many missings, while others contribute few. Third, a distinct Spain-specific pattern emerges. Spain is the only pilot exhibiting substantial variability that elevates the mean GPD in sections where the remaining pilots show minimal variability—particularly in quality of life (Spain: 100/1576, 6.3% missing; others combined: 10/3640, 0.3% missing) and in interpersonal communication, where the SPO profile departs markedly from the consistently low missingness observed elsewhere.

Discussion

Summary of Main Findings

This study investigated heterogeneity among people experiencing homelessness in 4 European countries and evaluated the quality of data collected in a multicenter cohort. Understanding variability in demographics, health status, and service use is essential for designing interventions tailored to this population's needs. The analysis showed pronounced between-pilot differences: for most questionnaires, the GPD exceeded 0.7 at both pilot and aggregate levels (Figures S1 and S2 in Multimedia Appendix 3), indicating substantial heterogeneity. The sole exception was the health questionnaire, whose lower GPD likely reflects that only a single quantitative item remained after discarding multichoice and free-text responses. Missing-data diagnostics revealed further site-specific discrepancies, with the Spanish cohort diverging most markedly, particularly in the use of health services, quality of life, and interpersonal communication (Figures 2 and 3).

Participants' responses reveal notable differences in the experiences of people experiencing homelessness across the various countries. While the heterogeneity observed within the homeless population can, in part, be attributed to country-specific factors, such as distinct socioeconomic and health care contexts, variations in responses may also stem from differences in the implementation of interventions and the subjective perceptions of individual participants. These discrepancies are particularly evident in key areas assessed by the PCA, including health-related domains, where divergent patterns emerge based on both contextual and personal factors. In the case of Q136: "Do you have a care plan (or a single plan of care) that takes into account all your health and wellbeing needs?" Spain stands out as the only country, where more individuals have health plans than those without. Additionally, Austria is unique in having no instances of "I don't know" responses to this question. For Q134: "Do you have a single professional (or several professionals) who takes responsibility for coordinating your care across the services that you use?" Spain and the United Kingdom are distinguished by having more positive responses than negative ones. Notably, the United Kingdom records the highest number of participants uncertain about their answers. Furthermore, Spain shows a substantially higher number of blank responses for both Q136 and Q134. Meanwhile, concerning 3 questions belonging to the HCEQ subquestionnaire: Q104: "During the last 6 months, how important is it that you obtained all the information you wanted?" Q106: "During the last 6 months, how important is it that you and your loved ones decide the need for the health care and services?" and Q108: "During the last 6 months, how important is it that you and your loved ones decide the amount of health care and services?" In general terms, both in the United Kingdom and Austria, the response rate is higher than in Spain and Greece. Meanwhile, the United Kingdom and Austria maintain the same number of answers for these questions, with the UK participants being the most important for all 3 questions and the Austrian participants the second most important. We see how, in the case of Greek cities and Spain, the difference lies in the type of question; in the case of Q106, the Greek cities considered it very unimportant, while the participants in the Spanish pilot considered it the most important of the 3. However, the opposite effect was observed in the case of Q104 and Q108. Finally, for Q88: "We would like to know how good or bad your health is today. 100 means the best health you can imagine. 0 means the worst health you can imagine." being the perceived health status is a major patient-reported experience measure of the study.

Significance

This study, as far as the authors know, is the first study confirming the heterogeneity within the group of people experiencing homelessness in a European multicenter study, as most of the previous studies have been primarily focused on the US-American context [22,23,47]. The study's results enable quantifying this heterogeneity between the different pilots that conform to the database through various factors that should be considered in a posteriori analysis. First, despite heterogeneity, the only set of items that can be assumed to be the most appropriate if a global analysis is desired is the health data questions since they do not present any missings, as are the ones with the least variability between pilots. Second, in the case of interpersonal communication and use of health care services, the global result could not be correctly determined since most of the data were imputed in the case of Spain, which does not make the analysis at a global level appropriate. Finally, the analyses at the section level should be done separately for each pilot, with the HCEQ being the most relevant since it presents greater variability between pilots and does not contain missing values. Therefore, the analysis of the pilots must be carried out independently, and the conclusions of one pilot cannot be extrapolated to the others, given the great divergence found between them. The disparities in the global dataset are more pronounced for Spain. In contrast to the other pilots, the methodology shows that ordinary missing values constitute the majority, especially within the interpersonal communication and health care utilization questionnaires.

In this context, it is important to recognize that eliciting such variation, whether through the proposed methodology or other approaches, is not necessarily a DQ issue. Rather, it is an expected step for adapting the interventions to the specific socioeconomic and health care contexts. However, the nature and source of this variation should be carefully considered, as concerns may arise if the variation is driven by systematic measurement error or bias, which could influence the validity of the findings and the effectiveness of the interventions. This proposed methodology can help to find such variation prior to any analysis and therefore approach it, considering the characteristics of the dataset under study.

Strengths and Limitations

Including this methodology to analyze the data enables us to demonstrate 3 objectives that help ensure DQ for improved analysis. First, our approach allows us to evaluate the variability existing in the data, especially the differences between the data from different sources from a more visual perspective and with a single iteration, considering all types of variables for the analysis, without going into detail in classical tests that are more sensitive to the analysis. The technique used for DQ of the

XSL•FO
RenderX

responses in the different pilots and to evaluate their quality in terms of missing information makes use of the comparative datasets, transforming them into probability distributions that allow using comparative metrics of similarity and, therefore, the level of nonoverlapping between them. Thus, it is necessary to know the boundaries regarding the exploitation capacity of the dataset for prospective uses, especially with the scarcity of homelessness quantitative information. Second, this hierarchical approach allows for monitoring the pilots' progress and comparing them as a whole and by different sections. As data become available, we can promptly detect and correct deviations from the established methodology or protocol. This approach also enables the systematic identification of patterns and causes of missing data, supports the implementation of targeted corrective measures, and—by embedding these methods in a control framework—drives continuous improvement in information quality. Third, further analyses of DQ with new data or batches can be applied thanks to the replicability of the methodology, given that the source code has been made public.

The analysis of the overall results is affected by the large number of missing values in the Spain dataset. Since there are many questions with missing data, an imputation had to be performed, which negatively influenced the results. In addition, the number of samples is not very high for our applied method, which may also impact the results. This is because the methodology used is sensitive and requires a large amount of data to generalize results more accurately. Missing values were imputed with reference to the pooled empirical distribution of all pilot sites. While this cross-site approach may introduce some location-specific bias, it enhances methodological robustness by preserving the overall variance structure; this was exemplified in the Spanish cohort, where the 2-part analysis coupled with the imputation procedure successfully pinpointed the sources of variability.

Future Perspectives

For all of those reasons, the results of this study will facilitate prospective dataset DQ labeling for prospective publication in related health data access bodies in the framework of the European Union's European Health Data Space (EHDS) initiative [48] in compliance with Article 78 on DQ that will allow secondary use of health data for research, innovation, and policymaking under conditions of security and privacy by ensuring a certain level of DQ that will enable users to know in advance the characteristics of the CANCERLESS dataset thanks to the applied methodology.

Following current best-practice guidance on dataset curation, other DQ dimensions not covered in this study—such as temporal coherence, consistency, or correctness—will be assessed as part of the mid-scale pilot of the EHDS project QUANTUM ("Quality, Utility and Maturity Measured"). QUANTUM will pilot an European Union–wide framework for rating both the intrinsic quality of health datasets and the maturity of their curation processes; CANCERLESS database will conform to one of these analyses, supporting our analysis and getting externally validated, a multidimensional appraisal that complements this analysis.

Conclusions

The analysis of this multicenter sample of people experiencing homelessness from 4 different European countries revealed substantial heterogeneity between sites of special importance for health care empowerment, quality of life, and interpersonal communication values, which showed the most differences between pilots. Particularly, differences in missingness patterns in data were larger than the ones found on the raw data, especially for the Spain pilot, highlighting that the interpersonal communication, health care empowerment, and use of health services data present a high number of nulls and should not be used for analysis. Further qualitative techniques are needed to understand the cause of this deviation from the other pilots. This methodology should be applied to multicentric data to monitor a pilot as the data become available and, therefore, amend possible protocol deviations. In summary, as quantitative data about homelessness are scarce, using a DQ-validated dataset in the context of the EHDS is crucial to ensure the reliable use of data to facilitate research on vulnerable populations such as people experiencing homelessness.

Abstract

Background: Information security within telemedicine systems is essential to advancing the digital transformation of health care. Telemedicine encompasses diverse modalities, including teleconsultation, telehealth, and remote patient monitoring, all of which depend on digital platforms, secured communication networks, and internet-connected devices. Although these systems have progressed in aligning with information security standards and regulations, there remains a shortage of comprehensive, practice-oriented studies evaluating which aspects of security are effectively addressed and which remain insufficiently managed, particularly within the Chilean context.

Objective: This study aims to examine how effectively telemedicine systems in Chile address the core security attributes of confidentiality, availability, and integrity.

Methods: Data were analyzed from an evaluation tool designed to assess the quality of telemedicine systems in Chile. Over a 6-year period, 25 telemedicine systems from different providers were assessed, and an in-depth examination of how companies manage key information security subcharacteristics within their systems was undertaken.

Results: The findings indicate that 52% (n=13) of telemedicine systems optimally implement cryptographic techniques to protect confidentiality. In contrast, 44% (n=11) lack robust strategies for adapting to, recovering from, and mitigating security-related incidents. Fault tolerance mechanisms are frequently integrated to minimize service disruption caused by system failures. However, the prioritization of data integrity varies: while some companies treat it as a critical requirement, others assign it limited importance.

Conclusions: This study offers an understanding of the security priorities and practices adopted by telemedicine providers. It highlights a prevailing tendency to prioritize security measures over usability, underscoring the need for a balanced approach that safeguards patient information while supporting efficient clinical workflows.

KEYWORDS

assessment; quality; security; telemedicine systems; usability

Introduction

Security within telemedicine systems constitutes a critical component of the digital transformation in the health care sector [1]. The rapid expansion in the utilization of these technologies, significantly accelerated by the COVID-19 pandemic, necessitates the enhancement of mechanisms to safeguard medical information, thereby ensuring the confidentiality, integrity, and availability of patient data [2]. Telemedicine encompasses a range of modalities, including teleconsultation, telehealth, and remote patient monitoring, all of which depend on digital platforms, secured communication networks, and internet-connected devices [3]. Nevertheless, the deployment of these systems presents substantial risks, such as vulnerabilities in data transmission, unauthorized access, cybersecurity threats, and interoperability challenges among diverse health information systems. Countries generally establish guidelines for the storage and processing of personal data, which also affect telemedicine services [4]. However, despite these advancements, security in telemedicine continues to pose a global challenge due to the

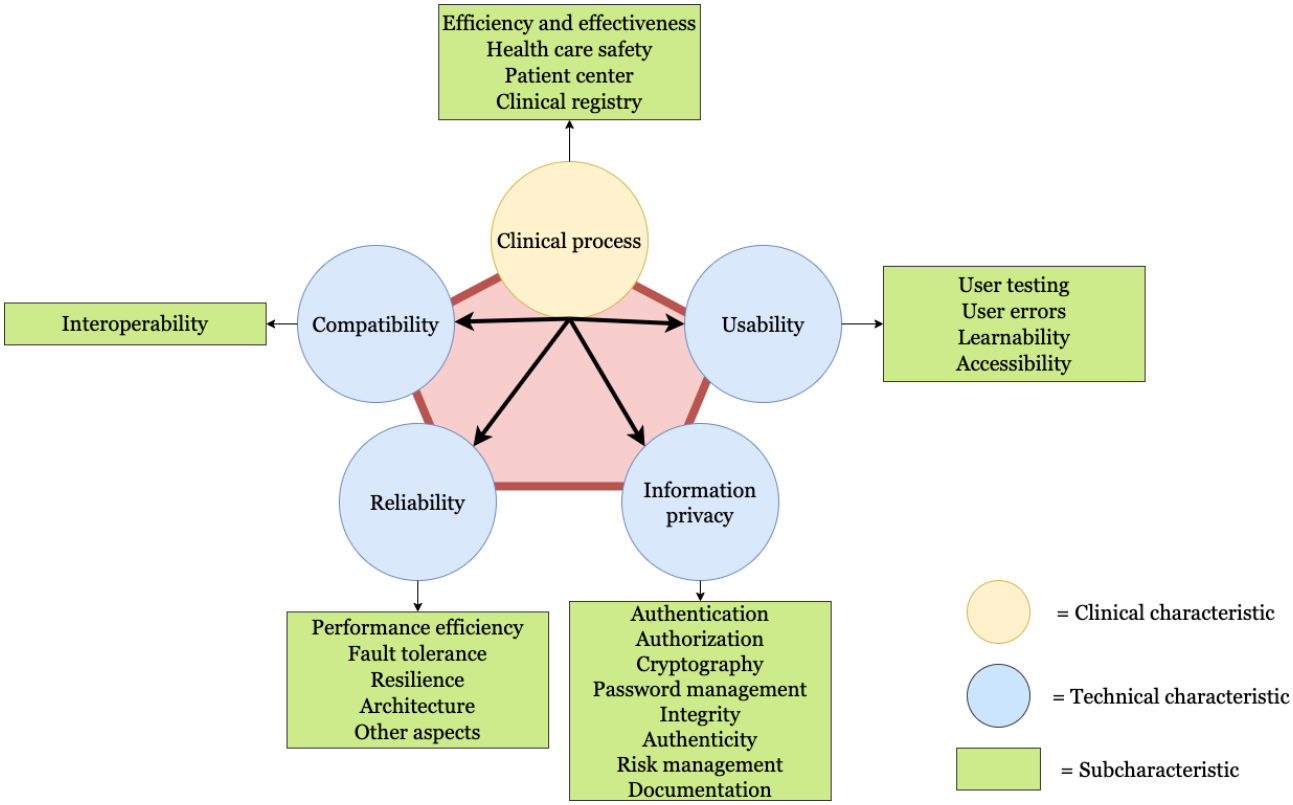
XSL•FO
RenderX

diversity of regulations, the rapid evolution of cyber threats, and the necessity for digital security awareness among health care professionals [5,6]. In this context, as reported by Nobili et al [7], hospitals and their information systems, including telemedicine systems, were the principal targets of cyberattacks, accounting for 42% of all computer-related incidents from 2022 to 2023.

In Chile, the regulation of personal data storage and processing is governed by law. Within the realm of telemedicine, the Chilean public health care systems have initiated efforts to enhance the digitalization of health care services among companies offering telemedicine services to their patients [8,9]. Specific guidelines have been established to safeguard patient data privacy and ensure the security of clinical information. Despite the notable advancements made by telemedicine companies in adhering to Chile's information security guidelines and regulations, there is a paucity of systematic research that practically examines the aspects of information security that telemedicine companies effectively address and those they do not. Furthermore, there is limited information regarding the trade-offs that telemedicine companies undertake to fulfill the information security requirements of their systems.

This study presents a study examining the success levels associated with information security subcharacteristics within telemedicine companies in Chile. This study aims to identify which subcharacteristics of information security are adequately addressed and which remain insufficiently addressed by current telemedicine systems from a practical perspective. Information security was characterized through the properties of confidentiality, availability, and integrity, utilizing 7 specific subcharacteristics. The study involved an analysis of data collected from an instrument designed to assess the quality of telemedicine systems in Chile. Over a period of 6 years, the success levels of 25 telemedicine systems from different companies were evaluated, and an in-depth discussion was conducted on how these systems address the information security subcharacteristics within their telemedicine systems. The study contributes a pragmatic analysis of the priorities and actions undertaken by telemedicine companies to address subcharacteristics related to information security, as well as the trade-offs these companies encounter in ensuring security in Chile. The findings of this study offer practical insights for professionals and researchers concerned with the security of telemedicine systems.

Methods



Instrument

The utilization of information technologies in health care delivery through telemedicine necessitates adherence to quality criteria typically mandated by public and private health organizations. Consequently, it is imperative to assess multiple technical and clinical aspects to ensure that the telemedicine tools employed meet the requisite minimum standards. In response to this scenario, we developed an instrument (see Multimedia Appendix 1) that evaluates the quality of telemedicine systems through an assessment process with the objective of verifying that the desired minimum requirements required by health care stakeholders are fulfilled (see Figure 1).

To validate the instrument, we conducted a comprehensive literature review to determine the elements used in the evaluation of telemedicine systems, particularly in the context of information privacy [5]. This preliminary research enabled us to identify the key security subcharacteristics considered in the assessment of telemedicine systems, as well as to derive and pinpoint additional characteristics and subcharacteristics, as illustrated in Figure 1. Subsequently, we conducted 3 pilot studies of the instrument in collaboration with (1) telemedicine experts, (2) clinical professionals, and (3) health care decision-makers. In each pilot study, we evaluated the instrument's usefulness in assessing Chilean public telemedicine systems. At the conclusion of each pilot, we collected feedback from participants and revised the instrument accordingly. Thereafter, we engaged 3 telemedicine companies, partners of our research group, to apply the revised instrument to their telemedicine systems. Upon the completion of the system evaluations, we considered the observations made by each company's teams and further refined the instrument.

XSL•FO
RenderX

Figure 1. Instrument for assessing the quality of telemedicine systems, including their corresponding technical and clinical characteristics as well as their subcharacteristics.

The evaluation process focuses on 2 characteristics: clinical and technical. Each characteristic evaluates multiple aspects. In the clinical characteristic, the context, description of the telemedicine solution, and role of the patient in the clinical process are evaluated. For this reason, we evaluated the following subcharacteristics: (1) efficiency and effectiveness, (2) health care safety, (3) patient center, and (4) clinical registry. These subcharacteristics represent the most relevant concerns regarding telemedicine in Chile. In the technical characteristic, 4 properties are evaluated: compatibility, usability, reliability, and information privacy. In turn, each characteristic has 18 subcharacteristics representing different concerns. The decision to evaluate the clinical and technical dimensions is based on the priorities faced by health decision-makers in Chile. These priorities aim to address laws that have been enacted in the country, which are oriented toward cybersecurity, data privacy, interoperability, and patient protection.

Each subcharacteristic evaluates the telemedicine company's adherence to both technical and legal standards. Consequently, the instrument requires the telemedicine company to provide pertinent information and documentation from the telemedicine system to confirm the accuracy of the responses recorded in the instrument. Given the complexity of evaluating telemedicine systems, our instrument employs a simplified scale for stakeholder comprehension. The scale considers a score of 3 points for optimal, 2 points for acceptable, 1 point for risky, and 0 points for unsatisfied.

An optimal score is defined when the telemedicine company proposes novel mechanisms or methodologies that exceed the baseline expectations defined by the instrument in each subcharacteristic; that is, when the telemedicine company implements additional or more advanced security techniques to provide a higher degree of patient trust. Some of these techniques include hash encryption algorithms, role and access management through identifiers, zero trust architecture, intrusion detection, multifactor authentication, and network micro-segmentation, among others. Similarly, an acceptable score is defined when the telemedicine company provides the explicit evidence required by the instrument and complies with the legal regulations associated with each subcharacteristic. A company receives a risk score when it does not explicitly describe the required evidence and does not fully comply with the legal regulations associated with each subcharacteristic. Finally, an unsuccessful score corresponds to a company that neither provides evidence nor complies with regulations.

Research Objectives

In this study, we focused on examining subcharacteristics related to security. Therefore, the conceptualization of security is structured into 3 fundamental properties: confidentiality, availability, and integrity. Confidentiality pertains to the protection of information, ensuring that access is restricted to authorized individuals by preventing unauthorized access, improper disclosure, or data breaches [10]. Availability guarantees that information is accessible and usable when needed by authorized users [11]. Integrity ensures that information remains accurate and reliable, without unauthorized modifications [11].

Correspondingly, as elucidated by the instrument presented in Figure 1, we established that the confidentiality characteristic encompasses 4 subcharacteristics: authentication, authorization, cryptography, and authenticity. Authentication refers to the

XSL•FO
RenderX

process of verifying the identity of a user, system, or device prior to granting access to a resource or service [12]. Authorization involves determining the actions or resources that an authenticated user is permitted to access [12]. Cryptography is the study of techniques for safeguarding information by converting data into an encrypted format, which can only be read or modified by authorized individuals or systems [13]. Information authenticity ensures that data originate from a legitimate source and have not been altered during transmission or storage [12].

Concurrently, the availability characteristic is composed of 2 subcharacteristics: fault tolerance and resilience. Fault tolerance refers to a system's capacity to maintain proper functionality despite the failure of 1 or more of its components [14]. Resilience, on the other hand, denotes a system's ability to adapt, recover, and continue operations following an adverse event, such as a cyberattack, hardware malfunction, or natural disaster [15].

Therefore, we define the following objectives:

1. Identify security-related subcharacteristics that telemedicine companies successfully address. This objective is oriented toward analyzing the subcharacteristics of the instrument that perform optimally in the context of security, demonstrating telemedicine companies' ability to meet information security requirements.
2. Investigate the factors enabling telemedicine companies to achieve optimal and acceptable scores in security-related subcharacteristics. This objective aims to explore the key elements that contribute to successful performance in the security subcharacteristics.
3. Determine the security-related subcharacteristics that telemedicine companies fail to effectively address. This objective focuses on identifying subcharacteristics that exhibit low scores and understanding their implications for information security.
4. Analyze the reasons telemedicine companies fail to achieve favorable scores in security-related subcharacteristics. This objective aims to uncover the underlying challenges or limitations that prevent companies from meeting their security requirements.
5. Examine the trade-offs telemedicine companies create between usability and security in their systems. Usability and security frequently exhibit conflicting objectives [11]. While usability aims to simplify access and enhance user experience, security focuses on safeguarding data and systems, which typically necessitates the implementation of restrictions or additional measures to ensure such protection. Therefore, this objective is oriented toward understanding how usability considerations influence security decisions and how companies balance these 2 critical aspects within their systems.

Although there are regulations and security standards, such as the Health Insurance Portability and Accountability Act (HIPAA) [16], ISO/IEC 27001 [17], Control Objectives for Information and Related Technologies [18], and the NIST Cybersecurity Framework [19], not all can be fully applied to the reality of telemedicine in Chile owing to work culture, institutional organization, and the level of maturity of telemedicine systems. For this reason, our instrument draws on these regulations and standards to adapt security assessments to the Chilean context, with the aim of establishing an initial security baseline for telemedicine systems in Chile.

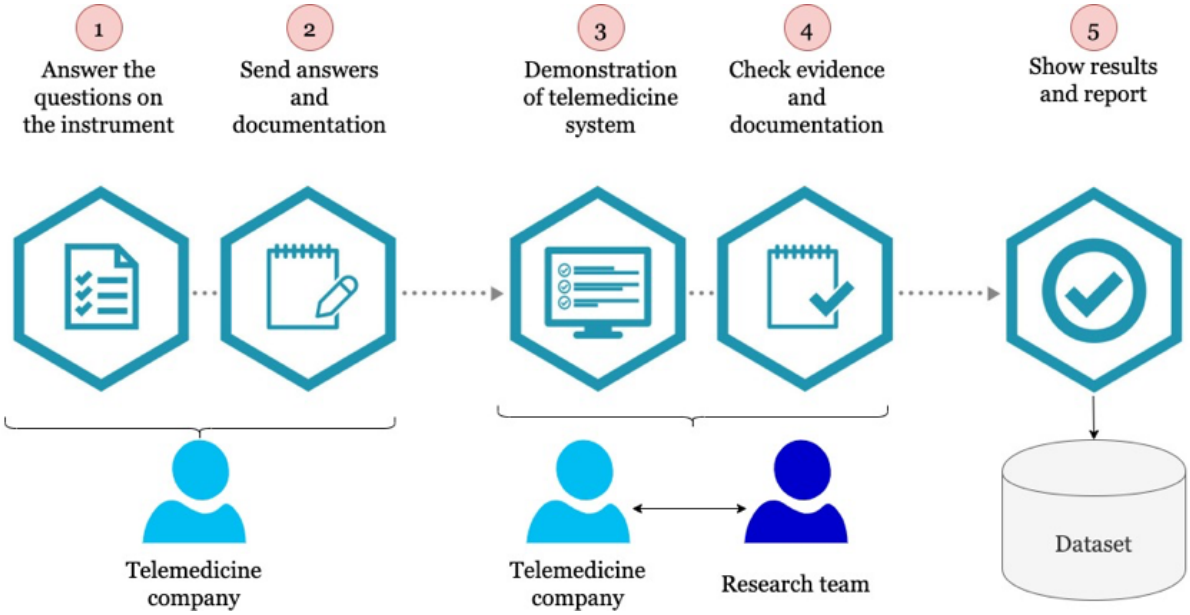
Research Questions

We defined the following research question:

RQ1: Which subcharacteristics of telemedicine systems address security concerns? Rationale: The objective of this research question is to elucidate the subcharacteristics of our instrument that performs optimally in the context of security. While the instrument employs a multidimensional approach, this research question aims to demonstrate the capacity of telemedicine companies to meet information security requirements.

RQ2: Which subcharacteristics of telemedicine systems do not address security concerns? Rationale: In contrast to RQ1, this research question aims to identify the subcharacteristics that exhibit low scores within the security context. In addition, this research question is intended to describe the reasons telemedicine companies are unable to achieve favorable security scores.

RQ3: In the context of usability, which trade-offs do telemedicine companies make to ensure security within their systems? Rationale: Addressing security necessitates a balance between the properties and quality of telemedicine systems. This research question aims to elucidate the trade-offs that our instrument identifies when addressing information security in telemedicine systems.



Data Collection

The data collection process is illustrated in Figure 2.

The data collection process is characterized by 2 distinct perspectives. First, it involves a self-assessment process conducted by the telemedicine company, wherein the company's technical and clinical representatives utilize our instrument to respond to key inquiries and provide corresponding documentation to substantiate their responses. Second, our research team performs a cross-validation of the documentation and responses obtained from the instrument through a demonstration of the telemedicine system, focusing on corroborating the answers provided in the instrument. The selection of the 25 telemedicine companies was based on a technical analysis of the telemedicine system each company offered, the number of clients, and the volume of telemedicine services provided to both public and private health care services in Chile. In addition, the quality agreements held by the companies were reviewed, as these had been granted by public health institutions, given that this sector serves the largest number of patients in Chile. We used a nonprobabilistic, convenience-based sampling approach. Specifically, we engaged companies willing to participate in order to provide them with reports on the security and quality of their systems, thereby supporting the continuous improvement of their security mechanisms.

XSL•FO
RenderX

Figure 2. Process for collecting data from telemedicine companies as well as from their telemedicine systems.

In the initial phase, the telemedicine company is tasked with assembling clinical and technical experts to address all inquiries associated with our instrument. The instrument was developed within a web-based system that facilitates the upload of documentation in various formats. Upon the compilation of all information and the completion of the instrument's inquiries by the telemedicine company, the subsequent phase involves transmitting the information to our research team. Upon receiving notification from the company and verifying that no information was pending, we informed the telemedicine company of the assessment's initiation. The third phase aims to mitigate subjectivism and bias in the company's responses by demonstrating the functionalities associated with the inquiries evaluated by the instrument. For this phase, our research team convenes with the stakeholders of the telemedicine company to discuss pertinent aspects of the instrument. Subsequently, in the fourth phase, the research team organizes to evaluate the telemedicine company's documentation and demonstration to assign a score to each subcharacteristic that our instrument assesses. The assessment is conducted by 3 members of the research team and subsequently validated by a senior researcher. The 3 investigators independently evaluated the responses and documentation submitted by the telemedicine company, ultimately determining the final score through consensus. Following score assignment, a preliminary report is generated, which must be approved or rejected by a senior researcher on the team. The company initiates an improvement process in which the aspects to be improved are addressed until the necessary score for approval is reached. The number of interactions depends on how the company presents corresponding evidence and documentation. If the report is approved, the fifth phase consists of creating a formal instance to present the results of our analysis and inform the company of its qualification. Additionally, the entire analysis and its results are stored in a dataset utilized for research purposes.

Data Analysis

We used descriptive statistics and manual analysis of documentation to address the research questions. About RQ1 and RQ2, we analyzed the frequency of scores to categorize the number of companies that achieved optimal, acceptable, risky, and unsuccessful scores.

Regarding RQ1 and RQ2, we conducted a comprehensive review of all documents and software artifacts that our instrument mandates companies to submit for the evaluation of their telemedicine systems, in addition to responding to the questions within the instrument. For each assessed security subcharacteristic, companies are required to furnish evidence demonstrating their compliance with the subcharacteristic, thereby substantiating the responses provided in the instrument. In our study, we requested explicit evidence from companies to ensure the objectivity of the evaluation. For instance, when companies submit evidence of authentication, they typically provide documentation on the authentication mechanisms implemented in the telemedicine system, along with source code packages. This procedure is similarly applied to other security subcharacteristics. Finally, a team of researchers independently assessed the evidence and provided a review, which was subsequently verified by a senior researcher on the team.

Concerning RQ3, the subcharacteristics related to security are classified into 2 categories: successful and not successful. The subcharacteristics categorized as "successful" are those that obtained optimal (score 3) and acceptable (score 2) scores. Conversely, subcharacteristics categorized as "not successful" are those that received risky (score 1) and unsatisfied (score 0) scores. Subsequently, we compared the percentages of usability and security. The percentage of successful corresponds to the ratio of subcharacteristics that are categorized as "successful" compared to the total (subcharacteristics with "successful" and "not successful" categories).

Ethical Considerations

According to the applicable ethical and legal framework in Chile, including Law No. 19.628 on the Protection of Private Life, research ethics review is required for studies involving human participants, biological samples, or personal data [20].

XSL•FO
RenderX

As this study did not involve the collection, processing, or analysis of any personal, sensitive, or health-related data, it was not subject to review by an institutional ethical research board.

Results

In relation to RQ1, Table 1 shows that telemedicine systems prioritize cryptography as principal subcharacteristic to ensure security.

A total of 13 companies, representing 52% of the total, obtained the optimal score as they considered cryptographic methods to be pertinent to ensuring the protection of sensitive patient data as well as the security of patient-physician communication. With the exception of the subcharacteristic of authenticity, where the distribution of scores is more equitable, in the subcharacteristics of authorization and fault tolerance, the acceptable score leads to the preferences (15 companies representing 60% are inclined toward this score in these 2 subcharacteristics). In the same context, authentication and integrity also share the same preferences for this score (10 companies representing 40% favor these 2 subcharacteristics). Table 2 summarizes the main reasons identified in the documentation provided by the companies for which telemedicine companies achieve favorable scores in security-related subcharacteristics.

Table . Frequency of scores obtained by telemedicine companies.

		Subcharacteristic	Optimal	Acceptable	Risky	Unsatisfied
Security	Confidentiality	Authentication	3	10	10	2
		Authorization	6	15	2	2
		Cryptography	13	8	1	3
		Authenticity	7	8	7	3
	Availability	Fault tolerance	6	15	3	1
		Resilience	4	7	3	11
	Integrity	Integrity	2	10	10	3

XSL•FO
RenderX

Table . Summary of the main reasons telemedicine companies achieve optimal and acceptable scores.

Subcharacteristic	Reason
Cryptography	Most telemedicine systems use AWS Cognito, SHA[a] 256, or HTTPS[b] as cryptographic tools. This means that the data encryption acts over the TLS[c]. In addition, most telemedicine systems have their infrastructure hosted in the cloud, mainly in AWS[d]. All telemedicine systems use cryptographic mechanisms for video encryption. DTLS[e] 1.2 or SRTP[f] is the most commonly used method for encrypting transmitted data.
Authentication	Most telemedicine systems employ username and password authentication. Furthermore, these systems utilize 2-factor access to enhance security mechanisms. Nevertheless, we observed that although the instrument requires explicit information regarding access to sensitive data, not all companies provide evidence of role-based access control within their telemedicine systems.
Authorization	Telemedicine companies have access control mechanisms that use specific permission profiles for each type of user. Nevertheless, not all companies explicitly describe whether they have validation from the Chilean Registry of Individual Health Care Providers to access data.
Authenticity	Telemedicine systems use unique and random login identifiers. This identifier changes when the user is authenticated. However, we note that some companies do not describe evidence that a single sign-on is implemented in the telemedicine system.
Fault tolerance	Most telemedicine systems have implemented functionalities that offer patients the possibility of resuming consultations in case of failure through a link and code provided by email. Although companies are able to identify failure scenarios and implement prevention and mitigation measures, not all companies are able to guarantee response times to allow users to continue using the services in case of failure.
Integrity	Telemedicine companies manage sensitive data through security protocols that classify information into public, proprietary, client, and privileged categories. They recognize the confidentiality of patients' clinical information, applying stringent protection measures.

[a]SHA: Secure Hash Algorithm.

[b]HTTPS: Hypertext Transfer Protocol Secure.

[c]TLS: Transport Layer Security.

[d]AWS: Amazon Web Services.

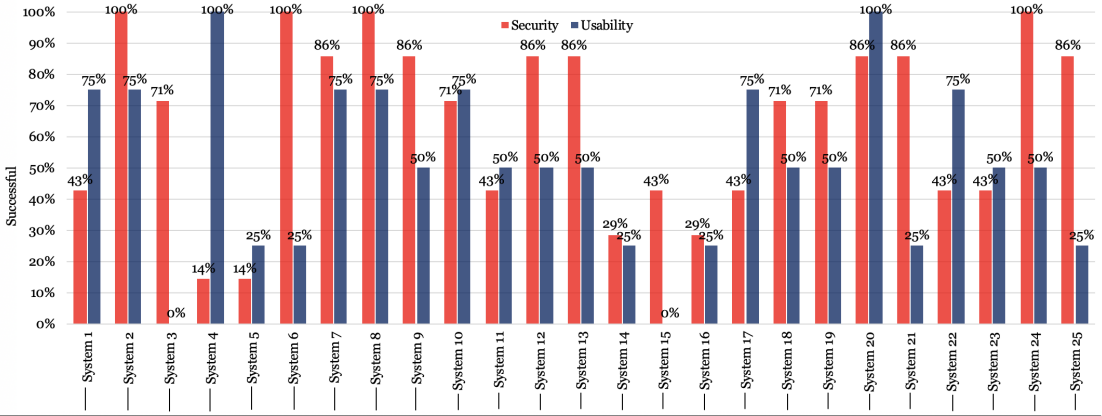
[e]DTLS: Datagram Transport Layer Security.

[f]SRTP: Secure Real-time Transport Protocol.

Regarding RQ2, Table 3 describes that the subcharacteristic with the lowest score corresponds to resilience. A total of 11 companies (44% of the total number of companies analyzed) did not address methodologies to adapt, recover, and overcome security-related situations effectively. As in RQ1, authentication and integrity exhibit equivalent frequencies of scores, but in this instance with respect to the risk score.

Regarding RQ3, Figure 3 compares the results of the security and usability subcharacteristics with their corresponding successful-related percentages for each company. The results reveal variations in success levels, ranging from significant to subtle.

For system 1, the system satisfied 75% of the usability subcharacteristics. However, in terms of security, the system only satisfies 43% of the subcharacteristics, with all availability and integrity subcharacteristics remaining unaddressed. For systems 2 and 3, both address a greater proportion of security subcharacteristics compared to usability subcharacteristics, with system 2 addressing 100% of the subcharacteristics. However, system 3 demonstrated inadequate performance in cryptography, despite exhibiting a higher successful percentage in security. System 4 focuses exclusively on usability but only successfully addresses 1 security subcharacteristic. It is noteworthy that this company does not address fundamental security standards such as cryptography and authorization.



Although system 5 demonstrates no significant difference between the successful-related percentages for usability and security, the overall percentage remains low. This indicates that the company maintains equilibrium between both properties, albeit at a substantially low level of success. Systems 6-9 have successfully addressed security concerns, but with varying levels of usability success: company 6 addressed only 25% of usability criteria, while systems 7-9 exceeded 50%.

XSL•FO
RenderX

Table . Summary of the main reasons telemedicine companies achieve risky and unsuccessful scores.

Subcharacteristic	Reason
Resilience	Documentation submitted by telemedicine companies indicates that they use a resilient mechanism in their telemedicine systems. However, when analyzing the documentation submitted to the instrument, companies do not necessarily explicitly describe a recovery plan.
Authentication	Table 2 indicates that the companies do not provide precise information regarding their roles. In these instances, companies attempt to elucidate role-based authentication mechanisms but omit pertinent information. However, certain companies, despite mentioning the utilization of roles for authentication, merely attach screenshots or provide no information whatsoever.
Integrity	Companies often lack explicit methods for eliminating unnecessary data and inadequately address error detection in data entry within telemedicine systems.

Figure 3. Distribution of percentages of success with security and usability.

		Subdomain	Score

Systems 10 and 11 exhibit a situation analogous to system 4, wherein they maintain a balance in addressing security and usability. However, system 10 demonstrates higher successful-related percentages compared to system 11. Systems 12 and 13 yielded identical results, significantly favoring security measures. System 14 maintains equilibrium in satisfying usability and security requirements, albeit at notably low percentages. In this regard, the company focuses exclusively on cryptography and fault tolerance as security mechanisms. Concerning usability, they have successfully addressed only user error control measures.

System 15 prioritized security over usability; however, it exhibited a notably low successful percentage. Similar to system 14, system 16 achieved equivalent percentages of success in both usability and security. System 17 placed greater emphasis on usability compared to security, specifically focusing on user error control in terms of usability. Systems 18 and 19 demonstrated identical results regarding success with security versus usability. Nevertheless, system 18 made a concerted effort to develop a user-accessible system.

System 20 distinguishes itself through high successful levels in both security and usability. In this regard, the company surpassed others in terms of usability and security success. System 21 addresses security to a greater extent than usability. However, this company does not delineate any process to address the resilience of telemedicine systems. System 22 satisfied more usability subcharacteristics than security subcharacteristics. System 23 demonstrates a balanced, albeit low, successful percentage. Systems 24 and 25 exhibited a trend of addressing more security subcharacteristics than usability subcharacteristics.

Discussion

Overview of the Findings

The instrument proposed in this study delineates the state of practice of characteristics that define the structure of telemedicine systems. The objective of this study is to elucidate the state of security from 3 perspectives: confidentiality, availability, and integrity.

From a confidentiality perspective, the results elucidate significant findings for the analysis. Regarding authentication, organizations balance acceptable and risky outcomes in the authentication mechanisms implemented in their telemedicine systems. As authentication verifies the identity of the user attempting access by validating credentials, 10 companies achieve acceptable results, while 10 companies exhibit risky outcomes. Among the acceptable results, organizations have adopted mechanisms that extend beyond basic username and password management. For instance, these companies utilize multifactor authentication to provide an additional security layer. Conversely, companies with risk scores limit themselves to the minimum requirements in user and password management. Analyzing the extreme scores, 3 companies achieved optimal results by not only implementing multifactor authentication but also incorporating biometric authentication features for users. Regarding unsuccessful scores, these companies demonstrated no evidence of documentation pertaining to authentication.

From the perspective of authorization, 15 companies adhere to acceptable mechanisms for authorizing access to sensitive data. It is deemed acceptable for a company to not only utilize basic authorization mechanisms but also to adapt to governmental regulations regarding access to clinical data. In Chile, specifically, there are legally mandated regulations governing access to sensitive information. In total, 4 companies that received risky or unsuccessful scores did not fully comply with these regulations. Conversely, 6 companies achieved an optimal score in authorization due to their implementation of internal processes and protocols for data authorization. This scenario is advantageous for security as it systematizes activities related to authorization, thereby facilitating traceability and auditing.

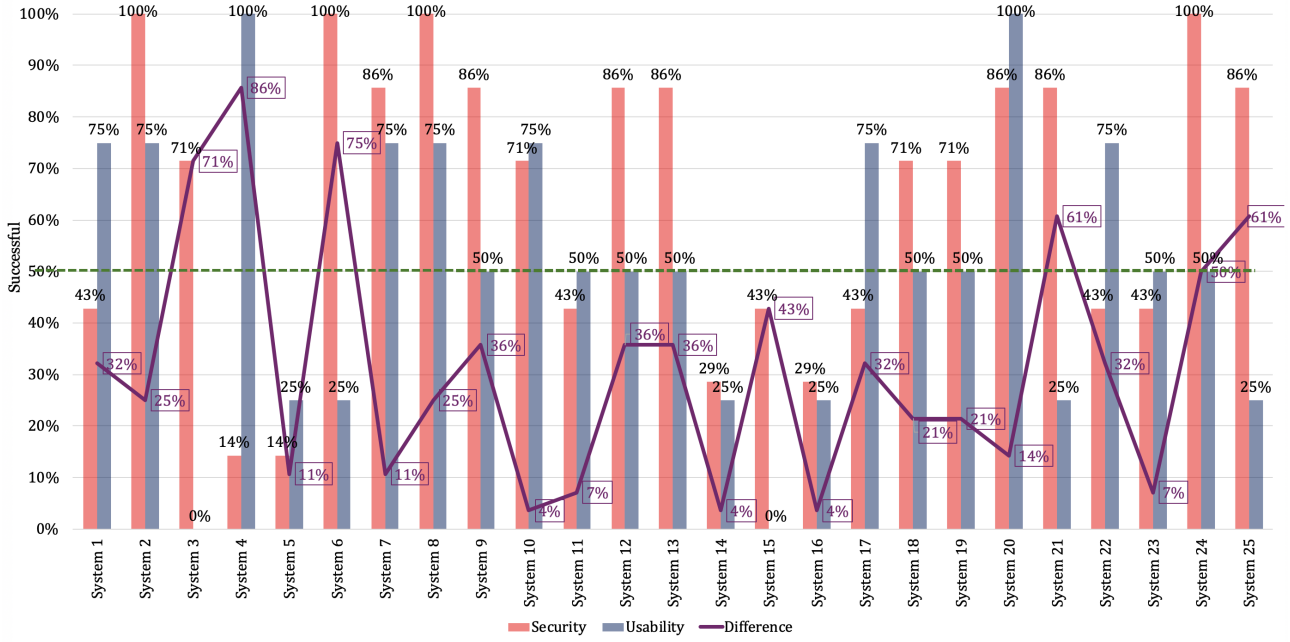
Cryptography is the preferred subcharacteristic for telemedicine companies. It was observed that 13 companies focused their efforts on providing adequate levels of cryptography using tools or algorithms specifically designed for this purpose. Similarly, 8 companies implemented cryptographic levels using libraries from development frameworks (eg, OAuth) but did not extend their efforts beyond those companies with an optimal score. Conversely, 1 company received a risk score because although it claimed to use cryptographic mechanisms, it provided no supporting evidence. Finally, 3 companies failed to meet cryptographic standards. This deficiency is primarily attributed to a lack of knowledge among telemedicine system developers regarding the implementation of cryptographic methods in their systems.

With regard to authenticity, ensuring that data, messages, or transactions originate from legitimate and reliable sources and have not been altered during transmission or storage is a primary concern for telemedicine companies. Although 8 companies adequately met the fundamental requirements for authenticity, 7 companies distinguished themselves by implementing nonrepudiation methods in their authentication processes. Specifically, these companies ensure that the data cannot be modified and that the sender cannot deny having generated the data. However, 7 companies failed to adequately describe the authenticity mechanisms in their systems. Furthermore, it was observed that some companies conflated the concept of authenticity with networking.

About availability, the results demonstrated disparities between fault tolerance and resilience. In terms of fault tolerance, 15 companies with acceptable scores implemented cluster strategies and load balancing. These companies opted for these techniques due to the availability of various technology stacks in the market that support their implementation. Furthermore, 6 companies employed additional mechanisms related to fault tolerance, specifically failover mechanisms. This technique ensures that in the event of a component or service failure, the system automatically transitions to an alternative resource capable of performing the same function. Conversely, it is imperative to note that the results presented in Table 1 elucidate a substantial disparity between resilience mechanisms.

A total of 11 companies failed to delineate the methodologies employed in their systems to address resilience, and 3 companies provided ambiguous indications of resilience, lacking sufficient clarity. The research team found that explicit references to resilience were uncommon among telemedicine companies, suggesting that further understanding of the related techniques and technologies could be beneficial. Among the companies that address resilience, 7 adhere to the recommendations from the Chilean Ministry of Health concerning the application of resilience in health information systems. In total, 4 companies implemented additional techniques specifically related to server redundancy.

Regarding integrity, the results in Table 1 are analogous to those of the authentication. The highest scores are concentrated in the acceptable and risky categories. The 10 companies that achieve an acceptable score primarily focus their efforts on delineating processes and mechanisms involving encryption protocols, such as Transport Layer Security [21], to safeguard data from tampering during transmission. Furthermore, 2 companies distinguished themselves in integrity by implementing hashing algorithms to verify data integrity.



Conversely, 10 companies attain risky results as they inadequately meet the minimum requirements for information integrity. In this regard, these companies have made insufficient efforts to address data integrity in teleconsultations. Figure 4 describes that telemedicine companies generally prioritize security over usability, although the disparity in successful-related percentages exhibits volatility.

Utilizing 50% as a threshold to differentiate successful levels, certain companies, specifically companies 3, 4, 6, 20, 21, and 25, described a difference in percentages exceeding 50%. In these instances, the trends are distinct, favoring either usability or security. Conversely, in the remaining companies, the difference between the percentages was less than 50%. While

XSL•FO
RenderX

this indicator does not comprehensively reflect the actual situation of companies, it serves as a parameter to determine the nature of trade-offs they make. Among the 6 companies with a difference greater than 50%, 5 exhibited a tendency to prioritize security in their telemedicine systems over usability, while 1 company demonstrated an inclination in the opposite direction.

Figure 4. Distribution of the difference in percentages of success concerning security and usability. The dashed line represents the upper and lower 50% threshold.

Principal Results

Cryptography is the subcharacteristic in which we observed the highest proportion of organizations that attained the maximum score. This phenomenon may be attributed to the prevalent perception that cryptography constitutes the most efficacious and widely utilized method for data protection and security. Of the 25 companies evaluated, 13 achieved an optimal score in cryptography, while 8 companies attained an acceptable score.

Another aspect in which the organizations demonstrated positive performance is fault tolerance. Although the majority of organizations performed adequately in this characteristic, most did not attain the highest scores. This can be attributed to limitations in infrastructure, scalability, dependence on third-party services, and integration with other systems. Most organizations are likely capable of managing basic faults, such as implementing backup mechanisms or addressing minor interruptions, but lack robust solutions to mitigate major failures such as complete system crashes, loss of critical data, or failures during high-demand situations.

In contrast, a significant negative aspect is recovery capability. The suboptimal results in this characteristic can be attributed to various factors, one of which is successful fault-tolerance scores. Both aspects are closely related as they address how systems manage failures. The recovery capability focuses on how the system restores itself after failure. Many organizations may prioritize developing fault-tolerant systems while neglecting the implementation of postfailure recovery measures. This situation can be problematic because although fault tolerance results are generally positive, most organizations did not achieve the highest scores, suggesting that their systems may not be resilient to severe errors. By not prioritizing recovery capability, a significant failure could render it extremely challenging to restore the system to its normal state.

Another subcharacteristic in which the majority of companies demonstrated suboptimal results is accessibility. The inadequacy of accessible systems impedes the utilization of these platforms by individuals with special needs as well as the elderly population, who frequently experience visual or auditory impairments. This deficiency represents a missed commercial opportunity, as a substantial number of elderly individuals and persons with disabilities could potentially derive significant benefits from telemedicine. Due to the absence of adequate accessibility options, these companies have restricted access to a crucial demographic segment, resulting in biased systems that can only be effectively utilized by young and middle-aged adults.

The findings identified critical areas with direct practical implications for the development of telemedicine systems. The high scores in cryptography indicate a strong emphasis on data protection; however, organizations must continue updating these measures to counter evolving threats. The moderate level of fault tolerance suggests basic resilience but also highlights vulnerabilities during significant system failures, necessitating investment in scalable and robust infrastructure. The poor performance in recovery capability is particularly concerning, as it may result in extended service downtime and compromise patient safety, underscoring the need for formal disaster recovery plans.

XSL•FO
RenderX

Limitations

First, the assessment of security in telemedicine systems frequently presents numerous challenges due to the complex and sensitive nature of clinical data and the system itself. Consequently, the development of an instrument to evaluate the current state of a telemedicine system across various characteristics may inadvertently omit aspects that are fundamental to telemedicine. From a systemic perspective, system evaluation encompasses diverse complexities and details, ranging from requirement identification to software architecture. Nevertheless, international regulations such as the HIPAA [16], the European Union's General Data Protection Regulation [22], and the Fast Healthcare Interoperability Resources or Health Level Seven standard [23], among others, establish various levels and concerns that must be addressed by telemedicine systems. Furthermore, the policies and regulations of individual countries constitute perspectives that must be considered in any instrument designed to evaluate telemedicine systems.

Second, the instrument proposed in this study to evaluate telemedicine systems has limitations in encompassing all variants and scenarios that should be considered in telemedicine. It is conceivable that this instrument may require adaptation to the diverse regulatory frameworks for telemedicine across different countries. Nevertheless, this instrument represents the first endeavor inspired by international telemedicine regulations and is focused on the Chilean context. This initial approach has been refined and endorsed by public and foreign health decision-makers in Chile, resulting in the participation of 25 companies in this study to determine the preliminary status of their telemedicine systems' quality. Regarding security, the results of this study enable the determination of the current status of fundamental aspects of confidentiality and privacy in telemedicine systems. While a comprehensive security assessment should consider multiple levels of abstraction, such as infrastructure, networks, and providers, this study represents an initial step in the pragmatic discussion of security in telemedicine systems within the Chilean context.

Third, the instrument described in this study does not evaluate the security techniques and mechanisms employed by telemedicine companies. Specifically, the instrument is not designed to empirically analyze cryptographic techniques or compare software architecture styles, components, or technological infrastructure. The scale assessed the level of evidence provided by the company regarding the implementation of security subcharacteristics in telemedicine systems. A more comprehensive and empirical analysis of the quality and efficacy of the techniques, processes, mechanisms, and methods utilized by telemedicine companies to implement security-related subcharacteristics should be conducted in a separate study. Additionally, in our study, we primarily focused on identifying the security mechanisms employed by telemedicine systems, rather than conducting an in-depth analysis of which techniques are more significant than others. This level of detail would require examining the source code of the systems and applying more advanced comparative methods to determine the degree of importance. Therefore, our intention was to illustrate to the reader what telemedicine systems are currently implementing in terms of security, rather than analyzing the complexity of the security mechanisms themselves.

Fourth, the 6-year span of our study may not fully capture the evolution of security threats related to telemedicine systems. The field of information security and cybersecurity in telemedicine is continuously evolving in terms of vulnerability techniques and methods. In this context, our study focuses on the responses provided by telemedicine system developers, without delving into whether the techniques implemented in these systems remain adequate in light of emerging security scenarios. Nevertheless, Chilean regulations require telemedicine companies to demonstrate, through a series of processes and software artifacts, that they comply with governmental information-security standards. Consequently, companies providing telemedicine services are obliged to stay up to date with new types of security incidents. Therefore, during the 6 years covered by the study, the information provided by the telemedicine companies at least meets Chilean regulations on information security in telemedicine.

While the limitations outlined in this section may affect the generalizability of our study's findings, the instrument we developed is adaptable to a range of contexts and security environments. At present, the instrument is tailored to the Chilean context. Nevertheless, as telemedicine regulations in Chile are largely based on international standards, the instrument can be adapted to suit different scenarios in other countries. Furthermore, although adverse security scenarios in telemedicine continue to evolve, our instrument enables a cross-sectional analysis of security, which may subsequently inform more in-depth analyses of each subcharacteristic. In this regard, our study focuses on the evidence provided by telemedicine companies concerning how they address the various aspects of security; however, it does not consider how these companies adapt to different security scenarios.

Future Work

Future research will concentrate on the systematic refinement and validation of the assessment instrument employed in this study, ensuring its alignment with the evolving landscape of telemedicine technologies and emerging regulatory requirements. While the current version offers a practical evaluation of key dimensions, such as security, interoperability, and usability, the rapid advancement of digital health tools, particularly those incorporating artificial intelligence, introduces new challenges in risk management, data governance, and ethical compliance.

In the Chilean context, recent legislative developments concerning cybersecurity, personal data protection, and artificial intelligence–driven clinical decision support systems underscore the urgency of equipping telemedicine providers with tools that not only evaluate but also anticipate compliance gaps and technological vulnerabilities. This calls for a research agenda oriented toward the codesign of adaptive, evidence-based instruments that integrate technical, clinical, and legal perspectives, thereby supporting secure and more trustworthy digital health services.

XSL•FO
RenderX

Comparison With Prior Work

Poleto et al [24] addressed the increasing adoption of telemedicine systems in Brazil, driven by the necessity for health care access in remote areas and expedited implementation during the COVID-19 pandemic. The authors proposed the utilization of fuzzy cognitive maps to analyze the complexity of cybersecurity, translating expert knowledge into maps that represent causal relationships between security concepts, facilitating scenario creation, and enhancing cybersecurity strategies. For security assessment, 15 variables influencing cyberattacks were identified and validated by an information technology manager, and a fuzzy cognitive map diagram was constructed. This study demonstrates how changes and incorrect configurations can overburden servers and how insufficient investment can generate inefficiencies, emphasizing the significance of controlling information technology services.

Vidanagamachchi et al [25] conducted an analysis of the privacy and security challenges in telemedicine systems in Sri Lanka, emphasizing their significance due to the rapid adoption precipitated by the COVID-19 pandemic. Despite technological advancements and the implementation of government policies for digitalization, deficiencies in patient data protection persist due to the lack of specificity in the regulations. The authors propose a self-assessment mechanism for patients to evaluate the security of telemedicine apps. To this end, a questionnaire was developed encompassing 7 critical characteristics related to telemedicine and cybersecurity, considering the demographic and ethnic diversity of Sri Lanka. The evaluation involved collecting responses from 100 users utilizing an online questionnaire. The results indicated that the majority of participants do not peruse privacy and security policies and are unaware of storage capabilities and backup policies.

Poleto et al [26] emphasized the significance of managing cyber risks in telemedicine, particularly in the exchange of medical images, due to the susceptibility of systems to cyberattacks. They proposed a cybersecurity risk management framework for telemedicine utilizing a bowtie analysis approach that integrates fault tree analysis and event tree analysis. To assess security, the framework identifies risk factors and potential risk events, prioritizes actions to mitigate the impact of cyberattacks, and provides recommendations for establishing effective security policies. This framework is predicated on the ISO/TS 13131:2014 standard, which delineates recommendations for developing quality objectives and guidelines for telehealth services. The study also elucidates the importance of control measures to ensure the confidentiality, integrity, and availability of medical information.

Zhou et al [27] addressed concerns regarding privacy and security in telemedicine services within the context of increased utilization driven by the necessity to enhance health care access in rural areas. They proposed the development and validation of a self-assessment questionnaire for telemedicine providers to evaluate their privacy and security measures. This questionnaire was constructed based on a systematic review of security practices and the HIPAA audit protocol. The study encompassed 31 telemedicine providers who responded to 49 questions in the questionnaire. The results demonstrated that the questionnaire exhibits high reliability for assessing privacy and security practices in telemedicine systems and identified key vulnerabilities in areas such as data storage, secure networks, encryption, data backup, and informed consent.

Kim et al [1] examined the necessity of managing security risks in telemedicine systems due to the increased utilization of these technologies for remote diagnosis and prescription, particularly in the context of infectious diseases such as COVID-19, SARS-CoV, and MERS-CoV. This investigation proposes the development of a security risk assessment model for telemedicine systems utilizing an attack tree approach with attack occurrence probability and attack success probability as variables. Security threats were analyzed across 7 characteristics of telemedicine services using data collected through surveys conducted at a medical institution. The model was implemented to identify system vulnerabilities.

The studies analyzed offer diverse perspectives on security within telemedicine systems and the approaches to addressing these concerns. Several of these perspectives are reflected in the security subcharacteristics examined in our study, as they are broadly applicable to telemedicine systems. Furthermore, these studies align with the cross-sectional analysis of security policies and practices in telemedicine systems in Chile, allowing us to adapt our study to different national contexts. However, most existing studies rely primarily on theoretical frameworks, high-level risk assessment models, or self-assessment questionnaires that provide general guidance but lack direct application to operational telemedicine environments. In contrast, our study adopts a practice-oriented approach that examines how security is effectively implemented and perceived in real telemedicine systems used in Chile. This approach contributes to a contextualized understanding of how security measures are operationalized in Chile with evolving telehealth regulation, thereby complementing and extending the insights offered by previous international frameworks.

Conclusions

This study presents an investigation into the security status of telemedicine systems. Utilizing an instrument developed by the research team, the study analyzed 25 telemedicine companies and their respective systems based on 3 critical security attributes: confidentiality, availability, and integrity. The analysis aims to identify the subcharacteristics of confidentiality, availability, and integrity that telemedicine companies effectively address and the underlying reasons for their success. Conversely, the study also aims to identify the primary reasons for telemedicine companies' failure to adequately address security and the factors contributing to these shortcomings. Furthermore, the study explores the trade-offs involved in ensuring security in telemedicine, particularly concerning the usability of telemedicine systems.

We investigated 3 research questions relating to the security subcharacteristics addressed by telemedicine systems (RQ1), those that are not addressed (RQ2), and the trade-offs telemedicine companies make to ensure security (RQ3). With regard to RQ1, the findings revealed that cryptography is the principal subcharacteristic of interest in telemedicine systems in relation to confidentiality. In terms of availability, fault

XSL•FO
RenderX

tolerance is consistently addressed to prevent disruptions in medical care caused by system failures. Data integrity emerges as a variable concern among telemedicine providers; some consider it highly important, while others do not regard integrity as a particularly relevant characteristic. Concerning RQ2, the subcharacteristic receiving the least attention is resilience. The findings for RQ3 indicated that telemedicine companies generally prioritize security over usability.

The findings of this study highlight critical areas with direct practical implications for the advancement of telemedicine systems. Strong performance in cryptography reflects a clear commitment to secure data; however, organizations must ensure these measures are continuously updated to address emerging cyber threats. The moderate level of fault tolerance indicates some degree of system resilience but also exposes vulnerabilities during major failures, emphasizing the need for investment in scalable and robust infrastructure. Of particular concern is the weak performance in recovery capability, which could lead to prolonged service interruptions.

Abstract

Background: Medical science data hold significant value, and open platforms play a crucial role in unlocking this potential. While relevant platforms are being developed, the overall usage of these data values remains limited.

Objective: This study aims to propose a set of practical and effective data value evaluation processes and methods for medical science data open platforms, enabling them to manage and unlock the value of these data.

Methods: Integrating the information system success model, technology acceptance model, and consumer perceived value theory, a set of medical science data value assessment index systems was developed by adopting the literature review and expert survey methods. Data from 10 domestic and international open platforms were collected and empirically analyzed using the entropy-weighted Technique for Order Preference by Similarity to Ideal Solution technique.

Results: Based on the scores of each indicator, the intragroup correlation coefficient was calculated to be 0.489, indicating consistency in the evaluation. The highest information entropy values and weights determined using the entropy weighting method were the number of datasets (0.70, 17.68%), data timeliness (0.77, 13.44%), search comprehensiveness (0.78, 12.92%), and system responsiveness (0.80, 11.55%), respectively. Based on the weighted analysis, the platform with the highest overall score was the National Population Health Sciences Data Center, with a score of 62.32.

Conclusions: The evaluation index system and model developed can be used not only to optimize the platform's data value evaluation processes, but also to enhance the platform's overall data value and encourage users to reuse data.

Introduction

Background

Medical science data refer to data generated through basic and applied research, experimental development, as well as raw and derived data obtained through observation, monitoring, inspection, and testing [1]. These data include electronic health records, long-term treatment outcome data, experimental drug performance data, and wearable device data. Medical science data are considered a strategic resource, offering significant scientific benefits such as reducing research costs, accelerating the research process, improving research quality, and increasing the impact of data [2]. For example, electronic health records can not only help doctors make diagnostic and treatment decisions more accurately and quickly, but also assist patients in understanding their own health status and promoting self-management.

According to investigations, approximately 469 and 750 medical science data platforms have been registered on FAIRsharing and Re3data, respectively [3,4]. Despite such widespread availability, user survey reports indicate that the usage and downloads of many platforms are far lower than expected. This gap stems from users' insufficient awareness of the research field and potential benefits. For example, clinicians still rely heavily on experience and traditional methods for clinical decision-making rather than using data-driven analytical tools. The public perceives medical data as overly specialized, thus overlooking its importance. Platforms often fail to demonstrate the value of data in an understandable and user-friendly way, making it difficult for users to grasp its practical applications.

XSL•FO
RenderX

Existing open health care platforms have challenges such as limited open sharing of data, low standardization, poor data quality, insufficient value mining, insufficient privacy protection, and low usage. The main reason behind these challenges is the inability of both platforms and users to objectively quantify the potential value of data. Platforms suggest identifying the key factors in the formation of data value and allocating resources effectively, while users are unable to carry out data activities based on the true value of data.

Prior Work

In the past, scholars have assessed the value of data in different scenarios, including the assessment of enterprise data value in business contexts [5,6], the evaluation of government data [7,8], and social media data [9] in nontransactional scenarios. Given that platform data are more readily accessible, research has increasingly focused on assessing the value of data from platforms. In terms of assessment theories and perspectives, assessment is usually conducted from the accounting perspective, stakeholder perspective [10], data life cycle or data value chain perspective [11], data traceability perspective [12], and seldom adopts a comprehensive perspective or innovative theories. In terms of evaluation content and methods, the valuation of intangible assets [13,14] typically uses approaches such as the cost method, market method, and income method, with a focus on data value components such as cost and income. In recent years, scholars have introduced revenue monetization, impact-based approaches, experimental and survey techniques, comprehensive multiattribute evaluation, and intelligent methods, which emphasize evaluation from multiple value dimensions and factors affecting data value [15-17].

Medical science data are rich and sensitive enough to generate valuable scientific insights, but the assessment of their value remains fragmented. Initially, Wang and Strong [18] proposed one of the most widely used frameworks for assessing data quality, but due to the complexity of the data quality concept, there is still no consensus on its measurement. Given that different types of data apply to different contexts, they cannot be assessed with a one-size-fits-all approach [19]. Scholars have made significant efforts to assess the value of research data. For example, Schmidt et al [20] developed a framework for assessing the quality of research data. Uribe et al [21] assessed the quality of research data based on the FAIR (Findable, Accessible, Interoperable, and Reusable) principle. Regarding the quality of health care data or information, Feder [22] summarized the dimensions and methods for assessing the quality of EHR data. Kim et al [23] proposed a conceptual model for the quality of health care data. Zhang and Trace [24] explored the quality of self-tracking data. Lasim et al [25] identified accuracy, timeliness, completeness, and consistency as key dimensions for assessing the quality of health care data. Wu et al [26] described the quality of health data in terms of dataset quality, descriptive data quality, and metadata quality.

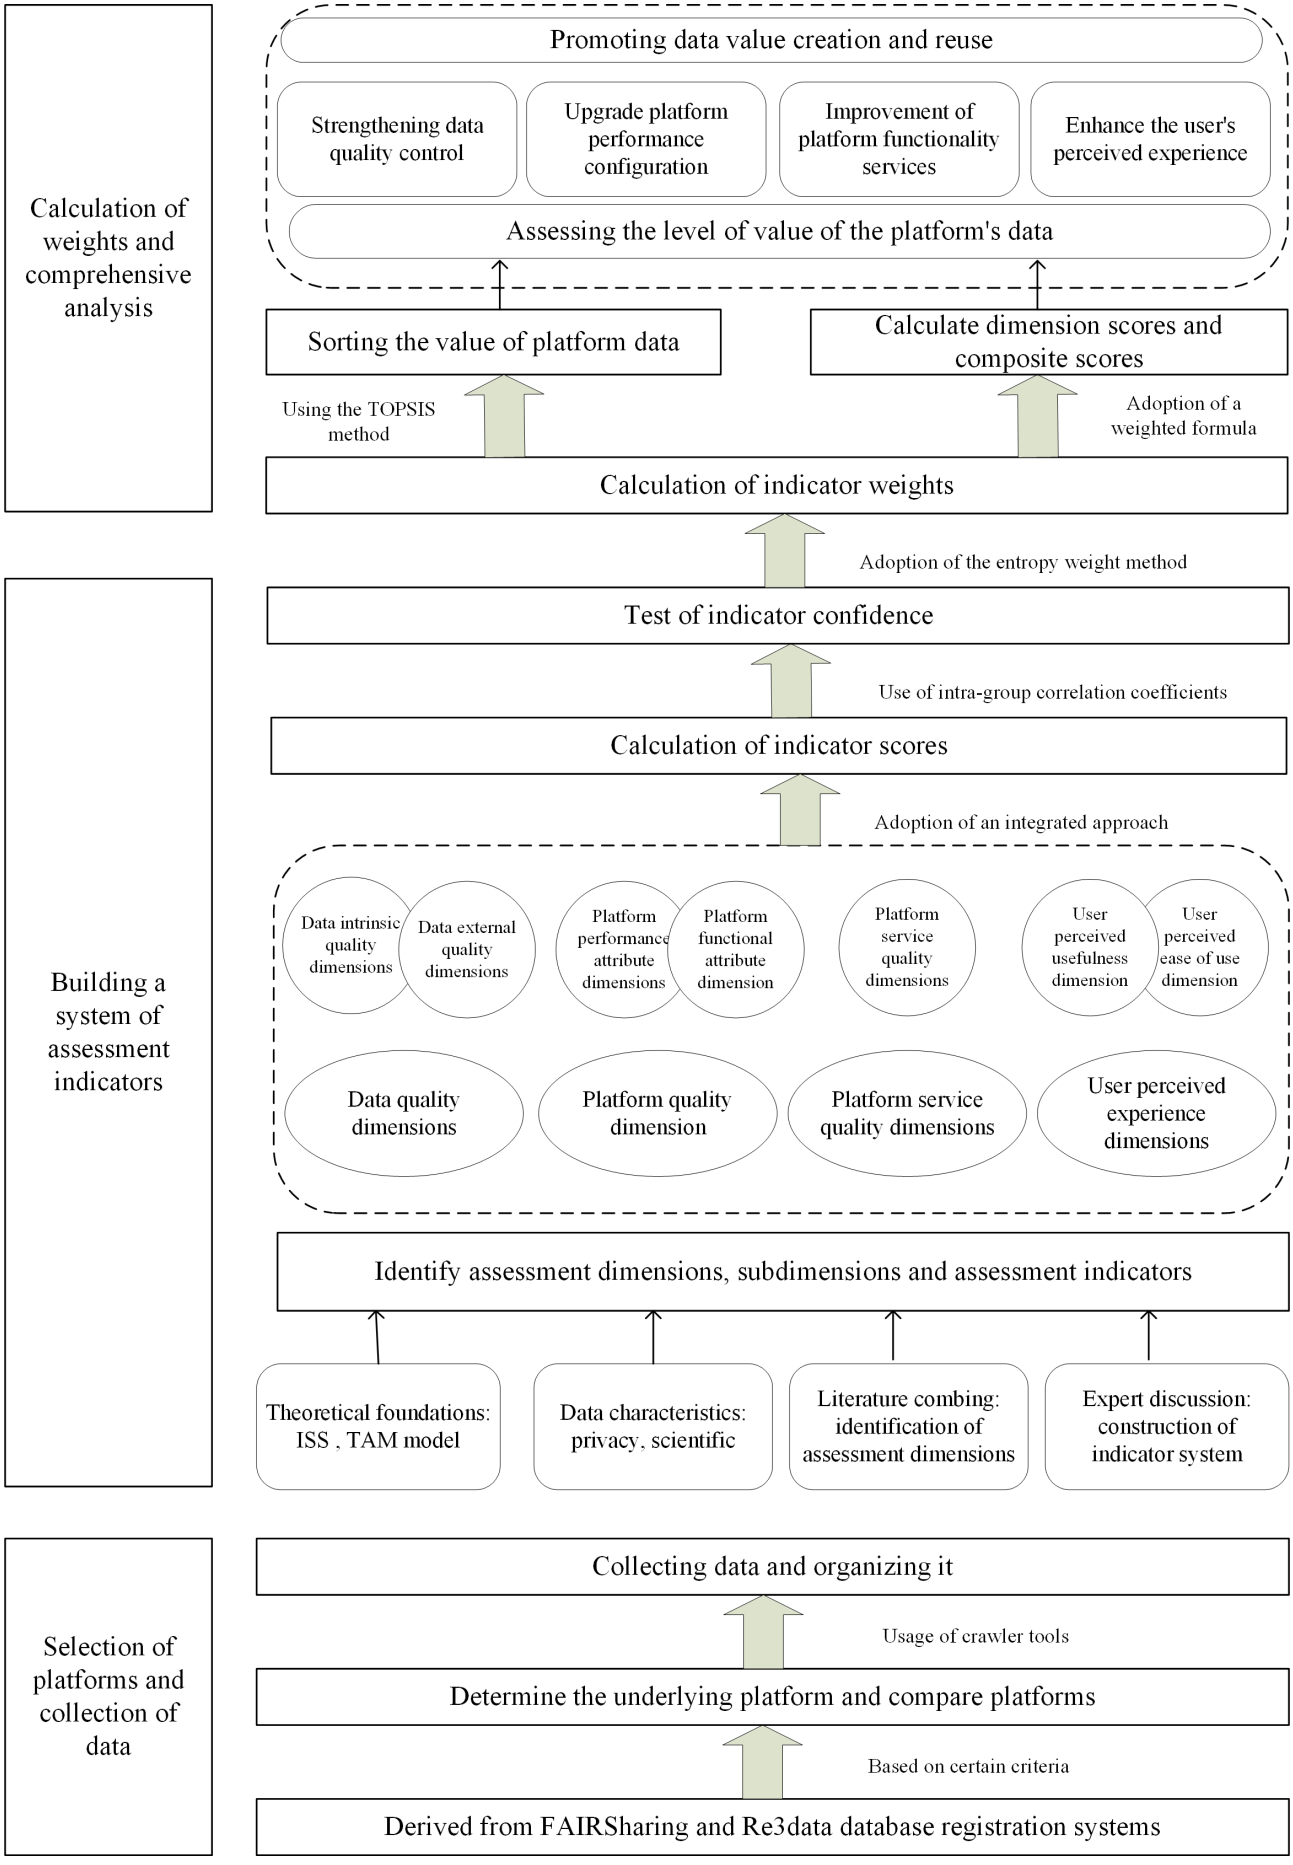
This study assesses the value of medical science data on open platforms based on an integrated perspective and using a combination of qualitative and quantitative methods, aiming to fill the gaps in existing research.

Objective

This study aims to construct the index system and model of medical science data value assessment from the perspective of the platform and propose the optimization process of data value assessment and data value enhancement strategy. Specifically, the medical science data open platform includes a medical science data resource base and a knowledge base. The platform perspective refers to analyzing and understanding the role, value, and function of the platform in a specific ecosystem from the perspectives of the platform's overall architecture, functional design, and interaction with users, data, and other stakeholders.

The questions to be addressed are as follows: (1) How to construct the medical science data value assessment index system and assessment model? (2) How much do different assessment dimensions and indicators contribute to the value of medical science data? (3) How scientific and usable are the constructed assessment models?

Methods



Study Design

The key steps in this process include developing an assessment index system, calculating weights, and conducting comprehensive analyses, which are as follows:

1. Determination of the assessment subject: a selection of domestic and international platforms was chosen as subjects for comparison, using FAIRsharing and Re3data as primary sources, with large datasets serving as standards. These data resources were mined using web scraping tools to provide the foundation for calculating indicator weights.
2. Development of the assessment indicator system: drawing on the theoretical model, a review of the literature, and the characteristics of the data, the initial set of assessment indicators was identified. The indicator system was refined through expert evaluation, with manual verification and other methods used to assess indicator scores and validate their reliability using the intraclass correlation coefficient (ICC).
3. Collection of indicator weights: the entropy weight method was used to determine the weights of the indicators. For a comprehensive evaluation, the Technique for Order Preference by Similarity to Ideal Solution method was applied. The weighted scores were then used to calculate the overall data value of each platform. This model aids platforms in quantifying the potential value of their data, assessing data quality, and enhancing control mechanisms. The study design is presented in Figure 1.

Construction of the Indicator System

Figure 2 shows the steps to build the evaluation index system.

Figure 2. Steps to construct an evaluation value indicator system. ISS: information systems success; TAM; technology acceptance model.

Assessment Framework Construction

The formation of the potential value of the data mainly relies on the platform, and the user is the platform experiencer and data user, who will develop specific subjective cognitions while using the platform data and will give an overall evaluation of the platform's data value. As a result, medical science data value can be defined as the perceived value generated by users in the process of discovering, acquiring, manipulating, and reusing medical science data captured and organized by the platform, involving data, platform, and user dimensions. The data dimension directly assesses data value, while the platform and user dimensions indirectly assess data value.

This study constructs an evaluation theoretical framework based on the information systems success model (ISSM), the technology acceptance model (TAM), and the theory of perceived value of users. An open platform can be regarded as an information system, so the influence factors of data value realization can be analyzed using ISSM. However, because ISSM focuses on analyzing the influence of the data and platform dimensions on the user's net benefit (perceived value), it is integrated with TAM to supplement the influence of the user dimension on the user's net benefit.

As shown in Figures 3 and 4, in ISSM, 3 factors—information quality, system quality, and service quality—affect users' willingness to use. In TAM, the user's perceived usefulness and perceived ease of use will also affect the user's attitude. Therefore, the dimensions of information quality, system quality, service quality, perceived usefulness, and perceived ease of use were selected to evaluate the value of data.

XSL•FO
RenderX

Figure 3. Information systems success model.

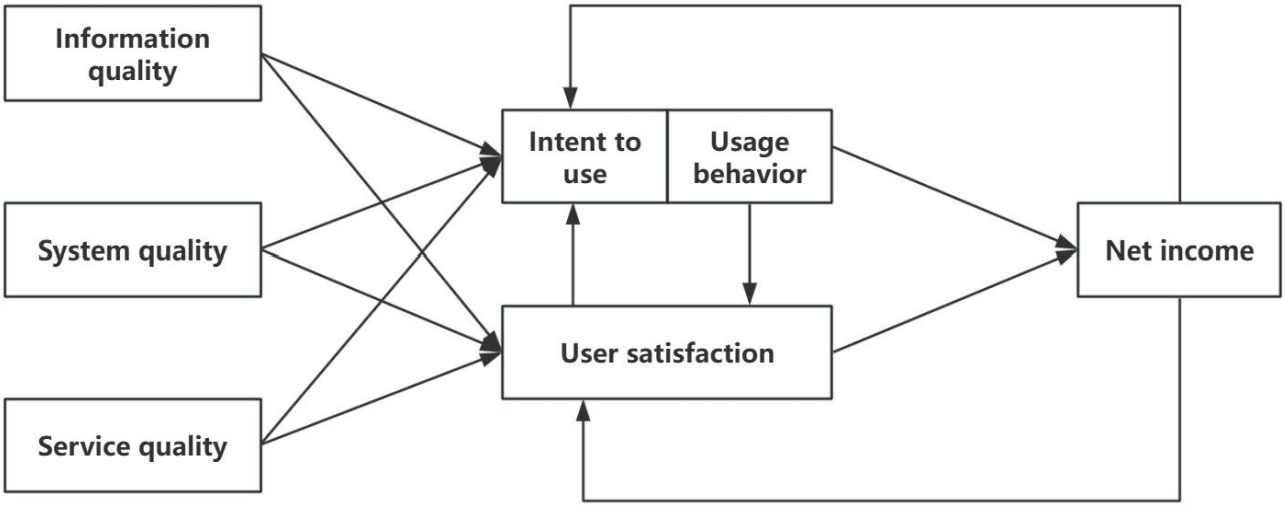

Figure 4. Technology acceptance model.

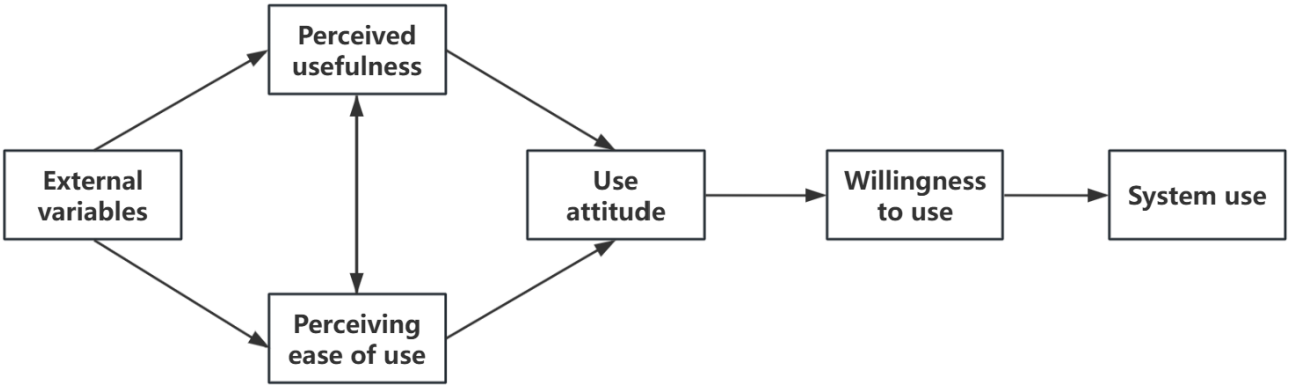

Table 1 illustrates the dimensions of each theory and their unique role in the model.

In this framework, good data quality ensures that users have access to high-quality data resources; good platform quality and platform service quality ensure access to perfect infrastructure and services; and perceived usefulness and ease of use ensure motivation to use the data. All 5 dimensions influence users' willingness to use the system and their behaviors, which stimulates the formation of data value.

Table . Theoretical dimension action table.

Theoretical model	Assessment dimensions	Unique role
ISSM[a]	• Information quality: data quality • System quality: platform quality • Quality of service: platform service quality	Evaluate the objective attributes of the data (eg, accuracy and completeness), stability of the technology platform, and effectiveness of support services.
TAM[b]	• User-perceived usefulness • User-perceived ease of use	Measure the user's subjective perception of the value of the data for their research or practice, and the impact of the platform's ease of use on willingness to use.
Consumer-perceived value theory	• Final value assessment	Integrate objective quality and subjective perception to form the user's overall judgment of the value of the data (eg, willingness to pay and willingness to recommend).

[a]ISSM: information systems success model.

[b]TAM: technology acceptance model.

Selection of Assessment Indicators

Based on the principles of objectivity, systematicity, and scientific rigor, this study identifies 5 dimensions: data quality, platform quality, platform service quality, user-perceived usefulness, and ease of use. The data quality dimension is subdivided into the quality of intrinsic data attributes and extrinsic attributes, while platform quality is subdivided into platform performance and functional attributes. Combined with

XSL•FO
RenderX

the literature research, specific assessment indicators were identified under each dimension.

Screening of Assessment Indicators

The Delphi method was used to construct the medical data assessment system. Thirteen cross-disciplinary experts (5 data assessment experts, 4 medical informaticians, and 4 clinicians) were invited to conduct 3 rounds of iterative review to screen the indicators based on a 5-level Likert scale (retention thresholds: mean ≥3.0 and SD <1.0). The data accuracy indicator was removed due to overlap with data integrity, and new indicators related to service confidentiality, assurance, and other medical-specific characteristics were added, resulting in a 5D, 35-indicator system, with complete definitions provided in Table 2 and Multimedia Appendix 1.

Table . Indicator framework for assessing the value of medical science data.

Dimension and source	Subdimension	Indicators
Data quality		
Saxena [8]	Quality of intrinsic data attributes	• Number of datasets • Data integrity • Data comprehensiveness • Data timeliness • Data authenticity
Zhang and Trace [24]	Quality of data external attributes	• Data consistency • Machine readability • Format openness • Data understandability
Platform quality		
Wu et al [26]	Quality of platform performance attributes	• System stability • System security • System responsiveness • System compatibility • Interface friendliness • Linguistic diversity
Martin et al [27]	Platform functional attributes	• Platform infrastructure • Platform overview function • Platform guidance function • Data access function • Results display function • Comprehensiveness of functions
Platform service quality		
Azeroual et al [28]	Quality of platform services	• Service interactivity • Service personalization • Service accessibility • Service confidentiality • Service assurance • Search comprehensiveness
User-perceived usefulness		
Imran and Ahmad [29]	User-perceived usefulness	• Relevance • Usefulness • Uniqueness • Novelty
User perceived ease of use		
Imran and Ahmad [29]	User perceived ease of use	• Findable • Accessible • Interoperable • Reusable

Empirical Analysis

Sample Platform Selection

China's open platforms for medical and scientific data boast several advantages, including "large data volume, diverse data sources, and high data quality." However, they also face challenges such as "an overemphasis on data security, limited data sharing, and reliance on a single data-providing organization." The sample platforms were screened from authoritative websites such as Re3data.org and FAIRsharing. The selection criteria required that the platforms be open and stable, provide basic data, regularly update content, offer comprehensive functionality, and demonstrate mature construction. The selection process for the sample platform is shown in the Multimedia Appendix 2. Table 3 lists the selected platforms, and data collection was conducted using Octopus (Shenzhen Digital Broad Information Technology Co).

Table . Overview of the 10 sample platforms selected for this study.

Nation	Name of platform	Developer	Data resource
China	National Population Health Sciences Data Center (NCMI)	Institute of Medical Information, Chinese Academy of Medical Sciences	Population health science data
China	GigaDB Database	Beijing Institute of Genomics, Chinese Academy of Sciences	Biological and biomedical field data
China	GSA[a] for Human	National Genomics Data Center (NGDC)	Raw data on human genetic resources genomics
United States	National Addiction and HIV Data Archive Program (NAHDAP)	Inter-University Consortium for Political and Social Research (ICPSR)	Data from research related to drug addiction and HIV
United States	PhysioNet	Massachusetts Institute of Technology (MIT)	Physiological and clinical data
Multinational	MGnify	European Bioinformatics Institute (EMBL-EBI)	Microbiome data and macrogenomic data
United States	OpenNeuro	Stanford University	Brain imaging datasets
United States	Immunology Database and Analysis Portal (ImmPort)	National Institute of Allergy and Infectious Diseases (NIAID)	Clinical and basic research data
Multinational	BioImage Archive	European Bioinformatics Institute (EMBL-EBI)	Bioimaging data
Multinational	EBRAINS	Human Brain Project (HBP)	Brain research data

[a]GSA: Genome Sequence Archive.

Calculation of Indicator Scores

The indicators can be divided into three categories: (1) simple indicators, such as the number of datasets and data completeness, can be determined by simple calculations and are suitable for manual checking, 0 - 1 assignment, and mathematical statistics; (2) text-based indicators, such as data comprehensiveness and comprehensibility, necessitate the processing of textual information, such as data categories and data summaries, and are suited for data crawling and text analysis; (3) subjective indicators, such as interface friendliness and relevance, are based on users' subjective feelings and can be calculated using the illumination interview approach. The formulas and results of each indicator are shown in the Multimedia Appendix 3.

Indicator Reliability Tests

The ICC can be used to determine consistency. In this paper, both the differences between different assessment indicators and the differences between different platforms are considered, while systematic errors are not considered. The output results from the Statistical Product and Service Solutions Automatically Using Software are shown in Table 4.

Because the evaluation index scores are processed in advance, the "average measure ICC(C,K)" is used, with an ICC value ranging from 0 to 1. ICC values of more than 0.40 typically indicate good consistency. Table 4 reveals that the final ICC value is 0.489, which is greater than 0.4, indicating that the evaluation's consistency is good and the indicator is reasonable.

XSL•FO
RenderX

Table . Results of correlation coefficients within intraclass correlation coefficient groups.

Bidirectional mixing and randomization consistency	ICC[a] (95% CI)
Single metric ICC(C[b],1[c])	0.027 (−0.003 to 0.137)
Average metric ICC(C,K)[d]	0.489 (−0.101 to 0.848)

[a]ICC: intraclass correlation coefficient.

[b]C denotes consistency.

[c]1 denotes a single measure.

[d]K denotes an average measure.

Calculation of Indicator Weights

The entropy weight approach is appropriate for dealing with the problem of multi-indicator empowerment because it can handle the interplay between various elements while also considering the correlation between different indicators. Its specific steps include (1) data standardization, (2) calculation of the ratio of each indicator in each scheme, (3) calculation of the information entropy of each indicator, (4) calculation of the weight of each indicator through the information entropy value, and (5) calculation of the comprehensive score of each scheme. Multimedia Appendix 4 shows the weights of the complete indicators derived from the entropy weight method.

Ethical Considerations

This study did not require formal ethics committee review, as it exclusively analyzed publicly accessible platform interfaces, technical documentation, and aggregated system-level characteristics, without the collection of identifiable human data. This exemption aligns with the National Health Commission of China Regulations, Article 24, which states: "Ethics review may be waived for studies using publicly available data or records where individuals cannot be identified, and the research does not interact with human participants." It also aligns with the JMIR policy on nonhuman participants research, which states: "Ethics approval is not required for studies evaluating technology systems, public documentation, or organizational practices where human participants are neither involved nor identifiable."

Results

Comprehensive Analysis

To determine the optimal and worst solutions, the positive and negative ideal solution distances and relative proximity were calculated, as shown in Table 5. From Table 5, it can be seen that the National Population Health Sciences Data Center (NCMI; Institute of Medical Information, Chinese Academy of Medical Sciences) has the highest data value, which is close to the ideal level and serves as a valuable benchmark for other platforms.

Table . Technique for Order Preference by Similarity to Ideal Solution (TOPSIS) evaluation calculations.

Platform	Distance to positive ideal solution, D^+ (unit:fraction)	Distance to negative ideal solution, D^- (unit:fraction)	Relative proximity, C (dimensionless)	Sort result
NCMI[a]	17.384	22.253	0.561	1
GigaDB	25.848	5.021	0.163	8

[a]NCMI: National Population Health Sciences Data Center.

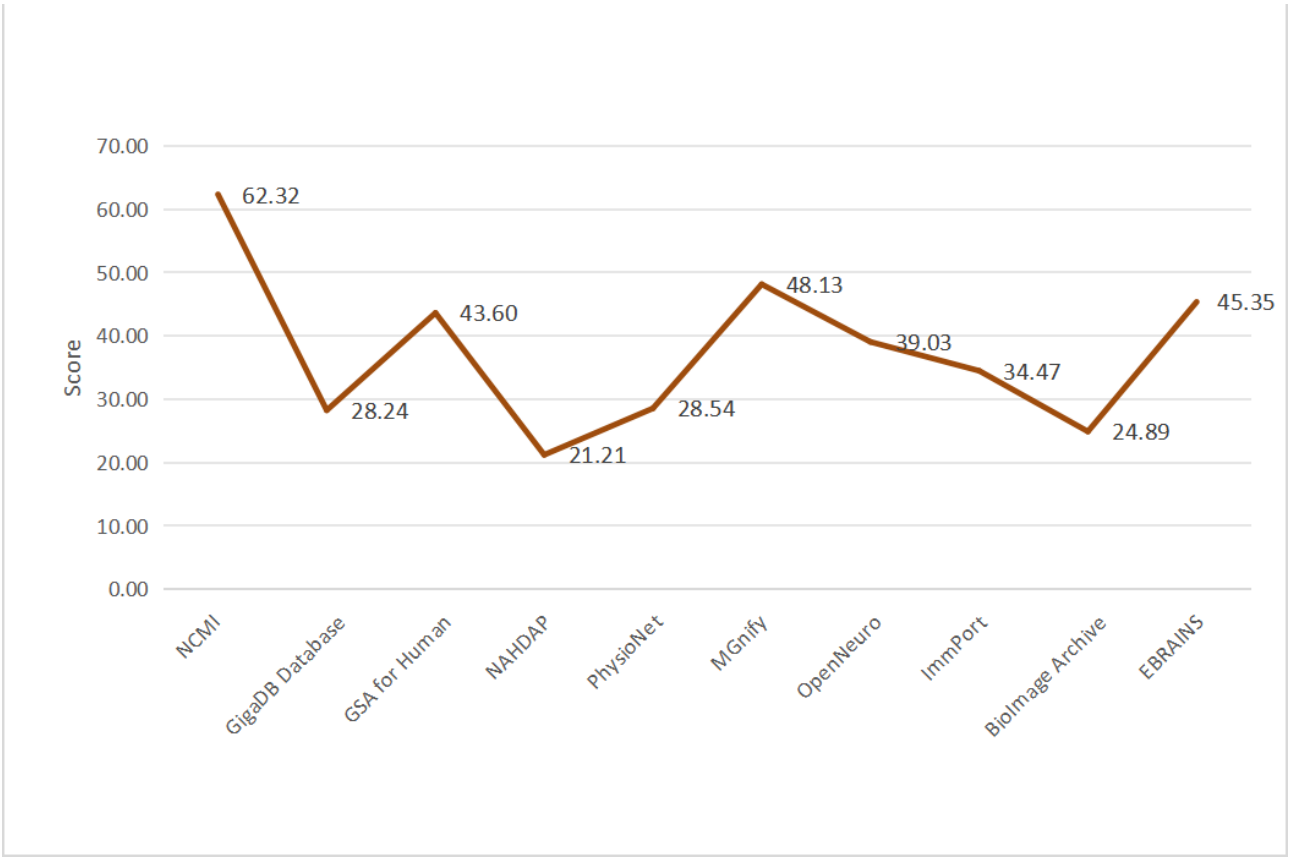
[b]GSA: Genome Sequence Archive.

[c]NAHDAP: National Addiction and HIV Data Archive Program.

The weighted formula was used to calculate the scores and composite scores for the different dimensions of data value for each platform:

$$(1)\text{Score}(Pij)=\sum wkXk$$

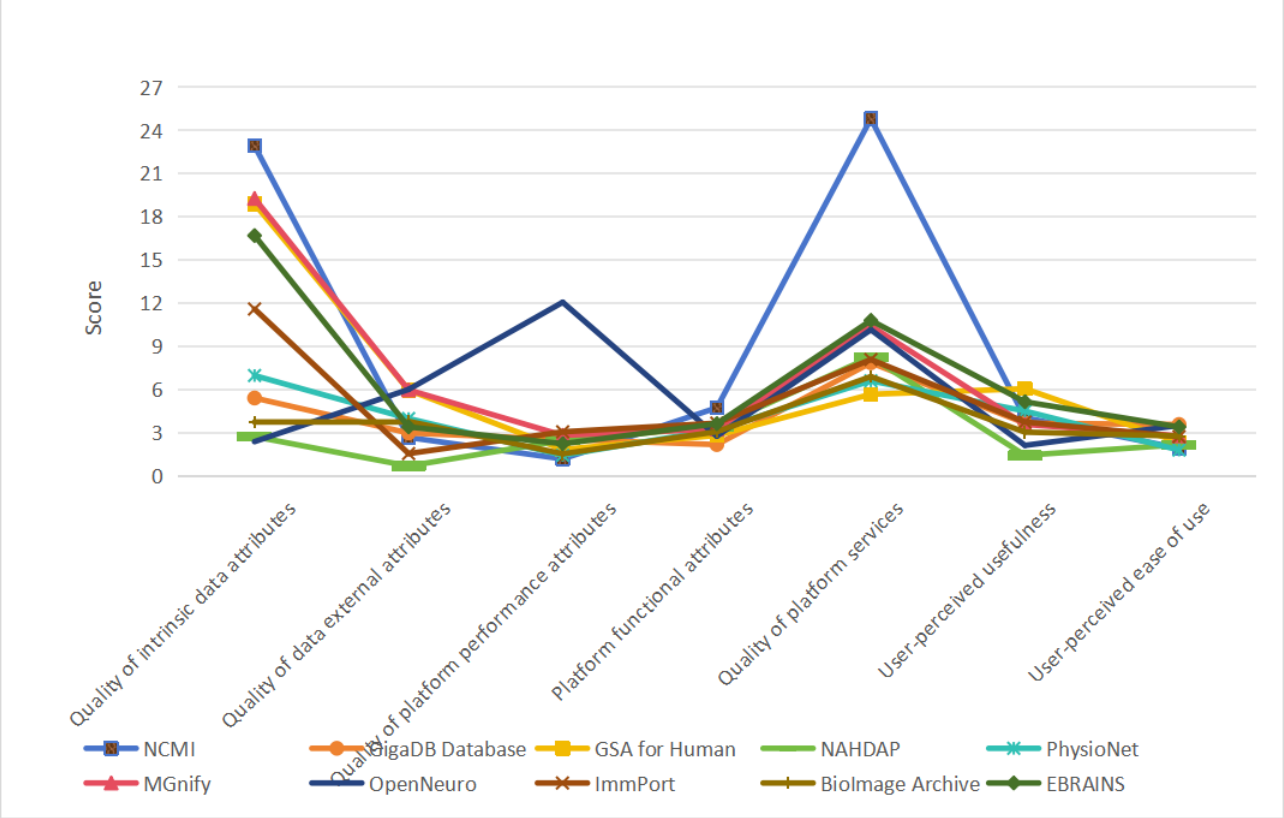
$$(2)\text{Score}(Pi)=\sum j=17wj\text{Score}(Pij)$$



Where i denotes the ith platform, j the jth dimension, and k the kth indication. Score (P) reflects the data value score of the jth dimension of the ith platform, as well as the platform's

XSL•FO
RenderX

overall data value score. Figures 5 and 6 show the differences between each platform's data value by dimension and their comprehensive scores.



As shown in Figures 5 and 6, there are large differences in data value across the dimensions of intrinsic attribute quality, extrinsic attribute quality, platform service quality, and perceived usefulness. The average score of the platforms is 37.579, with NCMI, MGnify (European Bioinformatics Institute), EBRAINS (Human Brain Project), GSA for Human (National Genomics Data Center), and OpenNeuro (Stanford University) scoring higher than the average, reflecting good overall performance.

Figure 5. Line graph of data value dimension scores for each platform. GSA: Genome Sequence Archive; NAHDAP: National Addiction and HIV Data Archive Program; NCMI: National Population Health Sciences Data Center.

XSL•FO
RenderX

Figure 6. Line graph of the composite data value score of each platform. GSA: Genome Sequence Archive; NAHDAP: National Addiction and HIV Data Archive Program; NCMI: National Population Health Sciences Data Center.

Model Validation

The evaluation reveals that (1) Chinese platforms demonstrate data quality strengths but require improvements (eg, NCMI shows slow updates and low availability of machine-readable format; GSA lacks completeness in data attributes/types), (2) platform functionality favors NCMI for comprehensiveness, while OpenNeuro leads in responsiveness, (3) service quality analysis shows NCMI's advantages in personalization and search capability; however, all platforms need enhancements in service assurance and confidentiality, (4) GSA excels in content novelty/relevance despite overall low data utility across platforms, and (5) GiagDB demonstrates strong usability despite partial FAIR compliance. The model successfully identifies critical gaps in China's platform data management and proposes targeted optimization pathways, thereby validating its scientific rigor.

Discussion

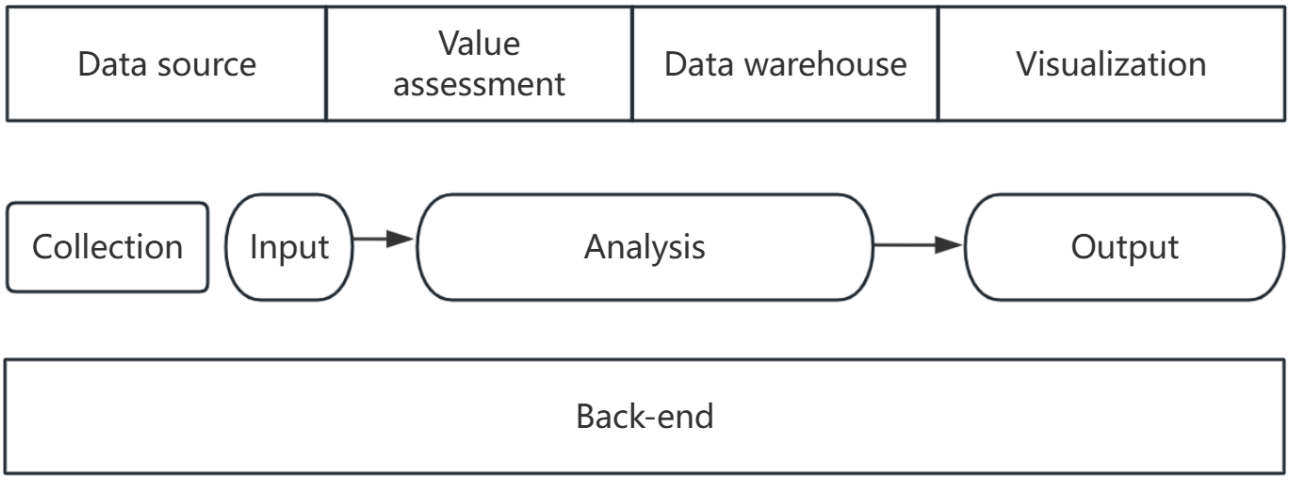
Principal Findings

This study establishes a novel medical data valuation framework through a 3D (data-platform-user) analysis, integrating service privacy metrics. By combining qualitative and quantitative methods, the hybrid approach reduces subjectivity bias, generating an evaluation model that enables data value quantification and personalized management strategies.

Comparing the results of government data value assessment, the following conclusions can be drawn: (1) indicators related to the data itself, such as the number of datasets, data timeliness, and machine readability, as well as indicators such as system responsiveness and service interactivity, are considered very important, (2) compared with government data, medical science data is private and scientific, so the weight of indicators such as service security, service confidentiality, accessibility, and reusability are more prominent, and (3) in the process of data value realization, the data itself have potential value, but their actual realization requires further development, so indicators related to platform quality and platform service quality, such as search comprehensiveness and service personalization, are also crucial.

Model Application

Optimize the Process of Assessing the Value of Platform Data



1. To assist platforms in efficiently assessing data value and formulating management strategies, this study proposes two practical solutions based on the established evaluation index system: (1) designing a universal self-assessment tool, leveraging the international Confederation of Open Access Repositories (COAR) community framework to enable convenient self-evaluation; and (2) developing an intelligent assessment system that enhances evaluation efficiency by integrating automation technologies with human intervention. These solutions synergistically advance data value assessment from theoretical frameworks to practical implementation.
2. Design of a generic self-assessment tool: the COAR, an international association that brings together repositories from around the world to build a global network of

XSL•FO
RenderX

knowledge repositories, has developed a global COAR Community of Good Practice for Repositories framework designed to help repositories in different regions and of different types evaluate and improve their practices [30]. In November 2023, the COAR Asia OA Webinar, based on the COAR community framework, proposed the survey toolkit—a self-assessment tool for repository development that asks repositories to answer 60 questions to assess their practices and identify areas for improvement. Repositories that provide affirmative responses to all "Essential" questions are awarded a digital badge, which can be displayed on their websites [31]. Drawing inspiration from these examples, this study can also propose a data value self-assessment tool, which will undergo iterative updates and refinements based on feedback and usage.

3. Development of an automated assessment system: creating automated and semiautomated assessment tools can improve the accuracy and efficiency of assessments. Blacketer et al [32] created the data quality dashboard, an open-source R package to evaluate the quality of observational health care data and indicate potential data quality issues by merging the Data General Model with established data quality assessment methodologies. The architecture of the automated data value assessment system (Figure 7) should cover the modules of input, analysis, output, and back-end, and the assessment of the implementation process should include several aspects: the data source, data quality assessment model, and data warehouse. Therefore, analyzing the data value of the platform should be done systematically and configured with automated assessment procedures and methods, tools, and software.

Figure 7. Architecture of the data value assessment system.

The automated assessment of data value faces a double challenge: at the technical level, it needs to break through data dependency, cross-domain generalization bottlenecks, and algorithmic interpretability defects; at the ethical level, it must construct a privacy-informed dynamic balancing mechanism that controls leakage risk through differential privacy and federated learning, and embeds fairness checking modules to eliminate group bias.

Multidimensional Improvement of the Data Value of the Platform

To advance medical data platforms holistically, this study proposes a multifaceted enhancement strategy spanning four critical dimensions: implementing dual-track data quality control (source integration and FAIR-aligned standardization), upgrading platform performance functionality through technical optimization and value-visualization tools, establishing a tripartite privacy governance framework (organizational-management-technical), and constructing user-centric service ecosystems with demand-driven customization and collaborative training.

A dual strategy is needed to improve data quality. First, a mechanism should be established for data aggregation from multiple sources, including integration of data resources from research institutions, development of unified classification standards, and implementation of update cycles to maintain data currency. Second, data presentation format should be standardized by mandating the use of machine-readable formats, ensuring metadata completeness, and aligning attribute descriptions with the FAIR principles. Technically, intelligent quality control tools can be integrated, such as an RNA-Seq data cleaning algorithm [33], to automatically filter contaminated data.

The quality of the platform must be improved in both directions through performance and functionality: the technical side adopts resource compression algorithms and multilevel content delivery network caching to ensure that page loading time is reasonable; the functional side builds a data value visualization system (dynamic leaderboards/timing trend charts) and integrates data challenges and health apps to improve the usage rate. The platform needs to expand higher-order functional modules (eg, thematic data aggregation, blockchain traceability verification, and knowledge graph mining), build a full-cycle service system (training-consultation-feedback closed-loop), and improve the effectiveness of data usage through intelligent operation and maintenance optimization.

In terms of data services, the platform can draw on the Tencent Foraging Open Experimental Platform (jointly developed by Tencent Cloud and a team from Tencent's Medical AI Lab) to build a comprehensive intelligent service system for medical imaging research application scenarios. This includes data

XSL•FO
RenderX

management and labeling, algorithm training, testing, and application. In addition, medical data privacy protection needs to build an organization-management-technology synergistic system: set up an ethical review committee at the organizational level and formulate a GDPR (General Data Protection Regulation)-compatible privacy agreement, implement k-anonymization and homomorphic encryption technology at the management level, and deploy a federal learning framework at the technical level to achieve data availability and invisibility. Given the existing problems, such as the disconnection between privacy algorithms and scenarios, and the shortcomings of a single level of protection, it is recommended that we borrow the concept of the United Kingdom's "five safe" to build a trinity of protection systems for "data-people-environment," and synchronize the development of a multilayered architectural platform similar to the MNSSp3, so that we can balance the value of medical research with individual privacy rights and interests [34]. The platform needs to build a user-centered service system. First, it should build a demand portrait based on collaborative filtering algorithms, collect user feedback on time, dynamically adjust the data opening strategy, realize the accurate push of high-value data, establish a grading model of user capabilities, and provide differentiated data service interfaces. Second, the platform should unite with academic institutions to create a modular training system, integrate multidimensional education scenarios such as workshops, internet-based communities, and data competitions, break through the traditional one-way training model, and improve users' data reuse capabilities. It can draw on the World Health Organization (WHO) to create automated tools and regional customized training experiences [35].

Limitations

This study acknowledges three principal methodological constraints that warrant consideration when interpreting the findings:

1. Indicator subjectivity: the construction of the indicator system and the scoring of certain indicators are more subjective, which may introduce assessment bias. The expert survey method was used to discuss and screen the indicators, and the ICC method was used to test the consistency of the assessment; the ICC value is 0.489, indicating that the consistency is at a medium level. This may be due to the differences among evaluators, overly complex measurement dimensions, or a small sample size. This issue can be improved by clarifying the scoring criteria, revising the scale, and increasing the sample size.
2. Sample coverage: the current empirical evidence covers 10 platforms. Although the number of sample platforms selected is relatively limited, it covers mainstream medical data types and has a certain selection basis (refer to Multimedia Appendix 2 for details). A follow-up study is planned to expand the number of sample platforms and include European medical science data platforms.
3. Limitations of value dimension: data value assessment is carried out along the mechanism of "value perception and identification→value realization→value assessment→data governance." However, this paper focuses on the assessment of perceived value and does not involve the mechanism of value realization. The next step is to construct a data trust assessment framework, develop value stream analysis tools, and explore collaborative governance models.

Comparison With Prior Work

At the theoretical level, this study broadens the perspectives, objects, and methods of data value assessment research and refines the strategies for value enhancement of medical science data on open platforms. At the practical level, the assessment model developed in this study can not only help platforms reasonably quantify the potential value of data, identify key factors in the formation of data value, discover deficiencies in data collection and organization, formulate data investment decisions and openness plans, and promote the effective allocation of data resources; it can also help users recognize the potential benefits of the data on the platforms and better use the data resources in their data activities, and help countries to understand the benefits of open medical science data to optimize data regulations and systems.

Conclusions

This study focuses on assessing the value of medical science data from the perspective of platforms, and the results of the study include (1) a data value assessment index system with 5 dimensions and 35 indicators was created by using ISSM, TAM, and the theory of perceived value of consumers, which is scientific, (2) 10 open platforms were selected, data were collected through Octopus and empirically examined using the entropy weight Technique for Order Preference by Similarity to Ideal Solution method, and the assessment model was established and scientifically verified, and (3) the practical application of the proposed model can not only optimize the data value assessment process, but also enhance the data value of the platform from multiple dimensions.

Acknowledgments

With the emphasis on the value of medical science data and the development of related platforms in full swing, it is critical to assess the value of medical science data from a platform viewpoint, which may assist platforms in managing data and unlocking data value. As a result, this research has emerged. The author would like to extend gratitude to every expert who took part in our research, since their insights substantially improved our findings.

Abstract

Background: Primary health care centers (Puskesmas) serve as the cornerstone of Indonesia's health care system, providing integrated services aimed at improving individual health through prevention, treatment, and health promotion. To fulfill these roles effectively, robust technological infrastructure, particularly reliable internet connectivity, is increasingly essential. Assessing the availability and quality of internet access in Puskesmas is therefore a critical step in understanding their readiness to implement digital health initiatives and fulfill their responsibilities in delivering accessible and effective healthcare services.

Objective: This study provides a national baseline assessment of internet quality and its relevant IT infrastructure in more than 10,000 Puskesmas across Indonesia.

Methods: A cross-sectional survey was conducted throughout all Puskesmas (10,382) in 34 provinces in Indonesia, using an online questionnaire. Categorization was done to analyze internet quality level results.

Results: A total of 10,378 out of 10,382 public health centers (99.96%) participated in this study. Overall, 745 of 10,382 (7.18%) did not have internet access, 1487 (14.33%) had limited internet access, 5567 (53.64%) had sufficient internet access, and 2579 (24.85%) had sufficient and fast internet access. Moreover, 832 of 10,382 Puskesmas (8.02%) did not have 24-hour electricity, 44,196 (43.7%) had a central processing unit (CPU) with i3 specifications, 43,044 (42.56%) had 512 GB hard disk capacity, and 67,272 (66.5%) used antivirus.

Conclusions: Although 79% (8201/10,382) of Puskesmas in Indonesia already had sufficient internet access, 21% (2180/10,382) still have limited and insufficient access. To ensure universal internet availability, it is essential to build collaborative support among internet providers and government to foster the availability and use of internet satellites, high-quality computers, and electrical power to support internet connectivity.

Introduction

Primary health care (Puskesmas) is a core component of health systems [1]. Based on the Alma Ata Declaration in 1978, Puskesmas is defined as essential health care that meets the needs of communities, is easy to access, acceptable, and affordable [2]. The declaration combined 3 elements considered core to delivering sustainable and equitable health services: multisectoral public policy, empowered communities, and primary public health care [2,3].

XSL•FO
RenderX

In 2022, the Ministry of Health (MoH) of the Republic of Indonesia launched its health system transformation strategy. There are 6 pillars of the transformation strategy, and one of them is primary health care (PHC) transformation, which in its implementation focuses on strengthening promotive and preventive activities to create more healthy people, improve health screening, and increase primary service capacity. The number of Puskesmas has increased since 2017, from 9825 units to 10,374 Puskesmas in 2022. The ratio of Puskesmas in Indonesia to subdistricts in 2022 is 1.4. This illustrates that the ideal ratio of Puskesmas to subdistricts, namely a minimum of 1 Puskesmas in 1 subdistrict, has been fulfilled nationally. In terms of an average ratio, each Puskesmas serves 27,000 - 30,000 residents in 2023. What needs to be considered is the distribution of the Puskesmas in all subdistricts, especially in remote, frontier, and outermost areas to provide public health services to households with a focus on maternal and child health services, elderly health, communicable disease, and noncommunicable disease prevention [4].

Puskesmas in Indonesia spread across all types of characteristic regions such as urban, rural, remote, and very remote in Indonesia within all 38 provinces and 514 districts or cities. In Indonesia, there are two main functions of Puskesmas: (1) provide an integrated individual health care that includes the activity and a series of basic individual medical services to improve the individual health, preventing and curing disease, and (2) provide essential public health services to the community, including health promotion, maternal and child health, nutrition, disease prevention and control, and environmental health. Puskesmas in Indonesia also has a responsibility to carry out technical guidance to clinics and other community health services as the Puskesmas networking partner institutions in the area. Other tasks of Puskesmas are to provide continuous and comprehensive care, to refer to specialists and hospital services, to coordinate health services, to guide the patient within the network of public health services, and to provide the best possible health services [5].

One of the elements that support health care services is IT. In the era of digital, Internet of Things, and artificial intelligence (AI), the digital transformation in health care also increases expectations of the quality of care [6]. Since the COVID-19 pandemic, digital information from the internet has gained importance in all areas of life. This trend was already evident before the COVID-19 pandemic. However, it accelerated this development and is also reflected in the health care sector [7]. With the widespread use of smartphones, downloadable or internet-based apps will play a major role in the diagnosis of diseases and monitoring and management of patients.

Technology and internet connection have played a significant role in bridging the gaps of health access and equity toward all individuals amid the geographic and socioeconomic challenges. In Indonesia's decentralized health care system, Puskesmas are mandated to deliver not only curative services but also promotive, preventive, and administrative functions, particularly within the framework of the national health insurance program (Jaminan Kesehatan Nasional). Achieving these responsibilities requires functional coordination across various health system components, many of which increasingly depend on stable internet connectivity.

Internet access supports critical digital infrastructure for public health surveillance, insurance claims, medicine supply chain management, and national health program reporting. For example, real-time reporting through the Sistem Kewaspadaan Dini dan Respon and Sistem Informasi Malaria enables early detection and response to disease outbreaks—a crucial function in archipelagic and remote regions where delayed reporting can lead to localized epidemics [8]. Similarly, routine reporting on immunization services and noncommunicable disease screenings is now conducted through the Aplikasi Sehat IndonesiaKu, a digital platform mandated by the MoH for primary care reporting and national dashboard integration [9].

In addition, internet connectivity is required to operate pharmaceutical inventory management tools, such as e-Logistik, which help prevent medicine stockouts—one of the persistent challenges in rural and remote areas [10]. The national Cek Kesehatan Gratis campaign, a government-initiated free screening program for all Indonesian population, also requires digital reporting systems for real-time coverage tracking and participant data documentation [11]. Administrative functions, particularly processing health care claims via Indonesia Case-Based Groups under Badan Penyelenggara Jaminan Sosial Kesehatan, are highly dependent on reliable internet access to ensure service reimbursement and continuity [12]. Moreover, in the absence of specialist doctors in many rural settings, internet-based coordination with referral hospitals has become a crucial alternative for maintaining continuity of care. More recently, the implementation of the SATUSEHAT (ie, Satu Data Kesehatan) platform by the Ministry of Health requires Puskesmas to connect their electronic medical record (EMR) systems to a national health data exchange ecosystem, making stable internet access a prerequisite for full participation in Indonesia's digital health integration efforts [13].

At the PHC level, internet connection has been a very critical infrastructure to support health data recording and reporting through a health information system, which is rooted from a routine data collection and serves as health indicators for government evaluations. These health data are critical to be disseminated to the health officials as evidence for program planning, and also to inform the patients related to immunization schedule, visit reminder, laboratory referrals, and other activities related to patients' follow-up [14].

Indonesia is the world's fourth most populous country with more than 270 million people residing across more than 17,000 islands [15,16]. As an archipelagic country, this condition results in disadvantages in terms of information and communication technology (ICT) infrastructure [17]. In addition, almost all internet users in Indonesia connect through mobile devices. Although mobile broadband (3G, but now increasingly 4G/LTE) is the most widely used internet service in Indonesia, it is not at par with fixed broadband with respect to capacity, quality of service, high bandwidth performance, and cost-efficiency. Such limited access to high-quality internet prevents the population from unlocking its productive capabilities to fully reap the benefits of a digital economy and points to two key challenges:

XSL•FO
RenderX

how to make fixed broadband internet access universal and increase internet quality. Increased optical fiber network coverage is a necessary but insufficient solution to meeting the key challenges. While investment by private service providers, along with government projects such as Palapa Ring, has steadily increased connectivity and service availability across Indonesian districts, internet subscriptions have not increased in parallel. Only 26% of homes with access to a fixed broadband provider subscribe to this service [18].

Several studies on IT infrastructure supporting health information systems in health care facilities have been conducted in Indonesia and other countries [19-21]. However, there is no detailed information available that can describe the accessibility and quality of the internet at Public Health Centers (Puskesmas) in Indonesia. This paper aims to provide, for the first time, a comprehensive overview of internet availability and connection reliability, as well as supporting IT infrastructure across Puskesmas throughout the country. While reliable internet connectivity is increasingly recognized as a foundational enabler for digital health transformation—including telemedicine, electronic health records, digital logistics, and surveillance systems—this study does not assess the direct impact of internet infrastructure on health care delivery or patient outcomes. Instead, it offers a baseline mapping of digital connectivity conditions to identify geographic disparities and inform future investments needed to enhance digital readiness in Indonesia's primary care system.

Methods

Data Collection

A cross-sectional approach was conducted, using a survey conducted between November 15, 2022, and March 16, 2023. The population study covered 10,378 Puskesmas in 34 provinces in Indonesia. A questionnaire was used to collect data from participants. To ensure the validity and reliability of the questionnaire, a pilot survey was conducted with a total of 20 participants from Puskesmas across 5 major islands in Indonesia. This sample size aligns with established methodological guidance, which recommends 10 - 30 participants for pilot testing to identify potential issues with instrument design and administration [22,23]. The pilot yielded a Cronbach α value of 0.76, indicating acceptable internal consistency [24] and supporting the reliability of the questionnaire items. These results provide a sound empirical and methodological basis for proceeding with the full-scale implementation of the instrument.

A standardized questionnaire survey was created using KoboToolbox (Kobo), an online application that allows users to create survey forms and collect data in real time. This tool was chosen because it can be accessed online or in offline mode (with automatic synchronization), even when the internet connectivity is poor. The tool also allows users to save drafts as they complete the surveys, giving them the flexibility to participate in surveys and carry out their daily tasks at Puskesmas. This is well suited to the uneven internet conditions in Indonesia.

The questionnaire was developed based on existing framework and literature, identifying aspects that may affect the internet quality. We adapted components from established internet quality assessment frameworks, primarily based on Quality of Service (QoS) and Quality of Experience (QoE) metrics, tailored to the infrastructure and operational context of Puskesmas in Indonesia [25-27]. The framework integrates both technical indicators (network performance) and infrastructure readiness (device and power availability). Network quality indicators (based on QoS) included type of internet connection (Wi-Fi, LAN, and routing), frequency and duration of internet disconnections, and bandwidth speed measured by Ookla speed test tool. In addition, we included device and environment indicators (infrastructure readiness): specifications and number of computers (CPU, RAM, and storage), availability of antivirus software, and electricity availability (uninterrupted power supply). To finalize the indicators, a series of discussions were carried out with experts from the infrastructure team at the Digital Transformation Office Ministry of Health Republic of Indonesia, IT specialists, public health professionals, and Public Health Governance team MoH. The final questionnaire (Multimedia Appendix 1) consisted of four sections, including (1) result of bandwidth speed test measured using Ookla speedtest tool in the morning and afternoon. Speedtest measures the speed between the device and the test server, using the Puskesmas device's internet connection. (2) Type and quality of internet network such as Wi-Fi, LAN, routing, and so on, This section also provides qualitative information such as the condition of frequent internet disconnections and how the internet speed in Puskesmas. (3) Specification and quantity of computers or laptops in Puskesmas. This section collects information such as the capacity of CPU, memory, RAM, the total number of computers or laptops, antivirus installation, and the ownership of the computer or laptop. (4) Availability of electricity in Puskesmas. This section collects information on 24-hour electricity availability and any backup electricity used in Puskesmas.

Univariate analysis was conducted by open-source tools, using Python (Python Software Foundation) and R languages (R Core Team) version 3.10.0, to examine the internet quality in Puskesmas across Indonesia. Scoring was performed to determine the categories of internet quality. There were 11 principal component indicators used for scoring the quality of internet, including: (1) result of morning upload speed test; (2) result of afternoon upload speed test; (3) result of morning download speed test; (4) result of afternoon download speed test; (5) type of internet connection; (6) the quality of internet connection; (7) computer or laptop RAM specification used; (8) computer or laptop CPU specification used; (9) 24-hour electricity availability; (10) presence of backup or alternative electricity power supply; and (11) the number of laptops or computers with installed antivirus. Each indicator was assigned a maximum score and relative weight based on its potential contribution to the internet performance in PHC services. A weighted scoring table was used to rank the overall internet quality per facility. Indicators were given weights based on literature evidence and expert consensus. The detailed scoring calculation and weighting can be seen in Multimedia Appendix 1.

XSL•FO
RenderX

Final scores were divided into 4 categories, namely levels 1, 2, 3, and 4. Level 1 is for Puskesmas that have fast and reliable internet connection with 24-hour electricity and backup, as well as high specification of computer or laptop. Level 2 is for Puskesmas with normal and sufficient internet connection, standard specification of computer or laptop, and 24-hour electricity availability. Level 3 is for Puskesmas that have unreliable or insufficient internet connection, computer or laptop below standard, and lack of 24-hour electricity. The lowest level, level 4, is for Puskesmas with no internet connection, computer, or laptop below standard, minimum quantity, and lack of 24-hour electricity.

The major islands of Indonesia were classified into five categories: (1) Java Island, which includes provinces such as Banten, DKI Jakarta (Special Capital Region of Jakarta), West Java, Central Java, Yogyakarta Special Region, and East Java; (2) Bali and Nusa Tenggara, comprising Bali, East Nusa Tenggara, and West Nusa Tenggara provinces; (3) Sumatra, encompassing Aceh, North Sumatra, West Sumatra, Riau, Riau Kepulauan, Jambi, South Sumatra, Bengkulu, Bangka Belitung, and Lampung provinces; (4) Kalimantan, which includes West Kalimantan, Central Kalimantan, South Kalimantan, East Kalimantan, and North Kalimantan provinces; and (5) Maluku and Papua, consisting of Maluku, North Maluku, Papua, and West Papua provinces. After weighting each performance category of Puskesmas and understanding the demographic landscape of Indonesia, we used descriptive analysis, a statistical method used to summarize and describe the characteristics of a dataset to depict the condition of the internet in Indonesia.

The data cleaning procedure was carried out to ensure the accuracy and consistency of responses prior to analysis. First, all survey responses were screened for completeness; records with more than 20% missing values across key indicators were excluded. For records with limited missing values, we chose to analyze only complete cases (complete case analysis) for each variable to maintain transparency and avoid introducing assumptions about missing values. Given that the proportion of missing data was low and appeared to be randomly distributed, the risk of bias was minimal. While complete case analysis may reduce the sample size slightly, it ensures that the results are based solely on observed data, preserving the integrity of variable-level relationships and simplifying interpretation [28,29]. After calculating individual facility-level scores based on weighted indicators, we summarized the results at the provincial level by aggregating the total number of facilities in each internet quality category or selected indicators. The findings are presented descriptively to illustrate provincial-level distribution and variation. This approach allows for transparent comparison across provinces while preserving the granularity of facility-level scoring.

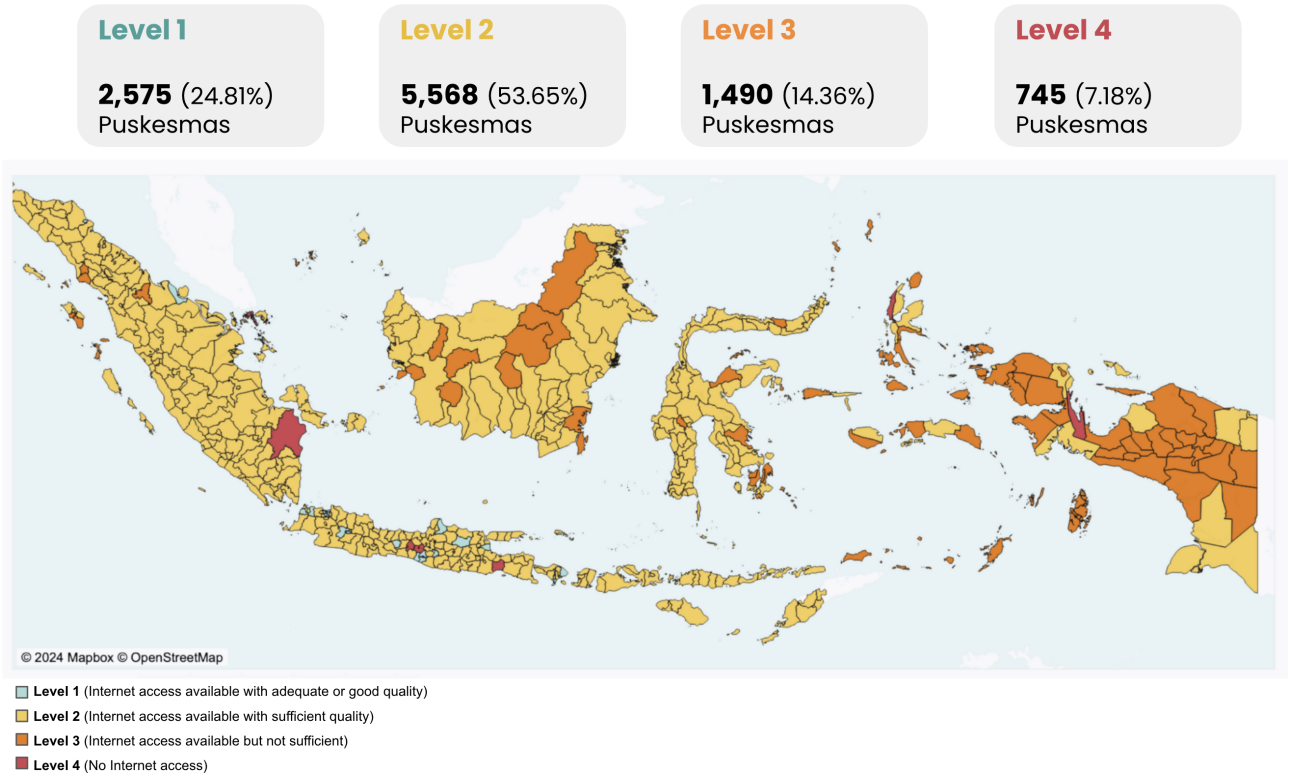
To minimize the risk of selection bias due to online survey assessment, we collaborated with the MoH Public Health Governance team working together with provincial and district health offices to ensure the survey completeness from Puskesmas. We allowed a 3-month period for survey submission for provincial and district health offices to have offline coordination with local Puskesmas, especially those located in remote and limited internet connectivity areas. We also conducted biweekly monitoring to ensure Puskesmas participation and completeness of the survey with provincial and district health offices.

Ethical Considerations

We confirm that the data collected for this study did not require ethical approval, as no identifiable individual-level information was obtained or presented. Written informed consent was obtained from all participants prior to the commencement of the survey. The consent form explicitly stated that no personal or sensitive data would be collected and that all responses would be stored and analyzed in anonymized form. Participants were also provided with an information sheet outlining the study objectives and duration. No incentives or compensation were provided to participants.

Results

Internet Quality Across Puskesmas



A total of 99.96% Puskesmas (10,378/10,382 Puskesmas in Indonesia), spread across 514 districts or cities from 34 provinces, participated in the survey. Among the 34 provinces, all Puskesmas in 30 provinces (88%) successfully participated in this survey. Based on the location of Puskesmas, 29.2% (3034/10,378) were located in urban areas, 45.3% (4700/10,378) in rural areas, 13.9% (1446/10,378) in remote areas, and 11.5% (1198/10,378) in very remote areas. The detailed participation rate across Puskesmas in 34 provinces can be accessed from Multimedia Appendix 2

Based on the study results, 7.18% Puskesmas in Indonesia (745/10,378) had no internet access (level 4), 14.33% Puskesmas (1,487/10,378) had insufficient internet access (level 3), 53.64% Puskesmas (5,567/10,378) had sufficient internet access (level 2), and 24.85% Puskesmas (2,579/10,378) had sufficient and fast internet connection (level 1). Given this condition, 78% (8,097/10,378) Puskesmas in Indonesia, categorized under levels 1 and 2, exhibited sufficient internet access, whereas 22% (2,235/10,378) of Puskesmas in levels 3 and 4 experienced inadequate internet connectivity.

After obtaining data on each Puskesmas, we calculated the level of internet quality at the provincial level by averaging the scores of all Puskesmas in each province (Figure 1). Provinces with the highest proportion of Puskesmas having level 1 internet access were DI Yogyakarta (86/121, 71%), followed by DKI Jakarta (206/315, 65.4%), and Bali (51/120, 42.5%). In contrast, 48.9% (222/454) Puskesmas in Papua, 48.9% (81/227) Puskesmas in Maluku, and 25.7% (42/163) Puskesmas in West Papua had the highest number of Puskesmas with no internet access in the province. Out of 745 Puskesmas without internet, the provinces with the highest number of Puskesmas with no internet access were Papua (222/745, 29.79%), Maluku (81/745, 10.87%), North Sumatra (45/745, 6.04%), West Papua (42/745, 5.63%), and North Maluku (35/745, 4.69%). Further details are available in Multimedia Appendix 3.

RenderX

Figure 1. Distribution of Puskesmas internet quality across provinces in Indonesia.

The disparities in the distribution of Puskesmas with different levels of internet quality across the islands of Indonesia were identified. Java Island led with a large number of Puskesmas having level 1 internet access (1525/3635, 41.95%), marking a stark contrast to other islands, such as Sumatra Island, Sulawesi, Kalimantan, Bali, and Nusa Tenggara, where the proportion of Puskesmas with fast internet access did not exceed more than 20%. Nationally, the level 2 internet category is the most common, with 53.64% (5,567/10,378) Puskesmas having sufficient internet access, and Sumatra Island having the highest proportion within this category (1,556/2,704, 57.54%). In sharp contrast, the Maluku and Papua Islands have the highest distribution of level 4 internet quality with 38.31% (380/992) Puskesmas having no internet access, which is significantly higher than other islands (Figure 2).

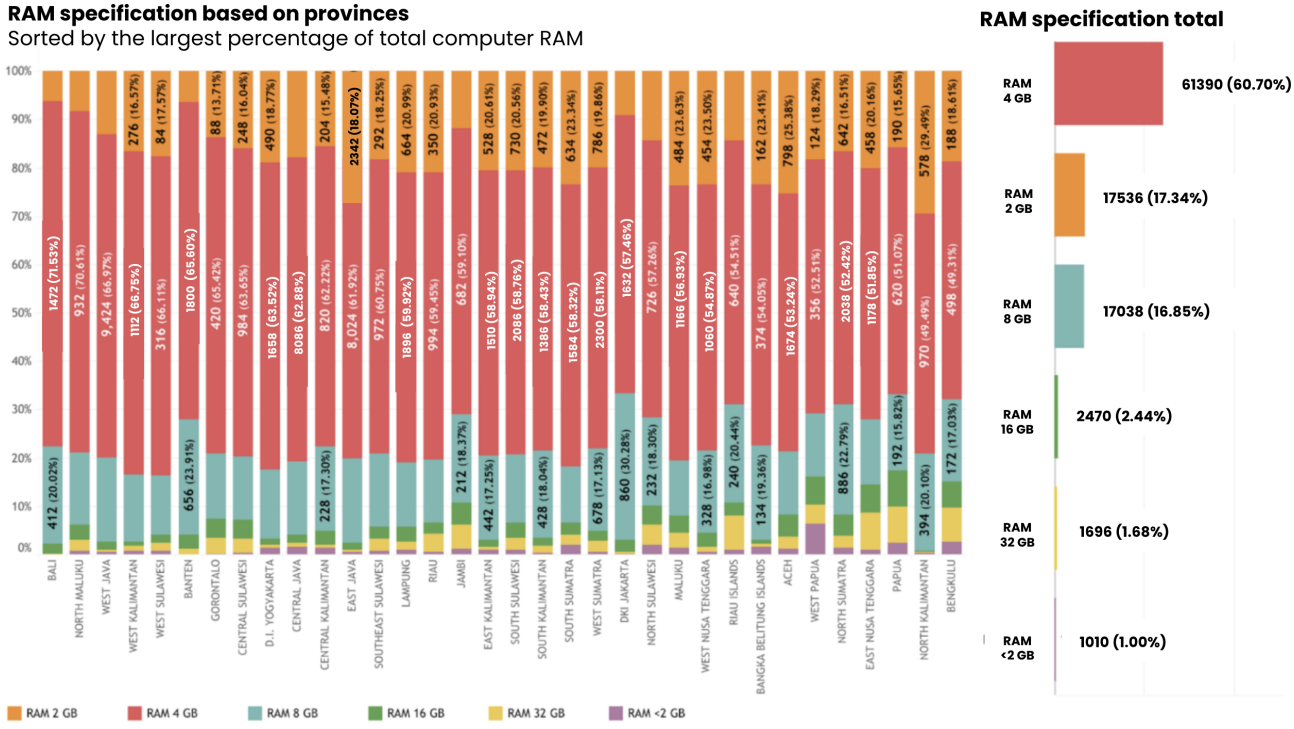
Figure 2. Distribution of Puskesmas internet quality based on islands and locations in Indonesia.

The distribution of Puskesmas with varying levels of internet quality is also significant across different locations in Indonesia. Puskesmas located in urban areas were more likely to have better internet quality, with 39.42% (1177/2986) Puskesmas having sufficient and fast internet access. Puskesmas located in rural areas were more likely to have sufficient quality internet with 59.34% (3004/5062) Puskesmas in level 2. Puskesmas in very remote areas were disproportionately affected by lower

XSL•FO
RenderX

internet quality, with the highest occurrences of level 4 and level 3 internet quality (335/959, 34.93% and 293/959, 30.55%, respectively) (Figure 2).

Based on computer connection, majority type connections in Indonesian Puskesmas were Wi-Fi (5179/10,378, 49.9%), followed by Wi-Fi and LAN (2288/10,378, 22.05%), and tethering from mobile data (772/10,378, 7.44%). Referring to participants' perspective, 38.83% (4030/10,378) Puskesmas had robust internet access, 31.83% (3303/10,378) had slow internet connection, 22.16% (2300/10,378) had very slow internet connection, and lastly 7.18% (745/10,378) had no access to internet at all (Multimedia Appendix 4). Type of internet connection and internet connection quality in public health centers have a weight of 8% each of the total assessment.



Factors Influencing Internet Quality Across Public Health Centers

Computer Specification

A separate analysis was conducted to determine other factors that affect internet quality, including RAM specifications, CPU, hard disk capacity, and antivirus updates on the hardware used. Based on the study, the most common RAM specification used in Puskesmas was 4 GB RAM (61,390/101,140, 60.7%), followed by 2 GB RAM (17,536/101,140, 17.34%), and 8 GB RAM (17,038/101,140, 16.85%).

Based on regional distribution, the provinces with the largest proportion of 4 GB RAM were Bali (1472/2058, 71.53%), followed by North Maluku (932/1320, 70.61%) and West Java (9942/14,072, 66.97%). In addition, East Nusa Tenggara had the highest proportion of Puskesmas with 23 GB RAM computer specification (174/2272, 7.66%), followed by Papua (90/1214, 7.41%), Riau Islands (84/1174, 7.16%), and Bengkulu (70/1010, 6.93%). On the other hand, West Papua Province was the province with the highest proportion of hardware with a low specification less than 2 GB RAM (44/678, 6.49%), followed by Bengkulu (28/1010, 2.77%), Papua (30/1214, 2.47%), and North Sulawesi (26/1268, 2.05%) (Figure 3).

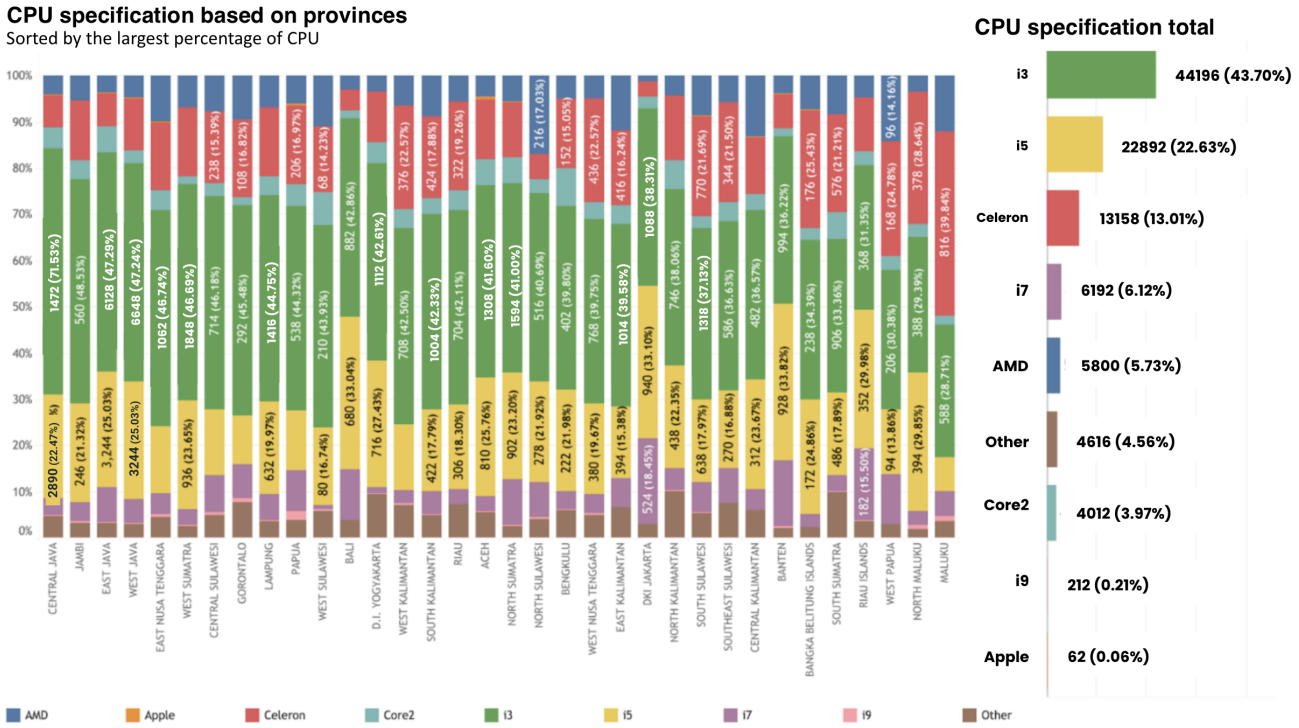


Figure 3. RAM specification based on provinces and total values.

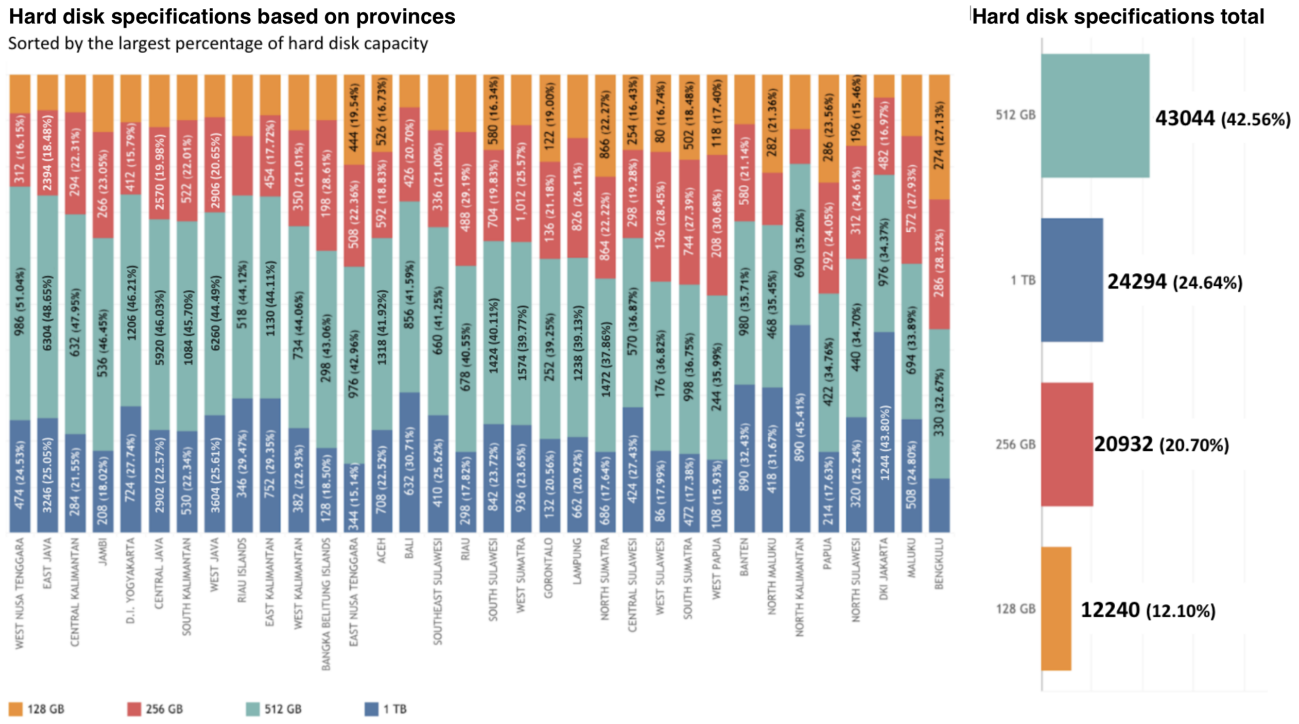
By region, the provinces with the highest proportion of hardware with CPU type i3 were Central Java (6860/12,860, 53.34%), followed by Jambi (560/1154, 48.53%), and East Java (6128/12,958, 47.29%). In addition, provinces with the highest CPU specification of i7 type were DKI Jakarta (5242/2840, 18.45%), Riau Islands (182/1174, 15.5%), and Banten (390/2744, 14.21%). In contrast, the provinces that had below-average CPU type distribution with Celeron type were Maluku (816/2048, 39.84%), followed by North Maluku (378/1320, 28.64%) and Bangka Belitung (176/692, 25.43%) (Figure 4). Based on CPU specifications, nationally, hardware with i3 specifications dominated at 43.7% (44,196/101,140), followed by i5 at 22.63% (22,892/101,140), and Celeron at 13.01% (13,158/101,140) (Figure 4).



XSL•FO
RenderX

Figure 4. CPU specification based on provinces and at the national level.

At the province level, the provinces with highest distribution of 512 GB hard disk capacity were West Nusa Tenggara (986/1932, 51.04%), followed by East Java (6304/12,958, 48.65%), Central Kalimantan (632/1318, 47.95%), and Jambi (536/1154, 46.45%). In addition, provinces with the highest proportion of highest hard disk capacity of 1 TB were North Kalimantan (890/1960, 45.41%), followed by DKI Jakarta (1244/2840, 43.8%), Banten (890/2744, 32.43%), and North Maluku (418/1320, 31.67%). In contrast, the province with the highest distribution of lowest hard disk specification of 128 GB was Bengkulu (274/1010, 27.13%), followed by Papua (286/1214, 23.56%), North Sumatra (866/3888, 22.27%), and North Maluku (282/1320, 21.36%). The details can be seen in Figure 5; it shows that nationally, the most hard disk capacity used in Puskesmas was 512 GB (43,044/101,140, 42.56%), followed by 1 TB (24,924/101,140, 24.64%), 256 GB (20,932/101,140, 20.7%), and 128 GB (12,240/101,140, 12.1%).

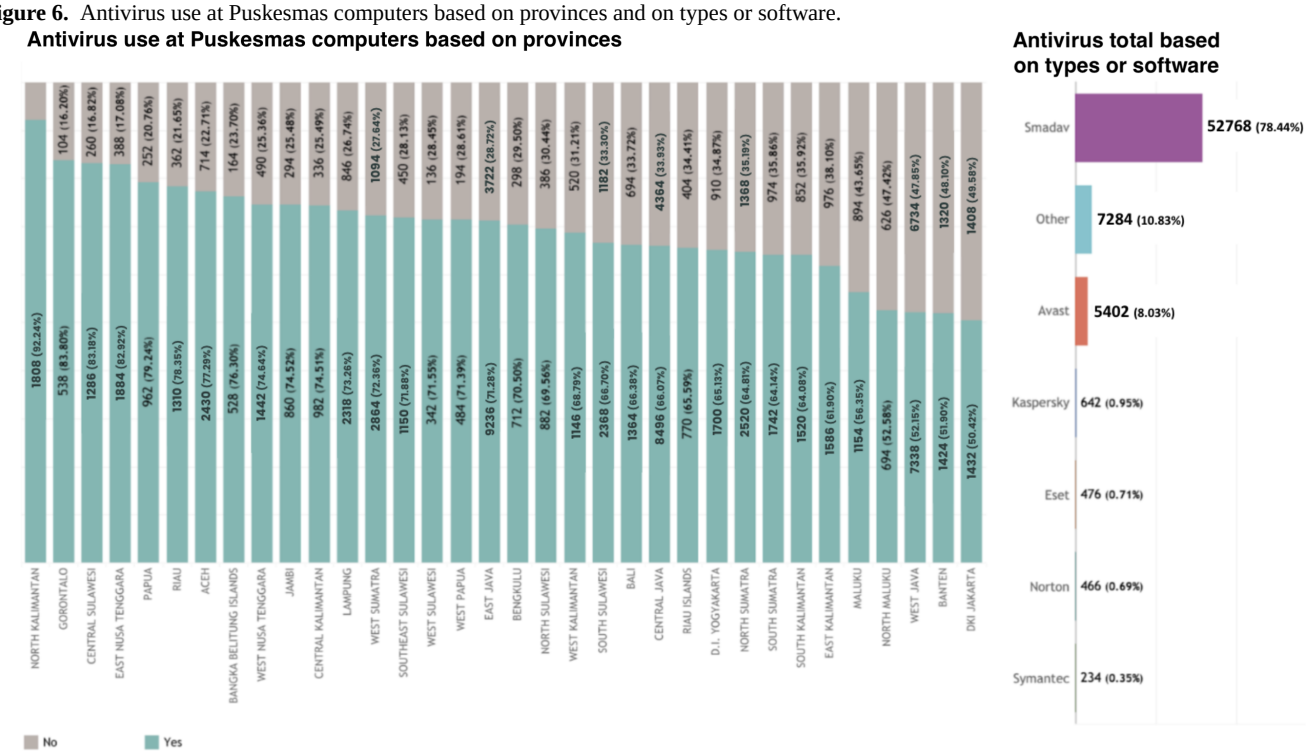


Figure 5. Hard disk specification based on provinces and at the national level.

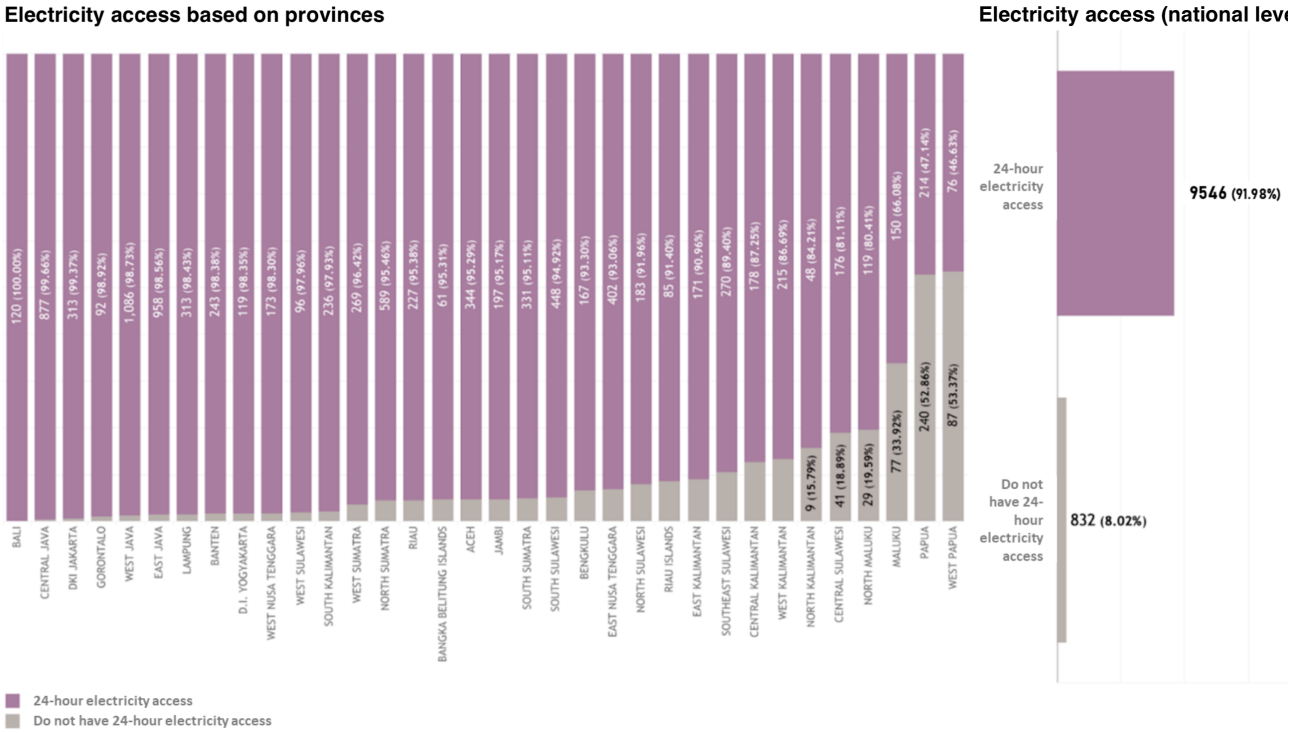
XSL•FO
RenderX

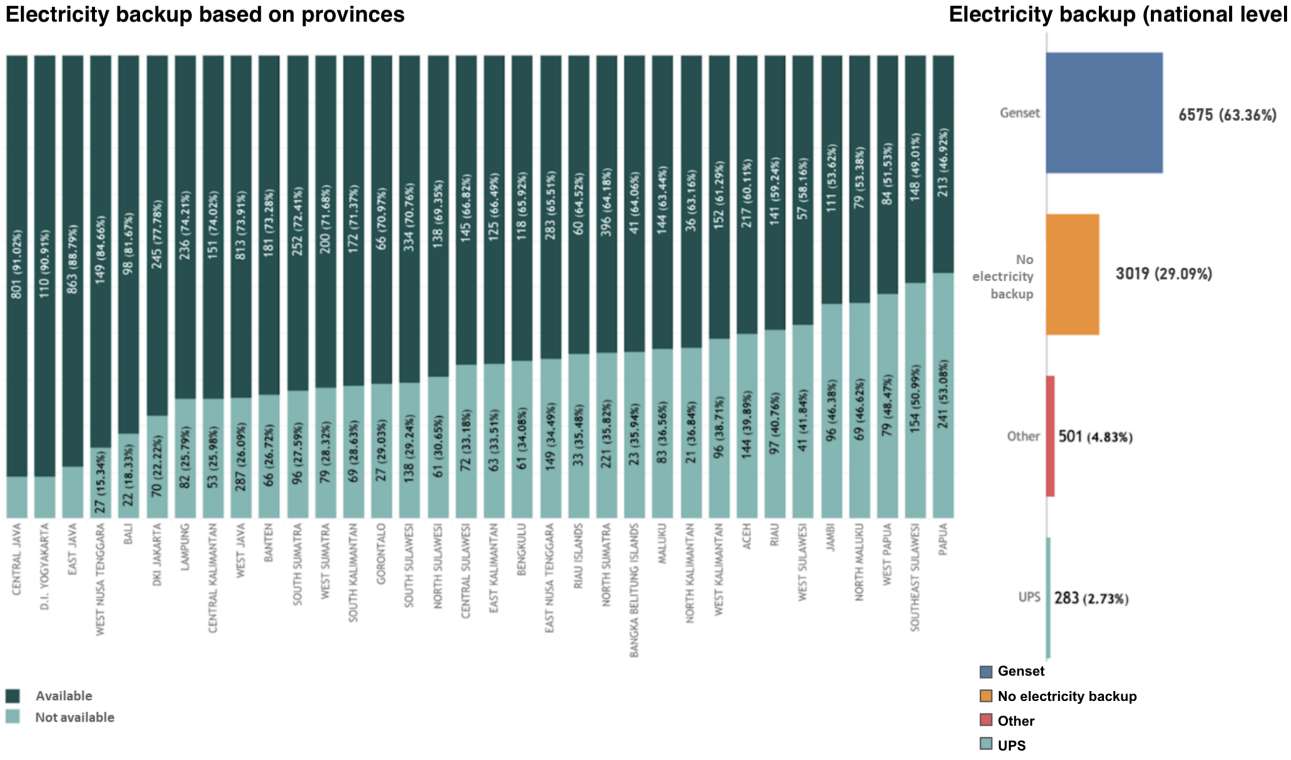
The province with the highest proportion of computers with installed antivirus was North Kalimantan (1808/1960, 92.24%), followed by Gorontalo (538/642, 83.8%), Central Sulawesi (1286/1546, 83.18%), and East Nusa Tenggara (1884/2272, 82.92%). In contrast, DKI Jakarta, with 49.58% (1408/2840) of their computers, did not install antivirus, followed by Banten at 48.1% (1320/2744), West Java at 47.85% (6734/14,072), and North Maluku at 47.42% (626/1320) (Figure 6). Based on the study, 33.5% (33.868/101,140) of computers in Puskesmas did not install antivirus. Among the computers with installed antivirus, the most antivirus used was Smadav (52,768/67,272, 78.44%), followed by Avast (5402/67,272, 8.03%), and others (7284/67,272, 10.83%) (Figure 6).

Figure 6. Antivirus use at Puskesmas computers based on provinces and on types or software.



Electricity Access

In terms of province distribution, 100% (120/120) Puskesmas in Bali have access to 24-hour electricity, followed by Central Java (99.66%, 877/880), DKI Jakarta (313/315, 99.37%), and Gorontalo (92/93, 98.92%). In contrast, provinces with the highest number of Puskesmas that do not have access to 24-hour electricity were West Papua (87/143, 53.37%), followed by Papua (240/454, 52.86%), Maluku (77/227, 33.92%), and North Maluku (29/148, 19.59%) (Figure 7A). At the national level, 91.98% (9546/10,378) Puskesmas in Indonesia have electricity access for 24 hours, whereas 8.02% (832/10,378) Puskesmas do not have access to 24-hour electricity (Figure 7B).



XSL•FO
RenderX

Figure 7. Electricity access based on (A) provinces and (B) at the national level.

The provision of electricity backup is also an important point in the operational process of public health centers. Based on the study, 29.09% (3019/10,378) of Puskesmas did not have electricity backup (Figure 8). Among the Puskesmas who had electricity backup, the most common type of electricity backup owned by Puskesmas was a generator (6575/10,378, 63.36%), followed by other backups (501/10,378, 4.83%), and UPS (uninterrupted power supply; 283/10,378, 2.73%). At the provincial level, the provinces with the highest number of Puskesmas having electricity backup were Central Java (801/880, 91.02%), followed by DI Yogyakarta (110/121, 90.91%), East Java (863/972, 88.79%), and West Nusa Tenggara (149/176, 84.66%). In contrast, 53.08% (241/454) Puskesmas in Papua did not have any electricity backup, followed by South East Sulawesi (154/302, 50.99%), West Papua (79/163, 48.47%), and North Maluku (69/168, 46.62%).

Figure 8. Electricity backup based on (**A**) provinces and (**B**) at the national level.

Discussion

The internet's significant role in aiding public health services is undeniable. This paper marks the first comprehensive depiction of the accessibility and quality of internet connections and computer systems across Indonesia's Puskesmas, providing crucial insights into the information technology infrastructure. The internet availability in the health facility is highly crucial to foster the delivery of healthcare among communities [28,29]. By presenting baseline data on internet quality across Puskesmas, this study contributes foundational insights to support future efforts aimed at strengthening health information systems and expanding the digital infrastructure needed for more equitable and efficient PHC delivery in Indonesia.

Indonesia presents a particularly interesting case when it comes to internet connectivity and accessibility to health care services, especially in the context of health care digitization [30]. In numerous instances, technological advancements have the potential to significantly reduce health care inequalities. Furthermore, digital health is recognized as a valuable technological approach that can effectively bridge the significant gap between urban and rural populations [31] and between high-income and low- and middle-income countries (LMIC) [32].

One way of improving health care service delivery is through adoption of broadband Internet access [33]. In the health system, service delivery refers to where patients receive the treatment as well as supplies entitled. Broadband internet access helps to reshape many health-related processes and supports effective treatment of patients [33]. It helps medics to provide patients with faster diagnosis to their respective health conditions, the development of treatment plans, making patient records as well as test results accessible by patients from the examination room, facilitates faster consultation electronically on treatment plans, helps patients and their attendants access practice guidelines faster [15,34,35], and led to the adoption of telehealth technologies which has contributed to easy access to health services [36]. The availability of Internet access, coupled with the accelerated adoption of eHealth and mHealth platforms and the rapid evolution of digital technology access, has generated a significant opportunity to enhance the reach, quality, and efficiency of PHC service delivery, thereby facilitating the achievement of universal health coverage [37].

According to this study, it was found that 78.4% (8,143/10,378) of Puskesmas have good and sufficient internet quality, 14.4% (1,490/10,378) Puskesmas have insufficient internet connection, and 7.2% (745/10,378) of the Puskesmas do not have internet access at all. The study depicts that the eastern part of Indonesia had the least internet connection in Puskesmas compared to other parts of Indonesia, which includes Maluku and Papua regions. This is aligned with previous findings related to the limited internet access in the eastern part of Indonesia and low ICT development index in 2020 - 2021 throughout the areas [38-41]. The ICT Development Index, published by the United Nations International Telecommunication Union, serves as a crucial benchmarking tool for measuring the information society by utilizing internationally agreed ICT indicators, assisting governments, operators, development agencies, researchers, and others in assessing the digital divide and comparing ICT performance globally [42]. Poor internet connectivity is one of the barriers to implementing telehealth [43]. Studies reveal varying rates of internet connection across different countries affect the adoption and implementation of telehealth and eHealth [44,45]; and digital health initiatives, especially in rural areas [46]. The underlying causes of limited internet access in the eastern part of Indonesia may be due to several aspects, including challenging geography, archipelagic region, size of territory to cover, limited infrastructure, which should be taken into account as barriers that limit the accesses [47-49]. High service costs to provide IT infrastructure (including tower, fiber optic, etc) have become the challenge to evenly provide internet access across the country, especially in remote areas [50]. While at the same time, the user also finds it a burden to subscribe to the certain internet monthly fee [51-53]. Some studies also showed that sociobehavioral values and perceptions toward digitalization also influence enhancing or limiting the internet availability, including unwillingness of the local people to allow the internet infrastructure development, lower education attainment, and low adult literacy [52,54].

For completing administrative tasks in Puskesmas, such as browsing, data input, upload and download files, or to support any other health service tasks, according to information and technology literatures, it requires a minimum specification of 4 GB RAM and CPU i3 or above for computer or laptop to perform basic data management (input/edit/delete data or simple online browsing) [55,56]. These findings show that the majority (60.70%, 61,390/101,140) of the Puskesmas in Indonesia already had 4 GB RAM or above in their computers, while 18.34% (18,546/101,140) of them were lower (2 GB and 1 GB). As for the CPU specification, 83% (83,970/101,140) of the Puskesmas had the sufficient CPU specification (i3 type or above), while 17% (17,170/101,140) of them had insufficient, which were Celeron and Core2. It is understood higher RAM capacity and newest CPU specifications are linked with better computer performance, which is highly important to be provided in Puskesmas to ensure smooth operation of critical health care software, efficient management of electronic health records, and reliable services, ultimately supporting effective patient care delivery in the health care facilities [57,58].

Although CPU, RAM, and memory do not directly control bandwidth or download speeds, they significantly influence the user's ability to use the internet efficiently for digital health service. The CPU determines how quickly a computer can process incoming data from the internet, execute scripts, and render web pages. A slower CPU may lead to delays in page loading, application responsiveness, and user interaction, particularly with web-based health information systems. Goel et al [59] demonstrated that lowering CPU performance (eg, through power-saving modes on Android devices) results in slower page loading and degraded user experience in accessing online resources. Similarly, another study notes that a slow processor can act as a bottleneck when decoding or rendering content received over the internet, making the browsing experience sluggish [60]. RAM enables systems to temporarily store and quickly access active data. Systems with insufficient

RAM often struggle when running multiple applications or browser tabs, leading to frequent slowdowns or crashes. This affects the usability of internet-dependent applications, especially in environments such as health centers where simultaneous tasks are common. While RAM does not increase raw internet speed, having adequate memory ensures smoother browser and application performance [61]. Another report supports this by showing that memory capacity and technology trends directly influence web system performance and throughput [62].

Similarly, with RAM capacity and processors, hard disk was also found to affect the computer's capacity to process [58]. This study reveals that the majority of Puskesmas have a sufficient hard disk of 256 GB or above (88%, 20,932/100,510), and 12% (12,240/100,510) of them have an insufficient one (128 GB). Literature findings show that 128 GB internal storage is able to undergo basic operations; however, it will demand higher capacity for extensive computer use [63]. The hard disk is crucial for computer performance as it stores and retrieves data, including the operating system and applications, facilitating efficient multitasking and overall system responsiveness [57,58].

Across various low- and middle-income countries, the results consistently highlight significant disparities in hardware infrastructure at the PHC level, which directly impact the implementation of digital health systems [64]. In Nigeria, many PHC centers still rely on desktop computers with only 512 MB to 2 GB of RAM and outdated Pentium IV processors, limiting their ability to run modern eHealth applications [65]. Similarly, in Uganda, facilities were found using laptops with 1 GB RAM and low-speed CPUs, which caused frequent delays and hindered real-time data entry and synchronization [66]. In Kenya, a study revealed that more than half of the PHC sites were equipped with low-specification devices using Intel Atom processors and 2 GB RAM, often unable to handle multiple web-based platforms simultaneously [67]. In parts of Latin America, such as Peru and Bolivia, rural clinics were reported to operate with refurbished computers having less than 2 GB RAM, rendering them incompatible with many EMR systems [68]. These findings underscore the urgent need for targeted investment in basic digital infrastructure to ensure the successful adoption of health information systems in resource-constrained settings [69].

As for the antivirus, this finding shows that the coverage of antivirus installation in Puskesmas' computers is still incomplete, especially in DKI Jakarta, Banten, and West Java provinces, which leave almost half of its Puskesmas unprotected with the antivirus. In health care facilities, malware protection is critical for computer performance as it safeguards sensitive patient data, prevents potential cyberattacks, and ensures the uninterrupted operation of vital medical software, maintaining the integrity and security of patient care services [70,71]. Several studies have highlighted the limited implementation of antivirus software and weak cybersecurity practices in PHC facilities across LMICs. Hasegawa et al [72] conducted a scoping review and found that antivirus installation in PHC settings was often inconsistent or absent due to limited funding, lack of technical support, and absence of standardized cybersecurity policies. Similarly, the World Health Organization (2021) reported that many LMIC PHCs do not regularly update or install antivirus software, making them vulnerable to malware and data breaches [73]. A scoping review study by He et al [74] found that one of the major challenges of healthcare cybersecurity is the lack of security awareness. Collectively, these findings underscore the urgent need for national digital health policies that mandate and support sustainable cybersecurity infrastructure, including antivirus software, within PHC systems across LMICs.

This study found that 8.02% (832/10,378) of Puskesmas in Indonesia have no access to electricity for 24 hours. Most provinces that did not have access to 24-hour electricity were located in the eastern part of Indonesia, such as Maluku and Papua island. Modern energy enables health service delivery. Access to electricity is, however, unreliable in many health facilities in developing countries [75]. Reliable basic infrastructure, particularly electricity, is a critical enabling factor in improving health systems [76]. Previous literature showed that the availability of electricity is an important determinant of receiving health information and use of health services [77,78]. Based on a literature study conducted in developing countries [65,], there are many barriers that can occur during the electricity provision across the nation, this includes the lack of IT infrastructure, especially electricity supply. Indonesia started the rural electrification program in the late 1950s, but how to provide electricity in a sustainable way both organizationally and institutionally still becomes a big challenge [79]. According to the World Health Organization (2023), nearly 1 billion people globally are served by health care facilities that either lack electricity altogether or rely on highly unreliable sources, with PHC centers being especially affected [78]. A systematic review by Ibrahim et al [80] found that fewer than 30% of PHC facilities in LMICs had consistent electricity access, which severely undermines the ability to store vaccines, operate diagnostic equipment, and provide emergency care [80]. In a multicountry study of surgical hospitals across 21 LMICs, continuous electricity availability was reported in less than two-thirds of facilities, with countries such as Sierra Leone and Malawi experiencing 0% reliable power supply [81]. These power gaps directly limit the deployment of digital health technologies, vaccine cold chains, and essential services. According to the Electricity Power Supply Business Plan 2019 - 2028, Indonesia's average electricity growth is at 6.42%. Indonesia successfully surpassed its electrification ratio target at the end of the year 2018 [81]. However, there are still 2510 villages across Indonesia that are not yet electrified [82]. Increasing the electrification ratio always becomes a challenging task because Indonesia has many islands, and many communities are isolated from one another [79]. This geographical situation also worsens with poor infrastructure access, making the area hard to reach [83]. There are several fundamental requirements that need to be implemented in order to cope with the rural electrification challenges [84-86]. The lessons learned from other countries that have successfully achieved universal electricity access were summarized in several studies [87]. Committed governance and supportive regulations and policies are one of the most often stated in the literature [87]. Moreover, a collaboration of appropriate policies and government will increase the private sector's participation in the rural electrification program [88].

Based on this study and consultation with experts, it is recommended that Puskesmas facilities in Indonesia require a minimum internet bandwidth of 10 to 20 Mbps. This range is deemed as a minimum essential requirement to ensure reliable access to digital resources and the efficient input of patient EMR data. In addition, PHC services should be equipped with at least Intel Core i3 processors, 8 GB RAM, and 256 GB solid-state drive storage to enable smooth operation of digital applications and web-based platforms [69]. Optimal performance, especially in urban or high-volume facilities, may require upgrading to Intel Core i5 processors and 16 GB RAM, which align with the performance needs of multitasking systems and real-time data entry [67,68]. This study provides a structured and evidence-based framework for assessing internet quality in PHC facilities, which is especially relevant for benchmarking across comparable middle-income countries. Many countries with similar socioeconomic and infrastructural conditions face shared challenges in ensuring reliable digital connectivity in remote or underserved health centers [89,90]. By developing and validating a weighted, multi-indicator scoring system, grounded in technical, infrastructural, and operational factors, this study offers a replicable model that can inform digital health readiness assessments beyond Indonesia. Such benchmarking tools are essential as countries pursue universal health coverage and integrate eHealth systems in alignment with the World Health Organization's Global Strategy on Digital Health 2020 - 2025. Additionally, initiatives like the International Telecommunication Union and the World Bank's Digital Economy for Africa and Asia programs emphasize the need for context-sensitive indicators to guide investments in health ICT infrastructure [91,92]. Therefore, this study not only addresses a national implementation gap but also contributes to the global evidence base supporting digital health infrastructure development in resource-constrained settings.

Successful implementation, rollout, and use of the digital system require PHC facilities to be equipped with appropriate digital and data infrastructure. In Tanzania, as part of the National PHC Rolling Digital Transformation Roadmap, service delivery points for in-facility continuity of care are using a LAN that is installed within facilities [93]. While interfacility referrals and integration with public domain systems. While in China, in order to guide the development of internet health care, the Chinese government has issued a series of regulations and guidelines. The State Council of the People's Republic of China has issued the Guidance on Actively Promoting the Action of "Internet Plus." It proposed to develop internet-based health care services, encourage internet enterprises to cooperate with medical institutions for establishing medical network information platforms, reinforce the integration of regional health care resources, and actively apply the mobile internet to explore and provide health services [94]. Depending on the different initiators, there are 3 main modes of internet health care service provision in mainland China: hospital-led, government-led, and enterprise-led internet healthcare platforms [95].

This research exhibits several strengths that contribute to its significance in the field. The study at hand is a groundbreaking research effort that has comprehensively assessed a wide range of internet components in PHC facilities, including device availability, access, and internet quality in nearly all public health centers across Indonesia. The findings of this study provide valuable insights into various supporting factors that can facilitate the implementation of IT transformation. The study highlights the significance of the availability, quality, barriers of computer systems, hardware, and software devices, which can serve as instrumental inputs for the government in their decision-making processes regarding the implementation of such transformations.

However, certain limitations must be acknowledged: (1) Bandwidth checks to assess the quality of internet access were only carried out in the morning and evening, which depends on local conditions and the respondent's honesty; (2) the completeness of filling out the questionnaire was influenced by the capacity of the assigned respondents; (3) validation of CPU, RAM, and antivirus could not be done directly; (4) potential selection bias may occur as we performed the assessment using an online survey, although we have minimized this bias by having coordination with the designated Public Health Governance team MoH and district or Provincial Health Offices allowing them to complete the survey within a 2-month period, having offline coordination to ensure we obtained survey feedback from Puskesmas. Nevertheless, this study provides a deeper overview of the access and barriers of internet access and other supporting IT infrastructure in 10,378 public health centers throughout Indonesia.

Conclusions

The internet plays a vital role in health care services, facilitating communication, information exchange, and access to medical resources. Despite the fact that 78% of health care centers in Indonesia have sufficient internet connectivity, challenges persist, with some areas experiencing limited access or complete absence of internet connectivity. To ensure universal availability of the internet across primary care services in Indonesia, additional measures are imperative. This study demonstrates the need for collaborative actions among government, health care workers, and telecom providers to allocate a supportive budget for sustainable internet infrastructure, including satellite-based internet services that enable strong internet connection in remote, underserved, and digitally excluded regions. Technology infrastructure should also follow, including high-quality computer systems with adequate specifications to handle health care–related tasks efficiently, as well as ensuring uninterrupted 24-hour access to electrical power to support continuous internet connectivity and operational efficiency in health care facilities. Future studies are encouraged to explore the relationship between internet quality and health care service delivery outcomes to better understand its operational impact. Additionally, longitudinal assessments could help monitor improvements over time and guide digital infrastructure investments in public health systems. Although this study does not assess clinical performance or health care outcomes, it provides crucial baseline evidence on digital infrastructure status. These insights can help guide targeted investments and future evaluations as Indonesia advances toward nationwide digital health integration.

Acknowledgments

The authors would like to thank the Digital Transformation Office Ministry of Health Republic of Indonesia for supporting the study implementation; the Public Health Centers, Districts, and Provincial Health Offices across Indonesia who have participated in the study; and MoH Data and Information Centre (Pusdatin), Directorate General of Public Health, Directorate General of Health Care Services who have supported the study implementation. All authors did not receive funding for the creation of this manuscript. This work was supported in part by the IARC/WHO, through training by the Biobanking and Population Cohort Network (BCNet; CRDF Global, Award No. 66415). The company does not have a role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript. Where authors are identified as personnel of the International Agency for Research on Cancer or World Health Organization, the authors alone are responsible for the views expressed in this article and they do not necessarily represent the decisions, policy or views of the International Agency for Research on Cancer or World Health Organization.

Disclaimer

The company does not have a role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript. Where authors are identified as personnel of the International Agency for Research on Cancer/World Health Organization, the authors alone are responsible for the views expressed in this article and they do not necessarily represent the decisions, policy or views of the International Agency for Research on Cancer/World Health Organization.

Data Availability

The data sets generated during and/or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

DNA led the study design, built the paper concept, main structure and methodology. AHS, CAM, and AFL carried out the study. MTAE, VW, SD, IL, and MA accessed and analyzed the data. DNA, AHS, CAM, AFL, MTAE, VW, SD, and IL wrote the first draft of the paper. ZK and LM validated the study and critically revised the manuscript content. DNA and AHS had primary responsibility for the final content.

Conflicts of Interest

While two authors (LM and DNA) are affiliated with Aceso Global Health Consultants Pte Limited, which is a private company, we declare that this research project does not receive funding from Aceso Global Health Consultants. LM is the director of the company, and DNA is a consultant of the company. However, both of them contributed to this paper on a pro-bono basis.

Abstract

Background: Medication errors represent a widespread, hazardous, and costly challenge in health care settings. The lack of interoperable medication data within and across hospitals not only creates an administrative burden through redundant data entry but also increases the risk of errors due to human mistakes, imprecise data transformations, and misinterpretations. While digital solutions exist, fragmented systems and nonstandardized data hinder effective medication management.

Objective: This study aimed to assess medication data available across the multiple systems of a large university hospital, identify a minimum dataset with the most relevant information, and propose a standard interoperable FHIR-based solution that can import and transfer information from a standardized drug master database to various target systems.

Methods: Medication data from all relevant departments of a large German hospital were thoroughly analyzed. To ensure interoperability, data elements for developing a minimum dataset were defined based on relevant medication identifiers, the Health Level 7 Fast Health Interoperability Resources (HL7 FHIR) standard, and the German Medical Informatics Initiative (MII) specifications. To enhance medication identification accuracy, the dataset was further enriched with information from Germany's most comprehensive drug database and European Standard Drug Terms (EDQM) to further enrich medication identification accuracy. Finally, data on 60 frequently used medications in the institution were systematically extracted from multiple medication systems used in the institution and integrated into a new structured, dedicated database.

Results: The analysis of all the available medication datasets within the institution identified 7964 drugs. However, limited interoperability was observed due to a fragmented local IT infrastructure and challenges in medication data standardization. Data integrated and available in the new structured medication dataset with key elements to ensure data identification accuracy and interoperability, successfully enabled the generation of medication order messages, ensuring medication interoperability, and standardized data exchange.

Conclusions: Our approach addresses the lack of interoperability in medication data and the need for standardized data exchange. We propose a minimum set of data elements aligned with German and international coding systems to be used in combination

XSL•FO

with the FHIR standard for processes such as the digital transfer of discharge medication prescriptions from intensive care units to general wards, which can help to reduce medication errors and enhance patient safety.

(JMIR Med Inform 2025;13:e64099) doi:10.2196/64099

Introduction

Medication Errors

In 2022, approximately seventeen million patients were treated in German hospitals, of which more than 2 million were admitted to an intensive care unit (ICU) for the treatment of life-threatening conditions due to the dysfunction of one or more organs [1], which inevitably requires the administration of multiple medicaments [2]. As a result of the complexity of the medication process, medication errors have been a frequent and safety-relevant problem in medical care [3]. The first major groundbreaking study that quantified this situation was the "To Err is Human: Building a Safer Health Care System" report conducted by the Institute of Medicine in the United States [4]. In recent years, as reported by the Joint Commission in 2020 [5], medication errors are involved in 5.4% of all severe injuries or patient deaths, with a total annual cost of USD 42 billion according to estimates of the World Health Organization (WHO) [6,7].

This situation is caused, among other factors, by a lack of interoperable pharmaceutical documentation systems [8] as well as because many steps of the process (ie, prescription, transmission of the information, and documentation) are still highly dependent on manual input and prevent the implementation of medication reconciliation systems (MedRec). As a result, medication errors and adverse drug events related to unintended medication discrepancies in electronic health records (EHR) are still a major public health problem and are listed unsurprisingly among the top 10 health technology hazards for 2020 by the Emergency Care Research Institute [9-11].

Interoperability, Standardization, and Data Access

There is evidence that interoperable IT systems and the use of international standards can help to mitigate medication errors and facilitate the exchange of information across different platforms and software used for drug prescription and administration [12].

The Healthcare Information and Management Systems Society defines interoperability as the capacity of at least 2 IT systems to communicate by exchanging standardized data, allowing the use of the exchanged information [13]. Its implementation in the medication field is critical for the digital transformation of drug prescription, administration, and research [14], and relies on the employment of internationally standardized data and terminologies.

For the health care industry, Health Level 7 (HL7) has provided a comprehensive set of international standards for clinical and administrative data transfer across software that numerous health care providers employ to promote data exchange and interoperability, including our hospital and its EHR. It remains the most popular and widespread health care framework, improving diagnostics, therapy, and patient safety and outcomes. [15,16].

In 2011, due to the rapidly growing amount of health data, HL7 started developing the Fast Interoperability Resources (FHIR), a standard that addresses the need for faster and better methods for interoperable data exchange.

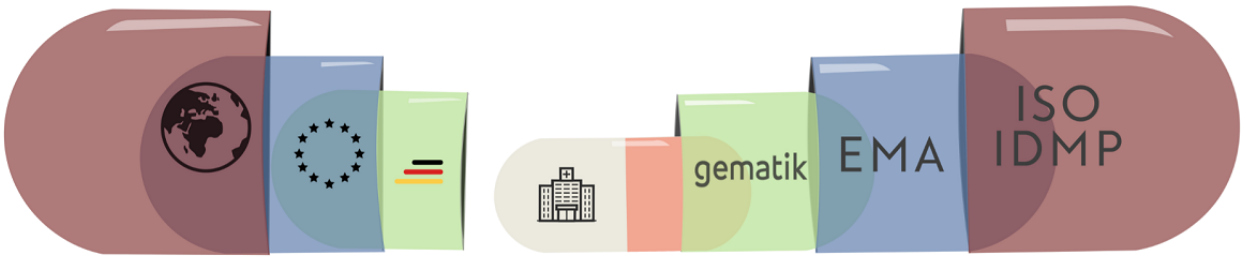
FHIR was designed to be flexible and adaptable, making this standard easy to implement and suitable for a wide range of clinical processes. It uses a modern web-based application programming interface (API) [17].

For global standardization and interoperability of medication data, the International Organization for Standardization (ISO) has been developing the Identification of Medicinal Products (IDMP) since 2012, providing a suite of 5 standards (ISO 11615, ISO 11616, ISO 11238, ISO 11239, and ISO 11240) for identifying and exchanging the information of each medicinal product for human use throughout the world [18-23].

Although these standards were created for pharmacovigilance purposes, over the years, the ISO IDMP standards have come to support various other activities, including those related to the norms for the unique identification and exchange of regulated information about medicinal and pharmaceutical products.

In Europe, the European Medicines Agency (EMA) is the institution responsible for gradually implementing ISO IDMP standards through a plan and services based on four domains of master data in pharmaceutical regulatory processes (Substance, Product, Organization, and Referential [SPOR]), which are crucial to ensuring interoperability [24,25].

In cooperation with the EMA, the European Directorate for the Quality of Medicines and HealthCare (EDQM) promotes the development of a common pharmacopoeia in Europe. In this context and as part of the implementation of quality standards for medicines, the EDQM [26] released the EDQM standard terms, comprising terms and definitions to describe (among others) pharmaceutical dose forms, routes and methods of administration, administration devices, and units of presentation [27], providing a legal and scientific basis for quality control of medications from development to marketing as well as a framework for the safe use of medicines on patients [28].



According to the EMA, the standards and services mentioned above enable operational benefits, especially considering their positive impact on the regulation of medicines and the simplification of medication information exchange in Europe and internationally. This higher degree of standardization and

XSL•FO
RenderX

regulation aims to provide a framework to improve data transfer, patient safety, and public health [29].

At the national level, the German Medical Informatics Initiative (MII) is a federal effort dedicated to digitizing the German health care system. As a part of this initiative, a medication task force group has been established to leverage standardized frameworks for different medication processes [30]. In addition, the gematik [31] is the current organization responsible for the federal telematics infrastructure (TI), a central platform for digital applications. One central function of the gematik is the definition and enforcement by law of binding standards for services, components, and applications for the TI and the implementation of standards' specifications like FHIR, SNOMED CT (Systematized Nomenclature of Medicine Clinical Terms), and LOINC (Logical Observation Identifiers Names and Codes). In the case of medication, the gematik is developing the ISiK-Modules (Informationstechnische Systeme in Krankenhäusern; English: Information technology systems in hospitals) based on FHIR resources for exchanging medication data [32]. An overview of the different standardization levels is presented in Figure 1.

Figure 1. Visualization of the standardization levels of medicinal products. EDQM: European Directorate for the Quality of Medicines; EMA: European Medicines Agency; IDMP: Identification of Medicinal Products; ISO: International Standardization Organization.

Responding to the need to make digital data assets and their associated metadata more usable by machines and reusable by humans, Wilkinson et al [33], developed a set of 15 guiding principles for scientific data management and stewardship, which are grouped into the four higher principles of Findability, Accessibility, Interoperability, and Reusability (FAIR). Implementing the FAIR Principles is relevant to improving efficiency and access to research and health care data. Since their publication, many authors have highlighted the benefits of its adoption [34-36].

In contrast, the most comprehensive medication records in Germany, such as the ABDA (Federal Union of German Associations of Pharmacists) or ABDA-MED (ABDA Medication Database) and MMI Pharmaindex Plus, are commercial, proprietary databases that can only be accessed under license, limiting public availability, and requiring authorized usage for comprehensive pharmaceutical data retrieval [37,38].

Objective

As our institution is not immune to the risk of medication errors, and modern IT solutions for medication management are set to be gradually implemented in the coming years, this paper aims to (1) assess the extent to which medication systems in our hospital use standardized medication data and comply with established standards and (2) propose a proof-of-concept FHIR-based interoperable solution with noncommercial, standardized, minimal, and FAIR medication data to enhance medication interoperability.

Methods

Departments Involved

The key units involved in the medication process were identified by the Chief Medical Informatics Officer (CMIO) team before the start of the study. Therefore, no additional partners were required for this project. The study included the IT department, the pharmacy, the PDMS used throughout the institution's ICUs, and selected general wards. It examined their databases, focusing on data quality, standardization, storage, governance, and both semantic and technical interoperability. The medication data provided and extracted from these datasets were systematically structured and classified to develop a standardized database.

Selection of Drugs and Data Components for the Standardized Database

As medication datasets are not freely accessible by default for safety and commercial reasons, governance staff responsible for managing medication records on a particular stakeholder's software provided access to the data. They provided the authors with access to the medication databases, detailed information about the software communication protocols for exchanging data, and the methods used to keep the information up to date. The selection criteria for drugs included in this study's novel and standardized database were based on the 60 most frequently administered medications in an anesthesiology ICU. These drugs are documented using quick-access buttons in the medication section of the ICU Patient Data Management System (PDMS), designed for recording commonly used medications. For this study, data related to these drugs were extracted from the datasets of the units participating in the study, which used different systems, and were integrated into our database.

We searched and selected data components from multiple datasets used in the institution to develop a minimal, FAIR, and

XSL•FO
RenderX

standardized dataset capable of accurately identifying every single drug with the least possible amount of data. Our selection was based on the Medication and Medication Request resources of the HL7 FHIR standard, given a future modernization of medication software. The following data elements for each drug were included: drug name, institution-specific product number, Pharmacy Central Number (PZN), Pharmacy Product Number (PPN), Anatomical Therapeutic Chemical (ATC), and the German Drug Substance Catalog (ASK) code.

Data provided from institutional databases was complemented with records drawn from the most comprehensive German medication register, the ABDA or ABDA-MED proprietary database [39]. To ensure compatibility with European standards [40], we added information available on the EDQM standard terms [41], incorporating standardized data on administration methods, intended site, and routes of administration. Ultimately, all data was compiled into a single medication core dataset [42], used to generate FHIR order message prototypes.

As summarized in Figure 2, the different pieces of information were gathered according to their availability to the different stakeholders as well as national and international databases.

Figure 2. Source of specific medication data and included data elements in the standardized database. ABDA: Federal Union of German Associations of Pharmacists; ABDA-MED: ABDA Medication Database; ASK: German drug substance catalog; ATC: Anatomical Therapeutic Chemical; EDQM: European Directorate for the Quality of Medicines and HealthCare; PPN: Pharmacy Product Number; PZN: Pharmacy Central Number.

	Pharmacy	IT department ABDA/ABDAMED	ICU's PDMS	General ward	EDQM
Drug name	x		x	x

PPN	x	x			
PZN		x		x	
ATC		x	x	x	
ASK		x			
Administration method					x
Intended site					x
Basic dose form			x		x

Ethical Considerations

This work was conceived as part of an operative medication project at Charité - Universitätsmedizin Berlin and the Berlin Institute of Health (BIH) to assess the status quo and modernize medication software and management across the institution. The study did not gather patient data and focused solely on general medication records that included drug information for the analysis. Consequently, the authors did not pursue approval from the institutional ethics committee.

Results

Overview

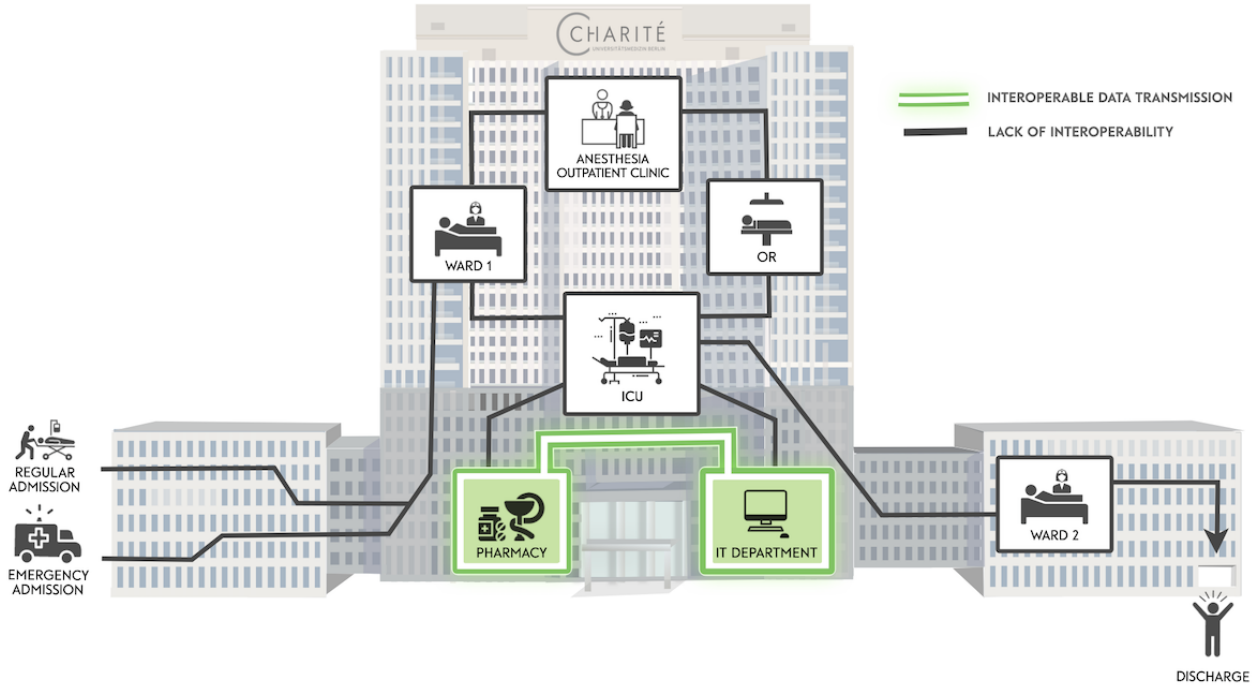
Multiple medication software and datasets were used throughout the hospital. Medication software was provided by different companies with limited data compatibility and transfer capabilities between them. Different departments maintained medication records separately. For these reasons, it was necessary to contact the hospital staff responsible for each medication software and dataset used to analyze medication.

The EHR maintained the relevant medication master data by using the commercial medication database ABDA or ABDA-MED as the basis for the internal medication data managed by the IT department. A critical unit relying on this information was the pharmacy. The pharmacy information system (PIS) could exchange data directly with the ABDA-MED database, demonstrating interoperability through the shared use of the same database.

However, we found that the PIS lacked an interface to share data directly with other systems, such as the ICU PDMS or medication software in the general wards. Its working database was a spreadsheet listing 3146 medications available in the hospital's drug storage, containing four data attributes: institution-specific material number, PZN, drug name, and manufacturer. In other words, apart from communicating with the main database, the pharmacy was isolated and unable to exchange information in an interoperable manner with any other system involved in the medication process.

The assessment of the study ICU showed that medications were always prescribed and documented in digital form using the ICU's PDMS. Nonetheless, the digital user interface (UI) was founded on a spreadsheet-based database containing information about 4818 drugs, which was compiled and imported manually by a senior physician and an employee from the division of clinical procedures.

The PDMS database contained nonstandardized information, including drug ID, PDMS name, trade name, generic name, active ingredient, medication family, main administration method, application form, calories, weight, dosage, and incomplete administrative data. The PDMS was also isolated



XSL•FO
RenderX

and noninteroperable, as it lacked an IT interface to transfer data to the EHR, PIS, or general wards.

The medication workflow in the examined general wards required a medication application to digitalize the medications prescribed to a particular patient. This system used data stored in another proprietary dataset, the MMI Pharmaindex, comprising the following information: ATC and *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) codes, company type, country of production, molecule type, pharmaceutical form, molecule unit, molecule nature, and package unit. This software was incompatible with the other medication applications mentioned earlier due to the absence of an interface, and its data access was highly restricted.

In summary, we examined communication flow concerning medication in a large hospital. This process spans across several phases and departments, such as admission, ward, anesthesia, ICU, pharmacy, inpatient stay, and discharge as shown in Figure 3. Little interoperability was found across the examined systems; medication information was isolated and needed human intervention to be exchanged. The absence of a central database with uniform medication standards led to the maintenance of a wide range of isolated, noninteroperable datasets by different stakeholders, except for PIS and the IT Department, which used the ABDA-MED database.

Figure 3. Visualization of pharmaceutical data flow within the assessed organization: Green lines represent departments where interoperable data transmission has been successfully implemented, while black lines highlight areas where interoperability is still lacking. The visualization emphasizes the significant work that remains to be done.

After analyzing various databases and identifying a minimum dataset of the most relevant medication-related information, we developed a standardized medication database. This novel database incorporates a minimal set of FAIR-compliant data for 60 drugs frequently used in our hospital's ICUs, enabling accurate identification of each drug. The final database includes the following data: drug name, institution-specific product number, PZN, PPN, ATC, ASK, and EDQM codes for administration method, intended site of use, and routes of administration. Examples of 10 drugs are shown in Figure 4. A full version of the database is accessible on Figshare [43].

Technical Validation and Proof-of-Concept Development

By using the developed database together with HL7 FHIR specifications, we generated order messages for communication within medication software (Multimedia Appendices 1 and 2). These messages incorporated drug-specific, standardized data essential for the exchange of information between various software and applications. These are the messages that each source node in the network would generate to be validated and forwarded to its destination by the FHIR server.

Another essential aspect identified during the analysis of medication prescriptions in the ICU was the standardization of custom formulations, where a composition of 2 or more drugs must be represented. These are frequently used in an ICU setting and thus have high therapeutic relevance. In this regard, an agreement between the IT and pharmacy departments was established, introducing a new material number for identifying compounded medications to comply with the proposed standardization (Multimedia Appendices 3 and 4).

Discussion

Principal Results

This study assessed pharmaceutical records in a large university hospital and proposes a standardized solution for digitalization and interoperability across various medication systems and datasets. Leveraging the HL7 FHIR standard, it outlines the development of a proof-of-concept solution to enhance seamless data exchange and integration.

As described by Lehne et al [44], noninteroperable systems lead to undesired outcomes, such as redundant data storage, manual data maintenance, data discrepancies, difficulty in drug tracking, billing problems, inefficiency, and resource waste due to the high costs and time demands on trained personnel. Manual entry and transmission of medication information can contribute to clinical staff dissatisfaction and pose risks of patient harm, including errors that could result in injuries or death [45]. In addition, these practices hinder extensive medication research and artificial intelligence (AI) adoption [46-48], making large-scale studies nearly unfeasible. They also impede the implementation of closed-loop medication administration (CLMA) and MedRec systems, which could significantly reduce medication administration errors [49-51].

Integrating documentation software across different clinical departments (eg, emergency room, normal ward, operating room, and ICU) and including nonclinical areas (eg, pharmacy or IT department) in data management remains an open challenge. Therefore, a standardized central database and an interoperable interface enabling seamless communication among various software systems in hospital settings are needed.

At the time of analysis, our clinic lacked a central medication database that considered all stakeholders in the prescription process or the scientific reuse of data across departments, leading to data isolation and lack of interoperability. This issue is a crucial obstacle to enhancing patient safety and quality of care. Consequently, the institution is undergoing a significant overhaul of medication processes with FHIR standards playing a significant role.

These challenges are not unique to our institution but represent a global issue stemming from the general lack of standardization [52]. Efforts such as ISO IDMP standards, EMA medication guidelines, and local initiatives like MII and gematik [53] in Germany are crucial and should be considered when developing any IT medication solution. Overcoming obstacles such as the absence of public medication databases is a significant public health concern, as it directly affects data accessibility, exchange, transparency, management [54], and reuse.

To tackle these issues, we propose a FHIR R4–based solution designed to seamlessly import and transfer information from a standardized drug master database to various target systems in a configurable manner. Developed with an international perspective, this approach aims to enhance interoperability and standardization in medication data exchange.

The FHIR profiles used derive from the German MII, which is currently only used for secondary purposes by our large hospital. We rely on MII assets for terminology services, validation, and profile conformance.

To implement this solution, we propose creating a FHIR server, built upon an open-source FHIR implementation such as HAPI FHIR. The server would facilitate the interoperable exchange of medication data between existing hospital systems.

XSL•FO
RenderX

In a messaging-based approach, the server could act as a middleware between systems using FHIR messaging operations for real-time bidirectional communication, with clients publishing medication-related events that the server transforms and forwards. Either of these solutions will use the MII terminology service to validate medication codes. In the next stage of our project, we will validate this approach in our environment by developing an application for medication management.

Its primary objective is to address and solve local challenges while optimizing workflows for health care stakeholders both nationally and internationally in the context of health data management. By providing a nonproprietary, FAIR medication core dataset, our solution has the potential to be integrated into broader initiatives such as the European Health Data Space (EHDS) [55]. This integration would promote secure, efficient, and timely communication, as well as seamless use of electronic medication data across the EU.

Furthermore, it is designed to meet the needs of physicians, pharmacists, computer scientists, researchers, and administration personnel while adhering to national and international IT standards and guidelines, such as Germany's Interop Council for Digital Health [56] and the WHO's 2020 global strategy on digital health [57]. It aligns with the widely accepted perspective that standardization and interoperability are crucial for enhancing patient care and safety [58], improving workforce satisfaction and productivity, and fostering research and innovation. To the best of our knowledge, no comparable proposal has been presented in the literature.

Limitations

This investigation has several limitations. Due to our institution's large size, we did not consider medication data transfer and documentation of each general ward or ICU, potentially overlooking an already interoperable solution that could serve as a model for further development. However, given the widespread use of diverse medication software standards, an institution-wide analysis would likely reveal more interoperability conflicts when implementing any IT solution.

In addition, although HL7 version 2.3 is the most popular and widely used health care framework, we focused on FHIR due to its efficiency, flexibility, and suitability for mobile applications, her, and cloud communications [59,60]. Nonetheless, the database presented here could also be adapted for HL7 v.2.3 thanks to its standardized structure.

Code Availability

All FHIR order messages were developed using Microsoft Visual Studio Code Version 1.90.2 and are available without restrictions on Figshare [61].

Conclusions

Our results show that it is very challenging to achieve standardization and interoperability of medication records across the different IT platforms used in a hospital ecosystem.

To address this situation, we propose a solution that facilitates seamless data exchange among stakeholders using medication software, leveraging FHIR standards to overcome system disparities and data silos based on a noncommercial minimal, and FAIR medication dataset. This approach seeks to streamline digitization efforts across hospital departments, in key processes like patient discharge from the ICU to general wards. Beyond improving operational efficiency, our interoperable medication solution can help to reduce errors, enhance patient safety, and elevate the quality of care by enabling standardized data exchange and seamless stakeholder communication across the hospital ecosystem. Our study represents a conceptual proposal for a future solution at this stage, with no specific application or API interactions developed yet.

Acknowledgments

The authors would like to thank Josef Schepers, Moritz Lehne, and Prof Marcus Friedrich, for providing a valubale overview of this complex topic. Our gratitude to Muazzez Weiss and Jan Fahrenkrog-Petersen for their support in gathering data for standardization, and to Thomas Ocker for his remarks on the standardization of custom drug mixtures.

This project was financed with special funds from the Berlin Institute of Health (BIH).

Authors' Contributions

JS performed supervision. ESB, RH, ID, and ER performed the investigation. ESB, ST, and FB contributed to the methodology. ESB, RH, ID, and ER performed data curation, supported by VR and JS. ESB performed formal analysis, supported by RH, DF, ASP, RDD, and JS. ST and FB acquired funding. JS handled project administration. VR and JS managed resources. JS, ESB, and ST managed software, including code creation for communication within IT medication platforms. JS and all authors conducted validation. RDD performed visualization. ESB wrote the original draft. All authors contributed to the conceptualization, writing—review and editing, and approval of the submitted manuscript and will be accountable for its contents.

Conflicts of Interest

None declared.

Abstract

Background: Cirrhosis is a leading cause of noncancer deaths in gastrointestinal diseases, resulting in high hospitalization and readmission rates. Early identification of high-risk patients is vital for proactive interventions and improving health care outcomes. However, the quality and integrity of real-world electronic health records (EHRs) limit their utility in developing risk assessment tools.

Objective: Despite the widespread application of classical and ensemble machine learning for EHR-based predictive tasks, the diversity of health conditions among patients and the inherent limitations of the data, such as incompleteness, sparsity, and temporal dynamics, have not been fully addressed. To tackle those challenges, we explored a framework that characterizes patient subgroups and adaptively selects optimal predictive models for each patient on the fly to enable individualized decision support.

Methods: The proposed framework uniquely addresses patient heterogeneity by aligning diverse subgroups with dynamically selected classifiers. First, patient subgroups are generated and characterized using rules indicating medical diagnosis patterns. Next, a meta-learning framework trains a meta-classifier for optimal dynamic model selection, which identifies suitable models for individual patients. Notably, we incorporated a tailored region of competence to refine model selection, specifically accounting for cirrhosis complications. This approach not only enhances predictive performance but also elucidates why individualized predictions are better supported by selected classifiers trained on specific data subsets.

Results: The proposed framework was evaluated for predicting 14-day and 30-day readmission in patients with cirrhosis using multicenter data obtained from 6 hospitals. The final dataset comprised 3307 patients with at least 2 admission records, along with a range of factors including demographic information, complications, and laboratory test results. The proposed framework achieved an average AUC (area under the curve) improvement of 5% and 4% compared to the best baseline models, respectively.

Conclusions: By leveraging the expertise of the most competent classifiers for each patient subgroup, our approach enables interpretable training and dynamic selection of heterogeneous predictive models. This advancement not only improves prediction accuracy but also highlights its considerable potential for clinical applications, facilitating the alignment of diverse patient subgroups with tailored decision-support algorithms.

Introduction

Cirrhosis, a chronic condition caused by hepatocyte injury and liver fibrosis [1], is often accompanied by complications [2] such as ascites and hepatic encephalopathy, posing severe risks to patients' health and survival. Patients with cirrhosis typically have high hospitalization rates, prolonged hospital stays, and frequent readmissions [3]. Notably, patients with decompensated cirrhosis are particularly vulnerable, with a 5-year survival rate of merely 14% - 35% [4] and a readmission rate ranging from 10% to 50% within 7-90 days postdischarge [5]. These challenges not only disrupt the continuity of care and degrade patients' quality of life but also impose a substantial economic and societal burden on hospitals and health care systems [6]. Statistics indicate that the annual economic expenditure attributable to unplanned readmissions from cirrhosis amounts

XSL•FO
RenderX

to approximately US $17.4 billion [7]. Given the significant impact of the readmission issue on health care resource allocation [8], the Patient Protection and Affordable Care Act (2010) established reducing hospital readmission rates as a pivotal objective in the reforming of fee-for-service hospital reimbursement policies [9]. Even though the readmission rate is not commonly used as an evaluation metric by hospitals, the global significance of the readmission problem cannot be ignored [10,11].

Research has demonstrated that a substantial proportion, up to 27.1% [12], of readmissions are potentially preventable, highlighting a substantial opportunity for the development of predictive models aimed at identifying high-risk patients. In recent years, electronic health records (EHRs) have gained widespread adoption in both clinical practice and research endeavors, providing a vast and diverse dataset for machine learning algorithms [13]. By harnessing clinical indicators embedded within EHRs, such as laboratory test results and vital signs, researchers have developed numerous predictive models to precisely evaluate patients' risk of readmission. For instance, Berman et al [14] used comprehensive EHR data sourced from 2 prominent academic medical centers to identify variables predictive of 30-day readmission among patients with liver disease. Similarly, Hu and colleagues [15] conducted an analysis of 30-day and 90-day readmission rates for patients with end-stage liver disease, leveraging EHR data in conjunction with models such as logistic regression, support vector machines, and random forests. These models hold significant potential to enhance our ability to anticipate and mitigate the risk of readmission in vulnerable patient populations [15].

However, the diverse patient population and the inherent challenges of EHR data [16], including high dimensionality, incompleteness, sparsity, and temporal dynamics, pose substantial obstacles for model development. While individual machine learning models have demonstrated effectiveness on specific datasets, they frequently face difficulties in comprehensively addressing these complexities [17]. Multiple classifier systems [18] with dynamic ensemble selection (DES) [19] emerge as a promising approach to address those challenges. DES typically surpasses single models in predictive performance by selecting and integrating diverse classifiers tailored to unknown test instances during the inference process, thereby enhancing predictive accuracy.

The META-DES (dynamic ensemble selection using meta-learning) framework [20] transforms the task of classifier selection into a meta-problem. This approach entails extracting meta-features pertinent to the base classifiers and training a meta-classifier to assess their classification prowess. Nonetheless, when applied to tabular data classification, particularly in predicting readmissions for patients with cirrhosis, the existing DES algorithms do not always outperform state-of-the-art ensemble models. This performance gap seems to stem from 2 challenges. First, the development of predictive models needs to be deeply integrated with the characteristics of specific clinical problems, such as the complexity and diversity of inpatient care. Second, the quality issues of EHR data, such as incompleteness, sparsity, and temporal dynamics, further exacerbate the difficulties in model development.

To address these challenges, this study aims to develop an interpretable framework that dynamically aligns patient subgroups with optimized classifier selection. Specifically, the aim of this study is threefold: (1) to generate and characterize patient subgroups through clinically meaningful rules based on complication and comorbidity patterns; (2) to design a tailored region of competence incorporating medical diagnoses, enabling optimized dynamic selection of patient-specific predictive models; and (3) to establish a paradigm shift from conventional one-size-fits-all approaches to an adaptive methodology that accounts for heterogeneous patient profiles. By integrating medical knowledge with DES, this approach not only improves predictive performance but also provides interpretable insights into the classifier selection rationale for diverse clinical subgroups.

Methods

Ethical Considerations

The study received ethics review and approval from the institutional review board of Chongqing Medical University (approval no. 2023098). Due to its retrospective nature, this study required no informed consent. All collected data were fully anonymized with no personally identifiable information included. No financial or material incentives were provided to participants.

Data Collection

This retrospective prognostic study focused on decompensated liver cirrhosis data sourced from 6 tertiary hospitals in Chongqing, China. The initial cohort encompassed 13,476 patient records from January 2011 to June 2020, identified using cirrhosis diagnostic codes according to the ICD-9 (*International Classification of Diseases*, 9th Revision) or ICD-10 (*International Classification of Diseases*, 10th Revision) systems. We followed the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) [21] guidelines for reporting cohort studies. To refine our cohort, we applied the following exclusion criteria: (1) patients hospitalized for cancer, malignant tumors, tuberculosis, or HIV (n=1906); (2) patients lost to follow-up or who died during their initial hospitalization (n=151); (3) patients with no recorded readmissions (n=7150); and (4) patients with missing data exceeding 10% (n=1113).

Variable Description

The refined cohort consisted of 3307 patients, each with at least 1 readmission record. The dataset covered a wide range of variables, including 3 demographic factors, 5 etiological variables, 35 comorbidities and complications, 38 clinical test indicators, 10 surgical variables, 7 medication-related factors, 1 composite scoring variable, and 1 outcome variable. All included indicators were thoroughly reviewed by clinical experts. Demographic data included age, gender, and the number of hospitalizations. The list of complications featured hepatic encephalopathy, acute-on-chronic liver failure, ascites, and esophageal or gastric varices. The laboratory test indicators included prothrombin time, international normalized ratio, hemoglobin concentration, creatinine, and several other critical

XSL•FO
RenderX

measurements. A comprehensive list is provided in Multimedia Appendix 1.

Statistical Methods

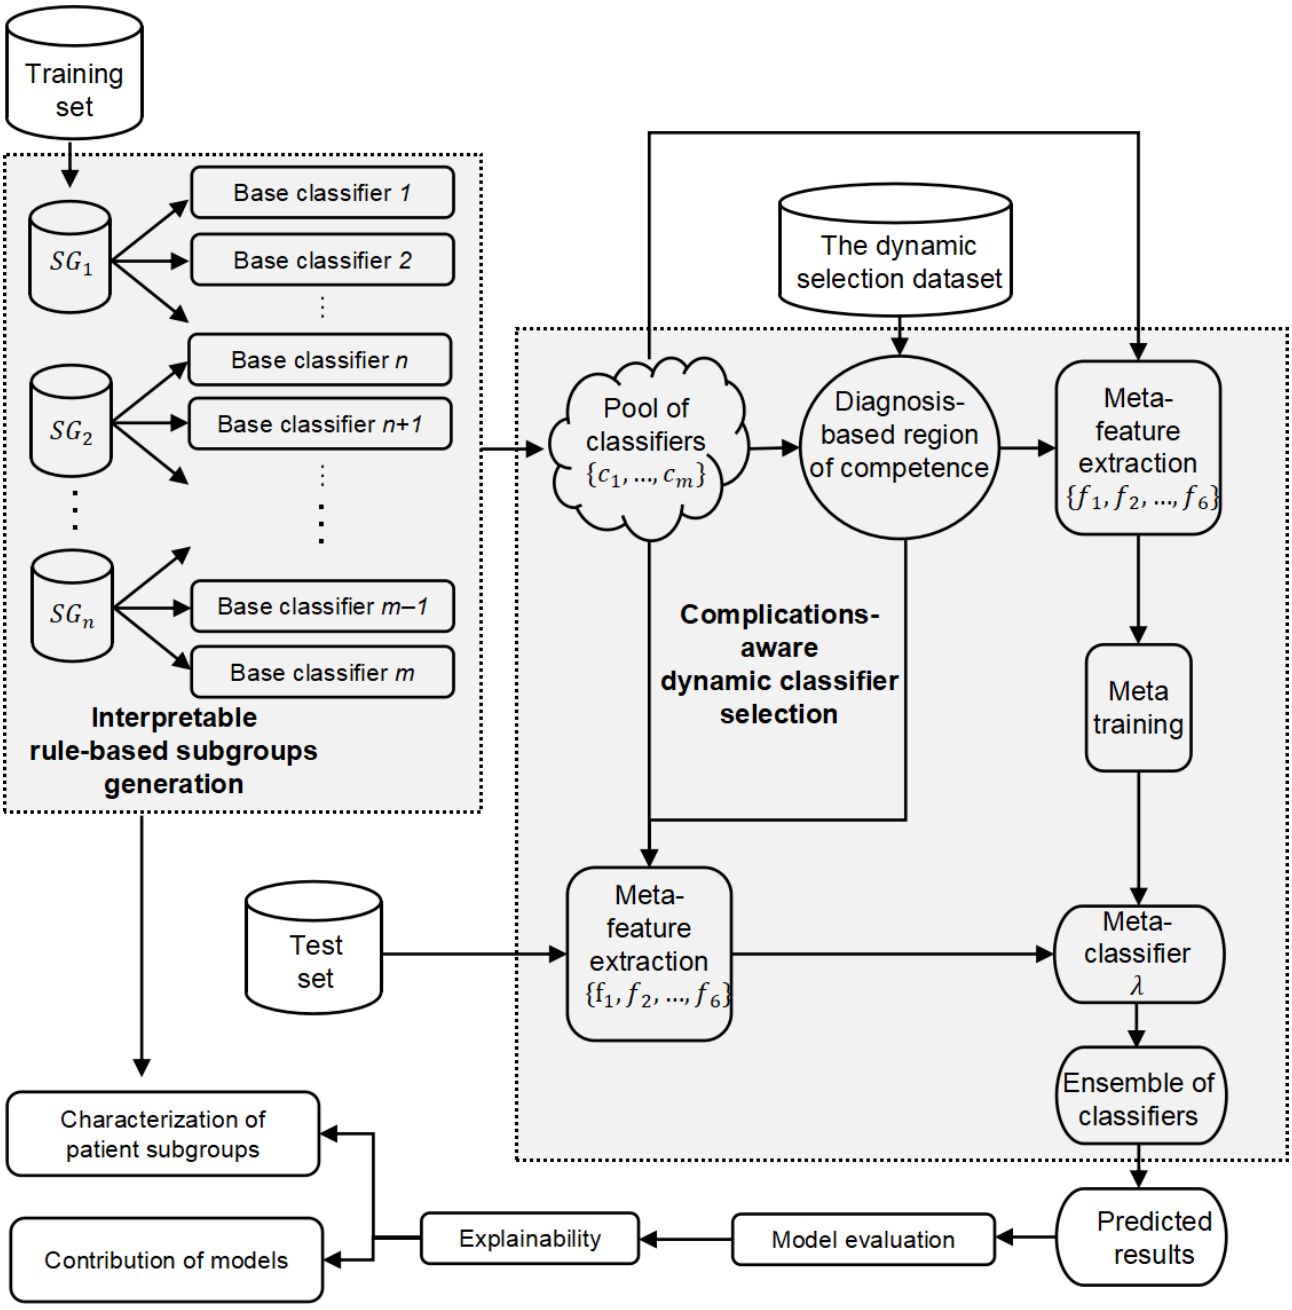
For descriptive analyses, continuous variables, such as laboratory indices, were summarized using medians and IQRs, while categorical variables were presented with frequencies and proportions. A 2-step variable selection process was used.

Univariate Analysis

Potential predictors of 14-day and 30-day readmissions were evaluated. Quantitative predictors were assessed using the Mann-Whitney *U* test, and binary predictors were analyzed with the chi-square test or the Fisher exact test. Considering the high dimensionality of the data and the complexity of the model, predictors with a *P* value less than .05 were retained for further analysis.

Automated Feature Selection

The selected predictors from the univariate analysis were then incorporated into an automatic variable selection process within the DES framework to identify the optimal subset of predictors. The final set of variables included in the model was determined based on a careful balance between accuracy and simplicity.



The DES Framework

Key Features of the Framework

The proposed framework highlights 2 critical components: the generation of the classifier pool and the dynamic selection of classifiers. The classifiers trained with different training subsets play a pivotal role in tackling issues such as the incompleteness and sparsity of EHR data by capitalizing on the diverse feature selection capabilities across the heterogeneous classifiers. This approach enables the framework to maximize data utility even with fragmented or scarce data. Moreover, as patients' health status evolves over time, the dynamic classifier selection process enables the framework to adapt more effectively to these fluctuations, enhancing its overall adaptability and relevance in real-world clinical scenarios. Notably, medical expert knowledge can be seamlessly integrated into both classifier pool generation and dynamic selection processes. This integration ensures that the framework is not only data-driven but also informed by the expertise and insights of medical professionals, adding a layer of clinical validity and practicality. An overview of the framework is graphically presented in Figure 1, providing a clear visual representation of its core components and interrelationships.

XSL•FO
RenderX

Figure 1. Overview of the proposed framework.

Classifier Pool Generation

Traditional DES systems typically generate diverse classifier pools through strategies such as altering initialization parameters, hyperparameter configurations, classifier models, training datasets, and feature subsets. In this study, to ensure the diversity of the base classifiers, we introduced a rule-based method to generate data subsets to support the training of classifiers. Given that complications are major causes of readmission in patients with cirrhosis as reported in existing studies, the descriptions of complications and comorbidities associated with liver cirrhosis are presented in Table 1. Based on this, we extracted rule sets that consist of binary variables representing medical diagnoses from real-world datasets. These rule sets allow us to characterize patient subgroups (SG_1, SG_2,..., SG_n) based on distinct combinations of these complications and comorbidities. For example, a rule might be

(Electrolyte metabolic disorders=TRUE) AND (Hepatic encephalopathy=FALSE)

This rule-based method, grounded in medical diagnosis patterns, represents an innovative approach to integrating medical knowledge into the classifier generation process. By examining these subgroups, researchers and clinicians can gain deeper insights into the underlying reasons why individualized predictions are supported by classifiers trained on certain subsets of the data. By leveraging diverse data subsets and training heterogeneous classifiers, the classifier pool can capture a wide range of patterns within the EHR data to enhance the overall predictive performance. In this phase, a classifier pool C={c1,c2,...,cm} was generated with *m* classifiers.

Besides diverse patient subgroups, a variety of machine learning algorithms can be integrated into the framework to create the classifier pool.

Table . Definition of complications and comorbidities.

Category	Complications	Comorbidities
Definition	Diseases or pathological conditions directly caused by liver cirrhosis	Other independent diseases or pathological conditions coexisting with the patient
Cause	Caused by liver cirrhosis (eg, portal hypertension and liver failure)	Caused by factors other than liver cirrhosis
Common stage	Most common in the decompensated stage	Can occur at any stage of the disease

Meta-Feature Extraction and Meta-Training

The DES problem involves selecting an optimal subset of base classifiers C′⊂C to classify a given test sample x_j. To train a meta-classifier λ that acts as a classifier selector, the key challenge is to define the criteria to evaluate the competence of base classifiers as meta-features. In this study, 2 sets of meta-features are used. The first set of meta-features includes the criteria to measure the local accuracy in the region of competence (f_1), extent of consensus in the region of competence (f_2), overall accuracy in the region of competence (f_3), accuracy in the decision space (f_4), and degree of confidence for the input sample (f_5). To extract those meta-features, a region of competence θ_j is defined, for instance, x_j, using the *k*-nearest neighbors clustering of the entire feature space of each data subset.

To effectively incorporate complications and comorbidities into the characterization of patients with cirrhosis and refine dynamic classifier selection, a novel competence region θj′ is defined. This region, grounded in medical diagnoses, emphasizes complications and comorbidities as binary indicators of their presence or absence. Notably, the competence region θj′ consists of an equal number of positive and negative data samples to ensure a balanced evaluation of the base classifiers' performance. The new set of meta-features (f_6) was defined as the local accuracy within the region of competence θj′ to be aware of patients' subgroup with specific complications or comorbidities. Thus, a meta-feature vector is extracted as vij={f1,f2,f3,f4,f5,f6} for classifier c_i and instance x_j. To construct the training set for the meta-classifier, labels are assigned to each meta-feature vector: for each meta-feature vector, its label αij=1 if classifier c_i correctly classifies instance x_j, otherwise αij=0. By embedding patients' medical diagnoses, this framework proficiently captures the impact of complications and comorbidities during the dynamic selection of suitable classifiers. This approach represents an improvement over traditional methods, as it explicitly incorporates the unique characteristics of patients with cirrhosis. The critical role of this redefinition lies in its ability to determine model applicability for specific patient subgroups. Technical details of the implementation can be found in the GitHub repository [22]. This dynamic framework not only improves the predictive performance but also enhances the model's adaptability to real-world clinical scenarios.

Dynamic Classifier Ensemble

In traditional machine learning workflows, a single model is typically used for both the training and testing datasets. Nevertheless, different models display diverse strengths and weaknesses in terms of accuracy, interpretability, and other aspects. The fundamental theory of dynamic classifier selection postulates that not every classifier in a pool is an expert for all unseen samples. On the contrary, each base classifier is proficient in distinct regions of the feature space. When we apply this concept to our study, it becomes clear that no single classifier can yield optimal prediction results for the entire test set. However, by using the dynamic classifier selection strategy, we are able to extract diverse meta-features for different data subsets and choose the base classifier that provides the most accurate prediction for each subset. This method guarantees the achievement of the optimal prediction results.

Given an instance xj,test, the dynamic selection dataset, and the classifier pool, the set of meta-features {f1,f2,f3,f4,f5} is extracted using the region of competence θ_j, and the meta-feature f_6 is extracted using the region of competence θj′ based on the diagnosis of patients. Once the meta-features are extracted, the meta-classifier λ is used to calculate competence scores for each classifier in the pool. These competence scores, typically expressed as probabilities estimated by the meta-classifier, indicate the capability of each classifier. The classifiers with the highest competence score are selected as the pool of ensemble of classifiers *C**. If multiple classifiers have equal competence scores, the predictions of those classifiers are aggregated using the majority vote rule.

Results

Data Analysis

The final dataset comprises 3307 patients with readmission records in this study. Among these patients, 1121 (33.9%) are female and 2186 (66.1%) are male, with an average age of 55 years. Within a 14-day period, 423 (12.8%) patients were readmitted, while within 30 days, 879 (26.6%) patients experienced readmission. Tables 2 and 3 present detailed descriptive statistics for the entire dataset. Taking total bilirubin levels (normal range of 1.7 - 21 μmol/L) as an example, it was observed that patients fulfilling the discharge criteria exhibited heightened total bilirubin levels. Upon admission, the percentages of patients with total bilirubin levels exceeding the normal range were 71.9% (304/423) for the 14-day period and 60.4% (531/879) for the 30-day period. However, at discharge, these percentages declined to 65.9% (279/423) and 54.7% (481/879), respectively. Both admission and discharge laboratory indicators aligned with the anticipated clinical outcomes for cirrhotic patients. The missing rates for all selected features are below 10%, and missing data were imputed using the mean of *k*-nearest neighbors.

[a]EMD: electrolyte metabolism disorder. It is an imbalance in the balance of electrolytes (eg, sodium, potassium, calcium, and chloride) in the body, usually caused by levels of electrolytes in the body that are outside of normal ranges.

[b]INR: international normalized ratio. INR = $(PTpatient/PTcontrol)^{ISI}$, where PTpatient is the patient's prothrombin time, PTcontrol is the average normal prothrombin time, and ISI is the international sensitivity. The normal range of INR varies among hospitals, laboratories, and patient,s and ranges from 0.8 to 1.2.

[c]MELD: Model for End-Stage Liver Disease [23]. MELD = 9.57*ln(creatinine) + 3.78*ln(bilirubin) + 11.20*ln(INR) + 6.43. The patient's serum creatinine value is in milligrams per deciliter (mg/dL), the patient's total bilirubin value is in milligrams per deciliter (mg/dL), and the INR is the patient's international normalized ratio for coagulation. The higher the value, the higher the risk level.

[a]EMD: electrolyte metabolism disorder. It is an imbalance in the balance of electrolytes (eg, sodium, potassium, calcium, and chloride) in the body, usually caused by levels of electrolytes in the body that are outside of normal ranges.

[b]INR: international normalized ratio. INR = $(PTpatient/PTcontrol)^{ISI}$, where PTpatient is the patient's prothrombin time, PTcontrol is the average normal prothrombin time, and ISI is the international sensitivity. The normal range of INR varies among hospitals, laboratories, and patients, and ranges from 0.8 to 1.2.

[c]MELD: Model for End-Stage Liver Disease [23]. MELD = 9.57*ln(creatinine) + 3.78*ln(bilirubin) + 11.20*ln(INR) + 6.43. The patient's serum creatinine value is in milligrams per deciliter (mg/dL), the patient's total bilirubin value is in milligrams per deciliter (mg/dL), and the INR is the patient's international normalized ratio for coagulation. The higher the value, the higher the risk level.

Feature Selection and Statistical Analysis

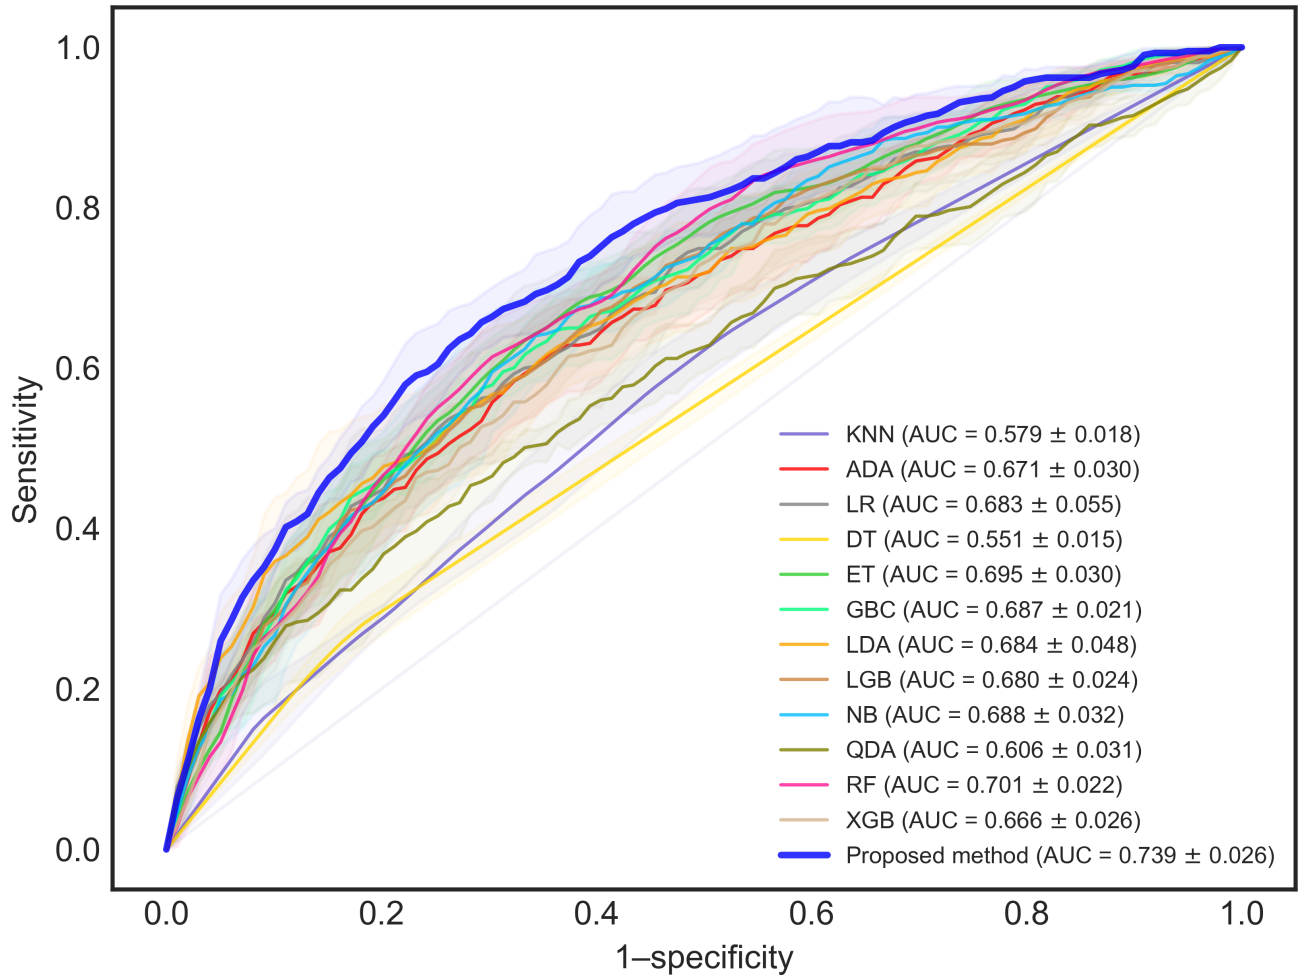
A 2-step variable selection procedure was applied to the 14-day and 30-day readmission datasets, using tailored statistical methods for both quantitative and binary predictive factors. The application of these methods resulted in slightly different sets of included predictors for the 2 datasets. The *P* values for each variable are presented in Tables 2 and 3. Predictive factors with *P* values less than .05 were subsequently considered in the automatic variable selection process within the DES framework, aimed at pinpointing the optimal subset of predictors. Selected variables for both datasets are detailed in Multimedia Appendices 2 and 3.

The DES Framework Development

In the proposed DES framework, the classifier pool generation phase used an ensemble of 11 machine learning algorithms, each trained on different subsets and feature sets, to enhance the diversity and accuracy of trained models. During this phase, an interpretable set of rules was derived from each training dataset. Notably, these rules exhibited considerable overlap, suggesting the existence of common features across different rules. Across all training datasets, a total of 80 rules were extracted, with each rule covering at least 500 instances. These rules served as patterns for identifying specific characteristics or conditions within patient records. Using these rules, tailored data subsets were generated for experiments. Subsequently, during the meta-feature extraction and meta-training phase, 2 groups of meta-features were defined and extracted. Specifically, a customized competence region was designed to leverage the complications and comorbidities of cirrhotic patients, to extract meta-feature vectors for training the meta-classifier. Finally, in the dynamic classifier ensemble phase, the meta-classifier calculated the competence score of each classifier. Either the classifier with the highest score was selected, or a majority voting rule was applied to make predictions, ensuring optimal predictive performance in local regions for each patient.

The machine learning algorithms used to train the base classifiers include Naïve Bayes, *k*-nearest neighbors, logistic regression, linear discriminant analysis, quadratic discriminant analysis, and ensemble models such as random forest, extra trees, AdaBoost (adaptive boosting), gradient boosting classifier, LightGBM (light gradient boosting machine), and XGBoost (extreme gradient boosting). The hyperparameter tuning in this study comprised 2 components. First, the PyCaret library was used to automate machine learning workflows, including feature selection, model training, and hyperparameter optimization. Each model required tailored tuning metrics, such as the selection of the optimal *k*-value and distance metrics for *k*-nearest neighbors, tuning the *C* and γ parameters for the support vector machine, and adjusting the number and depth of trees for the random forest. Second, for the DES framework, hyperparameters such as the type of meta-classifier and the number of neighbors in local regions were optimized via grid search.

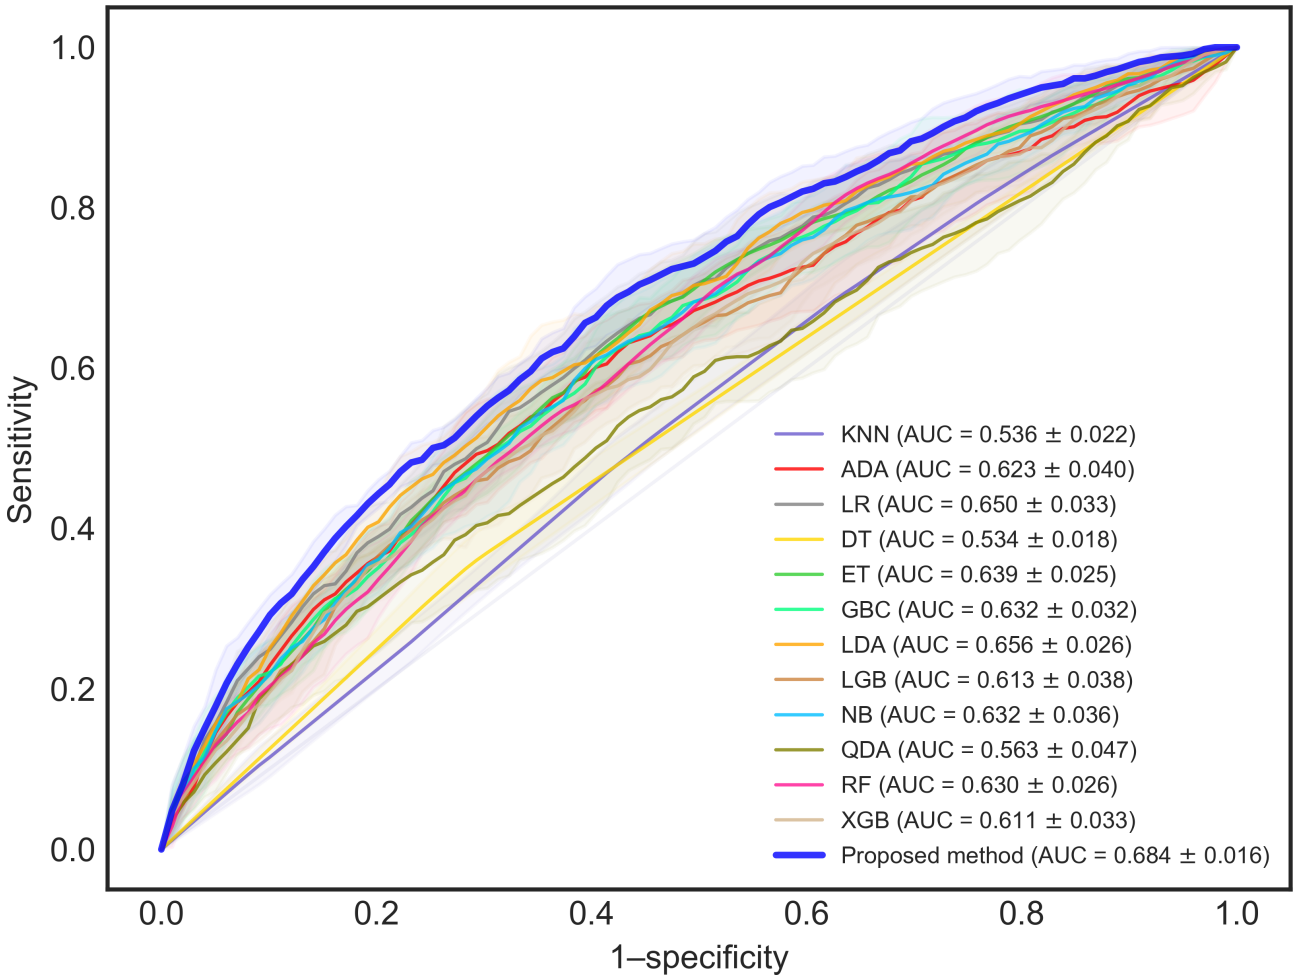
Furthermore, a 5-fold cross-validation approach was applied to maximize the use of a limited dataset, achieve stable predictions, and mitigate overfitting concerns. Building on the established framework of the DESlib library [24], the implementation of the proposed framework is accessible for online reference [22].



Evaluation Results

The evaluation focused on assessing unplanned readmissions within 14 days and 30 days. To address the challenge of imbalanced classification, where the model might tend to predict the majority class, we implemented a sensitivity-focused threshold adjustment. The threshold used for calculating the accuracy score was chosen to ensure a sensitivity greater than 0.5, indicating a focus on correctly identifying positive cases. The AUROC metric quantifies the area under the receiver operating characteristic curve, which illustrates the relationship between the true positive rate and the false positive rate at various thresholds. Visual representations of these metrics are presented in Figures 2 and 3. Table 4 summarizes the average scores obtained during cross-validation, alongside the maximum

XSL•FO
RenderX



and minimum values observed. For 14-day readmission prediction, the DES framework achieved the highest accuracy of 0.783 and the peak AUC (area under the curve) of 0.739. For 30-day readmission prediction, it attained the best accuracy of 0.683 and the highest AUC of 0.684. In both accuracy and AUROC, the proposed method demonstrated superiority over the baseline models. This performance improvement can be attributed to the innovative features of our framework, such as the dynamic classifier selection based on patient subgroups.

Although the accuracy of the model is not particularly high, a result similar to those reported in comparable literature, it was found that in some patient subgroups, the framework we used can exhibit more promising application prospects. This also constitutes one of the significant values of our research. Data-driven models are challenging to implement in real-world clinical applications due to their potential lack of generalizability across all patient populations. Within our framework, during the process of dynamic classifier selection, we can initially ascertain whether a model is suitable for a specific patient. This is accomplished by evaluating the performance of models with respect to the corresponding patient subgroups. As illustrated in Figure 4, patient subgroup 1 consists of patients with liver cirrhosis who have varices but no ascites or portal hypertensive gastroenteropathy. Patient subgroup 2 comprises patients with liver cirrhosis who have splenomegaly but no liver failure or peritonitis. Multiple heterogeneous classifiers were trained using multiple data subsets that meet these criteria to form the classifier pool. For patients 1 and 2, a gradient boosting classifier and a random forest classifier were selected, respectively. We evaluated the performance of the aforementioned subgroups. For the patients (n=152) in the test set who fit the criteria of subgroup 1, the accuracy, precision, recall, and F_1-score were 0.881, 0.862, 0.881, and 0.870, respectively. For the patients (n=195) in the test set who met the criteria of subgroup 2, the accuracy, precision, recall, and F_1-score were 0.891, 0.872, 0.891, and 0.879, respectively.

Interpretability

In addition to improving accuracy, the proposed method offers the capability to generate a classifier pool and facilitate dynamic selection of classifiers in a highly interpretable manner [25]. The interpretable rules used to generate the training subset for this classifier can describe clinical characteristics of patient subgroups. These rules provide insights into the specific features or conditions that contribute to the prediction, thereby assisting clinicians in making informed decisions and tailoring interventions for different patient subgroups. In cases where multiple classifiers are selected for prediction, analyzing the intersection of elements across these rules can provide additional insights for characterizing patient subgroups.

During the dynamic classifier selection phase, the proposed method selects classifiers with the highest competence scores for prediction. Our experiments revealed that, in most instances, a single optimal classifier was chosen for each individual to predict the risk of readmission. When the selected classifier is inherently intelligible and explainable, its predictions can be directly interpreted and understood. If multiple classifiers or black box models are selected for prediction, interpretability techniques such as SHAP (Shapley Additive Explanations) can be used to interpret the model's predictions. For instance, Figure 5 demonstrates that higher indirect bilirubin, total bilirubin at discharge, prothrombin time – international normalized ratio, ascites concentrate, and lower albumin at discharge were associated with higher predicted outcomes for a patient subgroup. Figure 6 presents individual SHAP force diagrams for non-readmitted and readmitted patients, with predicted probabilities of 0.41 and 0.80 for patients 1 and 2, respectively. For the first patient, total bile acid, platelet count, glutathione, aspartate aminotransferase, and peritonitis contributed negatively to the predicted outcome, while calcium and hemoglobin contributed positively. Conversely, for the second patient, calcium, hemoglobin, sex, electrolyte metabolism disorder, autoimmune diseases, total bilirubin at discharge, and sodium at discharge contributed positively to the prediction, while glutathione contributed negatively.

Discussion

In this study, we developed a DES framework that comprises 3 components: classifier pool generation, meta-feature extraction and meta-training, and dynamic classifier ensemble. Initially, the classifier pool was formed by generating data subsets using a rule-based method to characterize patient subgroups and train heterogeneous machine learning models. Subsequently, by defining competence regions that encompass both complications and comorbidities, meta-features were extracted, and a meta-classifier was trained. Finally, a dynamic classifier ensemble was used to select the optimal classifier based on competent scores calculated by the meta-classifier, while a majority voting strategy was used when deemed necessary. This framework demonstrates its potential for application in EHR-based predictive tasks, by adaptively selecting models for individuals, enhanced by the medical knowledge integrated into the DES framework. The dynamic alignment of classifier selection with diverse patient subgroups, identified as the core contribution of this research, significantly enhances the clinical applicability and reliability of the model. By capturing heterogeneous health profiles and treatment responses across patient populations, the framework accommodates the complexity of real-world clinical care, thereby facilitating clinical experts' comprehension and trust in model predictions.

Readmission, a critical indicator of hospital quality [26], performance [27], and patient care standards [12], imposes significant burdens on health care systems and costs, with nationwide readmission expenses surpassing US $4.45 billion annually [28] and posing substantial survival challenges for low-income families [29]. Accurate prediction of readmission is increasingly essential for the effectiveness of interventions aimed at reducing readmissions. While bed availability may influence the timing of readmissions, it is not a determinant of readmission occurrence itself. In China's highly efficient health care system, most patients requiring treatment can access timely care, and bed availability variations (eg, overcrowding vs idleness in specialized units) were not major factors in the hospitals included in this study. To address potential timing biases, this research reports predictions for 2 discrete time intervals (14-day and 30-day readmission), providing comprehensive coverage of readmission dynamics [30]. Although bed availability could theoretically be a confounding factor, its impact was minimized in our analysis.

Over the past decade, numerous studies have modeled readmission risks using diverse methods, typically reporting AUC scores within the range of 0.60 to 0.78 [10,14,15]. The majority of studies have focused on developing and validating a single machine learning model. In contrast, within our study, the proposed DES method demonstrated superiority over other approaches. Notably, the framework implicitly addressed class imbalance through subgroup-specific undersampling during classifier pool generation, whereas explicit techniques such as SMOTE (Synthetic Minority Oversampling Technique) did not improve performance in our experiments.

Our study revealed that the 14-day unplanned readmission rate for patients with cirrhosis was 12.8% (423/3307), while the 30-day readmission rate stood at 26.6% (879/3307). In contrast, the 30-day readmission rates among insurance-covered populations in 2014 and 2019 were 22.6% and 21%, respectively [7]. The slightly elevated readmission rates observed in our study may be attributed to the higher average patient age of 55 years, which is associated with increased disease severity and a greater propensity for comorbidities. These patients are also more susceptible to developing complications and infections during hospitalization [2]. According to weighted analyses of readmission databases, complications [31], MELD (Model for End-Stage Liver Disease) scores [7], and infections [28] are crucial predictors of readmission in patients with cirrhosis. Our study echoed these findings, with prevalent complications including ascites (14-day data: 368 cases vs 55 controls; 30-day data: 770 cases vs 106 controls), variceal bleeding (14-day: 245 vs 178; 30-day: 434 vs 445), hepatic encephalopathy (reference 21; 14-day: 368 vs 55; 30-day: 792 vs 87), spontaneous bacterial peritonitis (14-day: 312 vs 111; 30-day: 670 vs 209), and acute-on-chronic liver failure (14-day: 337 vs 86; 30-day: 739 vs 140). These results are largely in alignment with previous studies [32]. Our study further revealed a gender disparity in liver disease prevalence, with male patients comprising the

XSL•FO
RenderX

majority of readmissions (14-day: 305 vs 118; 30-day: 617 vs 262). This may be linked to unhealthy lifestyle behaviors, including a higher prevalence of alcohol-related cirrhosis in males [33] and increased susceptibility to infections, both of which contribute to elevated readmission rates. Smoking, another established risk factor for cirrhosis, underscores the need for early intervention targeting smoking and alcohol cessation in cirrhotic patients. However, the asymptomatic nature of early-stage cirrhosis often delays diagnosis, exacerbating disease severity and readmission risks in males.

The advantages of this study can be summarized as follows. First, by leveraging heterogeneous classifiers' diverse feature selection capabilities and integrating temporal dynamics of patient health status into the DES framework, the model's robustness and clinical applicability are enhanced to address real-world EHR data limitations. Second, medical expert knowledge is seamlessly integrated into both classifier pool generation and dynamic selection processes. Specifically, medical diagnosis-based rules are used to define patient subgroups and competence regions, ensuring the framework is not purely data-driven but also informed by clinical expertise. This integration adds clinical validity—for example, incorporating complications and comorbidities (critical factors in clinical assessments)—to enhance model relevance and interpretability in real-world practice. Third, the framework enables dynamic updates of classifier pools and meta-classifiers with incoming data, demonstrating flexibility and scalability that hold promise for extending its application to prediction and management of a broad spectrum of diseases.

This study acknowledges several limitations. First, the dataset used in this study does not include patients readmitted from other hospitals. Although previous research suggests that the majority of readmissions occur within the same institution, this limitation may potentially affect the comprehensiveness of the study. Additionally, the study only encompasses patients who have had at least 2 readmissions. Future research should strive to expand the dataset and the scope of the sample to improve the reliability and generalizability of the findings. Second, the risk of readmission is affected by a multitude of factors, including socioeconomic status, educational level, and health insurance. This complexity poses a certain constraint on the model's discriminatory power. In future research, the goal is to incorporate these indicators through prospective and follow-up studies, thereby enhancing the model's predictive accuracy. Third, the practical implementation of the model requires continuous monitoring and calibration in line with local medical environments. Future studies should give priority to developing methods to enhance data interoperability across different sites, which will facilitate a wider application of the model.

Abstract

Background: The digitalization of health care has increased the demand for efficient data exchange, emphasizing semantic interoperability. SNOMED Clinical Terms (SNOMED CT), a comprehensive terminology with over 360,000 medical concepts, supports this need. However, it cannot cover all medical scenarios, particularly in complex cases. To address this, SNOMED CT allows postcoordination, where users combine precoordinated concepts with new expressions. Despite SNOMED CT's potential, the creation and validation of postcoordinated expressions (PCEs) remain challenging due to complex syntactic and semantic rules.

Objective: This work aims to develop a tool that validates postcoordinated SNOMED CT expressions, focusing on providing users with detailed, automated correction instructions for syntactic and semantic errors. The goal is not just validation, but also offering user-friendly, actionable suggestions for improving PCEs.

Methods: A tool was created using the Fast Healthcare Interoperability Resource (FHIR) service $validate-code and the terminology server Ontoserver to check the correctness of PCEs. When errors are detected, the tool processes the SNOMED CT Concept Model in JSON format and applies predefined error categories. For each error type, specific correction suggestions are generated and displayed to users. The key added value of the tool is in generating specific correction suggestions for each identified error, which are displayed to the users. The tool was integrated into a web application, where users can validate individual PCEs or bulk-upload files. The tool was tested with real existing PCEs, which were used as input and validated. In the event of errors, appropriate error messages were generated as output.

Results: In the validation of 136 PCEs from 304 FHIR Questionnaires, 18 (13.2%) PCEs were invalid, with the most common errors being invalid attribute values. Additionally, 868 OncoTree codes were evaluated, resulting in 161 (20.9%) PCEs containing inactive concepts, which were successfully replaced with valid alternatives. A user survey reflects a favorable evaluation of the tool's functionality. Participants found the error categorization and correction suggestions to be precise, offering clear guidance for addressing issues. However, there is potential for enhancement, particularly regarding the level of detail in the error messages.

Conclusions: The validation tool significantly improves the accuracy of postcoordinated SNOMED CT expressions by not only identifying errors but also offering detailed correction instructions. This approach supports health care professionals in ensuring that their PCEs are syntactically and semantically valid, enhancing data quality and interoperability across systems.

Introduction

Background

The ongoing digitalization in medicine has significantly increased the amount of available medical data in the health care sector. To optimize medical care, it is crucial to use this data efficiently. For this, it is essential that the data can be exchanged and processed automatically across different systems. This requires not only technical compatibility but also semantic interoperability. Semantic interoperability ensures that the meaning of the data is maintained when it is transferred to another system. A key aspect of semantic interoperability is the sophisticated use of suitable coding systems and medical standards for medical terms [1]. One example is the terminology SNOMED Clinical Terms (SNOMED CT). With over 360,000

XSL•FO
RenderX

concepts, SNOMED CT is considered the most comprehensive terminology in medicine. SNOMED CT facilitates machine-readable data exchange and reduces issues related to country-specific and domain-specific coding, as well as difficult versioning issues. However, despite its comprehensiveness, SNOMED CT cannot cover every possible medical circumstance by precoordinated concepts alone due to the complexity of natural language [2]. For instance, an allergy to metals: The SNOMED CT International Edition, version 2024-09-01, lists a total of 1575 different metals. However, only 43 specific allergies to metals are included in this edition and version of SNOMED CT. This indicates that not every allergy-relevant metal or substance can be expressed through a precoordinated concept, such as an allergy to Cobalt-chromium alloy. To address such gaps, SNOMED CT offers postcoordination in contrast to many other vocabularies. Here, existing precoordinated concepts are combined into new expressions using formal grammar. This avoids the well-known problem of combinatorial explosion [2]. An example postcoordinated expression (PCE) for an allergy to a Cobalt-chromium alloy based on Compositional Grammar [3] is as follows:

1155942004 |Allergy to metal and/or metal compound|:

{719722006 |Has realization| = 472964009 |Allergic process|,

246075003 |Causative agent| = 256526003 |Cobalt-chromium alloy|}.

Here, the focus concept Allergy to metal and/or metal compound is refined by combining attributes (eg, Causative agent) with corresponding attribute values (eg, Cobalt-chromium alloy) as attribute relations.

Creating PCEs improves the detailed recording of medical facts and enhances patient record quality and automated processing. PCEs are complex due to the syntactic requirements of the Compositional Grammar [3] and the semantic rules of the Concept Model [4]. The syntactic requirements ensure that PCEs are correctly structured, while the semantic rules ensure that they accurately represent medical concepts and their relationships. This complexity makes it challenging to create valid accurate PCEs [2].

Since Germany acquired a license for SNOMED CT in January 2021, the interest in using SNOMED CT has grown. SNOMED CT is increasingly being used in various national projects [5,6]. Despite this, postcoordinated SNOMED CT expressions are still used hesitantly. Nevertheless, PCEs are used in the Medical Information Objects of the National Association of Statutory Health Insurance Physicians [7] or in anamnesis forms from Thieme Compliance [8]. Nonetheless, some do not fully comply with the rules of the Compositional Grammar or the Concept Model. To address these issues, this work aims to develop a tool for the validation of PCEs. The focus is not only on determining whether a PCE is correct but also on providing detailed information and concrete suggestions for correcting a PCE (Figure 1). These suggestions are based on the analyzed errors and provide targeted recommendations for correcting specific PCEs.

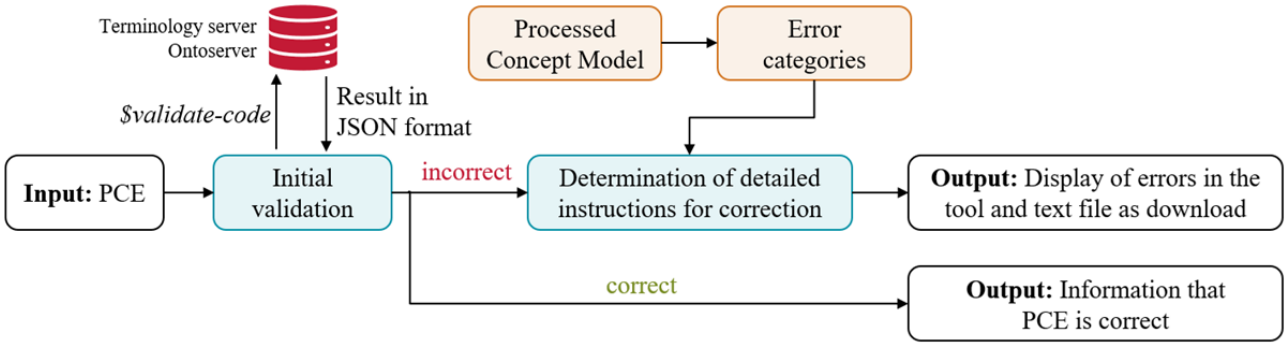
Figure 1. For every invalid PCE, a correction suggestion should be made automatically using the developed tool. PCE: postcoordinated expression.

Related Work

Currently, SNOMED International provides a tool called "SNOMED International APG Parser: SNOMED CT Compositional Grammar" which validates PCEs based on syntactic rules of Compositional Grammar [9]. Nevertheless, this tool only assesses syntactic correctness and does not consider the semantic rules of the Concept Model, which are essential for ensuring contextually accurate PCEs. This work aims to supplement this by adding semantic validation, which should provide better feedback for the user.

An alternative method for the syntactic and semantic validation of PCEs is using the commercial terminology server Ontoserver [10] of Commonwealth Scientific and Industrial Research Organization. Ontoserver is currently the only Fast Healthcare Interoperability Resource (FHIR) terminology server that supports postcoordination at all. Ontoserver is used to validate the PCEs in combination with the FHIR service $validate-code [11]. This checks a PCE against specific coding systems, such as SNOMED CT. This method provides a validation result through a Representational State Transfer (REST) request that returns a JSON object [11]. Although this service indicates errors, it presents them in a technical manner that requires a solid understanding of SNOMED CT. This work's tool will build upon the FHIR service $validate-code based on Ontoserver to offer more comprehensive validation and suggestions. Hence, the difference between this work and the Ontoserver is that the focus is on the individual correction instructions for each PCE.

Methods



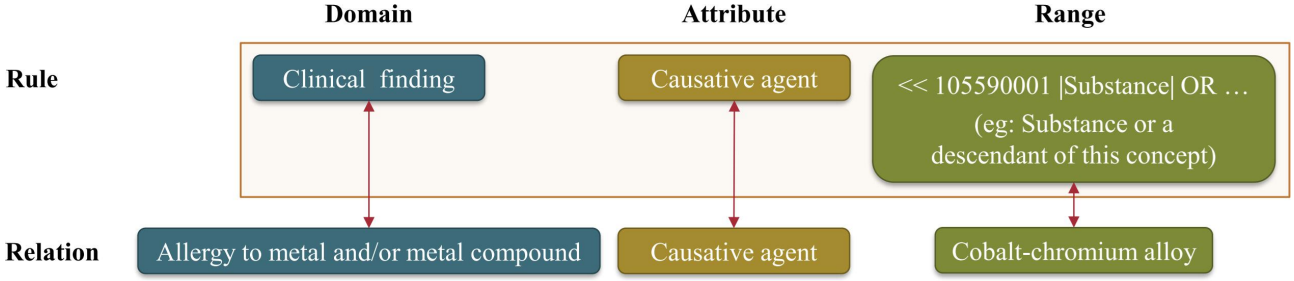
Overview

This work aims to develop a user-friendly tool for validating postcoordinated SNOMED CT expressions. The focus is on the automated provision of detailed correction instructions if a PCE contains syntactic or semantic errors. The tool's pipeline is illustrated in Figure 2. First, a PCE is validated using the FHIR service $validate-code [11] and the terminology server Ontoserver [10]. If the entered PCE is correct, this is communicated to the user, and the algorithm terminates. For incorrect PCEs, the tool generates detailed correction instructions in the next step, based on the results of the FHIR service. A processed Concept Model in JSON format and custom error categories are also used for this purpose. The correction

XSL•FO
RenderX

instructions are presented to the user. The individual components of the pipeline are explained in more detail below.

Figure 2. Pipeline for the validation of a PCE. PCE: postcoordinated expression.



Initial Validation

FHIR, an interoperable data standard developed by Health Level 7 [1], is gaining increasing importance both nationally [12] and internationally [13,14]. In addition to the exchange of patient-related health information, FHIR also offers a terminology module with various services [1]. In this project, the FHIR service $validate-code [11] combined with Ontoserver [10] plays a central role. This is used to verify the syntactic and semantic correctness of a postcoordinated SNOMED CT expression, in combination with a terminology server. The $validate-code service operates via an HTTP POST request. The response is a JSON object that contains the results of the validation. Figure 3 shows an excerpt from this JSON object for an invalid PCE. The error messages indicate that the concept 472964009 |Allergic process| is not a valid attribute. This detailed output is attributed to the commercial Ontoserver, which possesses extensive knowledge of SNOMED CT, enabling precise analysis of PCEs.

Although the output is focused on automatic processing rather than human readability, it remains particularly valuable due to this specialization. This output provides a crucial basis for the next stages of the tool's pipeline.

Figure 3. Domain and range example for the SNOMED CT attribute Causative agent.

Determination of Detailed Instructions for Correction

Processed Concept Model

The Concept Model defines rules for how SNOMED CT concepts and PCEs are structured using formal logic and specific guidelines. These rules ensure that medical expressions are meaningful and consistent. For each SNOMED CT attribute, the Concept Model specifies a domain and a range (Figure 4):

- Domain: This includes concepts (eg, Allergy to metal and/or metal compound) from at least one of the 19 Top-Level Hierarchies (eg, Clinical finding).
- Range: This specifies a subset of SNOMED CT concepts that are valid values for an attribute. For the attribute Causative agent, for instance, only certain substances, such as Cobalt-chromium alloy, are included in the range.

XSL•FO
RenderX

Figure 4. Extract of an error message for an invalid PCE based on an Ontoserver request. PCE: postcoordinated expression.

Invalid PCE:

1155942004 |Allergy to metal and/or metal compound|:
{719722006 |Has realization| = 472964009 |Allergic process|,
472964009 |Allergic process| = 256526003 |Cobalt-chromium alloy|}

Error message:

{"name": "reason",
"valueString": "MRCM: 256526003 is not in range for attribute 472964009"},
{"name": "reason",
"valueString": "MRCM: 472964009 IS NOT a valid attribute for 1155942004"},
{"name": "reason",
"valueString": "MRCM: Total 1 occurrence of attribute 472964009 is not allowed for 1155942004; expected []"}
…

Additionally, the Concept Model specifies the cardinality of the attributes and whether attributes must be grouped [2,4].

To facilitate the tool, a machine-readable Concept Model (MRCM) is included in the RF2 files for each SNOMED CT edition and version [15]. For our purposes, the MRCM Domain Reference Set (International Edition, 2024-05-01) is used. The MRCM Domain Reference Set is provided as a text file, with each domain represented by a detailed entry. Each entry includes all essential information about the respective domain, including a so-called template that is particularly significant for this work [15,16]. An excerpt from one of these templates is shown on the left side of Figure 5. The syntax of the templates is based on Compositional Grammar and includes the relevant attributes, as well as the cardinalities and value ranges for each domain. To further enhance usability, we developed an algorithm that decomposes the template into its individual components and presents this information in JSON format. This allows for a structured and efficient processing of the template components in the next step. All relevant information is already available in the appropriate format, enabling subsequent processes to use it directly without any further conversions. An extract of the JSON is displayed on the right side of Figure 5. The JSON is available on GitHub [17].

Figure 5. Extract from the processed machine-readable Concept Model in JSON format which proves to be advantageous for further processing.

```

Error Categories

Overview

Based on the authors' expertise in SNOMED CT postcoordination [2,18-20], a total of nine error categories have been identified. For each error category, specific guidelines have been developed and are provided for an individual PCE. A general overview of the error categories and the focus of the guidelines is shown in Figure 6. The following sections provide a detailed description of each error category. Examples of the individual error categories are available on GitHub [21].

XSL•FO
RenderX

Figure 6. An overview of the various error categories (left side) and the corresponding correction focus (right side). For all categories, the processed Concept Model in JSON format plays a certain role. For the correction instructions highlighted in red, a terminology server and FHIR services are also used.

Invalid Attribute

If a SNOMED CT concept is used that does not belong to the valid 126 attributes or is not valid in a specific domain, it is categorized under this category.

Correction Instruction

The solution involves identifying a valid SNOMED CT attribute. Users are provided with information about the domain of the focus concept, along with definitions and value ranges for alternative attributes. This helps to replace the invalid attribute with a suitable one. If no appropriate alternative is found, or if no attributes exist within the domain, the user must either modify the attribute value or create a new PCE with a different focus concept. For the invalid PCE shown in Figure 2, this error category is identified. The algorithm would also determine that the incorrect attribute Allergic process should be replaced with Causative agent or Associated with.

Technical Implementation

To implement this, the FHIR service $expand is used in combination with a terminology server and the Expression Constraint Language (ECL) of SNOMED CT [22]. The ECL in this case defines the value range of an attribute, such as << 105590001 |Substance| OR .... This allows for verifying whether the current attribute value is included in the provided list. If an alternative attribute is identified, the PCE is revalidated to check for any additional errors.

Invalid Attribute Value

In this case, the chosen attribute value is not in the value range for the attribute.

Correction Instruction

For manually created PCEs, the attribute value is typically chosen correctly as it directly relates to a specific medical circumstance. However, the chosen value might not be within the valid range. The focus is on identifying appropriate alternative attribute values. Users will receive similar guidance

XSL•FO
RenderX

as in the "Invalid Attribute" error category, including details on the acceptable value range and potential alternatives.

Technical Implementation

The process adheres to the same principle outlined in the "Invalid Attribute" section.

Invalid Domain

In this error category, the attribute relation (comprising an attribute and its value) is semantically correct but does not match the domain of the focus concept.

Correction Instruction

Achieving a semantically correct relation requires a different domain of the focus concept. Users are provided with a list of domains where the current attribute relation is valid, enabling them to modify the focus concept accordingly.

Technical Implementation

The appropriate domain is determined using the FHIR service $expand and a terminology server. The request is based on an ECL that specifies the domain constraint from the Concept Model. For instance, an expression might be << 404684003 |Clinical finding|. If the focus concept appears in the results returned by this query, it belongs to the corresponding domain.

Different Domains With Multiple Focus Concepts

Overview

According to the Compositional Grammar, it is valid to use multiple focus concepts connected by "+" (AND). If multiple focus concepts from different domains are used—such as Clinical finding and Procedure—this results in a semantic error. In such cases, the PCE is categorized under this error category.

Correction Instruction

The domains of the focus concepts used are displayed.

Technical Implementation

We determined the Concept Model Domain performed as described in the "Incorrect attribute relation" category.

Incorrect Grouping

Overview

This category includes errors related to the bracketing of RoleGroups, which are crucial for the syntactic and semantic integrity of PCEs. Common issues involve missing or incorrect brackets, as well as imbalances between open and closed brackets.

Correction Instruction

Users are provided with detailed information on which attributes are incorrectly grouped and where bracket corrections are necessary. Specific guidance is given on how to fix incorrectly placed brackets.

Technical Implementation

A straightforward analysis of the error message and the PCE is conducted to provide targeted correction instructions. The error message shows the position and the concept before which the error occurs. For example, it may indicate that the character "{" is missing, suggesting that a RoleGroup is missing and should be started at the specified location. In this case, the tool would also determine the position where the RoleGroup should be closed again. Technically, this is done through simple processing of the strings for the error message, as well as the JSON object of the PCE.

Inactivated Codes

This error category pertains to PCEs that include codes that are no longer valid or active in the current version and have been replaced by others.

Correction Instruction

Users are provided with an alternative concept that is semantically equivalent to the inactivated concept.

Technical Implementation

Identifying active concepts for inactivated codes is part of version management. SNOMED International offers Historical Association Reference Sets (RefSets) for this purpose. In this work, the following two RefSets are used:

- 900000000000527005 | SAME AS association reference set|: For identifying semantically equivalent active concepts.
- 900000000000526001 | REPLACED BY association reference set|: For linking deactivated concepts that have been replaced by new concepts.

These RefSets can be integrated into ECL. Additionally, ECL provides member filters that can be used in combination with respective RefSets, for example:

^ [targetComponentId] 900000000000526001 | REPLACED BY association reference set|

{{ M referencedComponentId = 224799004 |Unfamiliar environment (environment)| }}.

This ECL queries the REPLACED BY association reference set to identify the concept that has replaced the inactivated concept 224799004 |Unfamiliar environment (environment)|. In this case, the result would be 1186687002 |Unfamiliar environment (finding)|.

Syntactically Incorrect Codes

Overview

This error category refers to SNOMED CT Identifiers that cannot be linked to any valid SNOMED CT concept. The issue is not that the concept is inactive, but rather that the identifier is missing characters.

Correction Instruction

Identifying a valid SNOMED CT concept that corresponds to the numerical sequence of the incorrect identifier is necessary for correcting a PCE. The user will then be provided with this concept.

Technical Implementation

For this category, the FHIR service $expand, a terminology server, and ECL are also used. The ECL expression << 138875005 |SNOMED CT Concept| is used to return all

XSL•FO
RenderX

SNOMED CT concepts. Subsequently, all concepts containing the specified numeric sequence are identified. These concepts are then validated using the FHIR service $validate-code to determine which one fits both syntactically and semantically with the original identifier.

Cardinality Violation

Overview

As previously mentioned, the Concept Model defines cardinalities that specify the minimum and maximum occurrences of an attribute. A PCE is categorized in this category if it does not adhere to these cardinality constraints.

Correction Instruction

Initially, the user is shown the attribute that violates the cardinality constraints, along with the cardinalities defined for this attribute in the Concept Model. If there is a violation of the minimum cardinality, the attribute must be added. In case of a violation of the maximum cardinality, either a grouped attribute should be moved to an additional RoleGroup or ungrouped attributes should be deleted.

Technical Implementation

A basic analysis of the error message and the PCE is performed using the processed Concept Model in JSON format. The error message precisely indicates which attribute violates a cardinality (minimum or maximum) constraint. This information is automatically extracted from the JSON. Using the JSON object, an appropriate error correction can be easily determined.

Further Syntactic Errors

Overview

If a PCE contains characters that do not conform to the Compositional Grammar rules, it falls into this category. For instance, using the symbol ":@" instead of ":" before refinement would trigger an error indicating that the symbol "@" is not allowed.

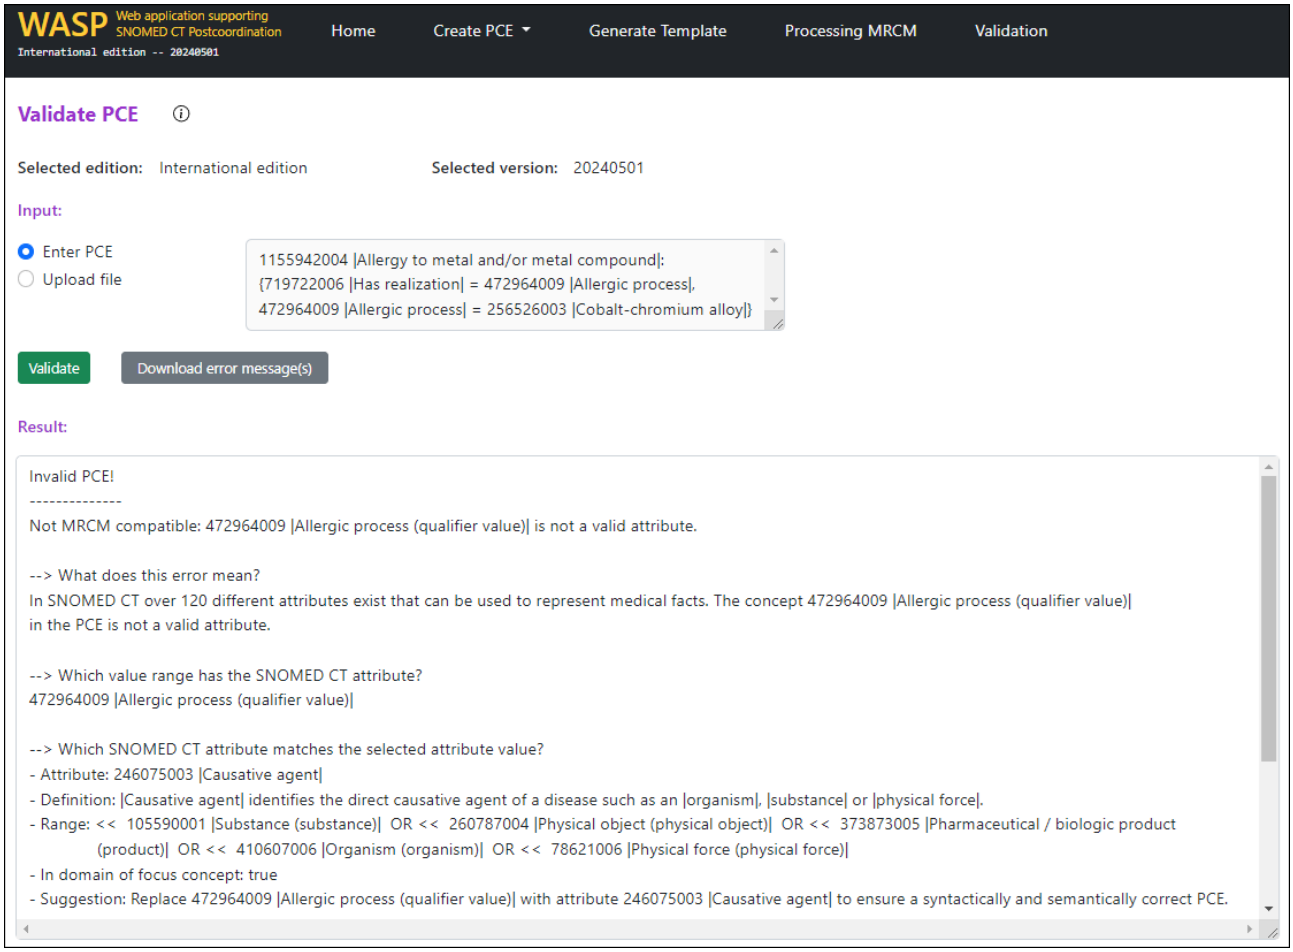
Correction Instruction

The instructions specify which character needs to be replaced and the exact position where the replacement should occur.

Technical Implementation

A fundamental analysis of the error message and the PCE is conducted to provide accurate correction instructions. Through string processing and parsing, the position and the incorrect character are also extracted here.

Results



Validation Tool

The validation tool has been seamlessly integrated into the existing web application WASP [18], which was developed in a previous project. Accessible to the public via [23], the application enables users to use the new tool through the "Validation" option in the main menu. Users can choose to validate a single PCE directly or upload a file for validation. The tool supports various formats, including FHIR Questionnaires [24] and FHIR ValueSets [25] in JSON format, as well as CSV files, offering a flexible and versatile approach for validating different types of data.

Upon completing the validation, users receive a comprehensive overview of any errors detected during the process. These errors are clearly displayed on the user interface, ensuring easy traceability and resolution. Additionally, users have the option to download the error reports as a text file, enabling further analysis or optimization when needed. A screenshot of the web application, highlighting the user interface and layout, is shown in Figure 7.

XSL•FO
RenderX

Figure 7. Extract from the tool for validating the postcoordinated SNOMED CT expressions.

Use Case 1: Existing PCEs in FHIR Questionnaires

For the validation of the tool, real existing postcoordinated SNOMED CT expressions were used to establish a practical and reliable testing environment. These PCEs were incorporated into the FHIR Questionnaires developed by Thieme Compliance, which are designed for modeling anamnesis forms. Thieme Compliance offers these anamnesis forms in multiple languages to enhance usability for both patients and medical professionals. For machine processing and analysis, on the other hand, language-independent codes are used, ensuring precise and efficient data evaluation regardless of the language used [8]. This validation specifically focused on the German-language anamnesis forms as FHIR Questionnaires [24].

In total, 1122 postcoordinated SNOMED CT expressions were identified across 303 FHIR Questionnaires. Since many of these PCEs were repeated, 136 unique PCEs were distinguished. The validation results using the developed tool were as follows:

- 118 (86.8%) correct PCEs
- 18 (13.2%) invalid PCEs

In addition to identifying the correct and invalid PCEs, the developed algorithm carried out a detailed error categorization, uncovering six distinct error categories as shown in Table 1. These errors were analyzed in collaboration with the coders from Thieme Compliance. It was confirmed that all errors were correctly identified, and the correction suggestions were content-wise accurate.

Table . Various error categories and their frequency in the 18 invalid PCEs[a].

Error categories	Frequency
Invalid attribute value	9
Invalid grouping	2
Inactivated codes (International Edition, 2024-05-01)	3
Syntactically incorrect codes	1
Cardinality violation	2
Further syntactic error	1

[a]PCE: postcoordinated expression.

XSL•FO
RenderX

Use Case 2: Existing PCEs in FHIR ConceptMaps

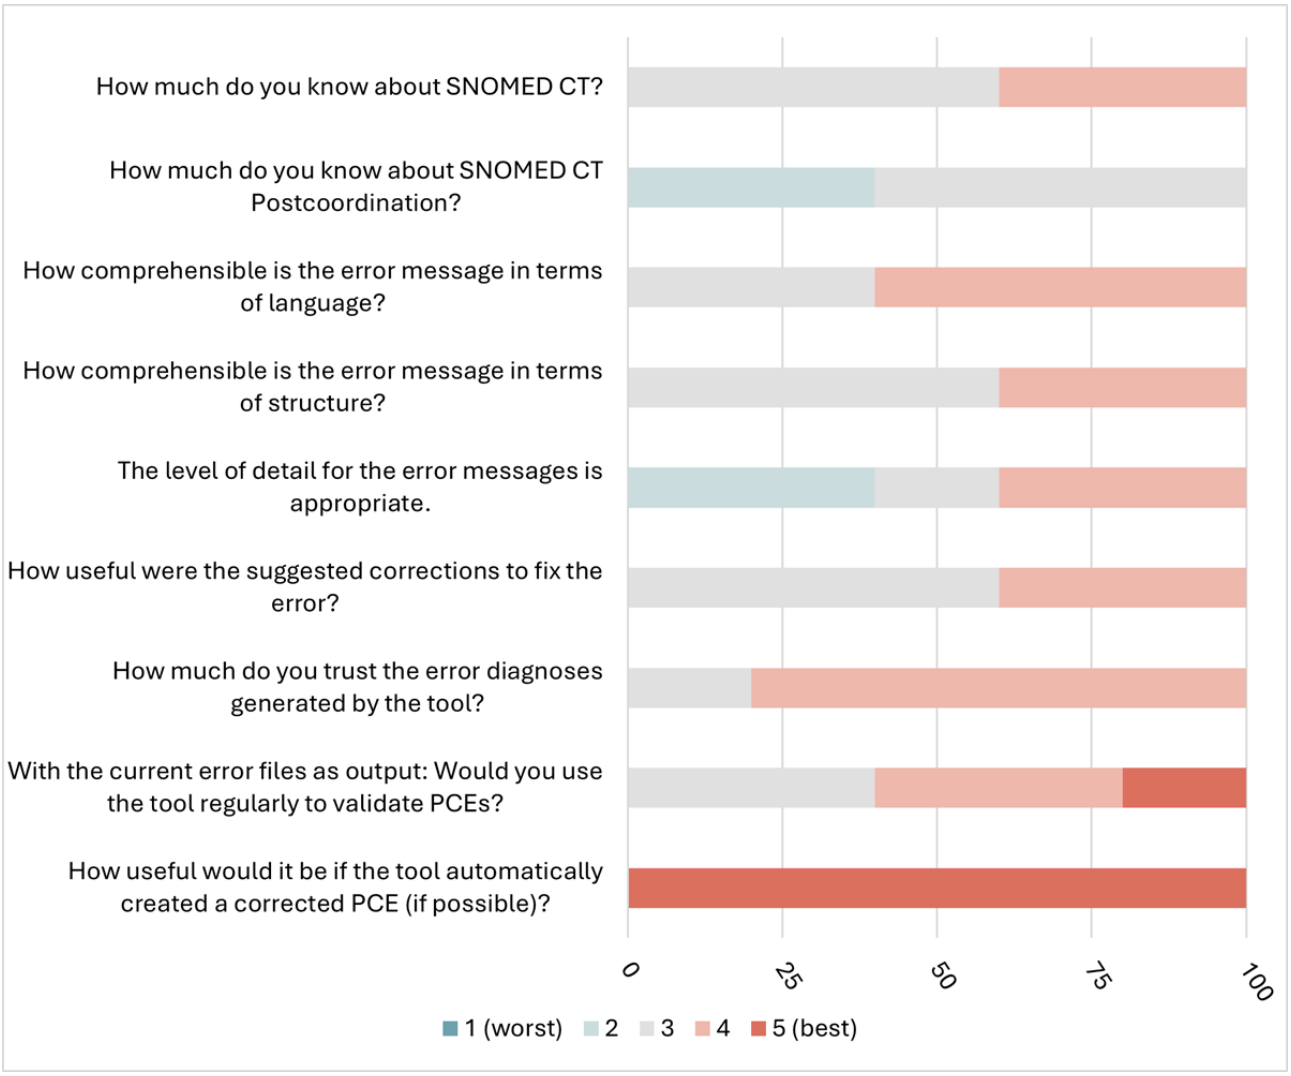
In a previous project, ICD-O tuples were mapped to the OncoTree, using SNOMED CT as an intermediary step [20]. All 868 OncoTree codes were represented as postcoordinated SNOMED CT expressions based on the International Edition, 2021-01-31 in a FHIR ConceptMap [26]. The developed tool is now being used to validate all PCEs. Since the ConceptMap is from 2021, it was expected to contain inactive concepts. If this is the case, they will be replaced by active concepts from the International Edition, dated May 1, 2024 [20]. Any other errors will also be corrected accordingly.

Using the tool, 161 (20.9%) out of 868 PCEs were identified, each containing a concept that is no longer present in the International Edition, 2024-01-05. Some of these inactive concepts occurred multiple times, leading to the identification of 79 distinct inactive concepts. For all inactive concepts, an equivalent active SNOMED CT concept was found and was manually validated by an SNOMED CT expert, ensuring that the PCEs in the newer version are once again both semantically and syntactically correct. In addition, no other causes of error could be identified in the data.

Usability Survey

For the user survey, the participants received four real existing invalid PCEs along with the corresponding error messages. It was ensured that each was assigned to a different error category (Multimedia Appendix 1). The following error categories were used:

- Syntactically incorrect code
- Inactivated code
- Invalid attribute
- Invalid attribute value



To select these categories, PCEs from the literature were reviewed and analyzed. Additionally, discussions were held with professionals actively involved in coding PCEs. This allows us to identify the error categories most commonly causing issues in practice.

In addition, the authors developed a customized questionnaire with ten questions that assessed both the self-evaluation of SNOMED CT knowledge and the overall user experience with the error messages. For nine of the questions, an ordinal scale with five levels ranging from 1=worst to 5=best rating was used, while the last question was open-ended. None of the questions were mandatory, and no answer options were preselected. The complete questionnaire with the answer options is displayed in Multimedia Appendix 1. The survey was conducted with five employees of Thieme Compliance, all of whom have basic knowledge of SNOMED CT postcoordination. Each participant was given the four invalid PCEs along with the corresponding error messages. Subsequently, the participants completed the questionnaire anonymously.

The chart in Figure 8 summarizes the survey results on various aspects of the tool's functionality. Overall, the tool received predominantly positive feedback, as indicated by the fact that only one question garnered slightly negative ratings from two participants. The comprehensibility of the error messages—both in terms of language and structure—was rated with high or neutral scores, with the structure being assessed somewhat more critically than the language. Opinions were divided regarding the level of detail in the error messages: two participants found the level appropriate, another participant gave a neutral rating, and two participants provided less favorable feedback. These were also documented in the free-text comments. Despite these criticisms, trust in the tool and the readiness to use it regularly for PCE validation remain high, as reflected in the overall positive ratings. Additionally, all participants rated the tool's potential expansion to include automatic PCE correction functionality with the highest score of 5. In summary, the chart demonstrates a positive assessment of the tool's functionality, though there is room for improvement in areas such as the level of detail in the error messages.

Discussion

Principal Findings

In this work, a tool for validating postcoordinated SNOMED CT expressions was developed that detects both syntactic and semantic errors. Incorrect PCEs are classified into one of the nine developed error categories, enabling the user to receive targeted feedback. The key added value and focus of the tool lies in generating specific correction suggestions for each identified error.

The successful integration of this tool into the existing web application WASP [23] was confirmed through tests with real existing PCEs in FHIR Questionnaires [24] and an FHIR ConceptMap [26]. The use of these PCEs, provided in the FHIR Questionnaires from Thieme Compliance [8], demonstrated that the tool can reliably verify the correctness and validity of expressions. This is particularly relevant for accurate modeling of medical data and its integration into electronic health records. Additionally, the error files of the 18 PCEs were provided to Thieme Compliance for correction. Another use case, the validation of PCEs in the context of a mapping between ICD-O and OncoTree [20], highlights the tool's flexibility and usefulness in identifying and replacing inactive concepts. The ability to replace outdated concepts with current ones is crucial for the quality and relevance of medical data. The tool contributes to enabling cross-version analyses. It offers a solution for legacy data coded with earlier versions of SNOMED CT, where certain concepts may no longer exist. In such cases, the developed tool can assist in replacing these concepts with current equivalents.

A user survey has indicated that there is both interest and trust in the application. The results show a generally positive evaluation of the tool's functionality, although there is some potential for improvement regarding the level of detail in the error messages. In fact, 50% of participants rated the messages as too complex. Considering this, the development of the tool will place a special emphasis on revision. The plan is to allow users to choose between a newly developed, concise error message, and a more detailed version.

A comparison with existing methods, such as the SNOMED International APG Parser [9] and the FHIR service $validate-code [11] combined with the terminology server Ontoserver [10], shows that the developed tool adopts a more comprehensive validation approach, placing particular emphasis on providing correction suggestions. While the APG Parser primarily checks syntactic correctness and the $validate-code

XSL•FO
RenderX

service is limited to technical errors, the developed tool goes a step further: it enables in-depth error analysis, allowing for more precise corrections. This ensures that PCEs are created not only with correct syntax but also with accurate semantics. As a result, the quality and applicability of these expressions in practice are significantly improved.

A key aspect of this work is that the tool should not be understood as an automatic system for improving PCEs; rather, it provides targeted suggestions for the manual optimization of expressions. As the results of the user survey indicate, this would be a worthwhile feature. Automated corrections are often difficult to implement, as there is rarely a single correct solution. For instance, the tool suggests alternative attributes for the example PCE of Figure 1:

1155942004 |Allergy to metal and/or metal compound|:

{719722006 |Has realization| = 472964009 |Allergic process|,

472964009 |Allergic process| = 256526003 |Cobalt-chromium alloy|} such as:

- Causative agent
- Associated with

In this case, the attribute Causative agent should be used because this attribute is typically used in combination with allergies. A system that autonomously selects the appropriate attributes by analyzing attribute relations would indeed be an advancement, yet, manual validation by users remains essential. This ensures that no invalid PCEs are generated, which could negatively affect subsequent processes.

It should also be noted that the output of error messages is always dependent on the input PCE. If very complex PCEs with numerous errors are created, it may not be possible to correct them immediately. In such cases, the user must refine the PCE and validate it again, repeating the process until all errors are resolved iteratively. Users should be encouraged to construct manageable PCEs rather than attempting to encapsulate an entire medical history within a single PCE.

Conclusions

In conclusion, this work demonstrates that the development of a comprehensive validation tool for postcoordinated SNOMED CT expressions can significantly enhance data quality and interoperability in health care, while also addressing and resolving versioning issues. The successful integration of the tool into existing systems highlights that it provides both syntactic and semantic support at a high level.

The creation of postcoordinated SNOMED CT expressions (PCEs) is not straightforward, as it requires adherence to the complex rules of the Compositional Grammar and the Concept Model. As seen in validations with real-world PCEs, ensuring syntactic and semantic accuracy can be challenging. The development of a validation tool for postcoordinated SNOMED CT expressions represents a significant advancement in addressing these challenges. In addition to technical validation, the tool provides helpful correction guidance, enabling the iterative improvement of PCEs. Users receive error reports and correction suggestions based on nine identified error categories. While the level of detail in the error messages can still be further optimized, the tool already offers valuable support for targeted and effective error resolution. The tool leverages state-of-the-art technologies such as the FHIR $validate-code service, the terminology server Ontoserver, and the SNOMED CT Concept Model. Ontoserver is indeed commercial, which poses a minor limitation. However, it was chosen because it is currently the only terminology server that supports postcoordination—a crucial criterion for the requirements of this project. The methodological approach combines intelligent error detection with tailored correction suggestions, making it easier for users to independently optimize their expressions. In this way, the tool makes a significant contribution to improving data quality in health care.

Abstract

Background: Large language models (LLMs) continue to enjoy enterprise-wide adoption in health care while evolving in number, size, complexity, cost, and most importantly performance. Performance benchmarks play a critical role in their ranking across community leaderboards and subsequent adoption.

Objective: Given the small operating margins of health care organizations and growing interest in LLMs and conversational artificial intelligence (AI), there is an urgent need for objective approaches that can assist in identifying viable LLMs without compromising their performance. The objective of the present study is to generate taxonomy portraits of medical LLMs (n=33) whose domain-specific and domain non-specific multivariate performance benchmarks were available from Open-Medical LLM and Open LLM leaderboards on Hugging Face.

Methods: Hierarchical clustering of multivariate performance benchmarks is used to generate taxonomy portraits revealing inherent partitioning of the medical LLMs across diverse tasks. While domain-specific taxonomy is generated using nine performance benchmarks related to medicine from the Hugging Face Open-Medical LLM initiative, domain non-specific taxonomy is presented in tandem to assess their performance on a set of six benchmarks and generic tasks from the Hugging Face Open LLM initiative. Subsequently, non-parametric Wilcoxon rank-sum test and linear correlation are used to assess differential changes in the performance benchmarks between two broad groups of LLMs and potential redundancies between the benchmarks.

Results: Two broad families of LLMs with statistically significant differences (α=.05) in performance benchmarks are identified for each of the taxonomies. Consensus in their performance on the domain-specific and domain non-specific tasks revealed robustness of these LLMs across diverse tasks. Subsequently, statistically significant correlations between performance benchmarks revealed redundancies, indicating that a subset of these benchmarks may be sufficient in assessing the domain-specific performance of medical LLMs.

Conclusions: Understanding medical LLM taxonomies is an important step in identifying LLMs with similar performance while aligning with the needs, economics, and other demands of health care organizations. While the focus of the present study is on a subset of medical LLMs from the Hugging Face initiative, enhanced transparency of performance benchmarks and economics across a larger family of medical LLMs is needed to generate more comprehensive taxonomy portraits for accelerating their strategic and equitable adoption in health care.

(JMIR Med Inform 2025;13:e72918) doi:10.2196/72918

KEYWORDS

large language models; health care; performance benchmark; taxonomy; redundancy

Introduction

Large language models (LLMs) continue to show considerable promise and growth in health care [1]. Popular health care LLM applications fall under three broad task categories, namely clinical tasks, documentation tasks, and medical research and education tasks [2]. Specific LLM health care applications include (1) virtual health assistants and language translation [3], (2) summarization of clinical narratives and ambient listening [4,5], (3) patient education [6], and (4) clinical trial matching [7]. More importantly, LLMs have continued to evolve in numbers, size, complexity, costs, and performance, impacting their adoption [8]. A recent perspective discussed three broad LLM implementation pathways (Training from Scratch, Fine-Tuned Pathway, and Out of the Box Pathway) along with the risks, benefits, and economics across four major cloud service providers for their equitable and strategic adoption in health care [9]. The study also elucidated the essential

XSL•FO
RenderX

ingredients such as digital data, infrastructure, workforce, ethics, and regulatory aspects that can significantly impact LLM implementations. While helpful, these three pathways represent broad categorizations of LLM implementations and do not necessarily provide insights into their similarities. Similarities between LLMs can be based on a number of characteristics including architecture, size, cost, and their performance across diverse tasks [10]. Understanding the similarities in LLM performance can assist in strategically selecting those with comparable performance while aligning with the budgeting and needs of health care organizations.

The present study focuses on standardized and objective performance benchmarks that interrogate the ability of LLMs across diverse tasks. Their weighted average, is often used to rank LLMs across leaderboards [11], impacting their adoption. These aggregated benchmarks implicitly map the multivariate benchmark profiles onto a univariate score, diminishing their usefulness, as each benchmark interrogates unique capabilities of the LLMs. Therefore, it should not be surprising to note that similarity in ranks may not necessarily imply similarity in performance benchmark profiles. The present study generates LLM taxonomies elucidating their similarities and hierarchical associations from multivariate performance benchmarks. The taxonomy is shown to reveal inherent partitioning of the LLMs into sub-groups with varying performance. LLMs can be either open-source or closed source. While these implementations have distinct advantages [12], proprietary aspects and lack of transparency in the performance of closed-source LLMs prevent their inclusion in the present study. In the case of open-source LLMs, domain-specific (DS) as well as domain non-specific (DN) multivariate performance benchmarks were available publicly from Open LLM [13] and Open Medical LLM [14] leaderboards at Hugging Face [15,16]. While DS benchmarks interrogate task-specific abilities of the LLMs, DN benchmarks assess their generic capabilities. Hugging Face has witnessed increasing visibility, growth, and adoption by the Generative AI and LLM communities over the years. Its structured and transparent approach enables enhanced reproducibility of the reported metrics and implementation; widespread collaboration between experts; unbiased comparison of the different models; and the selection of the LLMs based on the performance, needs, and affordability. The DS benchmarks considered include those that assess the medical question and answering capabilities and reasoning skills related to medical licensing examinations, a series of subject and DS evaluations broadly under massive multitask language understanding, and the ability of LLMs to comprehend and reason biomedical literature. The DN benchmarks were also retrieved for the medical LLMs through the Open LLM initiative to assess their ability to answer questions that are not specifically related to medical tasks. These benchmarks included (1) those that assess the LLMs ability to follow verifiable instructions, (2) chain of thought prompting, (3) mathematical problem-solving skills, (4) graduate level reasoning capabilities across diverse subjects, (5) multistep reasoning abilities, and (6) multitask language understanding on challenging reasoning-based questions. A detailed description of the DS and DN benchmarks along with the references and their abbreviations is included in Table 1. The taxonomies were generated by hierarchical clustering of the DS and DN multivariate performance benchmarks that assess the task-specific and generic capabilities of these LLMs. Subsequently, two broad groups of medical LLMs with markedly different performance benchmark profiles is discussed. Potential redundancies between the performance benchmarks across the DS and DN taxonomies are also elucidated. Given the low-operating margins [17] of health care organizations, understanding the taxonomy and potential redundancies between the performance benchmarks is expected to assist in objectively justifying the choice of LLMs while controlling costs [18].

Table . Description and abbreviations of domain-specific (DS) and domain non-specific (DN) performance benchmarks with references.

Type	Benchmark description	Abbreviation
DS	MedQA [Medical Question and Answer]: Consists of multiple-choice questions (11,450 questions in the development set and 1273 questions in the test set) from the United States Medical License Exam for benchmarking the LLMs general medical knowledge and reasoning skills on United States Medical Licensure.	MQA [19]
DS	MedMCQA [Medical Multiple-Choice Question and Answer]: Consists of multiple-choice questions (187,000 questions in the development set and 6100 questions in the test set) related to the Indian Medical Entrance Exam (AIIMS/NEET). As with MedQA, MedMCQA is used to benchmark the LLMs general medical knowledge and reasoning ability as it pertains to the Indian medical entrance exam.	MCQA [20]
DS	MMLU Anatomy: [Massive Multitask Language Understanding, Anatomy]: MMLU subset consists of multiple-choice questions (135 questions) for benchmarking the knowledge of the LLM[a] on human anatomy.	ANAT [21]
DS	MMLU Clinical Knowledge [Massive Multitask Language Understanding, Clinical Knowledge]: MMLU subset consists of multiple-choice questions (265 questions) for benchmarking the clinical knowledge and decision-making skills.	CLIN [21]
DS	MMLU College Biology [Massive Multitask Language Understanding, College Biology]: MMLU subset with multiple-choice questions (144 questions) for benchmarking the knowledge on college biology.	BIOL [21]
DS	MMLU College Medicine [Massive Multitask Language Understanding, College Medicine] MMLU subset with multiple-choice questions (173 questions) for benchmarking the college-level medical knowledge.	CMED [21]
DS	MMLU Medical Genetics [Massive Multitask Language Understanding, Medical Genetics] MMLU subset consists of 100 questions related to medical genetics.	GEN [21]
DS	MMLU Professional Medicine [Massive Multitask Language Understanding, Professional Medicine] MMLU subset consists of multiple-choice questions (272 questions) for benchmarking the LLM on knowledge required for medical professionals.	PMED [21]
DS	PUBMEDQA [PUBMED Question & Answer] Closed-domain dataset comprising expert-labeled question-answer pairs (500 questions in the development set and 500 questions in the test set) for benchmarking the LLMs ability to comprehend and reason biomedical literature.	PUBM [22]
DN	IFEval [Instruction Following Evaluation]: Benchmarks LLMs ability to follow verifiable instructions using 25 distinct types of verifiable instructions and 500 prompts, with each prompt containing at least one verifiable instruction.	IFEV [23]

XSL•FO
RenderX

Type	Benchmark description	Abbreviation
DN	BBH [Big Bench Hard]: Benchmarks the performance of LLMs on 23 challenging Big Bench tasks (BBH) where prior LLMs failed to outperform an average-human rater. Emphasized the importance of chain-of-thought prompting.	BBH [24]
DN	MATH [Math]: Benchmarks the mathematical problem-solving ability of the LLM using 12,500 mathematics competition problems.	MATH [25]
DN	GPQA [Graduate Level Google Proof Q & A]: Benchmarks LLMs using 448 multiple choice questions generated by experts in areas such as biology, physics, and chemistry.	GPQA [26]
DN	MuSR [Multistep Soft Reasoning]: Benchmarks LLMs ability on complex multistep reasoning instances and long-range (~1000 words) free text narratives from real-world domains.	MUSR [27]
DN	MMLU Pro [Multitask Language Understanding Pro]: Benchmarks the reasoning and language comprehension abilities of LLMs across diverse domains by incorporating challenging, reasoning-focused question, and expanding the choice of the original MMLU from four to ten.	MPRO [28]

[a]LLM: large language model.

Methods

Medical LLMs with DS and DN benchmarks were retrieved from Hugging Face Open Medical LLM [14] and Open LLM [13] leaderboards on January 2025. While Hugging Face features several contributions from the AI open-source community, it is important to note that these are voluntary efforts. Since there were instances of sparse documentation across LLMs by individual contributors, the present study excluded LLMs by individual contributors, resulting in 33 medical LLMs whose DS and DN performance benchmarks were available. Abbreviations and size of the 33 LLMs are enclosed in Table 2. LLM taxonomies were generated using hierarchical clustering [29] of the DS and DN multivariate performance benchmarks. As each performance benchmark interrogates specific characteristic of the LLM, they were scaled to zero-mean and unit variance prior to clustering to minimize the impact of potential variations in the magnitude across the different benchmarks. Subsequently, the Manhattan distance was used to assess the similarity between the LLMs, as it is robust to outliers. Other measures of similarity such as cosine distance can also be used as alternatives [29]. This study uses complete linkage that merges clusters based on the distance between the most dissimilar members (ie, farthest distance) [29]. While complete linkage is robust to outliers resulting in stable and well-formed clusters, other linkage approaches for merging the clusters can also be explored [29].

The DS taxonomy was based on the nine performance benchmarks, whereas the DN taxonomy was generated based on the six performance benchmarks, as shown in Table 1. Color-coded dendrograms were subsequently used to generate visualizations of the performance benchmark profiles of the respective taxonomies. Statistically significant differential changes in performance benchmark profiles between clusters for the DS and DN taxonomy were investigated using the Wilcoxon rank-sum test (α=.01), a non-parametric statistical test that does not impose normality assumptions on their distribution. Subsequently, Pearson correlation and scatter plots were used to elucidate potential redundancies between the performance benchmarks for the DS and DN taxonomies. Pearson correlation can provide insights into linear dependency (a=0.01) between variables. However, its estimates can be deceptive under sparse distribution of data points about the linear trend. Therefore, scatter plots of the pair-wise performance benchmarks are provided in addition to the statistical test for visualization. As differential changes in the performance benchmarks and the test for correlation involved multiple statistical tests, multiple testing correction (Bonferroni correction) [30] was used to control for the family-wise error rate, with the adjusted significance level α^* given by $\alpha^* = \alpha/M$, where M represents the total number of statistical tests.

Results

The DS and DN taxonomies of the 33 medical LLMs generated by hierarchical clustering (Figure 1) revealed two well-separated clusters of high (H) and low (L) with markedly different median benchmark profiles (Figure 2). For the DS taxonomy, the H cluster comprised 22 LLMs, whereas the L cluster had 11 LLMs. The Wilcoxon rank-sum tests were used to assess statistically significant differences between these clusters across the nine benchmarks at the adjusted significance level controlling for family-wise error rate ($\alpha^*=\alpha/M=.01/9\sim.001$). The corresponding *P* values were MCQA (*P*<.001), MQA (*P*<.001), ANAT (*P*<.001), CLIN (*P*<.001), BIOL (*P*<.001), CMED (*P*<.001), GEN (*P*<.001), PMED (*P*<.001), and PUBM (*P*<.001), revealing statistically significant differential changes in the nine benchmarks between the H and L clusters. LLMs in the H cluster were MISI-7B, MIS-7B, VIC-7B, LM3S-8B, QWN-14B, LM3A-8B, GEMI-7B, GEM-7B, QWN-7B, QWNC-7B, GEMS-7B, LM3SI-8B, ZEP-7B, MISD-7B, MISP-7B, AYA-8B, SL-10.7B, YIK-9B, YI-9B, LM3Z-8B, LMMI-8B, and LMM-8B, whereas those in the L cluster were PYT-2.8B, GPTN-2.7B, GEM-2B, GEMR-2B, PHI-1.3B, LMT-1.1B, STA-6B, GPTL-1.5B, GPT2-1.5B, FALI-7B, and FAL-7B. The L cluster with a relatively lower median performance profile consisted primarily of LLMs with relatively smaller numbers of parameters. While earlier studies [31,32] emphasized the impact of parameters on LLM performance, the present findings reiterated these empirical findings from a DS standpoint.

XSL•FO
RenderX

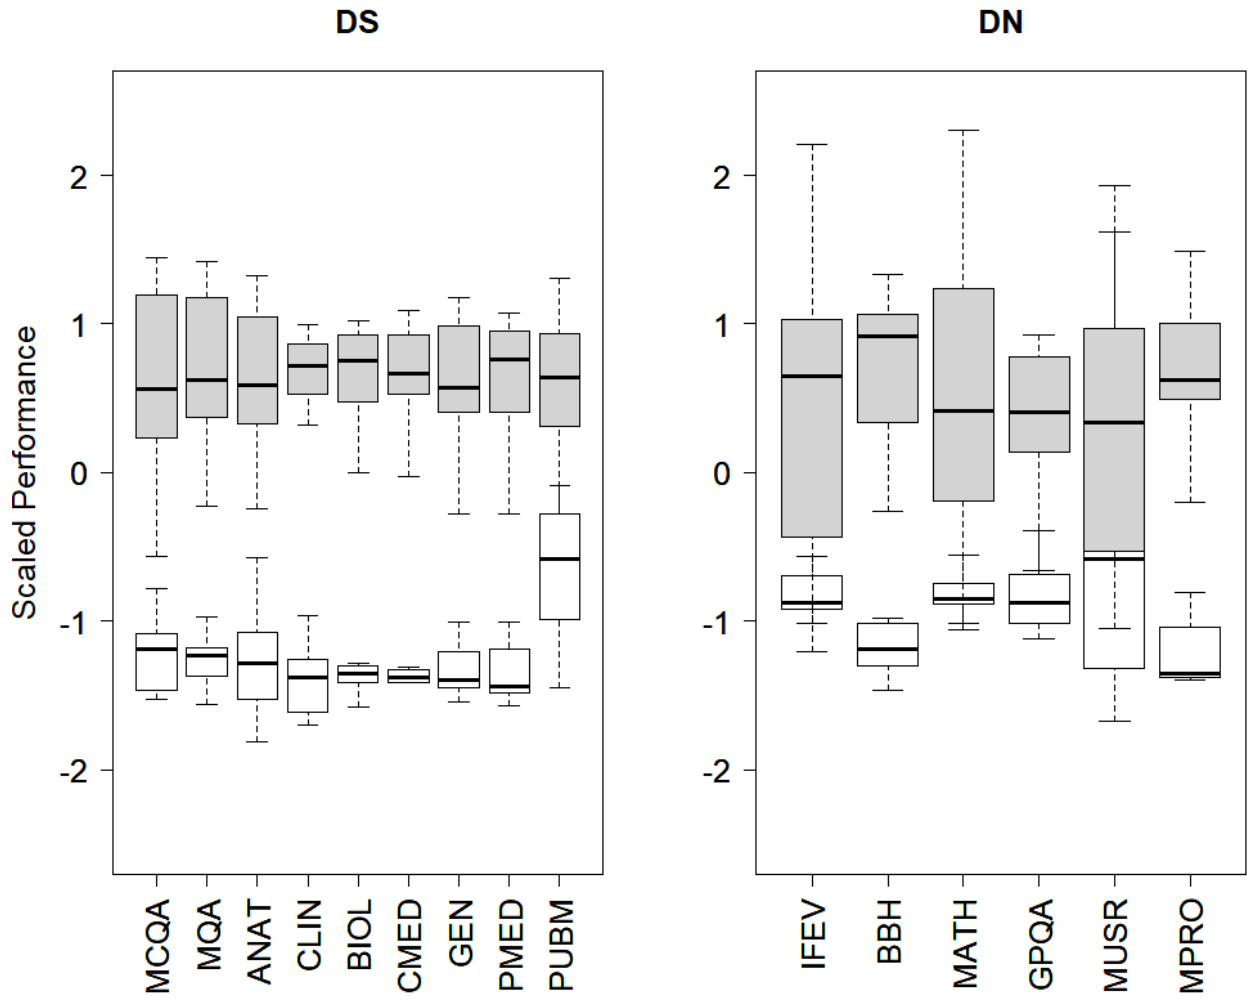

Figure 1. Dendrogram representing the domain-specific (DS; left) and domain non-specific (DN; right) taxonomy portraits from hierarchical clustering of scaled multivariate performance benchmark profiles of 33 medical LLMs. The magnitude of the scaled performance benchmark profiles increases from green (low) to red (high).

For the DN taxonomy, the H and the L clusters comprised 20 LLMs and 13 LLMs, respectively (Figure 1). The Wilcoxon rank-sum tests of differential change between the H and L clusters across the six benchmarks at the adjusted significance level controlling for family-wise error rate ($\alpha^*=\alpha/M=0.01/6\sim0.002$) resulted in IFEV ($P<.001$), BBH ($P<.001$), MATH ($P<.001$), GPQA ($P<.001$), and MPRO ($P<.001$), indicating significant differential change across these benchmarks. However, the differential change for MUSR ($P=.036$) was not statistically significant. The corresponding boxplots are shown in Figure 2. LLMs in the H cluster were MIS-7B, LM3S-8B, QWN-14B, LM3A-8B, GEMI-7B, GEM-7B, QWN-7B, QWNC-7B, GEMS-7B, LM3SI-8B, ZEP-7B, MISD-7B, MISP-7B, AYA-8B, SL-10.7B, YIK-9B, YI-9B, LM3Z-8B, LMMI-8B, and LMM-8B, whereas those in the L cluster were MISI-7B, PYT-2.8B, GPTN-2.7B, VIC-7B, GEM-2B, GEMR-2B, PHI-1.3B, LMT-1.1B, STA-6B, GPTL-1.5B, GPT2-1.5B, FALI-7B, and FAL-7B. In line with earlier empirical observations, LLMs in the L cluster with relatively lower median performance benchmarks were predominantly smaller in size. There were also marked consensus in the distribution of the LLMs between the L (11 LLMs) and H (20 LLMs) clusters of the DS and DN taxonomies, revealing the robustness of the LLMs across generic as well as domain-specific tasks. The variance for a majority of the performance benchmarks was markedly higher for the H cluster as opposed to the L cluster across DS and DN taxonomies, indicating considerable heterogeneity in the performance of the LLMs in the H cluster (Figure 2).

XSL•FO
RenderX

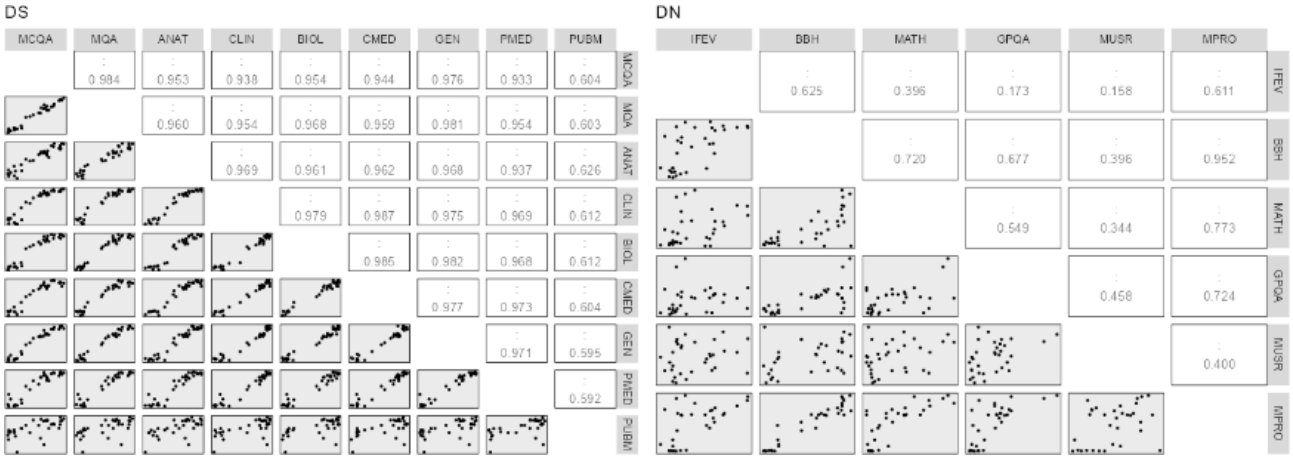

Figure 2. Box-whisker plots of the scaled performance benchmark profiles corresponding to high (H; gray) and low (L; white) clusters of the domain-specific (DS; left) and the domain non-specific (DN; right) taxonomies. Outliers are not shown for clarity.

The Pearson correlation was used to assess statistically significant correlations between pair-wise performance benchmarks of the DS and DN taxonomies (Figure 3). The nine DS performance benchmarks resulted in 9(9 - 1)/2=36 independent tests for correlation. Therefore, the adjusted significance level was chosen as (α^*=0.01/36~0.0002) to control for the family-wise error rate. The correlation for all pairs other than PMED-PUBM (P=.00028>α^*) were statistically significant (ie, $P<\alpha^*$). The linear trend was especially pronounced between MCQA, MQA, and MMLU for various subjects. A possible explanation is LLMs that perform well on the different medically related MMLU subject-wise benchmarks (ANAT, CLIN, BIOL, CMED, GEN, and PMED) may also perform well on comprehensive medical exams (MCQA and MQA). While the linear correlation between the MMLU subject-wise benchmarks was statistically significant, the scatter plots revealed instances of sparse distribution of points along the linear trend line for some of these pairs (eg, BIOL and PMED), challenging reliable correlation estimates (Figure 3). The clustering of points about the linear trend line may in fact align with earlier observations of statistical differences (Figure 2) between two broad groups of LLMs within the DS taxonomy (Figures 1 and 2). The magnitude of performance benchmark (PUBM), which assesses the LLMs ability to comprehend and reason biomedical literature, did not exhibit a strong correlation with others, as reflected by lack of a clear linear trend in the scatter plots (Figure 3). In contrast to DS taxonomy, the correlation structures between the performance benchmarks was noisy in the case of DN taxonomy, as reflected by the scatter plots in Figure 3. The six DS performance benchmarks resulted in 6(6 - 1)/2=15 independent tests for correlation. Therefore, the adjusted significance level was chosen as (α^*=0.01/15~0.0007) to control for the family-wise error rate. While there were instances of DN performance benchmark pairs with significant correlation, the redundancy was markedly lower than that observed in the case of DS taxonomy. Pairs that did not exhibit significant correlation ($P<\alpha^*$) included IFEV-MATH (P=.022), IFEV-GPQA (P=.336), IFEV-MUSR (P=.379), BBH-MUSR (P=.022), MATH-MUSR (P=0.049), GPQA-MUSR (P=.007), and MUSR-MPRO (P=.021). Since the correlation structure across DN performance benchmarks was much lower than that of DS performance benchmarks, DN performance benchmarks may assess the LLMs complementary characteristics of the LLM.

XSL•FO
RenderX

Figure 3. Scatter plots (gray panels) of the correlation structure between the performance benchmarks corresponding to domain-specific (DS; left) and domain non-specific (DN; right) taxonomies are shown. The pair-wise linear correlation (white panels) of the corresponding (row, column) pairs of performance benchmarks are shown in the upper triangle. The diagonals represent auto-correlation, and are hence not presented.

Discussion

The present study investigated taxonomies of LLMs whose DS and DN performance benchmarks were available from Open MedLLM and Open LLM initiatives at Hugging Face. As noted, LLM ranks estimated from aggregated benchmarks have been featured by leaderboards, impacting their adoption. However, similarity in these aggregated univariate scores and ranks may not necessarily imply similarity in the underlying multivariate performance profiles, making the study relevant. The DS and DN taxonomies revealed inherent subgroups and two broad clusters with statistically significant differences in performance. Overlap of the cluster members between the DS and DN taxonomies also indicated robustness of these LLMs across diverse tasks. As with some of the earlier empirical studies on LLM scaling laws, clusters with lower performance consisted predominantly of LLMs with relatively smaller size. The results also revealed redundancies in the performance benchmarks that was especially pronounced in the case of DS performance benchmarks.

Practical relevance of these taxonomies include their ability to assist in selecting LLMs with comparable performance while controlling costs. This is especially critical in low-profit margins industry such as health care that is in its initial phases of adopting AI tools for improved efficiency and outcomes. Taxonomies can also assist in choosing a combination of LLMs, perhaps across distinct clusters with diverse performance characteristics [33,34] as opposed to a single LLM. However, unlike performance benchmarks, the lack of transparency with regards to costs and LLM economics [35] discourages concerted analysis of costs and performance benchmarks. Moreover, several factors can impact LLM economics including digital readiness, infrastructure, workforce, and cloud-based implementations [9]. While faithful cost estimation can be challenging, economics of LLM training, fine-tuning, and inference is generally agreed to be proportional to the LLM size. Thus, the size of the LLM can serve as a surrogate for costs. The DS and DN taxonomies revealed considerable consensus and two broad clusters (H, L). For the H cluster, LLMs QWN-14B and YIK-9B were proximal across the DS and DN taxonomy. However, the size of QWN-14B (~14 billion parameters) was considerably larger than that of YIK-9B (~9 billion parameters). Based on the DS and DN taxonomies, YIK-9B is preferred over QWN-14B. On a related note, the L cluster also comprised LLMs of markedly different sizes with comparable performance. For instance, FALI-7B (~7 billion parameters) was proximal to GPTL-1.5B (~2.8 billion parameters) recommending GPTL-1.5B over FALI-7B. Pair-wise correlation profiles revealed marked association between the DS performance benchmarks. While performance benchmarks are expected to ideally interrogate complementary characteristics of an LLM, the presence of correlations indicated inherent redundancies between the DS benchmarks. As LLM ranks are generally estimated as the weighted average of the performance benchmarks, eliminating redundancies may be critical for generating unbiased rank estimates. Eliminating redundant benchmarks can also assist in minimizing the overall evaluation cost [36].

There are several limitations of the present study. The study focused primarily on medium-sized LLMs (n=33) with around tens of billions of parameters. Generating comprehensive taxonomy portraits with a larger pool of LLMs spanning a wider range of sizes (large, ~100 billion parameters; medium, ~10 billion parameters; and small, ~millions of parameters) can reveal universal patterns characteristic of medical LLMs. Such an analysis may also assist in selecting LLM ensembles with varying sizes and complementary performance benchmark profiles, as opposed to the popular practice of selecting a single LLM. While the present study focused on standardized performance benchmarks, it may have limited usefulness in assessing capabilities [37] such as summarization, used routinely by health care conversational AI agents (eg, Chatbots and Ambient Listening Tools). The non-deterministic nature of the LLM response can also pose challenges in assessing such summaries, especially when these tools are deployed in clinical workflows [38]. While performance benchmarks used in generating the DS and DN taxonomies interrogate certain unique characteristics of the LLMs, they are by no means exhaustive. The rapid evolution of LLMs and their health care applications might demand incorporating novel benchmarks. Assessment may also explore relative benchmarking strategies, where characteristics, such as factual accuracy of information, time to

XSL•FO
RenderX

retrieve information, and ease of use, are compared to tools that are currently in place using randomized controlled designs. While the size of the LLMs were used as surrogates for costs in the present study, e enhanced transparency on LLM economics across training, fine-tuning, and inference could assist in tailored recommendations for strategic decision making in health care settings. As noted earlier, several factors can dictate the economics of implementation, deployment, and operationalization of LLMs in health care workflows. This includes digital and analytics maturity, infrastructure, workforce across a spectrum of areas, choice of the LLM onboarding pathways, and the needs of the health system. While the focus of the present study has been primarily on open-source LLMs, enhanced transparency of closed-source LLMs can facilitate unbiased comparisons for equitable and strategic adoption of these tools across health care enterprises.

Abstract

Background: Over the last 10-15 years, US health care and the practice of medicine itself have been transformed by a proliferation of digital medicine and digital therapeutic products (collectively, digital health tools [DHTs]). While a number of DHT classifications have been proposed to help organize these tools for discovery, retrieval, and comparison by health care organizations seeking to potentially implement them, none have specifically addressed that organizations considering their implementation approach the DHT discovery process with one or more specific outcomes in mind. An outcomes-based DHT ontology could therefore be valuable not only for health systems seeking to evaluate tools that influence certain outcomes, but also for regulators and vendors seeking to ascertain potential substantial equivalence to predicate devices.

Objective: This study aimed to develop, with inputs from industry, health care providers, payers, regulatory bodies, and patients through the Accelerated Digital Clinical Ecosystem (ADviCE) consortium, an ontology specific to DHT outcomes, the Digital medicine Outcomes Value Set (DOVeS), and to make this ontology publicly available and free to use.

Methods: From a starting point of a 4-generation–deep hierarchical taxonomy developed by ADviCE, we developed DOVeS using the Web Ontology Language through the open-source ontology editor Protégé, and data from 185 vendors who had submitted structured product information to ADviCE. We used a custom, decentralized, collaborative ontology engineering methodology, and were guided by Open Biological and Biomedical Ontologies (OBO) Foundry principles. We incorporated the Mondo Disease Ontology (MONDO) and the Ontology of Adverse Events. After development, DOVeS was field-tested between December 2022 and May 2023 with 40 additional independent vendors previously unfamiliar with ADviCE or DOVeS. As a proof of concept, we subsequently developed a prototype DHT Application Finder leveraging DOVeS to enable a user to query for DHT products based on specific outcomes of interest.

Results: In its current state, DOVeS contains 42,320 and 9481 native axioms and distinct classes, respectively. These numbers are enhanced when taking into account the axioms and classes contributed by MONDO and the Ontology of Adverse Events.

Conclusions: DOVeS is publicly available on BioPortal and GitHub, and has a Creative Commons license CC-BY-SA that is intended to encourage stakeholders to modify, adapt, build upon, and distribute it. While no ontology is complete, DOVeS will benefit from a strong and engaged user base to help it grow and evolve in a way that best serves DHT stakeholders and the patients they serve.

Introduction

Over the last 10-15 years, the US health care industry and the practice of medicine itself have been transformed by a proliferation of digital health software applications. It has been estimated, for example, that more than 350,000 health and wellness apps are available in mainstream app stores [1], and that more than 300 million people have used them in one form or another [2]. Along with this breadth of applications comes a variety of terminology describing them. The colloquially used umbrella term "digital health," for example, encapsulates many concepts including wellness apps, consumer grade mobile health apps, personal health tracking devices, remote patient monitoring applications, telemedicine platforms, and software as a medical device [3].

Driven in part by regulatory agencies and industry advocacy groups in the United States and abroad, efforts have been undertaken to more clearly delineate the boundaries between these types of applications. For example, "digital health" has been defined as technologies, platforms, and systems that engage consumers for lifestyle, wellness, and health-related purposes; capture, store, or transmit health data; and/or support life science and clinical operations [4]. As such, digital health products typically do not require clinical evidence, and do not meet the regulatory definition of a medical device. Digital *medicine* products, on the other hand, include evidence-based software and/or hardware products that measure and/or intervene in the service of human health. These products require clinical evidence and may (or may not) be classified as medical devices. At the most regulated end of this spectrum, digital *therapeutics* are health software intended to treat or alleviate a disease, disorder, condition, or injury by generating and delivering a medical intervention that has a demonstrable positive therapeutic impact on patient health and produce real-world outcomes [5]. Digital therapeutics typically do fall under regulatory oversight, with prescription digital therapeutics as those that are prescribed by a licensed health care professional.

While these definitions organize digital health tools (DHTs), a term we use here for convenience to encapsulate digital medicine and digital therapeutic products into regulatory and potentially clinical versus nonclinical categories, they do not necessarily enable the side-by-side outcomes-based comparison of similar products for the purpose of understanding relative efficacy or safety, nor do they facilitate establishing, for regulators and for vendors filing 510(k) applications, whether certain products may be "substantially equivalent" to predicate devices [6,7]. This need to evaluate evidence of health technologies and compare them with predicate devices partially overlaps with the purpose of Health Technology Assessment (HTA) frameworks, formal, systematic processes for synthesizing and evaluating existing evidence for health technologies, often for the use of policy and decision makers [8]. Users of HTA frameworks (whether federal bodies abroad or individual stakeholders in the United States where no centralized federal HTA body exists [9]) might also benefit from a means to readily identify similar or related devices, particularly in a domain as complex and rapidly evolving as digital medicine. Furthermore, most DHT end users (eg, clinicians and patients) or decision makers (eg, health system leaders making subscription or purchasing decisions, digital pharmacy and therapeutic committees making formulary decisions, or payers making coverage decisions), have one or more *outcomes* in mind that they are hoping the digital application can be used to influence.

While a few taxonomies do exist that categorize DHTs on a limited set of functional categories and characteristics [10,11], these are narrow in scope, and lack the interrelationships of an ontology. Establishing DHT organizational frameworks as ontologies provides a solution to heterogeneity problems like this, thereby defining the concepts and relationships that make interoperability possible [12]. It is common, for example, for ontologies to have "off the shelf" tooling; logic-based, precisely defined semantics; modeling languages to describe complex relationships; machine processing capability allowing for the computation of relationships; rigorous relationship structures, and in many cases the ability to be incorporated into other ontologies. In these respects, a system to organize DHTs according to the outcomes they intend to influence, and a common set of outcome metrics, would be valuable.

The purpose of this work is to describe the development of an *outcomes-based* ontology, the Digital medicine Outcomes Value Set (DOVeS). This ontology came into being as part of the Accelerated Digital Clinical Ecosystem (ADviCE) consortium, a group of health systems, vendors, payers, policymakers, and patient advocacy groups whose mission is to enable and scale the safe and effective adoption of DHTs in clinical practice [13].

Methods

Phase 0: Defining Scope and Purpose

DOVeS emanated from needs of the University of California San Francisco-Stanford-FDA (Food and Drug Administration) Center of Excellence in Regulatory Science and Innovation-funded ADviCE consortium to identify real-world performance metrics with which the safety and efficacy of DHTs could be characterized, whether for health care system leaders seeking to comparatively assess and implement DHTs, or for regulators seeking to classify them into similar outcomes-based groupings [14]. The purpose of DOVeS was to establish common sets of DHT real-world performance measure (RWPM) outcomes to facilitate more straightforward comparison between DHT products. The scope of DOVeS was to capture a body of outcomes with the potential to be influenced by DHTs, preferably but not exclusively by products capable of integrating into the electronic health record (EHR). DOVeS was intended to satisfy questions posed to vendors in a Digital Health Common Application (DHCA, refer to "Phase 1: PreDOVeS Development [Background Context and Knowledge Capture]" section), and to address competency questions for use cases

XSL•FO
RenderX

such as: what DHT applications influence (specific outcome) pertaining to disease X, what DHT applications satisfy health care administrative outcome Y, what DHT applications potentially mitigate adverse event Z?

Phase 1: PreDOVeS Development (Background Context and Knowledge Capture)

DOVeS emanated from ADviCE, about which background context will be helpful. Briefly, in order to inform a RWPM framework, leaders from 5 health systems participating in ADviCE formulated a strategy to learn from the DHT marketplace and collaboratively developed a Digital Health Common Application. The purpose of the DHCA was to collect from vendors a standardized set of intake and discovery information about their products and the populations and disease areas these products serve. Information collected through the DHCA across many vendors could then empower health system decision makers with a variety of common metrics in 1 place as their health systems, or any other, embark upon initial DHT vendor discovery for implementation decisions. Fields captured in the DHCA included, for example: whether the DHT integrates with the EHR (and if so, which ones); mechanisms of integration (eg, application programming interfaces, flat files, and data warehouses); current or planned regulatory status of the DHT product; stage of company development (eg, conceptual, proof of concept, beta, or commercial deployment); security, privacy, and data sharing policies; disease indications; intended patient populations; device integration; safety and efficacy evidence; accessibility, equity, feature types; and the outcomes that the product seeks to improve.

Between April 2019 and June 2020, a total of 185 vendors voluntarily completed and submitted DHCA data to ADviCE. Based on these data, on the FDA's Developing Software Precertification Program: A Working Model [15], and on consensus-building work carried out by the ADviCE consortium, a RWPM taxonomical hierarchy was initially developed, with 3 top-level DHT classes: "Healthcare outcomes," "Non-clinical product performance outcomes," and "User experience outcomes." Beneath these top-level classes were 3 levels of descendant outcome classes. The taxonomy resided in a spreadsheet, but without the functionalities of an ontology.

Phase 2: Development of DOVeS Ontology

Ontology Engineering Methodology

A number of Ontology Engineering Methodologies (OEMs) exist to guide and structure ontology development from a state of informal knowledge to formal representation [16]. Many OEMs have been organized into different classes, including, for example, collaborative, noncollaborative, and custom OEMs [17]. Our approach, a custom, decentralized, collaborative OEM, emanated from the asynchronous nature of information acquisition and stakeholder input that spanned the course of the ADviCE project (a portion of which preceded DOVeS in which DHT vendors supplied data that would later inform the top-level classes of the ontology) and the DOVeS project itself (in which domain experts and engineers collaborated synchronously and iteratively with a consortium of stakeholders).

Specifically, our custom approach resembles aspects of the Human-Centered Ontology Engineering Methodology framework, emphasizing agile, collaborative, and community-driven ontology development, involving both "knowledge engineers" and "knowledge workers" (eg, DHT vendors) empowering the latter to participate iteratively in the ontology lifecycle leveraging their experience and their work setting-specific domain expertise [18]. This is consistent with recent trends in ontology engineering, and avoids rigidly defined workflows and phases, instead focusing on iterative development and leveraging tools like GitHub and Protégé to facilitate decentralized collaboration. Our synchronous, active collaboration with communities of practice included the ADviCE consortium consisting of partners from academic medical centers; community health systems; policy makers; patient advocacy groups; industry members including DHT vendors, pharma, and payers; and domain experts, an ontology engineer, and an additional round of DHT vendors during field testing (refer to Phase 3 below). Asynchronous collaboration included input from the 185 DHT vendors who completed and submitted DHCAs before formal DOVeS development began. Supported by GitHub for versioning and issue tracking, the open-source ontology editor Protégé for editing [19], and BioPortal for publishing [20], DOVES reflects principles of liveness, evolution, and reusability.

Content Addition

Beginning with the 3 top-level classes and the collection of descendant outcomes described above, we used the web ontology language (OWL) through the open-source ontology editor Protégé to create an ontology, and to populate subclasses, definitions, and axioms related to DHTs. Based on data supplied by the 185 vendors, input from members of the ADviCE consortium, 1 investigator's first-hand knowledge of the digital health space [BR], and 2 investigators' involvement in the University of California San Francisco's Digital Diagnostics and Therapeutics Committee, a digital Pharmacy and Therapeutics committee [21] [BR and AA], we added more structure including subclasses, definitions, relationships, and refining values.

Technical Considerations

The DOVeS ontology was developed specifically using the OWL2EL fragment. This fragment is commonly used in many biomedical ontologies due to its balance between expressivity and computational efficiency [22]. Throughout the development process, we aimed to follow the Open Biological and Biomedical Ontologies (OBO) Foundry principles [23]. While these principles do not themselves constitute a methodology, they represent well-established community standards that when used in conjunction with a methodology, help ensure that the processes for creating and maintaining DOVeS would be robust, scalable, interoperable, and aligned with widely accepted ontology development best practices [23]. Since DOVeS is specific to digital medicine and therapeutic applications, and not a general-purpose biomedical domain ontology, there are no plans to submit it to the OBO Foundry Library.

Of the OBO Foundry's 15 principles, the following 6 directly influenced our development environment and setup (Table 1),

XSL•FO
RenderX

while other principles such as P8: documentation, P10: commitment to collaboration, and several others were used for management and maintenance, and are accommodated through our use of GitHub and BioPortal.

Table 1. Open Biological and Biomedical Ontologies Foundry principles directly influencing Digital medicine Outcomes Value Set development environment and setup.

OBO[a] Foundry principle	Description
P1: Open	DOVeS[b] ontology sources and releases are publicly available on GitHub under the open and permissive CC-BY-SA Creative Commons license.
P2: Common Format	We represented DOVeS using OWL[c]. OWL supports serialization into several accepted concrete syntaxes, including the OBO syntax, allowing interoperability with various ontology tools. This choice aligns with the OBO principle of adhering to a common format across ontologies.
P3: URI[d]/Identifier Space	Uniform naming conventions were applied to the DOVeS ontology Resource Identifier and all associated terms. Each term is assigned a universally unique alphanumeric identifier, prefixed by "https://w3id.org/doves/." This approach follows the OBO Foundry recommendation to use a meaningless alpha-numeric identifier for ontology terms, with human-readable labels encoded separately, as noted above.
P4: Versioning	GitHub served as the primary platform for ontology development, providing out-of-the-box versioning and release functionality. Our development approach closely followed the established ontology engineering practices popularized by the Gene Ontology Consortium [24,25]. Released versions of DOVeS are made publicly available on BioPortal to support accessibility and dissemination [20].
P6: Textual Definitions	Terms within DOVeS are accompanied by textual definitions, which follow the Aristotelian genus-differentia descriptive format. This format defines a term by specifying its broader category (genus) and its distinguishing characteristics (differentia). These definitions are provided using the IAO:0000115 (definition) annotation property.
P12: Naming Conventions	We applied consistent naming conventions across all DOVeS terms. Specifically, terms are named in lowercase unless they are proper nouns, and each term has exactly 1 primary label specified by an "rdfs:label" annotation. In addition, synonyms and alternative labels are provided using "skos:altLabel" annotations.

[a]OBO: Open Biological and Biomedical Ontologies.

[b]DOVeS: Digital medicine Outcomes Value Set.

[c]OWL: Web Ontology Language.

[d]URI: Unique Resource Identifier.

Secondary Ontology Integrations

Because many DHTs are meant to influence diseases or disease trajectories, we incorporated the Mondo Disease Ontology (MONDO), an OWL ontology unifying multiple disease ontologies and terminologies. MONDO is a publicly available ontology with an active maintenance userbase that harmonizes multiple disease resources [26]. It consists of 54,000 classes of which the human disease branch has 22,500 classes. We extracted the human disease branch (MONDO:0700096) using the *minimum information to reference an external ontology term* (MIREOT) method [27] provided by the ROBOT command line tool [28]. We chose MONDO over the *ICD-10* (*International Classification of Diseases, Tenth Revision*), for example, because MONDO is a richly axiomatized OWL ontology whereas *ICD-10* is a structured taxonomy that is optimized for health care reporting and billing. Using MONDO, therefore, allowed us to leverage the built-in semantics of OWL and an OWL reasoner to infer relationships between disease terms and for runtime querying. Furthermore, terms in MONDO are, to a greater degree than *ICD-10*, richly annotated with synonyms and definitions, including synonyms from *ICD-10*. This makes MONDO more useful for DOVeS at runtime where applications may need to search for DHTs by synonyms. Finally, MONDO worked well with our build tools. We used the ODK (Ontology Development Kit), which works best with OBO-style ontologies, like MONDO.

Because many DHTs influence or improve outcomes by mitigating adverse events, feedback from collaborators strongly emphasized the importance of addressing adverse events in a manner that would be both scalable and interoperable. We therefore incorporated the Ontology of Adverse Events (OAE) [29]. The OAE is an OBO Foundry ontology available in OWL, which ensures compatibility with and facilitates seamless integration into DOVeS. This allows DHTs to be described in terms of outcomes that correspond to mitigation of certain types of adverse events such as the number or rate of diabetic hypoglycemic events (OAE:0001057).

Phase 3: Testing and Refinement

After initial ontology development based on input from the ADviCE consortium, internal expertise, and DHCA data of vendors in the ADviCE database, the DOVeS ontology was then externally field tested with an independent sample of DHT vendors who had not been through the DHCA intake process and were not otherwise familiar with it. Lists of potential vendors for outreach were provided by ADviCE collaborators, the Digital Therapeutics Alliance, and ORCHA (Organization for the Review and Care of Health Apps). Inclusion criteria consisted of vendors serving the US market with digital medicine or digital therapeutic products that in some way served patients, clinicians, or both, for clinical care and were not purely administrative in nature.

XSL•FO
RenderX

To carry out this field testing, we reached out by email to 206 new DHT vendors from the above lists between December 2022 and May 2023. Nonresponses were followed up with an additional 2 outreach emails of varying invitation language. A total of 40 vendors replied, expressing interest (19.4% response rate), and were subsequently invited to one-on-one semistructured interviews (Multimedia Appendix 1) by web meetings to allow them to visually inspect the ontology in a dynamic manner in Protégé, and to suggest additions and modifications. Thirty-seven of these vendors (92.5%), 17 of which were manufacturers of FDA-listed Artificial Intelligence/Machine Learning Medical Devices, accepted this invitation and participated in the web meetings. To plan for these meetings and to facilitate quickly honing in on the areas within the ontology of greatest relevance to each of the vendors during the limited time of the 1 hour web meetings, vendors were sent REDCap (Research Electronic Data Capture; Vanderbilt University) surveys in advance (Multimedia Appendix 2), asking them to describe the areas in which their products operated and the types of outcomes their products aimed to influence, including: clinical outcomes, educational outcomes (eg, patient comprehension), engagement and adherence outcomes (eg, user engagement), health economic outcomes, health care operations outcomes (eg, operational efficiency), health care utilization outcomes (eg, hospital readmission), patient reported outcomes (eg, patient reported outcome response rates), process of care outcomes (eg, adherence to HEDIS [Healthcare Effectiveness Data and Information Set] measures), cybersecurity (eg, security and privacy certifications), interoperability, EHR integration, user experience (eg, Net Promoter Score), product uptime or downtime outcomes, and any peer reviewed manuscripts describing outcomes. Vendors could respond to 1 or more of these areas, or to none of them, thereby providing investigators insight as to where within the ontology to begin the semistructured interview. Of the 40 vendors sent REDCap surveys, 26 (65%) completed them before meeting with us. Those that did not complete them, but that nevertheless participated in one-on-one web meetings (11), had opportunities to describe their outcomes and areas of focus verbally. Information gleaned from the web meetings were captured in a database for potential DOVeS modifications.

Before new ontology information was to be captured through these meetings, we preidentified a stopping point for the one-on-one vendor meetings, as the point in time at which a "steady state" had been achieved in the top-level classes and their 3 descendent generations (ie, the original hierarchy from ADviCE plus any updates from the Phase 2 development process). This steady state was defined as the absence of additional suggestions for modification to these classes in the top 4 generations from no less than 5 sequential vendors. Any single vendor suggestion to modify one of these high-level classes constituted a signal to continue to interview vendors, record their suggestions, and make modifications as indicated. The stopping point of 5 vendors in a row without modification suggestions to these top classes was achieved by the 35th one-on-one meeting, but we nevertheless completed the remaining vendor meetings that had already been scheduled. Although some vendors late in the process had no ontology modification suggestions at all (suggesting some degree of ontology maturity even at deeper generation levels), many had highly use-case specific outcomes suggestions particular to their products at generations greater than 3 descendants deep from the top class. Although no ontology can be considered "complete," we took this trend in modification suggestions as a sign of reasonable high-level class content and structural stability.

Phase 4: Prototype Development for Real-World Application Demonstration

To demonstrate the potential use of DOVeS for practical application, we built a prototype DHT Application Finder that allows a user to search for DHTs based on filter settings, outcomes-based search terms, conditions, specialties, procedures, types of technology, regulatory status, and EHR integration capabilities. The backend of the DHT Application Finder used OWL reasoning in particular standard subsumption tests, to compute answers to queries from the frontend. To identify specific DHTs, the DHT Application Finder referenced the ADviCE database of 185 vendors' products. The records in the database were annotated with ontology terms from DOVeS that described the conditions treated by the application, outcomes of relevance, and other product parameters that were available in the original data collected by the DHCA. At runtime we constructed an OWL class expression that ontologically described each DHT application. When a user submits a search request, the criteria in the search request are translated to a complex OWL class expression that describes a general class of DHT applications. Then OWL reasoning is used to classify and retrieve the DHT applications that are entailed to be subclasses of the general class.

Results

Phases 0-3 Scope, Background, Development, Refinement, and Testing (Principal Results)

Despite the large set of classes pertaining directly to health care outcomes, "Non-clinical product performance outcomes" and "User experience outcomes" were nevertheless felt to be important not only to health systems and regulators, but to DHT vendors themselves. These classes consisted respectively of (1) technical outcomes associated with the product (cybersecurity and privacy certification outcomes), interoperability, technical certification, and system availability outcomes to name a few, and (2) a variety of outcomes associated with user satisfaction and usability.

In its current state, DOVeS contains 42,320 and 9481 native axioms and distinct classes respectively (Table 2). These numbers are enhanced when taking into account the axioms and classes contributed by MONDO and the OAE. A static view of a selected portion of the ontology hierarchy is shown in Figure 1. Dynamic views of the full ontology can be explored at BioPortal [30].

XSL•FO

[b]MONDO: Mondo Disease Ontology.

[c]OAE: Ontology of Adverse Events.

Figure 1. A selected hierarchical segment of Digital medicine Outcomes Value Set from the Protégé development environment.

Phase 4 Prototype Development (Principal Results)

The prototype DHT Application Finder front end and sample search results are shown in Figure 2. The DHT Application Finder's functionality is best illustrated with an example. Because of the availability of multiple DHTs in the ADviCE database pertaining to diabetes, we describe a use case in which a health system decision maker seeks to find candidate DHTs to help patients with diabetes in their health system achieve glycemic control (ie, glycemic control is the outcome of interest). The example is most informative by illustrating an end user seeking to identify DHTs first without, and then with outcomes-based search terms. In this example, the end user initially searches for DHTs based only on "diabetes" in the Conditions field. (Figure 3A) The user selects "diabetes mellitus" from the type-ahead list that appears, and presses "Search." The search results show a list of DHTs associated with diabetes mellitus including those for "type 2 diabetes mellitus" as well as "diabetic retinopathy." However, neither of these provides a list of DHTs exclusively related to the outcome of glycemic control.

Therefore, the user, in addition, (or could have done so as the first step) enters the term "Glyc" into the "Outcomes to be influenced" entry field (Figure 3B), and the type-ahead offers 2 choices: "Glycemic Control" and "Reduction in Glycemic Events." Choosing "Glycemic Control Outcome" and performing the search again, the user obtains a list now of only those DHTs specific to achieving glycemic control (eg, this time not including DHTs associated specifically with diabetic retinopathy). In the case of the ADviCE database, this outcomes-based search reduced the field of products that the user might otherwise have needed to explore further by 33%.

The fields show type-ahead completion options for conditions known to the system, along with their synonyms that are drawn directly from Mondo Disease Ontology (MONDO).

Discussion

Principal Results

In developing DOVeS, we describe an ontology framed by outcomes specific to DHTs, rather than technical or implementation features. Because our goal was to address products that would potentially be used in clinical practice that might fall under regulatory oversight, we focused on digital medicine and digital therapeutic products, and did not intend to capture outcomes associated with the much broader category of digital health.

The 3 top-level classes of DOVeS, derived from the background work done by the ADviCE consortium, consisted of "Healthcare outcomes," "Non-clinical product performance outcomes," and "User experience outcomes." The top-level class "Healthcare outcomes" is central to DHTs, as most such products intend to influence something in this class. It is composed of descendent classes including, for example, clinical care outcomes (eg, health benefits and mitigation of adverse events), health care utilization outcomes, health care operational outcomes, process of care outcomes, medico-legal outcomes, education outcomes, health care economic outcomes, socioeconomic outcomes, family and caregiver outcomes, and engagement and adherence outcomes (Figure 1).

Related Works

Efforts to organize DHTs to date have been described in part based on the specialties they serve, disease areas, user types,

XSL•FO
RenderX

and certain functionalities [31], but this can limit the way in which DHTs that are platforms, serving functions across multiple specialties, or that span diseases of multiple organ systems (eg, diabetes) are organized. The World Health Organization developed the Classifications of Digital Health Interventions as a nonontological framework according to different user types (persons, health care providers, health management, and support personnel), data services, and services and application types, but not on outcomes, and not in a computable format [32].

Although some limited outcomes-based taxonomies [33] and classifications exist [34], to our knowledge, none are specific to digital medicine or digital therapeutics applications. Organizing DHTs into common categories based on the outcomes they influence then gives the marketplace an opportunity to compare different DHTs side by side for their impacts on common outcomes, and with the appropriate outcomes results, may make regulatory, purchasing, formulary, and coverage decisions more efficient and objective.

Limitations

Several limitations to this work exist. First, by design, DOVeS was informed by DHTs excluding those in the "digital health" class (that class of products focused on wellness that does not fall under regulatory oversight). Second, while it would be methodologically satisfying after DOVeS development to return to the original 185 DHT vendor products and quantitatively describe the degree of concept mapping achieved, doing so could be misleading because the only data available to us from these vendors were high-level concepts captured in the DHCAs before DOVeS was built. Therefore, a future and important direction for the DHT Application Finder will be a guided intake module through which the vendor can submit a product for automated annotation based on the dynamic class content of the ontology at the time of submission. Another limitation is that, while the classes for the ontology were developed with academic, regulatory, community health, payer, and patient advocacy stakeholders, and included field testing with an independent set of DHT vendors, DOVeS, like most ontologies, is not complete, but will rely and depend on an active base of engaged supporters to continue to build and maintain it. In addition, outcomes and the metrics to measure those outcomes are not necessarily universal in the DHT industry. In the process of outcome and metrics discovery, we attempted to select outcomes through both internal and external consensus. However, these outcomes and metrics may need modification in the future as the ontology grows and is further informed by the broader community of stakeholders and the evolving industry.

Conclusions

An ontology for organizing DHTs into outcomes-based groupings is an important step as the digital medicine and digital therapeutics industry matures. While the DOVeS ontology provides an open-source framework as a starting point to do this, real-world value from the ontology will be achieved through the development of robust tools similar to the prototype DHT Application Finder that will leverage the ontology for specific use cases. These may include, for example, use by regulators to streamline the process for determining substantial equivalence to predicate devices, and use by health system decision makers to identify products that influence the same or related outcomes so that the universe of potential DHT products being considered for implementation can be rapidly narrowed to only those that are most relevant. While it is not known whether the 33% reduction in products that were more specifically identified with an outcomes-based search relative to a disease-based search described in the example from the ADviCE database above will necessarily translate if the entire marketplace of DHT products were to be indexed, any reasonable reduction would nevertheless offer savings in time and effort by decision makers attempting to identify DHTs for deeper discovery for potential clinical use.

DOVeS is publicly available on BioPortal [30] and GitHub [35], and has a Creative Commons license CC-BY-SA that is intended to encourage stakeholders to modify, adapt, build upon, and distribute it. Only with an engaged userbase will the ontology continue to grow and evolve, and when applied to the marketplace help organize DHTs in a way that is beneficial to stakeholders and ultimately to the patients they serve.

Acknowledgments

We thank Leeda Rashid and Vinay Pai of the FDA for thoughtful project feedback. We acknowledge the Digital Therapeutics Alliance, and ORCHA for assistance in identifying potential vendors to review the ontology. This project was supported by the Food and Drug Administration of the US Department of Health and Human Services as part of The Center for Radiological Health Digital Health Center of Excellence and The Center of Excellence in Regulatory Science and Innovation grant to University of California, San Francisco (U01FD005978). The contents are those of the author(s) and do not necessarily represent the official views of, nor an endorsement, by FDA/HHS, or the US Government.

Abstract

Background: Integrated health data are foundational for secondary use, research, and policymaking. However, data quality issues—such as missing values and inconsistencies—are common due to the heterogeneity of health data sources. Existing frameworks often use static, 1-time assessments, which limit their ability to address quality issues across evolving data pipelines.

Objective: This study evaluates the AIDAVA (artificial intelligence–powered data curation and validation) data quality framework, which introduces dynamic, life cycle–based validation of health data using knowledge graph technologies and SHACL (Shapes Constraint Language)–based rules. The framework is assessed for its ability to detect and manage data quality issues—specifically, completeness and consistency—during integration.

Methods: Using the MIMIC-III (Medical Information Mart for Intensive Care-III) dataset, we simulated real-world data quality challenges by introducing structured noise, including missing values and logical inconsistencies. The data was transformed into source knowledge graphs and integrated into a unified personal health knowledge graph. SHACL validation rules were applied iteratively during the integration process, and data quality was assessed under varying noise levels and integration orders.

Results: The AIDAVA framework effectively detected completeness and consistency issues across all scenarios. Completeness was shown to influence the interpretability of consistency scores, and domain-specific attributes (eg, diagnoses and procedures) were more sensitive to integration order and data gaps.

Conclusions: AIDAVA supports dynamic, rule-based validation throughout the data life cycle. By addressing both dimension-specific vulnerabilities and cross-dimensional effects, it lays the groundwork for scalable, high-quality health data integration. Future work should explore deployment in live clinical settings and expand to additional quality dimensions.

Introduction

Background

The integration of high-quality, complete, and interoperable patient health records is essential to modern health care and medical research [1-4]. Accurate and well-structured data enhance research reproducibility [5-7], which in turn drives more effective clinical decision-making and improved patient outcomes. However, as health data is collected across diverse and heterogeneous sources [8,9], its quality can be compromised by fragmentation [10,11], variability [12,13], and incomplete

XSL•FO
RenderX

information [14-16]. These challenges compromise data usability and hinder the development of unified, clinically meaningful datasets suitable for both primary and secondary uses [17,18].

Existing efforts on health data quality often focus on defining standardized quality dimensions and organizing these into structured frameworks [19-23]. However, many current approaches rely on static, 1-time evaluations that do not reflect the dynamic and iterative nature of the entire data life cycle [24,25]. This limits their effectiveness in identifying evolving quality issues that emerge across stages of data transformation—such as extraction [26,27], harmonization [28,29], or final validation [21]—as they do not provide continuous, iterative assessment.

To address this gap, the AIDAVA (artificial intelligence–powered data curation and validation) project [30], launched in 2022 as part of a Horizon Europe initiative, proposes a dynamic data quality framework that enables continuous assessment throughout the data life cycle. At its core is the personal health knowledge graph (PHKG), a patient-centered, interoperable data model built using knowledge graph (KG) technologies and validated with SHACL (Shapes Constraint Language)–based rules. This approach allows for the assessment of data quality constraints across multiple integration stages. For instance, if a patient record includes a diagnosis of prostate cancer but the patient is listed as a female, or if a discharge date appears earlier than the admission date, AIDAVA's rule-based validation will automatically detect and flag these inconsistencies during the integration process.

This paper also demonstrates how completeness directly influences the interpretability of consistency scores.

This paper evaluates the AIDAVA framework's effectiveness in detecting and improving data quality issues, with a particular focus on completeness and consistency. The framework's ability to validate data dynamically across stages of integration is essential for supporting artificial intelligence–driven, automated curation workflows, a central goal of the AIDAVA project. As health care systems increasingly rely on semantic technologies and automation to manage large-scale, heterogeneous data, life cycle–based quality monitoring becomes a requirement. By situating this work within that broader vision, we aim to demonstrate how dynamic rule-based validation can enhance the reliability and scalability of next-generation health data integration pipelines. It also investigates how these dimensions evolve across the data transformation pipeline, highlighting their interdependencies and implications for integrated health data (Textbox 1).

Textbox 1. Main contributions of this paper.

- Introduces the AIDAVA (artificial intelligence–powered data curation and validation) framework for dynamic health data quality validation using SHACL (Shapes Constraint Language) and knowledge graphs.
- Defines and applies completeness and consistency rules across the integration pipeline.
- Simulates realistic data quality issues using controlled noise in the MIMIC-III (Medical Information Mart for Intensive Care-III) dataset.
- Evaluates SHACL validation across different integration sequences and noise levels.

Related Work

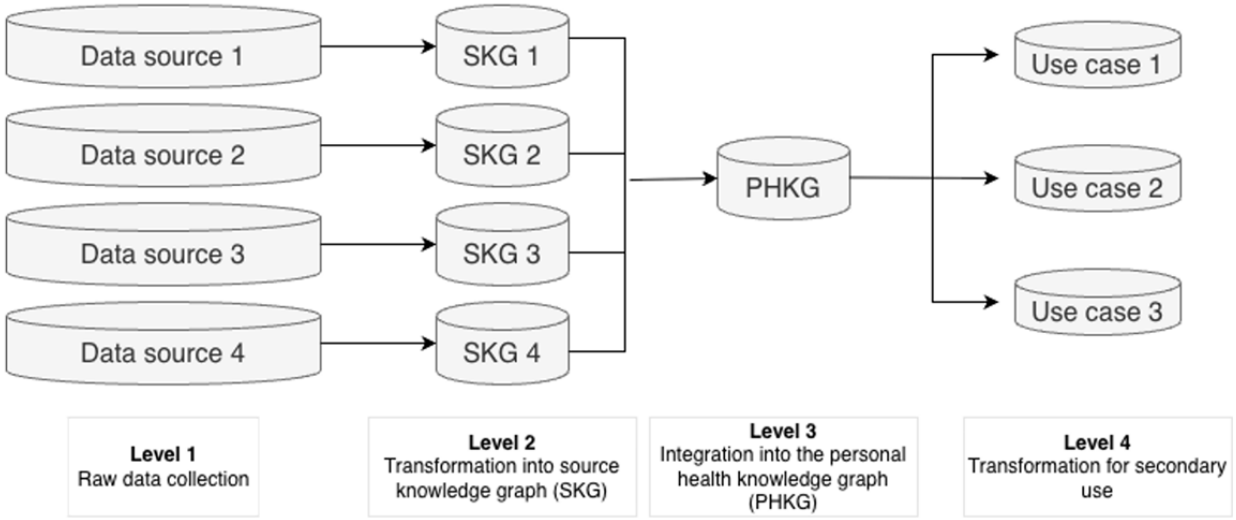
Ensuring the quality of integrated health care data, particularly for the secondary use of electronic health records, has been the subject of extensive research [31]. Prior efforts generally focus on defining and measuring data quality along dimensions such as completeness, consistency, conformance, and plausibility [20-24]. These dimensions serve as the foundation for several frameworks and tools developed to detect anomalies and enforce standards across clinical datasets [15,22,32].

Framework-based approaches have sought to structure and formalize the assessment of health data quality. Notably, Kahn et al [21] introduced a widely adopted framework that groups quality concerns into 3 core dimensions—completeness, conformance, and plausibility—further divided into verification and validation contexts. This framework laid the groundwork for systematic quality checks but remains limited to static evaluations that do not adapt to the changing nature of data pipelines.

Dimension-specific studies have also provided deeper insights. Issa et al [33] conducted a comprehensive review of completeness in KGs, identifying 7 distinct subtypes, including 3 previously unclassified forms. Their findings emphasized the interplay between completeness and other quality dimensions such as consistency and correctness—further highlighting the need for more context-aware, dynamic quality assessments.

Tool-based solutions, such as Achilles Heel [34], offer practical mechanisms for identifying data quality issues. As part of the Observational Health Data Sciences and Informatics (OHDSI) ecosystem, Achilles Heel applies 70 predefined validation rules to detect anomalies in large-scale clinical datasets. While effective in identifying static inconsistencies, these tools typically evaluate data quality at a single point in time and cannot accommodate the iterative transformations that occur during integration workflows.

In contrast to these prior approaches, the AIDAVA framework introduces a life cycle–based, dynamic model of data quality validation. By embedding SHACL-based validation rules directly into a KG pipeline, AIDAVA allows for continuous monitoring and enforcement of constraints during data ingestion, transformation, and integration. It extends existing methodologies by addressing data quality not as a 1-time task, but as an ongoing process—ensuring that completeness and consistency are maintained across evolving data structures.



AIDAVA Data Quality Framework

The AIDAVA data quality framework is designed to ensure semantic and structural standardization across the entire health

XSL•FO
RenderX

data life cycle, addressing the complexities of integrating heterogeneous health data sources. The framework operates across 4 levels, each targeting specific points in the health data integration process. These 4 levels of the framework are illustrated in Figure 1.

Figure 1. The 4 levels of the AIDAVA data quality framework. AIDAVA: artificial intelligence–powered data curation and validation; PHKG: personal health knowledge graph; SKG: source knowledge graph.

Level 1: Raw Data Collection

At the initial level, the framework relies on data providers to provide data that meets baseline standards. Given the variability of data sources, direct transformations or validations at this stage are limited. Instead, the framework ensures compliance with transfer specifications, verifying that incoming data adheres to structural and format requirements before progressing to the next level.

Level 2: Transformation Into Source Knowledge Graphs

In this stage, raw data are transformed into source knowledge graphs (SKG) by executing a data curation tool from the library of tools available in AIDAVA and delivering data sources in a KG format aligned with the AIDAVA Reference Ontology. The AIDAVA Reference Ontology plays a dual role in enabling semantic interoperability and systematic quality evaluation. It provides a formal semantic layer that aligns PHKGs with standards such as Health Level Seven International Fast Healthcare Interoperability Resources (FHIR), SNOMED CT (Systematized Nomenclature of Medicine–Clinical Terms), and Clinical Data Interchange Standards Consortium. This process ensures semantic and structural standardization of each data source, which is critical for interoperability. Standardizing the data at this level minimizes inconsistencies and enables proper integration with multiple sources.

Level 3: Integration Into the PHKG

In this phase, multiple SKGs are integrated into a unified PHKG, creating a longitudinal representation of an individual's health history. This step consolidates fragmented patient data sources while maintaining consistency and logical coherence in the integrated patient record. The integration process ensures that patient data is well-structured, complete, and free of inconsistent and redundant information to support clinical decision-making and research applications. For example, during PHKG integration, a birth year recorded as 1875, implying an implausible age of over 140 years, would be flagged by age-consistency rules. This type of anomaly is automatically detected through SHACL-based validation during the integration process.

Level 4: Transformation for Secondary Use

In the final stage, the PHKG is transformed into formats tailored for secondary use. This step adapts integrated data to align with specific output formats, enabling accurate analysis (eg, Breast Cancer registry in Observational Medical Outcomes Partnership [OMOP] compliant format), improved patient care (eg, patient International Patient Summary in FHIR format), and effective reuse across clinical and research settings.

This study focuses on levels 2 and 3, as they are the earliest feasible and scalable stages for enforcing semantic standardization and integrating fragmented, heterogeneous data sources. Performing this at level 1 is not practical due to diverse formats and limited control over data provider systems. Level 4 is only partially addressed, as downstream transformation is performed, but full data quality assessment from the perspective of a specific use case lies outside the scope of this paper.

Data Quality Dimensions and Categories

To evaluate data quality, the AIDAVA framework adopts a structured approach based on dimensions and categories. Dimensions provide a high-level perspective on data quality, grouping related categories to help identify systemic issues. Recent research underscores the increasing need to evaluate diverse data quality dimensions, especially when repurposing health data for secondary use [19]. While multiple dimensions contribute to ensuring high-quality health data, the AIDAVA

XSL•FO
RenderX

framework currently focuses on 2 data quality dimensions: completeness and consistency. Completeness ensures that all necessary data elements are present, preventing critical information gaps. Consistency verifies that data adheres to defined constraints and logical relationships, such as ensuring that diagnoses and procedures align with a patient's demographic details. Within these dimensions, categories provide a more granular level of assessment, as outlined in Table 1.

The decision to focus on completeness and consistency is driven by their widespread use in data quality research [35-37] and their suitability for automated assessment [23]. Unlike other dimensions, which often require subjective interpretation or manual validation, completeness and consistency can be systematically measured using predefined rules and automated validation techniques. By prioritizing completeness and consistency, the AIDAVA framework establishes a scalable approach to data quality assessment. These dimensions not only support automated validation but also provide a foundation for expanding the framework to address more complex data quality dimensions.

Table 1. Overview of data quality dimensions and categories in the AIDAVA[a] framework.

Dimension and category	Description	Example
Completeness		
Essential variable completeness	Identifies when critical data elements are missing	Missing patient date of birth
Conditional variable completeness	Detects cases where missing variables prevent consistency checks	Diagnosis present, but no recorded gender
Consistency		
Data type for property	Ensures values conform to expected data types	Text found in a numeric age field
Time sequence consistency	Identifies implausible event sequences	Discharge date before admission date
Diagnosis for gender consistency	Detects diagnoses incompatible with a patient's gender	Prostate cancer assigned to a female patient
Diagnosis for age consistency	Flags diagnoses that are incompatible with a patient's age	Lung cancer diagnosed in an infant
Procedure for gender consistency	Detects gender-incompatible procedures	Hysterectomy assigned to a male patient
Procedure for age consistency	Flags procedures that are inappropriate for the patient's age	Radiotherapy procedure in a toddler

[a]AIDAVA: artificial intelligence–powered data curation and validation.

Data Quality Instruments

The AIDAVA framework relies on a robust instrument for scalable and automated data quality assessment: the SHACL. As a World Wide Web Consortium standard, SHACL defines and enforces semantic and structural constraints on Resource Description Framework (RDF) KGs, enabling rule-based validation to detect inconsistencies, missing elements, and structural misalignments.

Within the AIDAVA framework, SHACL validation rules are categorized into 2 types, as outlined in Table 2: ontology-based and domain-specific rules. Each category includes several validation rules, technically known as SHACL shapes—an SHACL term referring to rule templates that define how data should conform to expected structures or values. The number of rules differs between categories due to the nature of the information being encoded. For instance, completeness checks such as "essential variable" rely on the fully connected structure of the admission node to validate the presence of key attributes (eg, admission date and discharge status) across sources. In contrast, rules such as "diagnosis for gender" require a distinct SHACL shape for each valid gender related pairing (eg, "prostate cancer – male" and "ovarian cancer – female"), increasing the number of shapes. Table 2 shows the number of SHACL shapes associated with each rule category, reflecting the complexity and granularity of the validations.

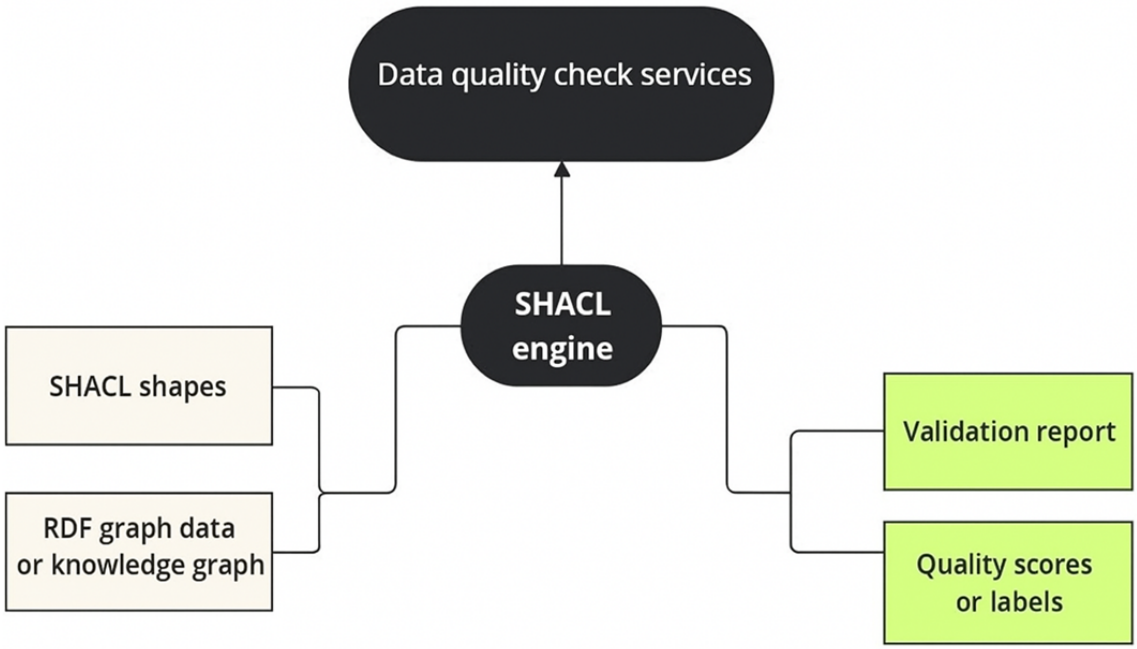
To enable meaningful evaluation of data quality across different rule categories, we use normalized data quality scores rather than raw violation counts. This is necessary because the number of rules (SHACL shapes) and corresponding checked nodes varies significantly by category (Table 2). Violation counts alone would disproportionately reflect rule volume rather than actual quality trends. We calculate a category-specific quality score using the formula:

$$\textit{Quality score} = 1 - e$$

Where e represents the error rate, calculated as the violation count divided by the total number of checked nodes. This provides a relative measure of how well the data conforms to the specified rules within each category.

XSL•FO
RenderX

Table 2. Categories and counts of SHACL[a] validation rules in the AIDAVA[b] framework.



Type and category	SHACL shape count
Ontology-based checks	
Essential variable completeness (eg, admission date must be present)	14
Conditional variable completeness (eg, discharge status cannot be validated without discharge time)	1
Data type for property (eg, age must be a number, not text)	6
Medical and common-sense checks	
Time sequence consistency (eg, admission after discharge flagged as invalid)	6
Diagnosis for gender consistency (eg, female patient assigned prostate cancer code)	5208
Diagnosis for age consistency (eg, infant patient assigned prostate cancer code)	130
Procedure for gender consistency (eg, male patient assigned hysterectomy code)	640
Procedure for age consistency (eg, infant patient assigned colonoscopy procedure)	79

[a]SHACL: Shapes Constraint Language.

Ontology-based rules in the AIDAVA framework are derived from the AIDAVA reference ontology [38], which builds on established standards such as Health Level Seven International FHIR, SNOMED (Systematized Nomenclature of Medicine), and LOINC (Logical Observation Identifiers Names and Codes) to ensure interoperability and support automated curation. These rules ensure conformance with predefined semantic standards, such as verifying data types, relationships, and the presence of mandatory variables. Domain-specific rules are informed by health care–specific knowledge. These rules address real-world data quality challenges, including validating gender-appropriate procedures and ensuring consistency in clinical attributes. The definition and validation of domain-specific rules require expert consensus. However, data quality research has established a variety of validated domain-specific rules over time [39]. The AIDAVA framework leverages these existing, literature-validated rules, allowing it to build upon proven methodologies while avoiding redundancy, ensuring alignment with best practices in health data quality management.

These SHACL shapes are applied within SKGs (intrasource consistency and completeness) and PHKGs (across data source consistency and completeness), ensuring semantic and structural standardization at each stage. Figure 2 illustrates this validation process, applied at both the SHKG and PHKG levels.

Figure 2. SHACL-based data quality check pipeline. RDF: Resource Description Framework; SHACL: Shapes Constraint Language.

The SHACL engine processes health data represented as an RDF graph—a structured format used to build KGs—by applying predefined constraints (SHACL shapes). These rules define the expected structure and content of the data, including semantic relationships and required elements. As the engine executes these rules, it produces an SHACL validation report that highlights data quality violations, such as missing values, incorrect data types, or inconsistent relationships. This validation step is critical for identifying and addressing quality issues before integration into the PHKG.

Methods

Study Design

To evaluate the robustness and effectiveness of the AIDAVA framework in detecting and managing data quality issues, we conducted a controlled experiment using the MIMIC-III (Medical Information Mart for Intensive Care-III) dataset, a publicly available and well-structured critical care database. While MIMIC-III offers a rich and diverse set of clinical variables, it does not contain the types of data quality issues typically encountered in real-world health information systems. As such, this study introduced artificial noise to simulate common completeness and consistency problems found in heterogeneous clinical data. This approach allows us to systematically assess how well the AIDAVA framework, particularly its SHACL-based validation rules, can identify quality issues under different conditions and at multiple stages of data integration. The following subsections describe the dataset, noise injection methodology, and the process of KG construction and validation.

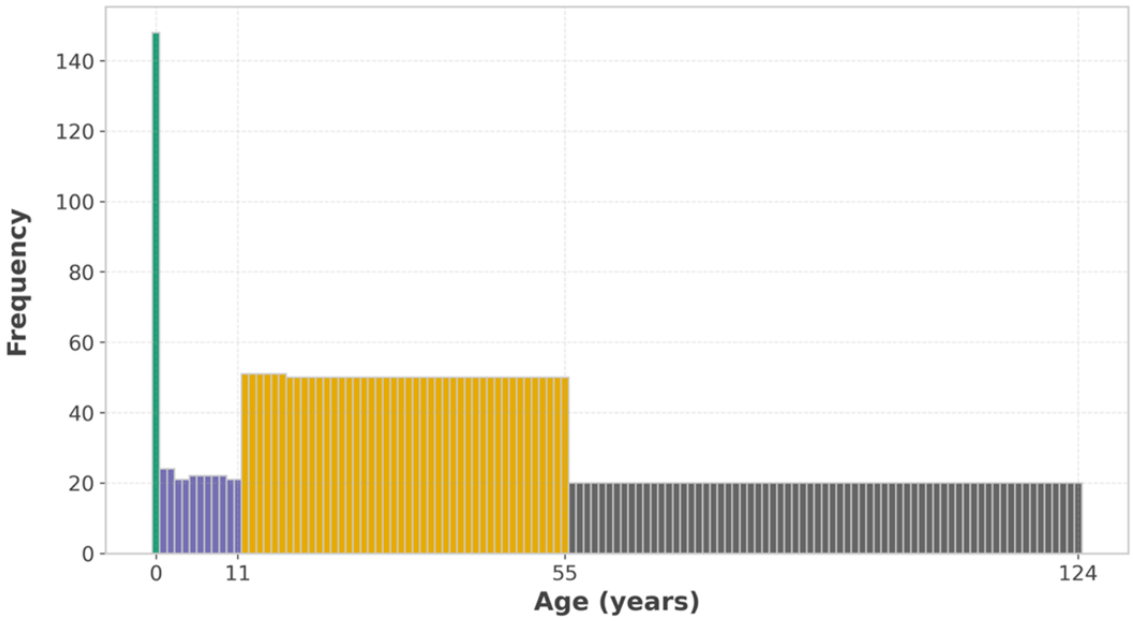
Data Source and Data Preparation

We used the MIMIC-III dataset due to its structured format and breadth of clinical variables, offering an optimal foundation for simulating real-world integration scenarios. The dataset includes deidentified health records from over 58,000 admissions. For this study, hospital admissions lacking relevant diagnosis or procedure codes (as required for SHACL validation) were excluded, resulting in a final cohort of 13,607 admissions. A total of 4 tables were used: PATIENTS, ADMISSIONS, DIAGNOSES_ICD, and CPTEVENTS.

Data cleaning was performed using OpenRefine [40], with date fields standardized to ISO 8601 format (YYYY-MM-DDThh:mm:ss+zz:zz) and gender values mapped to SNOMED CT codes to support interoperability and nonbinary classifications. These steps ensured alignment with the AIDAVA reference ontology and interoperability across sources.

Adding Noise to the Dataset

To simulate real-world data quality challenges [41-43], artificial noise was introduced into the dataset based on 2 parameters: noise level and completeness ratio. Noise level ($\in$ [0,1]) defines the proportion of KG statements impacted by errors. The completeness ratio specifies the share of this noise that results in missing values (as opposed to logically inconsistent entries). For example, a noise level of 0.50 and a completeness ratio of 0.25 imply that 50% of selected statements are altered, with 25% of them made incomplete and the remainder made inconsistent. Noise was introduced across 2 categories: consistency noise, reflecting logical contradictions, and completeness noise simulating missing information. All injections were performed in a reproducible manner using a fixed randomization seed.



Consistency Noise

We targeted error types that frequently occur in clinical data entry or integration processes [41-43]. These methods included:

1. Gender swapping: male and female values in the PATIENTS table were randomly exchanged. This modification introduced inconsistencies in gender-specific diagnoses and procedures, affecting validation rules such as diagnosis for gender consistency and procedure for gender consistency. Gender values are sampled from a binomial distribution with 2 trials and success probability, P=.5, ensuring a balanced distribution of changes.
2. Age alteration: instead of randomly changing a patient's age, we introduced interval-based errors by defining plausible age groups. These age groups were determined based on clustering patterns observed in diagnosis for age consistency and procedure for age consistency rules (Figure 3). In this implementation, age groups were defined as [0,1] for infants, [1,12] for children, [12,56] for teens and adults, and [56,124] for seniors. Birth years in the PATIENTS table were altered so that a new age was randomly selected from another age group, triggering violations in age-dependent diagnosis and procedure rules. To ensure realistic distribution, the selection of a new age group was sampled using a multinomial distribution with 4 trials, where the event probabilities were weighted based on the frequency of each age group in the dataset.
3. Swapping admission and discharge dates: in the ADMISSIONS table, admission, and discharge dates were swapped. This modification introduced inconsistencies relevant to time-sequence validation rules and triggered errors in age calculations that depended on the admission date.
4. Day-month swapping in dates: day and month values in date fields across PATIENTS, ADMISSIONS, and CPTEVENTS were randomly swapped, leading to invalid date formats where month values exceeded 12, or sequences where the chronological order of events became disrupted. These errors mirrored common data entry mistakes in hospital settings, where clinicians or administrative staff may mistakenly invert date components.
5. Inconsistencies in medical coding: we randomly changed diagnosis and procedure codes in the DIAGNOSES_ICD and CPTEVENTS tables. *ICD-9* (*International Classification of Diseases, Ninth Revision*) diagnosis codes and Current Procedural Terminology procedure codes were replaced with alternative codes randomly drawn from their respective rulesets. This change indirectly caused invalid gender and age violations in both diagnoses and procedures because certain codes are only applicable to specific demographic groups. To implement this, each affected record had its original code excluded and replaced with another randomly sampled value from the remaining choices, ensuring a uniform distribution of errors across the dataset.

XSL•FO
RenderX

Figure 3. Age distribution histogram.

Completeness Noise

Missing data, based on real-world completeness issues, was introduced to replicate the effects of incomplete records on validation outcomes [41-43]. The affected tables and fields were:

1. Patient demographic records: missing values were introduced by randomly removing gender (GENDER) or date of birth fields in the PATIENTS table with equal probabilities of being chosen. This noise is intended to represent missing or deidentified patient information.
2. Hospital admission records: missing values were introduced by deleting admission or discharge timestamps (ADMITTIME, DISCHTIME) as well as admission or discharge locations (ADMISSION_LOCATION, DISCHARGE_LOCATION) from the ADMISSIONS table. As with demographic records, the field to be deleted is chosen with equal percentages of 25%. The selection of omitted records was performed randomly yet consistently across the experiment, preserving the dataset's structural integrity while reflecting real-world gaps in clinical administrative case documentation.
3. Procedure records: missing values were introduced by removing procedure chart dates (CHARTDATE) or procedural codes (CPT_CD) in the CPTEVENTS table. Same with the others, equal probabilities of 0.5 decided which cell type should be deleted. The omission process was randomized across the experiment, replicating common record-keeping errors that lead to incomplete procedural documentation.
4. Diagnosis records: missing values were introduced by deleting *ICD-9* diagnosis codes (ICD9_CODE) from the DIAGNOSES_ICD table. As there is only 1 column type able to be deleted, it is chosen with the probability of 1, dissimilar to other categories of introducing completeness noise. This modification simulates errors observed by not typing *ICD* (*International Classification of Diseases*) codes for billing purposes.

While these noise injection scenarios may overlap in their effects, the incompleteness was introduced independently at this stage. The combined effects of the above, as they relate to triage and patient data acquisition progressions, are further elaborated and investigated in the following section. To account for the randomness in choosing the cell types to be deleted, this process was carried out in a reproducible manner using a fixed randomization seed.

Data Integration and Data Quality Assessment

After noise injection, the dataset was mapped into SKGs using RDFCraft [44], aligning data elements to the AIDAVA reference ontology. These SKGs were then integrated into a unified PHKG, following a typical data ingestion workflow. We began with demographic information from the PATIENTS table, which provided key patient attributes. Next, temporal data from the ADMISSIONS table was incorporated, establishing admission and discharge events. This was followed by procedural details from the CPTEVENTS table, and finally, diagnostic information from the DIAGNOSES_ICD table. This stepwise integration reflects a typical hospital workflow, where patient registration occurs first, followed by admissions, treatments, and recorded diagnoses. At each step, SHACL validation rules were applied to assess data quality in terms of completeness and consistency. As each patient is modeled as an independent SKG, SHACL validation can be parallelized across patients, supporting scalable execution on large datasets. This staged validation aligns with levels 2 and 3 of the AIDAVA framework and reflects both intrasource and cross-source quality checks.

To evaluate the effect of the order of data addition on data quality, alternative sequences were also tested by changing the ingestion order (eg, loading procedures or diagnoses before demographics). This allows us to observe how quality issues propagate or get masked depending on integration order.

XSL•FO
RenderX

Results

Overview

The integration process followed a sequential order, beginning with the PATIENTS table, followed by ADMISSIONS, CPTEVENTS, and DIAGNOSES_ICD tables. The framework assessed completeness and consistency at each stage, tracking how data quality changed throughout the process. To evaluate the robustness of the framework, we also conducted an alternative integration sequence, starting with CPTEVENTS, followed by DIAGNOSES_ICD, ADMISSIONS, and finally PATIENTS.

In the following section, we first present the baseline data quality assessment without noise, establishing a reference for comparison. We then provide the final data quality scores after full integration across varying noise levels for both integration orders, highlighting key trends. A detailed breakdown of progressive changes at specific noise levels is available in Multimedia Appendix 1.

Data Quality Assessment Without Noise

The baseline analysis, presented in Table 3, was conducted without artificial noise to establish a reference for data quality. The results showed that most dimensions and categories achieved nearly perfect quality scores, indicating that the integration process preserved data integrity and did not amplify errors. “Essential variable” completeness remained at 100% (13,607 of 13,607 admissions), confirming that all mandatory data elements were present in the KG. The domain consistency checks for diagnosis and gender, as well as diagnosis and age, yielded perfect quality scores. Similarly, data type adherence at all integration stages is achieved with no errors.

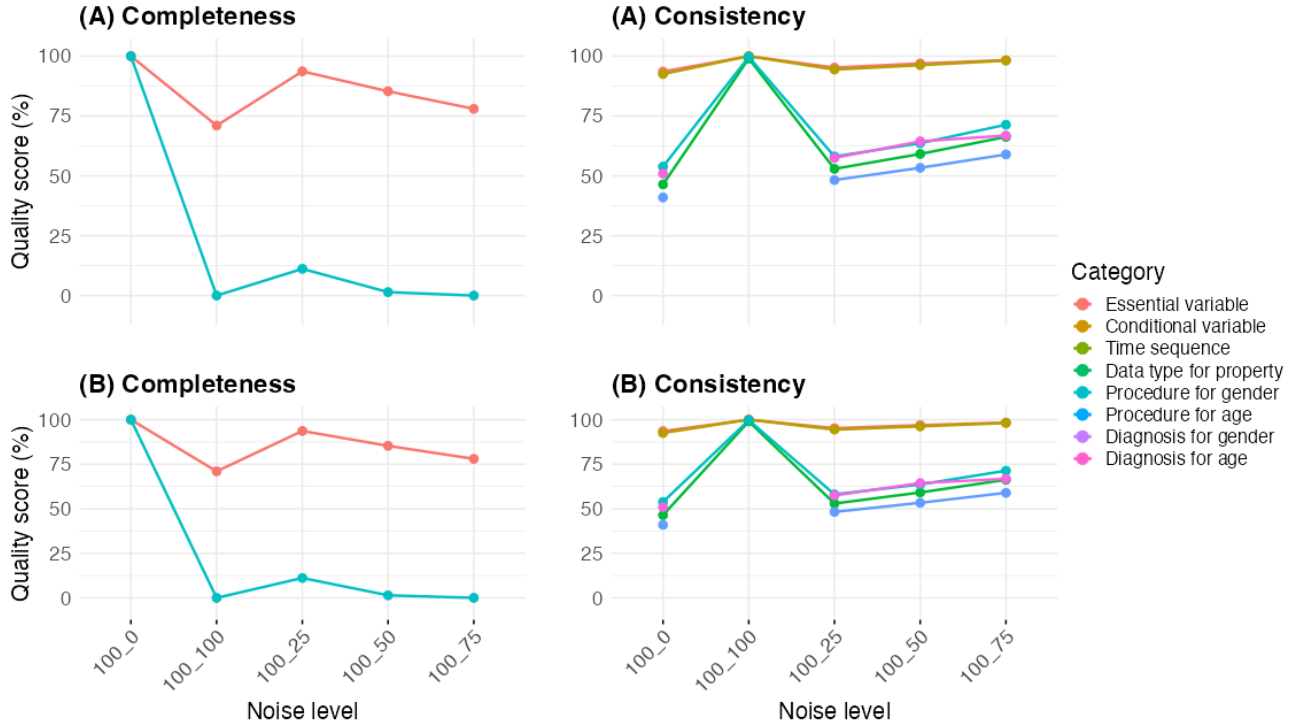
Table 3. Baseline data quality analysis results.

Dimension and category	PATIENTS	ADMISSIONS	CPTEVENTS	DIAGNOSES_ICD
Completeness				
Essential variable (%)	100	100	100	100
Conditional variable (%)	N/A[a]	N/A	N/A	100
Consistency				
Time sequence (%)	100	99.9	99.9	99.9
Diagnosis for gender (%)	100	100	100	100
Procedure for gender (%)	100	100	100	100
Diagnosis for age (%)	100	100	100	100
Procedure for age (%)	100	100	99.89	99.89
Data type for property (%)	100	100	100	100

[a]N/A: not applicable.

Although overall data quality is high, minor discrepancies were observed in specific categories. “Conditional variable” completeness category assesses whether all necessary concepts from different sources are properly integrated and complete. As SHACL rules evaluate conditional variables across every table, an incomplete graph would return 0% (0 of 13,607 admissions) quality score until the last stage of integration. To reflect this dependency, the “conditional variable” completeness scores for PATIENTS, ADMISSIONS, AND CPTEVENTS were marked as “N/A” because these values would not be meaningful to assess. Only at the DIAGNOSES_ICD stage could this category be properly evaluated, where all variable nodes will be reachable.

The procedure for gender and age categories received near-perfect scores of 99.99% (13,606 of 13,607 admissions) and 99.89% (13,593 of 13,607 admissions), respectively. These errors were not due to integration issues, but rather pre-existing errors in the MIMIC-III dataset. The errors in the “procedure for age” category originated from the dataset’s deidentification process, which assigned a few birth dates to years in the 1800s, resulting in implausible patient ages exceeding 300 years—a violation of age-related consistency rules. Similarly, errors in the “procedure for gender” category were traced to a data entry mistake in MIMIC-III, where a laparoscopic procedure on the oviduct or ovary (Current Procedural Terminology 58660) was attributed to a male patient. Additionally, time sequence consistency scored 99.9% (13,594 of 13,607 admissions), with errors primarily linked to discharge times recorded earlier than admission times. This discrepancy is a known artifact of the MIMIC-III data collection process, likely caused by inconsistent timestamp recording practices [45].



Data Quality Assessment With Noise

Overall Trends Across All Noise Levels

To simulate real-world data quality challenges, we introduced artificial noise and repeated the integration process under 2 different orders. Figure 4 presents the final data quality scores after full integration for both orders. The results confirm that data quality scores remained consistent regardless of integration sequence, indicating that the order of data source integration does not alter overall data quality scores. While intermediate values may vary slightly, the progression of completeness and consistency follows the same overall patterns.

XSL•FO
RenderX

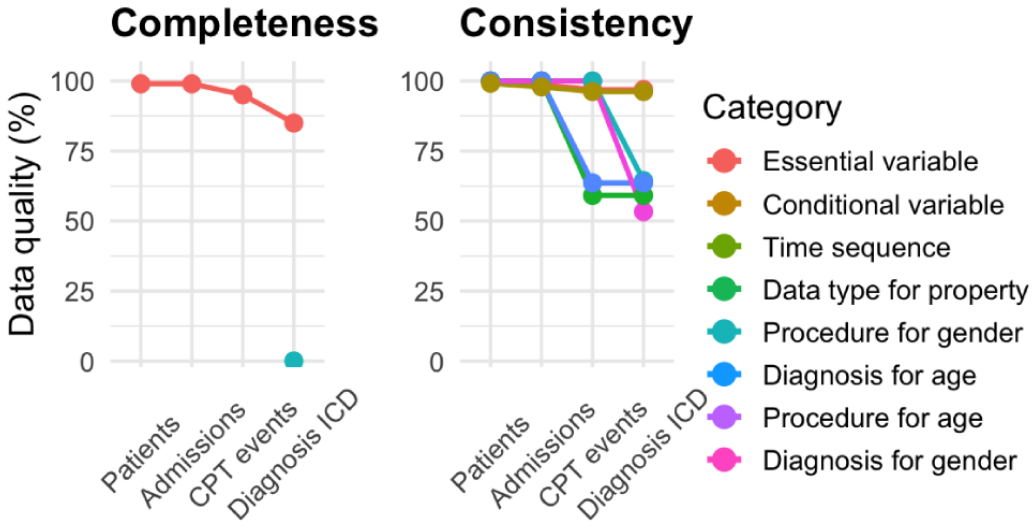
Figure 4. Final data quality scores after full integration.

"Essential variable" completeness declined gradually from 100% to 71% (9661 of 13,607 admissions), with the largest drop occurring between 100_0 (100%) and 100_25 (93.65%), continuing to decrease at higher noise levels. "Conditional variable" completeness dropped sharply from 100% to 11.17% (1521 of 13,607 admissions) at 100_25, reaching near zero at higher noise levels, reflecting its strong dependence on cross-source relationships.

Time sequence and data type consistency improved throughout the integration, rising from 93.57% (12,732 of 13,607 admissions) and 92.51% (12,588 of 13,607 admissions) at 100_0 to 100% at 100_100. Procedure consistency for gender and age increased, starting at 46.43% (6136 of 13,607 admissions) and 53.86% (7329 of 13,607 admissions), respectively, and reaching 99.01% (13,472 of 13,607 admissions) and 99.68% (13,563 of 13,607 admissions) at 100_100. Diagnosis consistency for gender and age followed a different pattern, increasing steadily from 40.98% (5576 of 13,607 admissions) and 50.91% (6927 of 13,607 admissions) at 100_0 to 58.94% (8021 of 13,607 admissions) and 66.82% (9089 of 13,607 admissions) at 100_75, but both became unmeasurable at 100_100.

Detailed Analysis at 100% Consistency and 50% Completeness Noise (100_50)

To gain deeper insights into how data quality changes during data integration under specific noise levels, this section provides a detailed analysis of the 100_50 noise level. Figure 5 presents the data quality scores at each step of the integration process, illustrating how completeness and consistency evolve as new data sources are incorporated.



At this noise level, where consistency noise is set to 100% and completeness noise to 50%, all relevant KG statements (100%) are modified, with 50% of them containing missing data. The introduction of ADMISSIONS caused time sequence consistency to decrease slightly to 98.64% (13,422 of 13,607 admissions). With CPTEVENTS added, this metric dropped to 96.94% (13,191 of 13,607 admissions), where it remained stable after DIAGNOSES_ICD. Procedure consistency for gender declined to 59.14% (8047 of 13,607 admissions), while procedure consistency for age dropped to 63.63% (8658 of 13,607 admissions).

As expected, missing data impacted completeness measures. "Essential variable" completeness declined sharply, reaching 85% after DIAGNOSES_ICD. "Conditional variable" completeness remained "N/A" for PATIENTS, ADMISSIONS, and CPTEVENTS. Once DIAGNOSES_ICD was incorporated, "conditional variable" completeness increased slightly to 1.45% (195 of 13,607 admissions), reflecting a minimal recovery of required data.

An analysis of data quality trends across other noise levels is provided in Multimedia Appendix 1, detailing variations in completeness and consistency scores under different conditions.

Discussion

Principal Findings

Our findings demonstrate consistent patterns in data quality dynamics across all noise levels, characterized by a progressive degradation in consistency scores and a steady decline in completeness as noise levels increase. The category of "essential variable" completeness deteriorates gradually as noise accumulates, while "conditional variable" completeness declines more sharply due to its dependence on relationships across data sources. Meanwhile, "time sequence" and "data type consistency" remain relatively stable, whereas procedure and diagnosis consistency degrade significantly based on integration order, underscoring the importance of cross-source attribute alignment.

These trends confirm the adaptability of the AIDAVA data quality framework, which maintains stability in core structural checks (eg, time and data type validation) even as data volume and disorder increase. AIDAVA's patient-level modularity enables SHACL validation to be performed independently per patient, supporting parallel processing and scalability. This design allows for incremental integration of new patient data without reprocessing the full dataset, making the framework suitable for real-time or batch-based deployments. However, the results also revealed that procedure and diagnosis consistency were more sensitive to integration order, emphasizing the need for targeted, domain-specific validation strategies during data merging.

To more explicitly frame these insights, the AIDAVA framework not only detects data quality issues with high granularity but also enables their continuous assessment throughout the integration pipeline. By embedding SHACL-based rules directly into the SKG and PHKG construction process, AIDAVA captures completeness and consistency violations both within and across data sources. This staged, rule-based validation empowers the framework to not only detect anomalies but also manage them by pinpointing their origin and timing—enabling early intervention and downstream reliability.

Completeness and Conditional Dependencies in Data Integration

When examining the completeness dimension, the results reveal distinct patterns of degradation across our 2 categories: "essential variable" and "conditional variable" completeness. As expected, both categories are increasingly affected as the completeness ratio level rises. However, their rates of decline differ, highlighting important nuances in their behavior during the integration process. "Essential variable" completeness steadily declines, suggesting that core patient attributes are progressively impacted by noise—particularly those embedded in the PATIENTS table. In contrast, "conditional variable" completeness cannot be meaningfully assessed until the final integration step, as it depends on the availability of interconnected variables across all datasets. This explains why intermediate scores are marked as "N/A" and only become valuable after the final source (DIAGNOSES_ICD) is added.

These findings emphasize that "conditional variable" completeness is inherently linked to the integration process itself rather than noise alone. Unlike "essential variable" completeness, which is primarily affected by missing values within a single dataset, "conditional variable" completeness is more directly influenced by the presence or absence of cross-source relationships. As a result, its behavior differs from other completeness measures, demonstrating that missing values alone do not dictate "conditional variable" completeness trends—rather, it is the sequence and completeness of integrated sources that determine its final value.

Consistency Challenges in Stepwise Data Integration

The consistency results reveal that step-by-step integration of data sources introduces challenges related to compliance with data type and time sequence consistency. However, these declines are relatively minor, suggesting that the overall format

XSL•FO
RenderX

of the ontology remains stable and that temporal relationships are preserved throughout the integration process. Notably, time sequence consistency exhibits only minor fluctuations, reinforcing its resilience to integration steps. In contrast, the categories related to procedure consistency and diagnosis consistency show more pronounced declines, highlighting the critical role of integration order in determining data quality outcomes. The results indicate that integrating the CPTEVENTS table first has a substantial impact on procedure consistency, causing notable drops in gender and age consistency. Similarly, the integration of DIAGNOSES_ICD exacerbates diagnosis-related inconsistencies, suggesting that diagnostic data is particularly vulnerable to integration-induced errors. This trend highlights that procedure and diagnosis consistency are more reliant on cross-source relationships and attribute alignment than on other categories, such as data type and time sequence consistency.

The findings suggest that a case-specific data quality strategy is essential when integrating different types of health data. This underscores the need for tailored validation approaches that consider the vulnerabilities of various clinical data types during integration. This need for targeted strategies is evident both within and across data quality dimensions. For instance, within consistency, procedure, and diagnosis categories exhibit greater instability, highlighting that medical domain-specific content is more sensitive to inconsistencies than general data attributes such as timestamps or data types.

Interdependencies Between Data Quality Dimensions

Beyond individual dimensions, these findings offer an in-depth perspective on the interrelationships between data quality dimensions, reinforcing the complex and dynamic nature of data quality in health data integration. While previous research has suggested that data quality dimensions are interrelated [42,46], our results offer a unique demonstration of how these interdependencies manifest in real-world integration scenarios. A key finding from the results is that consistency measures alone cannot be fully trusted without ensuring adequate completeness. The results reveal that missing data directly impacts the interpretability of consistency scores, making it difficult to determine whether the observed consistency is genuine or merely an artifact of incomplete data. When key information is missing, certain contradictions—such as conflicts between diagnoses and procedures—may go undetected, creating a false impression of data reliability.

These insights highlight the critical need for health data integration strategies that not only address individual data quality dimensions but also account for their interdependencies. Overlooking these relationships can lead to misleading assessments, where high consistency scores mask underlying data gaps, or missing values distort the true extent of consistencies. To ensure reliable data quality assessment, integration of data must prioritize completeness validation before consistency assessment, ensuring that inconsistencies are accurately detected rather than artificially hidden. By adopting an approach that considers both dimension-specific vulnerabilities and their cross-dimensional effects, we can enhance the integrity of downstream analyses, clinical decision-making, and secondary research applications—ultimately improving the reliability of integrated health data. Overall, our findings demonstrate that ontology-constrained SHACL validation enables interpretable, dynamic assessment of health data quality, with robustness across integration orders and degradation levels. This paper also extends prior research [47] (REF) by embedding semantic and clinical context into the data validation process. While existing tools such as OHDSI's Data Quality Dashboard provide valuable population-level data quality checks after extract, transform, load into the OMOP common data model (eg, conformance, completeness, and plausibility), AIDAVA complements these approaches by offering patient-level validation throughout the integration pipeline. This facilitates early detection and localized resolution of issues that might otherwise remain hidden in aggregate-level analyses.

Limitations

Several limitations must be acknowledged to contextualize the findings and guide future research directions. First, this study was conducted using the MIMIC-III dataset, a structured and deidentified critical care database. While this dataset provides a controlled environment for testing data integration, it does not fully capture the heterogeneity and complexity of live health care data environments. Relying on a single dataset also limits the generalizability of our findings, as results may differ across other institutions, coding practices, and patient populations. Although MIMIC-III was chosen for its structured format and public availability, access to additional well-curated benchmark datasets remains restricted due to privacy, licensing, and interoperability constraints. Future research should evaluate the framework on diverse, nondeidentified hospital datasets that better reflect real-world conditions. Second, this study simulated real-world data quality issues by introducing structured artificial noise, allowing for a systematic evaluation of the framework under different levels of data inconsistencies. However, artificial noise does not fully replicate the unpredictability of errors found in operational health data. Health datasets often contain context-dependent inconsistencies, undocumented missingness patterns, and human-introduced biases that cannot be easily simulated. Future research should explore how the framework performs when applied in a real-world scenario. Third, the AIDAVA framework evaluated consistency and completeness as the core data quality dimensions. However, other important dimensions, such as timeliness and uniqueness, were not explicitly assessed in this study. Future work should extend the framework to incorporate a broader range of quality dimensions, ensuring a more complete evaluation of integrated health data. Last, this study demonstrated the effectiveness of the AIDAVA framework in a controlled dataset; its scalability for large-scale, high-velocity health data integration was not examined in depth. Future research should investigate the framework's performance in large-scale deployments. Finally, while AIDAVA was tested using structured simulations, adapting the framework for use with unstructured or semistructured real-world data (eg, electronic health records or clinical registries) remains a future challenge. These sources often include free text, heterogeneous coding, and loosely structured formats that require preprocessing steps (eg, terminology mapping). Investigating these adaptations

XSL•FO
RenderX

is part of the ongoing research agenda within the AIDAVA project.

Conclusions

This study evaluated the AIDAVA data quality framework for its effectiveness in detecting and managing data quality issues—specifically completeness and consistency—during the integration of heterogeneous health data. Using the MIMIC-III dataset, we simulated real-world challenges by introducing structured noise and systematically assessed how the framework performed across different integration sequences and noise levels. The staged SHACL-based validation enabled fine-grained analysis of data quality at multiple points along the integration pipeline. Our findings show that the AIDAVA framework successfully identifies both missing and inconsistent data elements and provides interpretable feedback at each stage of transformation. Together, these findings support the AIDAVA framework's suitability for dynamic, life cycle–based data quality assessment. By enabling validation at each transformation step, the framework allows early detection, interpretable tracking, and strategic mitigation of data quality issues. Importantly, it encourages a holistic view of data quality—one that considers not only dimension-specific weaknesses but also how dimensions influence each other across the pipeline. As health systems increasingly rely on integrated datasets for clinical and research applications, frameworks such as AIDAVA provide essential infrastructure for building trust in secondary health data use.

Future Research

Future work should focus on improving the AIDAVA data quality framework by aligning SHACL shapes with the OMOP common data model [41] and comparing multiple integration orders to assess their impact on data quality. Developing an OMOP-based RDF schema and implementing SHACL constraints would also support interoperability with OHDSI tools and promote the broader adoption of semantic, constraint-driven approaches to data quality. Expanding SHACL validation to laboratory results, prescriptions, and other hospital records will enhance its clinical applicability. Additionally, developing more realistic noise introduction methods will better simulate real-world inconsistencies, strengthening the framework's robustness.

Acknowledgments

The authors are grateful to all the members of the AIDAVA consortium who diligently support the project with their expertise. A special thanks goes to the team at the Department of Advanced Computing Sciences, Institute of Data Science at Maastricht University, for their invaluable contributions in setting up the experiment and developing the mechanism for noise addition, which was essential for this study. The authors declare that financial support was received for the research, authorship, or publication of this paper. This work was supported by the European Union's Horizon Europe research and innovation program under grant agreements No. 101057062 (AIDAVA). Supported by a license waiver from SNOMED (Systematized Nomenclature of Medicine) International for a period of 2 years (2024-2025), on condition that SNOMED CT (Systematized Nomenclature of Medicine – Clinical Tems) is not used or deployed commercially. The work of the Swiss Partner (MIDATA) received funding by the Swiss State Secretariat for Education, Research and Innovation (SBFI), subvention contract 22.00093, REF-1131-52104.

Abstract

Background: Patients with stroke have high rates of all-cause readmission and case fatality. Limited information is available on how to predict these outcomes.

Objective: We aimed to assess whether adding the initial National Institutes of Health Stroke Scale (NIHSS) score or modified Rankin scale (mRS) score at discharge improved predictive models of 30-day nonelective readmission or 30-day mortality poststroke.

Methods: Using a cohort of patients with ischemic stroke in a large multiethnic integrated health care system from June 15, 2018, to April 29, 2020, we tested 2 predictive models for a composite outcome (30-day nonelective readmission or death). The models were based on administrative data (Length of Stay, Acuity, Charlson Comorbidities, Emergency Department Use score; LACE) as well as a comprehensive model (Transition Support Level; TSL). The models, initial NIHSS score, and mRS scores at discharge, were tested independently and in combination with age and sex. We assessed model performance using the area under the receiver operator characteristic (c-statistic), Nagelkerke pseudo-R^2, and Brier score.

Results: The study cohort included 4843 patients with 5014 stroke hospitalizations. Average age was 71.9 (SD 14) years, 50.6% (2537/5014) were female, and 52.1% (2614/5014) were White. Median initial NIHSS score was 4 (IQR 2-8). There were 538 (10.7%) nonelective readmissions and 150 (3.9%) deaths within 30 days. The logistic models revealed that the best performing models were TSL (c-statistic=0.69) and TSL plus mRS score at discharge (c-statistic=0.69).

Conclusions: We found that neither the initial NIHSS score nor the mRS score at discharge significantly enhanced the predictive ability of the LACE or TSL models. Future efforts at prediction of short-term stroke outcomes will need to incorporate new data elements.

ischemic stroke; readmission; predictive modeling; mortality; National Institutes of Health Stroke Scale; NIHSS; modified Rankin scale; mRS

Introduction

Stroke has a massive impact on patients, their caregivers, and the health system. Approximately 795,000 stroke cases occur annually in the United States. It is the fifth leading cause of death and the leading cause of long-term disability, with nearly 7 million stroke survivors in the United States. With an increasing aging population, it is estimated that nearly 4% of the US adult population would have had a stroke by 2030 [1]. It is all the more tragic that a substantial proportion of stroke survivors will be readmitted to the hospital: current 30-day all-cause readmission rates range from 6.5% - 24.3% and these rates increase to 30% - 62.2% within a year [2]. Mortality following the initial hospitalization is also substantial: the case fatality rate in the hospital is 5% - 7%, increasing to 13% - 15% at 30 days, and 25% - 30% by 1 year [3].

Nearly one-fifth of Medicare beneficiaries discharged from a hospital get readmitted within 30 days [4]. Spurred by a landmark paper by Jencks et al [5] hospitals across the United States have begun implementing strategies to identify and reduce avoidable readmissions. Furthermore, beginning in 2013, 30-day readmission rates for a hospital's Medicare patients with acute

XSL•FO
RenderX

myocardial infarction, heart failure, and pneumonia have been compared with the expected rate of readmissions, using risk adjustment to account for age, gender, medical diagnosis, and selected medical history. Under the Hospital Readmissions Reduction Program, Medicare penalizes hospitals for higher-than-expected rates of readmissions among patients with these diagnoses [6,7]. Additional conditions are likely to be added in the future.

Given the clinical and policy significance of stroke, identifying factors that influence readmission risk is important to assist clinicians and hospitals in the care of patients with stroke and to prevent the preventable. Many factors may contribute to a hospital's readmission rate after stroke, including patient preferences, demographics, socioeconomic status, comorbidities, stroke severity, health system, clinical care or process, and health outcome. It is important that the risk adjustment mechanisms account for these factors so that hospitals caring for a more complex patient mix are not unduly penalized for readmissions.

The purpose of our investigation was to determine whether we could develop predictive models, specific to patients with stroke, for nonelective readmission or death within 30 days after hospital discharge. In these models, we assessed the ability of commonly used administrative data, newer predictors from the electronic health record (EHR), and 2 manually assigned stroke-specific scales (National Institutes of Health Stroke Scale [NIHSS] and modified Rankin scale [mRS]).

Methods

Study Setting

Kaiser Permanente Northern California (KPNC) provides care at 21 Joint Commission certified stroke centers serving 4.5+ million members, who are highly representative of the ethnic and socioeconomic diversity of the surrounding and statewide population [8]. There are approximately 1.3 million ED visits and 3500 ischemic stroke discharges per year. Patients are cared for by a single provider group of 9600 physicians (including approximately 100 neurologists) of The Permanente Medical Group, Inc. In 2016, KPNC implemented the Stroke EXPRESS (Expediting the Process of Evaluating and Stopping Stroke) program [9]. The program included immediate evaluation by a teleneurologist, expedited intravenous thrombolytic treatment, rapid computed tomography angiographic study, and expedited transfer and treatment for patients with large vessel occlusion. Deployment of the Epic EHR [10] was completed in mid-2010.

Study Cohort

The study cohort included patients meeting the following criteria: (1) admitted to a KPNC hospital between June 15, 2018, and April 29, 2020, (2) at least 18 years of age, (c) diagnosis of incident ischemic stroke (*ICD-10* codes: I63.xx, see Multimedia Appendix 1), and (4) for patients who experienced interhospital transport, the first hospital stay was at a KPNC hospital. Patients with in-hospital deaths were excluded from the final analysis of the study cohort.

The dependent variable for our analyses was a composite outcome (nonelective readmission or death within 30 days of discharge from index event). We defined nonelective readmission as one that began in the emergency department. These were captured from KPNC databases using methods we have recently described [11].

Data Collection

We obtained the following data elements for all patients directly from the EHR: demographic data; traditional claims (administrative) data (admission and discharge dates, diagnosis and procedure codes, and discharge disposition); newer clinical data such as laboratory test results; vital signs; neurological examinations as recorded in nursing flow sheets; admission and discharge care directives (code status) [12]; bed histories [13]; and length of stay. We assigned all patients a Charlson Comorbidity Index score [14].

As a measure of stroke severity, we captured the initial NIHSS score [15] electronically from the EHR. NIHSS score ranged from 0 to 42, with higher score indicated higher severity and poorer prognosis. Preferences were given to NIHSS performed by neurologists, then by emergency department physicians, then by hospitalists, and finally by nursing. As a measure of functional status at the time of discharge which may influence the patient's ability to care for self at home and subsequently contribute to readmission, we captured the modified mRS at discharge, which has been mandated for all patients with stroke. The mRS score ranged from 0 to 6, with 0 being no disability and 6 being dead. On a daily basis, the study team identified all patients with stroke admitted in KPNC hospitals. This list was reviewed by 2 research assistants who communicated daily with the local stroke coordinators to ensure that the mRS score has been completed before discharge. If unable to complete before discharge, the research team contacted the patients and their caregivers to complete the equivalent mRS-9Q [16] through phone within 7 days of discharge. The mRS-9Q has been validated for use in person or by telephone.

We also evaluated the following in-hospital data elements as potential predictors: presence of a foley catheter, feeding tube, tracheostomy, peg tube, whether an interpreter was needed, and Functional Independence Measurement (FIM) [17,18] score components. However, the rate of missing data was high without full individual chart reviews (for example, the FIM was only found in 11% of hospitalizations). We did not include these variables in our analyses. Validation of these variables was beyond the scope of our project at this time.

We also captured patients' longitudinal comorbidity burden and severity of illness at admission. At KPNC, all adults with a medical record number are assigned a Comorbidity Point Score monthly, version 2 (COPS2), which is based on CMS Hierarchical Condition Categories (score range, 0 - 1014 [scores above 300 are rare], with higher scores indicating increased mortality risk) [12]. The score is assigned based on all diagnoses a patient has accrued in the preceding 12 months. Patients are also assigned a Laboratory-based Acute Physiology Score, version 2 (LAPS2; range 0 - 414 [scores above 200 are uncommon] on admission and every hour after hospitalization, with higher scores indicating worsening instability). The LAPS2 incorporates patients' vital signs, neurological status checks, pulse oximetry, and 16 laboratory tests. For example, in July

XSL•FO
RenderX

2018, the median hourly LAPS2 among all patients in the intensive care unit was 110, whereas the median ward score was 52. It is not possible to admit a patient to KPNC hospitals without specifying code status, which can be subsequently updated. We classified each patient's care directive as full code or not (which included partial code, do not resuscitate, and comfort care only).

For our outcomes, we examined readmission within 30 days or mortality within 30 days postdischarge. For readmission and mortality within 30 days, there were no missing data. For those who were readmitted to a non-Kaiser hospital, we identified their readmission through claim data. The study was limited to health plan members only, for whom we had full data on mortality.

Using the above data elements, we assigned all patients a LACE (Length of Stay, Acuity, Charlson Comorbidities, Emergency Department Use) score [19], which is commonly employed in some Kaiser Permanente regions as well as in other hospital systems. The LACE is widely used to predict a 30-day readmission or mortality composite outcome. We also assigned patients a Transition Support Level (TSL) score [20]. The TSL, an automated score that was developed in KPNC included the LAPS2, COPS2, recent use, and a patient's care directive on the day of discharge, was assigned in real time daily to all KPNC hospitalized adults.

The paper adheres to recommended reporting guidelines for observational studies, and the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines (Checklist 1) were followed.

Statistical Analysis

We performed bivariate comparisons using chi-square and *t* tests. We fit logistic regression models to predict the composite outcome. We tested the following as independent predictors: NIHSS, mRS, LACE, and TSL; the individual components of the LACE and TSL; and combinations of these (NIHSS+age+sex; MRS+age+set; LACE+NIHSS, LACE+MRS; TSL+NIHSS, TSL+MRS). To establish the probable maximum performance of these predictors, we also tested a random forest model that included age, sex, NIHSS, mRS, and all of the individual predictors included in the LACE and TSL.

We evaluated model performance using the area under the receiver operator characteristic curve (c statistic, the Nagelkerke pseudo-R^2, and the Brier score) [21-23]. All models were assessed using 5-fold cross validation, and the models' performance metrics are those based on 5-fold cross validation. All analyses were done in SAS (version 9.3; SAS Institute).

Ethical Considerations

All KPNC facilities are under the jurisdiction of one institutional review board for the protection of human participants. This study was approved by the KPNC Institutional Review Board, which waived the requirement for written informed consent (IRB number: 1279378). Only aggregate data is provided here. Participants received no compenstation from the study.

Results

Between June 15, 2018, and April 29, 2020, there were 5808 hospitalizations for adult patients with ischemic stroke. Of these 5808 hospitalizations, 794 (13.7%) were excluded from the study analysis because the patient died during the index hospitalization (n=198, 3.4%), the hospitalization originated at a non-KPNC facility (n=504, 8.7%), or follow-up data was incomplete (n=92, 1.6%). The final study population included 5014 hospitalizations. The average age of the study population was 71.9 (SD 13.99) years and 49.4% (2477/5014) of patients were male. The racial and ethnic distribution was 52.1% (2614/5014) White, 15.6% (782/5014) Hispanic, 15% (751/5014) Asian, and 14.3% (718/5014) Black. The median initial NIHSS score was 4 (IQR 2-8). The average mRS score at discharge was 2.8 (SD 1.64). Mean length of stay was 6.5 days (SD 7.71), and 55% (2756/5014) were discharged home. Table 1 presents the other characteristics of the study population.

Out of 5014 hospitalizations, 688 (13.7%) had a nonelective readmission within 30 days or died within 30 days postdischarge (composite outcome). Out of 5014 hospitalizations, 492 (9.8%) had a readmission only within 30 days, 150 (3.0%) died with no readmission within 30 days, and 46 (0.9%) had both a readmission within 30 days and died within 30 days (see Figure 1 and Table 1). Patients who died but had no readmission within 30 days, had an elevated history of atrial fibrillation (47/150, 31.3%). Patients who had no readmission or death within 30 days tended to be more likely to have received alteplase during the index hospital stay (639/4326, 14.8%). The proportion of patients with full code orders at discharge varied across patient groups (range 8.7%-80.4%). The proportion of patients who were discharged home after the index event varied by outcome group. Of those who were both readmitted and died, 28% (13/46) had been released to home, compared with 40.7% (200/492) of those who were readmitted and alive, and 56.2% (2433/4326) of those who were alive and had no readmission. In total, 50% of patients (23/46) who died within 30 days but had no readmission within 30 days, had been released to a regular (noncustodial) skilled nursing facility. Furthermore, 4% (6/150) of patients with death but no readmission, were originally discharged to a custodial skilled nursing facility (Table 1).

For hospitalizations that resulted in readmission within 30 days or death within 30 days post-discharge, the patients tended to be older (median age 78, IQR 68-86 years vs 72, IQR 62-82 years), were less likely to be male (290/688, 42.2% vs 2187/4326, 50.6%; $P<.001$), and more likely to have a Charlson comorbidity score greater than or equal to 4 (387/688, 56.3% vs 1584/4326, 36.6%; $P<.001$). More patients without the composite outcome had full code care directive at discharge (3476/4326, 80.4% vs 402/688, 58.4%; $P<.001$; see Table 2).

Table 3 shows results from performance testing of several multivariable predictive models of the composite outcome. The best performing models were TSL (c-statistic=0.685) and TSL plus mRS score at discharge (c-statistic=0.694). The model with TSL+NIHSS performed similarly (c-statistic=0.684) to the model with TSL alone (Table 3).

[a]KFHP: Kaiser Foundation Health Plan.

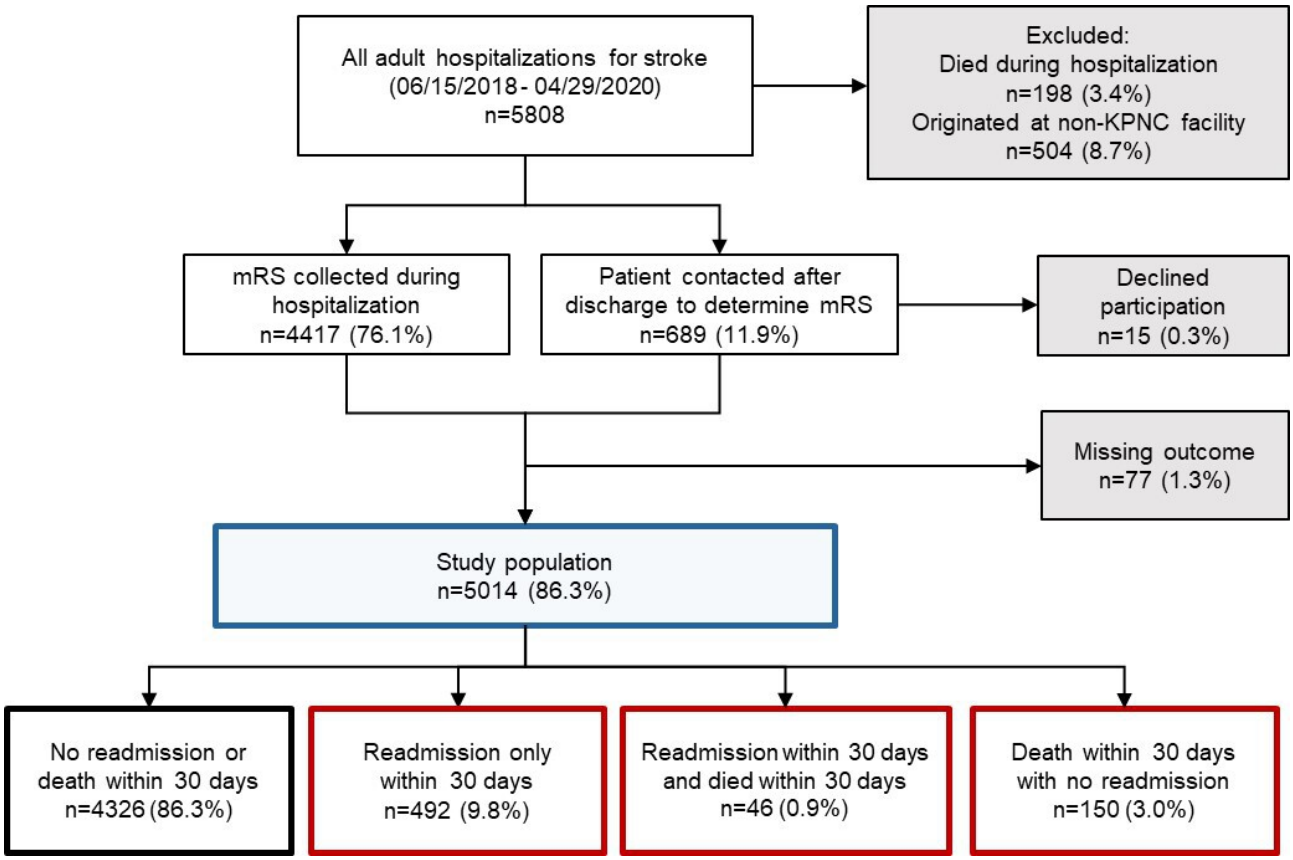
[b]COPS2: Comorbidity Point Score, version 2.

[c]COPS2 (range: 0 to 1010; higher scores indicate increasing comorbidity burden) is assigned based on all diagnoses incurred by a patient in the 12 months preceding the index hospitalization. The univariate relationship of COPS2 with 30-day mortality is as follows: 0-39, 1.7%; 40-64, 5.2%; 65+,9.0%. See Escobar et al [12] for details.

[d]LAPS2: Laboratory-based Acute Physiology Score, version 2.

[e]LAPS2 (range: 0 to 414; higher scores indicating increasing physiologic derangement) is assigned based on a patient's worst vital signs, pulseoximetry, neurological status, and 16 laboratory test results in the 72 hours preceding hospitalization. The univariate relationship of an admission LAPS2 with 30-day mortality is as follows: 0-59, 1.0%; 60-109, 5.0%; 110+, 13.7%. See text and Escobar et al [12] for details.

[f]mRS: modified Rankin Scale.



[g]NIHSS: National Institutes of Health Stroke Scale.

[h]LOS: length of stay.

[i]CSNF: custodial skilled nursing facility.

[j]RSNF: regular skilled nursing facility.

Figure 1. Definition of study cohort. Eligible patients are those patients meeting the following criteria: (1) admitted to a KPNC hospital between June 15, 2018, and April 29, 2020; (2) age ≥18 years; (3) diagnosis of incident ischemic stroke; and (4) for patients who experience interhospital transport, the first hospital stay was at a KPNC hospital. KPNC: Kaiser Permanente Northern California; mRS: modified Rankin Scale.

[a]Not available.

[b] ED: emergency department.

[c] CCI: Charlson Comorbidity Index.

[d]CCI score (range 0-40; higher scores indicate greater comorbidity burden) was calculated using the methodology of Deyo et al [14].

[e]Length of stay is extracted in hours and reported in days, rounded to the nearest 0.1 day.

[f]mRS: modified Rankin Scale.

[g]mRS score range is 0-6 (0=no symptoms at all,1=no significant disability despite symptoms, 2=slight disability, 3=moderate disability, 4=moderately severe disability 5=severe disability/bedridden, 6=dead). See text and van Swieten et al [24] for details.

[h] NIHSS: National Institutes of Health Stroke Scale.

[i]NIHSS score range is 0-42 (0-5 typically indicates minor stroke; higher scores indicate more severe stroke). See text and Brott et al [25] for details.

[j]Assignment is based on patient's last care directive before discharge.

[k]LACE: Length of Stay, Acuity, Charlson Comorbidities, Emergency Department Use.

[l]LACE score range is 0 to 19, with higher scores indicating increased risk of the composite outcome. See text and van Walraven et al [19] for details.

[m]COPS2: Comorbidity Point Score, version 2.

[n]COPS2 (range: 0 to 1010; higher scores indicate increasing comorbidity burden) is assigned based on all diagnoses incurred by a patient in the 12 months preceding the index hospitalization. The univariate relationship of COPS2 with 30-day mortality is as follows: 0-39, 1.7%; 40-64, 5.2%; 65+, 9.0%. See Escobar et al [12] for details.

[o]LAPS2: Laboratory-based Acute Physiology Score, version 2.

[p]LAPS2 (range: 0 to 414; higher scores indicating increasing physiologic derangement) is assigned based on a patient's worst vital signs, pulse oximetry, neurological status, and 16 laboratory test results in the 72 hours preceding hospitalization. The univariate relationship of an admission LAPS2 with 30-day mortality is as follows: 0-59, 1.0%; 60-109, 5.0%; 110+, 13.7%. See text and Escobar et al [12] for details.

[q]Number with any hospitalizations in the 30 days preceding the index hospitalization.

[r] TSL: transition support level.

[s]This is expressed as a % risk of the composite outcome within 30 days of hospital discharge. The score incorporates the LAPS2, COPS2, discharge care directive, and previous hospitalizations in the 30 days preceding the index hospitalization. Patients with TSL scores ≥25% are enrolled in Kaiser Permanente Northern California readmission prevention program. See text and Escobar et al [20] for details.

TSL[e]	0.69	0.08	0.11
TSL+NIHSS	0.68	0.09	0.11
TSL+mRS	0.69	0.10	0.11
Random forest[f]	0.66	0.04	0.11

[a]All models except the random forest model employed logistic regression. Metrics reported: c-statistic (area under the receiver operator characteristic curve); Nagelkerke pseudo-R^2 (Nagelkerke [22] and Brier score [23].

[b]NIHSS: National Institutes of Health Stroke Score (range 0-42; higher scores indicate more severe stroke). See text and Brott et al [25] for details.

[c]mRS: modified Rankin Scale, (range 0-6; higher scores indicate severe disability or death). See text and van Swieten et al [24] for details.

[d]LACE: Length of Stay, Acuity, Charlson Comorbidities, Emergency Department Use. Score range is 0 to 19, with higher scores indicating increased risk of the composite outcome. See text and van Walraven et al [19] for details.

[e]TSL: Transition Support Level. This score is expressed as a % risk of the composite outcome within 30 days of hospital discharge. The score incorporates the Laboratory-based Acute Physiology Score, version 2; Comorbidity Point Score, version 2; discharge care directive; and previous hospitalizations in the 30 days preceding the index hospitalization. Patients with TSL scores ≥25% are enrolled in Kaiser Permanente Northern California readmission prevention program. See text and Escobar et al [20] for details.

[f]For the random forest model, we included age, sex, NIHSS, mRS, and all subcomponents of the LACE and TSL scores.

Discussion

We have completed a study where we developed an adult patient stroke-specific predictive model for a composite outcome of readmission within 30 days and mortality within 30 days postdischarge. Among the models that were tested, the TSL model performed the best. Adding manually assigned stroke scales such as initial NIHSS (as a measure of stroke severity) and mRS at discharge (as a measure of functional status) to clinical data from a comprehensive EHR did not improve the performance of the TSL model significantly. The previously published TSL model [20] included an extensive amount of data for each patient including the LAPS2, COPS2, discharge care directive, and previous hospitalizations in the 30 days preceding the index hospitalization. Some of these data (such diagnoses in the previous 12 months before hospitalization, vital signs, laboratory data, and code status) were unique to our dataset and were never examined in previously published studies on 30-day readmission or mortality poststroke.

Readmissions after stroke are associated with worse disability, higher mortality, and higher costs of care [26,27]. Reduction of 30-day readmission is a quality metric set by the Centers for Medicare & Medicaid Services. Publications on readmission have been more focused on reported global performance and other conditions, and less so on stroke. In addition, most previous studies excluded patients aged <65 years. Being able to predict readmission after stroke may help to identify high-risk patients for targeted interventions and postdischarge programs, limit preventable readmissions, and improve long-term outcomes.

Previously published studies on readmissions after stroke provided only limited data on patient-level factors in their risk analysis. A systematic review of stroke readmission in 2010 identified only 16 published studies that reported risk-adjustment models at the patient level [2]. Considerable variation in reported outcomes was identified: 30-day all-cause readmission rates ranged from 6.5% to 24.3%, 1-year all-cause readmission rates from 30% to 62.2%, 30-day stroke-related readmission from 7.4% to 9.4%, and 1-year stroke-related readmission from 10.5% to 31.1%. Patient characteristics that were found to be associated with stroke readmissions included age, longer index hospital length of stay, worse physical functioning after stroke, and increased number of hospitalizations before stroke. Although some of these included stroke severity measures, no consistency existed across the models. A statement from the American Heart Association on risk adjustment of ischemic stroke outcomes for comparing hospital performance emphasized a minimum list of patient-level variables including age, sex, stroke severity, comorbid conditions, and risk factors [3]. However, in order to improve the usability of risk-adjusted models, the statement recommended that researchers should try to identify other factors, especially those not typically measured in administrative databases. To our knowledge, no previously published models on 30-day readmission or 30-day mortality included the mRS at discharge (a functional status assessment).

XSL•FO
RenderX

A number of studies on readmission and mortality poststroke used Medicare database therefore restricting their cohorts by older age and limited the generalizability of their results [28,29]. Our 30-day readmission rate of 9.7% was lower than rates (12% - 14%) reported from those studies using Medicare data. However, advanced age is associated with increased readmission after ischemic stroke [29]. On the other hand, a recent analysis of 30-day readmission after ischemic stroke for adults 18 years and older using the 2019 Nationwide Readmission Database reported a rate of 9.7%, which was nearly identical to ours [30].

For our cohort, the rate for 30-day mortality postdischarge was 3%, and the inpatient mortality rate was 3.4%, totaling 6.4% for 30 days from admission. Studies from Canada and the United Kingdom reported a 30-day mortality rate from admission of about 12% [31,32]. A US study using Medicare data reported a 30-day mortality rate of 13.6% [33]. Our lower 30-day mortality rate may be a reflection of a cohort of patients with insurance and access to care, inclusion of younger patients (ages 18 years and older), and an excellent performance of acute stroke treatment time as previously published [9].

The current state of predictive analytics for hospital readmission has not evolved enough to guide effective prevention efforts [4,5,34,35]. In addition, medical record technology, along with other aspects of health care in the United States is both fragmented and—from an informatics perspective—heterogeneous. Some institutions, such as university medical centers and KPNC, have sophisticated EHRs, while others still use paper charts. Similarly, the ability of institutions to retrieve electronic data varies considerably, as does the timeliness of such retrieval. Given this heterogeneous information environment, it is important to (1) highlight desirable characteristics of future readmission predictive models for patients with stroke, and (2) develop models that can be instantiated in different settings (ie, ranging from those using only claims data to those that use comprehensive EHRs). This would permit the development of modular approaches that individual institutions could adapt to their specific circumstances.

It was not surprising that models using only administrative data (LACE) did not perform well. However, it was disappointing that the TSL model with inclusion of detailed EHR data (longitudinal comorbidity in the 12 months preceding index hospitalization, COPS2; and LAPS2) did not result in great discrimination. Adding the initial NIHSS score and the mRS score at discharge to the model did not improve its performance, perhaps because the TSL model at baseline already contained other data elements relating to patient status and severity of their condition while hospitalized. NIHSS and mRS were moderately correlated to LAPS2 score, LACE, and TSL. We did not have other potential measures of stroke severity such as infarct size from neuroimaging study, or change in mRS at discharge compared with baseline prehospital mRS, or mRS postdischarge.

Our study had several strengths. Our approach synthesizes two types of expertise: deep understanding of the clinical aspects of stroke (including intimate familiarity with the current state of the art in assessment of its severity and prognosis) combined with sophistication in the area of predictive analytics. Tools developed by our experienced predictive analytics team have entered routine operations in one of the most advanced integrated health care delivery systems in the United States. We were able to characterize the study cohort better than has been done previously. The TSL model included detailed data from index hospitalization not in previous studies on readmission poststroke, including vital signs, laboratory data, patient's care directive and mRS score at discharge. This study was embedded in a community setting with comprehensive longitudinal information infrastructure. The study cohort was diverse in race-ethnicity and included all ages, not just Medicare-eligible patients. We used prospective validation. All analyses were based on two basic data standards: claims data (functionally, the lowest common denominator) and modern EHR data. This study started from the premise that prediction of a patient with stroke's risk for readmission should be automated, presented through a comprehensive EHR, and occur in real time.

There were also limitations with our study. We relied on data collected in the course of routine clinical operations rather than strict research protocols. While our hospitals treat patients with stroke regardless of insurance, our study cohort and analysis were limited to an insured population with access to care to one of the most highly integrated health care delivery systems in the world. The study results may not be applicable to the uninsured population. All of our centers are Joint Commission certified stroke centers with the highest awards from the Get With the Guidelines program. More than 50% of acute ischemic stroke cases qualifying for intravenous thrombolytic were treated within 30 minutes [9]. Therefore, our study results may not be representative of all hospitals caring for patients with ischemic stroke. We did not have baseline functional status and, therefore, could not include a change in functional status to the models. We also did not have indicators for postdischarge functional status. We were unable to include other in-hospital data such as placement of feeding tube or trach due to a high rate of missing data perhaps due to difficulty with pulling correct data electronically. We did not have data on social support or a cognitive function measure at discharge, which may play a significant role in readmission. Our study results are generalizable to an adult population with ischemic stroke who have insurance and access to care who survive the index hospitalization and are treated in certified stroke centers.

In summary, we have tested a more comprehensive predictive model (TSL) for readmission and death within 30 days post ischemic stroke. Having a comprehensive look at the important factors that may influence that decision-making process (socioeconomic status, living arrangement or social support, functional status, code status, cognitive status, etc) would go a long way at improving the performance of a predictive model. Future studies should seek to improve upon our study and evaluate other factors not included here, such as changes from baseline functional status, the volume of brain infarcted, social support, and cognitive status at the time of discharge.

Abstract

Background: Pelvic organ prolapse (POP) and stress urinary incontinence (SUI) often concurrently exist. The incontinence in some patients with POP resolves after POP surgery, but it persists in others. Some patients without SUI before surgery may develop de novo SUI. It is unclear whether a concomitant anti-incontinence procedure should be performed at the time of POP surgery to prevent postoperative incontinence. A prediction model is needed to guide clinical decision-making.

Objective: This study aimed to analyze the risk factors and develop prediction models for SUI after POP surgery based on machine learning to provide new tools for evaluating and predicting postoperative SUI.

Methods: Sample size calculation was performed using the Riley 4-step method. Data of patients undergoing prolapse surgery in Shanxi Bethune Hospital were prospectively collected from August 2022 to February 2025 and were retrospectively collected from January 2021 to August 2022. General clinical data, relevant laboratory test results, urodynamic examination findings, and pelvic floor ultrasound findings were collected. Lasso regression, univariate analysis, and logistic analysis were used to screen the predictors of SUI after prolapse surgery. Data were split randomly in a 7:3 ratio into training and validation sets. The training set was used to develop the prediction model involving Lasso regression, random forest, support vector machine (SVM), extreme gradient boosting (XGBoost), classification and regression tree (CART), and logistic regression, and the validation set was used for internal verification. The final implementation was achieved by developing a Shiny-based application for model deployment.

Results: A total of 286 patients were enrolled in this study, and 91 patients had postoperative SUI. The following 6 risk factors were identified through univariate, logistic, and Lasso regression analyses: preoperative SUI, urge urinary incontinence, urodynamic occult SUI, anti-incontinence surgery, genital hiatus, and anterior colporrhaphy. Five prediction models were constructed by using logistic regression, random forest, XGBoost, SVM, and CART. Based on a comprehensive evaluation of model discrimination, calibration, and clinical utility, the SVM model demonstrated optimal overall performance, with an area under the curve of 0.821 in the training set and 0.846 in the validation set.

Conclusions: This study developed 5 prediction models for postoperative SUI following prolapse surgery, which demonstrated good performance in internal validation. Among them, the SVM prediction model appeared to be the most promising. However, further external validation data are required to assess its generalizability. This model has the potential to become a high-quality clinical risk prediction tool for postoperative SUI in patients with prolapse, guiding clinical decisions on whether concurrent prolapse and incontinence surgeries are necessary.

KEYWORDS

prediction model; pelvic organ prolapse; de novo stress urinary incontinence; machine learning; support vector machine

Introduction

Pelvic organ prolapse (POP) and stress urinary incontinence (SUI) are the 2 most common types of female pelvic floor dysfunctions. POP refers to the abnormal positioning and dysfunction of female pelvic organs (vagina, bladder, uterus, or rectum) caused by weak pelvic floor supportive tissues, which can lead to significant physical and emotional discomfort [1]. SUI refers to the involuntary leakage of urine during physical exertion, coughing, or sneezing (increased abdominal pressure) [2]. SUI occurs in 50% of patients with POP [3]. After POP surgery, 14.3% - 32.5% of patients have SUI, likely due to either uncorrected bladder neck defects after prolapse repair or the unmasking of pre-existing SUI symptoms that were

XSL•FO
RenderX

previously concealed by the kinking of the lower urinary tract during prolapse [4]. To reduce the risk of postoperative SUI, prolapse surgery and incontinence surgery can be performed concomitantly. However, concomitant operations have caused many patients who would not have SUI to undergo an unnecessary operation, and the current common operation for the treatment of SUI, midurethral sling, is often accompanied by many postoperative adverse reactions [5,6]. There is still no consensus on whether patients with coexisting POP and SUI should undergo staged surgeries or a concomitant anti-SUI surgery.

The risk factors for urinary incontinence after prolapse include point Ba (the lowest point of prolapse between point Aa anteriorly and the vaginal apex), preoperative SUI, preoperative occult SUI, diabetes, sacral colpopexy, etc [7,8]. A risk prediction model is a statistical model that estimates the probability of an individual having a certain outcome according to the risk factors of the disease. Predictive models for assessing SUI risk after prolapse surgery can effectively aid patient decision-making. Jelovsek et al [9] used data from the OPUS (Outcomes Following Vaginal Prolapse Repair and Midurethral Sling) trial to construct a predictive model for de novo SUI in patients with POP who do not have SUI before surgery, and the area under the curve (AUC) of this model was 0.72. Based on data from the CUPIDO (Concomitant Surgery and Urodynamic Investigation in Genital Prolapse and Stress Incontinence: A Diagnostic Study Including Outcome Evaluation) trial, van der Ploeg et al [10] developed a prediction model for postoperative SUI in patients with POP who did or did not have preoperative SUI. Compared with the model constructed using OPUS data, the predictive factor stress test was added. This prediction model has an AUC of 0.79. An article published in BJOG reviewed 1142 patients who underwent POP surgery from 2 tertiary hospitals in South Korea and developed a predictive model for SUI after prolapse surgery, with an AUC of 0.74 [11].

With the development of artificial intelligence in recent years, machine learning has become an important method in the field of predictive model construction. Compared to traditional methods, machine learning methods have higher predictive accuracy and are commonly used in the medical field to predict various outcomes [12,13]. In a study conducted by Peking Union Medical College Hospital in China, a predictive model was constructed for the first time using machine learning methods (logistic regression, random forest, and extreme gradient boosting [XGBoost]) [14].

Previous studies were retrospective, and the machine learning predictive model approach used only random forest and XGBoost methods. No prospective studies have been conducted to establish a predictive model for SUI after POP surgery. This study prospectively followed patients with POP and retrospectively collected data from additional POP surgical cases to increase the sample size. Detailed clinical parameters were obtained, including pelvic ultrasound findings, hematologic markers, and operations. Machine learning prediction models for postoperative SUI in patients with POP (with or without SUI) were developed and validated to enable more accurate risk stratification and clinical decision-making.

Methods

Study Design and Population

This study collected data prospectively from August 2022 to February 2025 and retrospectively from January 2021 to August 2022 from patients undergoing POP surgery at Shanxi Bethune Hospital in China. The study enrolled patients with Pelvic Organ Prolapse Quantification (POP-Q) stages II-IV, regardless of preoperative SUI status, who had undergone prolapse surgery or were scheduled to undergo prolapse surgery. The follow-up period was at least 6 months. The exclusion criteria were prior prolapse surgery and postoperative urinary tract infection.

The Riley 4-step method, specifically used in clinical prediction models, was adopted for sample size calculation [15]. This study developed binary prediction models with an anticipated 8 predictor parameters. For internal validation, the anticipated shrinkage level was set at 0.9. The postoperative SUI incidence rate at our hospital is approximately 30%. With an assumed model C-statistic of 0.8, we calculated the sample size requirement using the R package “pmsampsize.” The results showed that the minimum sample size required for the new model was 276.

Data Collection

Considering SUI risk factors in previous studies, relevant clinical characteristics of patients were collected, including age, height, weight, BMI, parity, vaginal delivery count, cesarean section count (due to low positive rates, this item was finally excluded), menopausal status, surgical age minus menopausal age, smoking history, type of medical insurance (Employee Basic Medical Insurance/Resident Basic Medical Insurance), educational background, preoperative estrogen supplement, postoperative estrogen supplement, preoperative SUI, preoperative urge urinary incontinence (UUI), hypertension, diabetes, comorbidities, POP-Q points and grade, biochemical indicators (albumin, liver function tests, and lipid profile; renal function tests were excluded due to low positive rates), cystocele Green type, residual urine, urodynamic occult stress urinary incontinence (UOSUI), urine leakage point pressure, anterior colporrhaphy performed (yes or no), perineal body reconstruction performed (yes or no), anti-SUI procedure performed (yes or no), hysterectomy performed (yes or no), and prolapse surgery method. Since urine leak point pressure only exists in patients with urodynamic stress incontinence, it is not conducive to model construction, and thus, it was not considered. Surgical methods for prolapse included colpocleisis, sacrospinous ligament fixation, round ligament suspension, high uterosacral ligament suspension, transvaginal mesh implantation, Manchester procedure, sacrocolpopexy, and lateral abdominal wall suspension. If only hysterectomy or anterior/posterior colporrhaphy was performed, the patient was coded as 0 in surgical evaluations. The operation for SUI was midurethral sling. Preoperative urinary incontinence status was determined through retrospective review of medical records combined with patient recall during postoperative follow-up. Postoperative SUI was defined as the reporting of bothersome SUI symptoms during any follow-up visit. Patients were followed up via outpatient clinic visits or telephone interviews.

XSL•FO
RenderX

Data Preprocessing

Smoking history was excluded because of more than 10% missing data and a low positive rate (2 out of 286). Educational background was excluded because of more than 10% missing data. The remaining missing values were multi-interpolated using the R package "mice." Patients with missing postoperative SUI outcomes were ultimately excluded from the study. Therefore, all postoperative SUI outcomes were based on the actual postoperative follow-up.

Model Development

Data were split randomly in a 7:3 ratio into a training set and a validation set. We ensured that there were no statistically significant differences in baseline characteristics between the training set and the validation set. The training set was used to develop the model, and the validation set was used for internal validation.

We performed 5-fold cross-validated Lasso (least absolute shrinkage and selection operator) regression using the R package "glmnet" to screen for predictive variables. Lasso regression was implemented with L1 regularization (tuning parameter λ) to select variables via coefficient shrinkage and prevent overfitting, thereby improving generalization. Multivariate logistic regression analysis was performed using the variables obtained by Lasso regression to construct a nomogram prediction model.

The decision tree model in this study was constructed based on the classification and regression tree (CART) method developed in 1984 [16]. CART analysis is a nonparametric, nonlinear method that generates binary trees by feature selection based on Gini index minimization criteria.

Random forest and XGBoost are both integrated machine learning methods based on decision trees. The random forest prediction model is created based on the bagging algorithm and can be used for both classification and regression analyses [17]. We developed the random forest model using bootstrap resampling techniques. We assessed feature importance in 2 metrics: mean decrease accuracy (based on permutation) and mean decrease Gini (based on Gini impurity). Considering the direct relevance of mean decrease accuracy to model prediction accuracy, its stronger robustness, and its better interpretability in clinical contexts [18,19], we ultimately selected the top 8 most predictive features based on the ranking results of mean decrease accuracy to construct the final model. XGBoost develops the model by gradually adding decision trees, each of which resolves the error weakness of the previous one to achieve an accurate classification effect [20]. The XGBoost model incorporates regularization terms based on tree complexity, effectively reducing overfitting and thereby enhancing generalization performance. XGBoost was configured to utilize the top 8 most important variables. The optimal parameters were selected via hyperparameter optimization, with additional L2 regularization (lambda) and L1 regularization (alpha) penalties incorporated to mitigate overfitting.

Support vector machine (SVM) is a powerful and versatile machine learning method that excels at both classification and regression tasks. Based on the limited sample information, it seeks the best compromise between the complexity and learning ability of the model. Its objective is to identify the optimal hyperplane that separates data into 2 distinct classes, where support vectors represent the critical data points that maximize the margin between the 2 classes. In this study, 4 SVM methods were employed: linear SVM, polynomial SVM, radial basis SVM, and sigmoid SVM. The kernel with the best performance was finally selected to develop the model [21].

The "glmnet," "rms," "random forest," "XGBoost," "e1071," and "rpart" packages in R software (R Foundation for Statistical Computing) were used to construct logistic regression, random forest, XGBoost, SVM, and CART prediction models.

Model Evaluation

The models were internally validated using validation sets. AUC, accuracy, precision, sensitivity, specificity, and F_1-score were used to evaluate the discrimination of the models. The prediction model calculated the AUC based on probability outputs. AUC values approaching 1.0 were considered to indicate superior predictive performance for postoperative SUI, while AUC values near 0.5 were considered to suggest limited clinical utility.

Model calibration was evaluated by both the Brier score and calibration curves. The Brier score quantifies prediction accuracy, with values approaching 0 indicating perfect prediction and values nearing 1 representing the poorest performance. Calibration curves were used to visualize the agreement between predicted probabilities and actual frequencies, where perfect calibration follows the 45-degree line.

Decision curve analysis (DCA) was used to evaluate the application value of the model in practical clinical decision-making and provide guidance for clinical decision-making.

Statistical Analysis

All data processing and statistical analyses were performed using R software (version 4.4.2). Numerical variables have been presented as mean (SD) for normally distributed data (analyzed with the Student *t* test) or median (IQR [P25, P75]) for nonnormally distributed data (analyzed with the Mann-Whitney *U* test). Categorical variables have been expressed as frequency (n) and were compared using chi-square tests.

Ethical Considerations

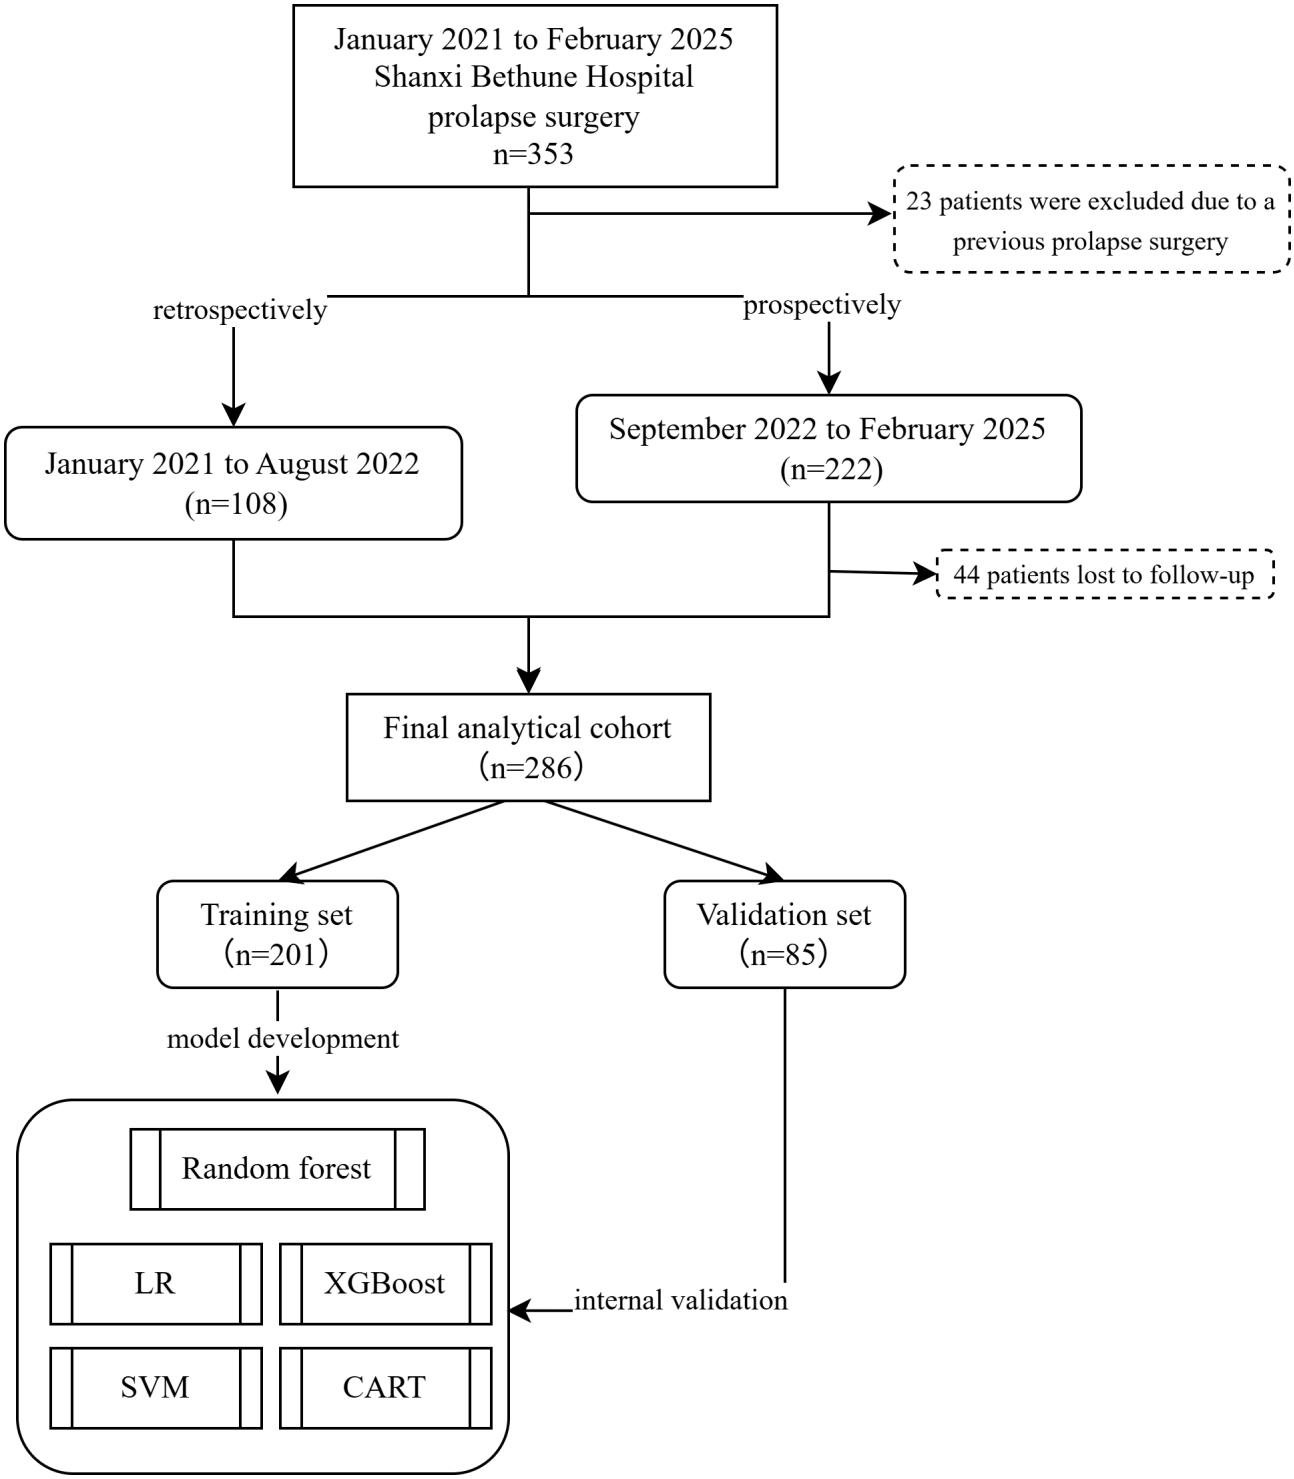
The study was approved by the Shanxi Bethune Hospital Medical Ethics Review Committee (YXLL-2025 - 072) and was performed in accordance with the principles of the Declaration of Helsinki. Written informed consent was obtained from each participant before taking measurements. All data were anonymized, and the study was conducted without offering any financial or material incentives to the participants.

Results

Clinical Characteristics

Between January 2021 and February 2025, 353 patients underwent prolapse surgery at Shanxi Bethune Hospital. Of

XSL•FO
RenderX



these patients, 23 were excluded due to a history of previous prolapse surgery, leaving 108 retrospectively enrolled patients from January 2021 to August 2022 and 222 prospectively recruited patients from September 2022 to February 2025. However, 44 patients were lost to follow-up. Thus, the final analytical cohort included 286 patients (Figure 1). These patients were randomly allocated to the training (n=201) and validation (n=85) sets in a 7:3 ratio, with no significant differences in baseline characteristics between the groups (all $P>.05$).

A total of 286 patients undergoing prolapse surgery were included, and of these patients, 91 (31.8%) developed postoperative SUI, including 27 (9.4%) with de novo SUI and 64 (22.4%) with persistent SUI. In univariate analysis, preoperative SUI, UUI, UOSUI, and longer genital hiatus were identified as significant predictors of postoperative SUI, while concomitant anti-SUI surgery was identified as a protective factor. Variables with $P\leq.05$ in univariate analysis are presented in Table 1.

Multivariate logistic regression analysis was performed for these 5 variables (Table 2). The results showed that preoperative SUI, UOSUI, length of genital hiatus, and concomitant anti-SUI surgery were influential factors for SUI after prolapse surgery.

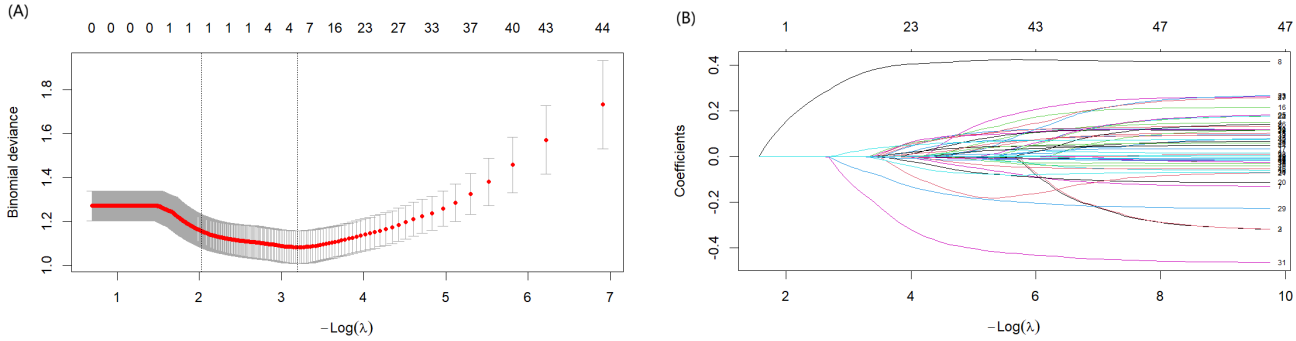
Model Development

Logistic Regression Predictive Model

Lasso regression was used to identify nonzero coefficient predictors from both the postoperative SUI and non-SUI groups, thereby refining the risk factors for postoperative SUI complications (Figure 2). The optimal λ value (0.041) was selected through 5-fold cross-validation, and 4 nonzero coefficient predictors were selected, including preoperative SUI, anterior colporrhaphy, anti-SUI surgery, and length of genital hiatus.

Subsequently, the risk factors selected by Lasso regression were incorporated into the logistic regression predictive model, with the corresponding nomogram presented in Figure 3. The model demonstrated an AUC of 0.817 (95% CI 0.755 - 0.880) in the training set, maintaining robust discrimination upon internal validation (AUC=0.869, 95% CI 0.791 - 0.947).

Figure 2. Lasso regression for filtered predictors. (A) Cross-validation error; (B) Coefficient paths.



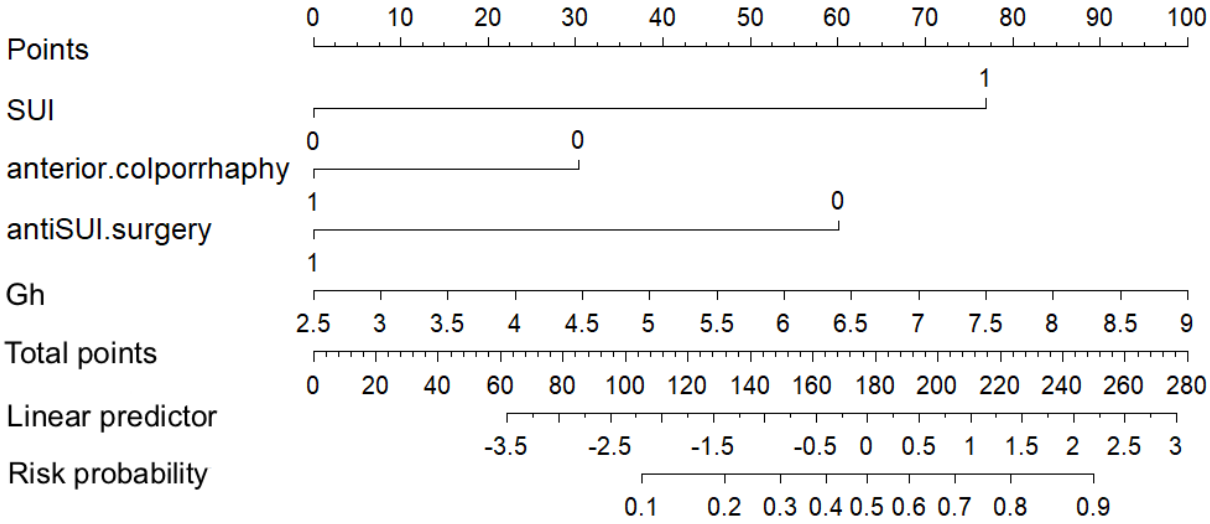


Figure 3. Logistic regression model nomogram. Gh: genital hiatus; SUI: stress urinary incontinence.

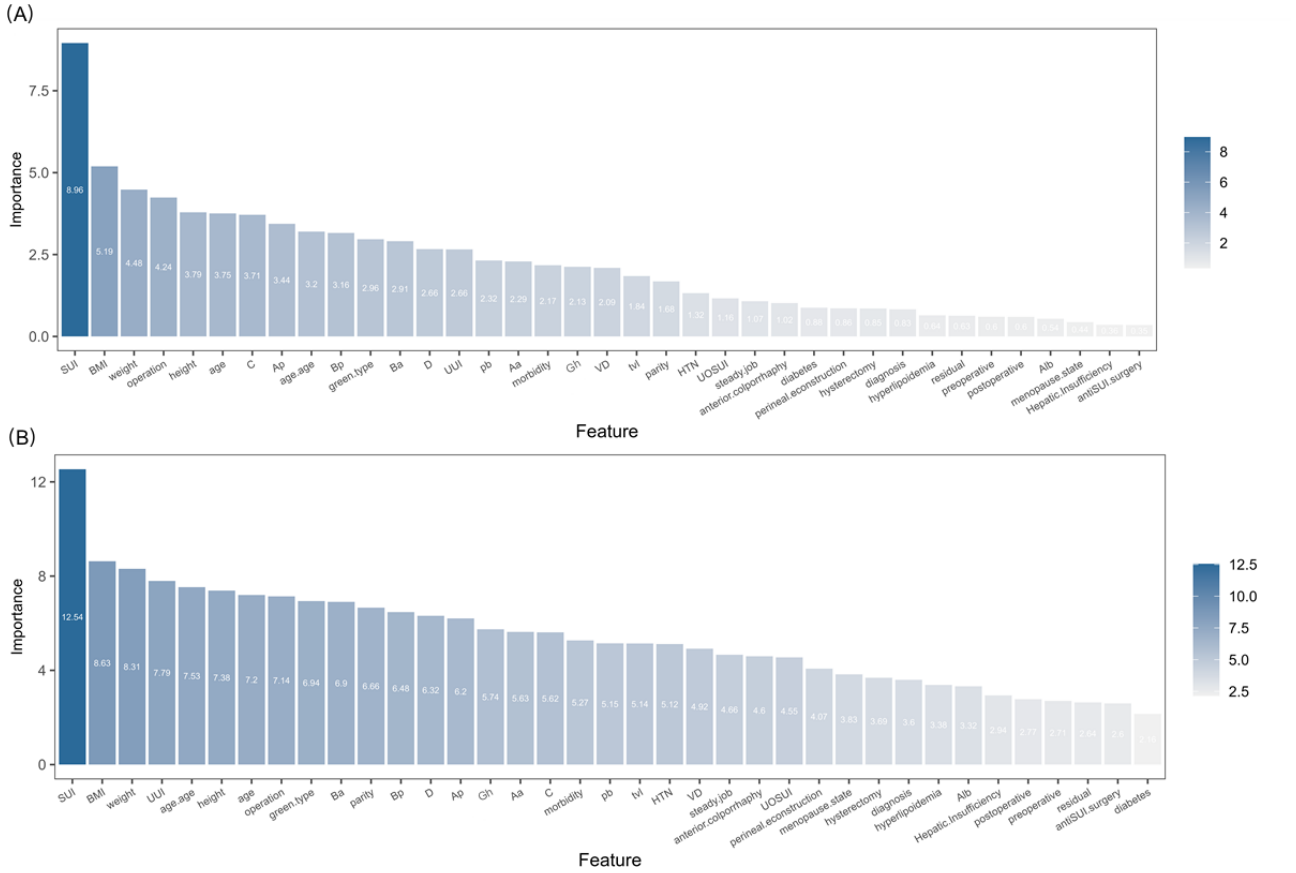

Random Forest Predictive Model

A preliminary random forest model was constructed with 38 variables, and the importance of the variables was calculated, as shown in Figure 4. We chose to include the top 8 features (SUI, BMI, weight, UUI, age at menopause, height, age, and operation) as ranked by mean decrease accuracy, since this measure more directly reflects a feature's contribution to classification performance and mitigates the evaluation biases associated with the Gini index. To optimize model performance, hyperparameter tuning was conducted through cross-validation to determine the optimal *mtry* value. Subsequently, the out-of-bag error was used to identify the ideal number of decision trees (ntree) for ensuring model stability and convergence. After parameter adjustment and bootstrap resampling (n=500 iterations), the parameters of the final random forest prediction model were set as follows: max_depth=5, min_samples_split=10, min_samples_leaf=5, mtry=3, ntree=146, maxnodes=20, and nodesize=5. The random forest model showed good differentiation in the training set (AUC=0.855, 95% CI 0.796 - 0.914), but the AUC dropped to 0.731 (95% CI 0.604 - 0.858) in the internal validation.

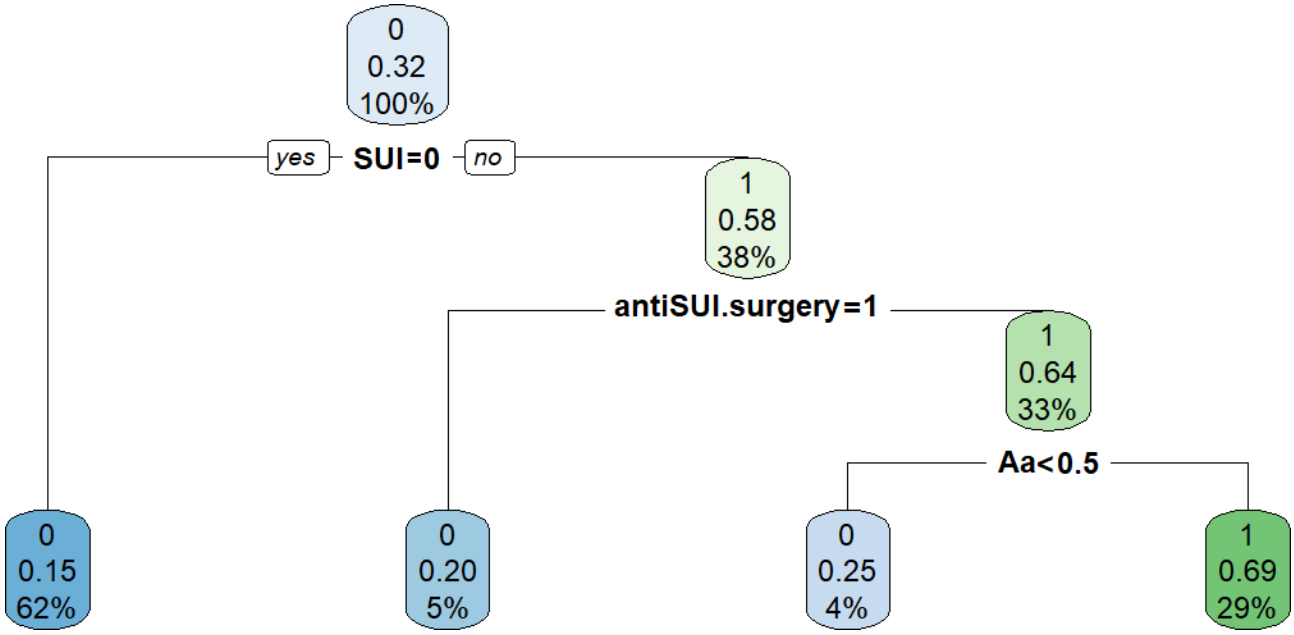
HTN: hypertension; SUI: stress urinary incontinence; UOSUI: urodynamic occult stress urinary incontinence; UUI: urge urinary incontinence; VD: vaginal delivery.

XGBoost Model

The regularization and early stop methods were used to reduce the overfitting of the model, and the optimal parameters and top 8 variables of importance were selected to build the XGBoost prediction model. The importance of accuracy based on the preliminary XGBoost model is shown below (Figure 5). After hyperparameter tuning by the train() function and 5-fold cross-validation, the final XGBoost model demonstrated enhanced predictive performance with the following configuration: eta=0.01, max_depth=3, gamma=0.1, colsample_bytree=0.8, min_child_weight=1, subsample=0.8, lambda=3, alpha=.5, early_stopping_rounds=10, and nrounds=200. The XGBoost prediction model had an AUC of 0.899 (95% CI 0.856 - 0.943) and an AUC of 0.783 (95% CI 0.680 - 0.886) in the training set.

Figure 5. Feature importance of the extreme gradient boosting model based on accuracy. HTN: hypertension; SUI: stress urinary incontinence; UOSUI: urodynamic occult stress urinary incontinence; UUI: urge urinary incontinence; VD: vaginal delivery.



CART Model

The CART model, after pruning according to the optimal complexity parameters (0.625), is shown in Figure 6, illustrating the final classification tree used to predict the occurrence of postoperative SUI. The CART model contained 3 branches based on 3 key predictive factors: preoperative SUI status, concomitant anti-SUI procedure, and POP-Q point C, which

XSL•FO
RenderX

simplified postoperative SUI assessment. The model directed "yes" responses to the left node and "no" responses to the right node. For patients without preoperative SUI (representing 62% of the cohort), the postoperative SUI probability was 0.15. The AUC of this decision tree model was 0.764 (95% CI 0.695 - 0.832). In the validation set, the AUC was 0.782 (95% CI 0.677 - 0.886). The model exhibited minimal overfitting.

Figure 6. Decision tree. SUI: stress urinary incontinence.

SVM Model

After hyperparameter tuning of the 4 kernel functions (linear kernel, radial base kernel, polynomial kernel, and sigmoid kernel), their accuracy, precision, recall, specificity, and F_1-scores were calculated, and the findings are summarized in Table 3. We observed that the sigmoid kernel predicted all samples as class 0. This phenomenon may be attributed to a mismatch between the sigmoid kernel function and the characteristics of the dataset in our study. Under the optimized hyperparameters (gamma=0.1; coefficient 0=3), the decision function values for all samples were negative (ranging from −0.92 to −4.05) and were classified as class 0 according to the decision rule of SVMs, resulting in the model's failure to form an effective classification boundary. Consequently, the precision, recall, and F_1-score of the sigmoid model were considered invalid.

The preliminary analysis found that the polynomial kernel SVM classifier had better performance than the other 3 kernel classifiers (Table 3), and thus, polynomial kernel modeling was selected. Finally, the SVM prediction model was developed with 4 variables obtained by Lasso regression. The AUC of the final SVM model was 0.821 (95% CI 0.760 - 0.883), and the validation set AUC was 0.846 (95% CI 0.757 - 0.936).

Comparison of the 5 Models and Applications

The performance metrics of all 5 models are summarized as follows: Figure 7A displays the combined AUC values for the training set, while Figure 7B presents those for the validation set. Except for the CART model, the AUC values of all other models were above 0.8, demonstrating excellent discriminative ability, while the AUC values in the validation set were above 0.7. Comprehensive evaluation metrics, including AUC, accuracy, precision, recall, specificity, and F_1-score, for the training set are detailed in Table 4, with corresponding validation set metrics provided in Table 5. Across all models, we observed a consistent pattern of relatively low recall coupled with high specificity.

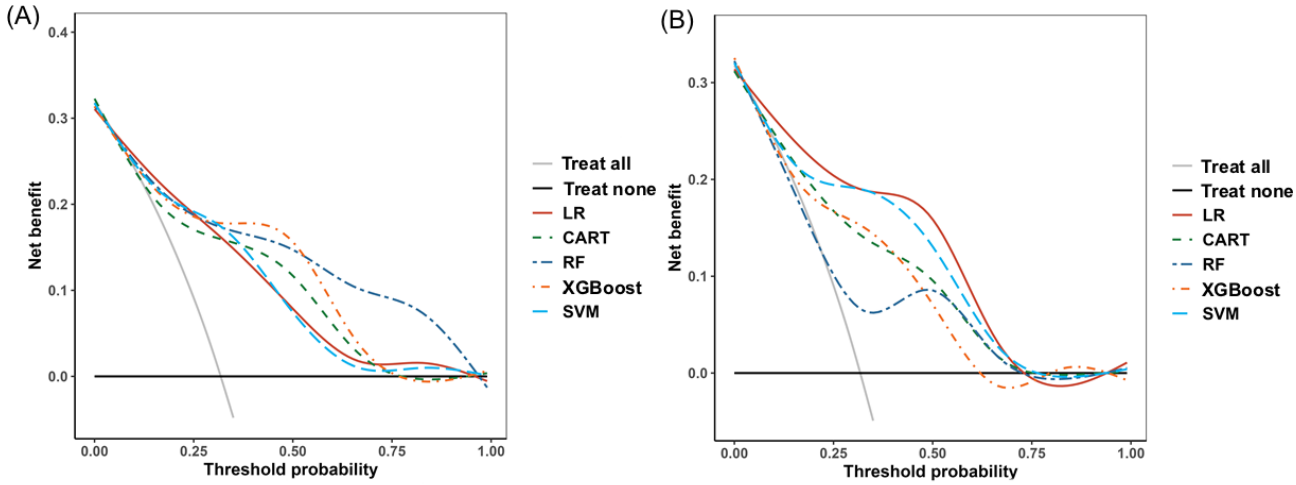
Figure 8 presents the Brier scores and calibration curves for the 5 models. Given that the CART model produces only 4 discrete predicted probabilities, its calibration curve was plotted directly using the binning method. The calibration curves for other models were generated using the Lowess smoothing method. The Brier index of the logistic regression model in the training

XSL•FO
RenderX

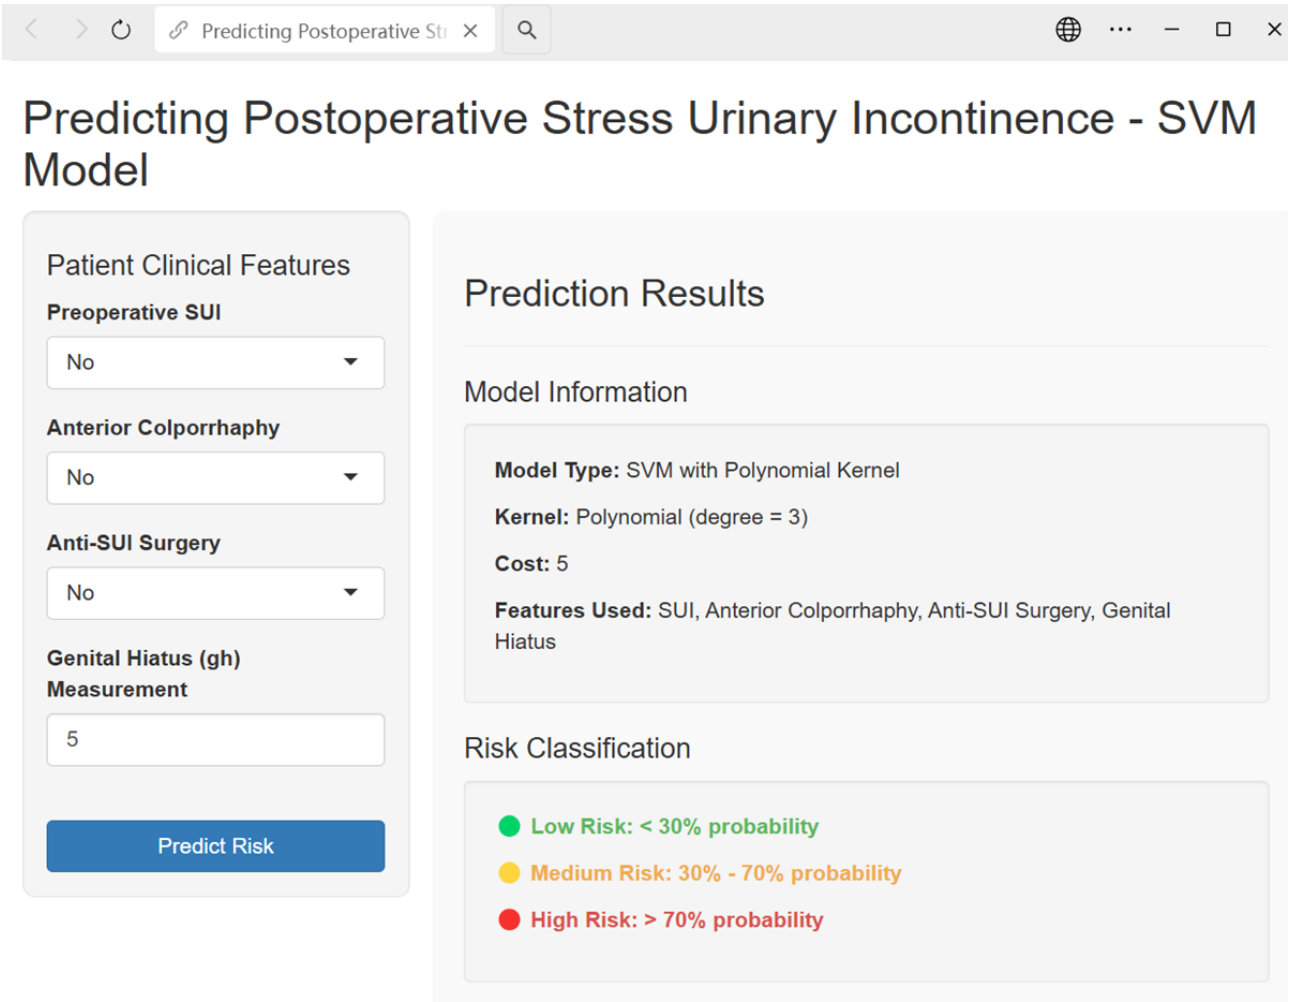


set was relatively high (0.259). The performance of the 5 models in the validation set was worse than that in the training set. It can be seen from the calibration curve that there is a high consistency between the predicted outcomes of the models and the actual outcomes of the training set (Figure 8A). The calibration of the validation set (Figure 8B) was worse than that of the training set.

Figure 8. Brier index and calibration curves of the 5 models. (A) Brier index and calibration curves in the training set; (B) Brier index and calibration curves in the validation set. BS: Blair score; CART: classification and regression tree; LR: logistic regression; RF: random forest; SVM: support vector machine; XGBoost: extreme gradient boosting.

From the DCA (Figure 9), in the training set, the curve of the XGBoost model (at predicted probabilities of 0.8 - 0.9) was slightly below the *treat none* curve, while all other models performed above both the *treat all* and *treat none* curves, demonstrating high net benefit. However, in the validation set's DCA, the overall performance was acceptable, though slightly inferior to that of the training set. Meanwhile, the logistic regression model appeared to achieve the highest net benefit in the validation set.

Figure 9. Decision curve analysis of the 5 models. (A) Decision curve analysis in the training set; (B) Decision curve analysis in the validation set. CART: classification and regression tree; LR: logistic regression; RF: random forest; SVM: support vector machine; XGBoost: extreme gradient boosting.



Overall, the logistic regression prediction model demonstrated a high AUC; however, its overall performance in terms of recall and F_1-score, as well as its calibration, was inferior to that of the other models. Both the random forest and XGBoost models exhibited an AUC difference of more than 0.1 between the training and validation sets, indicating a high degree of overfitting. The CART model offered advantages in ease of interpretation and demonstrated acceptable discriminatory power. However, due to its inherent algorithmic structure, the CART model produced a limited number of discrete risk categories (n=4), which consequently resulted in poor calibration performance.

The SVM model demonstrated good stability in AUC and DCA. However, DCA revealed its tendency to overestimate the probability of positive outcomes in negative cases and underestimate the actual risk in positive cases. It should be noted that this phenomenon in the calibration curve was not unique to the SVM model, as similar phenomena were observed in the other models. The SVM model seemed to have the best performance according to current data and analysis.

XSL•FO

In addition to the nomogram and decision tree, we developed prediction tools for the random forest, XGBoost, and SVM models using Shiny to facilitate clinical implementation, as illustrated in Figure 10.

Figure 10. Example of support vector machine model application.

Discussion

Principal Findings

This study analyzed the data from 286 patients who underwent prolapse surgery, obtained the risk factors for postoperative SUI, and developed 5 novel prediction models, including a conventional logistic regression–based model and 4 machine learning–based models (random forest, XGBoost, CART, and SVM). Among the models, the SVM prediction model demonstrated relatively robust performance.

Comparison With Prior Work

Jelovsek et al [9] developed the first logistic regression prediction model for SUI after prolapse surgery (termed the OPUS model) based on data from the OPUS trial, achieving an AUC of 0.72. Since the OPUS study exclusively enrolled patients without SUI, this model is only applicable to patients without SUI for predicting de novo SUI. External validation using data from the CARE (Colpopexy and Urinary Reduction Efforts) trial yielded an AUC of 0.62. When conducting external validation using available data from the CUPIDO trial, the model's AUC was 0.63 [22]. Yasa et al [23] reported a markedly lower AUC of 0.56 during external validation with data from the Istanbul University Faculty of Medicine, concluding that the OPUS model demonstrated poor diagnostic performance.

van der Ploeg et al [10] developed the second logistic regression prediction model for SUI after prolapse surgery based on data from the CUPIDO trial (termed the CUPIDO model), achieving an AUC of 0.76. The CUPIDO-1 trial enrolled 134 patients with preoperative overt SUI, and the CUPIDO-2 trial enrolled 225 patients with occult SUI. Consequently, this model is not well-suited for patients without either overt or occult SUI preoperatively. To date, no external validation of the CUPIDO model has been conducted.

Oh et al [11] developed the third logistic regression prediction model (termed the Oh model), which is applicable to all prolapse women, regardless of preoperative SUI status or prolapse surgery type, achieving an AUC of 0.78. They partitioned data in a 4:1 ratio, allocating 20% for external validation, which yielded an AUC of 0.73.

Fu et al [14] developed the first machine learning–based predictive model for postoperative SUI following prolapse surgery by using the retrospective data of 555 patients. The study used 3 modeling approaches: random forest, XGBoost, and logistic regression. The authors determined that the

XSL•FO
RenderX

XGBoost model demonstrated optimal predictive capability, with an AUC of 0.714 in the training set, 0.721 in internal validation using 5-fold cross-validation, and 0.704 in external validation with a randomly partitioned validation set. Regrettably, they only provide model parameters without the model application available.

In our study, 5 methods were used to construct the prediction model, covering tree model, linear model, and ensemble learning. It is suggested to use various methods to build a predictive model of machine learning and finally select the best model based on performance indicators [24]. Our prediction models, developed using retrospective and prospective data, are applicable to all patients with prolapse irrespective of the preoperative SUI status or prolapse surgical approach. Compared with previous random forest and XGBoost prediction models, the validation set randomly divided by our data had a higher AUC, and 2 other machine learning models were constructed: SVM and CART.

The logistic regression prediction model developed in our study demonstrated high AUC values in both the training and validation sets, though sensitivity and F_1-scores were slightly lower. The low incidence of SUI after prolapse may lead to an imbalance between positive and negative samples, resulting in high specificity and low sensitivity. In contrast, both the random forest and XGBoost models exhibited notable discrepancies between the AUC of the training set and that of the validation set, with validation AUCs remaining above 0.7 yet still demonstrating signs of overfitting. As ensemble methods based on decision trees, random forest and XGBoost typically resist overfitting; however, excessive tree numbers or depth may still lead to overfitting. Despite employing various mitigation strategies, including parameter tuning, bootstrap resampling, and 5-fold cross-validation, overfitting persisted. The reproducibility of machine learning models remains a significant challenge in health care applications [25,26]. Furthermore, the observed overfitting in these models may be partially attributable to insufficient sample size. For machine learning–based predictive models, larger datasets are typically required to ensure reproducibility. Although the CART model demonstrated inferior overall performance compared to other algorithms, it showed remarkable consistency between training and validation sets. Its user-friendly nature made it more applicable in clinical work. Notably, the SVM model exhibited better performance in the validation set compared to the training set, suggesting strong potential for clinical generalization.

Risk Factors for Postoperative SUI

Based on univariate analysis, multivariate logistic regression analysis, and Lasso regression analysis, several influencing factors of postoperative SUI were obtained: preoperative SUI, UUI, UOSUI, anti-SUI surgery, genital hiatus, and anterior colporrhaphy. SUI, UUI, and UOSUI are lower urinary tract symptoms closely related to POP. SUI is caused by the laxity of the local supporting structures of the bladder neck. In some patients undergoing POP surgery, the anatomical defects at the bladder neck remain uncorrected, leading to persistent SUI symptoms postoperatively [4]. Studies indicate that 5.2% - 31% of urinary incontinence persists after surgery [27,28]. In patients with UUI, surgery may not address the cause of UUI, and the implanted mesh and other irritative factors may even aggravate UUI. Nationwide prolapse surgery data from Finland suggested that de novo SUI occurs more frequently in patients with preoperative UUI [3].

Occult SUI refers to SUI after prolapse reduction, with an incidence of 23.5% - 42.5% [29,30]. With the progression of POP, particularly in cases of advanced anterior vaginal wall prolapse, the folding of the bladder and urethra may lead to the disappearance of SUI symptoms. After prolapse reduction, the fold of the lower urinary tract can be repaired, and the masked SUI symptoms will appear again [31]. Data from a randomized controlled trial suggested that 52% of patients with occult SUI progressed to SUI after surgery [32]. The International Continence Society, German Society of Gynecology and Obstetrics, and International Consultation on Incontinence recommend a preoperative urodynamic study to uncover occult SUI [30,33-35]. A prolapse reduction stress test for revealing occult SUI has been utilized in several predictive models [9-11].

Anterior colporrhaphy is a standard surgical procedure, just like appendectomy and tonsillectomy, and is widely performed around the world [36]. The principle of anterior colporrhaphy is based on the plication of the vesicovaginal fascia at the midline to strengthen the tissue between the vagina and bladder, previously known as the Kelly operation [37]. In the 1990s, multiple randomized controlled trials demonstrated that anterior colporrhaphy alone significantly improved SUI [38-40]. Bergman et al [38] reported an 82% cure rate for SUI following simple anterior colporrhaphy.

Genital hiatus length is defined as the distance from the external urethral meatus to the posterior edge of the hymen. An increase in genital hiatus may lead to a weakening of support for the urethra and bladder, contributing to the development of incontinence. A study about pelvic floor ultrasound and pelvic floor dysfunction found that women with urinary incontinence exhibited a longer genital hiatus [41,42]. A study by Huang et al [43] found that cystocele was associated with longer genital hiatus.

Advantages, Limitations, and Future Perspectives

This study developed CART and SVM models for predicting SUI after prolapse for the first time, and our random forest and XGBoost models also demonstrated superior discriminative ability compared to previous models. In addition, this is the first study to develop models incorporating prospective data for SUI after prolapse surgery, thereby reducing recall bias. Our 7:3 random split of the dataset into training and validation sets for internal validation provides greater representativeness than bootstrap resampling for internal validation [22].

This study has several limitations. First, the sample size was insufficient for robust machine learning prediction, and some models still exhibited overfitting. Second, external validation using independent datasets (eg, from other hospitals or regions) was lacking. Third, the inclusion of retrospective data introduced recall bias, and the absence of objective postoperative SUI assessments, such as standardized symptom quantification and pad tests, may have led to information bias. Additionally,

XSL•FO
RenderX

variability in POP-Q measurements across different clinicians over this long-term study might have contributed to measurement errors [44].

The 5 prediction models developed in this study demonstrated overall strong performance, with acceptable performance in randomly split internal validation. When considering discrimination, calibration, and clinical utility collectively, the SVM model appeared to exhibit robust performance. Based on both the current status of prediction models for SUI after prolapse surgery and this study's limitations, we recommend: (1) the publication of experimental data, (2) the establishment of large databases from prospective studies, and (3) the standardization of the diagnosis and treatment of POP. These steps are beneficial for reducing information bias, so as to establish a generalizable prediction model with high accuracy on a national and even global scale.

Conclusions

This study developed and internally validated 5 machine learning–based prediction models for SUI after prolapse surgery, which are applicable to all patients, regardless of preoperative SUI status and surgical approach. The model approaches included logistic regression, random forest, XGBoost, SVM, and CART. The SVM model demonstrated the most robust performance among all algorithms evaluated. We identified the following 6 predictive factors for postoperative SUI: preoperative SUI, UUI, UOSUI, concomitant anti-SUI surgery, genital hiatus, and anterior colporrhaphy. External validation is required to evaluate generalizability and determine the optimal model for clinical decision-making in postoperative SUI management.

Abstract

Background: In the rapidly evolving landscape of health informatics, adopting a standardized common data model (CDM) is a pivotal strategy for harmonizing data from diverse sources within a cohesive framework. Transitioning regional databases to a CDM is important because it facilitates integration and analysis of vast and varied health datasets. This is particularly relevant in China, where unique demographic and epidemiologic profiles present a rich yet complex data landscape. The significance of this research from the perspective of the Chinese population lies in its potential to bridge gaps among disparate data sources, enabling more comprehensive insights into health trends and outcomes.

Objective: This study aimed to understand biomedical professionals' and trainees' acceptance of the CDM in medical data management in China and to explore potential advantages and challenges associated with its promotion, implementation, and development in the country.

Methods: We conducted a questionnaire survey using Sojump and distributed it on WeChat to evaluate the Chinese population's acceptance of transitioning from local databases to a standardized CDM. The survey assessed participants' understanding of the CDM and the Observational Medical Outcomes Partnership CDM, as well as their views on the importance of CDM for regional databases in China. Analysis of the survey results revealed the current state, challenges, and trends in CDM application within Chinese health care, providing a foundation for future efforts in data standardization and sharing. The reliability of the questionnaire data was assessed using Cronbach α and Guttman Lambda 6 to determine internal consistency.

Results: Our survey of 418 participants revealed that 41.9% (175/418) were aware of the CDM. Recognition of CDM increased with higher education levels and was notably higher among professionals in contract research organizations and the pharmaceutical industry. Knowledge of CDM was primarily gained through literature and conferences, with formal education less common. Logistic regression analysis indicated that individuals with doctoral degrees, researchers, executives, medical professionals, data engineers, Centers for Disease Control and Prevention staff, and statisticians were more likely to be aware of CDM. Subgroup analyses showed higher awareness among doctoral versus nondoctoral and Beijing-based versus non-Beijing respondents, while perceived necessity was broadly comparable across subgroups. Overall, 94.7% (396/418) of respondents believed CDM integration

XSL•FO
RenderX

in China is necessary for standardization and efficiency. Despite 60.7% (254/418) optimism for the Observational Medical Outcomes Partnership as the preferred CDM, challenges such as mapping traditional Chinese medicine or Chinese medical insurance remain.

Conclusions: A large proportion of respondents expressed a favorable view of implementing the CDM in regional databases in China, with notable endorsement from the doctoral group and professionals in contract research organizations or pharmaceutical sectors; subgroup differences were concentrated in awareness rather than perceived necessity. Participants suggested enhancing CDM-related education and establishing clear data-sharing regulations to support CDM advancement in China.

Introduction

In the rapidly evolving landscape of health informatics, adopting a standardized common data model (CDM) is a pivotal strategy for harmonizing data from diverse sources within a cohesive framework. This approach enhances the interoperability and utility of health data and supports the advancement of precision medicine, public health monitoring, and evidence-based policy making while maintaining governance of sensitive data [1].

The transition of regional databases to a standardized CDM is vital because it facilitates the integration and analysis of large and varied health datasets. This is particularly relevant in China, where unique demographic and epidemiological profiles present a rich yet complex data landscape [2]. The significance of this research from a Chinese population perspective lies in its potential to bridge gaps between disparate data sources, enabling more comprehensive and nuanced insights into health trends and outcomes [3]. The country's unique mix of Western medicine and Traditional Chinese Medicine, along with evolving insurance codes and inconsistent digitalization, creates challenges for data harmonization. While global studies highlight the benefits of CDMs, research on Chinese biomedical professionals' perceptions of their adoption is limited. Globally, CDMs such as Observational Medical Outcomes Partnership (OMOP) and Vaccine Safety Datalink (VSD) have played a key role in pharmacoepidemiology, enabling large-scale, multicenter research. The United States has been a leader in using CDMs for vaccine safety and drug surveillance. These efforts offer valuable insights for China's ongoing adoption and expansion of CDM applications [4]. Given that the CDM use in China is slightly lower than in other countries [5], a survey questionnaire was developed to investigate the perspectives and sentiments of individuals within the Chinese health care system regarding the implementation of a CDM in regional databases. Furthermore, by analyzing the factors that influence acceptance, this study aims to provide a solid foundation for promoting and expanding CDM in China's medical field, thereby enhancing the capacity for data-driven decision-making and research.

This survey aims to examine the perspectives and sentiments of individuals within the Chinese health care industry regarding the implementation of a CDM in regional databases.

Methods

Ethical Considerations

The researchers explained the purpose of the study to all participants, either orally or in writing, and obtained informed consent. No compensation or incentives were provided for participation. The study was approved by the Peking University Institutional Review Board (IRB00001052-24052). No personally identifying data were collected.

Questionnaire Survey

A questionnaire study was conducted among the Chinese population working or studying in the medical field from September 18, 2024, to November 8, 2024, to assess the acceptance of transitioning from regional databases to standardized CDMs among Chinese health care professionals. The study explored participants' understanding of CDM and the OMOP CDM, as well as their perspectives on the importance of CDM for regional databases in China. Analysis of the survey results can reveal the current status, challenges, and trends in CDM application within the Chinese medical field, providing a reference basis for future data standardization and sharing. Survey data were collected using Sojump [6], an online survey platform, and the questionnaire was distributed through WeChat (Tencent). Reliability of the questionnaire data was assessed using Cronbach α and Guttman Lambda 6 to measure internal consistency [7,8]. The 20-question questionnaire is included in Multimedia Appendix 1. Participants viewed an information page and provided electronic informed consent before accessing the questionnaire. This web-based survey adhered to the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) checklist. The fully completed checklist is available in Multimedia Appendix 2 [9].

Statistical Analysis

The sample size was calculated to estimate the overall acceptance rate of the CDM among Chinese health care professionals. The sample size calculation used the standard proportion formula [10]. We adopted the most conservative assumption (P=.5) with a 95% CI (z=1.96) and a margin of error of 5% (E=0.05). To further justify the sample size, we reviewed similar questionnaire-based studies in the field, which reported sample sizes ranging from 249 to 683 participants [11-13]. Given this range, a sample size of 418 participants is considered appropriate and aligns with similar research.

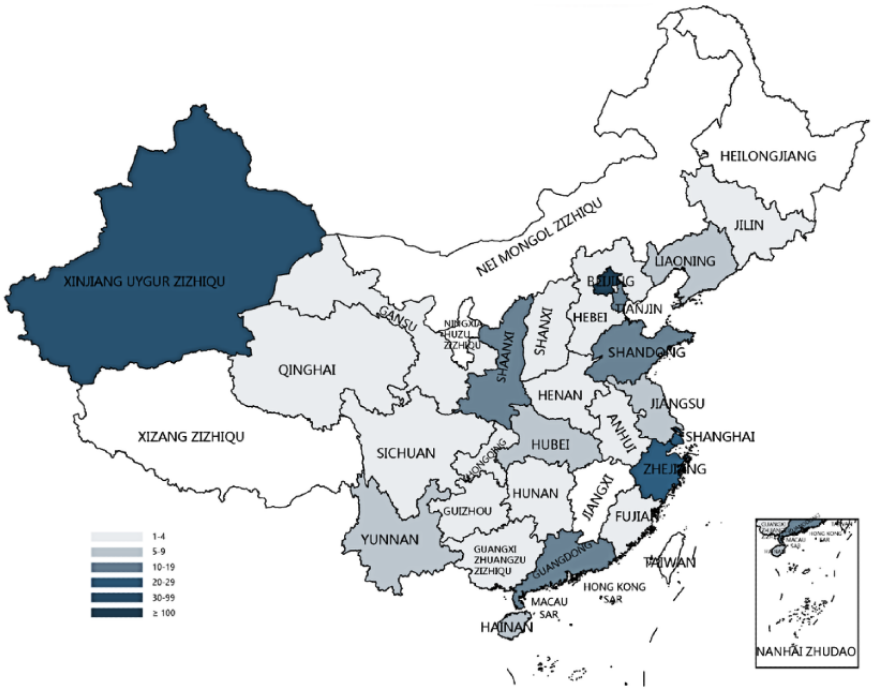
XSL•FO
RenderX

To ensure that all questions were answered before submission, the survey was designed to prevent incomplete responses, eliminating any missing data. Convenience sampling was used to efficiently gather participants for the survey. The distribution of categorical variables is expressed as numbers and percentages. Chi-square tests were used to compare nonordered categorical data. A *P* value of less than .05 was considered statistically significant. All statistical analyses were conducted using R version 4.4.1 (R Core Team).

Results

Basic Information

A total of 418 responses were collected. Guttman Lambda 6 reliability coefficient was 0.98, while Cronbach α coefficient was 0.96, indicating high internal consistency and strong inter-item correlations within the questionnaire. These results support the notion that the questionnaire is an effective tool, bolstering confidence in its structural soundness and reliability.



The minimum sample size was determined through a power calculation for estimating CDM acceptance prevalence among Chinese medical practitioners. Assuming a conservative proportion (*P*=50%) with a 5% margin of error at a 95% CI, the required sample size was 385. Our final sample (n=418) exceeded this threshold, ensuring sufficient precision for population-level estimates. Required sample sizes across various assumed proportions are shown in Table 1.

The median filling time was 121.5 (IQR 83.0-201.5) seconds. Zhong et al [14] recommend estimating the time required to answer a question as approximately 2 seconds per question, which all participants met in this study. Among the participants, 40.2% (168/418) were from Beijing and were notably more engaged, indicating a higher level of interest in the topic. This was followed by Xinjiang at 20% (84/418). Furthermore, significant interest was also observed in economically prosperous regions such as Zhejiang (21/418, 5%), Shanghai (20/418, 5%), and Guangdong (16/418, 4%). This may be related to economic development, medical resource allocation, and enhanced health awareness among residents in these areas. The regional distribution of participants is shown in Figure 1 [15], and participant characteristics are shown in Table 2.

Table 1. Sample size calculation.

Anticipated acceptance rate (p)	Required sample, n
10% or 90%	138
20% or 80%	246
30% or 70%	323
40% or 60%	369
50%	385

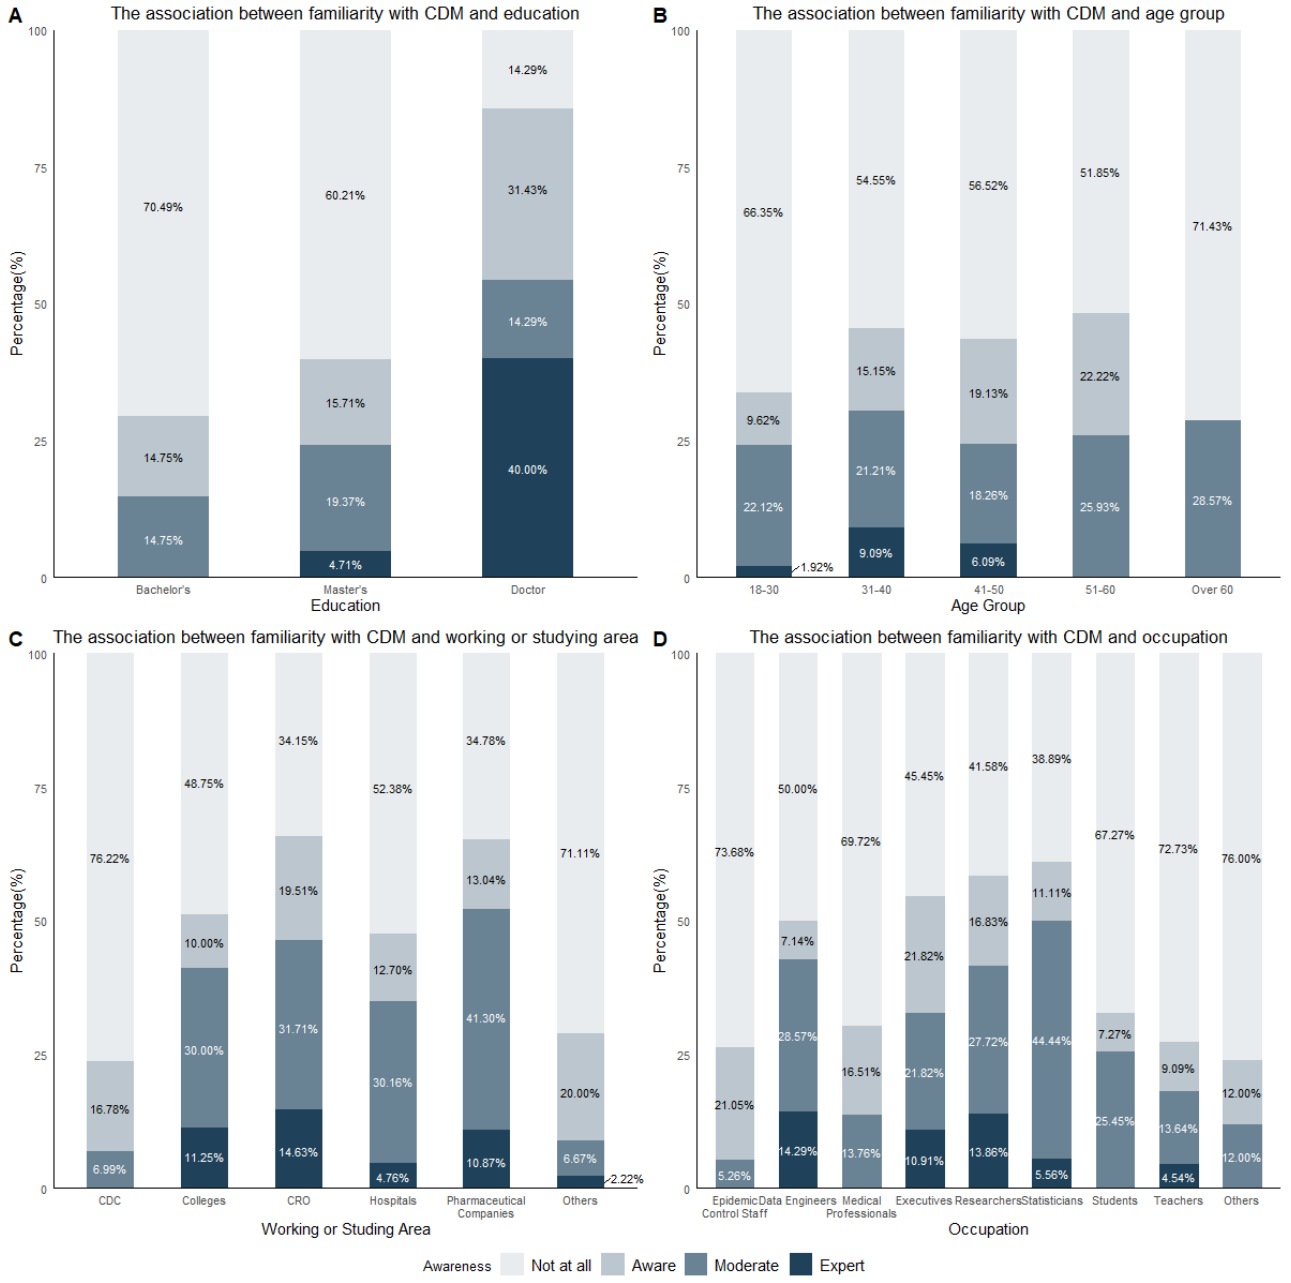
[d]The others mentioned in institutional affiliation refer to research institutes, the National Health Commission of China, and not specified.

Degree of CDM Understanding



A total of 41.9% (175/418) of participants had heard of CDM before, whereas in the doctoral group, the percentage was higher at 60% (63/105). There was a statistically significant association between awareness of CDM and education level (χ^2_2=22.2; P<.001), occupation (χ^2_8=33.1; P<.001), and working or studying area (χ^2_5=46.1; P<.001), while no significant differences were observed in terms of age group and sex.

Among participants who were aware of CDM, only 14% (24/175) reported having a comprehensive understanding, whereas within the doctoral population, this percentage increased to 24% (15/63). Figure 2 illustrates a positive correlation between education level and the extent of CDM understanding. Notably, familiarity with CDM tends to decrease with increasing age. Specifically, within the 31-40 years age group, 9% (15/165) of participants demonstrated a profound understanding of CDM, representing the highest proportion among all age groups. Contract Research Organizations (CROs) and the pharmaceutical industry exhibit heightened interest in

XSL•FO
RenderX

CDM, potentially attributable to the elevated demand for scientific research within these sectors. Data engineers and researchers typically reported higher familiarity with CDMs, and executives also reported relatively high levels of understanding.

Figure 2. The association between familiarity with CDM and different factors. CDC: Centers for Disease Control and Prevention; CDM: common data model; CRO: contract research organization.

Among the 175 participants familiar with CDMs, conferences and academic literature emerged as the 2 primary sources of knowledge, cited by 119 (68%) and 109 (62.3%) respondents, respectively. Digital platforms and informal networks also played notable roles: medical subscription accounts, such as medical public accounts or newsletters on WeChat and similar platforms, were mentioned by 64 respondents (37%), information shared by peers by 58 (33%), and social media by 31 (18%). In contrast, formal education served as a source for only 3 participants (2%), highlighting a considerable gap in structured curricula and suggesting an urgent need to integrate CDM training into established academic and professional education programs.

Univariate and multivariate logistic regression analyses were conducted to assess the association between having heard of CDM and various demographic and clinical characteristics. The results are presented in Table 3. No differences between univariate and multivariate models were observed for age groups. Regarding education level, individuals with a doctoral degree (odds ratio [OR] 2.751, 95% CI 1.214-6.345; *P*=.02) exhibited a significantly greater likelihood of having heard of CDM compared with those with an undergraduate degree, whereas no significant difference was observed for those holding a master's degree. Researchers (OR 5.893, 95% CI 1.520-9.469; *P*=.02), executives (OR 5.716, 95% CI 1.179-9.844; *P*=.04), medical professionals (OR 4.964, 95% CI 1.984-8.162; *P*=.008),

XSL•FO
RenderX

data engineers (OR 1.782, 95% CI 1.009-7.707; *P*=.01), Centers for Disease Control and Prevention (CDC) staff (OR 2.139, 95% CI 1.519-6.809; *P*=.02), and statisticians (OR 3.746, 95% CI 1.336-6.878; *P*=.03) all had previous knowledge of CDM compared with students. This suggests that the concept of CDM has gained some recognition within their professional fields. Such preexisting awareness may stem from their educational background, work experience, or attention to industry trends. It is noteworthy that this early familiarity with CDM could have influenced their attitudes and behaviors toward participation in the study and may also reflect their professional competence in data management. Specifically, compared with those working or studying at the CDC, individuals in the pharmaceutical industry (OR 3.993, 95% CI 2.691-6.940; *P*<.001), CROs (OR 3.138, 95% CI 1.289-8.409; *P*<.001), and colleges (OR 4.650, 95% CI 1.680-8.335; *P*<.001) demonstrated greater awareness of CDM.

Table 3. Univariate and multivariate logistic regression analysis for common data models awareness.

Necessity of CDM

Considering that some participants were not familiar with CDM and had only a vague understanding of its definition, the definition of CDM was provided in the questionnaire. After the definition was clarified on the first page, 94.7% (396/418) of participants indicated that incorporating CDM into regional databases in China is necessary. Univariate and multivariate logistic regression analyses were conducted to assess perceptions of CDM necessity, and the results are presented in Table 4. In univariate analysis, individuals in the 31-40 years and 41-50 years age groups were more likely to be aware of CDM as necessary compared with the 18-30 years age group, whereas individuals aged 51-60 years and older showed the opposite tendency. In multivariate regression analysis, after adjusting for confounders, the differences between the 31-40 years and 41-50 years age groups and the 18-30 years age group were no longer statistically significant, whereas individuals in the 51-60 years (OR 0.205, 95% CI, 0.065-0.602; *P*=.005) and 60 years and older (OR 0.050, 95% CI 0.019-0.313; *P*=.003) age groups still held significantly different attitudes. Individuals with master's (OR 2.153, 95% CI 1.054-4.516; *P*=.04) and doctoral (OR 3.083, 95% CI 1.317-7.470; *P*=.01) degrees showed a higher degree of agreement with CDM as necessary than those with bachelor's degrees, which remained significant after controlling for other potentially confounding variables, suggesting an independent association between education level and perception of the need for CDM. Researchers (OR 2.829, 95% CI 1.301-5.808; *P*=.03), executives (OR 4.227, 95% CI 1.198-7.236; *P*=.03), medical professionals (OR 4.189, 95% CI 1.279-8.196; *P*=.02), data engineers (OR 5.014, 95% CI 1.593-9.558; *P*=.04), and CDC staff (OR 3.371, 95% CI 1.098-5.315; *P*=.008) all agreed that CDM is necessary compared with students. Considerable differences were observed in awareness and perceived requirements for CDM among different work and study environments. Specifically, staff in pharmaceutical industries (OR 2.107, 95% CI 1.846-8.139; *P*=.003) were more likely to perceive CDM as necessary than CDC staff, while those in CROs (OR 0.340, 95% CI 0.135-0.941; *P*=.04) showed the opposite view. In addition, it is important to note that staff in other areas (OR 4.701; 95% CI 1.453-9.624; *P*=.02), such as research institutes and the National Health Commission, were more likely than CDC staff to agree with the need for CDM. This phenomenon may reflect different understandings and levels of awareness of the value of CDM and the urgency of its implementation in various areas.

[f]Others refer to research institutes, the National Health Commission of China, and not specified. The majority of respondents, 93.7% (371/396), identified the integration of heterogeneous health big data from multiple sources and the enhancement of data consistency as key rationales for the implementation of CDM, underscoring the significance of data integration and consistency in contemporary data management practices. In addition, 87.1% (345/396) of respondents highlighted the crucial role of structured data in augmenting the efficiency of scientific research endeavors, whereas 81.8% (324/396) of respondents emphasized the importance of improving data quality and reliability. Furthermore, 69.4% (275/396) of respondents, representing a substantial proportion of the sample, regarded the enhancement of data use rates and the conservation of storage space as another pivotal incentive for the adoption of CDM. Collectively, these data reveal the multidimensional value of CDM in facilitating data standardization, optimizing research processes, bolstering data reliability, and enhancing storage efficiency. In contrast, 5% (22/418) participants believed that CDM is not necessary for regional databases in China. More than half (12/22, 55%) felt that existing databases already meet their needs. A total of 45% (10/22) of respondents indicated that the implementation and maintenance of CDM are relatively complex and costly, whereas 36% (8/22) expressed concerns regarding data security and the potential leakage of patient privacy.

XSL•FO
RenderX

CDM Type

Among the databases known to participants, the top 5 included OMOP, VSD, Sentinel, Clinical Data Acquisition Standards Harmonization, and National Patient-Centered Clinical Research Network, with OMOP having a significantly higher awareness rate (Table 5). It is particularly noteworthy that while only 16% (21/132) of respondents working at the CDC chose OMOP, this figure increases to 24% (11/46) among those who selected VSD, possibly because their work provides them with a better understanding of VSD in the vaccine field [16]. Within this subgroup of 175 respondents who had heard of CDMs, only 14 (8%) individuals reported knowledge of more than 5 types. By contrast, when considering the entire sample of 418 participants, as many as 327 (78.2%) indicated that they were unfamiliar with any type of CDM. In recent years, Chinese medical institutions have progressively explored the application of OMOP CDM in real-world studies. As demonstrated in a systematic review conducted in 2023 [17], 12 institutions nationwide had successfully implemented data standardization, with notable breakthroughs particularly in chronic and mental disease research.

Table 5. Ranking of common data model (CDM) types known to participants.

Ranking	CDM type	Participants, n/N (%)
1	OMOP[a]	132/175 (75.4)
2	VSD[b]	45/175 (26)
3	Sentinel	41/175 (23)
4	CDASH[c]	36/175 (21)
5	PCORnet[d]	28/175 (16)
6 (tie)	ASPEN[e]	23/175 (13)
6 (tie)	FHIR[f]	23/175 (13)

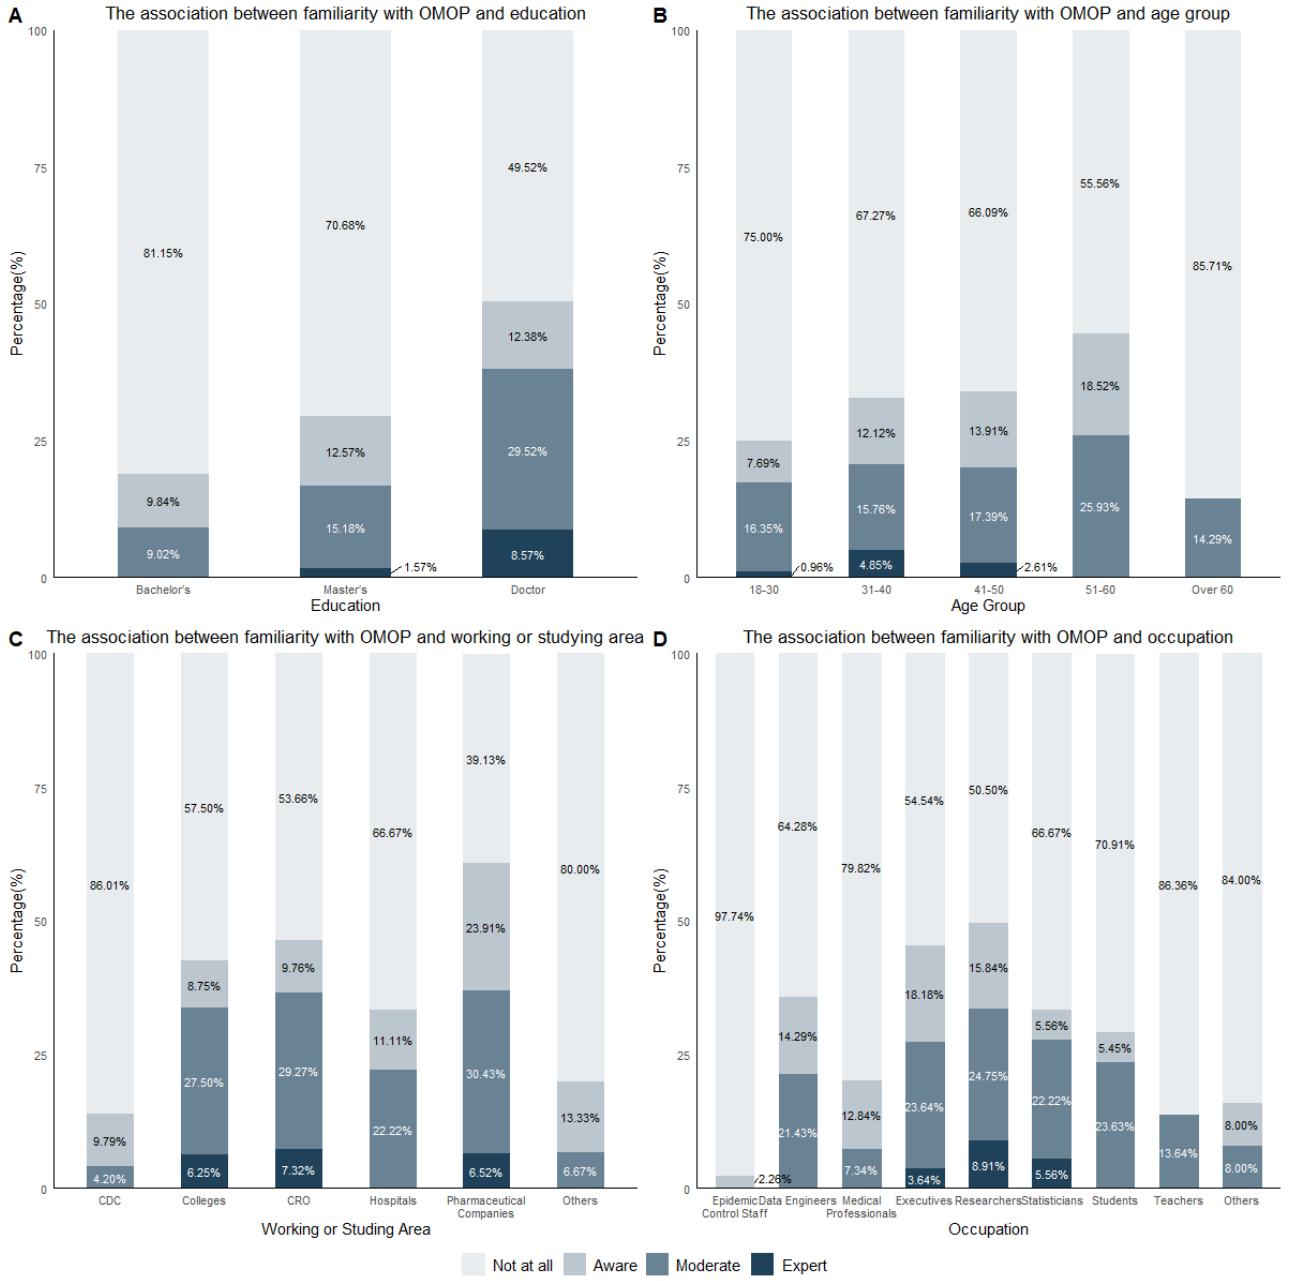
[h]PEDSnet: Pediatric Evidence Discovery and Surveillance Network.



[i]CRN-VDW: Health Care Systems Research Network Virtual Data Warehouse.

Equal counts were assigned the same rank (ties); subsequent ranks were skipped.

The bar charts illustrating familiarity with OMOP (Figure 3) appear to closely resemble those for CDM. Among the 132 respondents who reported being aware of OMOP, the primary avenues for OMOP awareness were conference introductions and literature, reported by 90 (68%) respondents and 75 (57%) respondents, respectively, underscoring the significant role of professional events and scholarly resources in knowledge dissemination. In addition, 44 participants (33%) learned about OMOP from peers, and 41 (31%) from medical public accounts, while only 13 respondents (10%) obtained such information through video platforms. Survey findings indicate that the majority of respondents recognize significant advantages associated with the implementation of OMOP. The most widely acknowledged benefit, reported by 89.4% (118/132) of participants, is that it enables different data sources to be more easily shared, compared, and integrated. This is followed by the enhancement of data operability and comparability, cited by 104 respondents (78.8%). Furthermore, 98 respondents (74%) believe that OMOP helps promote innovation and progress within the research field. Additionally, a substantial proportion of respondents, 64% (84/132), identified the reduction in data cleaning workload as a notable advantage. However, respondents also identified challenges faced by OMOP in China. Specifically, 76% (100/132) of respondents aware of OMOP cited barriers between various data sources, 71% (94/132) reported the high manual effort required for mapping, and 52% (69/132) encountered an inability to match some localized information to standard concept IDs. Particular mapping issues were noted for data related to ethnicity, Chinese medical insurance, and traditional Chinese medicine.

Subgroup Analysis

To examine whether sample composition might influence the main results and to enhance interpretability, we conducted prespecified subgroup comparisons by education (doctoral vs nondoctoral) and region (Beijing-based vs non–Beijing-based) in Tables 6 and 7, respectively. Doctoral respondents showed higher CDM awareness (χ^2_1=11.1; P<.001), greater self-rated CDM expertise (χ^2_1=16.9; P<.001), and higher OMOP awareness (χ^2_1=22.0; P<.001). Perceived necessity did not differ materially by education (P=.31 for CDM and P=.15 for OMOP). By region, Beijing-based participants had higher awareness of CDM (χ^2_1=5.1; P=.02) and OMOP (χ^2_1=14.2; P<.001), whereas differences in CDM and OMOP expertise and perceived necessity were not statistically significant. Overall, heterogeneity was concentrated in awareness rather than perceived necessity, suggesting differential exposure rather than divergent attitudes toward adoption.

Discussion

Based on the statistical analysis of the questionnaire results from Sojump, it is evident that participants generally hold a positive attitude toward the application of CDM in regional databases in China. This positivity is underpinned by the high internal consistency and strong inter-item correlations within the questionnaire. Notably, participants from Beijing constituted the highest proportion, which may indicate a regional focus or interest in CDM. The doctoral group, with their deeper professional knowledge and experience in the medical and research fields, tended to have a higher understanding of CDM. This understanding equips them to comprehend the structure and potential applications of CDM, and how to use it to support clinical research and health care decision-making. Furthermore, CROs and pharmaceutical industries showed a strong interest in CDM due to its standardized data models and processing methods, which can accelerate project processes, reduce costs, and enhance efficiency. This interest and support are instrumental in driving the widespread adoption of CDM, thereby providing more opportunities for data management and analysis in the health care sector. Literature and conferences were identified as the primary channels through which participants learned about CDM. Among various CDM frameworks, OMOP ranked highest in terms of awareness. However, participants generally believed that implementing OMOP in China would face numerous challenges, such as the inability to map traditional Chinese medicine information to standard datasets. Mapping challenges in China include the difficulty of translating traditional Chinese medicine concepts, such as “Qi deficiency” and “Blood stagnation,” into OMOP-standardized terms, as no direct equivalents exist. Similarly, local insurance and billing codes, which are frequently updated and vary by region, present significant challenges in adapting them to the OMOP framework.

Some local adaptations are underway, with certain Chinese institutions developing crosswalks and custom vocabularies to address these challenges. However, these adaptations are still in the pilot phase and require further collaboration to be fully integrated into the global OMOP ecosystem.

Participants put forward a series of recommendations to enhance the involvement of domestic technical, medical, informational, and scientific research personnel and to promote the development of CDM in China. They emphasized the importance of establishing small-scale OMOP data specialty and disease-specific databases, as well as the possibility of building OMOP thematic databases based on existing databases. To increase the operational strength of OMOP data, they suggested increasing investment in scientific research and commercial projects to enhance scientific and commercial outputs. At the same time, the necessity of popularizing CDM

XSL•FO
RenderX

education was highlighted, along with an emphasis on policy precedence. They hope to develop a CDM suitable for China that aligns with international standards, while also focusing on quality control in data collection. Additionally, they discussed the feasibility of using Clinical Data Interchange Standards Consortium standards in real-world data and suggested a comprehensive promotion of the use of a unified data format. Participants also stressed the importance of establishing rules to clarify the value of data assets and the need for national-level promotion of a rational data-sharing mechanism. Questions were raised regarding whether to charge fees, how to charge fees, and the possibility of customization, emphasizing the importance of data integration, collection, and processing. It was suggested to popularize CDM in universities and consider opening and sharing some data with enterprises. At the same time, the importance of information encryption and network security was emphasized, along with a proposal to pilot initiatives in specific areas first. Finally, they discussed the issue of defining cross-institutional data usage permissions and strategies to enhance users' enthusiasm.

The recommendations put forward by the participants hold significant guiding importance in promoting the application and development of CDM and OMOP in China. Standardization and privacy are complementary facets of data sharing, where CDM can serve as an effective solution for both. Standardization facilitates and enhances the efficiency of data sharing, while privacy ensures that data sharing is conducted appropriately and under sufficient control. Recent nationwide implementations, such as South Korea's successful integration of national claims data into the OMOP CDM framework, demonstrate how standardization can support both data utility and privacy protection at a national scale. This approach enables transparent and "Findable, Accessible, Interoperable, and Reusable" data stewardship while maintaining appropriate access controls through distributed research environments [18]. There is active development in both domains, including advancements in government regulations and common data models to promote standardization, as well as the application of technologies such as blockchain and synthetic data to address privacy concerns [19,20]. Enhancing the interoperability and security of information systems is crucial, necessitating increased awareness and implementation of current standards and the expansion of ophthalmic data standards to fill gaps in existing norms. As data sharing becomes more prevalent, advancements in data privacy are also of critical importance.

The use of OMOP has facilitated standardized data-driven research across various clinical sites, establishing a robust foundation for data use. Furthermore, numerous research papers in the medical field have used OMOP to present their findings. Artificial intelligence is increasingly being applied within CDM. Kang et al [21] introduced a deep learning–based automatic term mapping tool specifically designed for application within the OMOP framework, enhancing the efficiency and accuracy of data standardization. The review by Ahmadi et al [22] highlights the pivotal role of OMOP in discovering and refining machine learning models. Some studies have explored disease risk factors in detail and conducted epidemiological investigations [23-27], while others have used machine learning to build risk prediction models [28-32].

This study has several limitations. First, while the sample size of 418 meets basic statistical requirements, it remains relatively limited for comprehensively assessing the perspectives of all health care professionals and researchers across China's diverse health care landscape. Second, this study used convenience sampling, which may introduce selection bias, as the selection of participants was not entirely random and may not fully reflect the opinions and characteristics of all health care professionals and researchers in China. Convenience sampling likely overrepresented highly educated professionals, particularly those with doctoral degrees, and respondents from regions such as Beijing. These biases may lead to more favorable attitudes toward CDMs and higher familiarity with them compared with the broader population of health care professionals in China. To improve the accuracy and reliability of future studies, stricter sampling techniques should be adopted to ensure sample diversity and broadness. Additionally, other potential biases in the study design and implementation process need to be addressed in subsequent research. Furthermore, the assessment of "comprehensive knowledge" of CDMs was based on self-reported responses rather than an objective knowledge test. While this method provides valuable insights into participants' perceptions, it may not fully capture their actual understanding of CDMs. Given the online survey format, digital literacy could be a potential source of bias. However, as all respondents held at least a bachelor's degree and were capable of using electronic devices, the impact of this bias is likely minimal.

In conclusion, respondents were generally supportive of adopting CDMs in regional databases in China, with higher awareness among doctoral respondents and staff in CROs or pharmaceutical sectors; however, deep understanding remains limited, and exposure through formal training is low. Accordingly, these findings should be interpreted with caution. Implementation efforts should prioritize targeted education and capacity-building, alongside clear data-sharing and governance frameworks, as well as practical pilots—including terminology mapping—to enable sustainable uptake.

Acknowledgments

Abstract

Background: Efforts are being made to integrate digital health technologies into clinical care for multiple sclerosis (MS) to improve patient monitoring. Efficiently probing how they might impact clinical care could streamline digital tool development. The Floodlight digital tool, comprising 5 smartphone sensor–based tests, was used to generate health-related data on patient function and symptoms in a clinical simulation.

Objective: The study had 3 objectives: (1) assess the utility of simulated clinical encounters as a research methodology for exploring the introduction of digital health technologies into clinical practice in MS, (2) confirm the fidelity of the simulated environment and patient cases developed and understand what metrics (eg, workflow, comprehensive evaluation) could be generated, and (3) generate insights into the utility of digitally collected data, including usability, clinical decision contribution, and impact on workflows, in clinical practice.

Methods: A total of 2 patient cases consisting of clinical, radiological, and digital health data were developed with clinician input. US-based neurologists prepared for and conducted 2 simulated teleconsultations each, with an actor briefed on case profiles. Floodlight data were available, via the Floodlight MS™ Health Care Professional Portal, for 1 of the 2 consultations. Participant neurologists completed interviews and surveys assessing the fidelity of the cases presented, user experience and workflow metrics, patient concerns identified, care decisions made, and confidence in making decisions.

Results: All 10 neurologists indicated that the simulations were high-fidelity representations of real consultations. Using the Floodlight technology for the first time, median time taken to prepare for and conduct the consultation was ~1.7 - 2 minutes longer, with slightly greater mental effort reported by participants, compared with not using the tool. The Floodlight MS Health Care Professional Portal scored an “above average” 79 on the System Usability Scale and an “acceptable” Net Promoter Score of 10. In total, 6 of the 10 neurologists “strongly agreed” that it was easier and quicker to identify patient concerns when they had access to the patient-generated Floodlight data to prepare for their encounters than when they did not. Overall, more care and management decisions were taken when the digital tool was used (37 vs 29). Of those 37 decisions, Floodlight data were reported as a trigger for 20 decisions, always in combination with other elements including patient history (20/20) and clinical exam findings (9/20).

Conclusions: These findings advance our understanding of clinical simulation as a method for evaluating digital tools and other innovative technologies for MS care. High-fidelity patient cases could be provided for the mock teleconsultations, and the simulated clinical environment was useful for evaluating usability and utility of a new digital tool—yielding preliminary evidence on how digital data could be accessed and utilized by neurologists to support routine MS care.

Introduction

Background

Multiple sclerosis (MS) is a central nervous system disorder marked by significant heterogeneity in its clinical presentation and characterized by disease progression from onset [1,2]. MS, often commencing with subtle signs and advancing to substantial disability, manifests through a wide spectrum of symptoms, ranging from sensory disturbances and motor deficits to cognitive impairments and emotional challenges, profoundly impacting patients, their families, and society [3,4].

To date, monitoring in MS has been reliant upon brief, infrequent clinical assessments (typically occurring once or twice annually, or at the time of a relapse), without sufficiently sensitive and objective (ie, free from rater-dependent variability) assessments of progression available to health care professionals (HCPs) [5]. Moreover, due to time constraints, standard assessments of disability in MS, such as the Expanded Disability Status Scale (EDSS) [6], which requires ~30 minutes to conduct [7], are not always performed in clinical appointments. Remote consultations (teleconsultations) are a recognized alternative to clinic visits [8] and have been adopted by the MS community, particularly during the COVID-19 pandemic [9,10].

Digital health technologies offer greater access to care in MS and opportunities to improve frequent monitoring [11], enabling the capture of ongoing subtle or subclinical progression of MS [1,12-14] in specific domains such as cognition (which can often be missed). These technologies can be remotely administered and are patient-centered and operated, allowing longitudinal assessment of multiple functional domains in a naturalistic environment [15,16]. Furthermore, they offer the opportunity to improve the involvement of patients in their disease or treatment course [17,18] and to enhance conversations between HCPs and people with MS [19]. By providing objective data and bridging the gap of information in between clinical visits, sensor-based digital assessments may ultimately allow HCPs to make more informed decisions, evaluate treatment effects, and act earlier on indications of disease progression [11] or symptomatic exacerbation prior to scheduled clinical visits.

Despite the potential benefits, evaluating, testing, and optimizing the integration of new and innovative solutions into health care settings can itself be a time- and resource-consuming process. Hence, there is growing demand for agile methods to rapidly learn how digital solutions can play a role in clinical practice [20]. Clinical simulation, a low-cost and scalable methodology whereby data are collected from users as they perform tasks in realistic clinical scenarios, can rapidly generate new insights. For example, they allow the exploration of the possible impact of novel methodologies without the risks inherent in deploying them in real clinical settings (eg, of misdiagnoses [21,22]) or of the expansion of technology to new user groups or in new clinical contexts [22]. The preliminary insights generated from simulation models can support the refinement of technologies before rollout or scaling up [23]. To confirm that the insights gained from these clinical simulations are meaningful, they must be of high fidelity and account for a number of variables (including behavioral ones) and the differences inherent among real-world practices [21,22].

Aims and Objectives

This feasibility study was designed to evaluate clinical simulation as a method for assessing the preparation and conduct of teleconsultations. This included evaluating the fidelity of the simulated environment (compared with real practice) and the patient cases developed. An additional aim was to assess the feasibility of using data derived from smartphone-based remote assessment technology in combination with MS teleconsultations, including their usability and impacts on clinical workflows (eg, preparation time and time to identifying primary patient concerns), care decisions, and disease management. The Floodlight technology [24] was utilized as the digital tool for evaluation. Accordingly, the aim of this study was to evaluate the potential impact of integrating Floodlight MS into clinical practice, generating insights that may also be relevant to similar digital health tools. As it is expected that any new test or technology will initially impose a higher mental load on clinicians, the study also aimed to quantify the extent of this increase.

Floodlight MS comprised 5 smartphone sensor–based tests (hereafter referred to as “smartphone-based tests”) presented on an app, measuring information processing speed (Cognitive Test [25]), hand function (Pinching Test [24] and Draw a Shape Test [26]), and gait (U-Turn Test [27] and 2-Minute Walk Test [28,29]), as well as a Patient Journal including 2 patient-reported outcome (PRO) measures (Daily Status Questions and a Symptom Tracker [30]). The data were consolidated in a dashboard for HCPs (Floodlight MS HCP Portal), which was accessible between clinical visits [5], and constituted the focus of the technological assessment in this research.

Methods

Recruitment of Neurologists

US-based neurologists were recruited from Prova Health’s existing network, professional communities (eg, LinkedIn), and academic publications, and through snowball sampling (where research participants recruit future participants), and they were sent email invitations to take part in the study. Neurologists were required to have managed a minimum of 40 people with MS per month and to have had no previous experience using the Floodlight technology. Convenience sampling was utilized to recruit primarily academic neurologists, as they were expected to give more granular feedback on the technology. There was no defined sample size due to the exploratory nature of this feasibility study.

Patient Case Overview

A total of 2 patient cases were presented to each participant neurologist. Radiology reports and clinical letters were drafted by qualified radiologists and medical doctors to describe the cases and reflect the real magnetic resonance imaging and clinical data in a realistic narrative. For additional authenticity, synthetic social and family histories consistent with typical MS presentations were included. All cases were validated by 2 expert neurologists.

XSL•FO
RenderX

The goal was to achieve high-fidelity patient cases that were representative of real-world cases while minimizing the variation inherent among people with MS. Patient cases included (experimental) or did not include (control) Floodlight data, thus simulating real-world scenarios in which neurologists manage people with MS with or without access to the Floodlight technology (see the *Patient Case Development* section for more details).

Patient Actor

A professional actor was recruited to play the patients' roles during the teleconsultations. They were recruited from a company with 25 years of experience in providing trained actors to simulate patients with medical, surgical, and psychiatric conditions. The patient roles were based on generated behavioral profiles, which were used to inform the biographies for the 2 patient cases. The actor was provided with detailed scripts developed by a medical doctor and validated by neurologists to ensure [1] the consistency and correctness of answers.

Conduct of Clinical Simulations

Each clinical simulation session lasted approximately 2.5 hours and was conducted via Zoom. Medically qualified team members from Prova Health served as moderators, facilitating introductions (~5 min), reviewing the simulation session guide with the neurologists (~5 min), and providing training on the Floodlight technology (~30 min). After the simulated teleconsultations had begun, the moderators took notes with their cameras and microphones switched off. Teleconsultations were designed to replicate those that the participant neurologists would perform in their clinical practices. The individual simulated teleconsultation sessions for each of the 2 presented patient cases consisted of preparation (~5 min) and conduct (~30 min) phases, both led by the participant neurologist. Participant neurologists were instructed to evaluate the relevant information and recommend an appropriate management plan. In the preparation phase, clinical information provided with or without Floodlight data was reviewed for each patient case. The "patient" (played by the professional actor) then joined the call. Following the conclusion of each simulated teleconsultation, participant neurologists completed a short survey (~5 min) to collect feedback on the examined case. At the end of both sessions, the moderator shared a link to the postsimulation survey (~7 min) and conducted a brief interview (~5 min) with each participant neurologist.

Patient Case Development

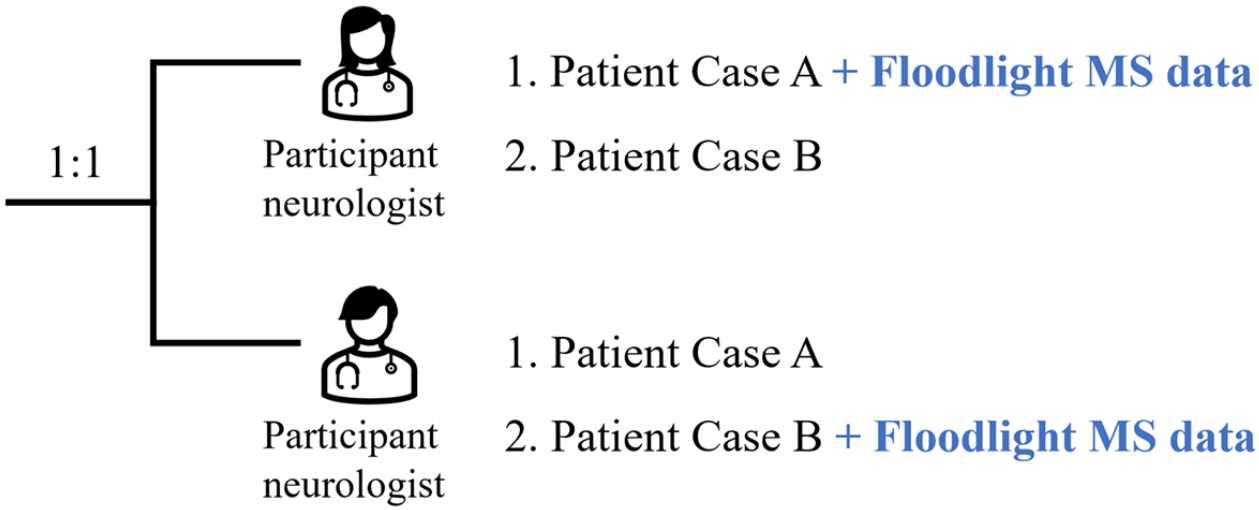
The 2 patient cases presented to each participant neurologist were developed using deidentified clinical and Floodlight data (see the *Patient Cases Selection Criteria* section). For both cases, the participant neurologists reviewed data from 3 recent clinical visits, including patient demographics, symptoms, diagnosis, treatment and medical history, and radiology reports based on original magnetic resonance imaging metrics.

The clinical data presented in the letters included EDSS scores, Symbol Digit Modalities Test (SDMT) scores, 9-Hole Peg Test times, and Timed 25-Foot Walk times. The main clinical traits emerging from clinical case narratives are presented in Table 1. It should be noted that although both patient cases presented gait impairment, Patient Case B was designed to show significant worsening of gait impairment in the last year.

Floodlight data visualized in the Floodlight MS HCP Portal were presented for 1 of the 2 cases reviewed by each neurologist. The orders of the patient cases and of the interventions were randomized before the participant neurologists started the teleconsultations (Figure 1).

Table . Clinical traits, per patient case, presented during teleconsultation simulation.

Simulation patient case	Main clinical traits emerging from clinical case narratives and actor's interpretation
Patient Case A	• Cognitive function decline: decrease in SDMT[a] score of ≥20% in the previous 12 months • Hand motor function decline: increase in 9HPT[b] time of ≥20% in the previous 6 - 12 months • History of gait impairment, as per T25FW[c] test data • Bowel and bladder issues reported in the previous 12 months • Vision changes in previous history • Fatigue
Patient Case B	• Gait capacity decline: increase in T25FW time of ≥20% in the previous 6 - 12 months • Reported bladder issues in the previous 12 months • Reported mood issues in the previous 12 months • Spasticity and pain in the previous 12 months



[a]SDMT: Symbol Digit Modalities Test.

[b]9HPT: 9-Hole Peg Test.

[c]T25FW: Timed 25-Foot Walk.

XSL•FO
RenderX

Figure 1. Randomization of patient cases before the initiation of teleconsultation. The order of cases and experimental conditions was randomized between participant neurologists, and consultations were conducted with 2 patient cases (A and B). Half (n=5) of the participant neurologists were randomized to have access to the Floodlight MS HCP Portal for the first case, while the other half had access to the solution for the second case. Due to a randomization error, 6 out of the 10 participant neurologists were assigned to the Floodlight MS HCP Portal for Patient Case A, instead of 5 out of 10. HCP: health care professional; MS: multiple sclerosis.

Data Sources

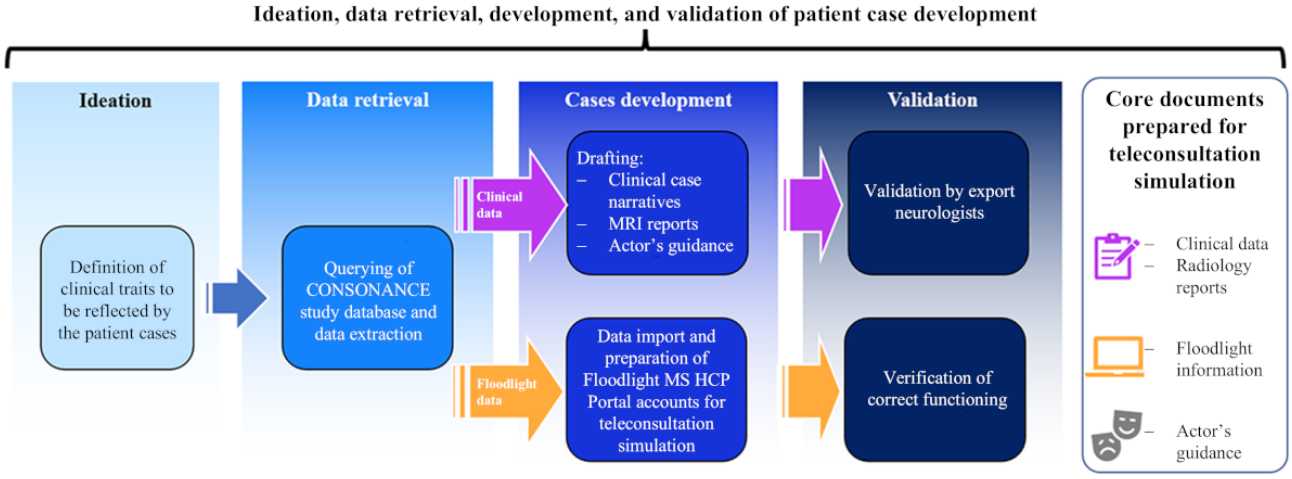
Clinical data from the CONSONANCE study (NCT03523858) were used in conjunction with Floodlight performance and symptom tracker data collected over 12 consecutive months. CONSONANCE is an ongoing, phase 3b, 4-year, open-label study assessing the effectiveness and safety of ocrelizumab in adults with progressive multiple sclerosis.

Participants enrolled in the CONSONANCE study performed smartphone-based tests using a precursor to Floodlight MS for clinical research purposes, providing a battery of digital assessments and digital PROs. Data from the Pinching Test, the Draw a Shape Test, the U-Turn Test, and the 2-Minute Walk Test (all performed daily) were utilized, alongside data from a version of the Cognitive Test (performed weekly; involving matching a sequence of symbols to digits within 90 s).

Data from 2 PRO measures collected via the Floodlight Patient Journal were also used. These were Daily Status Questions (“How are you feeling physically now?” and “How is your mood now?”) and a biweekly Symptom Tracker to track symptoms related to cognition (attention deficit, memory loss, brain “fog” sensation, mental fatigue), upper extremity function (sensory disturbance, muscle weakness, clumsiness, muscular spasm, pain), lower extremity function (sensory disturbance, muscle weakness, clumsiness, muscular spasm, pain), gait (trouble walking, lack of balance, walking fatigue), and bowel or bladder dysfunction (incontinence, bladder or urinary problems, constipation), as well as the time that any new or worsening symptoms manifested and whether or not this was perceived to be a relapse. All Floodlight data collected in the CONSONANCE trial and used in this study were imported into the Floodlight MS HCP Portal (version 1.5 at the time of the research).

Patient Cases Selection Criteria

Patient profiles were selected from the CONSONANCE dataset based on selected criteria that indicated a clinical performance decline observed in the previous 6 - 12 months, based on standard clinical assessments of cognitive function, hand motor function, or gait capacity.



For Patient Case A, the key selection criteria included cognitive function decline (a decrease in SDMT score of ≥20% in the previous 12 mo) and hand motor function decline (increase in 9-Hole Peg Test time of ≥20% in the previous 6 - 12 mo). For Patient Case B, the criteria included gait capacity decline (increase in Timed 25-Foot Walk time of ≥20% in the previous 6 - 12 mo) as well as 2 consecutive reports of fatigue and bladder issues (score of 3 - 6; some of the most impactful “invisible” symptoms of MS sourced via the SymptoMScreen). Some of the symptoms experienced by people living with MS may not be externally evident or easy to report and quantify, such as fatigue, mood disorders, cognitive impairments, pain, bladder or bowel dysfunction, sexual dysfunction, and vision changes. These symptoms can be difficult for the patient to report and articulate during a clinical encounter (eg, due to subjectivity bias, poor recall, or stigma), and for physicians to capture (limitations in available measurement tools, ample reliance on patient recall on the visit day) [31]. The clinical performance decline, together with reported signs of “invisible” symptoms, provided impetus for a care decision to be taken during the clinical simulation.

Data Extraction

Clinical data from 3 recent in-person clinical visits were extracted to present to the participant neurologists (Figure 2). No clinical data from the final in-person visit (the time point corresponding to the day of the teleconsultation in the simulation) were provided. Of note, cognitive decline had been confirmed at this visit for the patient in Patient Case A (as measured by the SDMT); these data were not provided to the participant neurologists in order to mimic a common clinical scenario in MS, where evident patient deterioration may precede formal confirmation through standard clinical assessments.

XSL•FO
RenderX

Figure 2. Clinical data extraction for teleconsultation simulation. Clinical data on ideation, data retrieval, case development, and validation of patient cases were extracted for teleconsultation simulation. Parameters such as multiple sclerosis (MS) phenotype, clinical factors, symptom reports, and synthetic data such as age and sex were included to provide transparency in demographic data. Floodlight data from the most recent 12-month period for each clinical profile were extracted for one of the cases presented to each participant neurologist. HCP: health care professional; MRI: magnetic resonance imaging.

To build the patient cases, MS phenotype and date of diagnosis; clinical parameters, including recent disease history (eg, relapses, EDSS evolution); symptom reports; and current and prior treatments (eg, disease-modifying therapies) were also extracted. Additional "synthetic" data were used to construct demographic (age, sex) and radiology reports.

Floodlight data from the prior 12-month period for each clinical profile were also extracted to be provided for 1 of the 2 cases presented to each participant neurologist.

Study Outcomes and Data Collection

Study outcomes were either moderator-reported or participant neurologist–reported (via participant surveys and interviews; Table 2). Measures included questions regarding the fidelity of the simulated cases developed; use of the digital tool (Floodlight MS), including user experience metrics for data visualization, overall experience (Net Promoter Score), and usability (System Usability Scale [32]); and workflow metrics, including time for case preparation, teleconsultation time, and mental effort required (Paas scale [33]). Confidence in approaching clinical consultations was also measured. Additionally, moderators recorded the time taken for the identification of patient concerns, the recognition of "invisible" MS symptoms, and the care decisions prompted and taken (including change in treatment management) with versus without having Floodlight data available.

A medically qualified moderator from the research team observed each simulation session and recorded outcome measures such as time spent on each case. The participants were asked to self-report on the fidelity of simulation, user experience metrics, workflow metrics, clinical consultations, patient concerns, and care decisions. This was done using postcase surveys, postcase conduct surveys, postsimulation surveys, or a postsimulation interview. Each of these was measured using various questions.

changes can be experienced by people living with MS. Some of these symptoms may not be externally evident or easy to report and quantify and can be difficult for the patient to report and articulate during a clinical encounter (eg, due to subjectivity bias, poor recall, or stigma) or for physicians to capture (eg, limitations in available measurement tools, ample reliance on patient recall on the visit day).

Data Analysis

For continuous, time-dependent, moderator-assessed measures, the median times were calculated and presented as box and whisker diagrams. Additionally, these time-dependent measures were collated into groups, and all categorical results were presented as absolute numbers within each category and presented as bar charts. An a priori decision was made not to perform hypothesis-testing statistics on data from this feasibility study.

Ethical Considerations

CONSONANCE patient data anonymity was retained throughout the preparation and conduct of this study. The protocol (22-PROH-102: Evaluation of Floodlight MS using clinical simulation) was reviewed by Pearl Institutional Review Board on September 20, 2022, and determined to be exempt from ethics approval according to U.S. Food and Drug Administration 21 Code of Federal Regulations (CFR) 56.104 and 45CFR46.104(b)(3): (3) Benign Behavioral Interventions - Adults. The study was conducted in accordance with the most recent version of the Declaration of Helsinki. Signed consent forms were obtained from the participant neurologists before the simulated teleconsultations were conducted. Participant neurologists were compensated for their time according to local Fair Market Value rates.

Results

Participant Neurologist Demographics

A total of 10 US-based neurologists were recruited as participants (7 from large academic centers and 3 from specialist neurology centers). A total of 6 participant neurologists had >10 years of experience in performing MS consultations, 1 had 5 - 10 years of experience, and 3 had 3 - 5 years of experience. The number of consultations performed by participant neurologists in their current practice in a typical week was >50 (n=2), 40 - 50 (n=1), 30 - 40 (n=1), 20 - 30 (n=3), or 10 - 20 (n=3). Further, participant neurologists performed 25% - 50% (n=3) or <25% (n=7) of all consultations as teleconsultations in their current practice.

Patient Case and Simulation Fidelity

Participant neurologists felt that the simulations were high-fidelity representations of real consultations. All reported that the patient cases and scenarios were “very” or “somewhat” similar to typical practice (Table 3). Feedback from participants on the performance of the professional patient actor was mostly very positive:

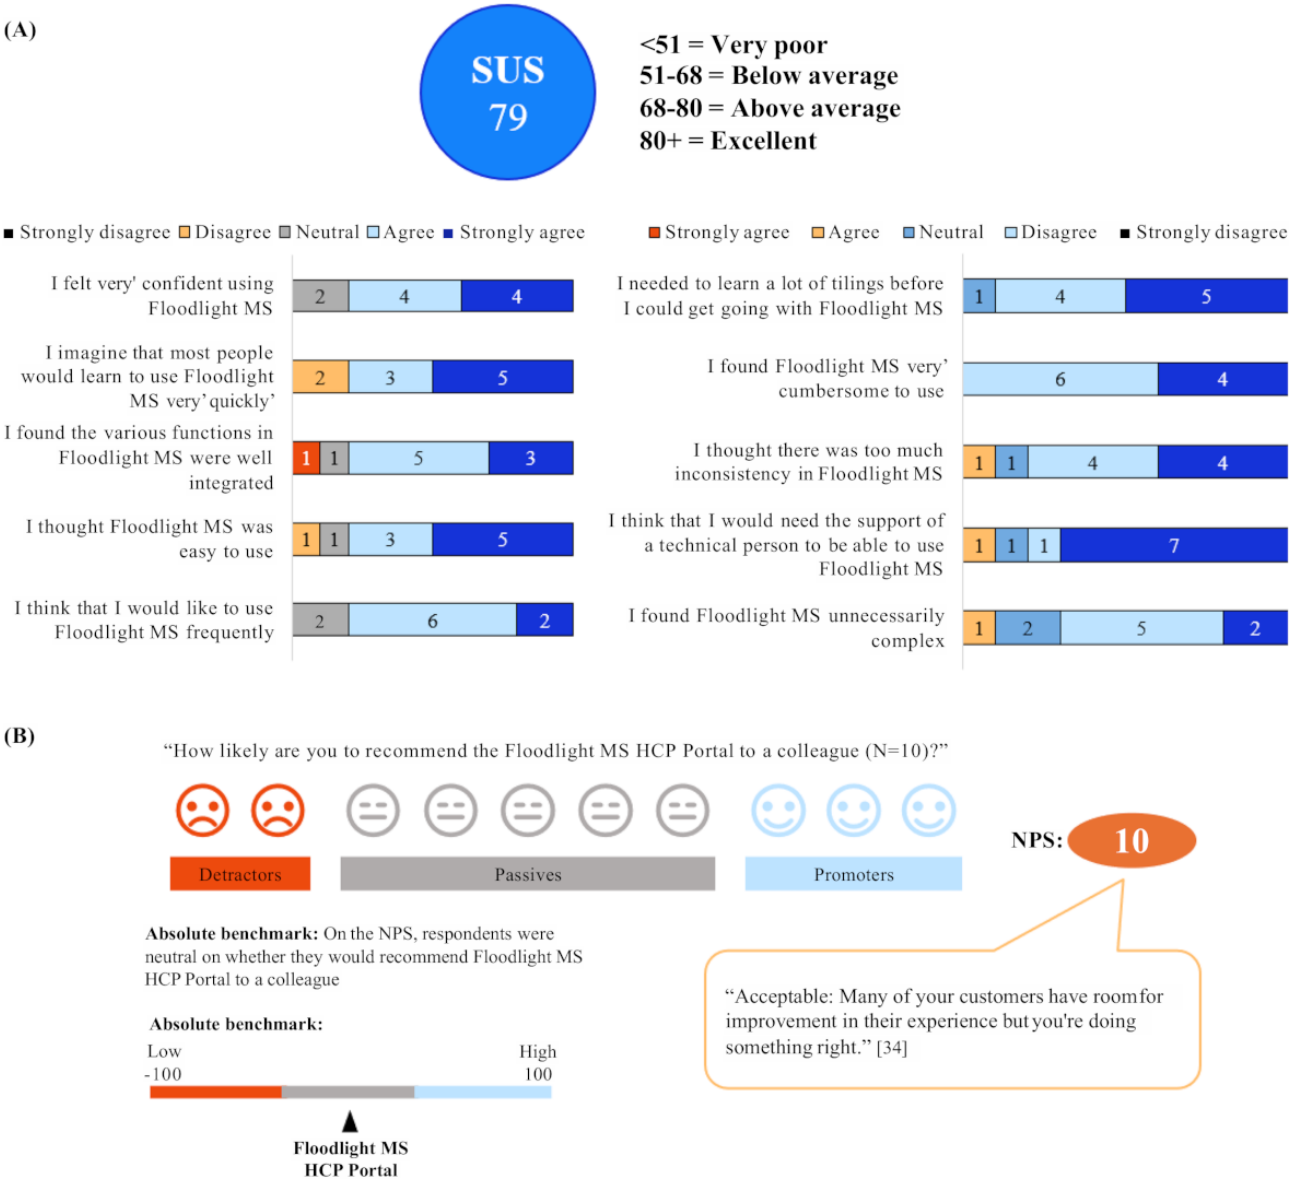
> *Shockingly. He was very good. I say that. I haven’t done this in a while, but very often a mock patient doesn’t get the real essence of MS. This guy did great. I even wondered, did he have MS, how he got so good at it? ... They would have had to practice and discuss things with many patients and doctors to get this good.*
>
> *The actor did a great job. Intuitively knew how to pick up on what I was asking.*

Table . Participant neurologists’ experiences of patient case and simulation fidelity.[a]

Participant neurologists’ experiences	Number of participant neurologists				
	Very different	Somewhat different	Neutral	Somewhat similar	Very similar
How similar were these patient cases to those you see in your day-to-day practice?	0	0	0	4	6
How similar were these consultations to the consultations you complete during a typical week?	0	0	0	5	5

[a]Participant neurologists reported similarity of patient cases to those seen in day-to-day practice and similarity of simulation to day-to-day practice consultations via surveys and questionnaires.

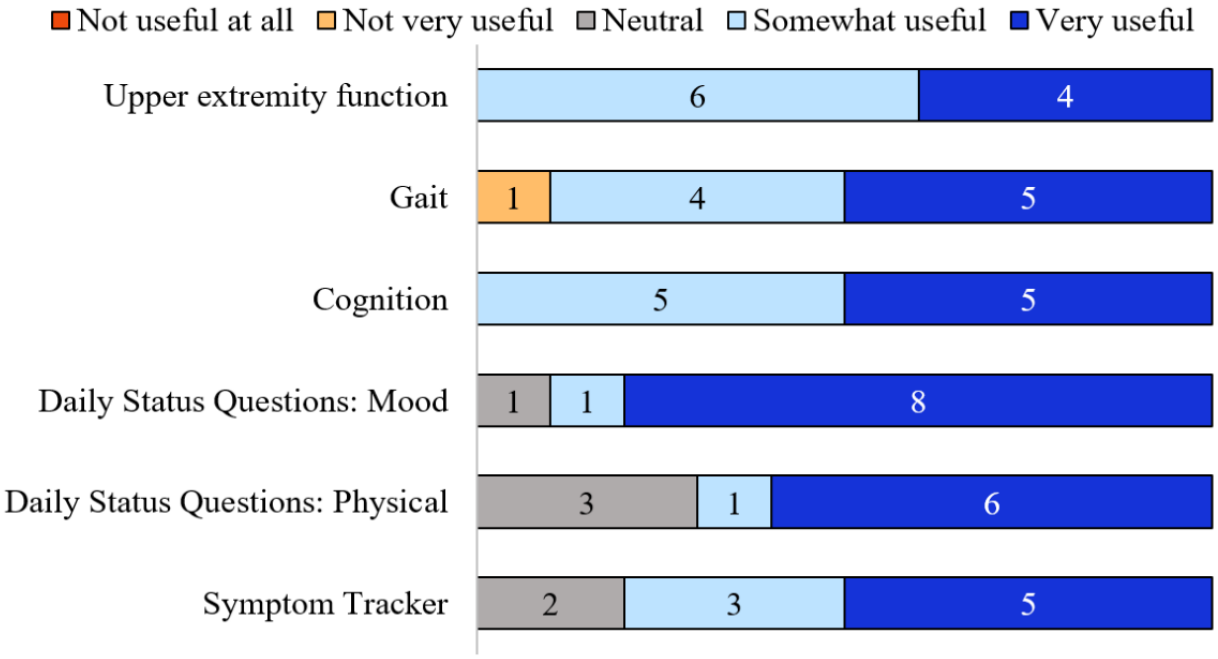
User Experience Metrics



The Floodlight MS HCP Portal scored an “above average” score of 79 on the System Usability Scale (Figure 3A). In terms of overall experience of using the Floodlight technology, the Floodlight MS HCP Portal scored an “acceptable” Net Promoter Score of 10, based on the participant neurologists’ reports of how likely they would be to recommend it to a colleague (Figure 3B).

Participant neurologists agreed that data visualizations in the Floodlight MS HCP Portal were “very” or “somewhat” useful for upper extremity function (10/10), cognition (10/10), gait (9/10), and mood status (obtained via the Floodlight Daily Status Questions; 9/10; Figure 4). The “mood status” aspect of the

XSL•FO
RenderX



Patient Journal was rated as the most useful of the data visualizations presented, with 8/10 ratings of “very useful”.

Figure 3. User experience metrics for the Floodlight technology, including (A) SUS and (B) NPS [34]. The bars represent responses on the user experience of Floodlight MS (SUS) and user experience for data visualization and the overall experience (NPS); these were reported via participant surveys and interviews. Items alternate between positive and negative phrasing, with higher scores indicating more favorable usability perceptions. HCP: health care professional; MS: multiple sclerosis; NPS: net promoter score; SUS: System Usability Scale.

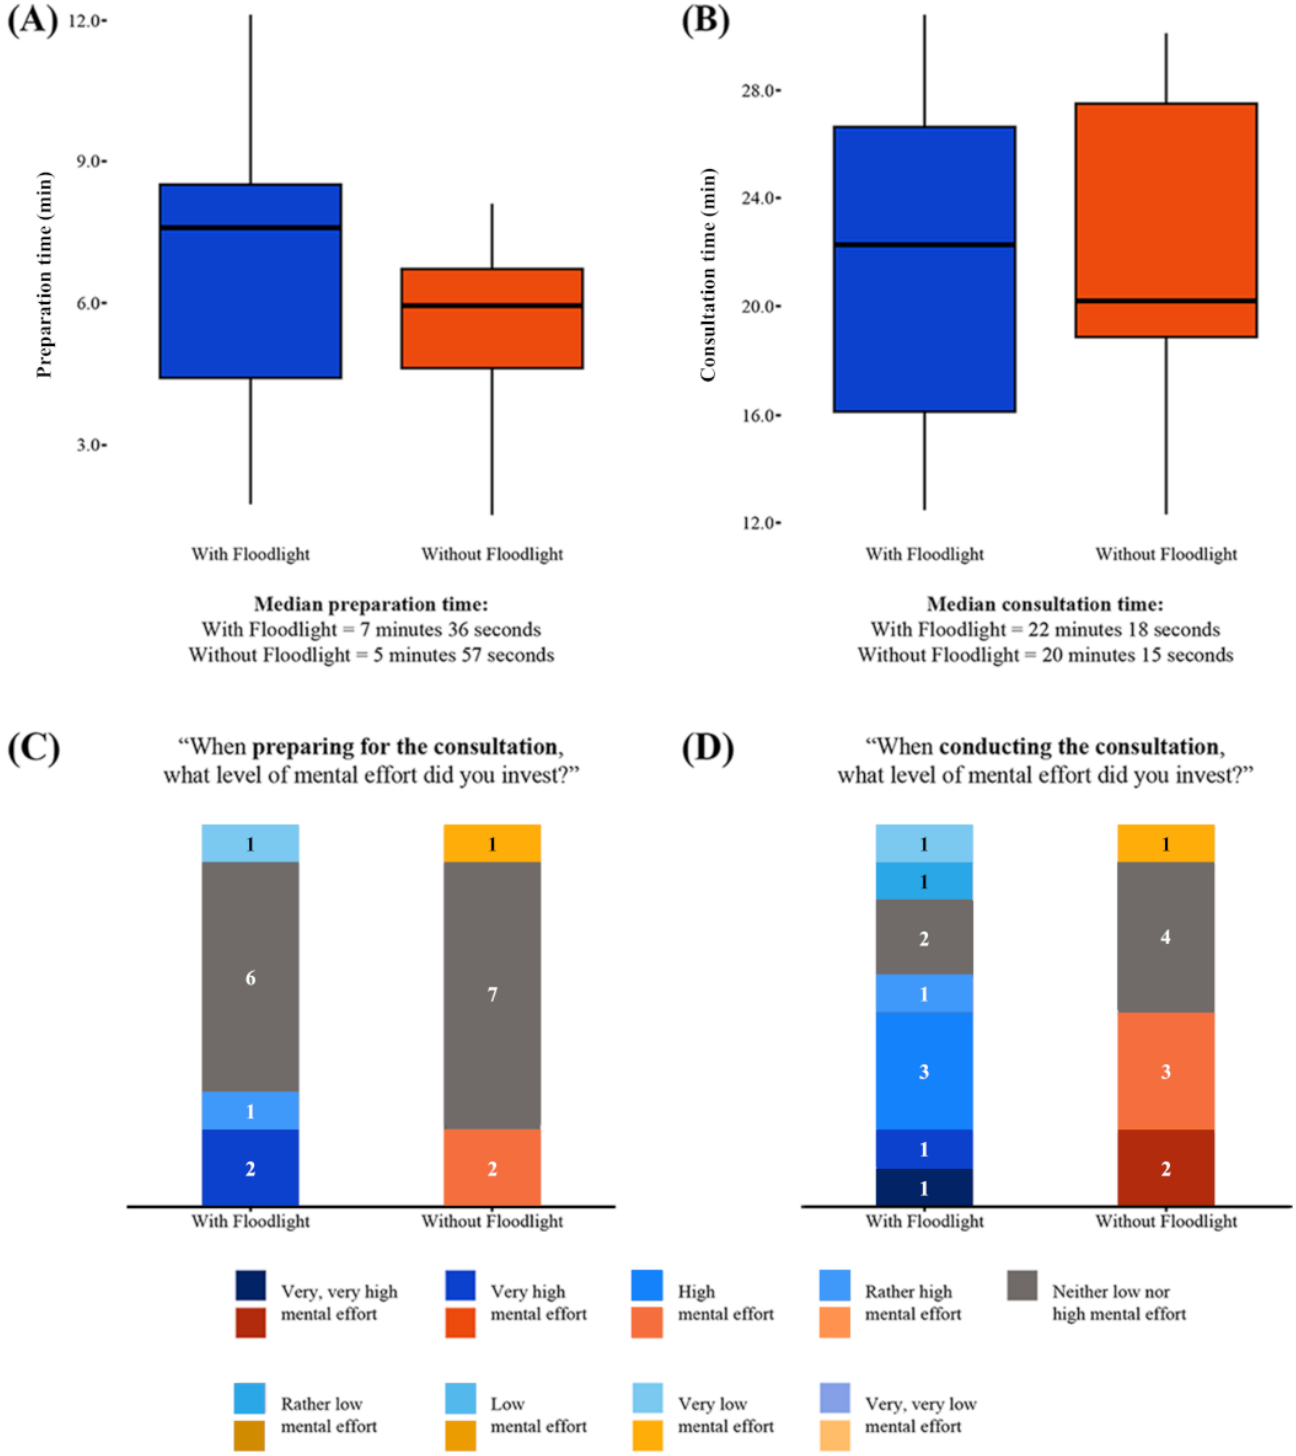
RenderX

Figure 4. User experience metrics for the usefulness of data visualizations in the Floodlight MS HCP Portal. Participant neurologists provided feedback on whether data visualizations in the Floodlight MS HCP Portal were useful for factors including upper extremity function, gait, and cognition. HCP: health care professional; MS: multiple sclerosis.

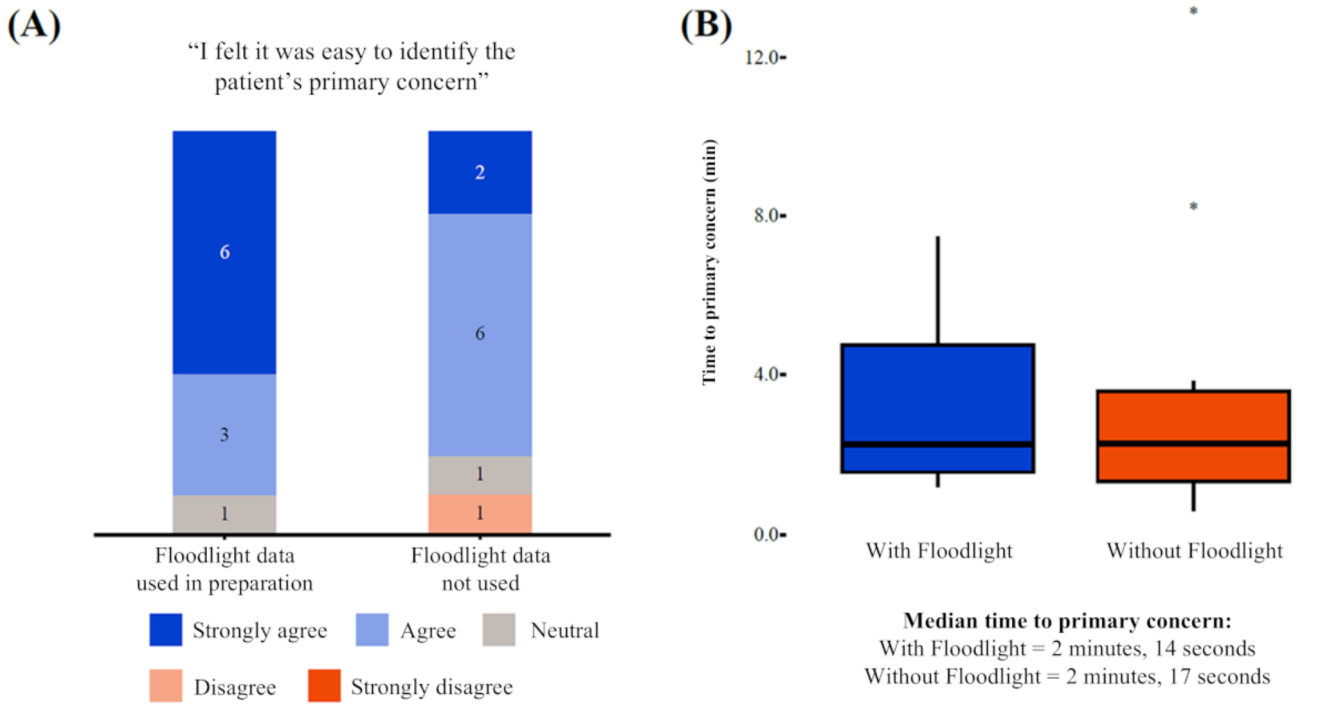


Workflow Metrics

In terms of the time taken for patient case preparation, cases took a median of 7 minutes and 36 seconds with Floodlight and 5 minutes and 57 seconds without Floodlight (Figure 5A). The median time taken to conduct the teleconsultations was 22 minutes with Floodlight and 20 minutes without Floodlight (Figure 5B). When using the Floodlight technology, participant neurologists also reported investing a slightly higher level of mental effort to prepare for (Figure 5C; very high mental effort to rather high mental effort: n=3 vs n=2) and conduct patient cases (Figure 5D; very, very high mental effort to rather high mental effort: n=6 vs n=5).

XSL•FO
RenderX

Figure 5. Workflow metrics. (A) Preparation time for patient cases with and without Floodlight data. (B) Teleconsultation time with and without Floodlight data. (C) Mental effort required preparing for patient cases with and without Floodlight data. (D) Mental effort required when conducting patient cases with and without Floodlight data. The classification key uses shades of blue for data obtained "with Floodlight" and shades of red for data obtained "without Floodlight"; shade of gray uses the same classification in both "with Floodlight" and "without Floodlight".



Clinical Consultations and Patient Concerns

About 6 out of the 10 neurologists "strongly agreed" that it was easier to identify patient concerns within the relevant functional domains with access to Floodlight data during the consultation preparation phase versus without access (where 2/10 "strongly agreed"; Figure 6A). The median time taken for participant neurologists to start discussing the primary domain of concern was 2 minutes, 14 seconds when using the Floodlight technology and 2 minutes, and 17 seconds without the Floodlight technology (Figure 6B).

XSL•FO
RenderX

Figure 6. Patients' primary domains of concern: (A) identification and (B) time taken. The identification of patient concern and the median time taken for participant neurologists to initiate discussions on the primary domain of concern were assessed during the consultation preparation phase with and without access to Floodlight data.

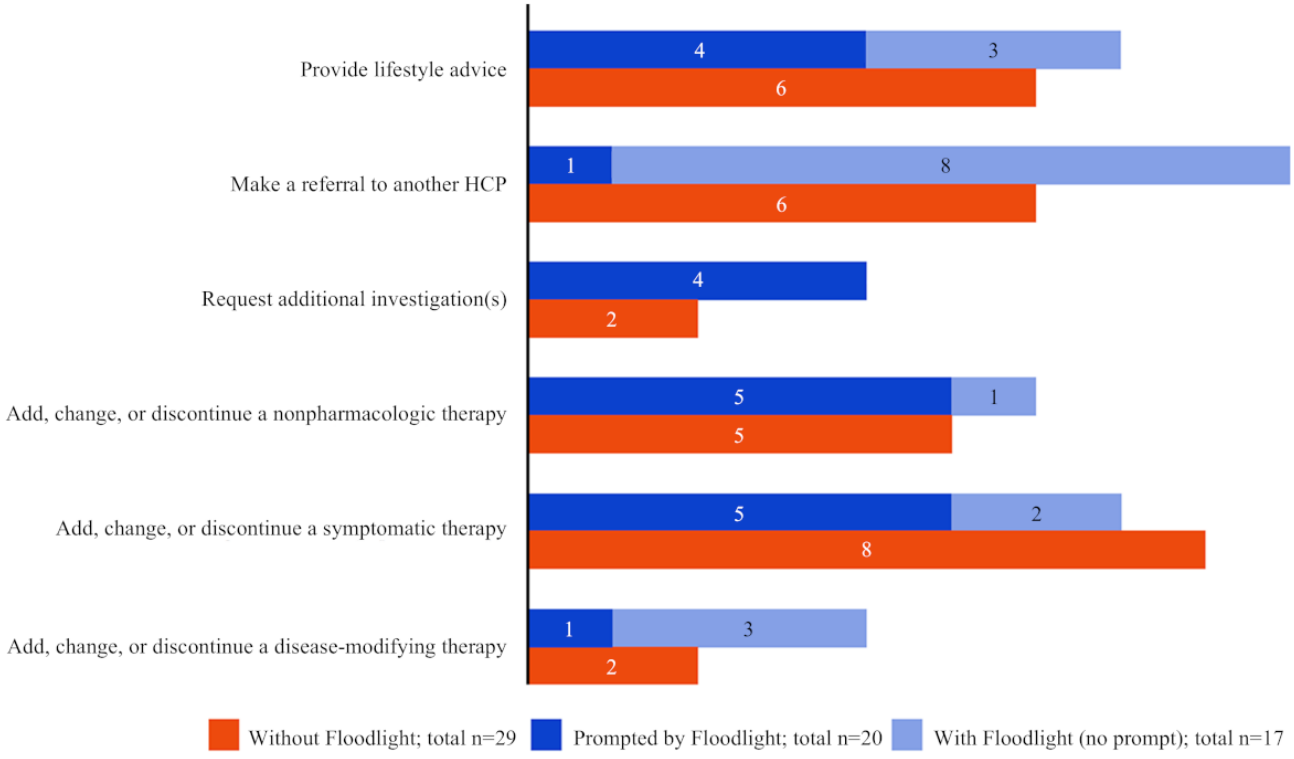
Recognition of "Invisible" Symptoms of MS

The median time taken to discuss each "invisible" symptom was between 1 and 1.5 minutes (Table 4). In Patient Case A, which was structured to show a prominent cognitive decline, cognitive issues, and mood change, discussions exceeded 2 minutes. In Patient Case B, bladder dysfunction (which was referred to in the clinical letters and without the support of Floodlight information) was also discussed for over 2 minutes. While differences can be gleaned at the individual symptom level, there was no clear pattern to the length of the discussions. Being aware of the symptom by means of the clinical letters did not necessarily seem to be a clear determinant in the participant neurologist spending more time on discussions with the patient actor. There were also no consistent differences in the median time spent discussing symptoms across domains with and without the use of the Floodlight technology.

Table . Median time spent discussing each "invisible" symptom[a] with patients (such as fatigue and bladder dysfunction that are difficult to evaluate by health care professionals [HCPs]) across all teleconsultations with and without the Floodlight technology.

Symptom	Patient Case A[b]		Patient Case B[b]	
	With Floodlight (min)	Without Floodlight (min)	With Floodlight (min)	Without Floodlight (min)
Vision changes	01:32[b]	01:18[b]	00:30	00:10
Sexual dysfunction	00:05	01:15	00:17[b]	00:55[b]
Mood changes	02:18	01:26	01:32[b]	01:50[b]
Physical and emotional pain	01:55	01:15	01:54[b]	01:12[b]
Bowel and bladder dysfunction	00:30[b]	01:10[b]	01:14[b]	02:47[b]
Cognitive changes	02:16[b]	02:06[b]	00:27	00:53
Fatigue	00:40[b]	01:01[b]	01:08	01:39
Median across all domains	01:25	01:22	01:07	01:34

[a]Invisible symptoms, including fatigue, mood disorders, cognitive impairments, pain, bladder or bowel dysfunction, sexual dysfunction, and vision changes can be experienced by people living with MS. Some of these symptoms may not be externally evident or easy to report and quantify and can be difficult for the patient to report and articulate during a clinical encounter (eg, due to subjectivity bias, poor recall, or stigma) or for physicians to capture (eg, limitations in available measurement tools, ample reliance on patient recall on the visit day).



[b]These are the symptoms that were previously reported, per the clinical documentation provided, for Patient Case A and Patient Case B.

RenderX

Care Decisions and Change in Disease Management Decisions

Floodlight data were reported as a trigger for 20 of the 37 care and change in disease management decisions (including regarding disease-modifying therapies, additional medications, referrals, or investigations), always in combination with other triggers such as patient history (20/20) or clinical exam findings (9/20; Figure 7). Overall, a greater number of care decisions were taken when using the Floodlight technology (37) versus without (29), including making a referral to another HCP (9 vs 6), or adding, changing, or discontinuing a nonpharmacologic therapy (6 vs 5) or disease-modifying therapy (4 vs 2).

Figure 7. Care decisions, including change in disease management, prompted by Floodlight data and taken when using the Floodlight technology, versus without. Floodlight data were reported as a trigger for care and change in disease management decisions, including regarding disease-modifying therapies, additional medications, referrals, or investigations. In all instances, Floodlight data were used in conjunction with other triggers such as patient history or clinical exam findings. HCP: health care professional.

Overall Feedback

Overall, participant neurologists valued access to longitudinal data, particularly regarding hand function and cognition. Many participant neurologists found the aspects of the user interface challenging when using the Floodlight MS HCP Portal. They felt that user interface improvements were the most important changes to be made, and they noted the following could help improve the interface: “Separating different data points and putting them into separate charts,” “...an overall curve, visualizing the trend over time,” and “…being able to change the y axis to separate data points for easier review.”

Data Availability

Discussion

Principal Findings

The clinical simulations of MS teleconsultations described in this study demonstrate the ability of this research methodology to deliver high-fidelity patient cases. They also enabled direct comparison of teleconsultations conducted with and without the use of digital health technologies.

Clinical simulation offered several advantages, including the ability to present relevant, representative, paradigmatic MS cases and to efficiently generate insights on the utility and usability of new digital technology in clinical visits. This provided early real-world insights from neurologists who were naïve to the Floodlight technology and who received only brief introductory training on its use. Specifically, it provided an opportunity to move beyond the expected impact of the tool and, instead, explore the approach used by participants naïve to the digital technology (after a brief orientation) in actual clinical decision-making.

Using real patient data from the CONSONANCE study enabled access to extensive existing data without additional patient consent or data acquisition, allowing case selection based on in-depth clinical information. The richness of the CONSONANCE dataset minimized the need for synthetic data, which was limited but where used, derived from valid sources such as narrative radiology reports and clinical letters. While this approach ensured high-fidelity and clinically relevant patient scenarios, it introduced a limitation in the generalizability of the simulated cases as the patient population in the

XSL•FO
RenderX

CONSONANCE study was composed entirely of people with progressive multiple sclerosis. This highlights the capability of clinical simulation to leverage rich, real-world datasets while also underscoring the importance of including a broader spectrum of patient profiles and validated synthetic cases to enhance external validity, scalability, and applicability across diverse MS phenotypes. Additional simulated patient cases can be easily generated from other clinical trials or by generating synthetic (but realistic) patient case data. Further simulation research should expand the number and diversity of patient cases, including data from varied trial populations and validated synthetic cases to better capture the heterogeneity of MS care. It is important to ensure that these cases are representative of typical patients seen in clinical practice and developed with appropriate ethical considerations to avoid the introduction of unwanted bias. Additionally, it is also essential to ensure that clinical trial data used for patient cases do not allow patient identities to be inferred and that blinding procedures are preserved.

This study explored complex MS cases, with multiple patient concerns and functional domains affected, to capture the complexity of real-world MS clinical visits and explore the impact of utilizing a digital tool (Floodlight technology). As with "real" clinical encounters with people living with MS, distilling prior history and functional testing into condensed clinical letters for use in the consultations was challenging, due to the heterogeneity of symptoms, scales, and other assessments used. For example, bladder symptoms reported by patients in the SymptoMScreen were consistently underscored in the clinicians' EDSS Bowel/Bladder Functional System [36-38].

Research applications of simulation can include training methodologies for educational purposes [22], such as in training for medical students or less experienced HCPs, and to enhance clinical competence [21]. Additionally, simulation can be used to improve primary care office–based readiness to respond to medical emergencies [39] or to enhance cultural sensitivity, communication, and empathy among HCPs [40]. Simulation can also be used as an investigative methodology to answer research questions that otherwise could not be answered feasibly, safely, ethically, or in a timely fashion in clinical settings [22], as pertains to our study.

The simulation methodology provided key insights into integrating a digital health tool into routine MS care. Initial findings pertained to how neurologists naïve to this technology began to access and interpret these data. Indeed, there is a known socialization process required for the adoption of new technology [41], and this must be accounted for in the plans that developers have for the implementation of new tools. Neurologists scored the clinician-facing HCP Portal for accessing Floodlight MS data "above average" on the System Usability Scale, indicating a high level of usability. Feedback from postsimulation surveys and interviews provides a foundation for iterative improvements to the user interface. Among the available data on the portal, the "mood status" aspect of the Patient Journal (Daily Status Questions) was rated as the most useful of the data visualizations presented, which is potentially indicative of a medical need (eg, more systematic depression monitoring). Finally, as expected, incorporating Floodlight data into teleconsultation preparation required slightly more time and mental effort than consultation without such technology. Interestingly, the median time was only 1.7 minutes longer for patient case preparation, which seems relatively modest compared with the potential gains from having Floodlight data available. This also indicates that the brief presimulation training was effective and supports the tool's scalability. With increased familiarity, time required to use the Floodlight technology during the visits would likely decrease. However, even a short amount of additional time requirement could nonetheless present a potential barrier to use. For example, when evaluating the initial launch of the patient codesigned, high-usability-scoring, point-of-care clinical dashboard MS NeuroShare, clinicians were less likely to use it on busy clinic days, despite the reported improvements in the quality of communication and patient understanding of management care plans. New solutions to alleviate clinician workloads must be evaluated against the time required to implement them, such as educating patients on the clinical applications [41].

Digital health tools can capture objective data between clinical visits. This can avoid reliance on patient recall of symptoms, helping to provide clinicians with a more complete picture of symptoms and enabling discussions between HCPs and patients. The second set of exploratory insights, therefore, concerned the impact that ready access to Floodlight data might have on clinical discussion and management. Overall, while participant neurologists started discussing the primary domain of concern after 2 minutes both with or without the Floodlight technology, most participants said that it was easier to identify patients' concerns when they had access to the Floodlight MS HCP Portal (Figure 6A). Further, more care decisions were taken when using Floodlight data versus without, for example, making a referral to another HCP or amending a disease-modifying therapy.

Limitations

While simulations can represent and provide insights on the dynamics of MS in real-life clinical practice, the method is limited by the ability to account for operational and behavioral variables that occur in clinical practices, and it may, therefore, not be a fully accurate representation. While this methodology is inherently scalable, its primary limitation lies in the effort needed to recruit and train actors. By comparison, on-site studies involving real patients are even more constrained, as they can only include individuals residing near the clinical study site(s). Although the actors performed convincingly, simulations cannot fully substitute for real patient interactions. Real patients may experience factors such as anxiety about their clinical outcomes, fatigue from poor sleep, or depression, all of which can influence the dynamics of clinical encounters; however, it must be noted that this is not one of the aims of this study. The limited numbers of participants and patient cases in this study, important for this initial testing of the research methodology, naturally limit generalizability to real-life clinical consultations. Virtual simulations could enrich the recruitment of diverse neurologists by offering more convenient participation as well as the potential to recruit neurologists from a wider geographic area. This will be important in studies that seek to quantify differences in clinical decision-making. Furthermore, a potential source of

XSL•FO
RenderX

bias relevant to all simulations involving observation of tasks is the Hawthorne effect, where participants modify their behavior when they know they are being observed [42,43]. Mitigation strategies to overcome this included informing participating neurologists in advance about the study objectives, emphasizing that the research focus was not primarily on diagnostic accuracy, and assuring them that their identities would remain confidential. To further minimize the Hawthorne effect, the observer's camera and microphone were switched off during sessions; however, the observer remained present on the call to ensure study fidelity and provide technical support if needed. It should be acknowledged that despite these measures, such biases cannot be entirely eliminated in simulation-based research, although increasing the number of participants might reduce their impact.

Further, exploring cognitive impairment as a primary domain of concern highlighted some limitations of using simulated encounters because some participant neurologists described typically engaging patients' family members or care partners when assessing the extent and impact of a patient's cognitive challenges, and family members were not included in the simulated scenarios. An alternative approach in clinical simulations exploring more focused digital tools would be to curate simpler patient cases with only 1 domain of concern and a few specific invisible symptoms and to focus the investigation on more specific aspects.

Conclusions

Clinical simulation of MS teleconsultations allowed evidence generation on the potential utility of a digital health technology tool in MS care. The simulated patient cases and environment were found to be of high fidelity and enabled the direct comparison of teleconsultations conducted with and without the use of the Floodlight technology. A number of domains could be explored, including tool usability, influence of Floodlight data on clinical decisions, and impact on clinical workflows. Employing this methodology provided preliminary evidence that the Floodlight technology could support routine MS care, as it was found to be usable and useful, with minimal additional time and mental effort required on the part of neurologists previously naïve to the technology.

The findings of this study support expanded research into and development of clinical simulation methodologies for neurological research. This could expedite integrating innovative methods or interventions in health care settings, as well as in medical training. In the digital health space specifically, simulations could help to anticipate what socialization of technologies may require, to steer guidance on usage, explain their value to clinicians, and help health systems plan implementation.

Acknowledgments

We would like to thank all study participants and their families. We would also like to thank Active Image Roleplay for providing the professional actors, and Philipp D'Alfonso, Joan Piñol Fustero, and Harold Gonzalez Hernandez, who helped with the technical setup of the Floodlight MS HCP Portal simulated environment. Writing and editorial assistance for this manuscript was provided by Cynthia J Henley-Smith, PhD, and Terri Desmonds, PhD, of Nucleus Global, an Inizio company in the United Kingdom, and funded by F. Hoffmann-La Roche Ltd.

Abstract

Background: Telemonitoring can be implemented using either centralized or distributed organizational models. However, few published studies explore which conditions make one model preferable over the other, or how to choose between these two.

Objective: This study aimed to investigate the decision-making factors across several domains (eg, technological, personal, and organizational) when selecting the telemonitoring model.

Methods: We conducted a multiple case study across 4 purposively sampled hospitals to gain a range of perspectives on organizational models for telemonitoring. Selection criteria included: (1) type of organizational model, (2) type of collaborating partners, (3) task division of handling notifications, and (4) it had to be implemented at scale, rather than being in an exploratory phase. Data was collected in a document study, 13 semistructured interviews, and a focus group. The topic list was based on the domains of the NASSS (non-adoption, abandonment, scale-up, spread, and sustainability) framework. Interviewees (n=13) were 5 project leaders, 2 tele-nurses, 4 health care professionals, and 2 clinical informaticians. Data analysis was performed iteratively and included reflective thematic analysis. A member-checking focus group was organized to verify and reflect on the findings.

Results: Various preferential factors based on the seven domains of the NASSS framework were explored for both centralized and distributed telemonitoring models: (1) Condition: the choice of objective, usually based on organizational strategy, determines whether telemonitoring will be centralized or distributed. (2) Technology: the preference for a model is determined by the anticipated number of notifications the application generates for a specific patient group. (3) Value proposition: the perceived cost-effectiveness and overall value to the patient shape the value proposition for each model. (4) Adopters: the new role of tele-nurse emerged in centralized monitoring centers (CMCs), necessitating new competencies, task redistribution, and shifts in responsibility. The importance of trust among staff became evident in the context of task redistribution. (5) Organization: CMCs are typically organized regionally, in partnerships or network arrangements, which can be time-consuming yet offer significant potential for impact. (6) Wider system: The existing Dutch reimbursement system does not incentivize CMCs because the payment structure is still based on a per-treatment model. (7) Adaptation over time: with advancements in technology, including artificial intelligence, organizing telemonitoring through CMCs is likely to gain popularity.

Conclusions: Our study highlights that when decision makers are choosing which telemonitoring model—centralized or distributed—to implement in their organization, deciding on the suitability of the model depends on multiple contextual factors. Our findings illustrate that decisions made for patient group selection, technology design, and value proposition significantly influence each other. It is therefore crucial for decision makers to understand these interactions and corresponding dynamics to better align their strategies with the operational realities of their organization.

Introduction

Telemonitoring outpatient and inpatient care (also coined remote patient monitoring, telehealth, and telemedicine) is a recognized solution to address health care challenges such as rising costs, staff shortages, and the need to improve cost-effectiveness, treatment quality, and reduce waiting times [1-4]. Telemonitoring is defined as "the use of information technology to monitor patients at a distance" [5]. Telemonitoring enables clinicians to maintain and adjust their patients' plan of care by using remotely gathered data, such as vital signs, to proactively make medical decisions about a patient's care [6]. It involves the collection, transmission, evaluation, and communication of individual health data from patients to health care providers using technology [7]. Because telemonitoring is widely touted to improve patient care while reducing staff workload and costs, governments worldwide stimulate it as a paramount innovation [8,9]. While much research has focused on the positive outcomes of telemonitoring for patients and organizations [10-12], less attention has been given to the organizational aspect of telemonitoring. Specifically, the considerations for various organizational models—centralized, distributed, or a combination of both [13-15]. However, which model is preferable in a given context and how to choose between the models remains unclear.

In general, 2 organizational models are in place. First, a centralized organizational model, which places patient monitoring in a physical or virtual centralized monitoring center (CMC) and is primarily conducted by tele-nurses rather than physicians. CMC can involve monitoring patients across an entire health care organization, network, or even a region [13,16,17]. The literature reports notable advantages to a centralized organizational model, including improved efficiency and cost-effectiveness through economies of scale and pooled resources, which are especially beneficial in rural areas and alleviate staff shortages [18,19]. The larger volume of cases in centralized telemonitoring permits 24/7 operation, instead of being confined to office hours in outpatient clinics [8,20]. Since 2019, structural financing for remote care (telehealth) was established in the Netherlands. Under specific conditions and for designated diagnoses, hospitals became eligible to claim reimbursement for remote care through the existing diagnosis treatment combination system [9]. This reimbursement facilitated the digital transformation of health care, aiming for more efficiency in health care delivery. Recent studies have shown that patients are satisfied with centralized telemonitoring [8,21]. Most professionals view centralized telemonitoring as favorable, although some are less acquainted with telemedicine and harbor reservations [8,22]. The second is a distributed organizational model in which professionals monitor their specific patient population [15]. Professionals believe they possess a better contextual understanding of their patients' data than tele-nurses who do not know a specific patient [18]. Some studies have shown that the doctor-patient relationship enhances patients' adherence to telemonitoring restrictions and therapy agreements. However, studies on the differences between centralized and distributed organizational models are lacking [13,15,18].

Numerous studies, including several literature reviews, have explored the implementation of telemonitoring for patients with diseases such as hypertension, heart failure, diabetes, and chronic obstructive pulmonary disease (COPD) [eg, 10,23,24]. These studies highlight various organizational models and the challenges associated with the complexity of implementing telemonitoring [25]. However, the challenges of organizing telemonitoring extend beyond adoption or implementation obstacles. They require a deeper exploration of different aspects, including context variables at the micro, meso, and macro levels [26,27].

This is particularly relevant, as both centralized and distributed organizational models for telemonitoring can be implemented in a single organization or across multiple organizations, potentially spanning the entire care chain [26]. To address this complexity, the NASSS (non-adoption, abandonment, scale-up, spread, and sustainability) framework provides a comprehensive lens, through which 7 key domains are examined: condition, technology, value proposition, the adopter's perspective, organizational context, the wider context, and adaptation over time [28]. Importantly, the framework does not imply a linear relationship between the domains but instead emphasizes their interconnectedness and mutual influence [29]. With this framework, barriers and facilitators for implementation can be identified, and the complexity of each domain can be assessed [30,31]. Given this, our research question is as follows: which considerations are taken into account when choosing between centralized or distributed telemonitoring, following the NASSS framework?

Methods

Study Design

Using a qualitative research approach, we conducted a multiple case study to explore the factors hospitals consider when choosing between centralized and distributed telemonitoring models. The study complied with the COREQ (Consolidated Criteria for Reporting Qualitative Research; see Checklist 1) [32]. The first author is a medical student in health sciences; the other authors are experienced researchers (PhD, associate professor, and endowed professor).

Ethical Considerations

Ethical approval was secured from the Ethics Review Board of Tilburg University (ReferenceTSB_RP741). Data storage is compliant with the General Data Protection Regulation.

Setting

This study was executed in the Netherlands. This country has been implementing a series of policy measures aimed at facilitating the digital transformation of health care since 2012. Measures include the introduction of incentive grants, national guidelines, specific volume targets for hospitals, and structural financing for remote care (telehealth encompassing telemonitoring) [33-35]. In the face of staff shortages, this has led to new forms of (hybrid) care that aim to reduce the number of follow-up outpatient clinic visits for chronic patients, reduce hospital length of stay after surgery, etc. The Netherlands manages the health system through self-regulation among private

XSL•FO
RenderX

entities: health care services are provided by private providers and managed by private health insurers. Every individual in the Netherlands has the option to select their health care insurer and health care plan [36]. Since 2019, hospitals are eligible to claim reimbursement for remote care under specific conditions and for designated diagnoses, through the existing Diagnosis treatment combination (comparable to Diagnosis Related Group) system, with costs covered under the statutory basic health insurance package. Hence, telemonitoring is covered by the Dutch health insurance system [9]. In the Netherlands, the availability of high-speed broadband internet and 4G mobile network is high, and an estimated 90% of the Dutch people use this on a daily basis. Still, health care organizations do not have the funds to upscale telemonitoring and therefore implementation progresses slowly.

Within this context, a purposive sample of teaching hospitals based on 2 organizational models (ie, centralized monitoring and distributed monitoring) was selected. (See Multimedia Appendices 1 and 2 for a visual representation of the centralized and distributed telemonitoring models). Hospitals using telemonitoring were selected from a network of Dutch teaching hospitals (Samenwerkende Topklinische Ziekenhuizen). Given the relatively small number of hospitals in the Netherlands (69 nonprofit hospital organizations), and the fact that only a few have implemented telemonitoring at scale, due to its relatively innovative nature, the selection of potential participants was constrained. To ensure comprehensive representation, all (12/12) early adopters of telemonitoring were put on a list. Project leaders responsible for telemonitoring in these hospitals were approached via email, which detailed the aim and design of this study. A total of four hospitals declined to participate (4/12,33%) citing as reasons: time constraints or maternity leave. Of the hospitals willing to participate (8/12, 67%), we purposely sampled that met the inclusion criteria outlined in Table 1, striving for a maximum variety of cases. An additional criterion was that the telemonitoring program had to be implemented at scale, rather than being in a pilot or exploratory phase.

We included 2 hospitals with primarily centralized telemonitoring (A and C) and 2 hospitals with predominantly distributed telemonitoring models (hospitals B and D). While hospitals B and D incorporated some centralized elements (300/3000, 10% and 1000/11,000, 9%, respectively, of their telemonitoring was conducted through a central unit) the vast majority (2700/3000, 90%) were organized in a distributed manner across care providers. In addition, in terms of collaborative partnerships, we included hospitals that operated independently without external collaboration (hospital A), those that collaborated with general practitioners in organizing telemonitoring (hospital B), and those that partnered with other hospitals (hospitals C and D). Finally, regarding role division in the monitoring process, we included hospitals where tele-nurses (hospitals A, B, and C), nurse practitioners (hospitals B and D), and residents (hospital D) were responsible for viewing telemonitoring alerts. Table 1 shows this overview. While the 2 distributed cases (hospitals B and D) also implemented centralized elements, they were classified as predominantly distributed.

Table . An overview of the hospitals included on the basis of the selection criteria.

Criterion	Hospital A	Hospital B	Hospital C	Hospital D
Organizational structure	Centralized	Predominantly distributed	Centralized	Predominantly distributed
Number of telemonitored patients	2000	3000 of which 300 (10%) centralized and 2700 distributed.	500	11,000 of which 1000 (9%) centralized and 10,000 distributed.
Partnerships	None	General practitioners	Hospital network	Neighbor hospital
Role division of handling telemonitoring alerts	Tele-nurses	Tele-nurses (both nurses and nurse practitioners)	Tele-nurses (nurses with physical disabilities)	Tele-nurses (both nurses and nurse practitioners); residents during outside-of-office hours.

Data Collection

Data collection included a document study, 13 interviews conducted between March and May 2023, and a member-checking focus group held in May 2023. The researchers began by requesting implementation-related documents (eg, implementation plans, current-state analyses, vision-related documents, or briefing materials for executive boards) from the project leaders of all 4 hospitals to study the organizational structures and challenges. Next, a researcher (NAE) conducted 13 semistructured interviews lasting between 30 and 60 minutes (see Table 2 for participant characteristics). The respondents were recruited via the project leader based upon criteria set by the researcher, including knowledge of telemonitoring and the respondent's involvement in the implementation process. Informed consent was obtained before the interview. The participants represented a diverse group of health care professionals and the project leaders, including a clinical informatician, which ensured multiple perspectives. Their varied backgrounds allowed for comprehensive insights into technical, practical, and organizational aspects, thereby collectively addressing all domains of the NASSS framework.

XSL•FO
RenderX

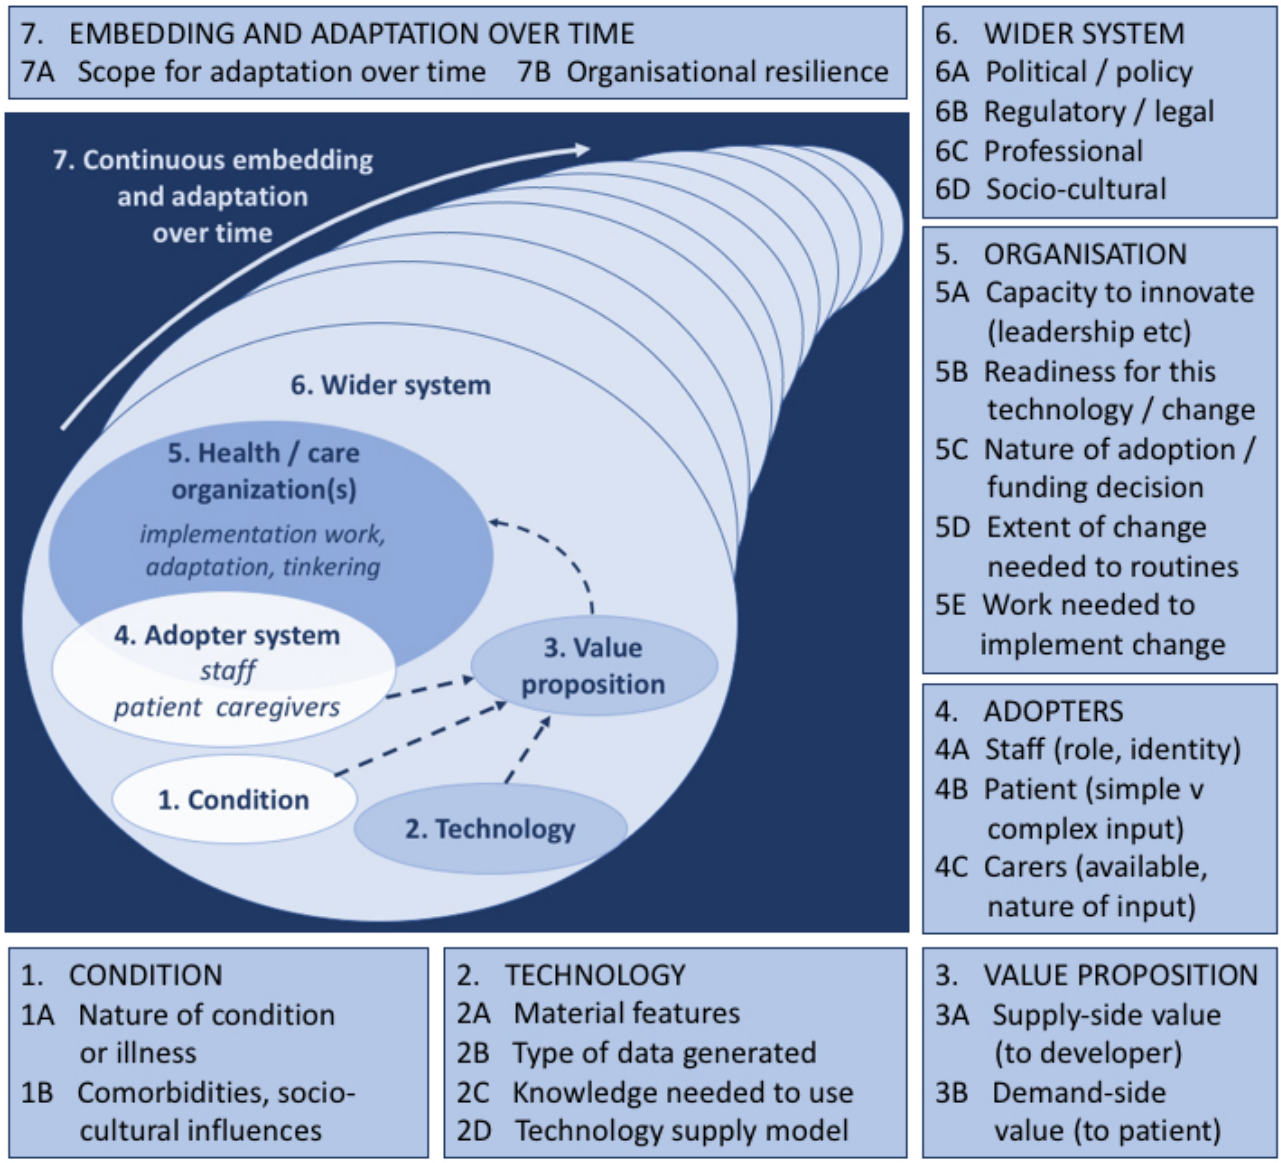

Table . Interview participants (N=13).

Background	Sex	Age
Project leader	Female (n=2) Male (n=3)	• 1 aged <30 y • 2 aged 30 - 39 y • 1 aged 40 - 49 y • 1 aged ≥60 y
Physicians	Male (n=3)	• 2 aged 30 - 39 y • 1 aged ≥60 y
Nurse practitioner	Female (n=1)	• 1 aged 40 - 49 y
Tele-nurse	Female (n=2)	• 2 aged 40 - 49 y
Clinical informatician	Female (n=2)	• 1 aged <30 y • 1 aged 40 - 49 y

Like previous studies that applied the NASSS framework to study telemonitoring (eg, 31,37-39), we based our topic list (see Multimedia Appendix 3) on this framework as well (see Figure 1) [27,40]. As the NASSS framework incorporates 7 interrelated domains that influence the implementation of innovative technologies, we considered it helpful to gain an understanding of relevant considerations of centralized versus (predominantly) distributed monitoring. The seven NASSS domains are as follows: (1) condition or illness, (2) technology, (3) value proposition, (4) adopter system, (5) organization, (6) wider context, and (7) embedding and adaptation over time [27]. Each domain can be defined by complexity (ie, dynamics, unpredictability, and interdependency) and their influence on other domains

XSL•FO
RenderX

Figure 1. The non-adoption, abandonment, scale-up, spread, and sustainability (NASSS) framework [27].

The interviews were video recorded through Microsoft Teams and transcribed verbatim. Afterward, the transcripts were verified for accuracy by a single researcher (NAE). A 1-hour focus group was subsequently conducted with the 5 project leaders to reflect upon our findings and enrich our insights by discussing the findings. This focus group was audio-recorded and transcribed verbatim. The participants mainly recognized and affirmed the results, thereby supporting the validity of our findings.

Data Analysis

The analysis was performed iteratively, ranging abductively between document analysis, transcripts (both interviews and focus group) and the literature [41,42]. A researcher (NAE) first open-coded the transcripts and documents via Atlas.ti 9 (Atlas.ti Scientific Software Development GmbH). To ensure reliability, a second researcher blindly thematically coded 3 interviews to cross-check coding. Afterward, the whole research team discussed both codes up to consensus, which resulted in a final code tree (see Multimedia Appendix 4), which guided a researcher (NAE) in the subsequent thematic coding [43]. Subsequently, selective coding categorized the codes and connected these to the themes of the NASSS framework domains. Next, each domain got a code, and the data was analyzed by these codes to identify similarities and differences across the cases, which led to an overview of complexities based on the criteria outlined in the NASSS framework. Finally, analysis and conclusions were discussed collectively (NAE, MJR, AMW, and MM). Overall, we applied a reflective thematic analysis as described by Braun and Clarke [43], “Reflexive TA [thematic analysis] approaches embrace researcher subjectivity as a resource for research (rejecting positivist notions of researcher bias (see [44]), view the practice of TA as inherently subjective, emphasize researcher reflexivity, and reject the notion that coding can ever be accurate—as it is an inherently interpretative practice, and meaning is not fixed within data.” Reflective thematic analysis was appropriate in this research, as we did not use the NASSS framework as a deterministic (ie, implementation steps) or even predictive model, rather as a sensitizing concept (see also abductive research methodology) providing us a reflexive lens in our analysis to deepen our interpretation [45].

XSL•FO
RenderX

Results

This section presents the findings of this study, organized according to the 7 domains of the NASSS framework. For each domain, we compared the considerations made between centralized and distributed monitoring models.

Domain 1: Selection Based on Patient Conditions and Telemonitoring Aims

The studied hospitals used various telemonitoring strategies: (1) centralized in the CMC, and (2) a predominantly distributed model in which most monitoring occurred locally, though some centralized elements were also present (see Table 1). The CMC strategy focused on identifying conditions suitable for central telemonitoring and aimed to incorporate all eligible patients into the CMC model. In contrast, in the distributed model, with the majority being managed through a distributed model, patients were selected on the basis of the telemonitoring objectives and disease complexity.

Our analysis revealed two objectives: (1) to enhance patient self-management, which is especially relevant in chronic diseases. Self-management was achieved through an online process involving telemonitoring that resembles e-coaching, in which advice is provided digitally, and hospital staff intervened only when the advice proved inadequate or when patients had questions. Since most alerts do not require an immediate response, distributed telemonitoring is feasible because it can be performed alongside other tasks. Several respondents mentioned that distributed telemonitoring was feasible for low-complexity cases only, because of time limitations; and (2) to monitor vital parameters. If patient measurements deviate from preset ranges, alerts are generated, prompting notifications to staff. Most alerts require immediate attention, as the patient may need acute care. Therefore, centralized telemonitoring aligns better with this aim.

Domain 2: Technological Features and Number of Notifications

In the Netherlands, 2 main vendors offer telemonitoring software applications to hospitals (Luscii and Sananet). All studied hospitals used both applications along with several additional applications to answer patient questions, often as part of their patient portal or an independent phone app. Consequently, health care staff used several applications. The visual and architectural design of these applications differed across hospitals. Our data reveals no relationship between the choice of software applications and the organizational model for telemonitoring.

Instead, our findings indicate that the intended telemonitoring objectives (ie, Domain 1: self-management or vital parameter monitoring) and the work that needs to be done, especially the expected notification numbers, drive the selection of the organizational model. Vital parameter monitoring generates many alerts that demand a timely response. Alerts requiring urgent response impact heavily on the workload of the involved staff who must assess and filter alerts based on clinical relevance. Current software cannot distinguish between relevant and irrelevant alerts. The high volume of alerts cannot be managed alongside other tasks, necessitating either centralized monitoring or staff assigned to this function.

> *The application captures most of the notifications or at least filters out the patients you don't have to see because they are in good health. The CMC eliminates another 80%-90%. The nurses remove another 15% so that leaves the physician with zero to 5% patients to actually see.* [Physician, hospital A]

In contrast, self-management provides less urgent alerts and, according to respondents, fewer alerts:

> *Because the app encourages self-management, the number of alerts is very low […] We work in a team of three. I think about 1 FTE is assigned [to telemonitoring] for a population of more than 1000 patients.* [Project leader, hospital B]

In sum, the technology setup is not tied to the organizational model. However, the aims of telemonitoring affect the expected volume of alerts and anticipated staff workload, which in turn influence the choice of organizational model.

Domain 3: Influence of Efficiency and Knowledge on Value Propositions

Centralized and distributed telemonitoring offer distinct value propositions for both professionals and patients. The respondents indicated that in a centralized model, telemonitoring is assigned to dedicated tele-nurses in the CMC, allowing them to focus on telemonitoring tasks. Compared with a distributed model, their concentrated effort enables quicker response times compared to a distributed model (see Domain 2 subsection). Many respondents suggested that centralized telemonitoring operates more cost-effectively due to economy of scale. The benefits grow with more partnerships with other organizations or general practitioners (see Domain 5) and large numbers of patients are monitored. In contrast, respondents highlighted the cost-effectiveness of distributed telemonitoring models, as the telemonitoring tasks can be performed alongside other duties:

> *[Nurses] in the outpatient clinic always have a spare moment between patients. They can answer a message. So, it is very energizing, and possible to do an 'in-betweenie'. So, the question is, how much capacity do you win if you centralize this?* [Project leader, hospital D]

In addition, our respondents said that delegating tasks to (tele-)nurses in both distributed and centralized monitoring alleviates the workload of nurse practitioners (NPs) and physicians, giving them more time for complex patient cases. However, task delegation sometimes requires specialist knowledge, especially with urgent vital parameter monitoring (see Domain 1 subsection). Specialist knowledge of many diseases is hard to transfer to CMC nurses and NPs, making it crucial for staff in centralized telemonitoring organizational models to have direct access to doctors. Respondents indicated that transferring specialized knowledge and maintaining close communication with doctors is easier to organize in distributed telemonitoring. Consequently, distributed telemonitoring models provide patients with direct access to health care professionals who possess specialist disease knowledge and, in some cases,

XSL•FO
RenderX

specific knowledge about the patient. As one respondent said: "This specific knowledge adds value for patients."

Thus, our data suggest that centralized telemonitoring is feasible for handling large patient and alert volumes (see Domains 1 and 2 subsections), which require nonspecialist knowledge, while distributed telemonitoring is preferable for alerts requiring specialist knowledge. Centralized telemonitoring is cost-efficient due to economies of scale when managing many patients or high volumes of alerts, whereas distributed telemonitoring is more efficient as it requires no additional personnel.

Domain 4: Evolution of the Telemonitoring Adopter's Role

In both organizational models, monitoring staff required specific competencies to incorporate the telemonitoring in their existing clinical workflows. Nurses took on a new role, expanded their responsibilities beyond those of traditional nursing. Consequently, the roles of NPs and physicians evolved, as now they supervise tele-nurses in their expanded responsibilities. In the cases we studied, the CMC tele-nurses were also responsible for developing telemonitoring clinical pathways for other medical conditions:

> *I'm currently contacting physicians to determine which patient groups we can add to our monitoring program […] That's my primary task besides monitoring. We also write the workflow protocols when we start monitoring a new condition.* [Tele-nurse, hospital A]

Respondents emphasized that this prominent role in organizing telemonitoring contributed to the growing enthusiasm for the tele-nurse role, which led to fewer personnel shortages in the CMC compared to other departments.

In addition, tele-nurses are taking on tasks that were previously performed by physicians and nurse practitioners. This shift in responsibilities requires a strong foundation of trust—particularly in the clinical judgment, decision-making, and actions of tele-nurses. This is especially important when task distribution occurs across departmental boundaries, as is the case in centralized monitoring models. Central to establishing trust were collaboratively developed protocols, grounded in evidence-based medicine guidelines. This joint development process ensured continuity by actively involving the original care providers (eg, physicians and nurse practitioners) in shaping the clinical procedures. With this approach, confidence in the transfer of responsibilities was fostered and the transition of clinical tasks was supported. In addition, our data indicated that trust was established through several approaches: (1) making individualized care plans including patient-specific threshold for alerts, rather than relying on standard ranges for patients. This approach fostered the trust in clinical judgment of tele-nurses. (2) Developing new working routines, aligned with the task distribution. Clear communication about these new routines, particularly regarding responsibilities and alert management, helped build trust among professionals involved in the telemonitoring. (3) Project leaders fostered trust in centralized telemonitoring by facilitating disease-specific and training concerning the specific electronic medical record to tele-nurses, enabling a competent transition of care. Responsibilities were transferred to the CMC gradually, beginning with administrative tasks and progressively expanding to the full spectrum of telemonitoring activities, allowing trust to develop through demonstrated capability. Furthermore, respondents mentioned that staffing the CMC with nurses from diverse specializations ensured access to specialist knowledge, thereby increasing the confidence of colleagues in their ability to manage complex conditions and patients (Domains 2 and 3).

Thus, in both organizational models (tele-)nurses took on greater responsibility, under the supervision of NPs and physicians. Trust between professionals was crucial for this task redistribution, established through the development of evidence-based protocols, training, and clear guidelines, ensuring that (tele-)nurses could manage complex cases and alerts effectively.

Domain 5: Telemonitoring Across Organizational Boundaries

Partnerships are a critical aspect of establishing CMC telemonitoring as efficiency depends on economy of scale. Collaborations can be either geographically bound (hospitals B and D) or based on previously established (national) network structures (hospital C). In our study, partnerships were primarily formed in centralized telemonitoring programs, likely due to the more structured coordination and larger scale of these programs compared to the more fragmented distributed models. Consequently, the objective function as a regional CMC appeared to be connected to their initial partner strategy. In contrast, hospital C is piloting a network-based collaboration also aimed at expansion. This network partnership involves complementary task delegation as the participants strive to delegate tasks to and from other organizations. Respondents also noted the potential for complementarity of regional and network collaboration, as the following quote shows:

> *In the case of a deviating measure [of a patient's vital signs], the CMC gets involved, prompting action. However, this action could potentially be delegated to a regional collaboration partner. The one does not rule out the other; they could work together very well.* [Clinical informatician, hospital B]

Partnerships often allocate task delegation by (regional) partners to the CMC. However, respondents mentioned task delegation-related concerns about the freedom to comply or not with collaborative agreements and regional or network protocols. To address these concerns, hospitals B and D, having a majority of distributed telemonitoring cases, initially focused on regional initiatives, engaging all the partners (including GPs) in discussions on the challenges emerging from discrepancies between the protocols of the newly formed network and those of the established regional partnership.

To recap, partnerships are essential for CMCs to achieve efficiency through economy of scale. Collaborations can be regional or network-based, with CMCs benefiting from structured coordination, though task delegation between regional and network partners. However, this poses challenges related

XSL•FO
RenderX

to protocol alignment and a need for making collaborative agreements.

Domain 6: Economic Context Impedes Using Telemonitoring to Solve Societal Challenges

Our respondents aimed to provide efficient care in the face of staff shortages and the need to meet the increasing demand for care due to more patients with comorbidities and more elderly living at home. They feel telemonitoring can help address these challenges as it makes admitting patients or recurring outpatient clinic visits unnecessary. In the studied cases, a CMC employed nurses with physical limitations who were otherwise unable to provide direct patient care on the ward, demonstrating that telemonitoring allows these people to contribute to the workforce. By providing these new staff roles, telemonitoring, in both organizational models, supports workforce retention and efficiency.

In the Netherlands, both CMC and distributed telemonitoring are reimbursed under the same scheme. However, the current financing model within the diagnosis treatment combination (similarities with DRG's systems) system is predicated on the substitution of physical care with remote care within the existing tariff structure. In practice, reimbursement rates for in-person care remain higher than those for remote services. Furthermore, hospitals are required to make substantial upfront investments in digital infrastructure and personnel to support telemonitoring and remote care services. As a result, costs are incurred in advance of potential long-term benefits, and providers risk losing revenue from reduced volumes of billable physical consultations and hospital admissions. Given that hospital funding in the Netherlands is still partially based on production-related agreements—largely tied to physical service delivery—this shift toward more efficient, home-based care may inadvertently lead to a decline in institutional revenue, thereby creating a financial disincentive for scaling up telemonitoring:

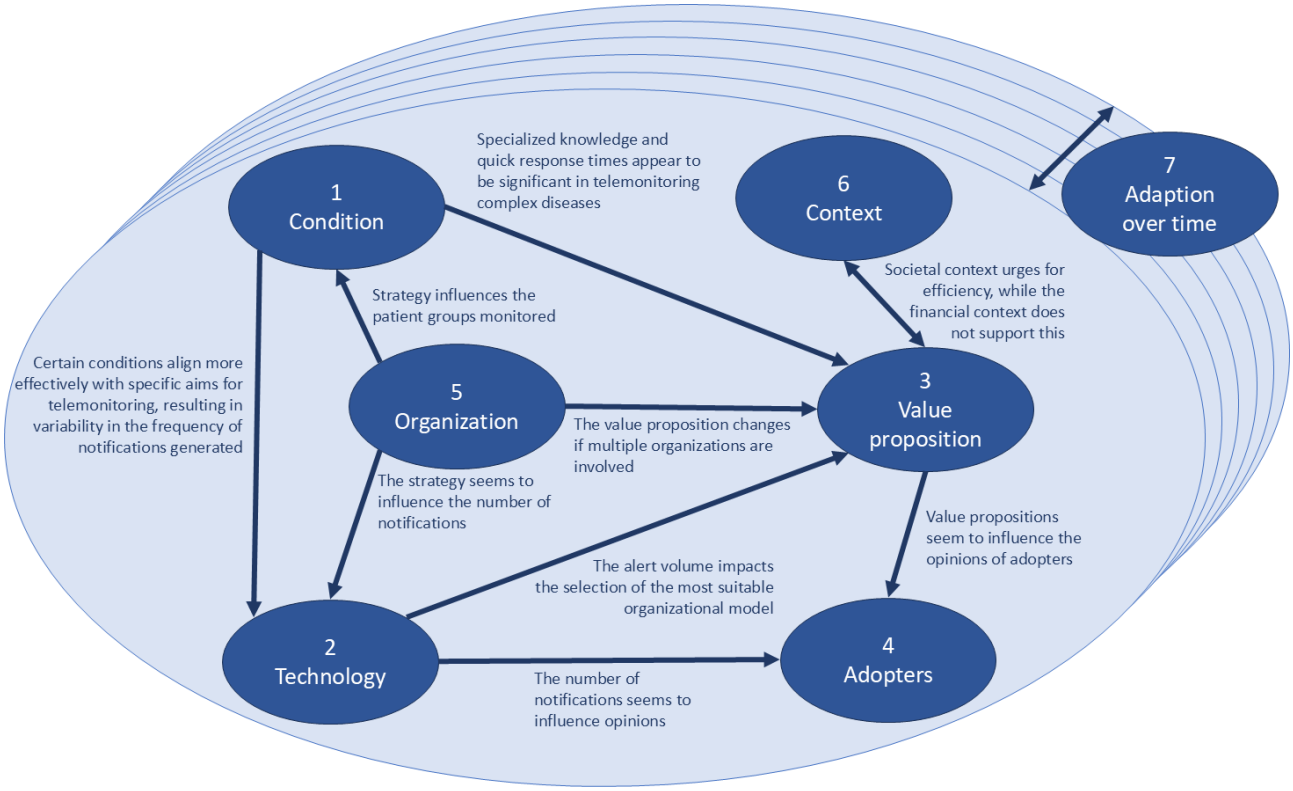
> *We have lots of telemonitoring and that costs us millions of euros [because we don't get fully reimbursed]. So, you're always thinking, what am I doing? I'm organizing my own downfall.* [Project leader, hospital A]

Since there is no difference in reimbursement for centralized and distributed telemonitoring, these financial challenges are the same for all hospitals in this study.

Domain 7: Embedding and Adapting Telemonitoring Over Time

The CMCs in all hospitals are currently expanding, and many respondents anticipate an even broader role for telemonitoring in the future. Expected developments include more partnerships in CMC, extending the number of patient conditions monitored, and increased patient volumes.

> *We're expanding to monitor more care pathways, and we're also aiming to increase the number of patients on each pathway.* [Project leader 1, hospital C]



Some respondents suggest that advancements in information and communication technologies and artificial intelligence (AI) could facilitate this role expansion, especially in automating tasks such as distinguishing relevant from irrelevant notifications. This is particularly applicable to acute-care patients who require intensive monitoring. However, if automation leads to reduced numbers of notifications, it could also reduce the need for centralization.

NASSS Framework

Using the NASSS framework enabled us to examine the domains while considering multiple decision-making factors. Figure 2 illustrates the interdependencies found among the various domains. For instance, value proposition (Domain 3) is primarily based on the perception of cost-effectiveness and added value to the patient. It is also affected by the selected patient group (Domain 1) and organizational strategy (Domain 5). The technology applied (Domain 2) affects how notifications are managed and handled, impacting the value proposition and opinion of adopters. When changes made in an area can affect other areas, interconnectedness underscores the complexity of decision-making in organizing telemonitoring.

Figure 2. Interactions between the domains of the non-adoption, abandonment, scale-up, spread, and sustainability (NASSS) framework [27].

Discussion

Principal Findings

This multiple case study shows that the decision to implement telemonitoring, whether through centralized or distributed organizational models, involves a complex array of considerations that must be carefully weighed. A definitive argument in favor of either model cannot be made, as each option presents distinct advantages and challenges across different domains. However, our findings highlight that strategic decisions made early in the implementation process—particularly those related to the telemonitoring of objectives on the basis of patient groups—are crucial in determining the appropriate organizational model. These decisions, in turn, shape possibilities related to personnel (eg, hiring tele-nurses or educating outpatient clinic or ward staff, and the role physicians play), partnerships, and the overall cost-effectiveness of telemonitoring.

Comparison With Previous Work

To date, many telemonitoring studies have focused on the design and development of the technology or the implementation of a specific telemonitoring care pathway [10-12,46]. To our knowledge, this is the first study to systematically compare considerations related to centralized and distributed telemonitoring models.

Model Follows Strategy

First, we would like to address the significant role of the selected patient condition, encompassing both the type of patient group enrolled in telemonitoring and the complexity of their health care needs. The patient condition drives the subsequent considerations that together determine the appropriate organizational telemonitoring model. For example, programs targeting chronic conditions aiming for self-management, typically associated with lower alert frequency and lower clinical complexity, can be organized through distributed care models. Conversely, telemonitoring programs focused on vital parameter tracking, such as those in early discharge scenarios [10,23,24,47], having high alert volumes and a need for rapid response, make centralized models more appropriate in those cases (domains 1 and 2). This observation is consistent with the current literature, which suggests that before implementation, telemonitoring systems are evaluated for their anticipated impact on patient safety, staff workload, and clinical usefulness [24,48], all of which depend on the specific patient group intended for remote care. This initial strategic decision sets the foundation for the primary objective of telemonitoring, whether that be to enhance self-management [48,49] or to monitor vital parameters [50]. Consequently, the selected patient condition and objectives influence the aims, and vice versa. Furthermore, the chosen aims directly affect the volume of alerts generated. For instance, a focus on vital parameter monitoring typically results in a greater frequency of alerts [51] compared to a self-management approach. Our findings indicate that the volume of alerts also affects how and for whom notifications are managed, ultimately shaping workload distribution [52] and task division [53,54] among health care professionals. Clearly, the interplay between patient condition, strategic objectives, and alert management is critical in determining the appropriate organizational model for telemonitoring. The choice of objectives impacts personnel, capacity, resources, and partnerships, outcomes that affect health care delivery in the region. It is crucial not to overlook the need for planning at this level, and decision makers must be educated to consider all the dimensions and understand how their choices will ripple through the system when determining the best

XSL•FO
RenderX

telemonitoring model for a patient. Looking ahead, the evolving role of AI will likely have significant implications for the organization of telemonitoring (Domain 7). AI has the potential to support clinical decision-making by filtering alerts, identifying patterns, and prioritizing cases [55]. In this way, AI may reduce the need for centralized monitoring by enabling distributed care teams to manage alerts more efficiently alongside their routine tasks. Conversely, the increasing amount of data and complexity requires centralized systems, where specialized staff works with AI to manage the increasing data streams. While the direction of this impact remains uncertain, these technological developments will influence the suitability of different organizational models.

Personnel

In our case studies, the respondents' perceptions of the effectiveness of telemonitoring and its added value for patients played a significant role in choosing a model. Even in the absence of clear evidence supporting the superiority of one model over another, in terms of cost-effectiveness or patient benefit, respondents based their preference on subjective evaluations [4,56,57]. This is notable, particularly given that the attitudes of health care professionals (eg, nurses and physicians) are a significant factor in the acceptance of telemonitoring in practice [24], and these professionals are regarded as the "most important gatekeepers for telehealth services" [58]. Thus, the attitudes and perceptions of health care professionals influence the implementation of telemonitoring, impacting not only local adoption but also broader upscaling [54]. Health care professionals also play an important role in deciding on the choice of telemonitoring aims in the process of selecting a suitable model. This makes it essential that their decisions are not based solely on subjective judgments. Rather, they should be well-informed about the rationale behind selecting specific telemonitoring models.

In addition, implementing telemonitoring, whether centralized or distributed, is driven by the objective of increasing efficiency and addressing staff shortages [2,4]. As patients increasingly adopt self-management techniques [59,60], and health care services evolve, the roles and tasks of health care professionals are undergoing significant transformation. The literature supports this shift, indicating that telemonitoring influences task division in health care organizations [61], resulting in the creation of new roles and responsibilities [62] while potentially disrupting established professional roles [63]. Given this knowledge, organizations must align their personnel preparation and organizational models accordingly. It is essential to equip staff for new responsibilities through targeted training programs that address the specific skills needed for telemonitoring [64,65]. In addition, our findings show that the redistribution of tasks, particularly when tele-nurses assume responsibilities previously handled by physicians, was eased by collaborative efforts in developing protocols and workflows. Finally, the division of created tasks should be compatible with the organizational model and available resources. Therefore, when selecting a telemonitoring model, organizations should consider their capacity, resources, and personnel.

Partnerships, Collaborations, and Networks

Our findings place key emphasis on the importance of partnerships and collaborations in organizing telemonitoring, particularly in the centralized monitoring context, although both models may involve multiple organizations [13,26]. The participants acknowledged both the potential benefits of working with various partners and the challenges associated with delegating tasks among health care providers. However, the discussion focused on the division of tasks between providers and the clinical pathway design, while the complexities of interorganizational collaboration remained largely unaddressed. This oversight parallels a notable gap in the literature on organizing telemonitoring collaboratively. Defining responsibilities, establishing safety protocols, streamlining workflows, sharing knowledge, and educating personnel are all important when multiple organizations participate in telemonitoring [24]. While some studies touch upon interorganizational collaboration among health care providers [24], there is still insufficient exploration of the necessary governance and management frameworks required for telemonitoring collaboration in practice [66,67]. This is concerning from a quality perspective, given that effective collaboration between care providers is essential for ensuring continuity of care [46]. Scholars suggest that successfully scaling telemonitoring on a regional or national level hinges on resources and reimbursement structures [54]. Both elements should be discussed when collaboratively organizing telemonitoring. Given that network theory offers valuable insights into managing networks with common goals, in this case regional telemonitoring implementation, we want to emphasize that scholars should not reinvent the wheel when there is a compelling opportunity to use this knowledge to navigate organizational boundaries effectively [68].

Strengths and Limitations

From a practical perspective, this research contributes to a deeper understanding of the decision-making processes involved in telemonitoring services. The insights derived from this study offer valuable guidance for health care organizations seeking to implement or scale telemonitoring programs, or to design effective telemonitoring pathways with regional partners. From a theoretical standpoint, this study extends the application of the NASSS framework by examining organizational-level decision making across all NASSS domains. In doing so, we illustrate how the various domains interact and influence one another in the context of organizing telemonitoring. We acknowledge, however, three primary limitations. (1) While the NASSS framework provides a comprehensive approach to integrating diverse perspectives on implementing eHealth technology, these categories may constrain data interpretation. Specifically, the framework tends to overlook the relational dynamics, for instance, between caregivers and patients, despite the literature that supports the importance of including human interactions in implementation [48]. Future scholars could benefit from using NASSS-CAT tools [40]. This combination allows for a theory-informed framework, supplemented by a pragmatic planning tool. (2) The limited exploration of ethical-legal considerations and data privacy in the context of telemonitoring may be attributed to the specific respondent

XSL•FO
RenderX

group chosen for inclusion. Issues related to data sharing, patient consent, and privacy must be addressed to ensure the ethical deployment of telemonitoring technologies [24]. These legal and ethical topics should be prioritized in future research to provide a more comprehensive understanding of the implications of telemonitoring on patient data and privacy rights. Another limitation lies in (3) the aim to contrast a centralized model with a fully distributed one. However, in practice, such clear-cut models are hard to find. As a result, we included 2 cases using predominantly distributed models, where respondents also had experience with centralized approaches or used centralized models for specific clinical pathways. Although this hybrid reality (literature) reflects the complexity of studying real-world implementation, it blurs the distinction between the two models.

Conclusions

This study provides insights into the complexities of decision-making involved in organizing telemonitoring and offers guidance to all stakeholders, including health care professionals, on understanding the considerations and consequences of the choices. It identifies specific rationales for selecting either a centralized or distributed telemonitoring model, depending on patient needs, such as those requiring vital parameter monitoring or self-management. The volume of notifications generated also is a critical factor in determining the most suitable model. In addition, perceptions of efficiency and the perceived added value to patients significantly influence decision-making. The study underscores the importance of considering technological, organizational, and societal factors when choosing between centralized and distributed models. Notably, decisions made in early stages, primarily by physicians, can have far-reaching implications for personnel, resources, and partnerships at a regional level. When starting out with telemonitoring, those in charge should recognize the interconnectedness of factors and carefully consider all seven NASSS domains.

Acknowledgments

We thank Prof Leon Oerlemans and Dr Remco Mannak for their guidance and expertise. Their insight and feedback have greatly contributed to the completion of this project. We are grateful to Tessa van Aken for her assistance with the data analysis.

Abstract

Background: The overwhelming COVID-19 situation in 2020/2021 required novel approaches that did not require additional personnel within the current health care system. Therefore, we initiated a trial of nonsupervised home monitoring via the emergency department of a tertiary hospital without the support of a virtual ward as part of the "Netzwerk Universitaetsmedizin" cooperation in Germany. Given that daily vital sign checks for inpatients with COVID-19 could indicate clinical deterioration, this approach might also be helpful in an outpatient setting and could help to identify the need for hospitalization and additional resources.

Objective: This study aims to determine whether patient-led home monitoring for acute SARS-CoV-2 infection can be implemented through the emergency department of a tertiary care provider.

Methods: Patients who tested positive for SARS-CoV-2 infection in our emergency department between May 2021 and May 2022, did not have a medical indication for hospitalization, and were discharged to the outpatient setting were offered the opportunity to perform nonsupervised home monitoring of vital signs. Those who agreed to participate received Bluetooth-enabled devices to measure temperature, oxygen saturation, and blood pressure and downloaded a smartphone app. Participants were encouraged to measure their vital signs for at least 28 days. There was no virtual ward or real-time surveillance of the recorded data, but these could be made available to primary care physicians. Compliance with self-measurements was determined, and participants were contacted after the monitoring period for a semistructured interview.

Results: A total of 828 patients with COVID-19 were treated at the emergency department. Of these, 262 were directly discharged into ambulatory isolation after initial assessment, 25 were offered the opportunity of nonsupervised home monitoring, 15 successfully activated the devices, and 9 performed more than one complete measurement using the app. These 9 participants used the devices for an average of 15.8 days after discharge. Interviewed participants reported various difficulties with device setup but said they were pleased to use home monitoring and felt that the measurement option gave them additional security.

XSL•FO
RenderX

Conclusions: This study highlighted the challenges associated with implementing nonsupervised home monitoring for outpatients with COVID-19 who presented to the emergency department of a tertiary hospital. Implementing such a system without the involvement of additional personnel does not appear to be the optimal approach. We suggest that the physician-patient relationship might be a factor that is essential for the success of patient-led approaches to home monitoring.

KEYWORDS

home monitoring; telemonitoring; patient-led monitoring; nonsupervised home monitoring; physician-patient relationship

Introduction

During the COVID-19 pandemic, intensive efforts were made to find appropriate options for providing adequate care without overburdening the health care system. Given the number of severe acute respiratory distress syndrome cases and overcrowded intensive care units, medical staff were in short supply, especially in Germany [1-3]. The novel nature of COVID-19 and initial lack of knowledge about when and to what extent medical care and hospital admission were necessary caused uncertainty in the general population, which could have contributed to increased use of medical care for respiratory symptoms [4]. It also resulted in excessive demands on health care resources, such as those described for disaster situations [5]. Subsequent evaluations in Germany suggested that the majority of patients with COVID-19 could be treated on an outpatient basis [6].

The idea of using home monitoring for pandemic management arose from the fact that the regular vital sign checks performed on inpatients with COVID-19 could provide useful prognostic information. Such values were not routinely available for outpatients but could allow better assessment of these individuals and potentially provide an early signal of clinical deteriorations. This approach was implemented across many countries [7]. Home monitoring using eHealth and mobile health technologies provides data on relevant parameters for individual patients and helps with patient stratification [8].

Various home monitoring approaches include so-called virtual wards, that is, medical monitoring of the recorded data and contact by a treatment team [7,9-11]. In the context of COVID-19, contact with the medical team at all times has been reported to be a success factor for home monitoring [12]. In contrast, patient-led approaches without a virtual ward have been successfully used for monitoring chronic lung diseases (eg, the IPF online or I-FILE app) (Curavista bv) [13,14], but to our knowledge, they have not been used in the acute setting for infectious diseases.

At our institution during the height of the pandemic, our focus was on evaluating approaches that were feasible with existing (personnel) resources. With an already difficult staffing situation in the German health care system, regardless of the pandemic [15,16], we consider it essential that novel solutions require as few additional staff as possible. For this reason, we decided not to implement a virtual ward or real-time monitoring, but to establish patient-led home monitoring to supplement existing health care structures without providing personnel-intensive support. Therefore, as part of the egePan Unimed project for app-based telemedical home monitoring of COVID-19 [17], we focused on home monitoring as a possible approach to effectively managing outpatients with COVID-19.

This pilot study was designed to evaluate the feasibility by assessing patient usage data and medical use of an outpatient program of vital sign self-monitoring to detect early deterioration in patients with COVID-19 who presented to the emergency department but did not require hospital admission.

Methods

Study Design

This single-center cohort pilot study was conducted at the University Hospital Aachen, Germany (a large tertiary care provider) in accordance with STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) reporting guidelines [18]. Recruitment was carried out by emergency department medical staff, supported by the study team for technical queries; no additional staff were made available to the emergency department to conduct the study.

Participants

Eligible participants were adults who had tested positive for SARS-CoV-2 infection on a rapid antigen or polymerase chain reaction test and presented at the emergency department but did not have a medical indication for hospitalization and had access to their own smartphone. If a study participant was subsequently admitted to the hospital, their participation in the study was paused for the duration of hospitalization and could continue after discharge. Pregnancy was initially an exclusion criterion, but this was removed after re-evaluation of the risks of study participation for these individuals.

Variables and Data Collection

Participants were given Bluetooth-enabled devices to record vital signs. Body temperature was measured using a noninvasive thermometer (Beurer FT 95 non-contact thermometer; Beurer GmbH), oxygen saturation (SpO2) was measured using a pulse oximeter (Beurer PO 60 pulse oximeter; Beurer GmbH), and blood pressure and heart rate were determined using a noninvasive sensor (Aponorm Basis Plus Bluetooth; WEPA Apothekenbedarf GmbH & Co KG). Participants were also given an installation code and emailed or given printed instructions on how to install the smartphone app (SaniQ Infect, Qurasoft GmbH). The study team contacted patients by telephone or video call to reaffirm that they met the inclusion criteria, to clarify remaining questions, and to provide support

XSL•FO
RenderX

for device and app setup on the day after discharge from the emergency department.

Participants were told to measure their vital signs at least once a day for at least 28 days (or until symptoms resolved if these persisted for longer than 28 days). Measurements were designed to transmit from the measurement devices to the app via Bluetooth, but patients were also able to manually enter values into the app. During the self-monitoring period, any necessary treatment was provided by the appropriate primary care physician or the ambulatory health care system. Vital sign data collected by participants could be made available to their treatment providers (eg, primary care physicians) via PDF export.

Compliance with daily vital sign measurements was calculated as (number of actual measurements)/(number of target measurements). In addition, to account for days when measurements may have been taken more than once a day, daily adjusted compliance was calculated as the ratio of the binary variable (daily target of measurements reached or exceeded)/(number of days). The duration of vital sign self-measurement was also recorded.

After the end of the study, participants underwent a semistructured interview to gain insights about their experience with home monitoring. The semistructured interview format was developed within the research team. A translation of the original German interview guide can be found in Multimedia Appendix 1.

Sample Size

Two hundred sets of monitoring devices were available for the study. The actual sample size was determined by the number of patients who requested treatment via the emergency department who could be included with the available staff.

Statistical Analysis

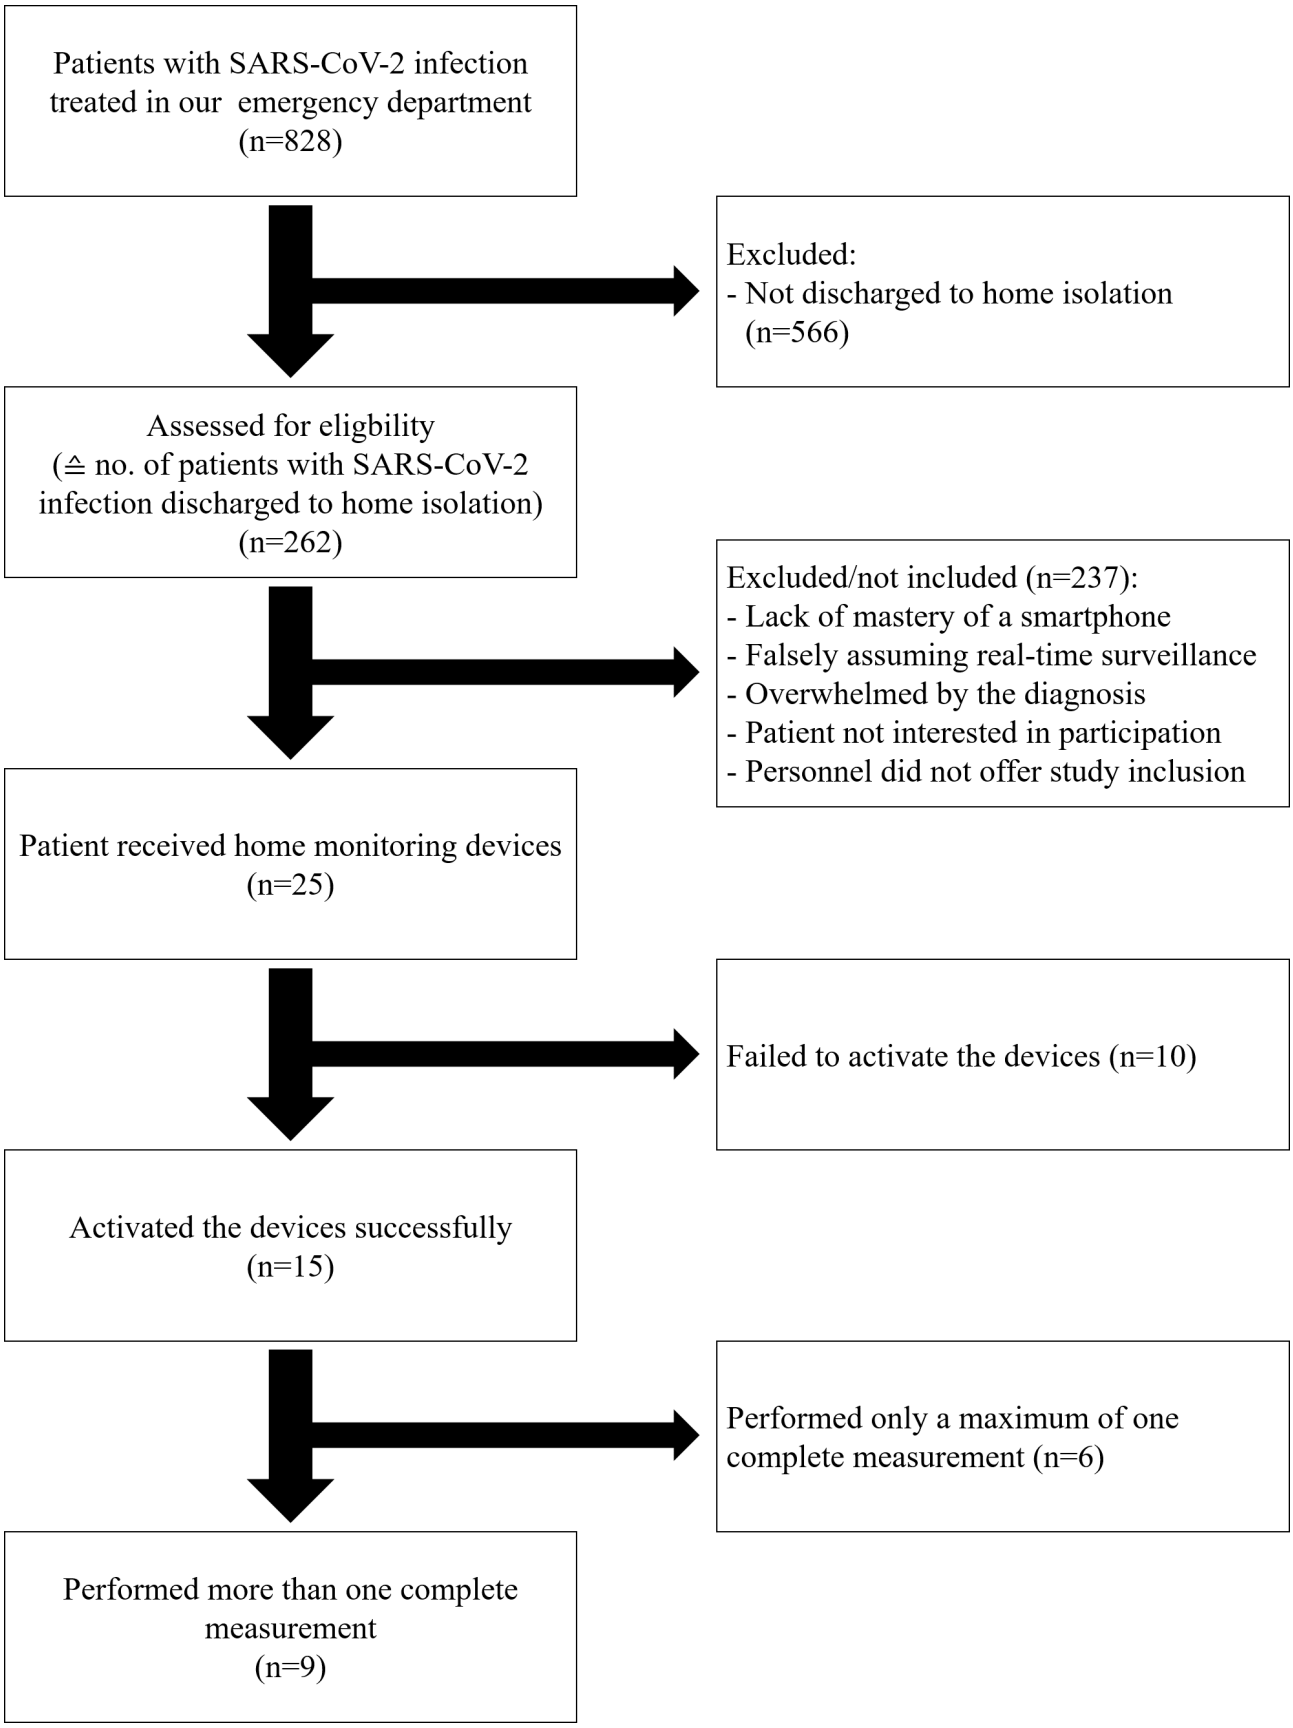
Due to the low inclusion rate, k-anonymity and l-variability were low, meaning that reidentification appeared possible with additional knowledge. Therefore, only aggregated data are reported. These are presented using descriptive statistics. For the same reason, interview responses are reported only in summarized form. Qualitative analysis of interview responses was planned to be performed by 2 independent researchers following the principles of qualitative content analysis by Mayring [19].

Ethical Considerations

The study protocol was approved by the Ethics Committee at the RWTH Aachen Faculty of Medicine (reference EK 099/21) and registered prospectively at the German Clinical Trials Register (ID DRKS00025123). All participants provided informed consent before enrollment in the study and could withdraw their consent at any time.

All recorded data were stored in an encrypted format on each participant's smartphone. Participants were able to share their data with the study center via a reference code; participants could terminate transmission of their data in the app. Data were deidentified for processing at the study center after the end of the study phase and stored exclusively on ISO27001-certified data centers in Germany. The servers used were subject to German data protection law.

For hygiene reasons, study participants were allowed to keep the home monitoring devices provided at the end of the study. No further compensation was granted for participation. The standard retail price of the devices provided amounted to around US $250 at the time of the study.



Results

Participants

Between May 2021 and May 2022, a total of 828 patients with SARS-CoV-2 infection were seen in our emergency department, of whom 262 (31.6%) were discharged to home isolation after being assessed. However, the majority of these were not enrolled in the study. Reasons for nonenrollment were lack of mastery of a smartphone, falsely assuming real-time surveillance, being overwhelmed by the diagnosis of SARS-CoV-2 infection, not being interested in the study, or because health care professionals were overburdened and did not offer study participation (Figure 1). Of the 25 enrolled participants (median age 42 years, IQR 20 years; mean age 42.9 years, SD 14.3 years), 15 successfully activated the devices and app, and 9 of these (median age 39 years, IQR 25 years; mean age 44.4 years, SD 15.9 years) performed more than one measurement with each of the 3 devices using the app.

XSL•FO
RenderX

Figure 1. Study flowchart.

Monitoring Usage and Compliance

The 9 participants who performed more than one complete measurement used the devices and app for an average of 15.8 days (range 1 - 28 days). Compliance varied, with 4/9 active participants exceeding the absolute number of measurements, and 2 even exceeded the required measurements every day. Overall, there were 399 measurements out of a target of 426

XSL•FO
RenderX

measurements (93.7%). The required number of measurements was performed on 85/142 user days (59.9%). Overall compliance ranged from 22.2% to 200% (median 100%, IQR 58.4%; mean 102.5%, SD 56%). Daily-adjusted compliance ranged from 4% to 100% (median 81.8%, IQR 61.4%; mean 64.1%, SD 39.2%).

Interview

Only 2 participants could be reached for the planned follow-up interview; an additional 4 agreed to a short informal conversation. For this reason, we decided to deviate from our planned approach to the analysis, as no meaningful evaluation seemed possible due to an insufficient number of participants. We decided to report the results only anecdotally. A formal analysis was not carried out. Nevertheless, in the setting of general practitioner care, an analysis was carried out based on a satisfactory number of cases, but this is reported elsewhere. The patients interviewed in our setting said that they were very pleased to use the home monitoring concept and felt that the measurement option provided additional security once the devices were set up. Various difficulties in setting up the devices were reported because this required each device to be paired with the patient's smartphone. Performing measurements was considered to be time-consuming and required a willingness to deal with the devices. It was also reported that the time available for additional measurements without immediate feedback decreased after the end of the home isolation period. One participant reported that their device data led to further examinations being performed when they contacted their general practitioner.

Discussion

Principal Findings

This study highlighted significant challenges relating to the implementation of a home monitoring program by the emergency department of a tertiary care provider during the height of the COVID-19 pandemic.

Although many of the patients with SARS-CoV-2 infection treated in our emergency department were potentially eligible for home monitoring, the majority did not enter the trial. There were several reasons for this. First, a large number of potential participants were not offered information about the study because health care professionals were too busy to have the time to do this. Second, a relevant number of patients were excluded due to their lack of mastery of a smartphone (self-reported or assumed by personnel). This was often, although not exclusively, seen in older individuals. Fifty-five patients discharged to home isolation were aged 65 years or older, and only 3 of these consented to participate in the study. Third, it appeared that some of the features of the study intervention (self-directed monitoring, no additional physician-patient contacts, no virtual ward) created a perception of lack of security of follow-up, making consent less likely. Finally, many patients simply did not have any interest in participating in the study or were psychologically overwhelmed by being diagnosed with SARS-CoV-2 infection. In summary, apart from the issue of overburdened emergency room personnel, it was largely patient attitudes that probably led to the low inclusion rate.

In general, the emergency department of a tertiary care provider is unlikely to be the first port of call for many patients with viral infections, and this is the case in Germany due to the sectoral design of the health care system [20]. Therefore, the characteristics of patients presenting in our study may have contributed to the observed challenges. We did not retrospectively gather potentially relevant patient information, including socioeconomic status and health literacy data. It has been noted that patients with mild symptoms who present to an emergency department in Germany with conditions that should generally be cared for by the primary care sector tend to have a lower socioeconomic status [21]. Although data on the relationship between lower socioeconomic status and adherence are not conclusive, some studies have shown that lower socioeconomic status is associated with lower adherence, at least in certain conditions [22,23]. For future research, especially in pilot projects focused on compliance and adherence to remote monitoring programs, we suggest that it would be important to have socioeconomic status and health literacy data.

Some patients presenting to the emergency department in our study, despite only having slightly symptomatic or asymptomatic SARS-CoV-2 infection, did not use the suggested home monitoring devices at all or often stopped using them. Many of the small group of participants stopped taking home measurements around 14 days after first testing positive for SARS-CoV-2 infection; this coincides with the duration of officially mandated isolation in Germany at the time [24]. Although these recommendations were gradually eased during the course of the pandemic [25], many people were still aware of the initial regulations and were also officially advised to reduce contact for 14 days.

Another important point is that there were no immediate consequences for the patients based on whether they did or did not perform daily measurements because the data were only stored locally on their device (unless shared with a health care professional at a future appointment). Given that we have shown that there is consistently better adherence to remote COVID-19 monitoring in primary care [26], it is reasonable to assume that socioeconomic factors are not the only contributors to the low adherence to monitoring in this study. We did observe interindividual differences in the use of home monitoring, but the study population was too small to be able to make valid statements about these variations. We were also unable to determine whether the home measurements taken by study participants were useful in their medical care because the sharing of home measurements at subsequent primary care visits was only reported by one individual.

One potential conclusion based on our data is that a close physician-patient relationship and the provision of feedback are important, as documented previously [27,28]. This physician-patient relationship might not necessarily occur in the setting of emergency treatment in a large clinic with changing staff. In addition to an easily accessible contact person and adequate infrastructure, continuous support seems to play an important role. Although we educated patients about the possible benefits and insights for them personally when providing information about the study, this single contact with a physician might not provide the level of motivation that might

come from a monitoring recommendation made by a more familiar health care professional, such as a general practitioner. Therefore, we suggest that the patient motivation issues seen in our study might have been mitigated by a closer physician-patient relationship or continuous feedback on device usage and readings obtained.

Our results on inclusion and device usage show that our approach, as it was, is not feasible in the German health care system without adaptations. Even if the study was planned with the existing personnel, the implementation still required additional workload and financial resources. With such a low uptake and usage rate as in our study, such an expense cannot be justified as feasible.

Concurrently, the small number of participants represents the greatest limitation of our study. Accordingly, we were unable to conduct our main objective, namely the analyses with regard to early markers of deterioration and our planned qualitative analysis in a reasonable manner. Although we are able to reconstruct the low number of participants at least in part with the explanations given above, this is not a pleasing result overall. Even if our study was able to provide important insights, it was not possible to establish a patient-led home monitoring concept.

Despite the disappointing uptake and use of home monitoring in our study, we believe that further evaluation of this approach in the tertiary care setting is warranted because home monitoring can provide valuable data for treatment and patient assessment. In specialized outpatient clinics and post-COVID follow-ups, where there is also repeated and regular contact with the same treatment team, it can be assumed that there is a stronger physician-patient relationship, which could have a positive impact on such an approach. Braun et al [29] introduced a similar concept for patients with chronic lung diseases using the same SaniQ app (Qurasoft GmbH) in routine secondary care during the COVID-19 pandemic. In this setting, patients showed satisfactory adherence and acceptance, but it must be noted that this program only required one measurement per month rather than the daily measurements in our study. Therefore, the frequency of measurements must be discussed critically when creating home monitoring concepts.

To create a reliable physician-patient relationship to maximize the benefit of home monitoring in patients with COVID-19, we advocate either the establishment of virtual wards [7,11,30] or involvement of the regular primary care sector [31], as described previously. Therefore, we suggest that the use of nonsupervised home monitoring in the primary care practice outpatient setting would be a better approach than initiation via the emergency department of a tertiary care provider.

Another factor that appears to be crucial to the success of a home monitoring program is a simple setup process. In our study, device and app setup created a lot of frustrations for both patients and the support team. Even though the setup should have been simple in principle (pairing the devices via Bluetooth with the patient's smartphone using the app), connection errors still occurred that could not always be easily resolved. Even with telephone support from the study team, some connection problems could not be solved quickly. General problem-solving approaches did produce the desired effect, but this was very time-consuming. To avoid such frustrations at the beginning of home monitoring, we recommend the use of technology that ensures the required external devices can be connected more easily. For example, this could be achieved by means of a base station assigned to the delivered measuring devices, meaning that only the base station would need to be paired with the patient's smartphone. Participants in our study also reported that the time burden of taking measurements was relatively high. The impact of this on motivation to continue performing daily measurements should not be underestimated. Therefore, there seems to be a need to balance the need for data density with a good user experience to create a robust and user-friendly home monitoring concept.

If we conducted the study again, in addition to the points mentioned above, we would also establish a monitoring board analogous to regulated drug trials: our analyses of the total number of potential study participants and the patients actually included were only evaluated at the end of the study and not during its implementation. If a corresponding monitoring board had been in place, the insufficient inclusion rates would have been noticed earlier so that we could have incorporated modifications into our recruitment process. A monitoring board of this kind can be operated with only a small amount of additional personnel resources if, for example, monthly intervals are selected.

Even though our aim was to investigate the potential of home monitoring with the available personnel resources, good staffing appears to be essential for the success of this kind of study: even a screening of the patient documentation by a study assistant (eg, a student assistant) and a resulting targeted indication to the study physicians could lead to potential inclusions not being missed despite the staff shortage. Once this has been established in a first phase, such support would probably no longer be necessary as soon as the staff had internalized the relevant processes.

However, such an approach would probably not have mitigated the low usage rate of the included patients. As far as can be deduced from our data and as explained above, the lack of ongoing care at home through the emergency department personnel appears to be the decisive factor here.

Limitations

Due to staff shortages in the emergency department at the time the study was conducted, there is a risk of selection bias. For example, it may have been easier to have time to provide information about the study when the emergency department was less busy. However, the study was designed to be conducted with existing personnel resources, and therefore, it was not possible to mitigate this potential source of bias. Similarly, we are missing socioeconomic data for participants because these were not collected to avoid placing an additional workload on the medical personnel involved. However, the main limitation of our study is the small number of participants recruited, and the even smaller numbers who were active users of self-monitoring and completed the postmonitoring interview. This limits the amount of data we were able to obtain, and therefore, the conclusions that can be drawn. Consequently, we were also unable to conduct our planned analyses with regard

XSL•FO
RenderX

to early markers of deterioration and our planned qualitative analysis in a reasonable manner.

Conclusions

Due to the small sample size in this study, the main conclusion that we can draw is that providing nonsupervised home monitoring to outpatients with COVID-19 through a single contact in an emergency department of a tertiary hospital is not the optimal approach. Although conducted during the COVID-19 pandemic, our data could provide useful information about the issues related to the setup of home monitoring for a variety of diseases based on a single emergency department contact. Key features for success are likely to be regular feedback and care and an ongoing physician-patient relationship.

Acknowledgments

The institutions employing LN, LSS, SH, SMK, ND, BSM, CC, RK, GR, CFV, and MD received funding for this study from the German Federal Ministry of Education and Research (grant number 01KX2021). Open access funding was provided by the Open Access Publishing Fund of RWTH Aachen University. The funder had no role in the design of the study or in the collection, analysis, or interpretation of the data. We presented preliminary findings at the 63rd Congress of the German Respiratory Society in 2023, and an abstract in German is available online [32]. The authors thank Ms Nicola Ryan, an independent medical writer, for providing English-language editing assistance.

Conflicts of Interest

ND received the CSL Behring award "Translational Research on Extracellular Vesicles in COPD." RK has been involved in projects and publications using the Kaia COPD App. SK is the founder and managing partner of MED.digital GmbH. SK holds shares of BioNTech, Pfizer, and CRISPR Therapeutics. SK is a member of the commission "New Professions" of Stiftung Münch and of committees of the German Medical Association ("Digitalization of health care" and "Medical Education and University Medicine"). BSM received personal honoraria for scientific consultancy to the health insurance fund "Die Techniker." GR reports personal fees from Astra Zeneca, Atriva, Boehringer Ingelheim, GSK, Insmed, MSD, Sanofi, Novartis and Pfizer for consultancy during advisory board meetings and reports personal fees from Astra Zeneca, Berlin Chemie, BMS, Boehringer Ingelheim, Chiesi, Essex Pharma, Grifols, GSK, Insmed, MSD, Roche, Sanofi, Solvay, Takeda, Novartis, Pfizer and Vertex for lectures. The other authors declare no conflict of interest.

Abstract

Background: Teledermatology consultations offer the advantage of rapid diagnosis and care. Since 2019, our institute at the University Medical Center Hamburg-Eppendorf has been part of an interdisciplinary team for teledermatology support in German prisons as an alternative to extramural transports of patients.

Objective: This study aims to analyze the benefits and limitations of teledermatology for patients with limited access to medical specialties.

Methods: We conducted a descriptive cross-sectional analysis of 651 teleconsultations from prisons from February 2020 to April 2023. All cases were performed in a store-and-forward (asynchronous mode) and optional hybrid live (synchronous) consultation for the patient or in-house staff.

Results: The main advantage of this case processing was the avoidance of external transport. Of the 651 teleconsultations, 608 (93.4%) could be finalized with telemedical support and 43 (6.6%) required additional workup, including verifications of the type of tumors (n=22, 51%), which needed biopsies, and open cases that were inflammatory (n=11, 26%) or involved infectious skin conditions (n=5, 12%). Digital imaging of the skin lesions improved with the experience of the personnel but remained a challenge, with the photo quality depending on the technical devices or available broadband supply.

Conclusions: Hybrid teledermatology consultation represents an effective and resource-saving method of providing specialized care to patients in situations with limited access to medical specialties. The video consultations with experts and exchange of knowledge about the cases presented opened the opportunity to support and train intramural colleagues. One of the main challenges remains the quality of digital imaging and transmission.

Introduction

The international recommendations for medical care in correctional facilities set high standards [1]. According to global agreements stated by the World Health Organization, prisoners should receive equivalent medical care in comparison to the standards for the respective population [2,3]; this includes primary care as well as access to all medical specialties, which is challenging for the correctional system [4-7].

Need for Health Services in Correctional Facilities

On average, prisoners are younger compared to the normal population, and more than 90% are male, which indicates a different scope of medical issues [8]. However, prisoners also have a higher proportion of individuals with chronic diseases, especially mental disorders or chronic infections like hepatitis, requiring ongoing medical care [9-14].

Prisons in Germany ensure these medical services not only using in-house resources but also regularly using external medical service providers to fulfill these tasks [15-17]. For dermatology issues, this means complete reliance on external dermatology

XSL•FO
RenderX

facilities because none of the more than 280 correctional facilities in Germany provide in-house solutions.

Economic Aspects of Medical Care in Prisons

Following the principle of equal standard of medical care for prisoners as people living in the community, the scope of medical services in German correctional institutions should correspond to the scope of services provided by the statutory health insurance funds. However, prisoners are no longer covered by statutory health insurance when they start their prison sentence in Germany [7]. The costs for medical care must be covered by the prison authorities of the federal state. The expenses for the correctional facilities [18,19] as well as the medical care in the German correctional system have risen steadily, and the federal states of Germany have to cover these costs [20]. A substantial amount is caused by personnel and transport costs. New solutions are needed to both provide the required standards of care and control costs [21].

Use of Teledermatology for Correctional Facilities in Germany

During the last decades, telemedicine in various settings has become a useful tool to support health services [22]. In 2018, the 121st German Medical Congress approved an amendment to the medical professional code of conduct (Muster-Berufsordnung für die in Deutschland tätigen Ärztinnen und Ärzte [MBO-Ä]) and enabled remote telemedical care [23]. Since 2019, German correctional institutions have started to use telemedicine for dermatology requests [20,24]. Initially, this service was provided through a pilot project by the Ministry of Justice of Baden-Württemberg and expanded to other German federal states and correctional facilities in subsequent years. Currently, these dermatology teleconsultations are offered on a fixed weekly basis for acute cases on demand within 24 hours. The prison can choose between a store-and-forward mode (asynchronous operation) with photos and a standardized form only or an additional hybrid option with a live video consultation in an interdisciplinary round including the treating primary physician simultaneously (synchronous operation). This allows a direct exchange of medical information as well as the opportunity for further counseling with colleagues in charge of the case. Both modes represent an alternative to transportation and presentation of prisoners in dermatology facilities outside the correctional institution, and we experience an increasing number of requests to our institute from German correctional institutions.

Although the rate of completed cases through video consultations in either store-and-forward mode or in live presentation is high [8], there are limitations to the processing of certain requests. With this paper, we analyzed 651 cases of our teleconsultations for German correctional facilities from February 2020 to April 2023. This study aimed to provide evidence on the value of teledermatology care provided to German prisons and detect limitations for this mode of service with a focus on cases that could not be processed without live on-site consultations.

Methods

Overview

A systematic comparison of the advantages and disadvantages of video consultations for prisoners was carried out based on a descriptive cross-sectional analysis of 651 applications for teleconsultations in German correctional facilities from February 2020 to April 2023, supplemented with literature research. The selection of the evaluation criteria was based on quality criteria from the German guidelines for teledermatology from 2020 [25].

We retrieved all data from the documented request forms from February 2020 until April 2023. Data included:

- clinical symptoms and anamnestic information of skin disease;
- patients' demographic data (age and gender);
- preliminary diagnosis and questions from the in-house medical team of the prison regarding the case (eg, special issues such as occupational or infectious matters, quarantine, or isolation);
- documentation of the consultation, including details of onset and clinical appearance of the skin disease, and number and quality of photos sent with the request; and
- further anamnestic information retrieved from the virtual presentation of the case and dermatological diagnosis and suggestions for treatment.

Ethical Considerations

The ethics committee of the Medical Association of Hamburg confirmed that there was no further ethical approval necessary for retrospective analysis of anonymized data in accordance with the ethical standards of the responsible committees (institutional or regional) and with the Helsinki Declaration of 1975, as revised in 1983.

Spatial Analyses

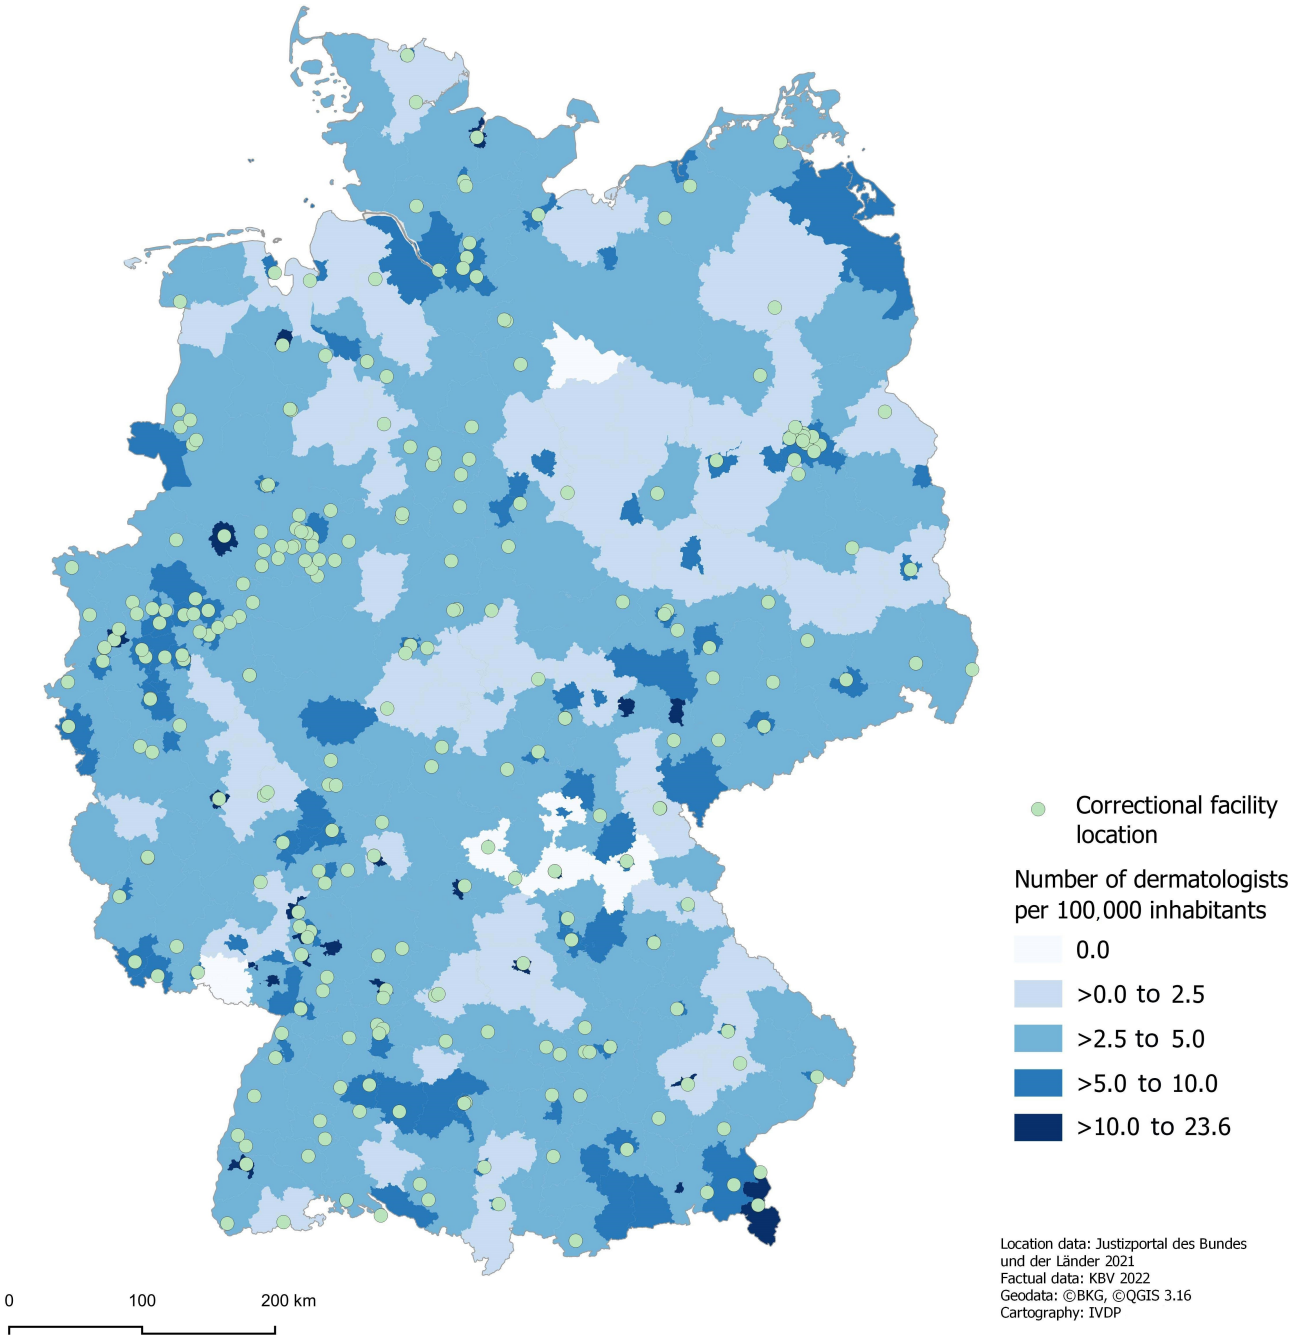
Part of this study was a spatial assessment of the potential physical accessibility of prisoners to dermatologists. The data basis for all 284 prison locations was a list from the justice portal of the federal and state governments from 2020. After geocoding and referencing the locations, they were loaded and mapped in a geographic information system in ArcGIS v. 10.8.1 (ESRI). As a proxy for accessibility, physician density was compared to correctional facility locations. Data were provided by Kassenaerztliche Bundesvereinigung (KBV; data status 2022).

Statistical Analysis

We conducted a descriptive analysis of all variables with SPSS v.26 (IBM Corp), including demographic data (eg, age and gender) and medical data (eg, diagnosis, suggestions for therapy, and further management of the skin disease). Thereby, we categorized open entries, for example, therapy modalities, into categories such as topical or systemic therapy. We conducted a subgroup analysis for cases that were not closed after one video consultation regarding diagnoses or recommendations for further management modalities.

XSL•FO
RenderX

Results



Overview

We offer teledermatology support for correctional facilities in Germany. As of May 2023, a total of 38 prisons in 6 federal states in Germany used this service regularly, with rising numbers. Of the 651 cases analyzed, we were asked for 412 diagnoses, 497 therapy recommendations, and 62 follow-ups for reconsidering or changed skin conditions. We provided a time-saving response within 1 week after the request or, in urgent cases, a response within 24 hours in store-and-forward mode. The most frequently diagnosed skin diseases were eczema, skin infections, acne or acneiform dermatitis, and tumor differentiation [26].

Accessibility of Dermatologists Through Telemedical Consultations: Spatial Considerations for Physical Contact

In Germany, there are 284 locations for correctional facilities distributed across all 16 federal states (Figure 1) [25]. The distribution of the prisons differs from being centrally located in metropolitan areas to being far from cities in rural areas. This is important for the accessibility and vicinity of medical specialists (eg, dermatologists).

Figure 1. Cartographic representation of all prison locations in Germany. Cartographic representation of prisons in Germany (green dots) and the density of registered dermatologists per 100,000 inhabitants (blue color scheme). Only a few districts have a high density of dermatologists, between 10-23.6 per 100,000 inhabitants. The majority of districts have between 2.5-5.0 registered dermatologists or fewer, and most prisons are situated outside the metropolitan areas. This results in heterogeneous accessibility.

XSL•FO
RenderX

Avoidance of Transports Outside the Prison

The transport of an inmate to extramural facilities requires at least two staff members, and in cases of low personnel resources, the police forces have to support the institutional staff in Germany. We analyzed our 651 cases for finalization and closure of the case in terms of sufficient data for a diagnosis, recommended therapeutic options in-house, and a need for further diagnostic or therapeutic procedures requiring transport to outside facilities.

Of the 651 cases, 608 could be finalized with a diagnosis and recommendations for treatment and further management without need for extramural transportation of the patient, 83 had to send additional material like laboratory results or images for proceeding with the cases, and 43 could not be solved by teledermatology and consequently needed extramural support on site.

Of the 43 cases, 22 were questions concerned with the type of tumor (Table 1), for which we recommended live examination on site or biopsies that could not be performed inside the prison itself. Usually, the in-house physicians do not perform biopsies, and therefore, the teledermatology consultation did not lead to a successful closure of the case in these requests.

A total of 2 cases were exanthems of uncertain origin with recommendation for biopsies; 6 cases were eczema with missing anamnestic or clinical information for a differential diagnosis and proper conduct; 5 cases were suspected skin infections, and the facilities did not respond to our request for further clinical information or laboratory results like swabs or culture; 1 case showed the clinical picture of psoriasis but insufficient imaging of the extent and a lack of information about comorbidities and previous management; 2 cases sent images of acneiform lesions but lacked clinical information; 1 case asked for differential diagnosis of dermatitis herpetiformis Duhring but did not send sufficient clinical or anamnestic data; and 1 case asked for management of alopecia without further clinical or anamnestic information. Interestingly, the number of cases that were sent without a question for dermatology was rare (1 question for dysesthesias with a neurological background and 2 cases without any information about a skin problem).

According to the Guideline for Teledermatology [27], general screening for skin cancer should not be made by teledermatology alone. If the prison was able to send accurate dermoscopic images, there was an opportunity to provide a statement about the type of lesion or to rule out malignancies, but if the digital imaging was not sufficient, there was a need to consult the physician in charge on site. Cases with the need for general inspection of the entire body or detection of small pigmented lesions as well as skin conditions with the need for palpation (eg, lymph nodes), had to be referred to a physician on site if available or transported to outside facilities. Of our 651 cases, 96 asked for diagnosis of different types of tumors, of which 22 could not be solved by digital imaging, clinical description, and additional video consultation. Some cases could be solved by educating the in-house physician about screening procedures.

Table . Distribution of video consultations with closure based on uploaded request forms, photos sent, and live presentation online.

Case status	Cases (N=651), n
Solved cases	608
Unsolved cases	43
Tumors	22
Eczemas	6
Infections	5
Acneiform	2
Exanthemas	2
No information	2
Psoriasis	1
Nondermatological	1
Duhring	1
Alopecia	1

Telemedical Expert Exchange of Knowledge With Intramural Colleagues of the Correctional Facilities

Due to the fact that no prison in Germany has dermatology resources, the intramural colleagues in charge of the facility service, mostly general practitioners, have to treat and follow dermatological cases. With the help of telemedical expertise and discussions online, we allowed for the exchange of knowledge about the case presented or skin diseases in general and, therefore, enabled the colleagues to become more capable of proceeding with further cases on their own. All of our video consultations were attended to by in-house medical staff from the prison, and in all virtual visits, we exchanged information about the present skin disease as well as therapeutic options and guidelines.

Data Provision and Photo Documentation From Institution to Dermatologist

The number of photos per case was not limited, and 0-27 photos were sent for one request. Insufficient photo quality of at least

XSL•FO
RenderX

one photo was found in 124 of the 651 requests from February 2020 to April 2023, but only 12 cases did not upload any sufficient imaging. The quality of the photos sent improved with the number of cases an individual prison performed and if the service provider supported technical solutions and devices.

Discussion

This study aimed to identify the benefits and limitations of teledermatology support for prisons in Germany (Textbox 1). Prisons are mostly situated outside of the city centers without proximity to medical specialties like dermatologists. The consequence of long distances to the dermatology institutions is the impossibility of visits on site by the nearest dermatologists. Although in metropolitan areas the distances might be low, it does not necessarily mean the availability of dermatologists who are willing to visit one patient in a correctional facility, considering the difficult and time-consuming organization of access and visit schedules aside from their routine medical care and duties.

With the abovementioned German prison locations and physician density of all 16 federal states in mind, the willingness and reality of established specialists coming to the prison should be questioned [28]. The time and effort required of medical specialists due to the treatment of prisoners in prison could force physicians to reject the requests. Even though the medical specialists will be paid based on treatment and the medical fee schedule [29], the opportunity costs could be seen as too high. Therefore, it is not unusual for there to be a noticeable shortage of physicians in the prison system [15].

With our institute, we provided time-saving access to dermatology expertise and avoided transportation in most cases. Compared to general waiting times in Germany for specialist appointments, this is a significant benefit for the patients [30]. Transporting a prisoner to an off-site facility is a challenge to security and human resources. Consequently, for the prison and the community, the risk of an outbreak is very low if the medical specialist comes to the prison instead of bringing the prisoner to the physician [31]. Avoidance of transports outside the prison enhances security and saves resources. In cases with telemedical support, transport is no issue. A recent systematic review of the implementation of telemedicine found that public security and the reduction of the risk of a prisoner escaping are some of the main arguments to enable the successful implementation of telemedicine interventions [32]. From the perspective of prisons and the community, and probably for the prisoner as well, due to a lack of exposure in public, avoiding transport for medical needs with the alternative option of telemedical consultation is preferable. Furthermore, the additional hourly security and transportation costs for each external practice visit should be considered [33].

Although the rate of finalized cases was high (608/651 cases) [8], we could not finalize every case by teledermatology with hybrid store-and-forward information, digital imaging, and video consultation alone. For pigmented lesions, differentiation should not be performed with video consultation alone, and digital imaging could not provide sufficient photo quality in all cases. From 97 requests for tumors or pigmented lesions, a total of 244 photos (including dermoscopic imaging) with a maximum of 9 photos for one case were documented, but in 12 cases, no photo was sent, and in 2 cases, the photo quality was insufficient for a statement concerning type or diagnosis.

Looking at the analyzed cases, we saw a benefit in the interdisciplinary exchange of medical expertise, especially for chronic inflammatory skin diseases like atopic dermatitis or psoriasis where the potential change in clinical picture and severity of the disease poses sometimes challenging situations and the need for knowledge about modern therapeutic options and updated guidelines for therapeutic approaches. Especially for darker skin types who form a relevant proportion of patients in custody, it is helpful to have experience with the different appearance of skin diseases on dark skin, a knowledge which cannot be anticipated for intramural medical personnel. If we compare it to dermatology consultations of previous years, where we saw prisoners live in our outpatient clinic in Hamburg with transports to our institute from the surrounding prisons, we found that the accompanying nonmedical personnel were not involved in the patient's case or disease and could not provide further information if needed. In reverse, the in-house physicians of the prison did not have direct contact with us and did not benefit from medical exchanges. Only a short medical letter provided the connection and flow of information between the prison and the dermatologist. In direct video consultation, the exchange of information from the medical file of the patient and information about the skin disease from the dermatologist was used for all cases discussed online, which was highly appreciated by both sides.

Not all prisons using teleconsultations were willing to send photos and dermoscopic imaging accompanying the request form due to data safety issues. Although the service provider offered a certified cloud solution, the individual prison responsible decided not to use this option. On the other hand, the resolution on both sides of the camera in live discussions online is not sufficient to detect high-resolution skin efflorescences such as telangiectasias, pigmented spots, or small appendages. This can be due either to the technology or to the available broadband supply. Studies show that, especially in rural areas, the conditions for sufficient broadband availability are not available everywhere to enable fast and, especially for medicine, reliable data transmissions [34].

Teleconsultations provide facilitated and time-saving access to medical specialties, and dermatology is most suitable for telemedical visualization of medical skin conditions. Both remote store-and-forward conduct as well as online discussion support the diagnosis of skin conditions and enable follow-up and guidance of therapy regimens.

Despite the significant progress telemedicine and teledermatology have made, the transition of medical treatment from face-to-face to only digital formats is not always appropriate to meet medical goals [35]. Overall, prisons have to analyze their demand for any kind of medical service that cannot be covered by their in-house general practitioner. The skin disease in focus, the possibilities of digital imaging of the condition, interventions needed, and follow-up requirements must be considered. Furthermore, both sides of the telemedical

XSL•FO
RenderX

support call need to take into account intramural possibilities for treatments and compliance of the patient, as well as individual preferences for treatment. To conduct a break-even analysis from the prison's view, transparency about all costs and benefits must be provided [33]. With the emerging lack of specialists in Germany, the option for telemedical support in prisons as well as other facilities has advantages that should be considered in the health services for patients with limited access to regular medical facilities.

Textbox 1. Benefits and limitations of teledermatology in the setting of teleconsultations for German prisons.

Benefits

- Accessibility
- Transport and personnel deployment
- Expert exchange

Limitations

- Need for general inspection or biopsy
- Data provision
- Photo quality

Abstract

Background: Communication among health care professionals is essential for effective clinical care. Asynchronous text-based clinician communication—secure messaging—is rapidly becoming the preferred mode of communication. The use of secure messaging platforms across health care institutions creates large-scale communication networks that can be used to characterize how interaction structures affect the behaviors and outcomes of network members. However, the understanding of the structure and interactions within these networks is relatively limited.

Objective: This study investigates the characteristics of a large-scale secure messaging network and its association with health care professional messaging behaviors.

Methods: Data on electronic health record–integrated secure messaging use from 14 inpatient and 282 outpatient practice locations within a large Midwestern health system over a 6-month period (June 1, 2023, through November 30, 2023) were collected. Social network analysis techniques were used to quantify the global (network)- and node (health care professional)-level properties of the network. Hierarchical clustering techniques were used to identify clusters of health care professionals based on network characteristics; associations between the clusters and the following messaging behaviors were assessed: message read time, message response time, total volume of messages, character length of messages sent, and character length of messages received.

Results: The dataset included 31,800 health care professionals and 7,672,832 messages; the resultant messaging network consisted of 31,800 nodes and 1,228,041 edges. Network characteristics differed based on practice location and professional roles (P<.001). Specifically, pharmacists and advanced practice providers, as well as those working in inpatient settings, had the highest values for all network metrics considered. Four clusters were identified, representing differences in connectivity within the network. Statistically significant differences across clusters were identified between all considered secure messaging behaviors (P<.001). One of the clusters with 1109 nodes, consisting mostly of physicians and other inpatient health care professionals, had the highest values for all node-level metrics compared to the other clusters found. This cluster also had the quickest message read and response times and handled the largest volume of messages per day.

Conclusions: Secure messaging use within a large health care system manifested as an expansive communication network where connectivity varied based on a health care professional's role and their practice setting. Furthermore, our findings highlighted a relationship between health care professionals' connectivity in the network and their daily secure messaging behaviors. These findings provide insights into the complexities of communication and coordination structures among health care providers and downstream secure messaging use. Understanding how secure messaging is used among health care professionals can offer insights into interventions aimed at streamlining communication, which may, in turn, potentially enhance clinician work behaviors and patient outcomes.

KEYWORDS

communication; electronic health record; EHR; interprofessional communication; secure messaging; social network analysis; social network; interprofessional; messaging network; messaging; health care communication; message; network analysis; behavior; messaging platforms

Introduction

Communication among health care professionals is key to effective clinical care, with reports suggesting that health care professionals spend >80% of their time on clinical communication [1,2]. Although face-to-face communication is often preferred, it is often not possible due to a lack of geographical proximity or other constraints [3]. As such, health care professionals rely on a number of synchronous (eg, phone) or asynchronous (eg, secure messaging, email, and pager) modes of communication. Asynchronous text-based communication—generally referred to as secure messaging—can be used either within the electronic health record (EHR) or through independent secure mobile platforms and is rapidly becoming the primary mode of communication in modern clinical settings [4]. Although recent studies have described the use of secure messaging in large health systems and its impact [5-10], our understanding of the structure and interactions within large clinical secure messaging networks is relatively limited.

Social network analysis methods allow for the quantitative and qualitative characterization of communication networks, including the behavioral patterns of use, interactions, spread of content or actions, and temporal changes in behaviors [11-13]. In other words, these approaches help in characterizing overall social interaction structure while simultaneously allowing for the investigation of how indirect connections, position within a network, and involvement of individual participants affect the behaviors, attitudes, and outcomes of other network members [14-22].

Prior studies using such methods for exploring interactive clinician-to-clinician communication have primarily relied on self-reported data (eg, surveys and interviews) using relatively small sample sizes of participants [23-31]. More recent studies have sought to characterize the communication behaviors of clinicians, often in specific patient populations (eg, patients with cancer) [32,33]. For example, Steitz et al [33] ascertained the communication network of care teams and characterized the message volume exchanged regarding breast cancer patients.

In contrast to prior studies, this study aims to understand the structure of secure messaging behaviors among health care professionals from a social network perspective. The primary aims of this study are (1) to characterize the network properties of a large-scale EHR-integrated secure messaging network and (2) to determine the association between network properties (eg, connectivity) and health care professionals' messaging behaviors.

Methods

Study Setting

This was a cross-sectional study conducted at 14 inpatient hospitals and 282 outpatient clinics affiliated with BJC HealthCare and Washington University School of Medicine. Hospitals and clinics included both academic and community practice settings serving diverse rural, suburban, and urban populations across Missouri and Illinois. All hospitals and clinics used the same Epic EHR system (Epic Systems Corporation).

Epic's Secure Chat virtual messaging platform is embedded within the EHR and allows health care professionals to send and receive messages. Messages are organized (ie, "threaded") as conversations, and a patient identifier can be attached (as needed) to a conversation to facilitate direct patient chart access from the conversation. Secure Chat was launched across all study sites in September 2019 and is accessible through the desktop and mobile versions of Epic.

Data Collection

Event logs related to secure messaging in dyadic conversations (ie, between pairs of health care professionals) using Epic's Secure Chat were retrieved from Epic EHR's Clarity database for the period June 1, 2023, through November 30, 2023. The choice of this period for the secure messaging data was primarily based on pragmatic considerations related to the availability of a continuous sample of data for at least 6 months, with no periods of missing data.

Communication event logs included time stamps recording when messages were sent and received, when messages were read (if they were), and when messages were responded to (if they were); the conversation thread to which a message belonged (ie, a conversation ID); the identities of the sender and receiver of the message; and the character length of each message. Additional metadata included both the senders' and receivers' most recent professional roles and most common practice locations. The content of the included messages was not retrieved or used for this study.

Data Analysis

Data Categorization

The data contained a total of 74 unique health care professional roles, which were categorized into the following: physician, nurse, pharmacist, advanced practice provider (APP, ie, nurse practitioner or physician assistant), therapist (physical, occupational, or speech language), medical assistant or technician, social worker or case management, or other (as reported previously [5]). Practice locations were categorized as inpatient or outpatient.

Network Analysis

Developing the Messaging Network

We constructed a global secure messaging network of dyadic conversations. Each node represented a health care professional who sent at least 1 message during the study period (June 1, 2023, through November 30, 2023). Edges were constructed between individuals if at least one message was sent between them, and edge directionality was maintained to indicate the sender and the receiver. Pairs of nodes could have a maximum of 2 edges between them, representing reciprocated communication. Edge weights were assigned as the sum of the total character length sent among all messages by the sender to the corresponding receiver over the study period.

The giant connected component (GCC)—a maximum set of nodes such that each included node can be reached from any other node regardless of the direction of the edges [34]—was used for subsequent characterizations and analyses. We excluded nonconnected nodes since our study period is a cross-sectional snapshot in time, and it was very likely that nonconnected individuals are either remnants of closed conversations or the beginning conversations of a new user.

Network Characteristics

To illustrate the structural properties of the network, we generated node-level and global metrics. Node-level metrics represent the importance, social power, and control of information flow among nodes based on their connectivity within a network [35]. We included the following commonly used node-level network metrics (see detailed descriptions and examples in Table 1): indegree [36], outdegree [36], closeness [26,37-39], eigenvector [37,39,40], betweenness centrality [26,36-41], and local clustering coefficient [35,37,38]. These network metrics provide insights into how users participate and shape communication dynamics (see Table 1). For example, closeness centrality indicates users who can easily reach—or be reached by—others due to their positional proximity in the network to all other users; similarly, the clustering coefficient measures a tendency of a user's contacts to also communicate with each other, revealing whether a user is communicating with mutually connected contacts.

Table . Definition and clinical implications for node-level network metrics.

Network metric	Definition	Clinical implications
Indegree	Number of incoming connections; edge weights were not considered.	The number of health care professionals a given health care professional sends messages to.
Outdegree	Number of outgoing connections; edge weights were not considered.	The number of health care professionals a given health care professional is receiving messages from.
Closeness centrality	The inverse of the sum of the lengths of the shortest paths, where a path is a sequence of nodes in which consecutive pairs of nonrepeating nodes are linked by an edge, to all other nodes. N−1∑ydy,x where N is the total number of nodes; $d(x,y)$ is the length of the shortest, inverse-weighted path between x and y, where the weighted, shortest path is the minimum sum of weights for a given distance between nodes x and y.	Health care professionals with greater closeness have the shortest path lengths to all other users. Health care professionals with higher closeness can more quickly disseminate information throughout the entire network.
Eigenvector centrality	Proportional to the sum of the centralities of a given node's neighbors. xi1λ∑j=1naijxj where x denotes the centrality of nodes i and j, and a represents whether an edge exists (a=edge weight) or not (a=0) between nodes i and j. Edge weights were considered.	A measure of the influence of a health care professional based on their connection to other well-connected individuals. A health care professional with a high eigenvector is centrally in direct communication with highly connected individuals in the network, and they have many connections to others. These individuals potentially receive a greater amount of incoming information from their incoming connections and can spread that information more efficiently through their outgoing connections.
Betweenness centrality	The number of shortest paths that pass through a given node. ∑s,t∈ VGvσstvσst σ_{st} denotes the weighted shortest path, the minimum sum of the inverse of the edge weights, between nodes s and t, and $\sigma_{st}(v)$ is the weighted shortest path through node v.	The extent to which a health care professional must act as a communication bridge or mediator between other health care professionals who are not directly connected. These individuals can act as connectors or brokers among groups of individuals who are not otherwise currently communicating.
Clustering coefficient	The fraction of pairs of nodes, which are neighbors of a given node, that are connected to each other by edges. Edge weights were not considered.	The tendency for a node to be embedded in a dense local neighborhood. Indicates the extent of clique structure for a given node.

XSL•FO
RenderX

Global network metrics help to understand the overall connectivity of the communication network (see detailed descriptions and examples in Table 2). Global metrics included the following: overall network density [40], reciprocity [26,35], diameter [36], transitivity [35,42], and assortativity [41]. These global-level measures illustrate the collective communication interactions to assess aspects such as the network's cohesion, reachability, and structure. For example, the network density metric captures the proportion of connections relative to all possible connections in a network of a given size (total number of nodes), signifying the overall level of interactions; similarly, the diameter numerically indicates the longest shortest path between any two individuals, providing a sense of the greatest number of steps it takes to traverse the network (see Table 2).

Table . Definition and clinical implications for global-level network metrics.

Network metric	Definition	Clinical implications
Density	The ratio of actual connections to the possible connections. Edge weights were ignored.	Indicates how cohesive the communication network is. Higher density indicates a more cohesive communication network, showing that health care professionals are directly communicating with the majority of the other health care professionals within the network.
Reciprocity	The ratio of directional connections that are reciprocated. Edge weights were not considered.	Indicates whether health care professionals receive responses for messages they send out to other users. This indicates how mutual communication is between individuals in the network.
Diameter	The longest distance, where distance is the sum of the edge weight between the farthest nodes, to traverse the entire network. Edge weights were considered.	An indication of how expansive the network is in terms of the longest path consisting of communicating health care professionals.
Transitivity	The fraction of pairs of neighboring nodes of a given node that are connected to each other by edges. Edge weights were not considered.	The likelihood that two providers sharing a messaging partner are also messaging each other. This could signify that a network is composed of a lot of small cliques as opposed to wide-reaching communication cascades.
Assortativity	Determines the tendency of edges to connect similar nodes by calculating the fraction of edges that connect nodes of the same class for a given node attribute (eg, location, health care professional role, and total degree). Edge weights were not considered.	Quantifies whether nodes directly communicating with one another in a network generally share characteristics or differ.

K-Core Hierarchy

To explore the connective hierarchy of nodes within the global network, a k-core decomposition was constructed to categorize nodes into hierarchical bins. K-core decomposition is used to identify progressively central cores and discover the structural hierarchy of a network [43]. Previous studies have shown that identifying influential nodes using the k-core approach enables the discovery of central nodes that are highly influential in the transfer of information, in the contagion process, and in the resilience of the system [44,45].

In the secure messaging network, we performed a k-core decomposition based on the outdegree properties to identify the central (ie, influential) health care professionals. K-cores were based on the median and IQR of the outdegrees of the GCC such that the 25th percentile, median, and 75th percentile delineated the cores into 4 groups. Individual nodes were then sorted into each core depending on their outdegree and whether it was equal to or above the designated outdegree for that core. The k-core labeled as the first core had the health care professionals with the highest quartile of outdegrees, and the k-core labeled as the fourth core had individuals in the lowest quartile of outdegrees.

Clusters of Secure Messaging Health Care Professionals

To determine the association between a health care professional's network characteristics and their behavioral messaging characteristics, we used a hierarchical clustering analysis to determine clusters based on network characteristics. We then clustered the health care professionals into clusters using node-level metrics (see Table 1). Features were standardized to a unit variance and a mean of zero to ensure consideration of all features as equally important in the clustering algorithm. To determine the optimal number of clusters, we calculated the silhouette score for values of 2 through 10 possible clusters.

Secure Messaging Behaviors

For each health care professional, we generated 4 measures related to secure messaging behaviors. Average read time for a message was calculated as the difference between a message's sent timestamp and its read timestamp; average response time for a message was calculated as the time difference between the first message sent by a sender and the first message sent by the responder in a conversation. The average total volume of messages included the total of both sent and received messages for a health care professional per day. Finally, the average character length per message sent and received for each health

XSL•FO
RenderX

care professional was calculated as the number of characters of the messages' text including spaces but excluding trailing spaces.

Statistical Analysis

Descriptive statistics for continuous metrics were calculated as medians and IQRs. Due to the nonnormal distribution of both the network and secure messaging metrics, nonparametric tests were used to test for statistical significance. Specifically, Mann-Whitney *U* tests were used to assess the differences in each numerical network metric between location setting categories (inpatient vs outpatient), the median differences were reported, and 95% CI were generated with bootstrapping for this comparison; Kruskal-Wallis tests were used to assess the differences in each network metric among the 8 health care professional role categories. Furthermore, chi-square tests were used to investigate whether the distribution of practice locations differed among the k-core hierarchy groups and for the distribution differences of health care professional roles per k-core. Finally, Kruskal-Wallis and a post hoc test, Wilcoxon rank-sum tests, were used to assess the differences between the secure messaging behaviors across clusters. Median differences and 95% CIs were reported for each comparison.

Data processing and clustering analysis were performed using Python 3.9.7 with the iGraph [46] and NetworkX [47] packages for network construction and network metric outputs and Scikit-learn [48] for hierarchical clustering. Statistical analyses were performed in R version 4.2.2 (R Foundation for Statistical Computing).

Ethical Considerations

This study was approved by the Washington University institutional review board (IRB) with a waiver for informed consent (IRB #202205084). This was a retrospective study, and participants' data were deidentified (eg, grouped based on IDs and roles) for analysis, and only trained researchers who were approved by the Washington University IRB office had access to the data. The participants were not compensated.

Results

Overall Messaging Patterns

This study included 31,800 health care professionals and 7,672,832 messages within 1,539,059 dyadic conversations. The included health care professionals practiced at 14 inpatient and 282 outpatient locations. Health care professionals had a median of 16 (IQR 4 - 49) messaging partners over the study period.

The network included 31,800 nodes and 1,228,041 edges. The GCC comprised 29,808 nodes (93.7% of total nodes) and 1,225,307 edges (99.8% of total edges). The GCC had a low density of 0.00138 and a low transitivity of 0.09. The GCC diameter was 65,078. However, the reciprocity was high, 0.92, indicating most individuals received reciprocated responses to their messages. Assortativity over the GCC was found to be 0.044, 0.41, and 0.001 for the total degree (ie, the sum of indegree and outdegree), practice setting (ie, inpatient vs outpatient), and provider group (eg, pharmacists), respectively.

Network Characteristics

Inpatient vs Outpatient Practice Setting

Health care professionals who practiced in an inpatient setting had significantly higher values (all $P<.001$) for the following network metrics compared with those who practiced in outpatient settings: eigenvector centrality (median –6.9e-11, 95% CI –1.0e-10 to –4.2e-11), betweenness centrality (median –174, 95% CI –359 to –72), outdegree (median 11, 95% CI 10 - 11), and indegree (median 11, 95% CI 9 - 11; Table 3). However, the local clustering coefficient and closeness were not statistically different between practice settings.

Therapist	3.8e-11 (2.5e-12 to 6.7e-10)	0 (0 to 29,806)	0.143 (0.053 to 0.286)	14 (4 to 39)	15 (5 to 40)	195 (159 to 224)

The distribution of health care professionals into the 4 k-core layers was found to be significantly different between the practice locations (ie, inpatient and outpatient settings) (P<.001; Figure 1). The innermost central core had 30.4% (6423/21,133) of inpatient health care professionals as compared to 22.5% (4761/21,133) of inpatient health care professionals in the outermost peripheral core. Additionally, the innermost central core had 13.4% (1159/8662) of outpatient health care professionals as compared to 29.9% (2586/8662) of outpatient professionals in the outermost peripheral core.

XSL•FO
RenderX

Figure 1. Distribution of users into the 4 k-core among each location and clinical role. Segments >5% were labeled with the percentage. APP: advanced practice provider.

Differences by Health Care Professional Role

There were statistically significant differences in all network metrics between health care professionals based on clinical role (P<.001 for all metrics; Table 3). Pharmacists and APPs had the highest values for all the network metrics, whereas medical assistants had the lowest values. For example, pharmacists had a median indegree of 47 (IQR 16 - 116) and APPs had a median indegree of 36 (IQR 10 - 107), while medical assistants had a median indegree of 7 (IQR 3 - 17).

The distribution of health care professionals among the 4 k-core layers was significantly different across the health care professional roles (P<.001; Figure 1). There were 52.1% (290/557) of pharmacists in the innermost central core and 43% (701/1629) of APPs in the innermost central core, whereas 38.5% (2272/5907) of medical assistants were in the outermost peripheral core.

Clusters and Messaging Behaviors

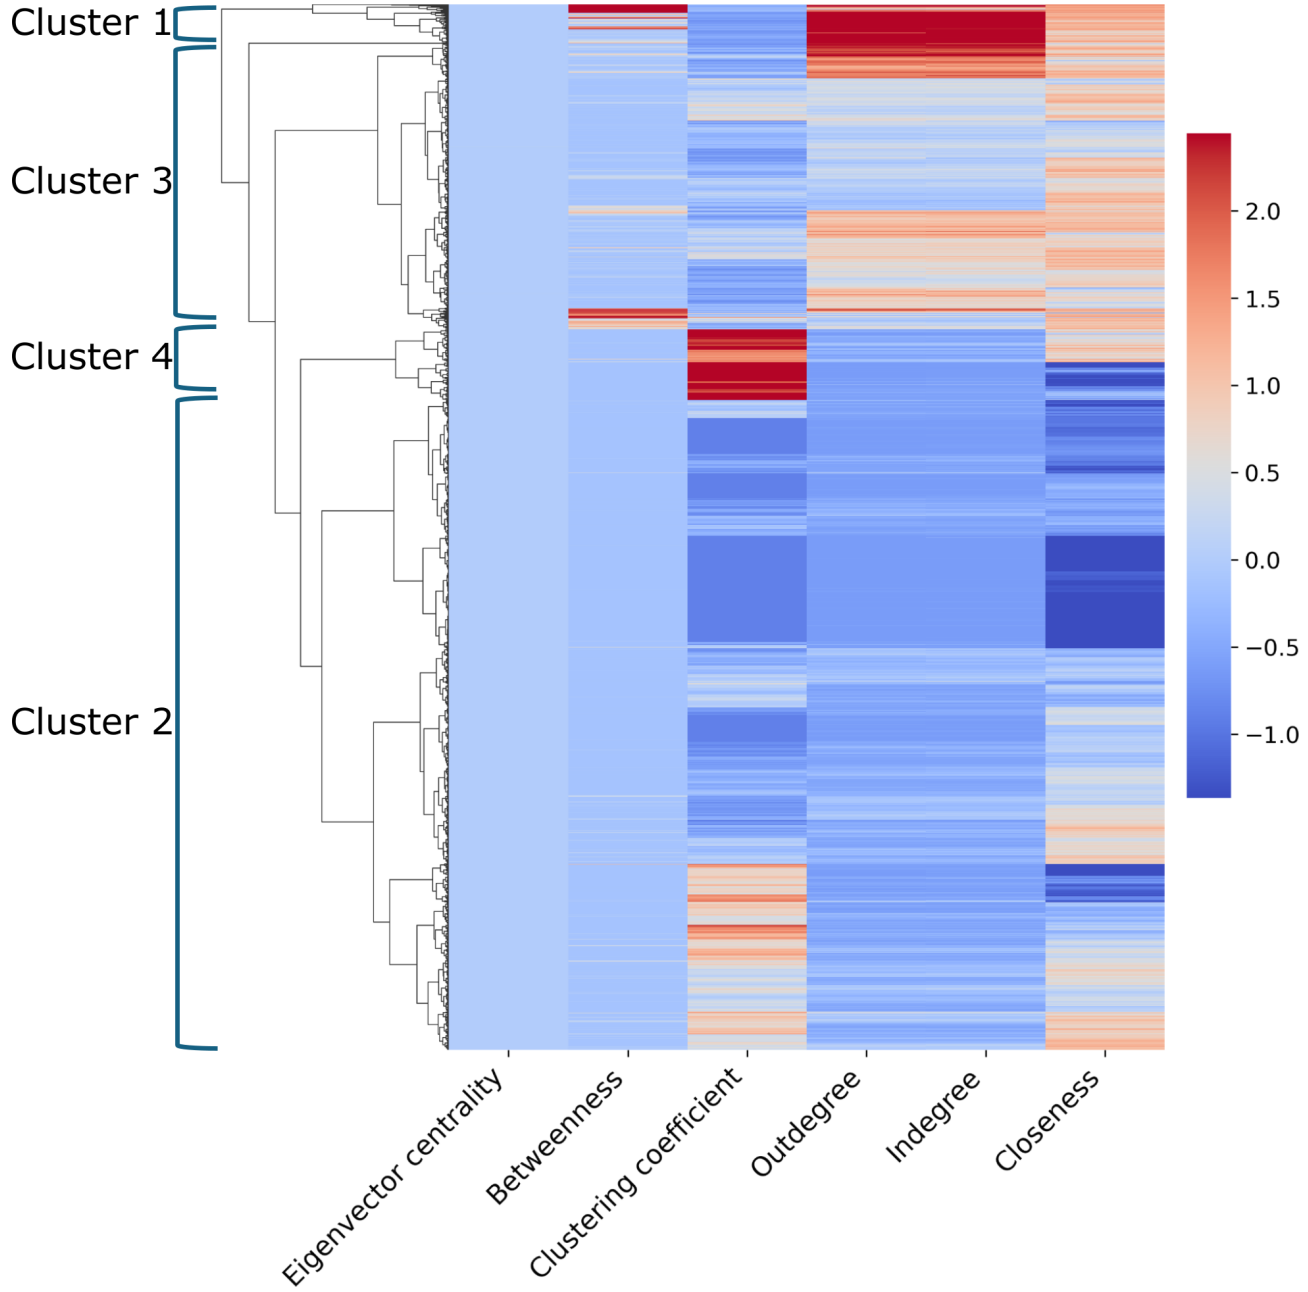
Hierarchical clustering on the node-level properties resulted in 4 clusters (see Table 4 and Figure 2). Cluster 1 had 82.2% (912/1109) of health care professionals working in an inpatient setting (Table 4). Furthermore, 59.2% (656/1109) of health care professionals in cluster 1 were physicians. The health care professionals in cluster 1 had the highest median values for the node-level metrics, except for the clustering coefficient, compared to the other groups.

Cluster 2 was the largest of the 4 identified clusters and included 62.1% (18,521/29,808) of the health care professionals from the study cohort. Cluster 2 had 68% (12,593/18,509) of health care professionals working in an inpatient setting. Furthermore, 37.4% (6933/18,521; Figure 3) of health care professionals in cluster 2 were nurses. The health care professionals in cluster 2 had the lowest median values for the node-level metrics compared to the other groups.

XSL•FO
RenderX

Table . Hierarchical cluster subgroups including the median (IQR) for the clustered node-level metric features and nonclustered secure message use features. Significance levels for pairwise comparisons with Bonferroni adjustment are indicated by letters a through c, as detailed in the footnote.

	Cluster 1	Cluster 2	Cluster 3	Cluster 4
Health care professionals, n	1109	18,521	8156	2022
Inpatient users, n/N (%)	912/1109 (82.2)	12,593/18,509 (68)	6674/8156 (81.8)	954/2021 (47.2)
Total messages sent over the study period, n	1,954,355	1,324,730	4,088,795	303,170
Total messages received over the study period, n	2,051,809	1,318,498	3,981,352	316,888
Eigenvector centrality, median (IQR)	4.934e-08 (1.473e-08 to 1.459e-07)	3.560e-11 (2.111e-12 to 5.647e-10)	3.927e-09 (4.942e-10 to 2.255e-08)	1.464e-11 (3.633e-13 to 1.896e-10)
Betweenness, median (IQR)	888,661 (233,794 to 3,700,421)	0 (0 to 3883)	64,866 (5270 to 269,634)	0 (0 to 3)
Clustering coefficient, median (IQR)	0.064 (0.051 to 0.087)	0.097 (0 to 0.244)	0.131 (0.082 to 0.194)	0.667 (0.6 to 1)
Outdegree, median (IQR)	265 (220 to 331)	8 (3 to 19)	71 (50 to 104)	6 (2 to 14)
Indegree, median (IQR)	264 (223 to 330)	9 (3 to 19)	70 (50 to 104)	6 (3 to 14)
Closeness, median (IQR)	266 (254 to 277)	180 (135 to 213)	244 (227 to 258)	186 (127 to 236)
Total message volume per day, median (IQR)	34 (25 to 48)	4 (3 to 7)[a]	12 (9 to 18)[a,b]	5 (3 to 8)[a,b,c]
Sent character length per message, median (IQR)	62 (48 to 80)	64 (44 to 93)	66 (52 to 85)[a,b]	49 (33 to 74)[a,b,c]
Received character length per message, median (IQR)	75 (63 to 83)	62 (45 to 86)[a]	61 (51 to 74)[a]	52 (39 to 73)[a,b,c]
Read time minutes, median (IQR)	14 (8 to 24)	22 (6 to 76)[a]	17 (9 to 33)[a,b]	26 (8 to 77)[a,c]
Response time minutes, median (IQR)	19 (13 to 30)	24 (8 to 71)[a]	27 (16 to 47)[a,b]	35 (8 to 107)[a,b,c]



[a]Indicates significant difference (adjusted $P<.001$) compared to group 1.

Figure 2. Heatmap for hierarchical clustering of health care professionals based on node-level metrics. The color bar depicts the magnitude of standardized values of the dataset, and the color range is computed with robust quantiles. The blue brackets indicate how clusters were divided into the final 4 groups with associated labels.

XSL•FO
RenderX

Figure 3. Composition of clinical roles within each cluster. APP: advanced practice provider.

Cluster 3 had 81.8% (6674/8156) working in an inpatient setting. Furthermore, 56.5% (4608/8156) of health care professionals in cluster 3 were nurses. Cluster 4 had only 47.2% (954/2022) working in an inpatient setting. Additionally, 42.4% (858/2022) of health care professionals in cluster 4 were medical assistants. The health care professionals in cluster 4 had the highest median value for the clustering coefficient compared to other groups.

There were statistically significant differences in secure messaging behaviors across the 4 clusters (see Table 4, Multimedia Appendix 1; all $P<.001$ and footnotes indicate significant pairwise comparisons among the 4 groups). Compared to the largest subgroup (ie, cluster 2), cluster 1 had the quickest read (median –7.1, 95% CI –8.9 to –5.4 minutes) and response time to messages (median −3.2, 95% CI −4.9 to −1.7 minutes), the largest message volume per day (median 28.4, 95% CI 27.7 - 29.2 messages), as well as the longest message character length (median 9.5, 95% CI 7.9 - 11 characters) (see Table 4). Similarly, compared to cluster 2, cluster 4 health care professionals had slower response times (median 4.1, 95% CI 2.8 - 5.6 minutes) and a marginally larger daily message volume (median 0.3, 95% CI 0.2 - 0.4 messages), as well as sent (median −13.5, 95% CI −15.1 to −12 characters) and received (median −8.8, 95% CI −10.1 to −7.5 characters) the shortest messages.

Discussion

Principal Findings

Based on a large-scale study of over 31,000 health care professionals and more than 7.5 million secure messages, we found that the connectivity of the interactive communication network varied based on health care professionals' roles and their practice settings. Specifically, inpatient health care professionals were generally more central and had the highest incoming and outgoing messaging connectivity compared to outpatient health care professionals, whereas pharmacists were the most central and highly connected among all the clinical roles. Hierarchical clustering analysis highlighted the differences in connectivity among the health care professionals and showed that cluster membership was associated with specific secure messaging behaviors such as read time, response time, total messaging volume per day, and character length per message. For example, cluster 1, which consisted of highly connected and central health care professionals, had the quickest read and response times to secure messages while also managing the largest message volume per day. Although preliminary, our findings highlight that an individual's messaging behaviors are

XSL•FO
RenderX

potentially driven by their networked peers. We describe some of the pragmatic implications of the current findings.

The degree of variation in connectivity between practice settings (ie, inpatient and outpatient) highlights the impact of setting-specific clinical context on resultant communication behaviors. For example, inpatient health care professionals, regardless of their role, had higher network connectivity in the communication network. The greater connectivity highlights their greater need for communication and care coordination, likely owing to the increased complexity of patient care delivery in these settings [49,50]. Ultimately, the setting-specific clinical context influences the extent of secure messaging need and burden.

The degree of variation in connectivity among clinical roles implies a potential relationship between the role-specific clinical context and the extent of secure messaging communication burden. For instance, pharmacists' central position in the network identified them as key players in clinical communication and care management. This has previously been described in other studies that highlighted the central role of pharmacists in medication management and safety [51]. Additionally, in inpatient settings, pharmacists are often embedded within teams to help with coordinating complex medication management of patients, acting as gatekeepers for medication safety [52-54]. Thus, the unique communication needs among specific roles are apparent in the stark difference in secure messaging utilization and burden among professionals in our study.

The hierarchical clustering results revealed a relationship between connectivity within the network and secure messaging behaviors. For instance, health care professionals in cluster 1 were centrally located, highly connected, and acted as communication bridges (see Table 1, betweenness centrality, for definition) and were primarily consisted of physicians and those working in an inpatient setting. Health care professionals in this cluster also had the highest volume of secure messages per day, the longest character length per message received, and the fastest read times compared to the other clusters.

The higher centralization and connectivity in cluster 1 is likely because of their expertise and role, as the cluster is primarily composed of physicians (ie, as a clinical decision leader) [55]. Role-based specialization is common in teams where specialized individuals are relied on for specific expertise leading to targeted communication for specific tasks [55,56]. This is also reflected in cluster 1's increased message volume and messaging behavior, most likely highlighting their role in clinical decision-making. However, such a centralized communication structure may also increase physicians' workload and cognitive burden arising from an increased messaging volume [57].

Similarly, there was one cluster (cluster 4) of nurses and medical assistants who had fewer connections and were not as central within the network. These individuals were mostly involved in "communication cliques" with their immediately connected neighbors (ie, clinical colleagues) such that a given individual's neighbors are also communicating with each other, forming close-knit circles in the network. The higher ratio of local clique structures for this cluster suggests increased mutual interaction and collaboration among health care professionals within a network [58,59]. Furthermore, cluster 4's lower centrality scores (eg, eigenvector, betweenness, and closeness) suggest a more decentralized conversation structure, where communication is more evenly shared [55].

Comparison to Prior Work

Understanding how secure messaging is being used can provide insights into communication and coordination patterns among health care professionals. More cohesive and collaborative networks of health care professionals have been shown to improve care quality for patients [23]. By understanding the state of collaborative interactions, we can potentially develop interventions targeted at improving these relationships and influencing downstream clinician and patient outcomes [26,27]. For example, network characteristics related to connectedness (eg, indegree) and structure (eg, clustering coefficient) can be used to identify "network traffic" and associated communication burden for specific health care professionals [51]. Such information about communication load can be used to develop "triaging strategies," including creating messaging pools, redirecting messages, or assigning personnel for messaging-only roles [60-62]. These strategies have been shown previously to reduce email inbox message volume and self-reported time spent on inbox management [63-65]. Similar strategies could be developed to mitigate the messaging burden among health care professionals.

Similarly, as shown in our hierarchical cluster analysis, there were centrally located clinicians in certain clusters whose messaging behaviors were driven by their extant network. For example, we found that clinicians in cluster 1 were likely to have a higher volume of messages and more likely to read and respond to messages the quickest. Such messaging behaviors are likely to affect their clinical work activities, increasing their likelihood for increased workload, cognitive burden, and errors [10,57]. For example, Lew et al [57] found that inpatient clinicians receiving more messages spent more time on EHR-based work and had increased attention switching (ie, increased cognitive load); similarly, Lou et al [10] found that an increased volume of messages was associated with increased likelihood of wrong-patient ordering errors. The current findings point to the fact that increased messaging volume was potentially associated with their external connectivity, highlighting the role of connected communication partners (ie, network) in increasing workload, cognitive burden, and errors.

Future Directions

Finally, it is important to emphasize that this was a preliminary study. More focused analyses (eg, among subgroups of clinicians such as hospitalists or outpatient clinicians) are necessary to ascertain specific strategies for bottlenecks in communication and improving clinician and patient outcomes.

Limitations

There are several limitations in this study. First, although this study included several inpatient and outpatient settings across academic and community settings (14 hospitals, >250 outpatient locations), all of these were part of the same health care system using the only secure messaging platform available, Epic Secure

XSL•FO
RenderX

Chat. Therefore, the generalizability of this study's findings to other health care systems and other secure messaging platforms may be limited. Second, we only used one form of communication: secure messaging. Other forms of communication (ie, face-to-face, telephone, and pager) were also used by our cohort throughout the study period; therefore, our study likely underrepresents the true communication structures and relationships between health care professionals. Third, our assignment of clinical location (ie, inpatient vs outpatient) was based on log-in information and was potentially imprecise since we did not have access to detailed work schedules.

Conclusions

This study characterized the network properties of a large-scale EHR-integrated secure messaging network using social network analyses. We found that health care professionals' connectivity varied by both role and practice settings. Furthermore, hierarchical clustering indicated a relationship between an individual's network connectivity and secure messaging behaviors. Ultimately, these preliminary findings highlight the importance of understanding secure messaging interactions and resultant secure messaging behaviors, as well as their potential impact on clinical work outcomes.

Conflicts of Interest

None declared.

Abstract

Background: Telehealth adoption has grown significantly, presenting valuable opportunities for the aging population to access health care remotely. Despite evidence of its benefits in managing chronic conditions and promoting independence, many older adults remain hesitant to adopt telehealth, preferring traditional in-person visits even post pandemic. Current literature largely focuses on younger or general populations, overlooking the unique barriers faced by older adults, such as technology literacy and access disparities.

Objective: This study investigates how telehealth adoption among the aging population is influenced and mediated by relevant factors, including the use of wearable devices, demographic factors, health conditions, and physical activity levels.

Methods: A secondary analysis was conducted on the Health Information National Trends Survey (HINTS 6) data collected from March to November 2022. Of the 6252 respondents, 1596 older adults (≥65 years) were included. Telehealth adoption was defined using 2 survey items on receiving or being offered telehealth services. We construct regression and mediation analyses to understand the relationships between telehealth adoption and influential factors, including demographics, physical activity levels, health conditions, and the use of wearable devices.

Results: We found that wearable device use, while not directly significant, plays a critical role in adoption when mediated by factors such as education, income, and general health. Specifically, higher levels of education and income increased the likelihood of telehealth adoption (P<.001), underscoring the importance of socioeconomic status. Additionally, rural versus urban residency emerged as a critical factor (P=.003), with rural residents demonstrating lower adoption rates, highlighting the accessibility and technology literacy barriers in these areas. Health conditions were inversely associated with telehealth adoption, suggesting that healthier individuals may perceive less need for telehealth services. The total effect of wearable use on telehealth adoption was significant (P=.007), with indirect effects via education (P<.001), income (P=.007), and health conditions (P=.004). The findings underscore the role of socioeconomic factors in influencing the adoption of health technologies.

Conclusions: While wearable device use is associated with increased telehealth adoption among older adults, its effect operates primarily through mediating factors such as education, income, and health status. These findings suggest that addressing disparities in socioeconomic status and health literacy is critical to increasing telehealth engagement in aging populations.

Introduction

Background

The health care system is under growing pressure, including an aging population, long-term health conditions, and increasingly higher standards of care expected by society, government, patients, and professionals [1]. The role of technology in health care has become increasingly important, giving rise to the concepts of telehealth and telemedicine as key components of modern health care systems [2]. While telemedicine specifically refers to the remote diagnosis and treatment of patients through telecommunications technology, telehealth covers a wider range of remote health care services, including remote nonclinical services, public health education services, and instruction to medical students [3]. Wearable devices are defined as consumer-facing, sensor-enabled devices that can continuously or intermittently track health-related data such as physical activity, heart rate, or sleep patterns. Examples include smartwatches, fitness trackers, and health-monitoring rings. These tools play a growing role in personal health management

XSL•FO
RenderX

and are increasingly integrated into remote care models like telehealth.

While there is increasing attention to adopting advanced technology in health care systems, the gap between the potential of telehealth and its actual adoption needs further exploration. Especially for the aging population, who are not early adopters of technology, it is crucial to understand their preferences and barriers. The Health Information National Trends Survey (HINTS) provides valuable data in this regard. HINTS is a major initiative of the National Cancer Institute that collects data on the American public's use of health information and technology [4]. The survey contains key issues such as how individuals access and use health information, their perceptions of health-related risks, and their health behaviors and conditions. HINTS 6 (2022) is the sixth cycle of the HINTS program and reflects the evolving landscape of digital health during the postpandemic period. This cycle includes updated questions on telehealth usage, wearable device adoption, and digital health communication, making it particularly well-suited for examining how older adults engage with emerging health technologies. The HINTS 6 survey results have been examined for patterns and predictors of telehealth utilization—a study used logistic regression analysis to reveal significant associations of social determinants, socioeconomic demographics, and health factors with telemedicine services utilization [5]. The study found that despite the widespread use of telemedicine, US adults still prefer in-person visits in the early postpandemic years, especially older adults, who showed a lower inclination toward telemedicine. This insight highlights the current challenge for telehealth utilization for older adults, despite the substantial benefits that broader telehealth services offer older adults, particularly in managing chronic conditions and promoting physical activity. Older adults are defined as individuals aged 65 and above, which aligns with demographic classifications used in national datasets such as HINTS and prior public health literature [4]. This age group is particularly relevant for examining telehealth adoption, as they face increasing health management needs and may benefit most from remote care solutions. However, the reasons behind this slow adoption are not fully understood. Our paper aims to bridge the gap by leveraging the HINTS 6 dataset to conduct a focused analysis of telehealth adoption among the aging population. By examining factors such as demographics, physical activity levels [6-8], health conditions, and technological barriers (use of wearable devices) [9], this study seeks to build a comprehensive understanding of the variables influencing telehealth utilization in older adults, especially the impact of technical barriers. In this study, we use the term "telehealth" to align with the terminology used in the HINTS 6 survey. The survey defines a telehealth visit as "a telephone or video appointment with a doctor or health professional." While e-health encompasses a broader variety of digital health technologies, our analysis specifically focuses on telehealth usage as defined and measured in the HINTS dataset.

Aging Population

The phenomenon of an aging population is a relatively recent challenge from a historical perspective [10]. In 1950, no nation had more than 11% of its population aged 65 years and older. By 2000, this figure had risen to 18%, and projections suggest a dramatic increase to 38% by 2050 [11]. The World Health Organization anticipates that by mid-century, the number of individuals aged 65 and older will surpass the number of youths aged 15 - 24. This demographic change is a medical and social issue worldwide, with the increase in the aging population affecting the socioeconomic structure and underscoring the need for specialized products and services for older adults [12].

Due to this worldwide challenge, the concept of healthy aging emerges, which emphasizes developing and maintaining functional abilities that promote well-being in older age, as defined by the World Health Organization [13]. This paradigm shift requires a re-evaluation of current health care models that focus not only on disease response but also on the multiple health determinants—behavioral, clinical, social, and environmental—that influence functional decline across the lifespan [14]. The primary goal of this approach is to extend health span rather than lifespan, aiming to reduce morbidity associated with age-related chronic diseases [15].

As life expectancy increases, the prevalence of noncommunicable diseases such as diabetes, renal failure, arthritis, Alzheimer disease, and Parkinson disease among older adults increases, requiring ongoing surveillance and a comprehensive management strategy. This demographic change is accompanied by physical and cognitive decline, increasing the risk of comorbidities and acute medical events such as falls or stroke [16]. Therefore, promoting healthy aging while ensuring the autonomy and safety of older adults at home has become a key social goal.

Adoption of Wearable Devices

The advent of technology has led to a wide variety of wearable devices that go beyond traditional smartwatches to include innovative smart jewelry designed to be worn around the fingers, ears, or neck [17]. These devices have revolutionized self-tracking, with physical health and activity levels becoming the primary interests of users. In addition, wearable devices enable a broader range of health indicators, including stress levels, emotional well-being, sleep quality, geographic location, nutritional habits, vital signs, and specific disease or symptom tracking [18]. This comprehensive monitoring capability allows health care professionals to have continuous access to the health status of older adults and offers unique opportunities for effective remote care [19], thereby facilitating effective remote care and personalized health management strategies. For example, a smartwatch equipped with a heart rate sensor can alert users and health care providers to irregular heartbeats, suggesting potential arrhythmia or other cardiovascular issues [20]. Similarly, wearable fall detection devices can automatically notify family members or emergency services in the event of a fall, significantly reducing the response time and potentially saving lives [21]. Furthermore, devices tracking sleep patterns can offer valuable data to adjust treatments for insomnia or sleep apnea, contributing to mental well-being [22].

Wearable devices enable older adults to manage their health proactively, continuously track chronic conditions and treatments, and monitor potential safety hazards—all without disrupting daily life [23]. This device not only supports independent living but also improves quality of life. In the health

XSL•FO
RenderX

care domain, wearable devices are gradually being integrated into patient care protocols and independent living programs for the aging population [24]. Researchers have explored the utility of wearable devices in forecasting clinical outcomes [25], monitoring patient activity levels, especially in those with chronic conditions like chronic obstructive pulmonary disease [14], predicting patient-reported outcomes such as pain scores [26], monitoring cardiac arrhythmia [27], and tracking the progression of symptoms in neurodegenerative diseases [28]. The growing interest in wearable devices among health care providers, including general practitioners considering prescribing mobile health apps and devices, signals a transformative shift in patient care and contributes to the growth in telehealth [28].

Combined with wearable devices, telehealth has become a key aspect of modern health care, seamlessly extending medical services directly into older adults' homes. By enabling continuous monitoring and management of chronic conditions, telehealth can reduce the frequency of hospital visits, lower health care costs, and improve the efficiency of health care delivery. In addition, telehealth can significantly improve the accessibility of health care services, ensuring that older people receive timely and appropriate care no matter where they are. The ability to conduct virtual consultations and access health care services from home is particularly beneficial during public health crises, such as the COVID-19 pandemic, when minimizing physical contact is critical [29]. Despite the significant advantages of telehealth, several obstacles hinder its widespread adoption, particularly among the aging population [30]. Digital literacy is a major barrier; many older adults are unfamiliar with the necessary technology, which can limit their access to telehealth services [31]. Privacy and security concerns regarding personal health data transmitted over the internet further exacerbate these challenges [32]. Additionally, the digital divide—a gap in access to digital devices and high-speed internet—disproportionately affects rural and underserved communities, thereby limiting the reach and effectiveness of telehealth solutions.

Hypothesis

As wearable devices are one of the prominent enablers of at-home health monitoring, we propose that being familiar with wearable devices may increase the adoption of other emerging technologies, including telehealth, particularly among the aging population (age ≥65). This hypothesized relationship stems from the strategy for breaking down technology barriers [33]. Adaptation to one technology can reduce barriers to the adoption of related technologies. Specifically, individuals accustomed to wearable devices may find the transition to telehealth services more intuitive. This relationship may be influenced by demographic factors: a higher level of education, which often correlates with greater openness to technological adoption; higher income ranges, being able to afford such health-related products and services; and the influence of living in rural or urban areas, which could affect the accessibility of in-person clinical care and hence the need for telehealth services. Additional variables that necessitate telehealth service and relate to health awareness include general health and intention to engage in physical exercise. In this study, we will explore the following hypotheses:

1. The use of wearable devices among the aging population is associated with telehealth adoption.
2. Demographic factors (including gender, education, income, and location) are associated with telehealth adoption in the aging population.
3. Demographic factors act as mediating variables, influencing how the use of wearable devices is associated with telehealth adoption.
4. Poor health conditions in the aging population are directly associated with higher telehealth adoption.
5. Health conditions mediate the relationship between the use of wearable devices and the adoption of telehealth among the aging population.
6. An active lifestyle is significantly associated with a higher likelihood of telehealth adoption among the aging population.

Methods

Study Design and Dataset

The HINTS survey is conducted every 2 years to gather comprehensive insights into the changing landscape of health communication and information dissemination [4]. HINTS 6 (2022) data were collected from March through November 2022, and it contains responses from 6252 participants. Participants were selected using a random sample of US households, with addresses drawn from the US Postal Service's Computerized Delivery Sequence File, and respondents were offered a paper survey or web option. This 2-pronged approach helped capture a wide demographic, including digitally literate individuals and those more comfortable with traditional survey methods. To ensure sufficient representation, HINTS incorporates a stratified sample design, oversampling rural populations and older adults to capture a broad range of health behaviors and technology use across different demographic groups.

We used 10 variables from the survey based on the hypotheses; 5 of them are demographic variables. All the variables and related survey questions are summarized in Table 1. Telehealth adoption is defined as the use of telehealth services delivered digitally and virtually, such as video or telephone consultations with health professionals. Responses indicating the use of video, phone calls, or a combination of both were considered evidence of telehealth adoption. The use of wearable devices in the HINTS survey and this study refers to the engagement with electronic devices designed to monitor or track health and physical activity, such as a Fitbit, Apple Watch, or Garmin Vivofit. While wearable devices may collect health data that can support telehealth services, they do not inherently constitute telehealth adoption. Notably, telehealth involves direct communication with health care providers, whereas wearable device use is focused on personal health monitoring.

Table . Descriptions of variables used in the study from the HINTS 6 survey.

Variable and variable name	Survey item
Age	
AgrGrpB	R1. What is your age?
Telehealth adoption	
ReceiveTelehealthCare	D1. In the past 12 months, did you receive care from a doctor or health professional using telehealth?
OfferedTelehealthOption	D2. In the past 12 months, were you offered the option to have a telehealth visit for any medical care you tried to schedule?
Use of wearable devices	
WearableDevTrackHealth	B8. In the past 12 months, have you used an electronic wearable device to monitor or track your health or activity? For example, a Fitbit, Apple Watch, or Garmin Vivofit.
Health condition	
GeneralHealth	H1. In general, would you say your health is...?
Physical exercise	
TimesModerateExercise	M1. In a typical week, how many days do you do any physical activity or exercise of at least moderate intensity, such as brisk walking, bicycling at a regular pace, and swimming at a regular pace (do not include weightlifting)?
Location	
PR_RUCA_2010	USDA 2010 Primary Rural-Urban Community Area Code
Education	
Education	R7. What is the highest grade or level of education?
Gender	
BirthGender	R2. On your original birth certificate, were you listed as male or female?
Income	
IncomeRanges	R14. Thinking about members of your family living in this household, what is your combined annual income, meaning the total pre-tax income from all sources earned in the past year?

[a]HINTS: Health Information National Trends Survey.

Data Processing

The primary outcome considered in this study is the adoption of telehealth among the aging population. The telehealth adoption score was assessed using the following 2 survey items: (1) “In the past 12 months, were you offered the option to have a telehealth visit for any medical care you tried to schedule?” and (2) “In the past 12 months, did you receive care from a doctor or health professional using telehealth?” We formed a composite score to represent the adoption of telehealth based on these 2 survey questions. We assume that the answers “Yes, by video,” “Yes, by phone call,” and “Yes, some by video and some by phone call” are indicative of telehealth use, while “No telehealth visits in the past 12 months” and “I did not try to schedule any medical care in the past 12 months” suggest no use of telehealth. Table 2 shows the telehealth adoption score.

To enhance the analytical clarity and efficiency of our study, we simplified categorical variables related to education level, income ranges, and frequency of moderate exercise. Then, we encoded all categorical variables, including demographic variables, health conditions, and physical exercises.

Table . Telehealth adoption conditions.

Telehealth adoption conditions	Label
Not offered telehealth and did not adopt	0
Offered telehealth but did not adopt	1
Adopted telehealth	2

To better represent the range of educational attainment in our dataset, we condensed the categories into 4 main levels: Less than high school (coded to 1): This category combines “less than 8 years” and “8 through 11 years” into a single

XSL•FO
RenderX

category, representing individuals who have not completed high school education.

High school plus (coded to 2): This new category merges "12 years or completed high school," "Post high school training other than college (vocational or technical," and "Some college" into one. It captures those who have achieved education beyond high school but have not obtained a full college degree.

College graduate (coded to 3): Retained as a distinct category, it signifies individuals who have completed a college degree.

Postgraduate (coded to 4): Also kept separate, indicating individuals with education beyond a college degree.

Income ranges were redefined into 3 broad categories to reflect the socioeconomic status of the study participants effectively: low income ($0-$49,999), middle income ($50,000 -$99,999), and high income ($100,000 or more), encoding as 1, 2, and 3 accordingly. The frequency of moderate exercise was encoded numerically to facilitate quantitative analysis of physical activity patterns among participants. The encoding represents the number of days per week participants engage in moderate exercise, ranging from 0 (no exercise) to 7 (daily exercise).

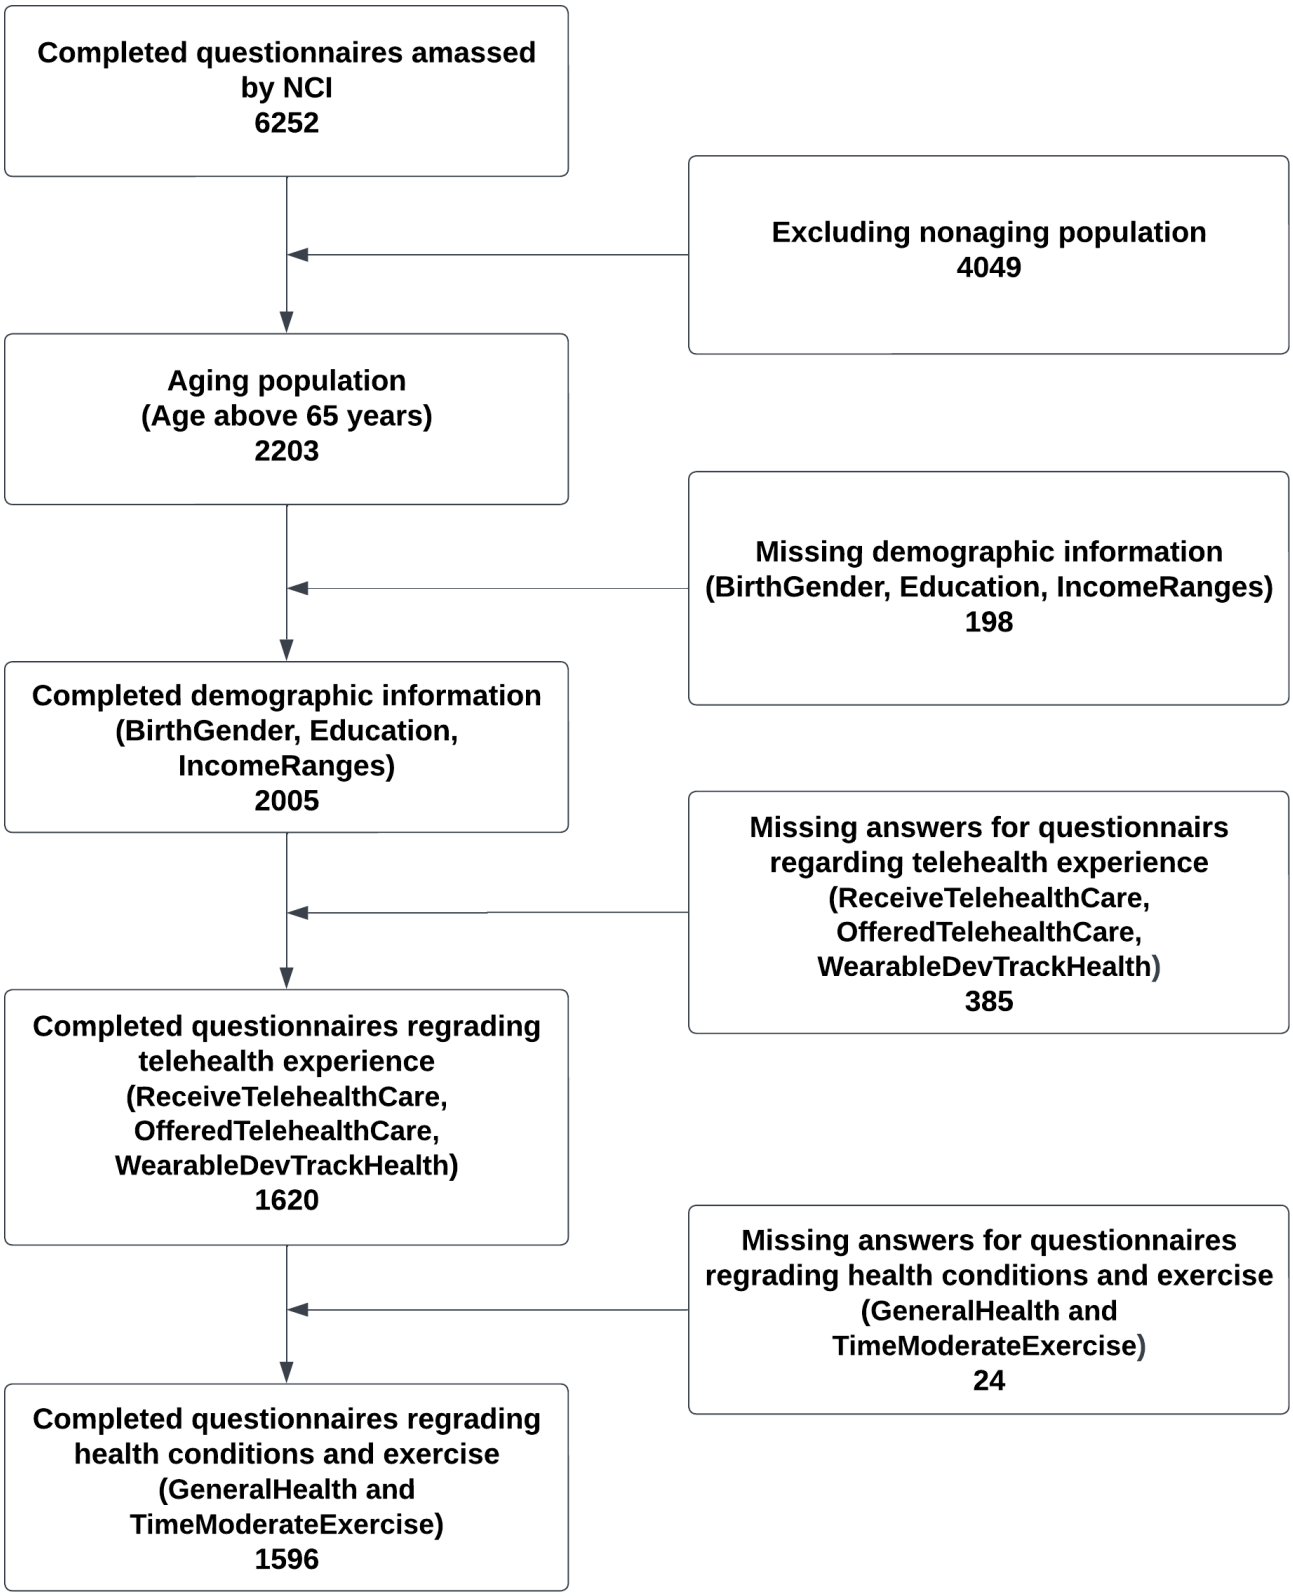
Data Analysis

The data analysis used ordinal regression and mediation analysis to examine factors that influence telehealth adoption among the aging population based on the HINTS 6 (2022) dataset. Ordinal regression was used to determine the direct associations between telehealth adoption and independent variables, including wearable device use, demographics (age, gender, education, income, location), health conditions, and physical exercise. The analysis was chosen because the outcome variable—telehealth adoption—is ordinal, represented by 3 levels indicating increasing engagement (no use, offered but not adopted, adopted). This method allows us to estimate the cumulative odds of telehealth adoption across the 3 categories, providing insight into how the predictors influence the likelihood of being in a higher adoption category.

After identifying factors—education, income, and health conditions—that influence telehealth adoption from the ordinal regression, we further decomposed the effect of each factor and conducted a parallel mediation analysis to quantify the mediating effects on the relationship between the use of wearable devices and telehealth adoption. This approach allows us to identify and quantify pathways through which these mediators influence adoption behavior, offering a more nuanced understanding of the mechanisms underlying telehealth adoption. To support this, a conceptual model was developed to illustrate both direct and indirect relationships. Such models are frequently used in behavioral and health policy research to enhance interpretation and effectively communicate findings, particularly when informing intervention design and strategy development.

Ethical Considerations

This study was a secondary analysis of publicly available data from the HINTS 6 administered by the National Cancer Institute. As such, it is exempt from institutional review board (IRB) review per US federal guidelines on secondary data use [34]. No compensation was provided by the authors for participation, as data collection was performed independently by the HINTS program. This manuscript does not include any identifiable individual participant data or images. Therefore, no consent forms for identifiable data are required.



Results

Data Processing and Selection

A total of 6252 surveys were included in the HINTS 6 dataset. For our study, we focused specifically on the aging population, defined as individuals aged 65 years and older. Out of the initial dataset, 2203 participants met this age criterion. After further refinement and excluding incomplete data, the subsequent processing and analysis were conducted on 1596 complete responses. The data selection process is shown in Figure 1.

XSL•FO
RenderX

Figure 1. Flow diagram illustrating the selection of survey respondents aged ≥65 years from the Health Information National Trends Survey (HINTS) 6 dataset. NCI: National Cancer Institute.

Ordinal Regression Analysis

The ordinal regression analysis was performed on the refined HINTS 6 dataset to establish the association between telehealth adoption and various factors, including the use of wearable devices, demographic variables, health conditions, and engagement in physical exercise. The result is shown in Table 3.

XSL•FO
RenderX

Table . Results from ordinal logistic regression that assesses the association between wearable device use, demographics, and telehealth adoption among older US adults (N=1596).

Factors	Coefficient	*t* value	*P* value	Odd ratios (95% CI)	Reference categories
Use of wearable devices	0.2762	2.2134 (1576)	.03	1.3181 (1.03-1.68)	No
Location	−0.2538	−3.1019 (1576)	.003	0.7758 (0.655-0.918)	Metropolitan
Gender	0.0347	0.3388 (1576)	.74	1.0354 (0.841-1.290)	Female
Income	0.1369	1.8648 (1576)	.07	1.1468 (0.993-1.323)	Low income
Education	0.3113	4.9108 (1576)	<.001	1.3653 (1.206-1.562)	Less than high school
Health condition	−0.2659	−4.5104 (1576)	<.001	0.7665 (0.683-0.860)	Poor
Physical exercise	−0.0376	−1.6056 (1576)	.11	0.9631 (0.920-1.008)	None

The use of wearable devices demonstrated a statistically significant positive association with telehealth adoption (*P*=.03). This finding supports Hypothesis 1 and shows that an increased use of wearable devices is associated with increased adoption of telehealth. Specifically, the odds ratio of 1.3181 suggests that individuals who use wearable devices are approximately 32% more likely to adopt telehealth compared to those who do not.

In addition, the location variable has a statistically significant association with telehealth adoption, with a *P* value of 0.0025. Residents in rural areas have lower levels of telehealth adoption. Education emerged as the most highly significant factor (*P*<.001), with a positive coefficient (0.3113). The odds ratio for education (1.3653) implies that with each increase in education level, the odds of telehealth adoption increase by approximately 36.5%. This strongly supports the notion that educational attainment plays a critical role in health technology adoption.

In contrast, gender does not have a statistically significant effect on the likelihood of adopting telehealth services. Income also did not reach the conventional threshold for significance (*P*=.07), but its marginal association suggests that further investigation should be required to understand income's role at a more granular level. Given the mixed results among these demographic factors, Hypothesis 2 is partially supported. The factors of gender and income did not show a significant impact, whereas rural location and lower education undermined telehealth adoption.

The self-reported health conditions are inversely associated with telehealth adoption (coefficient=−0.26597, *P*<.001), thereby supporting Hypothesis 4. Physical exercise, representing moderate levels of physical activity, may be negatively associated with telehealth adoption (coefficient=−0.03761, *P*=.11). Thus, Hypothesis 6 is not supported, and instead, an active lifestyle potentially decreases the likelihood of telehealth adoption.

Mediation Analysis and Conceptual Model Development

After excluding gender and physical exercise due to their lack of significant relationships with telehealth adoption, subsequent correlation analyses were performed on the remaining variables. The correlations between features are moderate to low (<0.5), which is illustrated in Table 4, so keeping them as separate mediators is acceptable.

Given that our primary outcome focuses on the relationship between the use of wearable devices for health tracking and telehealth adoption. We then explore how demographic factors like education, income, location, and health condition potentially mediate the effect of the use of wearable devices on telehealth adoption. The mediation analysis revealed that the location does not show a significant relationship with wearable device use, and thus, it does not play a mediating role in our model. This finding did not support Hypothesis 3, so the demographic factors, including location, would not moderate the relationship between the use of wearable devices and telehealth adoption in an aging population. Conversely, other factors such as education, income, and health conditions showed mediation effects, thus partially supporting Hypothesis 3 and fully supporting Hypothesis 5. Our mediation analysis highlights that the use of wearable devices is associated with higher telehealth adoption through the mediating effects of education and income. It indicates that individuals with higher education or income are more inclined to adopt wearable technology, which in turn facilitates the adoption of telehealth services.

We constructed a conceptual model in which the use of wearable devices for health tracking is considered an independent variable, while telehealth adoption is considered a dependent variable. Education, income, and health conditions are treated as mediating variables, potentially influencing the core relationship. This model considers the contextual influences of socioeconomic and health conditions and helps demonstrate pathways through which the use of wearable devices may lead to telehealth adoption. Such an approach allows for a more comprehensive understanding of the multifaceted influences on telehealth adoption. Table 5 summarizes the results of the conceptual model analysis, illustrating how each variable interacts within the model:

XSL•FO
RenderX

Table . Results of the regression analysis that estimate the direct and indirect effects of the wearable device use on telehealth adoption through education, income, and health conditions.

Regression	Estimate	SE	*z* value	*P* value (>|*z*|)
Telehealth adoption~Use of wearable devices (b1)	0.137	0.077	1.785	.07
Education~Use of wearable devices (a1)	0.339	0.054	6.291	<.001
Telehealth adoption~Education (c1)	0.162	0.034	4.772	<.001
Income~Use of wearable devices (a2)	0.347	0.047	7.383	<.001
Telehealth adoption~Income (c2)	0.114	0.039	2.885	.004
Health condition~Use of wearable devices (a3)	0.262	0.059	4.425	<.001
Telehealth adoption~Health condition (c3)	−0.125	0.032	−3.870	<.001

Conceptual Model Analysis

The analysis shows that the use of wearable devices for health tracking has a direct effect on telehealth adoption with a positive coefficient (b1=0.137), but this effect is not statistically significant (*P*=.07). The use of wearable devices is positively correlated with education (a1=0.339, *P*<.001), income (a2=0.347, *P*<.001), and health condition (a3=0.262, *P*<0.001). These results show that higher engagement with wearable devices is associated with higher educational attainment, higher income, and better self-reported health. Subsequently, education (c1=0.162, *P*<.001), income (c2=0.114, *P*=.004), and health conditions (c3=−0.125, *P*<.001) have significant effects on telehealth adoption. The results suggest that higher levels of education and income lead to a greater propensity to adopt telehealth services. This result is consistent with the regression and mediation analysis, supporting Hypothesis 2 and partially supporting Hypothesis 3. Conversely, better general health status appears to decrease the likelihood of telehealth adoption, reflecting a possible reduced need for remote health services among healthier individuals, which confirms the testing results of Hypotheses 4 and 5 in the regression and mediation analysis sections.

The mediated effects through education, income, and health conditions are captured by the parameters “indirect1,” “indirect2,” and “indirect3,” respectively, in Table 6, with visualization in Figure 2. The “Estimate” values reported in Table 6 represent standardized indirect effects. These coefficients quantify the extent to which the relationship between wearable device use and telehealth adoption is mediated by education, income, or health conditions. “Indirect1” and “indirect2” positively contribute to telehealth adoption, supporting the beneficial impact of higher education and income facilitated by the use of wearable devices. Conversely, “indirect” shows a negative mediation effect, suggesting that better health conditions actually reduce telehealth adoption. The “total effect” of 0.199 (*P*=.007) encompasses all paths and confirms a significant overall influence of wearable device use on telehealth adoption. To synthesize the statistical results as shown in Table 6 and visualized in Figure 2, we found that demographic factors and health conditions mediate the effect of the use of wearable devices on telehealth adoption among the aging population. This comprehensive model highlights not only isolated effects but also the interconnection of these factors, which is critical to developing targeted strategies to promote telehealth effectively. Table 7 summarizes the outcomes of the hypothesis tests, offering clear insights into the pathways through which the use of wearable devices influences telehealth adoption.

Table . Total and indirect effects in the conceptual mediation model.

Parameter	Estimate	SE	*z* value	*P* value (>|*z*|)
Indirect1	0.055	0.014	3.809	<.001
Indirect2	0.040	0.015	2.687	.007
Indirect3	−0.033	0.011	−2.915	.004
Total effect	0.199	0.074	2.695	.007

Table . Summary of hypotheses testing outcomes.

Hypothesis	Path	Coefficient (*P* value)	Outcome
1	• Use of wearable devices→Telehealth adoption	• 0.137 (.07)	Partially supported
2	• Education→Telehealth adoption • Income→Telehealth adoption	• 0.162 (<.001) • 0.114 (.004)	Partially supported
3	• Use of wearable devices→Mediators→Telehealth adoption	• Education: 0.055 (<.001) • Income: 0.04 (.007)	Partially supported
4	• Health conditions→Telehealth adoption	• −0.125 (<0.001)	Supported
5	• Use of wearable devices→Health conditions→Telehealth adoption	• −0.033 (.004)	Supported
6	• Physical exercise→Telehealth adoption	—	Rejected

Discussion

Principal Findings

The mediation analysis conducted in this study aims to explore the dynamics of telehealth adoption among the aging population, specifically related to the use of wearable devices, demographic factors, and health conditions. Hypothesis 1 was supported across both the ordinal regression and mediation analyses. The use of wearable devices showed a direct effect and also influenced telehealth adoption indirectly through income and education. This suggests that familiarity with digital health tools may help older adults navigate other health technologies more confidently. Although wearable use was associated with increased telehealth adoption, its direct effect was not strong in isolation, highlighting the importance of additional influencing factors. Hypothesis 2 was partially supported. Education and rural location were significant predictors, while gender and income did not reach statistical significance in the ordinal regression. However, income did emerge as a significant

XSL•FO
RenderX

mediator in the conceptual model, indicating its nuanced role in the adoption process.

One of the most interesting findings is the role of socioeconomic status, as measured by education and income, in influencing telehealth adoption. Consistent with literature suggesting that higher socioeconomic status facilitates better access to technological resources [35], our study finds that higher education and income levels significantly increased the likelihood of telehealth usage for the aging population too, acting as key mediators in the adoption process. Individuals with higher education and income levels are more likely to adopt technologies in general, which encourages the adoption of telehealth services. This also aligns with the finding in [36], which found similar trends in technology adoption among low-income older adults. Additionally, the role of general health conditions inversely affected telehealth adoption, suggesting that individuals in better health are less likely to perceive a need for such services. This reflects findings by Rodríguez-Fernández et al [37], who found that a history of long-term diseases was positively associated with the effective utilization of telehealth among the aging population. Furthermore, some studies have indicated that self-monitoring technologies not only provide patients with greater awareness and understanding of their condition but also are capable of triggering a virtuous circle [38,39]. Importantly, technology acceptance tends to be higher when adopted in the early stages of the disease [40]. Contrary to the hypothesis, our analysis did not identify a significant relationship between physical activity and higher telehealth adoption, indicating that while physically active individuals may be more health-conscious, they do not necessarily see more value in telehealth services. This observation is consistent with the work of Rochester [41], who also reported limited evidence of a relationship between telehealth usage and physical activity levels.

Although geographic location was not included in the conceptual model as a mediator, it emerged as a significant factor in both the ordinal regression and correlation analyses. Rural residency was associated with lower telehealth adoption, highlighting persistent disparities in digital health access across geographic regions [42]. This finding is particularly important in the US context, where rural residents often face greater travel distances to health care facilities but may lack the broadband infrastructure and digital literacy support needed to engage with telehealth services effectively [43].

The conceptual model in this study examines the use of wearable devices as a predictor of telehealth adoption. Although the direction of the effect was positive, the nonsignificant direct effect highlighted the complexity of the relationship. The increasing use of wearable devices by older adults may not be directly related to increased adoption of telehealth due to variables such as personal attitudes toward the technology, perceived ease of use, and perceived usefulness [44]. However, the significant total effect observed when considering both direct and mediated effects confirms that as wearable use increases, the likelihood of telehealth adoption also increases, driven by the mediating effects of education, income, and general health. This combined effect represents the cumulative impact of the various pathways through which the use of wearable devices impacts telehealth and telemedicine adoption. As discussed in the study by Gupta et al [45], the role of both socioeconomic and psychological factors is important in the acceptance of new technologies.

This study used a parallel mediation framework implemented through ordinal regression to estimate direct and indirect effects across multiple mediators. An alternative approach, such as the Preacher and Hayes bootstrapping method [46], provides robust confidence intervals and is well-suited for testing mediation effects in complex models. Incorporating bootstrapping in future analyses would strengthen the statistical inference of indirect pathways and further validate the conceptual relationships identified in this study.

In summary, this study shows significant indirect effects of socioeconomic factors and health conditions on telehealth adoption in the aging population. While the direct impact of wearable device use on telehealth adoption is subtle, its effects are clearly mediated through pathways mediated by education, income, and health status. This complex relationship highlights the need for multifaceted strategies to enhance access to and adoption of telehealth among older adults. The significant role of wearable devices in facilitating telehealth highlights the need for comprehensive strategies to expand access and adoption among older adults. The previous research highlights that most digital health technologies were not designed for the needs of socially disadvantaged groups, such as older adults or those with limited health literacy skills [47]. As a result, these populations often experience reduced access to and engagement with telehealth services. The COVID-19 pandemic accelerated the shift to telehealth and wearable devices but also amplified digital exclusion, especially among those without consistent internet access or familiarity with remote platforms [48]. The concept of the digital divide encompasses more than device ownership—it includes disparities in broadband access, digital skills, and the ability to meaningfully engage with health technologies [49]. Recent evidence during the COVID-19 pandemic suggests that these disparities directly translate into worse health outcomes [50]. For instance, counties with higher levels of digital exclusion experienced higher COVID-19 case and death rates and lower vaccination uptake compared to digitally connected communities [51]. This suggests that digital exclusion limited the ability of individuals to access timely public health information, schedule vaccine appointments, or participate in virtual care and social support networks. These compounding factors raise urgent concerns about digital equity as a social determinant of health. Consequently, there is an urgent requirement for policies that systematically address both technological and socioeconomic barriers to health technology utilization [52]. These measures are critical to ensuring that all segments of the population benefit from advances in health care technologies and services.

Limitation

This study has several limitations that should be acknowledged. First, there is a potential for self-selection and self-report bias in the survey responses, which could affect the accuracy of reported use of wearable devices, perceived health conditions, and telehealth adoption. Future studies might benefit from using

objective data collection methods, such as direct monitoring of wearable device usage and medical records for telehealth adoption. Second, although the study was controlled for several demographic factors and health-related variables, there may be other confounding factors that may influence the relationship between the use of wearable devices and telehealth adoption. For example, technological literacy, personal attitudes toward health, and availability of support for using digital tools may also play an important role. Third, the mediation model assumes a directional relationship based on theoretical frameworks and prior literature. This study is correlational in nature, and causal claims cannot be made. The findings should be interpreted as associations rather than confirmed causal pathways, and future research using longitudinal or experimental designs is recommended to validate the directionality of these relationships. Fourth, given that the survey was distributed via mail with an optional web-based response, participation may have been lower among those with limited access to or comfort with technology, introducing potential response bias. Fifth, the study focused on the aging US population, so the generalizability of the results may be limited. Differences in culture, economics, and health care systems may influence the adoption of telehealth in other regions. For instance, the US health care system is largely privatized and insurance-dependent, with varying levels of access to services based on coverage and cost. This structure can shape how older adults engage with both telehealth and wearable technologies. In contrast, countries with universal health care systems, centralized digital health platforms, or stronger community-based care models may exhibit different drivers of technology use among older adults. It is worth noting that North America has one of the highest adoption rates of wearable devices globally. According to Statista, by the end of 2022, North America had 439 million connected wearable devices, the highest of any region. Projections also show continued growth, with over 90 million US users expected in 2025 across smart bands, smartwatches, and smart scales [53]. This widespread adoption indicates that older adults in the US may already be more familiar with wearable devices, potentially increasing their openness to integrating telehealth solutions as well. Therefore, while the findings provide valuable insights into the American aging population, they may not be directly applicable to populations outside the United States without consideration of these structural and contextual differences.

Future Direction

Future studies should explore long-term patterns of telehealth adoption and address persistent barriers, particularly in low-income and rural communities. While our study sheds light on structural and demographic influences, it does not directly capture users' perceived benefits of telehealth. To complement these findings, future research could incorporate validated instruments—such as the Telehealth Usability Questionnaire or surveys based on the Technology Acceptance Model—to assess perceived usefulness, satisfaction, and ease of use among older adults. These tools can help inform more user-centered and effective strategies for promoting telehealth adoption.

Conclusions

This paper focuses on the influence of wearable usage and the mediating factors of socioeconomic status and health conditions on telehealth adoption among the aging population. The findings indicate that while wearable device use itself may lead to an increase in telehealth adoption, its impact is significantly influenced by factors such as education, income, and health conditions. This trend is consistent beyond the aging population.

Higher levels of education and income were positively associated with telehealth adoption, reflecting greater access and readiness to engage with digital health tools among socioeconomically advantaged individuals. Conversely, better overall health was negatively associated with telehealth adoption, suggesting that healthy older adults may not realize sufficient value in telemedicine services to change their traditional health care engagement habits. This finding suggests that targeted educational workshops may be needed to emphasize the benefits of telehealth not only for immediate care needs but also for preventive health measures.

Overall, the findings provide evidence that telehealth adoption in older adults is shaped by a complex interplay of wearable device use, socioeconomic characteristics, and health status. These insights contribute to a deeper understanding of digital health behaviors in aging populations and align with the study's objective to investigate key influences on telehealth engagement in this demographic.

Data Availability

The datasets generated or analyzed during this study are available in the Health Information National Trends Survey (HINTS) repository [4]. The HINTS dataset is a public dataset that supports the findings of this study, which can be found on the website [54].

Abstract

Background: Violence against doctors attracts the public's attention both online and in the real world. Understanding how public sentiment evolves during such crises is essential for developing strategies to manage emotions and rebuild trust.

Objective: This study aims to quantify the difference in public sentiment based on the public opinion life cycle theory and describe how public sentiment evolved during a high-profile crisis involving violence against doctors in China.

Methods: This study used the term frequency-inverse document frequency (TF-IDF) algorithm to extract key terms and create keyword clouds from textual comments. The latent Dirichlet allocation (LDA) topic model was used to analyze the thematic trends and shifts within public sentiment. The integrated Chinese Sentiment Lexicon was used to analyze sentiment trajectories in the collected data.

Results: A total of 12,775 valid comments were collected on Sina Weibo about public opinion related to a doctor-patient conflict. Thematic and sentiment analyses showed that the public's sentiments were highly negative during the outbreak period (disgust: 10,201/30,433, 33.52%; anger: 6792/30,433, 22.32%) then smoothly changed to positive and negative during the spread period (sorrow: 2952/8569, 34.45%; joy: 2782/8569, 32.47%) and tended to be rational and peaceful during the decline period (joy: 4757/14,543, 32.71%; sorrow: 4070/14,543, 27.99%). However, no matter how emotions changed, each period's leading tone contained many negative sentiments.

Conclusions: This study simultaneously examined the dynamics of theme change and sentiment evolution in crises involving violence against doctors. It discovered that public sentiment evolved alongside thematic changes, with the dominant negative tone from the initial stage persisting throughout. This finding, distinguished from prior research, underscores the lasting influence of early public sentiment. The results offer valuable insights for medical institutions and authorities, suggesting the need for tailored risk communication strategies responsive to the evolving themes and sentiments at different stages of a crisis.

Introduction

The rising incidence of doctor-patient conflicts has become a significant concern globally. The Global Health Workforce Statistics database of the World Health Organization (WHO) highlights an increasing trend in medical disputes driven by inequitable distribution of medical resources and heightened pressures on health care systems [1]. The WHO's "Global Strategy on Human Resources for Health: Workforce 2030" emphasizes the importance of equitable access to health care

XSL•FO
RenderX

workers and robust health systems to address and prevent doctor-patient disputes [2].

Doctor-patient conflicts, broadly defined as disputes or tensions between medical professionals and patients (or their families), arise from dissatisfaction with medical outcomes, communication breakdowns, or systemic health care challenges. These conflicts vary in intensity, ranging from verbal disputes to severe incidents of physical harm. Violence against doctors represents the most extreme form of these conflicts, involving verbal abuse, threats, or physical assaults that jeopardize the safety and well-being of health care providers while eroding trust in the medical system [3].

In China, doctor-patient conflicts have been shaped by unique cultural, social, and structural factors [4]. Surveys conducted by the Chinese Medical Doctor Association reported that over 60% of physicians experience verbal or physical conflicts with patients during their careers [5], reflecting pervasive tension in medical interactions. These conflicts are often exacerbated by high patient expectations and increased access to medical information, which amplify scrutiny of health care practices. Structural challenges in the Chinese health care system also contribute significantly. According to the National Health Commission of China, urban hospitals handle over 3 billion outpatient visits annually, resulting in overcrowded facilities and excessive workloads for medical staff [6]. These systemic pressures often lead to long waiting times and dissatisfaction, which can escalate into disputes. Given the critical nature of these issues, there is a pressing need for systematic research on doctor-patient conflicts. Analyzing specific incidents of such conflicts can provide valuable insights into their social, psychological, and institutional determinants. Effective research and targeted interventions can enhance communication, improve patient satisfaction, and ensure patients' and medical professionals' safety and well-being, ultimately contributing to a more efficient and humane health care system.

In health communication, understanding the different developmental stages of events is crucial for designing and implementing effective public relations strategies [7,8]. Analyzing health events from a temporal dimension can reveal the patterns of changes in public sentiment and attention throughout various stages, including incubation, outbreak, spread, and resolution. Furthermore, integrating temporal analysis with topic and sentiment dimensions offers a more comprehensive understanding of the effectiveness of health information dissemination [9].

In medical public opinion research, theme analysis is equally crucial as segmenting the development stages of public sentiment. It is a widely used method in academia [10,11]. Theme analysis involves profound interpretation of textual data to reveal underlying meanings and critical issues that capture public interest, thus helping researchers accurately identify the focal points of public attention. Additionally, through systematic data processing, theme analysis provides a dynamic view of changes in public opinion, aiding researchers with understanding the fundamental shifts in public responses to health information.

Although theme analysis can reveal topics of public interest, more is needed to comprehensively understand the complexity of public attitudes. Consequently, in recent years, the academic community has emphasized sentiment analysis to explore the public's deep emotional tendencies and responses to public opinion [12-14]. Sentiment analysis methods include deep learning, machine learning, and lexicon-based analysis. The lexicon-based approach has unique advantages when dealing with structured and unstructured text data. Compared with deep learning and machine learning methods, lexicon-based analysis relies on a predefined set of sentiment words, providing more intuitive and interpretable results [15]. When applied to sentiment analysis in specific domains, such as doctor-patient conflicts, this method can effectively capture the emotional nuances in professional terminology and industry-specific language, thereby ensuring the accuracy and relevance of the analysis [16,17].

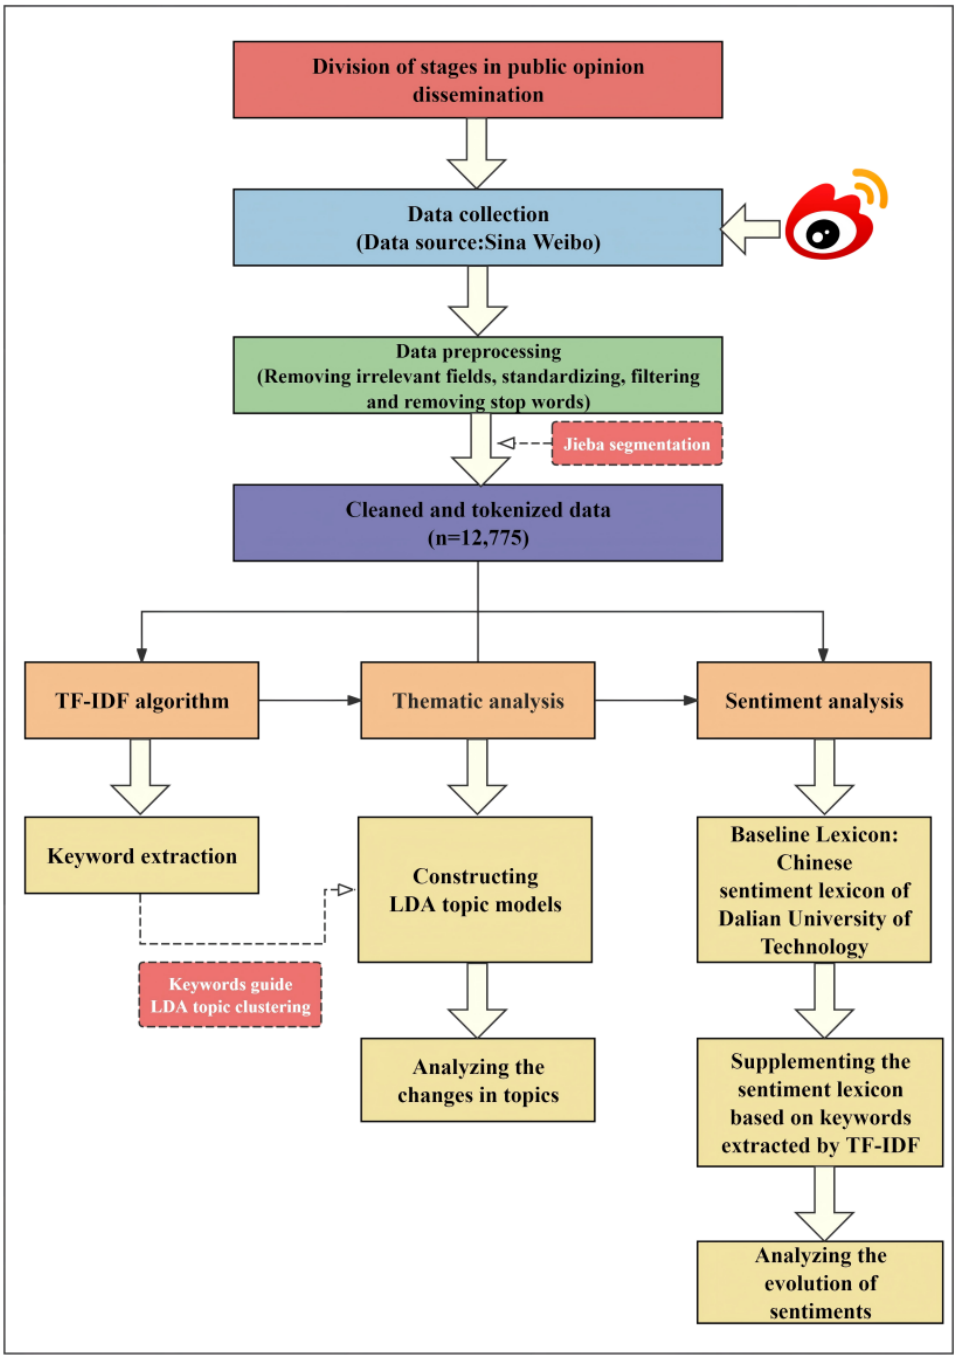
The occurrence of doctor-patient conflicts might be associated with the unequal distribution of medical resources [18], patient expectations and satisfaction [19], and communication skills between doctors and patients [20]. In 2021, an assault incident at Beijing Chaoyang Hospital garnered prolonged and extensive societal attention. During the incidents, Dr. Tao Yong, an ophthalmologist, sustained severe injuries to his head and arms, which put his life in jeopardy and subsequently impaired his ability to conduct surgeries postrecovery. The public response to this incident was significantly more intense than other medical disputes during the same period, indicating its profound impact on public sentiment and medical community relations.

This study, based on the theoretical perspective of the online public opinion life cycle, used the latent Dirichlet allocation (LDA) topic model and sentiment lexicon from Dalian University of Technology to conduct topic and sentiment analysis on the "Beijing Chaoyang Hospital assault incident," a significant doctor-patient conflict incident in China. The aim was to fill the research gap in medical public opinion and assist medical institutions and government departments to better understand the direction of public opinion dissemination and emotional contagion pathways in related events. By developing targeted content publishing and sentiment guidance strategies in response to doctor-patient conflict incidents, the study sought to improve communication effectiveness and ensure risk management and response efficiency.

Methods

Methodological Framework

This study divided opinion stages based on the life cycle of public opinion, which is often applied to the survey of public sentiment events. Life cycle theory, as a broadly adopted theoretical perspective, provides scholars with a structured framework to analyze the stages of change and development in events. Life cycle theory provides a systematic approach to dividing the public opinion cycle into stages, ensuring a theoretically grounded methodology for data segmentation and thematic analysis [21]. The life cycle theory, proposed by Steven Fink [22], posited that crises evolve through 4 phases: incubation, outbreak, spread, and resolution. Similarly, the life cycle of online public sentiment begins with initial attention, escalates with event progression, and declines after saturation,



XSL•FO
RenderX

mirroring societal public sentiment development [23-26]. This study followed this theoretical approach to segment public opinion into the outbreak, spread, and decline phases, aligning with previous applications in public discourse analysis [27,28].

Data were collected from Sina Weibo, the most widely used social media platform in China, akin to X (previously known as Twitter). According to the China Internet Network Information Center 2022 report, Sina Weibo had over 582 million monthly active users [29], making it a primary platform for public discourse and sentiment expression in China. The platform has been widely used in studies of Chinese public opinion, serving as a critical data source for analyzing sentiment and social behavior [30].

We collected relevant comment data from Sina Weibo according to the public sentiment development cycle. After cleaning and segmenting the data, the term frequency-inverse document frequency (TF-IDF) algorithm was used to extract keywords, and the LDA topic model was used to analyze the focal points across different stages. Finally, a sentiment lexicon was constructed using the Chinese Sentiment Lexicon of the Dalian University of Technology (DUTIR), and sentiment analysis was conducted based on this lexicon. Figure 1 illustrates the methodological framework.

Figure 1. The methodological framework of the proposed research. LDA: latent Dirichlet allocation; TF-IDF: term frequency-inverse document frequency.

RenderX

Public Sentiment Dissemination Stage Division

This study analyzed the trend of public opinion on the website Zhiwei Data. The trends were divided into 3 development periods, as illustrated in Figure 2. Zhiwei Data is a platform that monitors and analyzes China's internet big data. The platform uses social media data from across the internet to depict the development trends of events, communication effects, and trends in social communication.

Figure 2. Public opinion life cycle division of the "Beijing Chaoyang Hospital assault incident".

Data Collection

The research data were sourced from Sina Weibo, China's largest social media platform mirroring X's functionality and reach. It boasts a broad user base and spans various topics, providing a valuable snapshot of public discourse and sentiment. This study, based on the development of public opinion and the 3 life cycles of public opinion, selected 11 hashtags generated during the public opinion period of the "Beijing Chaoyang Hospital assault incident" in chronological order, with the "#The ophthalmologist at Chaoyang Hospital was hacked on 20 January 2020" as the starting point and the "#Dr. Tao Yong resumed clinic visits on 13 May" as the termination point to disseminate public opinion.

To collect comments related to these hashtags, the Python library Scrapy was used. Data collection occurred over a 4-week period, ensuring the capture of both initial reactions and ongoing public discourse. A total of 12,775 valid comments were collected after cleaning and filtering.

Data Preprocessing

Data preprocessing is a crucial step to ensure the consistency, accuracy, and relevance of the data used for sentiment analysis. The following subsections describe the key steps involved in preparing the data for analysis.

Data Cleaning

This stage involved removing invalid fields, standardizing data formats, and filtering out irrelevant content.

To remove duplicates, we identified and removed duplicate entries based on text, time stamps, and user IDs. This step reduced the data set by approximately 1200 comments.

To filter irrelevant content, we eliminated promotional, spam, or off-topic comments through keyword-based filtering and manual review. Approximately 500 comments were removed.

To eliminate invalid fields, we excluded records with incomplete or corrupted data fields, removing 500 comments.

After cleaning, the data set was reduced from 15,000 comments to 12,800 comments for further processing.

Stop Word Filtering

Stop words were identified and removed based on a predefined list derived from linguistic resources. These typically include high-frequency function words such as prepositions, conjunctions, and pronouns that do not contribute to the semantic content of the text. This process is consistent with best practices in sentiment analysis [27]. The stop word list was further refined by reviewing a sample of the data set to identify any frequently occurring terms that, although noninformative in general contexts, might carry domain-specific relevance (eg, medical terms) and should thus be retained. As a result, irrelevant terms such as "the," "and," and "of" were removed, while domain-relevant but functionally noninformative terms (eg, "patient," "doctor") were retained, following similar practices in health care sentiment analysis [31-33].

Lexicon Refinement

The word segmentation process was carried out using the Jieba tool, which uses a domain-specific lexicon tailored to the study's needs. This lexicon was iteratively refined based on the segmentation results. Initially populated with general terms, the lexicon was updated by adding domain-specific terminology, particularly medical and health care–related terms, to enhance segmentation accuracy. For example, terms such as "doctor-patient relationship" and "medical malpractice" were

XSL•FO
RenderX

incorporated to ensure that multiword expressions were correctly recognized. The lexicon was reviewed and updated after each iteration, ensuring it aligned with the research requirements and was capable of handling both general and specialized terms essential for analyzing public sentiment regarding doctor-patient conflicts [34].

Text Segmentation

Text segmentation was conducted using the Jieba tool, which splits text into individual words for further analysis. The lexicon refined in the previous step ensured that domain-specific terms were correctly segmented. The segmentation results were evaluated and adjusted manually to guarantee that critical multiword expressions were preserved and that the segmentation was contextually appropriate for the health care domain. This process was crucial in ensuring that the segmented words accurately reflected the topics discussed in the comments, particularly in the context of doctor-patient conflicts.

Final Data Volume

After preprocessing—including cleaning, stop word removal, lexicon refinement, and segmentation—the final data set comprised 12,775 valid and tokenized comments, as indicated in Figure 1.

TF-IDF

TF-IDF is a commonly used algorithm in text mining and information retrieval to measure the significance of a word in a text. The algorithm combines 2 crucial factors: term frequency and inverse document frequency. It calculates the frequency of each word in the text and its inverse document frequency in the corpus. It then assigns a weight to each word to reflect its importance in the collection of texts [35].

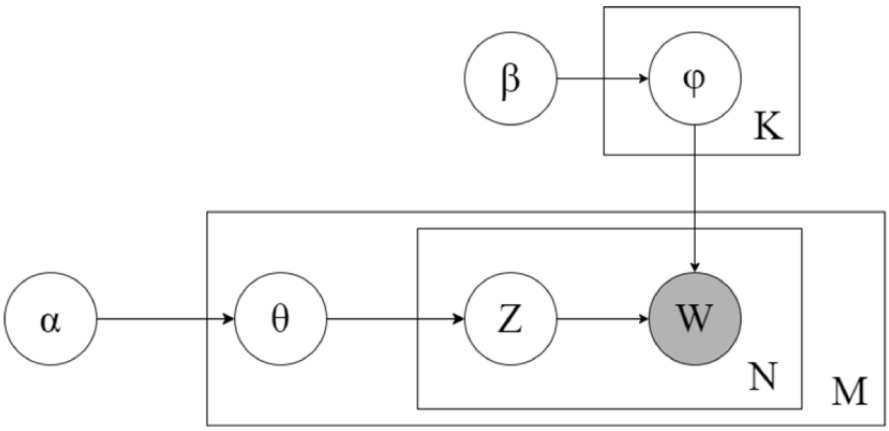
TF-IDF has been widely applied in various domains, including health care, where it is used to identify key terms in patient feedback, online health forums, and social media platforms. For example, research has demonstrated effectiveness in uncovering critical discussion themes in public health and medical services. Studies have used TF-IDF to analyze patient complaints and feedback to identify key areas for service improvement [36] and to extract critical health-related terms from social media during health crises such as the COVID-19 pandemic [37]. However, its application in analyzing the doctor-patient relationship remains limited, representing a gap this study aimed to address. In this study, TF-IDF was used to extract keywords from the Sina Weibo data set, ensuring the identification of terms most relevant to public discourse on doctor-patient conflicts.

TF represents the frequency of a word in the text. It is calculated as follows:

IDF represents the inverse document frequency of a word in the entire corpus. It is calculated as follows:

The TF-IDF weights are ultimately formed by the product of TF and IDF:

$$TF–IDF(t,d,D)=TF(t,d) \times IDF(t,D)$$



LDA Topic Model

LDA is a probabilistic graphical model to identify hidden thematic structures within text collections. The model was proposed by Blei et al [38] in 2003 and has become a classic method for topic modeling in text mining. The LDA model extracts potential topics from documents or corpora using a bag-of-words approach. It constructs a model that includes a “document-topic distribution” and “topic-word distribution” without considering the order in which words appear [39]. The document comprises one or more topics, with each word generated by one of the topics [40]. Therefore, LDA models can aid in text-based analysis processes for online opinion topic events in social media, such as identifying latent topics and clustering users. In the field of health communication, the LDA model has been widely applied to identify themes related to sudden public health events, such as COVID-19 [41,42].

The generation process of the LDA topic model is shown in Figure 3: (1) generate the hyperparameter α of the topic distribution and generate the topic distribution θ for each document; (2) for each document, generate the topic Z from its topic distribution θ; (3) for each topic K, generate the word distribution ϕ of the topic K from the hyperparameter β of the word distribution; (4) for the Nth word in each document, generate it from the word distribution of its corresponding topic Z; (5) W represents the words in the corpus, which are generated based on their respective topic-word distributions (ϕ); (6) N is the number of words in a document, representing the scope of word generation within each document; and (7) M is the total number of documents in the data set, defining the corpus-level scope of the generative process.

XSL•FO
RenderX

Figure 3. The generation process of the latent Dirichlet allocation (LDA) topic model.

Sentiment Lexicon

Sentiment analysis and topic modeling have been widely applied as effective tools to analyze public sentiment and identify thematic patterns in large-scale social media data sets [43]. It is first necessary to construct a lexicon of sentiments to dynamically analyze public opinion sentiments and themes in doctor-patient conflict cases. This study used the DUTIR, which was developed by the Information Retrieval Research Laboratory based on the Chinese language context, as the basic sentiment lexicon. It is used for sentiment analysis and sentiment calculation to help analyze the sentiment tendency in texts and is widely used in the field of Chinese text research as a whole. This lexicon has been used in various research studies, demonstrating its reliability and applicability in different sentiment analysis scenarios. In health care, sentiment lexicons have been extensively used to assess patient satisfaction [44], analyze public sentiment during health crises [45], and evaluate feedback on health care services [46]. Research has shown that DUTIR effectively captures nuanced emotional expressions in Chinese texts, such as in sentiment-aware word embedding for emotion classification. Additionally, DUTIR has proven valuable in analyzing sentiment trends in online media, including bullet screen comments on health care topics. Most existing sentiment analysis research in health care classified collected comment texts into binary categories, simply dividing public sentiment into positive and negative [47-49], which failed to vividly capture the diversity of public emotions. The sentiment lexicon used in this study introduced neutral, complex, and mixed emotional categories, allowing for a more refined capture of the comment texts and reflecting the multidimensional characteristics of emotions. The lexicon contains 27,466 sentiment words, and the sentiment categories are divided into 7 types: joy, happiness, anger, disgust, fear, sorrow, and surprise. The selection of these 7 categories is primarily rooted in the predefined structure of DUTIR, which has been validated in previous studies and widely applied in public discourse and health care research. Research has shown that DUTIR's categorization effectively captures emotional nuances, making it particularly suited for complex sentiment analysis tasks. Its application in health care sentiment analysis and public discourse has been widely documented [31,50], underscoring its relevance and reliability.

Additionally, the chosen classifications align with established psychological theories, such as the model of universal emotions by Ekman and Friesen [51] and wheel of emotions by Plutchik [52]. These frameworks identify emotions such as joy, anger, and fear as universal and fundamental, providing a robust theoretical basis for the classification system. This dual grounding in theoretical models and the practical structure of DUTIR ensures that the framework is both comprehensive and contextually relevant.

By leveraging the predefined structure of DUTIR and its theoretical underpinnings, this study effectively captured the multidimensional emotional dynamics in public sentiment surrounding doctor-patient conflicts, offering insights beyond binary sentiment classifications.

Ethical Considerations

This study involved the analysis of publicly available, anonymized data from Sina Weibo. Since no personally identifiable information was collected, stored, or analyzed, and no direct interaction with individuals occurred, the study was exempt from Institutional Review Board (IRB) approval in accordance with Sichuan University's Research Ethics Review Policy.

Informed consent was not required, as this study relied exclusively on publicly available user-generated content. Additionally, the study adhered to the terms of service and privacy policies of the Sina Weibo platform.

Results

TF-IDF Keyword Extraction

The study conducted TF-IDF keyword extraction to identify the primary words associated with the "Beijing Chaoyang Hospital assault incident" at different public opinion stages. During the outbreak period, the most frequently expressed words were "injury" (TF-IDF: 0.030589), "doctor" (TF-IDF: 0.028905), and "harm" (TF-IDF: 0.028270). In the spread period, "gentle" (TF-IDF: 0.05255), "blessings" (TF-IDF: 0.05179), and "kindness" (TF-IDF: 0.05060) surfaced frequently. By the decline period, the words "recovery" (TF-IDF: 0.050599), "injury" (TF-IDF: 0.047823), and "gentle" (TF-IDF: 0.047587) were most prevalent.

XSL•FO
RenderX

Table 1 summarizes the high-frequency keywords and their corresponding frequencies and TF-IDF values for the 3 periods, illustrating the changes in public focal points and high-frequency expressions at each stage.

In the outbreak period, the words were dominated by emotionally charged terms like “harm to doctors,” “injury,” and “angry to death,” reflecting public shock and outrage. During the spread period, supportive and empathetic words such as “blessings,” “gentle,” and “recovery” emerged, signifying a shift toward collective concern and healing. By the decline period, the focus remained on resolution with terms like “recovery,” “criminal,” and “hatred,” suggesting ongoing calls for justice alongside a desire for closure.

Table 1. Term frequency-inverse document frequency (TF-IDF) keyword extraction for 3 stages of public opinion.

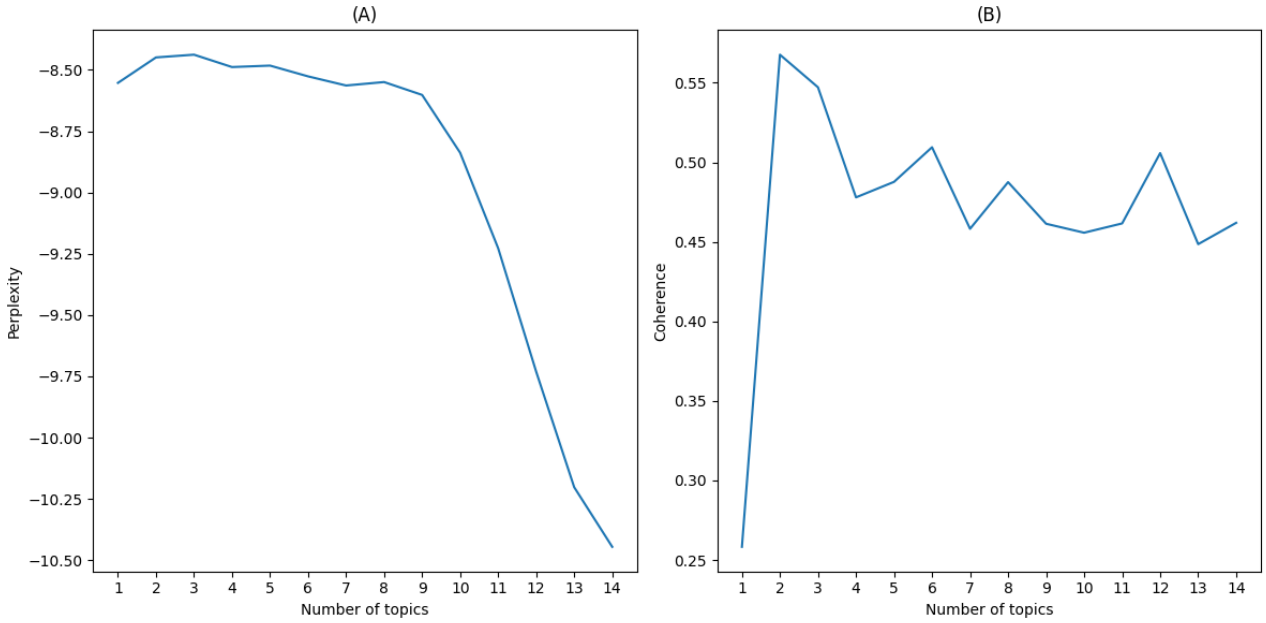
LDA Topic Model



Using the Gensim library in Python for LDA topic model training, the study focused on perplexity and coherence to gauge model quality and thematic clarity. Perplexity was used to measure the model’s ability to predict the test data, with lower perplexity indicating better model performance [38]. Coherence was used to assess the interpretability of the topics, with higher

XSL•FO
RenderX

coherence scores reflecting clearer and more meaningful issues [53]. Evaluating these metrics under different settings revealed the optimal theme count. Figures 4-6 illustrate these metrics across public opinion dynamics stages—outbreak, spread, and decline—aiding with precise determination of topic numbers in sync with data volume for effective topic identification and extraction.

To enhance the coherence and interpretability of the LDA results, TF-IDF–extracted keywords were used as seed words to guide topic analysis [54]. High-weighted TF-IDF terms ensured that LDA-generated topics were aligned with public discourse at each stage. For instance, during the outbreak period, keywords like “injury,” “doctor,” and “harm” shaped topics centered on medical accountability and incident responses. In the spread phase, terms such as “gentle” and “blessings” informed themes of empathy and community healing, while “recovery” and “criminal” in the decline period contributed to topics related to resolution and justice. This integration ensured that the LDA analysis was both data-driven and contextually grounded, aligning topic clusters with the most critical public concerns.

Figure 4. (A) Perplexity and (B) coherence scores of latent Dirichlet allocation (LDA) topics during the outbreak period.

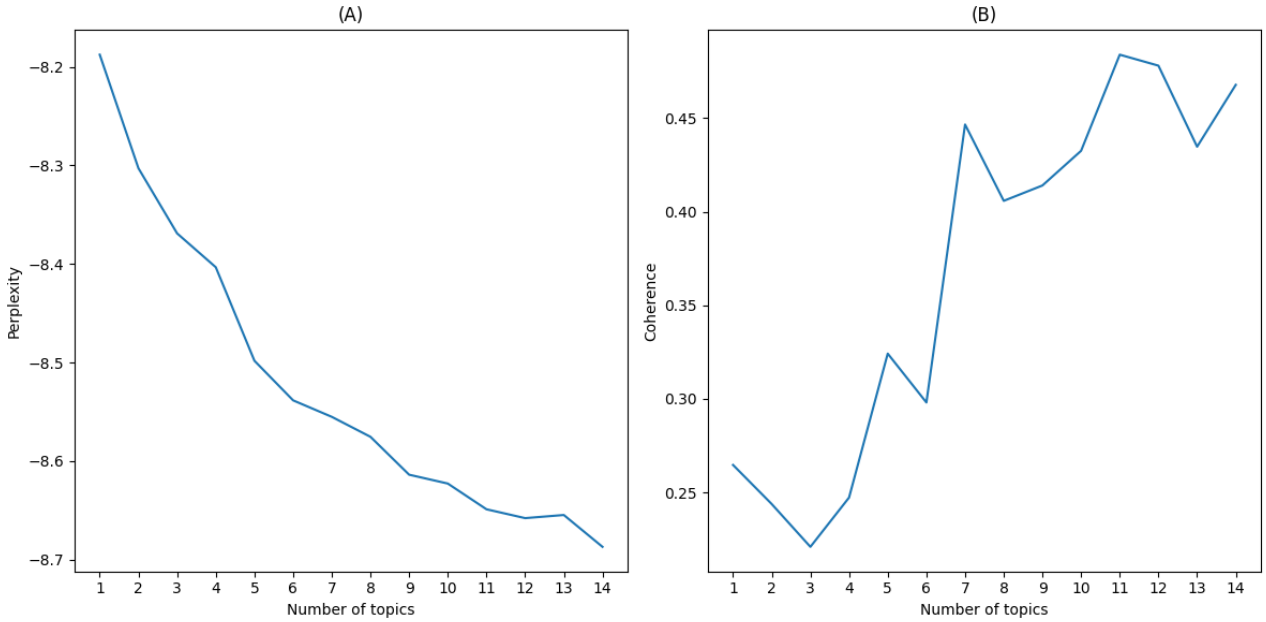
As illustrated in Figure 4, the perplexity score steadily declined with an increasing number of topics, while the coherence score peaked at 11 topics. This peak indicated that 11 topics provided the most meaningful representation of initial public reactions, capturing themes such as outrage, shock, and immediate demands for justice.

During the spread phase, as depicted in Figure 5, the coherence score reached its maximum value at 12 topics, while the perplexity curve exhibited diminishing returns beyond this point. This selection reflected the complexity of public discussions during this phase, including sympathy for medical professionals, criticism of systemic health care issues, and debates on policy implications.

Figure 6 shows that coherence peaked at 13 topics during the decline phase, while the perplexity score stabilized. This topic number aligned with the reflective and solution-oriented nature of public discourse in this period, encompassing themes such as health care reforms, institutional accountability, and the long-term impacts of the incident.

XSL•FO
RenderX

Figure 5. (A) Perplexity and (B) coherence scores of latent Dirichlet allocation (LDA) topics during the spread period.



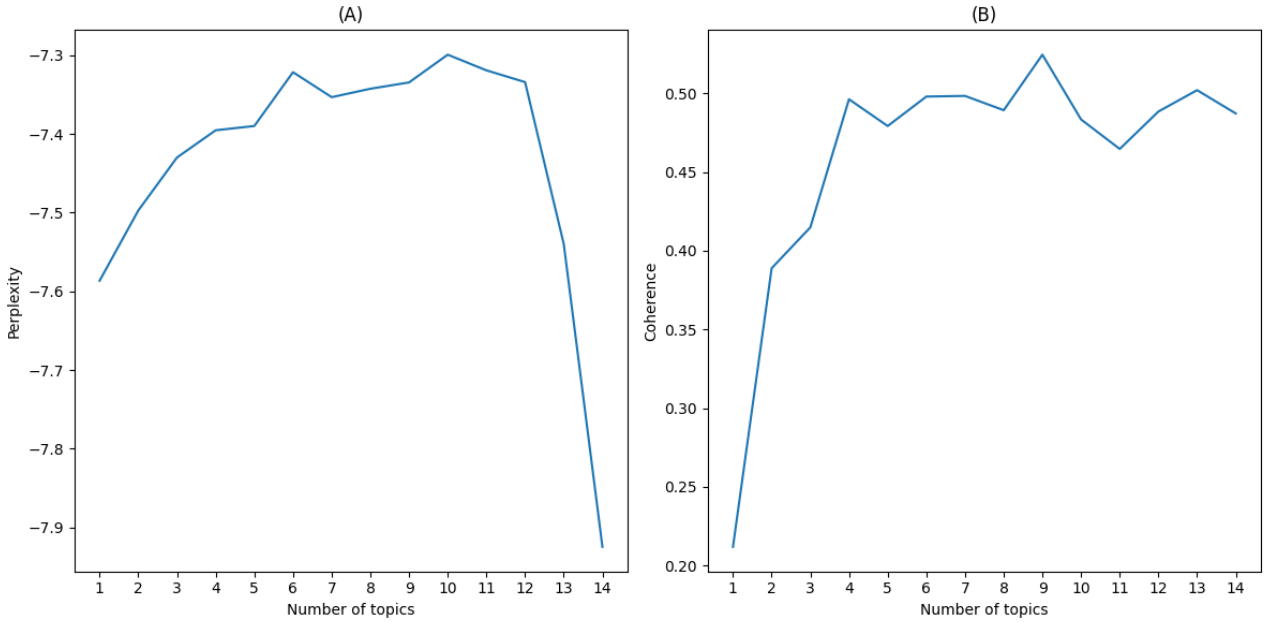


Figure 6. (A) Perplexity and (B) coherence scores of latent Dirichlet allocation (LDA) topics during the decline period.

After determining the optimal number of topics, we used the pyLDAvis library in Python to create an interactive visualization of the topic model. The study then selected 10 higher-weight keywords to annotate and analyze the topics. The results showed that, during the outbreak period, topics centered on immediate responses to medical violence (Topic 1), victim empathy (Topic 2), societal disillusionment (Topic 3), aggressor accountability (Topic 4), and recovery aspirations (Topic 5). As the incident progressed, the public focus shifted toward appreciating the victim's character (Topic 1), supporting their recovery (Topic 2), expressing concerns over the career impact (Topic 3), condemning the aggression (Topic 4), and expressing relief over the victim's recovery (Topic 5). In the decline phase, discussions centered on the patient's condition (Topic 1), the victim's virtues (Topic 2), well wishes for recovery (Topic 3), strategies for resolving medical disputes (Topic 4), and advocacy for stringent legal measures (Topic 5). This comprehensive thematic analysis highlighted the dynamic evolution of public sentiment and concerns throughout the incident's life cycle. The complete LDA topic extraction is presented in Table 2.

XSL•FO
RenderX

Table 2. Latent Dirichlet allocation (LDA) topic identifiers for 3 periods of public opinion.

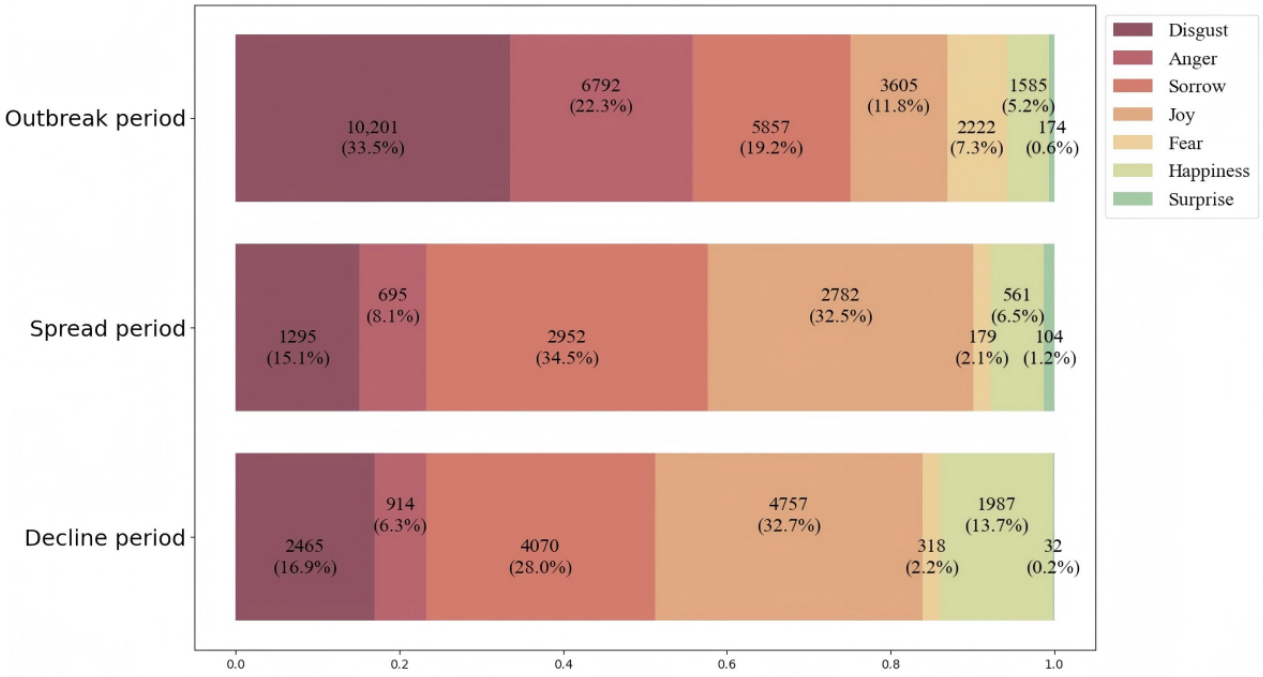
Life cycle period topics	Terms
Outbreak period	
Topic 1: Responses to Medical Violence	Enraged; security check; medical injury; medical disturbance; busy; injury; society; life; slash; harm
Topic 2: Victim Empathy	Effort; society; excellent; recovery; medical student; save lives; cry; cultivate; good person; contribute
Topic 3: Societal Disillusionment	China; study medicine; can't save; Lu Xun; disheartened; statement; epidemic; guard; darkness; difficult
Topic 4: Aggressor Accountability	Protection; death penalty; severe punishment; medical; country; murderer; law; medical disturbance; aggressor; expose
Topic 5: Recovery Aspirations	Pray; safety; heartache; sad; excellent; speedy recovery; light; medical disturbance; injury; destroy
Spread period	
Topic 1: Victim Character Appreciation	Sad; excellent; gentle; angel; harm; kind; heartache; self; death penalty; good person
Topic 2: Recovery Support	Cry; pay tribute; pray; save; care; indispensable; cheer up; heartache; speedy recovery; light
Topic 3: Career Impact Concerns	Heartache; pity; excellent; kind; top; recovery; unable; research; scientific research; cultivate
Topic 4: Condemnation of Aggression	Harm; furious; harsh punishment; strict punishment for murderers; heartache; destroy; medical disturbance; undeserving; sad; angry
Topic 5: Relief Over Victim's Awakening	Bless; miracle; safety; wake up; good news; take care; thankfully; hope; God; fortunately
Decline period	
Topic 1: Patient Condition Focus	Body; treatment; recovery; nerve; rupture; blood vessel; muscle; Gate of Hell; mental state; perception
Topic 2: Victim Virtue Highlight	Gentle; forgive; kind; benevolence; speedy recovery; strong; inner; moved; beautiful; blessings
Topic 3: Well-Wishes for the Victim	Wish; safety; good person; speedy recovery; gentle; heartache; angel; safe and sound; healthy; memory
Topic 4: Strategies for Medical Dispute Resolution	Doctor-patient; protection; doctor-patient relationship; policy; medical; respect; country; inspection; medical disturbance; security check
Topic 5: Advocacy for Stringent Legal Measures	Recovery; apology; harsh punishment for murderers; law; harm; cost; doctor-patient conflict; death penalty; medical injury; injure

Sentiment Analysis

Construction of Sentiment Lexicon

Owing to changes in language and the online environment, the connotations of certain words and sentences shifted, and new vocabulary emerged. Therefore, this study expanded the existing DUTIR by manually annotating the emotional characteristics of new words according to the ontology format of the existing database. This was done to cater to the demand for sentiment analysis in specific events or generic scenarios and to ensure accurate results. Multiple annotators working together to extract vocabulary is a recognized research method in sentiment analysis, as it helps improve reliability and reduce bias in the annotation process [55,56]. The expansion process involved several steps to maintain consistency and reliability. First, new words were identified based on their frequency and contextual relevance to the doctor-patient conflict data set. The emotional characteristics of these words were then annotated manually by multiple scholars. Each scholar independently assigned emotional labels to the words, following the ontology structure of the existing lexicon.

Discrepancies between annotations were resolved through discussion and consensus-building among the scholars. Finally, the updated lexicon was validated against a subset of the data to ensure alignment with the existing lexicon's structure and objectives. The study compared the keywords extracted by the TF-IDF algorithm with the sentiment vocabulary list of the Dalian University of Technology. We selected the keywords not included in the sentiment vocabulary ontology database and manually added them after labeling them with emotional features. This process formed an expanded sentiment lexicon.



Sentimental Trend

The sentiment analysis results for the 3 periods are shown in Figure 7, reflecting significant changes in public sentiment. During the Outbreak period, of the 30,436 comments, 10,201

XSL•FO
RenderX

(33.52%) expressed disgust, followed by 6792 (22.32%) showing anger and 5857 (19.24%) reflecting sorrow. In the Spread period, of the 8568 comments, 2952 (34.45%) expressed sorrow, and 2782 (32.47%) indicated joy. In the Decline period, of the 14,543 comments, 4757 (32.71%) exhibited joy, while 4070 (27.99%) conveyed sorrow and 2465 (16.95%) reflected disgust. Based on these results, the study mapped the evolution of sentiment to visualize changes in public sentiment across the 3 periods.

Figure 7. Sentiment trends in the 3 periods.

Discussion

Principal Findings

In this study, data from Sina Weibo were analyzed to investigate public sentiment during the Beijing Chaoyang Hospital assault incident using 3 analytical approaches. First, TF-IDF keyword analysis identified key terms such as “injury,” “doctor,” and “recovery,” illustrating how the initial public focus on the specifics of the incident gradually expanded to include broader health care issues. Second, thematic analysis via the LDA topic model revealed that public attention shifted from immediate responses to long-term implications, reflecting an evolution from shock to systemic consideration. Last, sentiment analysis using a Chinese sentiment lexicon indicated that negative sentiment was sustained despite progressing toward recovery-focused dialogue. Collectively, these findings revealed that negative sentiment persisted even as public dialogue progressed toward recovery-focused themes, underscoring the need for communication strategies responsive to immediate and evolving public sentiments in health-related crises.

TF-IDF Keyword Analysis

The keyword analysis through TF-IDF conducted during the Beijing Chaoyang Hospital assault incident revealed a nuanced evolution in public sentiment, corroborating findings from previous research on crisis communication and public health emergencies. During the outbreak period, keywords such as “injury,” “doctor,” and “harm” dominated the public discourse. These terms echoed sentiments typically observed in immediate responses to medical crises, aligning with studies that indicated initial public reactions were often driven by shock and a quest for immediate understanding of the incident [57,58]. As the situation progressed to the spread period, a noticeable shift occurred toward more empathetic and supportive terms such as “gentle,” “blessings,” and “kindness.” This transition from focusing on the incident’s negative aspects to fostering a healing-oriented dialogue was consistent with the “recovery phase” described in the Coombs Crisis Communication Model [59], where the public focus shifted toward rehabilitation and emotional support. By the decline period, the emphasis on “recovery” and “gentle” further confirmed the trend toward normalization and reconciliation. In this phase, the affected community began to heal and rebuild, as noted by Ogie et al [60].

Although the keyword analysis provided valuable insights into shifting public sentiment, it had limitations. Keywords alone could not fully capture the complexity of public emotions or the depth of thematic elements evolving during such incidents. Thus, this initial analysis laid the foundation for a more comprehensive exploration. The subsequent phase used thematic and sentiment analysis techniques to delve deeper into the underlying narratives and emotional contours of public

XSL•FO
RenderX

discourse, offering a more complete understanding of the incident's impact on public sentiment.

Thematic Analysis

Upon analyzing and summarizing the LDA topic model, it became evident that the theme evolved across all 3 phases of public opinion outbreak and spread. The decline period illustrated the theme's continuity and the distinctions between phases. This conclusion was consistent with previous public opinion research [61-63].

Initially, the public's response was characterized by a surge in negative sentiments, focusing on the incident's immediate impacts and demanding accountability. This intense reaction reflects the "shock phase" [59] in crisis communication theory, where the initial shock triggers a heightened emotional response from the public, demanding urgent and decisive actions. This phase often sees a spike in public engagement and outcry, evident from the prevalent themes of aggression and immediate accountability. As the crisis continued, public sentiment shifted toward a more nuanced and empathetic perspective, concentrating on the victim's personal and professional impacts. This transition aligns with the "deliberation phase" [59] described in situational crisis communication theory, where the public starts to process the incident more profoundly and show empathy toward the victims. The moderation in tone suggests a community moving toward a collective reflection, pondering the long-term effects on those directly affected and their implications on professional practices. In the later stages, the focus shifted toward legal measures and recovery, indicating a societal shift toward resolution and systemic reflection. This phase mirrors the "resolution phase" [59], where public discourse often turns to evaluating how the crisis was handled and the steps needed to prevent future occurrences. The decreased anger and increased discussions about recovery and legal implications suggest a maturing public opinion that seeks to address systemic issues and improve doctor-patient relationships for the future.

Sentiment Analysis

This study has highlighted the versatility and effectiveness of sentiment analysis for capturing multidimensional emotions and thematic evolution. Previous research demonstrated these methods as reliable tools for understanding public discourse and informing interventions in complex social systems [43]. Previous research had determined that public opinion on health-related topics was inconsistent and unstable. Fluctuations influenced by topic changes led to significant variations in the dominant sentiment at each stage of public opinion development [64-66]. This study, however, indicated that, in serious doctor-patient conflicts, negative sentiments from the initial stage often persisted despite potential positive developments, driven by the primacy effect—where early impressions resist change over time [67].

During the outbreak period, negative emotions like disgust and anger predominated, aligning with Le Bon's Theory of the Crowd [68], which attributed emotional contagion to impulsive group behavior. As the crisis matured into the spread period, the emotional landscape shifted significantly toward more nuanced emotions such as sorrow and joy. This transition was explained by the cognitive dissonance theory by Festinger [69], which explains attitude adjustments to reduce discomfort from conflicting information. However, in the decline phase, negative sentiments persisted longer than typical patterns observed in public health crises. The theory of affective intelligence [70] suggests that emotional responses could override cognitive assessments, mainly when initial emotions were intense and damaging. Such emotional endurance contradicted the general expectations derived from mood management theory [71], positing that individuals would seek to alter their mood toward more favorable outcomes, mainly as situations developed and new information became available.

The findings underscore the resilience of negative sentiments in severe doctor-patient conflicts, driven by the primacy effect and amplified by structural challenges. This persistence highlights the need for tailored communication strategies in health care settings, addressing the long-term impact of initial negative impressions and prioritizing transparent, empathetic engagement to shift public sentiment effectively.

Recent research has highlighted the importance of crisis communication in shaping public sentiment during health emergencies [72]. Clear messaging has been shown to reduce negative sentiments in the early stages, whereas delayed communication has exacerbated distrust and fear, prolonging negativity [73]. Furthermore, the cultural context plays a significant role, with collectivist societies experiencing more enduring negative sentiments due to heightened communal sharing of emotions [74]. These findings align with this study's observations.

Comparatively, sentiment trends in other countries revealed both similarities and differences. Globally, negative sentiment dominates during crisis outbreaks, but western countries often transition more quickly to themes of systemic reform and empathy [75,76]. In contrast, distrust and fear persisted longer in China, influenced by health care resource disparities and overcrowding [77]. These findings underscore the cultural and systemic factors shaping sentiment dynamics and highlight the importance of communication strategies tailored to local contexts.

Conclusion

Weibo, China's largest social media platform, provides a unique view of public sentiment through its rich emotional content. By analyzing these data, researchers can identify trends in public sentiment, aiding government and relevant departments with developing effective communication strategies for doctor-patient conflicts. The study found that public sentiment evolved through different phases of public opinion, showing predominantly negative emotions during the outbreak phase, balanced sentiments during the spread phase, and continued negative dominance in the decline phase. This finding differs from previous studies, highlighting the persistent impact of initial emotions throughout the public opinion life cycle.

To address this persistence, medical institutions should implement tailored communication strategies. Establishing dedicated crisis communication teams trained in empathetic

XSL•FO
RenderX

and transparent messaging can mitigate the long-term impact of negative sentiments. Timely information dissemination through clear protocols and community-based platforms can help reduce misinformation and foster public trust. Real-time sentiment monitoring systems can provide insights into public emotions as they evolve, guiding adaptive strategies to address emerging concerns effectively.

Furthermore, the methodologies used in this study, particularly the integration of sentiment lexicon analysis and LDA topic modeling, hold potential for broader adaptation across sociocultural contexts. Adapting the sentiment lexicon for other linguistic settings could enhance global sentiment analysis accuracy. Additionally, interdisciplinary applications of these findings—spanning health care management, psychology, and public health—could foster a deeper understanding of societal sentiments and their impact on health care practices. These insights can inform the development of targeted policies to improve communication strategies, train health care professionals in emotional intelligence, and enhance trust in health care systems, ultimately improving patient satisfaction and crisis management outcomes.

Future research could explore comparative studies across diverse health care systems and integrate multimodal data sources, such as images and videos, to provide a more comprehensive understanding of public sentiment dynamics.

Limitations

Although the study presented some innovative findings, it still has certain limitations. First, the data were obtained exclusively from Sina Weibo, which, although a leading social media platform in China, did not represent the full spectrum of social media users across different platforms like WeChat and Douyin.

This reliance on a single platform may have introduced platform-specific biases, as its user base and communication dynamics differ from those on other platforms, potentially affecting the representativeness of the findings.

Second, the study's reliance on textual data may have overlooked significant emotional and contextual information conveyed through images and videos, suggesting a need for multimodal data analysis. Furthermore, the sentiment analysis tools used might not have fully captured the nuances of sarcasm, irony, or regional dialects, leading to possible misinterpretations.

Future research can consider more diverse social media platforms and incorporate cross-cultural comparative studies on public sentiment in doctor-patient conflicts to understand the differences in public reaction patterns and emotional expressions across various cultural backgrounds. Incorporating multimodal data, such as visual and audio content, could enhance the richness and accuracy of sentiment analysis. Additionally, combining cross-platform data would allow researchers to compare public sentiment across different platforms and user demographics, providing a broader perspective.

Additionally, integrating social network analysis methods can provide a deeper analysis of the network structure and influential nodes of information dissemination, revealing opinion leaders and dissemination paths in doctor-patient conflict incidents. Longitudinal data collection and analysis would further enable the capture of temporal dynamics, offering insights into how sentiments evolve over time during such conflicts.

Acknowledgments

The authors would like to thank the National Natural Science Foundation of China for funding this work through the project titled "Implementation Science Research on Caries Risk Management for Children in Primary Health Care Institutions under the 'Medical-Dental' Integrated Model," under grant number 72374146.

Conflicts of Interest

None declared.

Abstract

Background: Hospital readmissions pose a significant burden on patients, health care providers, and systems, with an estimated annual cost of $17 billion. Timely follow-up within 7 days postdischarge is known to reduce readmissions but is often limited by access constraints. While transitions of care clinics have demonstrated benefits in reducing unplanned readmissions, physical space requirements can be logistically and financially challenging.

Objective: This study aimed to evaluate the effectiveness of a virtual transitions of care (VToC) clinic in reducing 30-day hospital readmissions and improving postdischarge care coordination.

Methods: University of California, San Diego Health implemented a hospitalist-led VToC clinic designed to support clinical management, medication reconciliation, primary care provider repatriation, and specialty care navigation. The study included 2314 patients seen in the VToC clinic between September 2021 and September 2024. Outcomes were compared to a benchmark group using regression analysis to assess the impact on 30-day readmission rates.

Results: The 30-day readmission rate for VToC patients was 14.9% (344/2314), significantly lower than the 20.1% (4659/23,129) observed in the benchmark group (P<.001). Regression analysis indicated that patients not participating in the VToC clinic had a higher likelihood of readmission (odds ratio=1.37; 95% CI=1.21-1.54; P<.001). The most substantial reduction in readmissions was observed among patients with moderate readmission risk (LACE+ score of 50-75).

Conclusions: VToC clinics are a feasible and effective strategy for enhancing postdischarge care, reducing hospital readmissions, and improving care coordination. This model supports the quadruple aim by promoting better health outcomes, improved patient experience, cost-efficiency, and care equity.

Introduction

Unexpected return to the hospital reflects systemic challenges in health care delivery and places a financial strain on the nation's health system [1]. Postdischarge follow-ups within 7 days is a well-established protective mechanism to reduce the risk of readmission and mitigate health care disparities but are limited by access challenges and physician shortages [2-5]. Transitions of care clinics have shown benefit in readmission reduction but may be cost prohibitive and logistically

XSL•FO
RenderX

challenging [4,5]. Virtual postdischarge clinics may achieve similar benefits with fewer costs and present an opportunity to enhance postdischarge access [6].

Methods

Overview

At the University of California, San Diego Health, we implemented a hospital medicine physician-led virtual transitions of care (VToC) clinic, focused on postdischarge clinical management, medication reconciliation, primary care provider (PCP) repatriation, and specialty care navigation, with the aim of reducing repeat hospitalization.

Based on internal pilot data showing a favorable readmission impact for patients with moderate risk of readmission, we created a criteria-based order to trigger referral for patients (aged 18 years and older) discharged from the hospital medicine service line. The discharging providers were automatically prompted at discharge to refer patients to the clinic if patients had a LACE+ index (a readmission risk prediction index based on length of stay, acuity of admission, comorbidities, and emergency department visit history) between 50 and 75 [7]. Patients with LACE+ scores outside this range could be referred at provider discretion. Patients were excluded from appointment scheduling if they were discharged to a care facility or hospice or had an existing PCP appointment within 7 days of discharge.

The virtual clinic was supported by 12 hospitalists, 2 medical assistants, 1 pharmacist and an on-demand interpreter service. Medical assistants contacted eligible patients to schedule web-based video visits. VToC visits were occasionally converted to telephone encounters when patients faced technical barriers, which occurred in fewer than 5% of cases and thus were not considered a distinct comparison group for analysis. Patients received phone call reminders 1 business day prior to scheduled appointments. Pharmacists conducted previsit medication reviews to identify fill history gaps, dosing inconsistencies, and potential drug-drug interactions. Note templates guided VToC providers in addressing medication management, social determinants of health, barriers to follow-up, and care coordination. A standardized electronic handoff was routed to the patient's PCP and relevant specialists summarizing the reason for hospitalization, follow-up needs, and timing recommendations. Additionally, post-VToC visit communication was sent to the discharging hospitalist to highlight potential care lapses and support quality improvement efforts.

Data were collected from the electronic health records using standard SQL queries. These included demographics (ages grouped as <45, 45-64, and ≥65 years; sex; and race and ethnicity); VToC status (yes or no); PCP (University of California San Diego or other); LACE+ score (<50, 50-75, or >75); and 30-day all-cause readmission. Patient characteristics were analyzed by VToC status (yes or no). A VToC status of "no" indicates patients who were discharged from the medicine service line to home and not seen in our clinic (because they did not meet eligibility criteria or could not be reached). Patients were excluded from analysis if they had missing demographic or clinical data. Readmission rates were analyzed for VToC status and by LACE+ score. Chi-square analysis was used to compare characteristics by VToC status with a $P<.05$ considered significant. Readmission rates (%) by VToC status stratified by LACE+ decile are reported. Error bars were calculated using 95% CIs. A multivariable logistic regression analysis was performed to assess independent associations with unplanned hospital readmission. Variables included in the model included age group, sex, race and ethnicity, PCP affiliation (UCSD versus non-UCSD), LACE+ score, and VToC enrollment. All analyses were conducted using the SPSS Statistics software suite (version 27.0; IBM Corporation).

Ethical Considerations

This study was conducted in an Institutional Review Board–exempt fashion in accordance with the ethical standards of the University of California San Diego Human Research Protection Program and the Office for Human Research Protections and adhered to the Helsinki Declaration of 1975, as revised in 2000.

Results

There were 25,970 patients identified for the study period of September 1, 2021, through September 17, 2024. A total of 527 (0.02%) patients had missing data and were excluded from the analysis. Of the 25,443 patients included in the study, 2314 (9.1%) were seen in VToC after discharge and 23,129 (90.9%) had standard of care follow-up. Table 1 shows the demographic comparisons of patients who were seen in VToC versus those who were not for the same time period.

[c]UCSD: University of California San Diego.

The overall 30-day readmission rate for patients seen in the VToC clinic was 14.9% (344/2314) compared to 20.1% (4659/23,129) in the benchmark group (Table 1; *P*<.001). In the regression model, the absence of a VToC clinic was independently associated with increased odds of readmission (odds ratio 1.37; 95% CI 1.21-1.54; *P*<.001). In the multivariable regression analysis, younger age, female sex, non-Hispanic Asian race or ethnicity, higher LACE+ scores, and non-participation in the VToC program were each independently associated with increased odds of hospital readmission." should be changed to "In the multivariable regression analysis, younger age, female sex, Hispanic and Non Hispanic Black/African American race or ethnicity, higher LACE+ scores, and nonparticipation in the VToC program were each independently associated with increased odds of hospital readmission. This analysis is available in Multimedia Appendix 1. Decile matching was performed to account for the difference in distribution of LACE+ in the VToC and non-VToC groups. Analysis of LACE+ decile groups revealed that the impact of readmission reduction was most prominent among patients with LACE+ scores ranging between 50-75; however, across most groups VTOC performed better than non-VToC (Figure 1).

XSL•FO
RenderX

Figure 1. This figure presents 30-day readmission rates for patients who received the virtual transitions of care (VToC) intervention (dark bars) versus those who did not (light bars), stratified by LACE+ score decile groups. The x-axis represents different LACE+ decile groups, while the y-axis shows readmission rates as percentages. Error bars are included for each proportion and represent the difference between the point estimate (proportion) and upper or lower CI. The targeted population for this intervention was patients with LACE+ scores between 50 and 75. Deciles outside this range are included for completeness. Across most LACE+ decile ranges, the VToC group consistently showed lower readmission rates compared to the non-VToC group.

	Overall	5-49	50-54	55-60	61-67	68-70	71	72-73	74-75	76-77	78-89
VToC	14.9	8.9	12.8	10.5	15	14	10	19.7	19.1	34.2	32
Non-VToC	20.1	7.6	14.5	14.5	18	18.6	17.8	21.7	25.9	27.6	33

Discussion

Here we present a hospitalist-led postdischarge virtual clinic aimed at improving transitions of care for patients. For patients at moderate risk, a VToC visit was associated with a significantly lower rate of readmission. Notably, our intervention group had a higher proportion of female and Hispanic patients, both of which were associated with increased odds of readmission in regression analyses.

This observational study is subject to selection bias, as clinic attendance could be influenced by patient-specific factors that influence readmission. Approximately 13% of patients referred to the VToC were not reached, which may introduce additional bias, as these individuals may differ in ways that influence outcomes. While we did not capture detailed data on patient acceptance, we addressed this limitation by matching the comparator group on readmission risk to reduce confounding. However, the stratified analysis according to the LACE+ index provides strong evidence in support of the impact of the program, and the positive impact observed is consistent with broader evidence that timely postdischarge access reduces readmission risk. VToC clinics address a critical gap in the care continuum while also providing the inherent benefits of telemedicine [6,8].

Results from this initiative are promising for the feasibility of telemedicine-based transitional care programs to promote the quadruple aim of improving population health, enhancing the care experience, reducing cost, and advancing care equity [9].

Acknowledgments

Thank you to Eric Lundin for project management support. Thank you to the hospitalist physicians including Drs Maryann Ally, Diana Childers, Catherine Firestein, Jonathan McIntyre, David Reis, Reid Sasaki, Jennifer Quartarolo, Supraja Thota, and Anne Xing and to Richard Nguyen for information support services. Special thanks to Trina Huynh for pharmacist support and leadership, and to Eileen Hailey and Nancy Renshaw for collaborative operational leadership from the Department of Population Health.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files.

Abstract

Background: Electronic health records (EHRs) can aid in provider efficiency, but may also lead to unintended consequences, such as documentation burden and increased length of notes. To combat issues related to documentation, copying and pasting (CP) and copying or carrying forward (CF) are tools that have been used to aid in documentation burden. Multiple studies have identified the benefits and challenges of using these tools; however, few studies have identified the unintended consequences of CP and CF, and how the adoption of these tools may affect users.

Objective: The objective was to describe providers' perceptions and use of copying tools available in the EHR and describe their suggestions for improvement on these copying tools.

Methods: Research team members conducted semistructured interviews with faculty members, advanced practice providers, residents or fellow trainees, and medical students at a single academic health sciences center. The Diffusion of Innovations Theory of Unintended Consequences guided the analysis and interpretation of interview results.

Results: A total of 22 semistructured interviews were conducted in 2023 and analyzed during 2024. The findings showed that respondents use and value these tools for efficiency and communication purposes. The negative unintended consequences include inaccuracies and errors in documentation and increased patient safety risks. Some respondents experience inner angst or moral injury related to using CP/CF, but they feel that they must use them to satisfy organizational requirements surrounding documentation. The respondents suggested that artificial intelligence will likely help improve documentation tools, as would further training around these types of documentation tools.

Conclusions: Some respondents noted feeling both internal and external pressures that influenced when and how they use CP/CF. Respondents noted that they value EHR copying tools for efficiency purposes, but they also understand the risks involved. This tension may lead to moral angst or moral injury. They offered numerous suggestions for lowering the risk, especially by improving the documentation capabilities of the EHR through artificial intelligence. Future research should investigate both technical and educational solutions to relieve the documentation burden and moral angst they are experiencing.

Introduction

Electronic health records (EHRs) were first introduced as a more efficient mechanism than paper for collecting and storing patient information such as test results, diagnoses, and clinical notes [1]. Although the EHR is effective in many aspects, the adoption of this technology has given rise to unintended consequences. One primary concern, documentation burden, includes increased length of notes ("note bloat") [2] and time spent documenting [3]. These unintended consequences contribute to another widespread problem: provider burnout [4].

To combat issues related to EHR documentation, vendors have developed and implemented documentation tools that facilitate copying and pasting (CP) text and copying or carrying forward (CF) entire notes [5] into their products that clinical users in health care organizations have embraced. CP allows users to copy elements of a note (eg, free text, test results, and clinical narratives) and paste that information into a new note. CF, available in some EHR systems, is used to copy an entire note, including templates and formats, to bring forward into a new note.

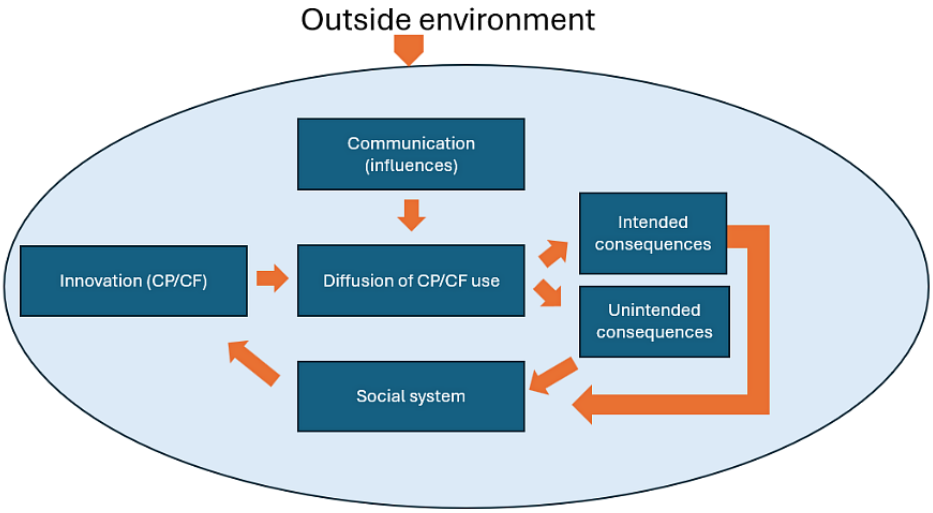
Prior studies suggest CP/CF is used to improve usability and efficiency in documentation [6], to decrease provider burnout [7], and to improve documentation quality, where quality was defined as the accuracy of the information, and timeliness of the information, and the overall readability of the information in the note [8]. However, CP can be a significant contributor to note bloat and error [3,5,9-14]. Some researchers found that 90% or more of inpatient service notes were either copied or templated, increasing length and number of errors in the notes [8,15], while others reported CP/CF-related diagnostic and process errors contributed to the potential for moderate to severe harm [16,17]. Please see Table 1 for a summary comparing intended versus unintended consequences.

Table 1. Summary of intended and unintended consequences of using CP[a]/CF[b] in EHR documentation from previous literature.

Intended consequences of CP/CF	Unintended consequences of CP/CF
Efficiency	Note bloat
Relieve burnout	Increase in errors in documentation
Improve documentation quality	Increase in diagnostic errors

[a]CP: copying and pasting.

[b]CF: copying or carrying forward.



Researchers have typically investigated CP/CF use via surveys [8,10,18,19] and large retrospective analyses of notes [11,12,14,20]. A mixed-methods study assessing the association of CP use and risk severity, as well as perspectives of CP/CF use in progress notes and reported a wide spectrum of the value of CP/CF and progress notes across note authors and consumers was carried out [21]. Other research has found similar variance in perception of value and efficiency by specialty, seniority, and setting [8,10].

Numerous studies have described the benefits (eg, efficiency) and challenges (eg, note bloat) of these tools. However, evidence considering the context in which these tools are implemented, and the potential to limit or avoid unanticipated and undesirable consequences of implementation, is lacking. The Diffusion of Innovations model posits that adoption of innovations proceeds through stages and is affected by properties of the innovations, adopters, social systems, change agents (individuals pushing for process improvement), and communication relationships [22,23]. While CP/CF may be considered successful innovations in terms of adoption, the unanticipated (and potentially contradictory) consequences of CP/CF use may have dramatic ramifications for users, consumers, and the health systems themselves [22]. This Theory of Unintended Consequences, a corollary to the Diffusion of Innovations Theory, is depicted in Figure 1, showing a cycle in which an innovation (in this case, CP/CF) is introduced and adopted. Adoption creates the intended and unintended consequences described in prior research, followed by iterative updates based on interactions with the social system. Throughout the process, the outside environment (eg, policy or cultural values) exerts pressure against the innovation usage.

However, the benefits and challenges of innovative tools, such as CP/CF, coupled with an understanding of how the unanticipated and unintended consequences of CP/CF adoption affect users, are poorly described in the current literature. We aimed to use qualitative methodologies, guided by the Diffusion of Innovation Theory of Unintended Consequences, to (1) investigate provider perceptions, thoughts, and attitudes about CP/CF in the EHR; (2) identify the consequences (both intended and unintended) of using CP/CF across different specialties, departments, provider roles, and training level in one academic health care system; and (3) better understand users' experiences with intended and unanticipated consequences of CP/CF by focusing on the futures of CP/CF.

XSL•FO
RenderX

Figure 1. The figure below depicts the modified Diffusion of Innovations Theory of Unintended Consequences, which is a theory showing a circular pattern where an innovation is introduced and adopted. The adoption of innovation then creates the intended and unintended consequences, which are followed by iterative updates based on interactions from the social system and the outside environmental pressures. CF: copying or carrying forward; CP: copying and pasting.

Methods

Ethical Considerations

This study was approved by the Institutional Review Board at Oregon Health & Science University (IRB #10027). Informed consent was obtained from respondents invited via email to participate in this study, and verbal consent was given before being recorded during the interview. The data used for this paper were deidentified, and the manuscript does not contain any information that would allow for the identification of respondents. Respondents were informed that study findings would be published, and their quotations would be presented anonymously. Participants were not compensated for participating in the interview.

Recruitment or Setting of This Study

Respondents for this comprised providers who initially responded to a prior quantitative survey [19] in 2022-2023 regarding use of CP/CF for documentation, and while completing the survey, self-identified to be interviewed for the present study. These providers included faculty, advanced practice providers (APPs), medical students, and residents or fellow trainees at a single academic health institution. For our study, we have defined APPs as health care professionals who have had special training to diagnose, treat, and manage common medical conditions, which include physician's assistants, certified nurses, nurse practitioners, and licensed social workers. APPs, faculty, medical students, and residents or fellow trainees who all used Epic (Epic Systems); and medical students and residents or fellow trainees on rotation at the Veterans Affairs health care system who also used VistA (Veterans Health Information Systems and Technology Architecture; US Department of Veterans Affairs). Thus, while the initial survey was purposively sampled, the participants identified for this study represented a convenience subsampling of a prior purposively selected cohort. The research team reached out to individuals who volunteered to participate in interviews to schedule virtual meetings.

Design

In 2023, the research team, consisting of four individuals from diverse and multiple backgrounds (informatics, qualitative research, quantitative research, psychology, and medical education), developed an interview guide. The interview guide included questions regarding demographics (eg, professional background, department or specialty, and patient population), innovation of CP/CF, CP/CF use, factors influencing use such as environmental pressures, types of consequences, and the future of CP/CF (Multimedia Appendix 1). Each interview was conducted by 2 team members virtually through Cisco Webex (one interviewer was the lead, who asked the questions on the interview guide, and the second interviewer asked follow-up questions as well as any questions that may have been missed by the lead interviewer). Interviews were recorded and professionally transcribed.

Analysis

In 2024, the research team used both a thematic deductive framework, deriving themes from existing theories, and a thematic inductive framework (where themes are derived organically from raw data) to analyze data. Two team members used 3 transcripts to develop the initial codebook. Five team members then analyzed all 22 transcripts, consisting of 322 pages of data, using a standard inductive grounded approach, iteratively developing a codebook, and generating patterns and themes. NVivo 12 (Lumivero) was used for the management and analysis of the data. The inductively generated themes naturally fell into categories described in the Diffusion of Innovations Theory of Unintended Consequences [22], so this framework was applied to describe the results.

Results

Overview

Findings are organized using the Diffusion of Innovations Theory of Unintended Consequences framework in Figure 1, enhanced by inductively produced themes. Rich quotes from interviewees are available in Multimedia Appendix 2.

Demographics

In 2023, we conducted 22 interviews (mean duration 48 minutes, range 29 to 65 minutes). Half were faculty (11/22, 50%), and most treated adult or family populations (17/22, 77%; Table 2). Most respondents were specialists (14/22, 64%). Many of the respondents saw patients in both inpatient and ambulatory settings (10/22, 45%), with some respondents reporting seeing patients in ambulatory settings alone (8/22, 36%).

Table 2. Demographics table: qualitative interview respondents' characteristics, including role or training level, population, department, and setting.

Respondent characteristic	Value, n (%)
Role or training level	
Faculty	11 (50)
APP[a]	7 (32)
Resident and fellow trainee	2 (9)
Medical student	2 (9)

Innovation

The model (Figure 1) starts on the left with the innovation. The innovation is a new idea: in this case, duplicative text tools in the EHR. Respondents believed that because the documentation burden was so high for providers, CP/CF were developed as innovative solutions. Textbox 1 depicts the themes and subthemes found in the results.

Framework component (from Figure 1) and subthemes

Innovation

Diffusion of CP (copying and pasting)/CF (copying or carrying forward) use

Communication (influences)

Social system

- Overview
- Differences in types of patient visits
- Difference in the health care delivery system
- Difference in specialty
- Difference in electronic health record (EHR) products

Intended consequences

- Overview
- Efficiency or decreased documentation time
- Organization and time management skills
- Increased communication
- Improved accuracy for objective data

Unintended consequences

- Overview
- Inaccuracies and errors in the note
- Plagiarism
- Note bloat
- Critical thinking issues
- Ultimate unintended consequence: inner angst or moral injury

Outside environment

- Overview
- EHR-related solutions
- Artificial intelligence–related solutions
- Innovation: people-focused solutions
- Cultural shifts in documentation

Diffusion of CP/CF Use

Moving to the center square (Figure 1), consideration of the diffusion of CP/CF includes (1) how people adopt tools, (2) why people use these tools, and (3) why some decide not to use these tools.

In the case of CP/CF, some respondents noted that at times, documentation duties occasionally fell onto the residents/fellow trainees and APPs, so these tools are necessary for efficiency purposes. Residents/fellow trainees are, at times, active change agents in the diffusion of CP/CF because “it would be impossible for trainees to not copy and paste” (faculty). However, residents/fellow trainees are not the only ones who document and use CP/CF. When faculty are not supervising residents/fellow trainees, they are writing notes themselves and use these tools regularly, so they can achieve a better work/life balance.

Communication Influences

The superior aspect of the model (Figure 1) indicates that communication impacts the diffusion and spread of an innovation (ie, CP/CF). Information about CP/CF was commonly communicated through informal training and education from other colleagues rather than through formal training. Medical students noted that communication about the appropriate use of these tools was inconsistent. Some direct supervisors (ie, resident/fellow trainees) vocalized and encouraged medical students to use the tools and “start building [these skills now]” (medical student), while others (ie, faculty

XSL•FO
RenderX

supervisors) did not want them to use the tools because, as students, they needed practice writing notes themselves and developing critical thinking skills.

Influence of Social Systems

Overview

The inferior aspect of the model (Figure 1) indicates there are societal or systems pressures influencing how and when CP/CF are used. Use of CP/CF varied greatly by type of patient visits, setting, specialty, and attributes of the EHR product.

Differences in Types of Patient Visits

The use of CP/CF differed depending on the type of patient visit (eg, telephone, virtual, or in-person visit; returning, new, or old patient). With a new patient, providers reported using CP to gather the patient's historical information, especially when the history was complex and involved many images. However, there were some notable differences in use among clinicians. For example, a surgical resident/fellow trainee noted that he was more likely to write down verbal history when meeting a patient for the first time versus gathering prior information and using CP. Other providers mentioned that they do not use CF because they view each visit as a new visit.

Difference in Health Care Delivery Setting

According to our respondents, CP/CF use is influenced by whether care is provided in an ambulatory or inpatient setting. For example, CF has been described as "the backbone of all (in-)patient charting" (APP) because it aids in the continuity of care between team members, which would not be applicable in ambulatory settings. Providers who work in both inpatient and outpatient settings mentioned using CP in both settings because they are used to doing so.

Difference in Specialty

Respondents described how different workflows and documentation requirements impact CP/CF use. When providers see long-term patients for chronic problems, they rely on CP/CF, but if they consistently see new patients, such as in emergency medicine, they tend not to use them.

Specialties vary in how they structure their notes, impacting the value of CP/CF. Those with more structured and templated notes used CP/CF less frequently, whereas other specialties required documentation of detailed thought processes and thus were less structured and used CP/CF more frequently. Volume and duration of the patient visits differed by specialty, which impacted providers' use of CP/CF, with one faculty member noting, "when I'm busier, I tend to copy/paste more and copy forward more" (faculty). The research team also noted that the value found in using CP/CF differed by specialty, so developing a single policy to guide CP/CF throughout a health system would be challenging.

Difference in EHR Products

EHRs vary based on product offerings and integration into a system, including access to and policies for use of duplicative text tools. One resident/fellow trainee compared one academic center's commercial EHR to the Veterans Affairs' EHR, noting that CP is not easy to do, and CF is not available at all.

Intended Consequences of CP/CF

Overview

The right aspect of the model (Figure 1) features the intended and unintended consequences of implementing any new technology. Our analysis revealed intended benefits from the innovation of CP/CF tools.

Efficiency or Decreased Documentation Time

When asked about the benefits of CP/CF, many respondents highlighted that these tools were "a survival mechanism" (faculty) that streamlines work processes, decreases documentation time, and increases efficiency, which reduces provider stress and promotes work/life balance.

Organization and Time Management Skills

Part of the CP/CF's efficiency is derived from organization and time management, allowing providers to update relevant data in a template rather than recreating an entire note from scratch. When used this way, CF can provide consistency, organization, and standardization of notes, helping providers find salient information quickly.

Increased Communication

Respondents discussed CP/CF's enhancement of communication within and across teams and disciplines and settings, which "saves [them] a great deal of time" (faculty). CP/CF help providers stay organized in their notes, which allows them to solve problems together.

Improved Accuracy for Objective Data

CP/CF may decrease errors in translating complicated or nuanced data from note to note, especially from specialists or when dictating notes. One example noted was radiology, because the integrity and accuracy of the original report should stay intact, and providers "don't have translational[/dictation-relations] errors" (faculty).

Unintended Consequences of CP/CF

Overview

While innovations bring about intended and desirable consequences, unintended consequences can also affect the adoption of innovations (Figure 1). Although the diffusion of CP/CF into EHR systems could be considered a success, respondents discussed the risks and challenges CP/CF use presented, which shaped their willingness to use CP/CF in their practice.

Inaccuracies and Errors in the Note

All respondents noted that CP/CF use can increase inaccuracies and errors in the notes, from the seemingly innocuous errors (spelling errors) to harmful errors (forgetting to update a note). Information can be outdated yet copied. Errors can be perpetuated. Respondents admitted to forgetting to update information they had previously copied, especially in hectic environments. Some respondents expect that inaccuracies and errors will occur due to the "amount of pressure they feel to get [notes] done" (faculty) and the pressure on providers to see higher volumes of patients.

XSL•FO
RenderX

Whether inaccuracies are accepted as part of the cost of using efficiency tools, these errors can be harmful, in some cases leading to legal as well as patient safety risks. One risk is putting the copied text into the wrong chart, allowing patients to see other patients' confidential information. Another risk is carrying forward a care management plan that may not be appropriate for patients. One faculty member noted, "whatever we are signing our name [to] should be our own work" (faculty), and that signing off on a note that they have not reviewed thoroughly is problematic.

Plagiarism

Respondents noted that plagiarism can be another unintended consequence of using these tools. Attribution was another issue, with respondents discussing how they, or others, copied from other people's notes without citing where they obtained this information or verifying that the information they copied is correct.

Note Bloat

One of the most cited challenges with the CP/CF innovation was the increased length of notes or note bloat. Note bloat makes quickly finding relevant or updated information within a large volume of data more challenging. The length of notes also contributes to the perpetuation of errors. As described by respondents, CP/CF contribute directly to note bloat. Additionally, longer notes mean that providers may not be reviewing and editing notes as carefully as they should, allowing errors to slip through.

Critical Thinking Issues

Respondents described how the use of CP/CF affected critical thinking skills and led people to not review information thoroughly. Providers, especially medical students and residents/fellow trainees, must learn how to think critically. As one faculty member noted, providers must "separate the wheat from the chaff" (faculty) and determine what to include in a note; critical thinking is an important part of training, which may be impeded by shortcuts in documentation.

Ultimate Unintended Consequence: Inner Angst or Moral Injury

The constant friction between the internal and personal desires to practice caution, review information thoroughly, and create concise and accurate notes, and the external pressures of practicing medicine in today's organizational environment, has led to the most important unanticipated and unintended consequence of the CP/CF innovation: a sense of inner angst, or moral injury, among respondents. The concept of medical moral injury (or distress) among providers has gained traction in the literature in recent years, and covered actions due to commission (providers acting against a belief) or omission (providers not able to act on their beliefs), whether due to a sense of being internally or externally constrained in their ability to provide what they believe is quality care in a high-stakes situation or betrayal from people, institutions, or systems in power [24]. Whether conscious of these feelings of inner angst or moral injury, respondents discussed at length the impact on and of CP/CF use.

Documentation burden, due to time constraints and increased pressure to see higher patient volumes, negatively affected providers' sense of well-being and created pressure to use these tools, even if they did not want to do so. With a higher patient census, documentation requirements increase, as does the amount of time providers need to review other people's notes. Due to these conflicting issues, the compromise between efficiency and accuracy is a challenge for providers. Respondents described a love/hate relationship with CP/CF, in that, despite the risks, the tools are necessary to function in the current environment.

Despite the acknowledgement that CP/CF can create some efficiencies, many respondents called CP/CF a "necessary evil" (APP) due to the risks and challenges arising from use.

Respondents experience this internal struggle with wanting to be thorough, efficient, and accurate with documentation, but they do not have enough time to document, so they use tools that they know have errors associated with them, with some calling CP/CF "sloppy and paste" (faculty). Respondents feel this inner angst or moral injury because they have no other choice when the institution is pushing them to see more patients without allocating more time or compensation to document.

Influence From the Outside Environment

Overview

Further complicating and adding to the inner angst experienced by providers, the outside environment influences diffusion of an innovation and its consequences (Figure 1). Not only are providers feeling internal pressures, but they are also experiencing outside influences, including legal, regulatory, and financial requirements regarding what content to include in the note. This pressure, and the possible consequences, directly impact how respondents use CP/CF. In one example, a faculty member noted that the Centers for Medicare and Medicaid Services require an enormous number of requirements for one note, with some calling the note the "patient Wiki[pedia]" (faculty) for how many purposes the note serves at one time.

EHR-Related Solutions

Respondents provided suggestions for improving the EHR infrastructure to increase efficiency, including smart phrases, as well as improving education on EHR use. Part of that education includes understanding what information is relevant to keep in the notes to increase the usefulness of currently available efficiency tools, whether through CP or smart tools (Epic Systems). Respondents also expressed a desire for dictionaries that autocorrect abbreviations or prepopulate problem-based notes.

Another suggestion was for a tool that automatically identifies whether any information had been copied, with author attribution prominently displayed, such as a pop-up alert when using or reviewing text created with CP/CF and requiring users to review common errors from CP/CF, such as dates or values, before closing an encounter. Respondents also mentioned needing alternative tools to display and integrate notes, as well as more standardization and guidelines in note creation. Others suggested

XSL•FO
RenderX

having some sections of the notes be collapsible, as well as being able to insert images and hyperlinks within a charting tool for easier access to other areas of the chart.

Artificial Intelligence–Related Solutions

Some respondents described recent advances in artificial intelligence (AI) and the potential for integration into documentation tools. They wished that the note could be automatically created "like Jarvis style from the Avengers" (faculty). One such advancement currently under investigation is the use of ambient scribes, which listen to the physician-patient encounter and write the notes on behalf of the providers.

New Innovations: People-Focused Solutions

As much of the training and communication in EHR use to this point has arisen from informal communication channels (eg, word of mouth) or piecemeal, based on workflows and department needs, respondents requested additional education and training on best practices for documentation. Respondents also suggested training should focus on what the "right tools are to do the work" (APP), which could minimize reliance on CP/CF as the primary documentation tools.

Equally critical to providing training on best practices in documentation is giving providers the amount of time necessary to set up templates and smart phrases in the EHR, as well as an understanding of what is important to include in a note, ensuring documentation is more efficient in the future. Respondents proposed new or updated guidelines and standards with clear teaching and expectations of use for CP/CF to ensure efficient use of the tools. Departmental guidelines and expectations surrounding CP/CF use could help new learners and faculty use these tools appropriately.

The creation of a super user role on teams to facilitate general knowledge-sharing could provide a point person to identify key workflow components and functionality within departments or systems, which could "eliminate the amount of overload that the Epic support team [gets]" (APP) and lessen prolonged waiting times for users.

Cultural Shifts in Documentation

One of the key barriers to reviewing and editing notes for conciseness and accuracy is time, where "[time spent on editing the notes] is seen as an extra burden" (resident/fellow trainee). This extra time often is uncompensated and means less time caring for patients. The time spent on editing notes has unanticipated consequences of external constraints (eg, reimbursement policies or patient volume targets) on inner angst. An APP noted she wished she could spend more time with patients and less time documenting in general. Another APP highlighted that, "there's been such an increasing pressure to see more and more patients… and that's just making it harder and harder to actually document" (APP). With the current documentation culture, one resident/fellow trainee noted that, "the only way to function really, is to be copy and pasting from yourself [and] from others" (resident/fellow trainee).

Providers argued that there needs to be a cultural shift with regard to best practices for what gets documented and put into the note, as well as how notes are used. The reliance on notes as a patient "Wikipedia" has contributed to note bloat and the rise in errors and inaccuracies, as well as provider burnout, and therefore, reliance on CP/CF to document quickly. Providing the time needed for reviewing the work is critical.

Some providers suggested that the use of these tools should be limited. One faculty member said attribution should be mandatory; others added that the copied portions should be cited in quotes and attributed to the original author as in peer-reviewed publications. It could also be helpful to use different fonts, italics, or bold typeface to indicate copied text. Others mentioned that CP/CF should only be used for what is necessary to contextualize or augment the note, with clear identification of the information's source.

Discussion

Summary

In this study, we identified perceptions of and attitudes toward CP and CF, as well as consequences of the diffusion of this innovation in note writing, in an academic hospital (Figure 1). Whereas prior studies have described provider perceptions and process improvement through the introduction of CP/CF, our research expands on this literature by qualitatively exploring the consequences of this innovation through the lens of unintended consequences in diffusion [19] (Textbox 2).

XSL•FO
RenderX

Textbox 2. Summary findings are split up by the components of the Diffusion of Innovations Theory of Unintended Consequences framework from Figure 1.

Communication (diffusion)

- Documentation burden falls greatly on providers—but with pressures on their time, diffusion (via communication or training) is limited and inconsistent—users have created ad hoc workarounds to deal with the workload, versus intentional evidence-based practice and critical thinking skills development.

Social system

- Note purpose and use vary by specialty, health care setting, patient visits, and EHR products, so a one-size-fits-all solution is not feasible.

Intended consequences

- Respondents report a more streamlined workflow and increased efficiency, especially those with templates to help with organization and consistency, and can help with inter- and intrateam communication—when used appropriately.

Unintended consequences

- Whether through limited training, anxiety around policies, or other challenges, inaccuracies in notes result in risks to the patient, author, and system, from simple to severe. Respondents experience the moral injury of spending more time documenting out of fear of liability, harm, and denial of reimbursement, versus spending time providing care to patients, changing the culture of care. Noat bloat increases, the culture changes, and consequently, users experience frustration and burnout.

Outside environment

- Legal, regulatory, and financial pressures require documentation, but users are having to adjust their workflow to the requirements, rather than the system adjusting to the workflow. Respondents hope innovations will help with efficiency, but question where they will fit in the current external environment, which is perceived as broken, or whether they will arise from within. There is a need for guidance and policy, but it is hard to do so when use is so variable.

Discussion of Framework Elements

Communication

Awareness of CP/CF tools spread by word of mouth (Figure 1). As reported by others, the diffusers (ie, the ones spreading the innovation) are sometimes residents/fellow trainees and APPs, rather than supervisory or more senior staff, a trend that has persisted over the years [8,20,21,25]. However, simple awareness does not guarantee the quality of the information communicated in the medical note, so tailored formal training is recommended [26,27]. Another recommendation to promote high-quality training is to have an EHR champion available, especially in the inpatient setting where CP/CF are most used [8,20,27,28].

Communication and training about the use of CP/CF in documentation can provide teaching opportunities to enhance critical thinking of relevant information to capture [29]. This may be less likely in high-pressure, dynamic systems, but some have had success in training through templated or team-based writing [29,30].

Social System

Innovations (Figure 1) such as CP/CF are highly complex and are integrated into similarly complex and evolving systems [22,31,32]. Implementation and adoption rely not only on individuals and their personal characteristics, but the innovation itself, as well as the structure and characteristics, and culture of the organization in which the innovation is deployed. By certain metrics, innovations may be successfully diffused (technically adopted), but a lack of consideration for the interdependency of the actors in a system may inhibit realization of the optimal or true value to the system, and can lead to unintended consequences [31,32].

Intended Consequences

Our results reflect those of other reports that CP/CF improve efficiency [6], continuity of care for patients [8], and communication with teammates [33], as well as decreased documentation burden [7]. Yet in the two decades of literature acknowledging the benefit of innovation in electronic records, these same reports highlight the double-edged sword of efficiency versus unintended consequences [8,34]. Without trust in the system or other users, or without bulwarks against our own inherent flaws as human users of technology [35], the optimal use and benefits of these innovations and the intended consequence of improving quality of care will not be realized [31].

Our respondents describe the need for short-term solutions, such as recurring formal training on how and when to use CP/CF. Others have similarly demonstrated that lack of knowledge of appropriate use results in increased length of notes [36] and the importance of training and education for safe practice regarding these tools [31].

Unintended Consequences

Documentation burden, note bloat, inaccuracies, and more time spent documenting to the detriment of patient care, training, and interpersonal communication and trust—all have led to a perceived worsening of culture, the work environment, and workflows [5,37]. These phenomena are not new; the same benefits and challenges have remained consistent over time and across systems [38-40]. This dichotomy of intended (often positive) consequences and unintended (often negative)

XSL•FO
RenderX

consequences results in providers experiencing increased inner angst and moral injury [41,42]. Providers report angst from constraints against practicing what they consider "quality" care, and despite knowing the myriad risks, use tools such as CP/CF as the only workaround right now in a broken system, calling CP/CF a necessary evil. While providers acknowledge that CP/CF and other tools aid in the continuity of care and create a sense of efficiency when documenting, the lack of time to review notes thoroughly is a consistent and pervasive structural barrier. In such instances, errors slip through the cracks—the role of CP/CF in errors, inaccuracies, and outdated information is of particular concern [6,12], as they have contributed to note bloat [5,8] and may play a role in patient safety [16]. Inaccuracies may damage a patient's trust in and experience with the clinician or system; contribute to diagnostic and safety errors (inaccurate or out-of-date records, difficulty in finding relevant data in bloated notes); and increase legal risks, including unintentional falsification of records or plagiarism and medical malpractice [16,17]. All of these factors conspire to reduce providers' overall perceived quality of care delivery. This, in turn, can further worsen provider dissatisfaction and burnout, with a study suggesting that clinician involvement in medical errors is an independent risk of burnout [43].

Outside Environment

The outer system (Figure 1) is a key factor for optimal diffusion and implementation of an innovation [32,39]. Recommendations to address challenges in using CP/CF include developing policies, both institution-wide and specialty-specific, for CP/CF use. These larger structural factors—policies, standards, legislation, system resources, and engagement of leadership—filter down into organizational workflow and processes and then to individual knowledge of the innovation [32,39,40]. Although improvements at this larger scale are difficult to accomplish and are often more long-term solutions, a fundamental shift is needed at the outer system level in how these innovations are built for and integrated into dynamic, complex systems. Notes should serve clinical purposes and not focus as much on reimbursement regulations and national quality measures [21,32,44].

New Innovations

In the short term, most providers report the need for specific interventions, such as training to improve optimal EHR use, continued EHR optimization, and improved awareness of best practices for use of the functionality are necessary. Others recommended some degree of restrictions on use as well. While shown in other health systems to have direct impacts on hospital readmission [45], the overall widespread reliance on its use, and the inability to remove this functionality (easily) from underlying operating systems, suggest this is a nonviable solution. As a result, one must look for more novel, sustainable solutions. With the growth of AI and tools such as ambient or digital scribes already in use in clinical care to reduce documentation burden, careful reflection on the appropriate use of innovative tools will be paramount in mitigating current and future unintended consequences [6,13,46-48]. Another way to mitigate unintended consequences for ambient scribing would be to develop measures and metrics of success (eg, provider satisfaction scores, decrease in pajama time charting, decrease in documentation time, and increase in work/life balance). That way, organizations could evaluate whether the ambient scribes are aiding providers related to the intended metrics. However, while ambient scribes hold promise, to date, no studies have documented the impact of the ambient scribes on the amount of CP present in notes. This is likely, in part, because studies on ambient scribes are limited to ambulatory settings [49]. This will need to be an area of future study as the technology becomes more widespread.

Strengths and Limitations

There were some strengths in our study. First, this paper addresses providers' perspectives toward CP/CF in a way that adds depth and insight to the body of literature already present. Second, this is one of the first papers that attributes the concept of moral injury to the use of CP/CF, which has not been explored in the literature. Third, this manuscript offers recent perspectives and alternative solutions to aid in the documentation burden (eg, AI scribing). Fourth, this paper provides a true direct negative harm of CP/CF to the users, something which has not been previously described. In essence, while CP/CF use is continuing to grow over the years, it is associated with higher rates of documentation burden and job dissatisfaction. Thus, it is not working to solve the primary problem it was adopted to address: to make providers efficient and alleviate documentation burden. One reason for this may be the unintended consequence of its use, that whatever benefit the provider obtains from using these tools, moral injury and guilt compound and hinder providers.

There were some limitations to our study. First, this research was conducted at one academic health care institution, which may limit the generalizability of the findings. However, we solicited a breadth of input from various departments, roles/training levels, and clinical settings. Further, reported results from previous research on CP/CF are consistent with our findings, suggesting that these phenomena go beyond our institution. We also engaged a diverse team of researchers from a variety of disciplinary and demographic backgrounds to analyze the data to ensure a multidisciplinary approach and perspective. Second, it should be noted that the respondents for interviews were recruited from a subset of respondents to a previously deployed anonymous survey [19], specifically those who had self-identified and volunteered to participate in interviews. This approach does raise the likelihood of amplifying potential selection bias. Additionally, we used a convenience sampling method to select participants for interviews, and while the initial survey used a more robust purposive sampling strategy, the subset of self-identified interview participants was predominantly faculty and APPs, as opposed to medical students and residents/fellow trainees. As the use of CP is ubiquitous across levels of training and professional experience, we believe that our sampling strategy does reflect a broad and adequate spectrum of perspectives despite the relative underrepresentation of medical students and residents/fellow trainees. Third, at the time these interviews were conducted, there had been some discussion within the institution about whether curtailing or banning the use of CP/CF was appropriate as a policy measure. However, despite this potential barrier, it should be noted that

XSL•FO
RenderX

respondents uniformly expressed both positive and negative perceptions of EHR documentation tools.

Future Research Directions

Research addressing the unintended consequences of CP/CF, such as the use of a note for multiple purposes (eg, legal and patient safety implications, billing, communication, and continuity of care), could lead to slimmer, more streamlined notes, a decrease in documentation burden, and less burnout.

While CP/CF has limitations, there are innovations that could encourage appropriate use or reduce the need for CP/CF in documentation. Some potential innovations discussed by our participants were EHR technical solutions, including automatically identifying information that has been copied and having pop-up alerts when using or reviewing texts. Future research on the role these proposed features have in documentation could inform additional technical innovations and support cultural practices for proper attribution. AI solutions, such as digital or ambient scribes, may decrease the documentation burden and the need to use CP/CF; research is ongoing [46,50,51], but future research is needed to understand use across systems with different EHR policies and capacities. People-focused solutions, including more robust orientation training on CP/CF and having staff EHR super users to facilitate general knowledge sharing, could support more efficient and appropriate use of EHR tools, which in turn could help address documentation burden. Future research of educational programs and inclusion of EHR super users pre- and postimplementation may provide justification to integrate these ideas into clinical practice workflows, supporting a culture valuing time for training. Furthermore, importantly, health care systems are complex environments, and implementing new tools can result in unintended consequences. Future work must consider the potential for these unintended consequences resulting from the implementation of a complex innovation in dynamic systems.

Conclusions

Our study aimed to use semistructured interviews with providers to investigate their perceptions and attitudes surrounding CP/CF in the EHR, using a modified Diffusion of Innovations Theory of Unintended Consequences framework to analyze the data. The intended consequence of the innovative CP/CF tool, efficiency, is valued by users. However, the unintended consequences, including note bloat, errors, and patient safety and legal risks, have given rise to moral injury, a finding consistent with the literature. The theory of unintended consequences framework addresses the complex system within which CP/CF exists. In the case of CP/CF, outside pressures on documentation requirements are one of the critical barriers to realizing the potential for innovative duplicative text tools. Fewer documentation requirements may lessen internal and external pressures, leading to inner angst or moral injury among providers.

Acknowledgments

This study would not have been possible without the support of Oregon Health and Science University. No generative artificial intelligence tools were used in the writing of this paper.

Abstract

Background: Telemedicine use surged due to its capacity to deliver safe, remote care. As the public health crisis subsides, evaluating the interplay among various tools, such as video, audio, and text, becomes critical to sustained use. With health care shifting back to in-person models, understanding whether telemedicine tools complement or compete provides valuable insights for future technology design and usage strategies.

Objective: This study investigates whether different types of telemedicine technology tools complement or compete while physicians deliver health care services through them. A clear understanding of the relationships between telemedicine technology tools, physicians' satisfaction, evaluation of care quality, and patient visit percentages is crucial for the design of new telemedicine technology platforms and ensuring quality of care services through technology platforms.

Methods: To fulfill our objective, we analyzed data from the 2021 National Electronic Health Records Survey. We used ordered logit and probit regression models to evaluate the effects of telemedicine technology tools on physicians' overall satisfaction, quality of health care evaluation, and the percentage of patient visits via telemedicine.

Results: A total of 1875 office-based physicians in the United States completed the survey. Three main outcomes were assessed, including physician satisfaction (n=1614), evaluation of health care quality (n=1617), and the percentage of patient visits conducted via telemedicine (n=1558). Ordered logit and probit regression analyses revealed that the aggravated use of telemedicine tools had a significant impact on improvements in all 3 outcomes. A unit increase in telemedicine tools was associated with a 4.2 percentage point increase in the predicted probability of physicians being "very satisfied" (P<.001) and a 5.2 percentage point increase in evaluating telemedicine quality as "to a great extent" (P<.001). For patient visits, a unit increase in telemedicine tools was associated with a 1.8 percentage point increase in the likelihood of reporting "≥75% of visits via telemedicine" (P<.001). Disaggregated analysis indicated that all individual tools were positively associated with physician satisfaction and quality evaluation (P<.05). Bundle models revealed patterns consistent with complementarity (several bundles exceeded their constituent tools) and competition (some significant bundles were smaller than at least one constituent tool), aligning with the presence of both reinforcing and overlapping functionalities.

Conclusions: Our study demonstrates that telemedicine tools interact in ways that can be either complementary or competitive, depending on how their functionalities align within physicians' workflows. Videoconferencing tools, especially when integrated with electronic health record platforms, act as a central complementary component that enhances physicians' satisfaction and evaluation of care quality. In contrast, combinations lacking video capability or involving multiple nonintegrated platforms fragment workflows and increase cognitive burden. These findings emphasize the importance of designing telemedicine tool bundles that align media capabilities with clinical communication needs, thereby improving satisfaction and supporting sustainable, high-quality telemedicine practice.

Introduction

Overview

Telemedicine, the use of telecommunications technology to provide health care remotely [1], has rapidly evolved to improve access to high-quality, efficient, and cost-effective health care, particularly during a major public health crisis like the COVID-19 pandemic [2,3]. Due to the unique characteristics of telemedicine, it has emerged as an ideal solution for mitigating the risks of secondary virus transmission and continuity of health care services. During the COVID-19 pandemic, there was a significant surge in demand for telemedicine, leading to substantial growth in the telemedicine industry, with remote appointments increasing by 154% within a year [4]. Meanwhile, the global telemedicine market is projected to grow from US $60.15 billion in 2023 to US $309.90 billion by 2032, with a compound annual growth rate of 19.98% [5].

Although telemedicine adoption was initially slow [6] and hindered by restrictive administrative regulations as well as limited financial investment [7], the COVID-19 pandemic significantly accelerated its adoption as it became the only alternative to in-person care, offering the safest mode of health care delivery [8]. This shift relied on using multiple telemedicine tools, which provided physicians and patients with multiple synchronous and asynchronous communication channels, including audio, video, and text (with and without electronic health records [EHRs]).

During and post the COVID-19 pandemic, most physicians received access to more than one type of telemedicine tool, which usually supports different functionalities (eg, telephone, videoconferencing, platforms without EHR, and platforms with EHR). Considering that individual tools and their combinations differ in efficacy and consequently influence the quality of health care delivery, it is essential to identify their performance both as independent tools and as integrated bundles.

However, there are only a handful of studies that have compared different telemedicine tools before or after the COVID-19 pandemic. For instance, the meta-analysis by Byambasuren et al [9] revealed no significant difference in clinical effectiveness between telephone and video consultations, though video was preferred for clinical assessment despite feasibility issues. In a separate study, Alhajri et al [10] found that physicians had greater confidence in acute care and patient education with video compared to audio but experienced longer consultation times. In addition, Orrange et al [11] suggested that most patients preferred video over telephone for telehealth visits despite encountering technical issues, due to the overall convenience. Collectively, these studies highlight that different telemedicine tools have unique strengths and limitations, which are shaped by user and usage context, as well as the mode of interaction. However, we still have very little knowledge about their perception and performance when they are deployed together.

Additionally, although studies compare different telemedicine tools from various perspectives, they often overlook the communication functions embedded within each tool. Communication is the core function of telemedicine tools, particularly crucial for ambulatory care physicians who face challenges related to technology infrastructure, such as low bandwidth and slow internet speeds [12]. While previous studies have compared different telemedicine tools, such as audio and video, in terms of perceived convenience, clinical effectiveness, or health care quality, they have mostly treated these tools as individual units.

Surprisingly, there is little exploration that investigates how these telemedicine tools, with their varying levels of media richness, synchronicity, and interactivity, work together and independently to influence clinical communication. For example, both Doxy.me (a telemedicine platform) and FaceTime are labeled as "video" tools. However, they may differ substantially in how they support real-time feedback, offering visual cues, or in interface stability. These communication functionalities, rather than the tool types themselves, shape how effectively clinical conversations are conducted and decisions are made. Therefore, it is also important to investigate whether telemedicine tools using different communication modes function in a complementary or competitive manner with existing physician workflows [13].

If these tools are complementary, they can collectively enhance health care delivery by improving system efficiency, ensuring better alignment between physicians' tasks and telemedicine tools, and providing a seamless experience that increases physician satisfaction [14]. On the other hand, if they compete, this may result in duplicated functionalities, fragmented workflows, increased cognitive burden, and communication fatigue, ultimately reducing satisfaction and the effective use of telemedicine [15].

Thus, understanding the nature of the relationship (complementary vs competitive) between telemedicine tools helps inform sustainable telemedicine use, especially when it is no longer a necessity but an optional provision. For a complementary relationship, there are different usage strategies and policies for physicians, clinical settings, or industry, compared to a competitive relationship. This leads us to posit our research question: "Do telemedicine tools compete or complement each other?"

In our study, we aimed to answer this question from the perspective of physicians, the primary users of telemedicine tools. We used data from the 2021 National Electronic Health Records Survey (NEHRS) [16-19] and applied media synchronicity theory (MST) to answer the research question. We used ordered logit and probit regression models for empirical analysis.

Our findings reveal that while both independent and combined uses of telemedicine tools enhance physicians' satisfaction and

XSL•FO
RenderX

quality-of-health care evaluations, their combinations are not always complementary. Instead, various telemedicine bundles produce either complementary or competing effects depending on how functionalities align within physicians' clinical workflows. Specifically, video-based communication tools serve as a central complementary element that enriches clinical assessment and communication, particularly when integrated with EHR-embedded platforms. However, bundles lacking video capability or comprising multiple nonintegrated platforms, like the simultaneous use of EHR-embedded and non–EHR-embedded telemedicine platforms, lead to workflow fragmentation and cognitive overload, ultimately lowering physicians' satisfaction and their evaluations of care quality. In addition, tool bundles with a higher number of telemedicine tools increase the percentage of patients who visit physicians via telemedicine by enhancing flexibility and accessibility. Based on our findings, we recommend telemedicine technology vendors and platform developers for technological systems designed to ensure the complementary behavior of different tools based on physicians' specific demands.

Aim

Understanding whether telemedicine tools operate in complementary or competing manners is essential for sustained use of telemedicine in the postpandemic era. This study examines the impact of individual telemedicine tools and combinations of tools on physicians' satisfaction, perceived quality of care, and the proportion of patient visits conducted via telemedicine. Specifically, we investigate whether different combinations of telemedicine tools function as complements or substitutes within the clinical workflows of ambulatory care physicians.

Literature Review

Although telemedicine technology has existed for decades, it was not widely adopted by physicians or patients until the pandemic. In our literature review section, we primarily focus on (1) the technological capabilities of telemedicine tools and their associated tasks, (2) the impact of telemedicine technologies on physicians' satisfaction, (3) the impact of telemedicine technologies on physicians' evaluation of telemedicine service quality, and (4) the impact of telemedicine technologies on patients' visits choices.

Telemedicine Technology Capabilities and Their Associated Tasks

Telemedicine tools can be grouped into 2 categories based on their synchronous (eg, real-time audio and video consultations) or asynchronous (eg, message-based or store-and-forward systems) communication features. Each telemedicine tool supports specific health care tasks depending on its technical features, such as media richness, interactivity, and synchronicity. Synchronous telemedicine tools, such as live video consultations or real-time chat systems, are widely accepted for their ability to facilitate immediate interaction between physicians and patients [20]. These tools aim to replicate in-person visits, enabling real-time diagnosis and immediate medical advice through audio and video communication channels [21-23]. However, they are dependent on both parties' (physician and patient) simultaneous availability. Alternatively, asynchronous telemedicine tools, like email, offer flexibility and convenience by enabling patients and health care providers to communicate without the need for simultaneous presence [24,25]. These tools are especially effective for follow-up care, chronic disease management, or sharing test results, where real-time interaction is not necessary. Their acceptance is high among patients seeking time-efficient solutions or health care providers managing a large number of patients. However, the lack of immediate feedback limits their effectiveness for patients who require urgent attention. Therefore, it is essential to strike a balance between the needs of physicians and patients when implementing telemedicine tools.

Impact of Telemedicine Technologies on Physicians' Satisfaction

Physician satisfaction is a crucial determinant of continuous telemedicine adoption and long-term system use [14]. Prior studies suggest that physicians' satisfaction is shaped by both system-level attributes, such as usability, interoperability, and reliability, as well as user-level experiences, such as workload, communication quality, and perceived clinical control [26,27]. For example, video-based telemedicine generally contributes to higher physicians' satisfaction levels than telephonic consultations, as it allows richer interactions, visual assessment, and enhanced rapport with patients [10]. However, video consultations are also associated with longer session times and potential technical issues, which can diminish physicians' satisfaction under certain conditions [28,29]. Therefore, current studies indicate that video should supplement, rather than replace, the telephone [28,29].

Moreover, when multiple tools are available, physicians' satisfaction depends on whether these telemedicine tools are seamlessly complementary and align with physicians' health care–related task requirements [27]. In contrast, physicians might report frustration when tools compete, for example, when an EHR-integrated video platform and an independent messaging app duplicate documentation or scheduling tasks [30].

Impact of Telemedicine Technologies on Physicians' Evaluation of Telemedicine Service Quality

Physicians' evaluation of telemedicine service quality reflects their comparison of the perceived quality of health care between telemedicine and traditional in-person visits [31]. Studies have shown that asynchronous tools, such as email, are valued for follow-up communication; however, their effectiveness in immediate medical decision-making is lower than that of face-to-face methods [32]. In contrast, synchronous video consultations enhance physicians' diagnostic confidence and clinical effectiveness. In particular, for acute care or clinical assessments, the quality of synchronous video consultations can be comparable to that of traditional in-person care, especially under acute external stress, such as during the pandemic period [28,33]. Furthermore, the integration of EHRs can improve physicians' perceived quality of care by facilitating decision-making through access to and sharing comprehensive patient medical information, thereby ensuring continuity of care [34,35]. However, excessive system complexity or poor

XSL•FO
RenderX

interoperability between platforms can have the opposite effect, increasing physicians' cognitive load, disrupting clinical workflows, and ultimately reducing their evaluation of telemedicine service quality [36,37].

Impact of Telemedicine Technologies on Patients' Visit Choices

The adoption of telemedicine technologies has also influenced patients' preferences and behaviors regarding the types of visits they prefer. For example, the availability of video and audio consultations increases health care access by reducing travel time, waiting time, and perceived risk of exposure [33,38,39]. Therefore, during the COVID-19 pandemic, patients widely adopted telemedicine as a substitute for in-person visits, with remote consultations dramatically increased across multiple specialties [8]. Postpandemic studies, however, indicate that visit choices now depend on perceived convenience, trust, and the nature of the medical issue [40].

Patients generally prefer video consultations over audio when visual assessment or relational communication is important; however, they choose telephone consultations for brief follow-ups or low-complexity issues [41]. Significantly, patients' continued usage in telemedicine is shaped by their communication experience, the reliability of the technology, and the perceived competence of the physician [42].

To provide an overview of the existing literature in this domain, we synthesized the relevant literature into Multimedia Appendix 1. Our review reveals that while literature often examines individual telemedicine tools or analyses multiple tools separately within a study, there is limited research investigating whether multiple tools complement or compete with each other.

This knowledge is critical, as understanding the interplay between telemedicine tools could provide insights into their collective impact on physicians' overall satisfaction, evaluations of health care quality, and the proportion of patient visits conducted via telemedicine. To address this knowledge gap, our study explores whether complementary or competitive relationships among various telemedicine tools influence the outcomes. We aim to contribute to the telemedicine literature, benefiting health care professionals, researchers, and designers of health IT alike.

Theoretical Framing

To better explore whether telemedicine tools compete or complement each other, we applied MST. MST emphasizes how different media capabilities support 2 fundamental communication processes: conveyance and convergence [43,44]. Conveyance involves transmitting complex information that requires the receiver to process and interpret it, whereas convergence aims to establish a shared understanding and reach a consensus among participants. Additionally, MST identifies five core media capabilities: (1) symbol sets, the variety of ways information can be encoded (eg, text, voice, video); (2) parallelism, the extent to which multiple conversations can occur simultaneously; (3) transmission velocity, how quickly messages are delivered; (4) rehearsability, the ability to fine-tune a message before sending it; and (5) reprocessability, the extent to which a message can be reviewed or revisited after transmission.

In the context of telemedicine, different tools embody distinct combinations of these capabilities and therefore serve different communicative purposes. For example, telephone audio (T1) offers low symbol diversity and reprocessability, making it suitable for simple updates rather than complex discussions. Videoconferencing tools (T2), with richer symbol sets and high transmission velocity, support synchronous interactions, visual assessment, and real-time convergence between physicians and patients. Non–EHR-integrated telemedicine platforms (T3) support structured, health-specific interactions but often lack continuity of documentation or direct access to clinical records, which limits their reprocessability and integration. However, they may offer higher parallelism and flexibility, especially for lightweight or routine consultations. EHR-integrated telemedicine platforms (T4) enhance both rehearsability and reprocessability by enabling real-time clinical documentation, access to patient history, and retrospective review. However, they also significantly increase the cognitive load on physicians [44] when navigating patient information in an EHR system, which remains a demanding task. Therefore, we argue that no single telemedicine tool is suitable for all tasks in all care contexts. Based on the above argument, telemedicine tools can be selected or combined to optimize communication according to the requirements of clinical or administrative tasks. MST thus provides a useful lens for interpreting how these tools complement or compete within ambulatory care, in the context of physicians' workflows.

Previous research has reported the application of MST in the domain of telemedicine. Tan and Yan [45] used MST to classify text and patterns in recognition, while Yan et al [46] used MST to design a comparative case study and conduct a deductive analysis of teleconsultation adoption in clinical settings. Tan and Yan [45] demonstrated that physicians' response behaviors and media features, particularly response speed and the availability of voice services, jointly influenced their perceived service quality in mobile health care, with media synchronicity capabilities acting as a moderating factor. Yan et al [46] suggested that when the media synchronicity of the adopted technology matches the synchronicity requirements of the communication process, teleconsultation services are facilitated. Although MST was used in the context of telemedicine, to the best of our knowledge, it was never used to investigate the complementary or competitive nature of telemedicine tools.

Health care delivery often involves multiple communication tools that must coordinate effectively with each other to achieve the best patient outcomes. MST offers a valuable theoretical lens to address this issue by distinguishing between conveyance and convergence communication processes and aligning them with specific media capabilities. This allows for a more precise evaluation of when tools should substitute for one another versus when they should be integrated to support different stages of communication. Therefore, applying MST enhances our understanding of media choice to explain whether telemedicine tools compete or complement each other.

Ethical Considerations

This study was a secondary analysis of deidentified data from the NEHRS, conducted by the National Center for Health Statistics (NCHS), US Centers for Disease Control and Prevention (CDC). NEHRS is a national survey of office-based physicians that collects information on the adoption and use of EHRs and related health information technologies. The analytic dataset used in this study was obtained from the public-use NEHRS files, which contain no direct identifiers and adhere to NCHS data confidentiality standards. As this study involved only analysis of existing, fully identified public-use data, no additional institutional review board or human research ethics committee review was sought for this secondary analysis, in accordance with institutional and national guidance on research using public-use survey data. The original NEHRS data collection was conducted by NCHS under applicable federal regulations and ethical guidelines governing human participants research, and participating physicians provided consent at the time of the primary survey. Privacy and confidentiality were maintained throughout the current analysis, and no individual physician, practice, or patient can be identified from the reported results.

Methods

Data Resource

This study used data from the NEHRS, a nationally representative survey of office-based ambulatory care physicians in the United States [16-19]. The NEHRS sample is designed to be representative of the broader population of office-based physicians in the United States. It provides crucial insights into EHR use, practice-related details, controlled substance prescribing, health information exchange, telemedicine use, and documentation-related burdens. The survey comprises 32 primary questions, further divided into many subquestions. The initial NEHRS sample in 2021 included 10,302 office-based physicians. After screening for eligibility, 2037 physicians were confirmed to meet the following inclusion criteria: (1) office-based; (2) principally engaged in patient care activities; (3) nonfederally employed; (4) not in the specialties of anesthesiology, pathology, or radiology; and (5) younger than 85 years of age at the time of the survey. Among them, 1875 physicians fully completed the survey by responding to all key items, and these completed responses form the final analytic sample used in this study. All statistical analyses and interpretations in this study are based on the 1875 individual respondents who completed the full survey. The survey provides information not only about physicians' satisfaction, perceived quality of health care, and the percentage of patient visits conducted through telemedicine, but also includes data on physician gender, age, and clinical setting, among other details [19].

Dependent Variables and Independent Variables

The dependent variables examined in our study are office-based physicians' satisfaction with telemedicine technology use (Telemedsat), physicians' quality-of-health care evaluation in comparison to in-person service (Telemedqual), and percentage of patient visits through telemedicine as a proportion of overall ambulatory care visits. Examining these 3 dependent variables would provide us with a more comprehensive understanding of telemedicine use among ambulatory care physicians. While satisfaction reflects physicians' personal emotional response to the use of telemedicine tools, physicians' evaluation of health care quality captures physicians' retrospective, task-specific judgment about the functional equivalence of telemedicine relative to traditional care delivery [10,47]. The second measure requires physicians to directly compare their own performance, focusing on their perceived ability to maintain clinical standards in a telemedicine setting. The percentage of patient visits via telemedicine tools measures physicians' active engagement and comfort with telemedicine tools while interacting with patients [11,12,48].

These variables collectively enable us to evaluate the experience, performance, and behavioral adoption of telemedicine tools among ambulatory care physicians. Table 1 presents the descriptive statistics of these 3 dependent variables along with the independent and control variables.

Variables and descriptions	Value
Other setting	554 (29.65)

[a]Telemedsat: physicians' satisfaction (ordinal variable measured on a 5-point Likert scale).

[b]Telemedqual: physicians' evaluation of health care quality (ordinal variable measured on a 5-point Likert scale).

[c]Telemedpct: percentage of patient visits via telemedicine (ordinal variable measured on a 5-point Likert scale).

[d]SumT: total number of telemedicine tools each physician used (continuous variable).

[e]Distribution of single-tool users: T1 only=121 (7.44%), T2 only=165 (10.15%), T3 only=175 (10.76%), T4 only=77 (4.74%).

[f]T1: telephone audio (binary variable).

[g]T2: videoconference software with audio (eg, Zoom, Ibex, FaceTime; binary variable).

[h]T3: telemedicine platforms not integrated with electronic health records (eg, Doxy. me; binary variable).

[i]T4: telemedicine platforms integrated with electronic health records (eg, updating clinical documentation during a telemedicine visit; binary variable).

[j]T1T2: physicians who use T1 and T2 simultaneously—binary variable (the following variables are expressed in the same way as this).

[k]Telemedbarrier1: limited internet access or speed issues (binary variable).

[l]Telemedbarrier2: telemedicine platform not easy to use or did not meet physician's needs (binary variable).

[m]Telemedbarrier3: telemedicine is not appropriate for physician's specialty or type of patients (binary variable).

[n]Telemedbarrier4: limitations in patients' access to technology (eg, smartphone, computer, tablet, internet; binary variable).

[o]Telemedbarrier5: patients' difficulty using technology or telemedicine platform (binary variable).

[p]Facilitator: improved reimbursement and relaxation of rules related to use of telemedicine visits (binary variable).

[q]Physex: physicians' sex (binary variable).

[r]Phyage50: physicians' age group (binary variable).

[s]Speccat: physicians' specialty type (multinomial variable).

[t]Numofphy: number of physicians working in the facility (ordinal variable).

[u]Setting: the nature of the practice setting (binary variable).

Independent variables include 4 telemedicine tools: telephone audio (T1); videoconference software with audio (T2; eg, Zoom, Ibex, and FaceTime); telemedicine platforms not integrated with EHR (T3; eg, Doxy.me); and telemedicine platforms integrated with EHR (T4; eg, updating clinical documentation during a telemedicine visit). We counted the total number of telemedicine tools each physician uses and considered them a singular construct (SumT). We also conducted further analysis on different combinations of telemedicine tools (TelemedCombination). For example, physicians used both telephone audio and videoconference software with audio (T1T2), or they simultaneously used telephone audio, videoconference software with audio, and telemedicine platforms not integrated with EHR (eg, Doxy.me; T1T2T3), among other combinations. Notably, in the survey, physicians were asked to indicate which telemedicine tools they used by selecting from a list of 4 options, with no restrictions or dependencies among the tools. This means that each tool could be adopted independently of the others and was not mutually exclusive.

We also consider a set of relevant control variables, including physicians' sex (Physex), physicians' age group (Phyage50), physicians' specialty type (Speccat), number of physicians working in the facility (Numofphy), the nature of the practice (Setting), and perceived barriers and facilitators to telemedicine tools usage. Perceived barriers when using telemedicine tools can be categorized into 5 groups, including limited internet access and speed issues (Telemedbarrier1), platforms that are difficult to use or fail to meet physicians' needs (Telemedbarrier2), telemedicine may not be suitable for specific specialties or patient types (Telemedbarrier3), limited access to technology for patients (eg, smartphones, computers, tablets, or the internet; Telemedbarrier4), and the difficulties patients experience in navigating telemedicine platforms (Telemedbarrier5). A notable facilitator for telemedicine adoption is the ease of reimbursement for telemedicine visits through third-party providers (Facilitator). To address potential endogeneity concerns, we control physicians' attitude toward innovation (Telemedbarrier2), patients' attitude toward telemedicine (Telemedbarrier3 and Telemedbarrier4), policy factors (Facilitator), and organizational factors (Numofphy and Setting).

Data Analysis

Telemedicine's impact on physicians' satisfaction, quality of care, and percentage of patients' visits are ordinal variables. Thus, we used the ordered logit regression model and the ordered probit regression model (for checking the robustness of our results) to examine the effects of telemedicine on 3 dependent variables, while controlling for other variables that might influence these variables.

$$y_i = \beta_0 + \beta_1 SumT_i + \gamma_1 Telemedbarrier1_i \gamma_2 Telemedbarrier2_i + \gamma_3 Telemedbarrier3_i + \gamma_4 Telemedbarrier4_i + \gamma_5 Telemedbarrier5_i + \gamma_6 Facilitator_i + \gamma_6 Physex_i + \gamma_7 Phyage50_i + \gamma_8 Speccat_i + \gamma_9 Numofphy_i + \gamma_{10} Setting_i + \varepsilon_i \textbf{(1)}$$

$$y_i = \beta_0 + \beta_1 T1_i + \beta_2 T2_i + \beta_3 T3_i + \beta_4 T4_i + \gamma_1 Telemedbarrier1_i \quad \gamma_2 Telemedbarrier2_i + \gamma_3 Telemedbarrier3_i + \gamma_4 Telemedbarrier4_i + \gamma_5 Telemedbarrier5_i + \gamma_6 Facilitator_i + \gamma_6 Physex_i + \gamma_7 Phyage50_i + \gamma_8 Speccat_i + \gamma_9 Numofphy_i + \gamma_{10} Setting_i + \varepsilon_i \textbf{(2)}$$

XSL•FO
RenderX

$$y_i = \beta_0 + \beta_1 TelemedCombination_i + \gamma_1 Telemedbarrier1_i \gamma_2 Telemedbarrier2_i + \gamma_3 Telemedbarrier3_i + \gamma_4 Telemedbarrier4_i + \gamma_5 Telemedbarrier5_i + \gamma_6 Facilitator_i + \gamma_6 Physex_i + \gamma_7 Phyage50_i + \gamma_8 Speccat_i + \gamma_9 Numofphy_i + \gamma_{10} Setting_i + \varepsilon_i \textbf{(3)}$$

For each equation, y_i represents the physician's satisfaction level, physician's quality valuation of using telemedicine, and the percentage of patients visit via telemedicine, respectively. As for equation 3, $TelemedCombination_i$ represents the 11 types of combination of telemedicine tools, including T1T2, T1T3, T1T4, T2T3, T2T4, T3T4, T1T2T3, T1T2T4, T1T3T4, T2T3T4, and T1T2T3T4.

Correlation Analysis

Phi (ϕ) correlation coefficients were used to assess the correlations among the binary independent variables (T1, T2, T3, and T4). As shown in Table 2, the correlations were weak, suggesting that the independent variables were free from the concerns of multicollinearity.

Table 2. Correlation analysis (phi correlation coefficients and 2-tailed *P* value) among the independent variables. Phi coefficients (ϕ) were used because both variables were dichotomous (binary).

Variables	T1[a]	T2[b]	T3[c]	T4[d]
T1				
ϕ	1.00	0.15[e]	–0.03	0.07[e]

[a]T1: telephone audio.

[b]T2: videoconference software with audio.

[c]T3: telemedicine platforms not integrated with electronic health records.

[d]T4: telemedicine platforms integrated with electronic health records.

[e]The correlation is significant at a significance level of .01 (2-tailed).

[f]N/A: not applicable.

Results

Inferential Statistics

We first used the ordered logit regression model to investigate the effects on each dependent variable (Table 3). We then used an ordered probit regression model to assess the robustness of our estimations (Multimedia Appendix 2).

XSL•FO
RenderX

Table 3. Estimated coefficients and SEs for all 3 dependent variables obtained from the ordered logit regression model. Effects of control variables are excluded to conserve space. We used 11 different ordered logit regression models for our 11 different bundles of telemedicine tools: T1T2, T1T3, T1T4, T2T3, T2T4, T3T4, T1T2T3, T1T2T4, T1T3T4, T2T3T4, and T1T2T3T4.

[a]SumT: total number of telemedicine tools each physician used.

[b]T1: telephone audio.

[c]T2: videoconference software with audio (eg, Zoom, Ibex, FaceTime).

[d]T3: telemedicine platforms not integrated with electronic health records (eg, Doxy. me).

[e]T3: telemedicine platforms integrated with electronic health records (eg, updating clinical documentation during a telemedicine visit).

[f]T1T2: physicians who use T1 and T2 simultaneously (the following variables are expressed in the same way as this).

[g]The coefficients for the telemedicine bundles are larger than those for the individual telemedicine tools, and the associations are statistically significant, suggesting that telemedicine tools function complementarily when used as bundles.

[h]The coefficients for the telemedicine bundles are smaller than those for the individual telemedicine tools, and the associations are statistically significant, suggesting that these bundles function as competing rather than complementary tools.

[i]The number of observations varies because each dependent variable, independent variable, and control variable is measured independently and may contain some null or missing values.

We identify the complementary versus competing effects of telemedicine tool bundles based on the relative magnitude of their estimated coefficients in the ordered logit and ordered probit regression models, where the dependent variables are physicians' satisfaction, physicians' evaluation of health care quality, and patients' visit percentage. When the coefficients for the telemedicine bundles exceed those for the individual telemedicine tools, the statistically significant associations suggest that the tools function complementarily when used in combination. For example, regarding the results of the ordered logit regression model, the coefficient of the T1T2 bundle (β=.32; *P*=.001) is higher than that of T1 (β=.24; *P*=.02) and T2 (β=.29; *P*=.004), indicating a complementary effect for this bundle (T1T2) in enhancing physicians' satisfaction.

Conversely, a bundle is considered competing when its coefficient is significant but lower in value than the coefficients of any of the individual telemedicine tool, suggesting potential competition among tools. For example, the coefficient of the T1T3 bundle (β=.305; *P*=.004) is higher than the coefficient of T1 (β=.24; *P*=.02) but lower than that of T3 (β=.311; *P*=.003), suggesting a competing relationship between these technologies.

We also calculated marginal effects at the mean for each outcome level of the dependent variables to interpret our results meaningfully. Table 4 reports the marginal effects on physicians' satisfaction levels, Table 5 reports the marginal effects on physicians' quality-of-health care evaluation, and Table 6 reports the marginal effects on the percentage of patients visiting via telemedicine.

[a]SumT: total number of telemedicine tools each physician used.

[b]T1: telephone audio.

[c]T2: videoconference software with audio (eg, Zoom, Ibex, and FaceTime).

[d]T3: telemedicine platforms not integrated with electronic health records (eg, Doxy. me).

[e]T4: telemedicine platforms integrated with electronic health records (eg, updating clinical documentation during a telemedicine visit).

[f]T1T2: physicians who use T1 and T2 simultaneously—binary variable (the following variables are expressed in the same way as this).

According to the results in Table 4, parameter estimates for the aggregate model (equation 1) suggest that the summative telemedicine tools have a significant positive relationship with physicians' satisfaction levels. To be precise, a unit increase in telemedicine tools is associated with approximately 1.8, 2.8, and 1.4 percentage point decreases in the predicted probability of physicians being at the "very dissatisfied," "somewhat dissatisfied," and "neither satisfied nor dissatisfied" level of satisfaction. However, a unit increase in telemedicine tools is associated with a 1.9 percentage point increase in the predicted probability of physicians being "somewhat satisfied" and a 4.2 percentage point increase in the predicted probability of physicians being "very satisfied," respectively.

According to Table 5, the summative telemedicine tools also showed a significant positive association with physicians' evaluation of telemedicine service quality. The results in Table 5 suggest that a unit increase in telemedicine tools is associated with a decrease of 1.2, 3.9, and 1.2 percentage points in the predicted probability for physicians' evaluation of telemedicine service quality to be at the level of "not at all," "to a small extent," and "some extent." Contrary to that, a unit increase in telemedicine tools is associated with an increase of 5.2 and 1.2 percentage points in the predicted probability for physicians' evaluation of health care to be at the level of "to a great extent and fully."

The results in Table 6 indicate that a unit increase in telemedicine tools is associated with a decrease of 0.3 and 5.5 percentage points in the predicted probability that the percentage of patients visiting via telemedicine will be at the level of "none" or "<25%." In contrast, a unit increase in telemedicine tools is associated with increases of 2.5, 1.5, and 1.8 percentage points in the predicted probability for this dependent variable to be "25%-49%," "50%-74%," and "≥75%," respectively.

Parameter estimates for the disaggregate model (equation 2) suggest that each individual telemedicine tool has a significant positive relationship with physicians' satisfaction level and physicians' quality of health care evaluation (Tables 4 and 5). However, while T1 and T3 showed a significant positive association with the percentage of patients visiting via telemedicine, T2 and T4 showed no such relationship (Table 6).

Regarding the parameter estimates for all the different telemedicine tools combination models (equation 3), we found that each combination of telemedicine tools shares a significant positive association with the physician's satisfaction level (Table 4). However, the combinations of T3T4, T1T3T4, and T2T3T4 do not share any significant association with physicians' quality-of-health care evaluation (Table 5). Additionally, the combination of T1T4, T2T4, T1T2T4, and T2T3T4 also does not share any significant association with the percentage of patients' visits via telemedicine (Table 6).

Additional Tests

We also considered the possibility of a moderating effect of patient visits via telemedicine tools, given the time period during which the data were collected (the pandemic era). This situation may have been caused by patients' limited access to in-person care rather than the bundle of technologies that the physician was using. To test this possibility, we conducted an additional analysis. According to Table 7, the results indicate that the moderator yielded no statistically significant interaction effects.

[a]SumT: total number of telemedicine tools each physician used.

[b]Telemedpct: percentage of patient visits via telemedicine.

[c]T1: telephone audio.

[d]T2: videoconference software with audio (eg, Zoom, Ibex, and FaceTime).

[e]T3: telemedicine platforms not integrated with electronic health records (eg, Doxy. me).

[f]T4: telemedicine platforms integrated with electronic health records (eg, updating clinical documentation during a telemedicine visit).

[g]T1T2: physicians who use T1 and T2 simultaneously (the following variables are expressed in the same way as this).

[h]The number of observations varies because each dependent variable, independent variable, and control variable is measured independently and may contain some null or missing values.

Discussion

Principal Results

Our study addresses the complementary versus competing nature of telemedicine tools. Our empirical analysis reveals that although both individual and combined uses of telemedicine tools positively affect physicians' satisfaction, quality of health care evaluation, and the percentage of patients' visits via telemedicine, various telemedicine tools compete rather than complement each other. Our study suggests that the relationships among telemedicine tools are not always positive; instead, their combined use can produce either complementary or competing effects, depending on how their functionalities interact within the context of physicians' clinical workflows.

Interpretation of Findings

For physicians, we found that various combinations of telemedicine tools significantly influence their overall satisfaction and partially affect their evaluation of health care quality. These findings are consistent with prior studies reporting generally high physician satisfaction and perceived usefulness of telemedicine [49,50], as well as comparable quality of care between telemedicine and in-person consultations [51]. However, these earlier studies did not examine how different combinations of telemedicine tools shape physicians' satisfaction and quality-of-care assessments. Our study extends this understanding by highlighting how the complementary use of telemedicine tools can influence these outcomes. Our findings suggest that satisfaction and the perceived quality of care are influenced by the coherence of the technology stack, with videoconferencing software (T2) acting as a powerful core. Bundles that include T2 create a complementary effect by providing a rich, high-fidelity communication channel essential for clinical assessment. The ability to observe visual cues and nonverbal information is fundamental to accurate diagnosis and building effective communication between physicians and patients. Notably, the combination of T2 with an integrated EHR (T4) represents the ideal modern workflow, creating an efficient interaction environment where the physician can focus on the patient through a high-quality video interface while the EHR seamlessly handles documentation. Even a simpler T2 and T1 (telephone) bundle is complementary, as the telephone serves as a reliable backup that reduces physician worry about technical failures and connectivity disruptions.

Conversely, bundles lacking video-based technological support generate a competing effect, characterized by cognitive overload and workflow fragmentation. Combinations such as T1 with platform T3 or T4 force physicians to split their attention between a low-fidelity audio call and a separate, complex software interface. Furthermore, the combination of 2 different platforms (T3 + T4) exemplifies competing technologies and cognitive overload, leading to technological redundancy, confusion, and a fragmented patient management process that detracts from the physician's core responsibilities [52-54].

From the perspective of MST, these findings can be interpreted in terms of differences in media capabilities and process alignment. Videoconferencing (T2) provides high levels of immediacy of feedback, variety of symbols, and transmission velocity, enabling physicians to convey and interpret complex medical information effectively. When such rich media are integrated with complementary systems (like EHRs), they enhance conveyance and convergence processes. Thus, both information exchange and shared understanding result in higher satisfaction and perceived quality. In contrast, bundles that rely on low-synchronicity tools (eg, telephone or nonintegrated platforms) fail to support these communication processes, increasing the cognitive effort required to maintain clinical

XSL•FO
RenderX

coherence and reducing the perceived effectiveness of telemedicine-oriented patient visits.

Additionally, the combination of T3 (nonintegrated telemedicine platforms) and T4 (EHR-integrated telemedicine platforms) exhibits a competing effect on physicians' satisfaction and does not significantly improve care quality, which may be due to their underlying system architecture. T3 platforms, such as Doxy.me, operate independently from the EHR system and function primarily as stand-alone communication tools. In contrast, T4 tools are embedded within the EHR environment, supporting real-time documentation and patient data access during telemedicine consultations. When these tools are used in combination, as in T3T4 or T1T3T4, physicians are required to switch between 2 unconnected noncompatible systems, which disrupts workflow and necessitates repeated actions such as reentering patient information or clinical notes [52-54]. This lack of interoperability increases the administrative and information searching burden and undermines efficiency.

In contrast to physicians' satisfaction and quality evaluation outcomes, physicians report a higher percentage of patient visits via telemedicine when the technological configuration is broader and more inclusive, incorporating multiple platforms (eg, T2T3, T3T4, T1T2T3T4). These complementary effects arise because more comprehensive bundles enable physicians to engage in a broader range of patient types and clinical scenarios through various modalities. For example, combining video (T2) and telemedicine platforms (T3 or T4) allows clinicians to conduct both structured and flexible consultations, manage follow-ups, and accommodate patients with differing technical capacities or conditions. From a physician's standpoint, such diversity enhances operational flexibility and reduces barriers to providing telemedicine services, thus naturally increasing the proportion of visits conducted remotely.

However, simpler 2-tool bundles (eg, T1T2 and T1T3) show a competing effect on the percentage of patient visits via telemedicine. There might be 2 reasons leading to this competing effect. From the physicians' perspective, while these configurations are easy to operate, they lack the integration required to sustain a consistent telemedicine workflow across different patient groups. A telephone-plus-video, or telephone-plus-stand-alone-platform setup without an integrated EHR may be functional for ad hoc consultations but insufficient for record-keeping or health care information exchange. From the patients' perspective, they may not perceive much difference between an in-person visit and interacting with physicians only via telephone or videoconference. Consequently, many patients may still prefer face-to-face consultations, as they feel more direct and personal.

Interestingly, combinations that include EHR-integrated tools (T4), such as T1T4, T2T4, T1T2T4, or T2T3T4, do not significantly impact the percentage of patient visits via telemedicine. We believe there are 2 main reasons for this outcome. First, physicians must complete patients' electronic records while simultaneously communicating with patients via video or phone, which makes each consultation more time-consuming [55]. As a result, the total number of telemedicine visits that can be completed in a day decreases. Second, the log-in and verification procedures add complexity to the communication process between physicians and patients, leading physicians to prefer phone consultations (audio call or FaceTime call) for many simple cases. Consequently, the combination of T4 with other tools shows no statistically significant impact on the overall percentage of telemedicine visits.

We also conducted an additional test to investigate the potential moderating role of patient visits via telemedicine tools, as data collected during the pandemic period may reflect patients' limited choices rather than the effect of physicians' technology bundles. However, our results do not support this moderation effect. We believe there are 2 main reasons for this. First, based on prior studies (eg, Moulaei et al [48], Reed et al [40], and Tzeng et al. [56]), patient visits via telemedicine tools are consistently conceptualized as an outcome shaped by demographic, contextual, and technological factors. Second, theoretically, drawing on MST [43], we believe that patient telehealth usage reflects media-task fit and can be better understood as a behavioral outcome. To ensure theoretical and empirical coherence, we therefore treat the percentage of patient visits via telemedicine tools as one of our dependent variables.

Limitations and Future Directions

One limitation of this study is the use of a self-reported measure to capture physicians' perceived quality of care, which introduces potential bias due to self-reporting. Although the survey item aimed to minimize this bias by prompting a direct comparison between telemedicine visits and in-person visits, the subjective nature of the measure limits the objectivity of our findings. Future research should apply objective clinical performance indicators or third-party assessments to validate physicians' evaluations.

Another limitation of this study is that the telemedicine tool usage variable does not capture the frequency or intensity of use for each tool. Thus, our study cannot determine whether physicians' satisfaction primarily comes from one tool or from a combination of tools. Our analysis, therefore, treats tool combinations as reported usage bundles. Future research should incorporate more data on usage frequency, duration, or physician preference to capture the priority of individual telemedicine tools. This would enable researchers to investigate the effects of specific technologies within multitool combinations and gain a deeper understanding of how different tools contribute to physicians' satisfaction.

Due to data limitations, our study cannot thoroughly test the possibility of endogenous variables. Although we have attempted to identify any possible source of missing variable bias theoretically, we have not been successful in doing so. Future research should investigate such possibilities by identifying a suitable instrumental variable. Our empirical analysis used data from the national survey conducted by the NCHS at the CDC [16-19], which notably excludes several specialties, specifically radiology, pathology, and anesthesiology. Consequently, the applicability of our findings to these clinical contexts is limited. This exclusion stems from the inherently procedural and in-person nature of these fields (eg, anesthesia administration and diagnostic imaging), which

XSL•FO
RenderX

may restrict the deployment of current telemedicine tools. We consider this data limitation as one of the key limitations of our research. Future research should incorporate these specialties to fully assess the generalizability of telemedicine usage across the broader clinical spectrum.

Last, this study focuses exclusively on the perspectives of ambulatory care physicians, which limits the ability to assess how tool combinations affect patient-centered outcomes or patient satisfaction. Future research should collect patient-centered data to build a more comprehensive understanding of the effectiveness and acceptance of telemedicine tools from the patient's perspective.

Conclusions

Our study contributes to practice that enhances understanding of how telemedicine tools can be effectively used in health care, particularly in postpandemic scenarios. Each tool offers unique advantages, so using the right tool for the right situation is not just a choice, but a crucial decision that can significantly improve both physician satisfaction and patient engagement in telemedicine. This insight provides clear recommendations to providers and platform developers, emphasizing the key to the success of telemedicine implementation—creating a seamless experience for physicians. Such a system needs to be designed in a manner that ensures the complementary behavior of different tools based on physicians' specific demands, highlighting the complexity of various clinical and communicative tasks.

Abstract

Background: Artificial intelligence/machine learning (AI/ML) has revolutionized the health care industry, particularly in the development and use of medical devices. The US Food and Drug Administration (FDA) has authorized over 878 AI/ML–enabled medical devices, reflecting a growing trend in both quantity and application scope. Understanding the distinct challenges these devices present in terms of FDA regulation violations is crucial for effectively avoiding recalls. This is particularly pertinent for proactive measures regarding medical devices.

Objective: This study explores the impact of AI/ML on medical device recalls, focusing on the distinct causes associated with AI/ML–enabled devices compared with other device types. Recall information associated with 510(k)-cleared devices was obtained from openFDA. Three recall cohorts were established: “All 510(k) devices recall,” “software-related devices recall,” and “AI/ML devices recall.”

Methods: Recall information for 510(k)-cleared devices was obtained from openFDA. AI/ML-enabled medical devices were identified based on FDA listings. Three cohorts were established: “All 510(k) devices recall,” “software-related devices recall,” and “AI/ML devices recall.” Root cause analysis was conducted for each recall event.

Results: The results indicate that while the top 5 recall root causes are relatively similar across the 3 control groups, the proportions vary, with AI/ML devices showing a higher impact for 87% of all recalls. Design and development–related factors play a significant role in recalls of AI/ML devices with root causes related to device design and software design accounting for 50% of recalls, emphasizing the importance of thorough planning, user feedback incorporation, and validation during the development process to reduce the probability of recalls. In addition, changes in software, including design changes and control changes, also contribute substantially to recalls in AI/ML devices.

Conclusions: In conclusion, this study provides valuable insights into the unique challenges and considerations associated with AI/ML–enabled medical device recalls, offering guidance for manufacturers to enhance verification plans and mitigate risks in this rapidly evolving technological landscape.

KEYWORDS

AI/ML-enabled medical device; recall; SaMD; 510(k); FDA; Food and Drug Administration; artificial intelligence/machine learning

Introduction

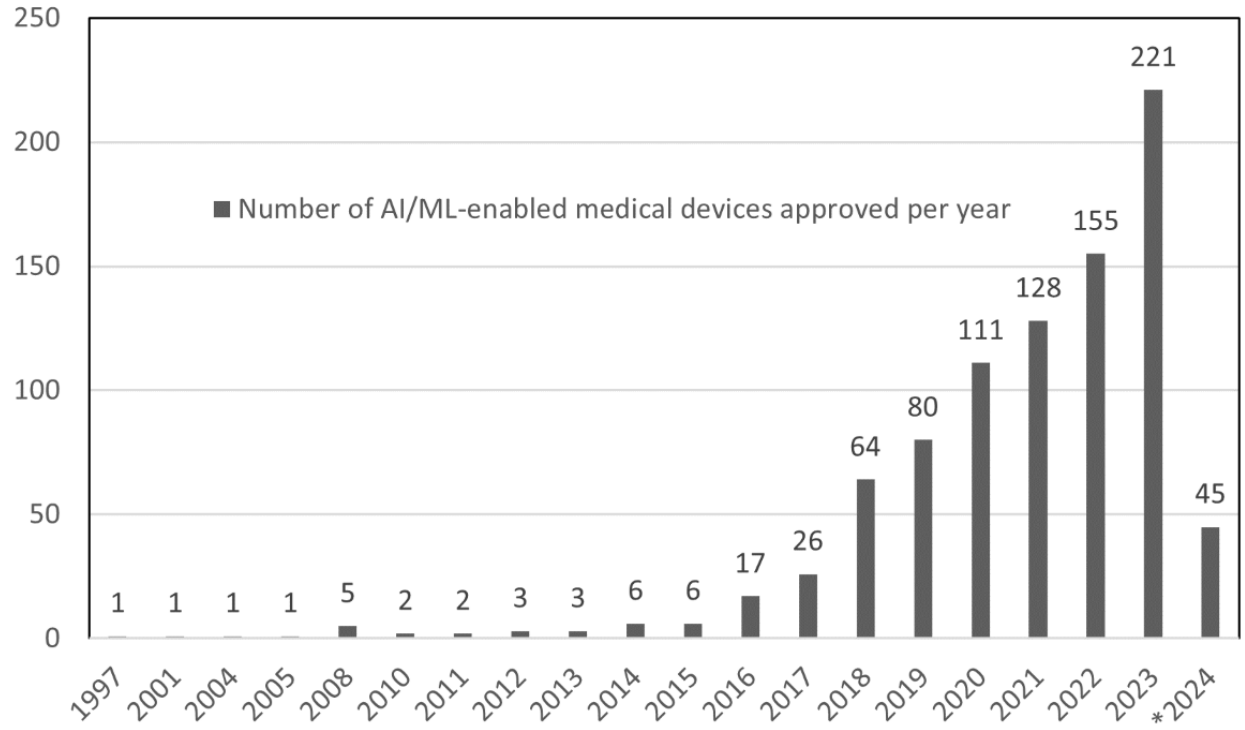
Background

Artificial intelligence/machine learning (AI/ML) has significantly impacted the health care industry, particularly in the development and use of medical devices. Key contributions include enhancing diagnostic accuracy through the analysis of medical imaging data, enabling predictive analytics for disease outcomes, personalizing treatment plans based on patient characteristics, facilitating remote patient monitoring, expediting drug discovery, and improving surgical procedures through robotics [1,2]. In addition, AI aids in optimizing health care management processes, enhancing cybersecurity for patient data

XSL•FO
RenderX

protection, and supporting continuous learning and improvement in medical devices.

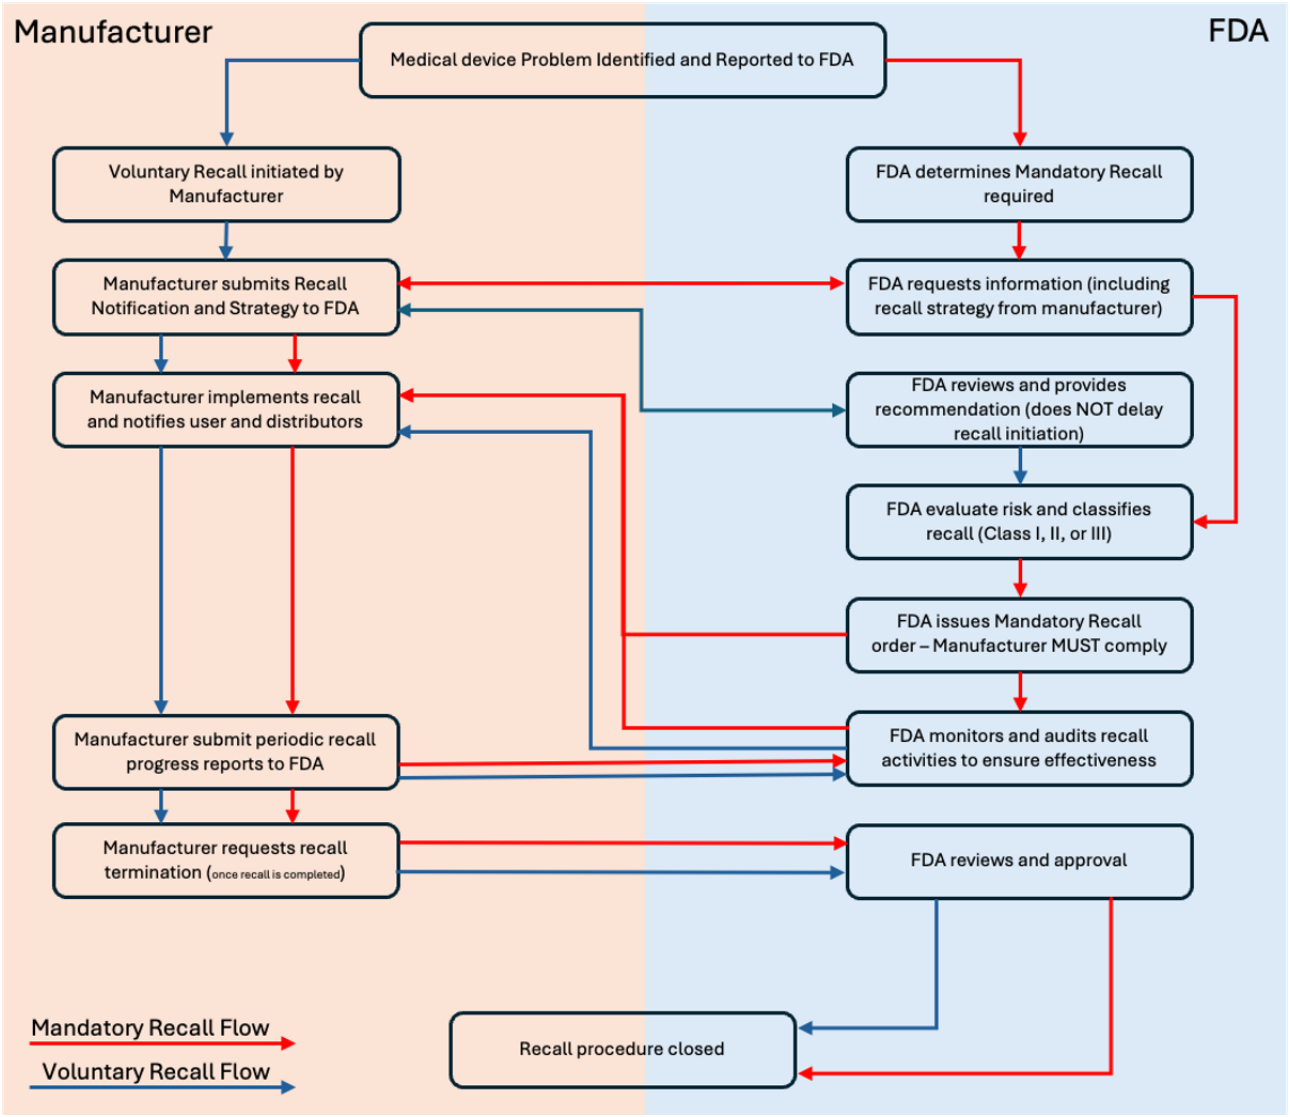
From 1997 to March 2024, the US Food and Drug Administration (FDA) has authorized over 878 Class II AI/ML–enabled medical devices (refer to (Multimedia Appendix 1)). The quantity may not be large, but from the annual registration records, it can be observed that such products are increasing year by year (refer to Figure 1).



At the same time, the scope of application is also expanding. This trend is reflected in the classification product codes covered by the registered products [2]. Benjamens et al [1] and Zhu et al [2] have successively pointed out in their research that the number of registered AI/ML products has been continuously increasing since 2010. Zhu et al [2] also mentioned that 82% of the registered AI/ML products are concentrated in the two medical specialties of radiology and cardiology, indicating a significant use of digital medical data (such as digital medical imaging data and electrocardiograms) and relevant applications of pattern recognition in diagnosis.

As the FDA approves more and more AI/ML–enabled medical devices, it is critical to understand the unique challenges they pose when it comes to recalls, which are for violations of FDA regulations. This study examines recall data from the FDA, identifying key causes for recalls specifically associated with AI/ML–enabled medical devices. Proactive measures taken for medical devices, Wallace and Kuhn [3] analyzed system failures caused by software faults using recall information and proposed insights for improving software development. Although their analysis was not specifically focused on AI/ML products, FDA data show that one-third of medical devices operated using software are recalled due to software failures. This noteworthy phenomenon has inspired our research thinking.

Recall is a proactive measure aimed at removing or rectifying products that violate laws enforced by the FDA. It is a voluntary action taken by manufacturers and distributors who recognize their responsibility to safeguard public health from products posing risks of injury, significant deception, or other defects [4-7]. Recalls are initiated when a medical device is found to be defective, poses a risk to health, or exhibits both defects and health risks [8]. In rare cases where a manufacturer or importer neglects to voluntarily recall a device jeopardizing health, the FDA may issue a recall order to the manufacturer under 21 Code of Federal Regulations (CFR) 810.



FDA 21 CFR 7 defines the recall as “a firm’s removal or correction of a marketed product that the FDA considers to be in violation of the laws it administers and against which the agency would initiate legal action, for example, seizure. Recall does not include a market withdrawal or a stock recovery” [9] (refer to Figure 2). Although recalls are intended to ensure patient safety, Zipp [8] points out that the system for initiating recalls often takes a long time to start the recall process [10]. Zipp [8] also uses the example of the recall of Philips sleep apnea ventilator devices to illustrate this situation and proposes using a Unique Device Identifier as a solution to track product flow and expedite the recall process.

Objectives

This study delves into the recalls linked to AI/ML–enabled medical devices, aiming to discern prevalent recall types unique to these products through comparative analysis with recalls from diverse device types. By scrutinizing recall data, the research endeavors to equip manufacturers with insightful information, enabling them to undertake a more comprehensive evaluation before product introduction. This proactive approach entails implementing measures to preempt root causes associated with recalls, thus mitigating the likelihood of recall incidents. FDA medical device recalls serve as a critical barometer reflecting the intricate landscape of medical device innovation challenges. Each recall unveils potential areas of vulnerability within the innovation process, shedding light on shortcomings in design, development, and regulatory oversight. Recalls highlight the delicate balance between pushing boundaries for technological advancement and ensuring safety and efficacy standards are met. They underscore the complexities of integrating cutting-edge technologies, such as AI/ML, into medical devices while maintaining regulatory compliance. Moreover, these recalls signal the need for continuous vigilance and adaptation in response to evolving risks and emerging technologies, emphasizing the dynamic nature of medical device innovation. As such, FDA recalls provide invaluable lessons for industry stakeholders, guiding them in navigating the intricate terrain of innovation while prioritizing patient safety and regulatory adherence.

Methods

Overview

Recall information associated with 510(k)-cleared devices was downloaded from openFDA, a publicly accessible data platform provided by the US FDA to facilitate access to structured regulatory datasets, including medical device recalls [11,12]. AI/ML–enabled medical devices were identified based on the list published by the FDA [13]. These devices were manually screened by the FDA and do not have a specific code to track them. This list comprises medical devices that incorporate AI and ML, based primarily on the information provided within the summary descriptions of their marketing authorizations. The root cause description associated with each recall event was used to characterize the particular recall. Some recall events may be associated with more than one root cause.

XSL•FO
RenderX

In 21 CFR 7.46 (firm-initiated recall), when the initiating firm decides to remove or correct distributed products, reasons for removal or correction must be provided. The Guidance of Initiation of Voluntary Recalls Under 21 CFR Part 7, Subpart C mentions referencing 21 CFR 820.100(a)(2), which requires procedures for implementing corrections or preventive actions to include an investigation of the causes for nonconformities related to the product, processes, and quality systems. Furthermore, in the FDA regulatory procedures manual, chapter 7 (recall procedures) states that when recalls are classified as Class I or significant Class II recalls, the need for an establishment inspection should be assessed to determine the root cause of the problem and document any potential regulatory actions (7-5-1, 3 Establishment Inspection) [9,14]. Investigation and analysis of the root cause, as outlined in the aforementioned FDA requirements, are a crucial part and one of the important factors for the firm's decision to remove or correct products. In practice, most companies' root cause statements align with FDA-recognized categories because they rely on the same industry-accepted terminology. However, the actual analysis and conclusion come primarily from the manufacturer's quality management system. The FDA's role is to verify and ensure that the manufacturer's reasoning makes sense and adequately addresses public health concerns.

Three cohorts were established for comparison and analysis including "All 510(k) devices recall" cohort, "software-related devices recall" cohort and "AI/ML devices recall" cohort (refer to Table 1).

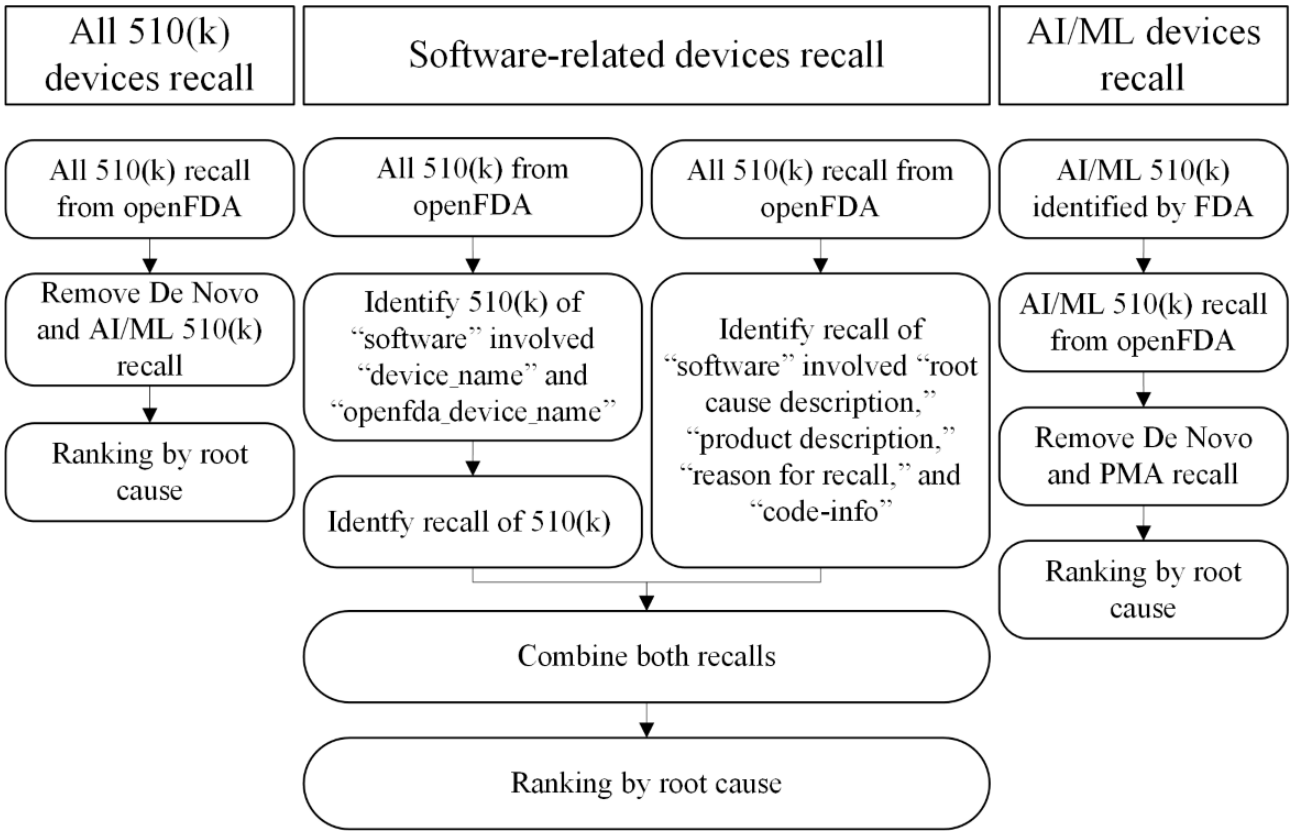
Data Processing



Each cohort required a specific analytical approach to accurately extract and rank recall events based on their causes. The following numbered list outlines the processes used to collect, filter, and analyze data to derive insights into the prevalence and nature of recalls within each group (refer to Figure 3):

1. All 510(k) devices recall: the "All 510(k) Devices Recall" cohort begins by gathering all 510(k) medical device recall events from the openFDA database [11]. We specifically exclude recalls related to AI/ML devices and De Novo devices to focus on traditional 510(k) recalls. Post exclusion, the recalls are ranked by the frequency of each root cause, helping identify the most common issues within this group.
2. Software-related devices recall: this cohort targets recalls specifically linked to software issues in medical devices. Due to the absence of a direct filter for software-related issues in openFDA, we apply two distinct criteria to accurately capture relevant recalls:
   - Criterion 1: we search within the "device_name" and "openfda_device_name" fields for entries that include the term "Software." Recalls identified under this criterion were then sequenced by the prevalence of each root cause.
   - Criterion 2: we further refine our search by examining the "root cause description," "product description," "reason for recall," and "code-info" fields for mentions of "Software." Similar to the first criterion, these recalls were then sequenced by root cause prevalence.

   After identifying and ranking recalls based on both criteria, we merge the results to form a comprehensive sequence of software-related device recalls.
1. AI/ML devices recall: the "AI/ML Devices Recall" cohort consists of recalls involving AI/ML–enabled devices as identified by the FDA [13]. Like the first cohort, we exclude any recalls pertaining to De Novo and premarket approval devices to solely focus on AI/ML 510(k) recalls. These are then ranked by root cause based on occurrence frequency.

XSL•FO
RenderX

Figure 3. The process for cohort distinction. AI: artificial intelligence; FDA: US Food and Drug Administration; ML: machine learning; PMA: premarket approval.

Ethical Considerations

All analyses were conducted using public data available on the FDA medical device databases and from openFDA. Therefore, ethics approval was unnecessary. This study does not include human subject information, primary data collection, or any form of experimentation involving individuals.

Results

The three cohorts presented in this study are as follows: the "All 510(k) devices recall" cohort includes 167,864 medical devices covering 4473 product codes with a total of 43,100 recalls and 42 root causes. The "software-related devices recall" cohort includes 3071 medical devices, covering 438 product codes with 9639 recalls and 42 root causes. The "AI/ML devices recall" cohort comprises 878 class II medical devices, covering 110 product codes with 162 recalls and 17 root causes (refer to Table 1).

Root Causes of Recalls

Recalls in both "All 510(k) devices recall" and "software-related devices recall" cohorts that are directly related to software have six common root causes: software design, software design change, software design manufacturing process, software change control, software manufacturing/software deployment, and software in the use environment. The number of recalls for each of these root causes is the same, indicating that the filtering criteria did not miss software-related 510(k) medical devices. In the "AI/ML devices recall" recalls related to software, there are only three root causes: software design, software change control, and software design change. When summing up all software-related root causes, "All 510(k) devices recall" has 3715 recalls, accounting for 9%, "software-related devices recall" has 3,715 recalls, accounting for 39%, and "AI/ML devices recall" has 75 recalls, accounting for 46% (refer to Table 2 and Figures 4-6).

Looking at the number of recalls for each root cause, the top five root causes for "All 510(k) devices recall" are other/6695/16% (recall root cause/number of recall/% of all 510(k) devices recall), device design/6207/14%, nonconforming material-component/4730/11%, process control/4717/11%, and under investigation by firm/4011/9%, totaling 26,360 recalls or 61%. These do not include software-related root causes. For "software-related devices recall," the top 5 root causes are software design/3103/32%, device design/1405/15%, other/1115/12%, nonconforming material-component/775/8%, and under investigation by firm/608/6%, totaling 7006 recalls or 73%. In "AI/ML devices recall," the top five root causes are software design/68/42%, under investigation by firm/37/23%, device design/13/8%, process design/11/7%, and process control/11/7%, totaling 140 recalls or 86% (refer to (Multimedia Appendix 2)).

Figure 6. Number of recalls based on the root causes description for "artificial Intelligence/machine learning devices."

Specific Root Causes

If the recalls with software-related root causes are added to the top five root causes, the total recalls for "All 510(k) devices recall" reach 30,075, accounting for 70%, "software-related devices recall" reach 7618, accounting for 79%, and "AI/ML devices recall" reach 147, accounting for 91%. Excluding recalls with software-related root causes, the top five root causes for "All 510(k) devices recall" have 26,360 recalls, accounting for 61%, "software-related devices recall" have 3903 recalls, accounting for 40%, and "AI/ML devices recall" have 72 recalls, accounting for 44% (refer to Table 3 and Multimedia Appendix 3).

Furthermore, the first root cause for both "software-related devices recall" and "AI/ML devices recall" is software design with extremely high percentages of 32% and 42%, respectively. In "All 510(k) devices recall," software design still accounts for 6% of total recalls, ranking sixth. After excluding root causes with unclear definitions, such as other and under investigation by firm, and adding the recall quantities for the second-ranking root cause with significance in the three lists, which is device design, the combined percentage of software design and device design increases to 47% for "software-related devices recall" and 50% for "AI/ML devices recall" reaching half of the total recalls. For "All 510(k) devices recall," it also reaches 22%, surpassing one-fifth of the total recalls (refer to Table 3).

In terms of product categories, recalls of AI/ML–enabled devices and software-related devices are concentrated in Radiology with another significant category being Cardiovascular. This corresponds to the number of product registrations. Recalls of all 510(k) devices are distributed across a greater number of product categories. However, Radiology and Cardiovascular remain among the categories with higher recall numbers. In addition to these, Orthopedic, General Hospital, and Gastroenterology/Urology are categories with relatively higher recall numbers.

Recall with specific root causes	All 510(K) devices		Software-related devices		AI/ML devices	
	Recall	%	Recall	%	Recall	%
Recall amount of all root causes	43,100	100%	9369	100%	162	100%
Recall amount of all software related root cause	3715	9%	3715	39%	75	46%
Recall amount of top 5 recall root causes	26,360	61%	7006	73%	140	86%
Top 5+ all software related root causes	30,075	70%	7618	79%	147	91%
Top 5 - any software related root causes	26,360	61%	3903	40%	72	44%
Device design + software design	9310	22%	4508	47%	91	50%
Top 5 - (other + under investigation by firm)	15,654	36%	5283	55%	103	64%
Recall amount of change related root causes	2122	5%	495	5%	11	7%

Discussion

Principal Findings

This study investigated the underlying reasons behind recalls linked to AI/ML–enabled medical devices, pinpointing distinct causes compared with other device types. The first control group encompasses all recalls linked to either a 510(k) device. The second control group encompasses recalls tied to software.

Comparing the root causes and their corresponding recall quantities among the "All 510(k) devices recall," "software-related devices recall," and "AI/ML devices recall" groups, it's evident that the combined recall occurrences for the top five root causes accounted for over 60% across all cohorts [15]. The recall total for "software-related devices recall" even surpasses 73%, while "AI/ML devices recall" reaches 86%. Despite the inclusion of unclearly defined root causes such as "other" and "under investigation by firm" in the top 5, removing these 2 root causes still results in proportions of 36%, 55%, and 64% for "All 510(k) devices recall," "software-related devices recall," and "AI/ML devices recall," respectively. Although the definitions of products in the three control groups differ, it is interesting to note that if the top seven recall root causes are considered, the three groups are not far apart. The ranking of recalls varies slightly, and in the case of "AI/ML devices recall," process design replaces component design/selection [14]. Improving the top seven recall root causes can have a significant positive impact on recalls and is a topic worthy of further investigation (refer to Table 3).

Looking at recalls related to software, it is clear they constitute a high proportion in "software-related devices recall" and "AI/ML devices recall" accounting for 39% and 46%, respectively. The software design root cause alone accounts for 32% and 42%, respectively with a combined percentage of 82% and 91% for all software-related recall root causes in "software-related devices recall" and "AI/ML devices recall." Software design can be considered the primary recall root cause for both groups. When adding the device design factor to recalls, the total reaches close to half for both "software-related devices recall" and "AI/ML devices recall," especially in "AI/ML devices recall," where it surpasses half, reaching 50%. Including recalls related to process design and labeling design further increases the proportion to 58% [14]. These design and development-related factors leading to recalls likely represent inherent risks present during the product planning or design phase. The impact of these factors on "AI/ML devices recall" is notably higher than in the other 2 control groups. Considering experienced design and development engineers, incorporating user feedback, and implementing thorough validation during the development process could effectively reduce the probability of recalls.

Another group of root causes affecting recalls in "AI/ML devices recall" is related to changes, including software design change, software change control, process change control, vendor change control, and labeling change control. Although the quantities are relatively fewer with 4 root causes, they account for over a quarter (29.4%) of the total root causes, causing 7% of recalls. Compared with the 5% for "All 510(k) devices recall" and 5% for "software-related devices recall," this is relatively higher. Particularly in "AI/ML devices recall," where changes in corresponding software are relatively frequent, it is crucial for manufacturers to have comprehensive verification plans after any alterations.

XSL•FO
RenderX

The primary reasons for recalls in AI/ML medical devices include software design errors, nonconforming materials, inadequate process controls, and software implementation issues. Among these, software design errors are the most common, potentially leading to device malfunction, incorrect dosing, and compromised patient safety. Unlike traditional medical devices, AI/ML systems involve dynamic algorithms that evolve through data-driven learning, necessitating specialized validation processes beyond conventional static software testing [1,2]. Moreover, many AI/ML medical device recalls result from implicit assumptions made during algorithm design, such as dosage calculations or diagnostic thresholds. These assumptions must be explicitly identified, documented, and integrated into rigorous validation processes [4]. As a result, AI/ML–enabled medical devices present unique validation and quality assurance challenges, requiring continuous monitoring and adaptive regulatory frameworks to ensure their reliability and safety.

Furthermore, as AI/ML devices adapt postmarket based on new data, continuous market surveillance and real-time feedback loops are imperative to identify risks and respond proactively. Regulatory guidance increasingly emphasizes the necessity of robust monitoring systems, postmarket validation, and rapid recall readiness to address emerging problems [5,9]. These elements should be systematically incorporated into development lifecycle management plans for AI/ML–enabled medical devices.

Specifically, our analysis indicates that the most frequent root causes for AI/ML–enabled device recalls are software design errors, inappropriate software changes, inadequate process controls, and issues in software implementation. These factors can lead to critical patient safety impacts, including incorrect dosing, system malfunction, diagnostic errors, or device stoppage, with the potential for severe adverse health outcomes.

Based on the author's over 20 years of experience in testing, inspection, and certification of medical devices within the testing, inspection and certification industry, including work with authorized third-party organizations such as US FDA Accredited Person and EU (European Union) Notified Body, the author recommends that manufacturers adopt the following strategies to ensure the long-term safety and reliability of AI/ML–enabled medical devices:

1. Implement specialized validation frameworks, where AI/ML models undergo rigorous adversarial testing, real-world scenario validation, and continual performance monitoring, moving beyond reliance on premarket testing alone,
2. Establish ongoing market surveillance mechanisms, shifting regulatory focus toward total product lifecycle oversight to ensure AI systems remain effective as they evolve with new clinical data, and
3. Integrate user-centric risk mitigation practices, such as proactive feedback loops, to enable rapid adjustments and software updates that address emerging risks in clinical settings.

These strategies will better align regulatory oversight with the evolving nature of AI/ML technologies, ensuring both patient safety and long-term technology sustainability.

Limitation

This study has several limitations. First, the FDA currently does not have specific product codes or identification methods for Software as a Medical Device or software-related medical devices. Therefore, the data used in this study were derived from existing FDA data related to software to identify and analyze recall data for software-related medical devices as comprehensively as possible. Second, AI/ML–enabled devices also lack specific product codes or identification methods. Although the FDA manually updates its registry of AI/ML–enabled medical devices, this process is irregular, potentially leading to omissions in the data. These limitations restrict the ability to fully capture and analyze the unique challenges of AI/ML–enabled medical devices, such as specialized algorithm validation, handling of implicit assumptions, and algorithm performance variability. In addition, the publicly available FDA recall databases lack comprehensive information on software-specific faults, manufacturer-specific internal verification processes, and the complexity inherent in AI/ML technologies, including algorithm adaptability over time, real-world performance drifts, and user interaction dynamics.

Future Work

To address these limitations, future research should incorporate direct interactions with device manufacturers, internal company data, qualitative insights from developers, and longitudinal analyses to better explore these challenges and validate effective risk management strategies [10,14,16,17]. Based on the results of this study, we also plan to further investigate each recall of AI/ML–enabled medical devices and the reported reasons behind them to conduct a more in-depth analysis.

We hope to systematically deduce the real factors leading to recalls and compare them with current regulatory requirements to see if there is a need to adjust or strengthen regulatory requirements to reduce the probability of recalls and enhance public safety.

As AI/ML continues to reshape medical practices, a proactive and informed approach to regulatory oversight and device development becomes imperative for ensuring the safety and efficacy of these transformative technologies.

Conclusion

As the FDA authorizes an increasing number of AI/ML–enabled medical devices, it becomes crucial to understand the distinct challenges they pose in terms of recalls. This study delves into the intricate landscape of medical device recalls, focusing specifically on those associated with AI and ML. Comparisons across three control groups, namely "All 510(k) devices," "Software-related devices," and "AI/ML devices," unveil similarities in the top 7 recall root causes with variations in proportions. Notably, AI/ML devices exhibit a higher impact, especially concerning design and development-related factors. This study underscores the importance of robust planning, user feedback incorporation, and thorough validation during the development process to mitigate the inherent risks associated with AI/ML–enabled medical devices. Recalls related to software, particularly software design, constitute a significant proportion in both "software devices" and "AI/ML devices."

XSL•FO
RenderX

Changes in software also emerge as a notable contributor to recalls in AI/ML devices, underscoring the need for comprehensive verification plans after alterations.

In addition to standard regulatory compliance, AI/ML–enabled medical devices face unique validation challenges due to their dynamic nature and reliance on continuous learning algorithms. Such devices require specialized validation strategies that accommodate algorithm adaptability and evolving real-world performance [4]. Continuous market analysis and proactive user feedback integration are also particularly crucial for these devices, as they help detect and address issues promptly, thereby preventing recalls related to software logic errors, data-driven failures, or algorithmic inaccuracies [3,4].

Abstract

Background: Inappropriate testing of urine cultures can lead to overuse of antibiotics, antimicrobial resistance, *Clostridioides difficile* infections, and increased cost. In Saudi Arabia, antimicrobial stewardship programs have improved antibiotic use but lack focus on asymptomatic bacteriuria. Targeted interventions are needed to address this gap.

Objective: We assessed the implementation of a clinical decision support (CDS) tool in diagnostic stewardship, focusing on the appropriateness of urine culture orders and antibiotic use.

Methods: We examined differences in urine culture testing and antibiotic use before and after implementation of a CDS tool in a 400-bed hospital in Riyadh, Saudi Arabia, from August 2021 to July 2022. We included adult patients with urine culture orders. Our outcomes were the percentage of urine cultures ordered that were inappropriate and antibiotic use after the implementation of the CDS intervention. We used a multivariable logistic regression model to determine factors associated with inappropriate urine culture testing and antibiotic use.

Results: The percentage of inappropriate urine culture orders were significantly lower in the postintervention period compared to the preintervention period (821/2254, 36.4% vs 754/1814, 41.6%; *P*=.001). The CDS intervention was associated with 16.7% lower odds of inappropriate urine culture ordering (adjusted odds ratio [aOR] 0.83, 95% CI 0.73 - 0.95; *P*=.008). Unnecessary antibiotics were significantly lower in the postintervention period (310/2254, 72.9% vs 288/1814, 85.7%; *P*<.001). The CDS intervention was associated with a 52% reduction in unnecessary antibiotic use (aOR 0.487, 95% CL 0.332 - 0.713; *P*<.001)

Conclusions: A CDS initiative can reduce unnecessary urine culture testing and antibiotic overuse.

KEYWORDS

urine culture; diagnostic stewardship; Saudi Arabia; automation; asymptomatic bacteriuria; antimicrobial stewardship program

Introduction

Urinary tract infections (UTIs) are common in both the inpatient and outpatient settings [1,2]. Despite being common, appropriate diagnosis and use of urine cultures remain a challenge. Inappropriate urine culture testing, for example, screening for asymptomatic bacteriuria (ASB), can be the first step in a chain of events that can lead to antibiotic overuse, antimicrobial

XSL•FO
RenderX

resistance (AMR), *Clostridioides difficile* infections, and increased health care cost [3]. Antimicrobial therapy is not recommended in most cases of ASB, and withholding treatment has no major adverse outcomes in most cases [4,5]. Current Infectious Diseases Society of America (IDSA) guidelines recommend screening for and treating ASB only in pregnant women or individuals undergoing invasive urologic procedures [6]. Despite these recommendations, ASB remain one of the most common causes of antimicrobial overuse, where up to 80% of patients with ASB are treated with antibiotics [7].

Challenges in the clinical differentiation between ASB and UTIs may offer a partial explanation for the excessive overtreatment of ASB [8]. Diagnostic stewardship of urine cultures can play an important role in reducing downstream overuse of antibiotics [7]. While many studies have evaluated stewardship of urine culture testing in Europe and North America, research is limited in other geographic settings [9]. For example, there are limited data about diagnostic stewardship of urine cultures from the Eastern Mediterranean region, which is a major research gap given the rising prevalence of AMR in that region [10]. In Saudi Arabia, antimicrobial stewardship programs (ASPs) have been successfully implemented to optimize antibiotic use and reduce antimicrobial resistance but have, thus far, generally lacked a focus on addressing antibiotic use associated with ASB [11]. Therefore, we sought to assess the impact of a clinical decision support (CDS) intervention on diagnostic stewardship, focusing on the appropriateness of urine culture orders and antibiotic use.

Methods

Overview

We conducted a quasiexperimental study at an academic medical center with 400 beds in Riyadh, Saudi Arabia. Our center is a referral center for women's health, pediatrics, and adolescent health. We compared clinical practice in a preintervention phase (August 2021 to January 2022) and a postintervention phase (February 2022 to July 2022) without incorporating a washout period, in both the inpatient and outpatient settings. We included adult patients (≥18 years old) with urine culture orders during the study period and excluded patients on antibiotics prescribed for infections prior to the urine culture and those with missing key data such as UTI signs and symptoms, laboratory results, and clear antibiotic indication.

Endpoints and Definitions

We assessed the impact of our CDS initiative on diagnostic stewardship through measuring inappropriate urine culture and antibiotic use. Appropriate practice for ordering a urine culture, as approved by the international guideline and institutional ASP committee, includes documentation of signs or symptoms of a UTI, pregnancy, and patients who are undergoing invasive urologic procedures, immunocompromised, or critically ill [6]. Therefore, we defined inappropriate urine culture testing in circumstances where patients had no documented signs or symptoms of a UTI, pregnancy, urologic procedures, immunosuppression, or critical illness [9]. Signs and symptoms of a UTI include dysuria, suprapubic pain, flank pain, costovertebral angle tenderness, septic shock, and altered mental status in older (≥65 years) patients [12]. Antibiotics prescribed for ASB without any of the approved indications listed above were deemed to be unnecessary.

Diagnostic Stewardship Interventions

We implemented the institutional ASP–approved CDS in electronic health records (EHRs) on February 1, 2022. The goal of this initiative is to serve as a voluntary guide for physicians to appropriately request urine cultures in the outpatient and inpatient settings. Prior to requesting any urine culture, appropriate urine request–directed questions are asked (Figure 1). If all answers are "no," an alert is triggered indicating that a urine culture may not be recommended for this patient. Physicians are able to override the CDS and still order a urine culture even if the alert is triggered. Alongside the CDS initiative's rollout, the ASP committee disseminated best practices related to UTI care, including indications for urine cultures, to all health care providers.

XSL•FO
RenderX

Figure 1. Urine culture request–directed questions implemented in the electronic health record. UTI: urinary tract infection.

A urine culture is recommended only if you answer "yes" to one or more questions	**Check ✓ if yes; X if no**
Does the patient have UTI signs and symptoms (dysuria, frequency, and urgency)?	
Is the patient pregnant?	
Is the patient undergoing a urologic procedure?	
Is the patient immunocompromised or critically ill?	

If all answers are "no," a clear message pops up: "urine culture request is not recommended."

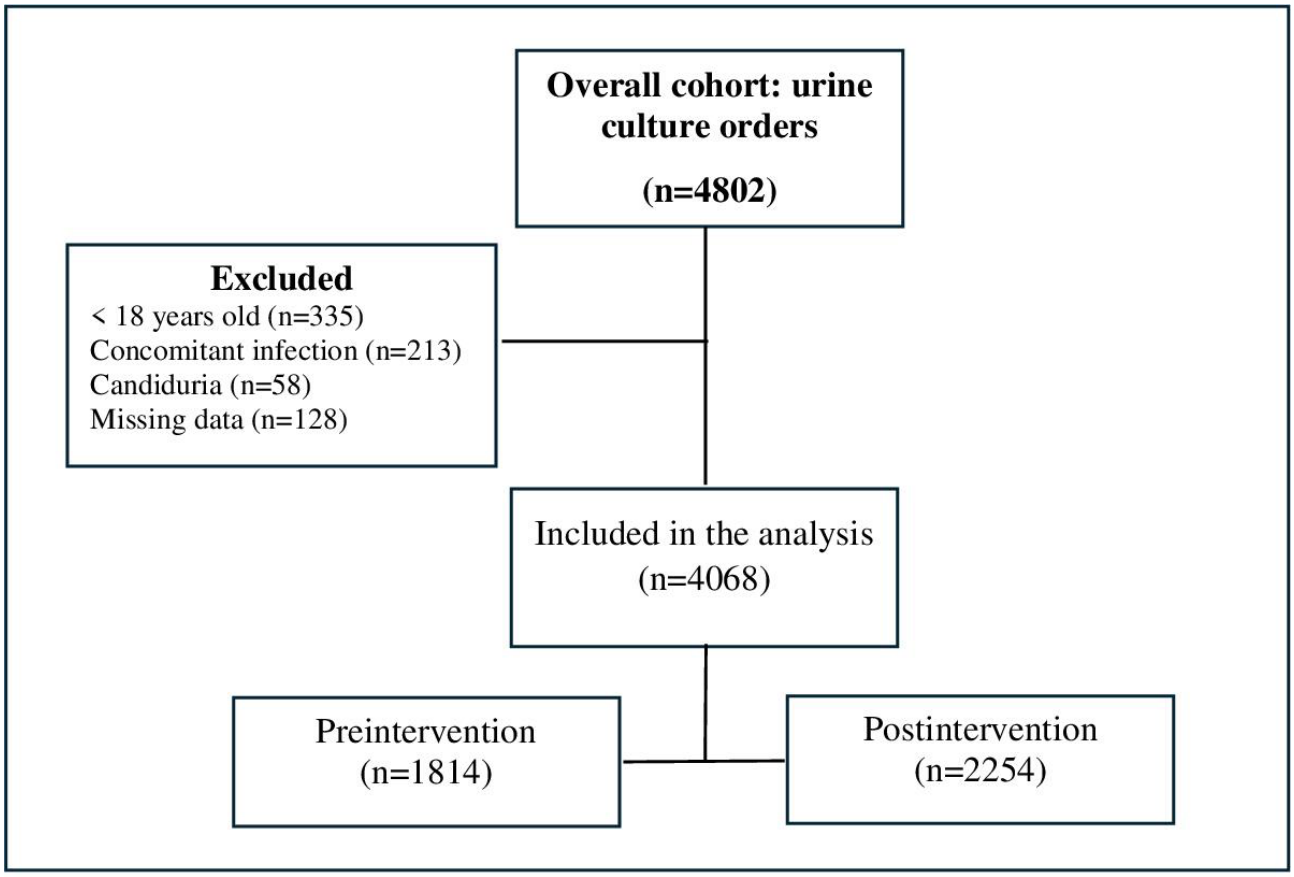
Statistical Analysis

We analyzed categorical data using a chi-square test or Fisher exact test, as appropriate, and continuous data using a Student *t* test. We also used a multivariable logistic regression model, adjusting for age, sex, diabetes mellitus, and chronic kidney disease, to evaluate the association between our CDS intervention and inappropriate urine culture orders and unnecessary antibiotic use. All analyses were conducted in STATA/BE (version 18; StataCorp).

Ethical Considerations

Ethical approval was obtained from the Institutional Review Board of King Abdullah bin Abdul-Aziz University Hospital (IRB log number: 22 - 0005). As this was a retrospective study, informed consent was not required. The study protocol was reviewed and approved by the institutional review board, which granted a waiver of informed consent in accordance with national and institutional ethical guidelines. All data were deidentified prior to analysis. Data were handled securely in compliance with institutional data protection policies to ensure participant confidentiality.

Results



During the study period, we identified 4068 urine culture orders among 3846 unique patients, of which 1814 were ordered in the preintervention period and 2254 in the postintervention period (Figure 2). Demographic information about the study participants is shown in Table 1. The mean age was 42.2 (17.40) years and the majority were female (3068/4068, 75.4%), which is consistent with our clinical setting. Approximately 33% (1375/4068) of patients were pregnant, 4.4% (180/4068) underwent urologic procedures, 4.4% (181/4068) were immunocompromised, and 1.8% (75/4068) were critically ill. Overall, 10.6% (435/4068) had a positive urine culture, of which 32.9% (n=143) were symptomatic and 67.1% (n=292) were asymptomatic (Table 1).

Inappropriate urine culture orders, per our stewardship initiative criteria, were significantly lower in the postintervention period compared to the preintervention period (821/2254, 36.4% vs 754/1814, 41.6%, respectively; *P*=.001). The CDS intervention was associated with a 20% reduction in inappropriate urine culture orders (odds ratio [OR] 0.805; 95% Cl 0.71 - 0.91; *P*=.001). In a multivariable logistic regression adjusting for possible confounders, the CDS intervention was associated with 16.7% lower odds of inappropriate urine culture ordering based on our ordering criteria (adjusted odds ratio [aOR] 0.83; 95% CI 0.73 - 0.95; *P*=.008; Table 2).

Additionally, we found that 1097 antibiotic regimens were prescribed: 336 in the preintervention period and 761 in the postintervention period. The use of unnecessary antibiotics was significantly lower in the postintervention period versus the preintervention period (310/2254, 72.9% vs 288/1814, 85.7%, respectively; *P*<.001). Our CDS intervention was associated with a 55% reduction in the unnecessary antibiotic use (OR 0.449; 95% CI 0.309 - 0.65; *P*<.001). In a multivariable logistic regression adjusting for possible confounding variables, the CDS intervention was associated with a 52% reduction in unnecessary antibiotic use (aOR 0.487; 95% CI 0.332 - 0.713; *P*<.001; Table 2).

Discussion

Principal Findings

To our knowledge, this is the first study to evaluate a diagnostic stewardship initiative targeting inappropriate urine culture orders and unnecessary antibiotic use in patients with UTIs and ASB in Saudi Arabia. Numerous stewardship programs have been implemented in various geographic regions to reduce unnecessary antibiotic use for ASB [13]. Some of these initiatives include continuous education, pocket cards, audit and feedback, and computer-based reminders [13]. In this study, we used a CDS tool embedded in EHRs to guide the physicians to appropriately order urine cultures, which could lead to a reduction in unnecessary antibiotic use. The CDS initiative we implemented successfully decreased inappropriate screening for ASB as measured by the decrease in urine culture orders. Similarly, our initiative also successfully decreased ASB overtreatment as measured by the decrease in unnecessary antibiotic use. While antibiotic prescriptions were numerically higher in the postintervention phase compared to the preintervention phase, the percentage of unnecessary antibiotics was significantly lower in the postintervention phase. The higher number of antibiotics prescribed is likely due to the fact that the postintervention phase comprised a higher proportion of patients who underwent urologic procedures or were immunocompromised. By implementing a CDS tool to address inappropriate urine culture orders and unnecessary antibiotic use in patients with ASB, our study contributes directly to efforts aimed at optimizing antimicrobial stewardship in Saudi Arabia.

XSL•FO
RenderX

The rise of AMR is a global public health crisis, associated with rising morbidity, mortality, and health care costs [14]. Single-center reports suggest a high prevalence of multidrug-resistant organisms, which complicate patient care and threaten gains made from other public health advances in the region [15,16]. In Saudi Arabia, as in many international settings, antimicrobial use is not well regulated and injudicious use of antibiotics is a major factor for AMR development [17]. Recent studies demonstrate that inappropriate antibiotic use in the management of UTIs is approximately 50%, with the primary reason being ASB [18,19]. In our study, the use of unnecessary antibiotics decreased by 52%, highlighting the value of our CDS tool to potentially aid in reducing the rate of AMR in Saudi Arabia.

Several studies have explored other diagnostic stewardship interventions aimed at reducing unnecessary antimicrobial therapy for UTIs and ASB. A recent study that was done in Hong Kong found that suppressed urine culture results led to a 23% reduction in antimicrobial use [20]. Similarly, another study implemented an initiative of not reporting positive urine culture results unless requested via telephone, which led to a decrease in antimicrobial use by 36% [21]. These findings collectively support the effectiveness of targeted interventions in optimizing diagnostic practices and antimicrobial stewardship. By reducing the number of unnecessary urine cultures, health care providers can reduce inappropriate antibiotic use, thus aligning with efforts to combat AMR and improve patient care outcomes.

Our study has limitations. First, as this was a retrospective analysis of a quality improvement project, the results are possibly susceptible to confounding factors. While we accounted for several factors influencing antimicrobial use in our multivariable regression model, these findings should be further confirmed in controlled prospective studies. Future studies should specifically evaluate outpatient versus inpatient urine culture ordering, which we were not able to do through our form of data collection. Moreover, our study may not be generalizable to other hospitals in the region, given that it was a single-centered study. Finally, although the assessments of unnecessary antibiotics were conducted by infectious disease specialists, they were not formally validated, potentially leading to discrepancies between evaluators.

Conclusions

In summary, we implemented an ASP-approved CDS initiative to optimize urine culture testing and antimicrobial use and to reduce overtreatment of ASB. This initiative resulted in a 16.7% reduction in urine culture testing and a 52% reduction in antimicrobial use for UTIs. This is one of the few studies of such initiatives from the Eastern Mediterranean region, which is a site of rising AMR.

Abstract

Background: As data-driven medical research advances, vast amounts of medical data are being collected, giving researchers access to important information. However, issues such as heterogeneity, complexity, and incompleteness of datasets limit their practical use. Errors and missing data negatively affect artificial intelligence–based predictive models, undermining the reliability of clinical decision-making. Thus, it is important to develop a quality management process (QMP) for clinical data.

Objective: This study aimed to develop a rules-based QMP to address errors and impute missing values in real-world data, establishing high-quality data for clinical research.

Methods: We used clinical data from 6491 patients with colorectal cancer (CRC) collected at Gachon University Gil Medical Center between 2010 and 2022, leveraging the clinical library established within the Korea Clinical Data Use Network for Research Excellence. First, we conducted a literature review on the prognostic prediction of CRC to assess whether the data met our research purposes, comparing selected variables with real-world data. A labeling process was then implemented to extract key variables, which facilitated the creation of an automatic staging library. This library, combined with a rule-based process, allowed for systematic analysis and evaluation.

Results: Theoretically, the tumor, node, metastasis (TNM) stage was identified as an important prognostic factor for CRC, but it was not selected through feature selection in real-world data. After applying the QMP, rates of missing data were reduced from 75.3% to 35.7% for TNM and from 24.3% to 18.5% for surveillance, epidemiology, and end results across 6491 cases, confirming the system's effectiveness. Variable importance analysis through feature selection revealed that TNM stage and detailed code variables, which were previously unselected, were included in the improved model.

Conclusions: In sum, we developed a rules-based QMP to address errors and impute missing values in Korea Clinical Data Use Network for Research Excellence data, enhancing data quality. The applicability of the process to real-world datasets highlights its potential for broader use in clinical studies and cancer research.

quality management; medical data; real-world data; colorectal cancer; data quality

Introduction

Medical datasets include various forms of data such as patients' health status, diagnosis, and treatment information, collected through electronic medical records, diagnostic tests, and treatment records [1]. These data support patient-specific treatment and accurate decision-making by medical professionals [2]. With the growing importance of data-driven medical research, studies using medical data have become increasingly common [3,4]. Advancements in artificial intelligence (AI) and machine learning technologies have further

XSL•FO
RenderX

expanded the potential uses of these data, such as for early disease diagnosis and prediction model development [5].

As the volume of medical data grows, infrastructures are being established to analyze and use the data efficiently [6]. Data sharing and linkage enable researchers to access the necessary data more easily. However, challenges such as heterogeneity and incompleteness of datasets remain [7]. For example, during the pseudonymization of integrated medical data, some information may be restricted, and differences in data formats or structures can compromise consistency during adjustment.

Issues such as missing data, inconsistencies, and errors can degrade data quality [8]. Medical data often exhibit imbalance, where some categories of data are underrepresented, which can lead to biased learning and distorted outcomes in AI-based predictive models [9,10]. These quality issues can undermine the reliability of analysis results. Therefore, it is essential to develop a quality management process (QMP) to correct errors and supplement data to improve the quality of medical data and build high-quality datasets. Given the current shortage of specialized personnel trained in handling and managing raw data, it is crucial to manage data quality effectively and enhance usability through systematic and standardized QMPs.

In the medical field, an increasing number of studies have addressed data quality issues [11]. Evaluations of data quality using colon cancer data and proposals for QMPs and frameworks are gaining traction [12,13]. Recently, new methodologies for managing the quality of AI training data have been introduced [14], helping to establish high-quality datasets that meet research purposes for diagnosis and prognosis prediction [15]. While medical data play a decisive role in clinical research and patient treatment, systematic quality management that ensures the consistency, accuracy, and completeness of data is crucial for solving various errors and dealing with missing information [16]. Although comprehensive quality management methodologies for the medical data collection stage are emerging [17], processes applicable to real-world data (RWD) are still lacking.

Therefore, the aim of this study is to develop a QMP for colorectal cancer (CRC) data from the Korea Clinical Data Use Network for Research Excellence (K-CURE). This process was designed to systematically align with the research objectives, identifying key prognostic variables for CRC. We implemented a rule-based approach to improve data completeness and evaluated the effectiveness of the QMP by comparing the data before and after its application.

Methods

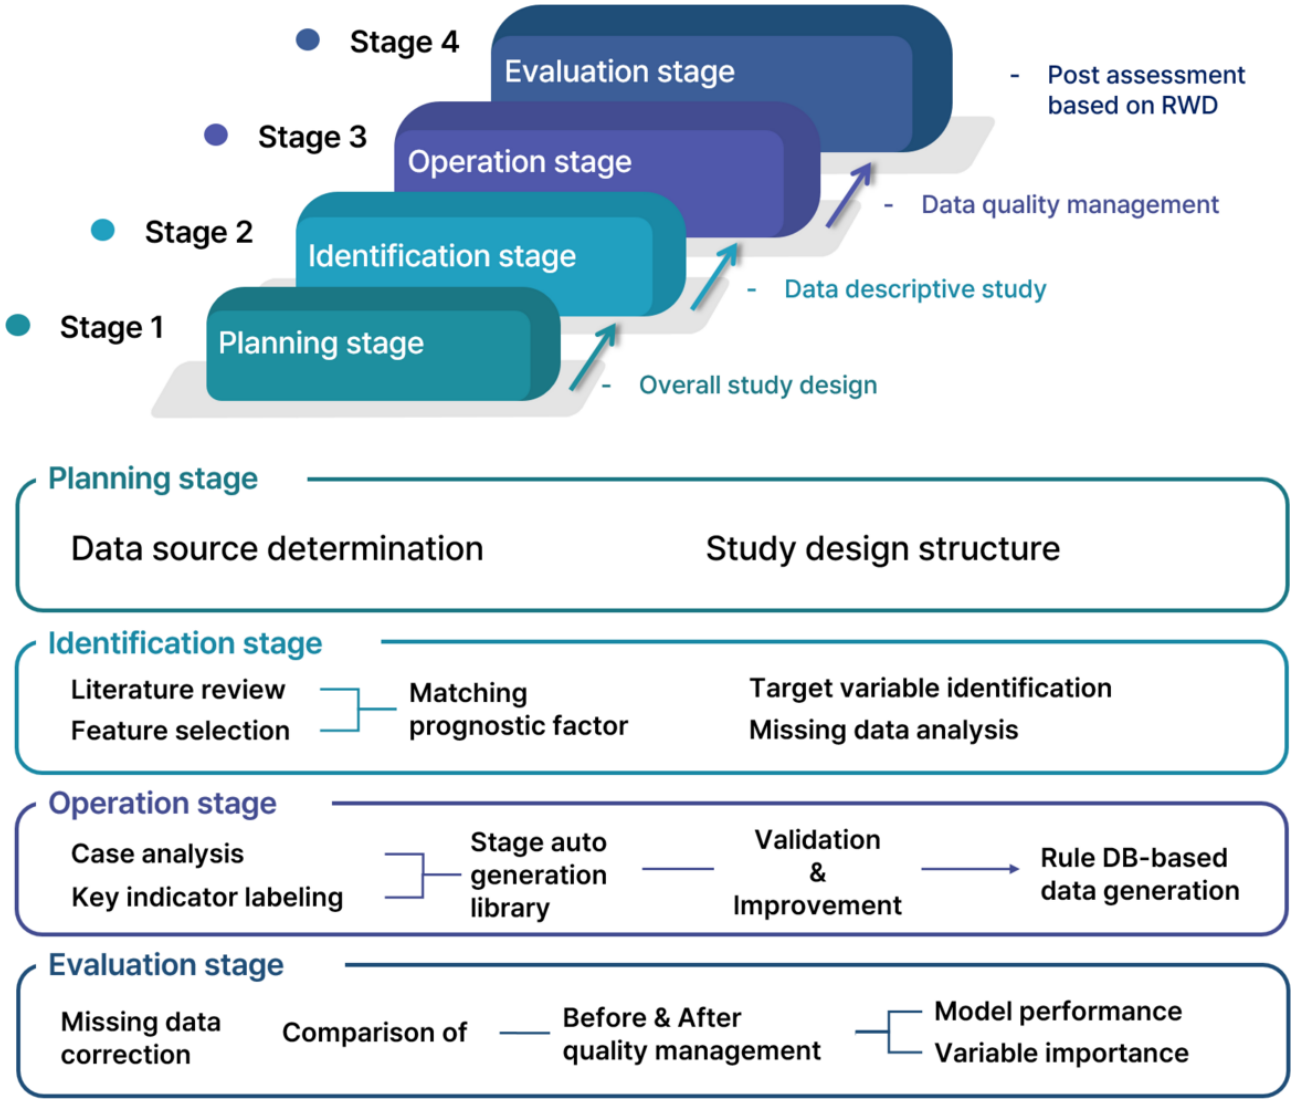
Stage 1: Planning Stage

Data Resources

We used CRC clinical library data established in the K-CURE project at Gachon University Gil Medical Center, approved for use through an institutional review board exemption (GFIRB2024-169). The K-CURE project supports AI-based research and technology development by sharing, providing access to, and linking clinical data from various hospitals. We used a pseudonymized clinical library of 6491 patients with CRC, collected between 2010 and 2022 for the K-CURE project. The pseudonymized clinical library refers to a deidentified dataset in which personally identifiable information has been removed and replaced with pseudonyms. The K-CURE clinical library includes patient information, medical history, diagnoses, cancer staging, test results, treatments, and follow-up data. In addition, structured text-based reports of imaging test results and pathology data from the clinical library were integrated to perform quality management.

Ethical Considerations

The study used CRC clinical library data established in the K-CURE project at Gachon University Gil Medical Center, which was approved for use through an institutional review board exemption (GFIRB2024-169). The dataset was pseudonymized, and personally identifiable information was removed and replaced with pseudonyms. Informed consent was waived due to the use of deidentified retrospective data. No compensation was provided to participants. Privacy and confidentiality of patient data were strictly maintained throughout the study.



Study Design

In Stage 1, we planned the overall research design to establish a QMP for clinical data that meets our research objectives. To systematize the quality management procedures, we designed a detailed step-by-step process across 4 stages: planning, identification, operation, and evaluation.

In the identification stage, we assessed the general status of the RWD to identify areas requiring quality management. In the operation stage, the QMP was applied to the identified targets. Finally, in the evaluation stage, we compared the pre- and post-quality management results to assess improvements in the data. The overall flow of this study is presented in Figure 1.

XSL•FO
RenderX

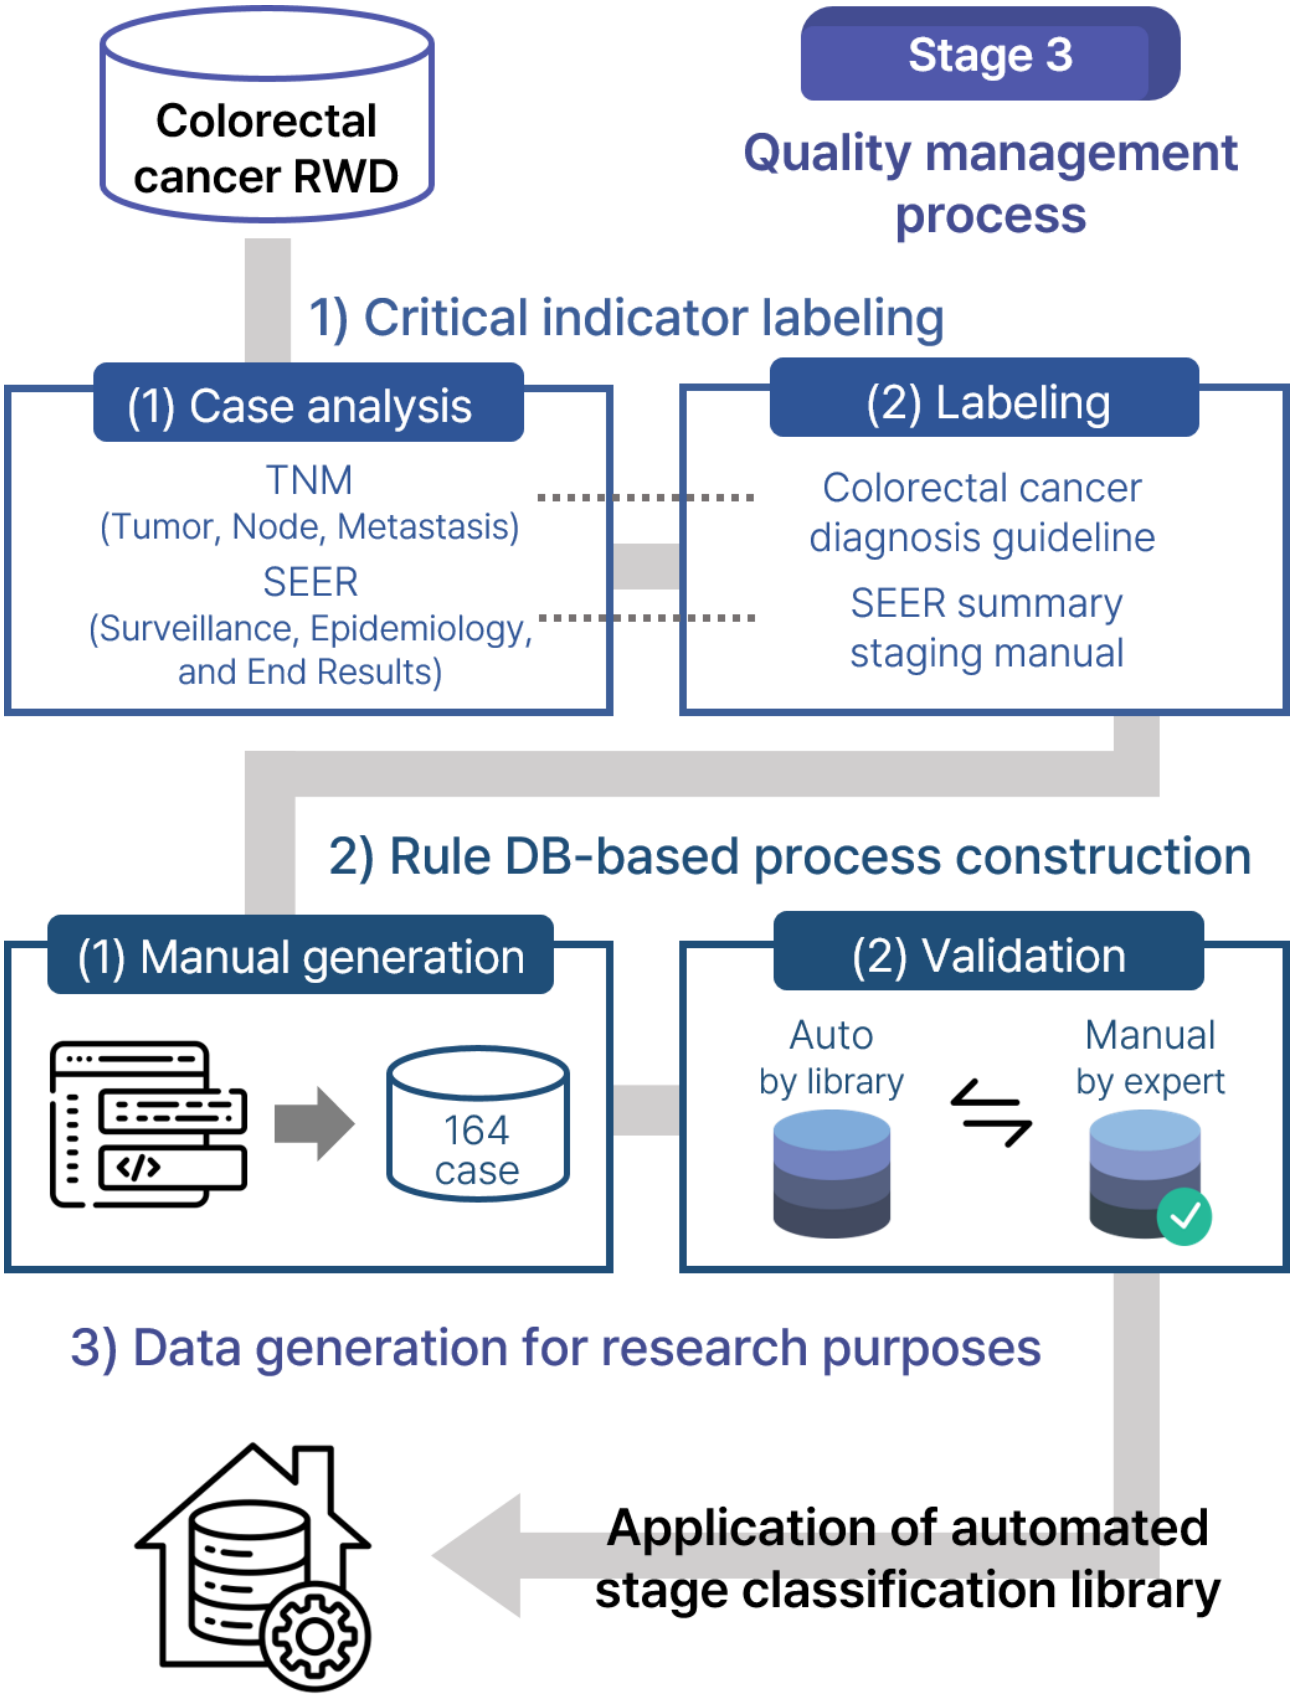
Figure 1. Study design. DB: Database; RWD: real-world data.

Stage 2: Identification Stage

Literature Review to Identify Prognostic Factors

In Stage 2, we conducted a literature review to verify whether the K-CURE CRC data are suitable for constructing a prognostic prediction model. In particular, we sought to identify the key factors influencing the prognosis of patients with CRC and the major variables to consider for constructing a prognostic prediction model for CRC. We searched PubMed for articles published from 2010 to 2024. Our key search terms were (CRC OR colorectal OR CRC) AND (prognosis OR prognostic factor OR predict OR risk factor). The inclusion criteria were as follows: articles published between January 1, 2010, and March 31, 2024, and studies that focused on overall survival, mortality, or 5-year survival as dependent variables. The exclusion criteria included studies with low relevance to the topic or insufficient information on prognostic factors for patients with CRC, and those that discussed only a research design without specific findings. Key influencing factors identified from the selected literature were quantified, and theoretically important factors were derived. These were then used to establish variables for the prognostic prediction model.

Feature Selection for Identifying Prognostic Factors



We performed feature selection to identify prognostic factors in the K-CURE CRC data. The Gradient Boosting Classifier was used to evaluate the importance of variables, and the results were compared to theoretically important variables. This model was selected due to its robustness in handling missing values and its effectiveness in evaluating variable importance, which makes it suitable for real-world clinical datasets [18]. Variables with low importance or those inconsistent with the literature review findings were selected as target variables requiring quality management. To conduct quality management, we performed frequency analysis of the major variables of the prognostic prediction model. Then, the error and missing data rates for these target variables were reviewed to examine the overall data distribution. The rate of missing data was calculated using frequency analysis for each variable. Error rates were measured by comparing manually generated stage codes with the data of 164 randomly selected samples, limited to cases without missing data.

Stage 3: Operation Stage

Figure 2 provides a schematic of the overall QMP.

XSL•FO

Critical Indicator Labeling for Automated Stage Classification Library

The target variables, tumor, node, and metastasis (TNM) and surveillance, epidemiology, and end results (SEER), are critical indicators for evaluating CRC staging. TNM stage is a standardized cancer stage classification system of the American Joint Committee on Cancer, based on the 8th edition of the American Joint Committee on Cancer Cancer Staging Manual [19]. It evaluates the progression of cancer based on tumor depth, lymph node metastasis, and distant metastasis. SEER summary stage is a standardized cancer staging system widely used in international cancer registration systems to classify how far cancer spreads from the primary site of origin.

Before establishing the QMP, a case analysis was conducted to correct errors and address missing data in the target variables. This analysis involved a detailed review of the TNM and SEER variables of cases in the CRC sample data. We identified cases for which the staging information was omitted or incorrectly recorded to assess the completeness and accuracy of the TNM and SEER variables. We also confirmed whether the missing or erroneous staging information could be supplemented using pathology reports and imaging test results according to a standardized classification system.

To identify key indicators for extracting target variables, we referred to the CRC guidelines, "Korean Clinical Guideline for Colon and Rectal Cancer v.1.0 [20]," and the most recent SEER manual, "Summary Stage 18[21]." Labeling was conducted on specific words and keywords to identify detailed codes for TNM and SEER in the pathology report and imaging test results, respectively. In the labeling process, medical knowledge related to CRC was incorporated to establish coding conditions and patterns for accurate staging extraction.

Development of QMPs and Improving CRC Data for Research

In total, 164 cases were randomly selected, and TNM and SEER codes were manually generated for each case. This process adhered to standardized guidelines and protocols for CRC diagnosis and staging classification. To evaluate data quality, the manually generated codes were compared with the corresponding codes in the existing dataset for the same cases, excluding those with missing values. The error rate was calculated based on the number of discrepancies identified through this comparison. The manually generated TNM and SEER code data were also used as reference criteria for validating the automated stage classification library and used as basic data to evaluate the accuracy and consistency of the generated codes.

We evaluated whether the automated library corresponded to guidelines in terms of extracting accurate staging information from clinical data. Then, the accuracy of the library was verified by comparing the concordance between the manually generated TNM and SEER codes and the codes derived from the library. This process focused on the consistency of codes, reasons for discrepancies, and major patterns.

Stage 4: Evaluation Stage

In Stage 4, the data generated by applying the QMP was evaluated. By comparing the rates of missing data for target variables before and after quality management, we could confirm to what extent the missing values were corrected through the process. Based on the data before and after quality management, initial and improved prognosis prediction models were constructed, and their performances were compared. Model performance was evaluated according to metrics such as accuracy, precision, recall, F_1-score, and area under the receiver operating characteristic curve, to assess whether the application of the QMP improved predictive performance. In addition, we analyzed the impact of target variables on CRC prognosis by checking the importance of variables in the model through feature selection before and after quality management. The prognosis prediction model was constructed using the Gradient Boosting algorithm, and the dependent variable was set as 5-year survival using death information. Python (version 3.12) was used for statistical analysis.

Results

Stage 2: Data Descriptive Study Results

Based on the literature review, the most frequently identified prognostic factors were T stage (tumor invasion depth) and N stage (lymph node metastasis), cited in 33 and 32 articles, respectively. Other significant factors included M stage (distant metastasis), the integrated TNM staging system, tumor location, pathological differentiation, and carcinoembryonic antigen levels. Staging may be classified as clinical TNM, pathological TNM, or postneoadjuvant pathological TNM.

As a result of stage 2, variables requiring quality management were identified. A summary of the variables derived from the literature review and feature selection is presented in Table 1. As target variables, we selected TNM stage and SEER, which are theoretically important for prognostic prediction.

[a]SEER: surveillance, epidemiology, and end results.

The results of the frequency analysis of the major variables are shown in Table 2. Among the key variables, missing data were observed for height, weight, BMI, total lymph nodes, positive lymph nodes, and the target variables TNM and SEER. The rate of missing data for TNM stage was notably high at 75.3%, while that for SEER was 24.3% across 6491 cases. Moreover, when the error rate was measured using manually generated stage codes from 164 randomly selected samples, the error rate for TNM stage was 50% (43 errors out of 86 nonmissing cases). For the SEER variable, the error rate was 31.1% (47 errors out of 151 nonmissing cases).

Stage 3: Data Quality Management

We developed guidelines for creating an automated stage classification library. Examples of critical indicator terms identified for TNM and SEER through labeling are highlighted in italics in Tables 3 and 4, respectively. These guidelines define labeled terms and conditions that allow rule-based automated classification of cancer stage.

[i]Not applicable.

As a result of the evaluation of the automated stage classification library, the concordance rates were 93.3% for TNM and 93.9% for SEER across the 164 cases. By leveraging a rule-based database in the QMP, we were able to supplement missing data in the target variables, resulting in a dataset aligned with the objectives of prognostic prediction.

Stage 4: Postassessment Based on RWD

Comparing the rates of missing data before and after the QMP, the rate decreased from 75.3% to 35.7% for the TNM and from 24.3% to 18.5% for the SEER across 6491 cases. This demonstrates the effectiveness of the QMP (Figure 3).

XSL•FO
RenderX

Figure 3. Missing values before and after quality management. SEER: surveillance, epidemiology, and end result; TNM: tumor, node, metastasis.

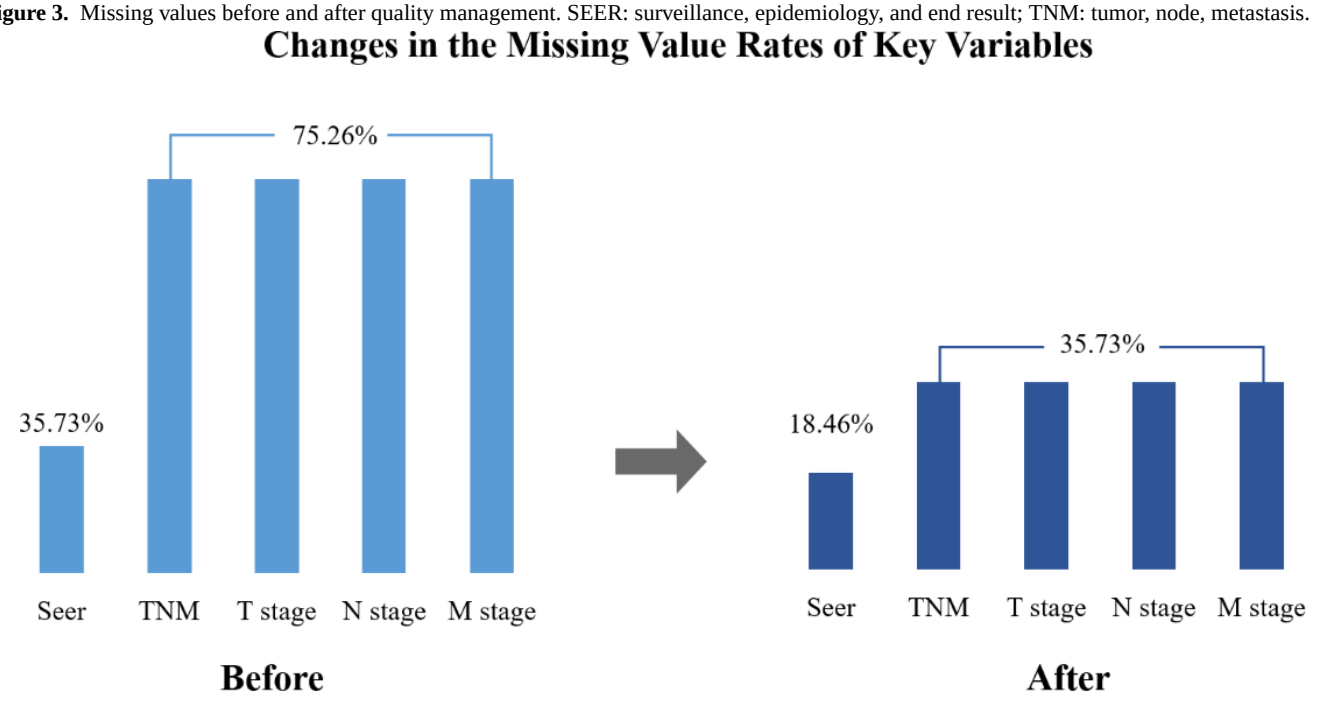

Table 5 presents a comparison of the performance of the models before and after the QMP; a slight improvement was observed. An evaluation of variable importance by feature selection revealed that TNM stage and detailed code variables (T, N, M), which were not identified before quality management, emerged as significant variables after quality management. The variable importance values are shown in Figure 4, and the corresponding importance values are detailed in Table 6. Incorporating these newly identified prognostic indicators into the final model enhances its clinical relevance and interpretability.

Discussion

Principal Findings

This study proposed a QMP to generate high-quality data. We used the K-CURE dataset to develop the QMP and applied it to a CRC clinical library to evaluate the quality improvement effects. After applying the process, TNM stage and individual T, N, and M codes emerged as important factors when constructing a prognostic model. This suggests that the proposed QMP can create high-quality data for research.

Gaps in datasets can occur due to direct omissions of data, limitations in data collection, and technical issues [22,23]. Missing values may arise due to patient movement, treatment interruptions, or omitted tests or procedures, resulting in the loss of important variables. Various methods, such as statistical imputation or ML-based techniques, have been proposed to address missing data but often fail to fully reflect the complexity of clinical environments [24,25]. This reduces the reliability of data over the long term, affecting dataset quality and reducing the reliability of findings.

Various basic statistical methods, such as imputation, have been used to address missing data [26-28]. More recently, ML-based methods such as K-nearest neighbor [29], matrix factorization [30], and random forest approaches have also emerged [31]. These methods are effective when missing data are not random and do not follow specific patterns, as they learn from the dataset itself and predict missing values [32]. This makes them relatively insensitive to the rates or patterns of missing data. Novel techniques such as attention-based models [33] or the large language model forest framework have also been applied [34]. However, previous studies have focused on evaluating and replacing missing values, rather than applying multistage processes to improve overall data quality.

In this study, we reviewed several previous studies on CRC to construct an improved dataset and identify prognostic factors. For clinical research, it is crucial to identify and evaluate factors with strong evidence-based associations with prognoses [35]. However, in our study, theoretically important variables were not always selected from the actual data, and some missing values could not be addressed through the QMP. This indicates that there was a lack of information on important variables during the initial stages of data construction. Therefore, important prognostic variables should be thoroughly reviewed and systematically managed from the initial stages of data construction.

Using CRC staging guidelines, we performed labeling by extracting text-based terms from pathology reports and imaging test results to establish a rule-based QMP. Recently, there has been a trend toward research focusing on developing rule-based quality management and quality assessment methodologies using medical data. This expands the possibility of systematically detecting and correcting errors in data [36]. This approach effectively analyzes clinical quality issues, improves data accuracy, and provides reliable information for clinical research and decision-making [37]. Such a strategy has been found to be applicable to real-world medical data [38]. The QMP developed in this study shows the utility of rule-based systems, generating data with improved completeness. Applying this approach could provide accurate data for future prognostic prediction and decision support systems.

Traditional quality management methodologies focus on preventing and correcting errors during data construction and operation [39]. For example, such methods often rely on automated systems or checklists to minimize input errors or to validate the accuracy of collected data [40]. However, we propose a rule-based QMP that identifies and corrects missing values and errors in datasets that are already established. This approach not only addresses potential issues that can occur during the data construction phase, but also facilitates the detection and resolution of missing data that arise during data analysis.

Recently, there have been active attempts in medical research to develop QMP systems using various clinical and public

XSL•FO
RenderX

datasets, including electronic medical record data [41-43]. This approach is essential for institutions with large-scale medical datasets and platforms built from multiple integrated datasets. In multi-center research, a method to prioritize data quality dimensions and key evaluation variables, supported by feedback systems to monitor and assess data quality, has been proposed. This study provides a foundation for the automation of future QMP systems and the development of new approaches using AI and ML, enhancing the usage of medical data by researchers in public data platforms.

We focused on addressing missing data for quality management; we have not proposed a comprehensive solution for various data errors in clinical environments. Also, a limitation is the complexity of clinical staging decisions—involving multidisciplinary discussions, treatments such as neoadjuvant therapy, and surgical findings—which can lead to discrepancies or missing values in retrospective research data. This complexity may influence the interpretation of the study results and may affect the generalizability of the data. Nonetheless, this work is important in that we propose a systematic process to improve the quality and applicability of real-world medical data. Future efforts should consider advanced processes that address the entire data lifecycle, from construction to usage and operation.

Conclusion

We developed a rule-based QMP that improves data quality and identifies key prognostic factors in CRC datasets. Although missing data and other complex challenges in real-world clinical data remain, the approach demonstrates the utility of systematic quality management. Future work should expand the QMP to address diverse data errors across the data lifecycle.

Abstract

Background: Automated, self-reported medical history-taking has the potential to provide comprehensive patient-reported data across a wide range of clinical issues. In the Clinical Expert Operating System - Chest Pain Danderyd Study (CLEOS-CPDS), medical history data were entered by patients using tablets in an emergency department (ED). Since successful implementation of this technology depends on understanding patients' views and willingness to use it, we have studied these factors following patients' use of the CLEOS program.

Objective: This study aimed to develop and use a questionnaire to investigate patients' attitudes, perceptions and skills related to using digital technology in health care in general, and specifically their experiences with the CLEOS program during their visit to an ED with a chief complaint of chest pain.

Methods: The study included the development of a questionnaire, followed by a cross-sectional study. Questionnaire design and the technology acceptance model underpinned the development of the questionnaire. The think-aloud method was used to test the questionnaire. Adults who participated in the CLEOS-CPDS were invited consecutively to respond to the questionnaire. Descriptive and correlational analyses were performed.

Results: The refinement of the questionnaire included language revision, removal of similar items, and replacement of some response formats. The final questionnaire consisted of 16 items and one free text comment that assessed attitudes, perceptions, and skills related to the use of digital technology in health care in general and the specific experience of using self-reported history-taking by CLEOS. The majority of the 129 patients (mean age 56, SD=17.3 y) who answered the questionnaire found it easy to use digital technology in general (118/129, 91%), that digital technology has a role when seeking health care (115/129, 91%), and that patient-reported symptoms are helpful in making a diagnosis (83/129, 65%). There were some concerns that the patient-physician interaction would be disrupted when using digital technology (48/129, 38%). The overall experience of using CLEOS was positive and most felt confident in answering the questions on a tablet (118/129, 91%). Older age was associated with less ease (P<.001), confidence (P<.001), and trust (P=.002) when using digital technology, as well as less confidence in answering the questions in CLEOS (P=.019). Moreover, older age was associated with more worry about the potential disruption of the patient-physician personal contact when using digital technology (P<.001).

Conclusions: This study suggests strong approval of usefulness and trust in digital technology among patients with chest pain visiting a cardiology ED, but the concern for lack of personal contact should be acknowledged. End users found the CLEOS program to perform well but recommend some adjustments for future studies. The questionnaire responses provided some new insights on perceived usability of digital technology for health care delivery, and it appears relevant for future evaluations of CLEOS in other contexts.

KEYWORDS

technology acceptance; chest pain; computerized history taking; digital technology; emergency department; health informatics; medical history; self report

Introduction

Automated, self-reported medical history-taking can become a key technology for maximizing outcomes for patients, for improving the physician-patient communication and for delivering patient-reported information to the point of care across a wide range of clinical issues [1,2]. Programs for computerized history-taking (CHT) that interact directly with patients in clinical settings collect more complete and accurate medical data as compared with physician entries in patients' medical records [3,4]. For example, the CHT program Clinical Expert Operating System (CLEOS) provided sufficient data for risk stratification for a major adverse cardiac event using the well-established HEART (Heart, ECG, Age, Risk factors, Troponin) score in approximately 77% of 1000 emergency department (ED) patients with chest pain [5]. In contrast, risk stratification was only feasible for 31% of the patients when relying on data from the electronic health record [6]. CLEOS collects self-reported medical history data entered by patients on a tablet during hospital waiting times before or after seeing a physician [7]. The program emulates clinical thinking continuously through its automated interpretation of all previous answers as data is collected.

In recent years there has been a rapid growth of digital tools in health care that allow patients to interact with health care professionals [8]. Digital health tools can empower patients' self-management and facilitate personalised communication with the health care system to improve health status awareness and increase adherence to therapy [8,9]. However, poor digital literacy, low health literacy, privacy and security concerns of medical data have been identified as barriers to adopting such tools [9]. As technical solutions are developed to improve health outcomes in patients with cardiovascular and other chronic conditions, patients' ability to understand and communicate basic health information and to express their health concerns to health care professionals should be considered [10]. Furthermore, user-friendliness and facilitation of patient-clinician interaction have been reported as important aspects for the uptake and adoption of digital technology in health care [11]. Effective implementation of CHT programs in health care requires that we understand patients' concerns, attitudes, and willingness to engage with such programs. Research on how CHT software is perceived by patients is very scarce. Early work in this field suggests that CHT is well accepted [12,13] but older age and low self-confidence in using computers were associated with lower perceived usability [13]. In a more recent study of the usability of an application designed for medical history-taking in general practice the participants of older age did not adapt equally well to the application [14]. We conclude that the ongoing development in technology and changes in health care with people seeking care at increasingly older ages requires an extended knowledge of patients' views on these issues.

We previously performed an interview study of patients seeking ED care for chest pain as part of our ongoing studies of patient experience with the use of CLEOS [15]. The interviews yielded insight into the influence of context, clinical content, and technology on the program's usability. Generally, CLEOS was well accepted by the patients and could be managed by them despite a busy ED, although the program was sometimes perceived too extensive. However, the sample interviewed was small and we did not address patients' perceptions of ease of using the program and its possible impact on the value of health care they could receive. These are 2 determinants identified in the technology acceptance model (TAM) for acceptance of computer technology by its potential users [16]. Obviously, effective development of patient-directed health care technology depends on thorough understanding of patient perceptions of the technology.

Most previous studies focus on digital health care tools aimed at delivering interventions, patient monitoring, symptom tracking, and communication. A study of patient perceptions of CHT based on real-time use by patients with significant medical issues has not been investigated in detail. This study will provide insights for developers of CHT and health care managers on important factors that influence an individual's intention to use such programs effectively as they seek emergency health care. Accordingly, this study aimed to develop a questionnaire and apply it to investigate patients' attitudes, perceptions, and skills related to using digital technology in health care in general, and specifically their experiences with the CLEOS program in an ED setting.

Methods

Design

The study design included (1) the development of a questionnaire and (2) a cross-sectional study using the questionnaire in a study population presenting to the ED with acute chest pain. This study is part of the Clinical Expert Operating System - Chest Pain Danderyd Study (CLEOS - CPDS) presented in detail elsewhere [7].

Questionnaire Development

Development

The questionnaire development was guided by questionnaire design [17,18] and by results from our previous interview study investigating patients interacting with CLEOS in an ED [15]. The construction of items in the questionnaire was inspired by the System Usability Scale (SUS) [19]. The SUS is a standardized questionnaire for the assessment of perceived usability. It does not cover all areas of significance for the research questions we address here. Therefore, we used the TAM [16] to give further structure to the development of questions. The TAM determines an individual's evaluative judgment of the target behavior in some dimension (attitudes). For example, it includes the perception that using an IT system

XSL•FO
RenderX

will be free of effort (perceived ease of use) and will enhance performance (perceived usefulness). Another determinant in the TAM is the specific behavior when interacting with the technology of the CHT program (use). The Swedish functional health literacy scale [20] was used for inspiration to develop questions to evaluate an individual's digital health literacy (skills). All areas of interest (attitudes, perceptions, use and skills) were entered into a template guiding the construction of the questionnaire (Multimedia Appendix 1). Furthermore, 2 scaling methods were chosen initially for capturing patients' responses in the questionnaire. These were the Likert method (strongly agree, agree, undecided, disagree, and strongly disagree), and a frequency scale with fixed choice responses (always, often, sometimes, seldom, and never).

Face Validity Test of the Questionnaire

In January 2022, 14 patients visiting the cardiology ED at Danderyd University Hospital with acute chest pain and taking part in the CLEOS-CPDS prospective cohort study were asked to participate in the development of the questionnaire. The selected patients represented a variation in age and gender. If they agreed to participate, an information letter and a questionnaire were sent to their home by post; and a few days later a researcher (KS or KF) contacted them by phone. We used the think-aloud (TA) method [21] to test the face validity of the questionnaire. During the phone call, the respondents were asked to fill in the questionnaire, encouraged to think out loud and to verbalize any thoughts while doing so. This provided an opportunity to listen to their understanding of each item as they worked through the questionnaire. In addition, probing questions were asked when the session leader needed further clarification. At the end of the TA session, all participants were asked if they had any additional comments that had not been addressed during the session. The content of the sessions was recorded in a spreadsheet to facilitate the evaluation and revision of the questionnaire.

Investigating Outcomes of the Questionnaire

Sample and Setting

Adult patients (≥18 y) with acute chest pain, presenting to the ED at Danderyd University Hospital and participating in the CLEOS-CPDS from May until November 2022 (n=288, mean age 55 y, 41% women) were invited to answer the questionnaire. Before discharge from the ED, patients were invited consecutively by a study nurse to participate. Those who agreed were given study information and a paper copy of the questionnaire, along with a prepaid return envelope. Of the 130 questionnaires returned, one was blank, leaving 129 participants. The mean age of the patients participating was 56 (SD 17.3) years (range 18-89 y). More men (79/129, 61%) than women (49/129, 38%) participated (Table 1).

Table . Sociodemographic characteristics for participants answering the questionnaire (N=129).

Characteristics	
Age (years), mean (minimum-maximum)	56 (18-89)
Gender [1], n (%)	
Women	49 (38)
Men	79 (61)
Missing	1 (<1)
Education level, n (%)	
Junior compulsory	7 (5)
Senior high school	47 (37)
Postgraduate or university	74 (58)
Missing	1 (<1)
Occupation, n (%)	
Working or student	87 (67)
Retired	40 (31)
Unemployed or sick leave	2 (2)

Analysis

The items in the questionnaire were analyzed using descriptive statistics, including frequencies and percentages. Spearman's rho was used to explore the correlations between age, attitudes of using digital technology and experience of using CLEOS. For analysis in SPSS Statistics 30 (IBM), the responses were labeled as "always"=1, "often"=2, "sometimes"=3, "seldom"=4, or "never"=5. The responses were ranked from low to high, with the item "always" given the lowest ranking of 5 and the item "never" the highest rank of 1. Thus, a positive correlation means a relationship between older age and "never" and a negative correlation means a strong relationship between older age and "always."

Internal item consistency was tested for 6 items corresponding to questions on health literacy: "I could make use of the content in the text, "It took a long time for me to read the text", "There were words that I did not understand," "It was difficult to answer the questions," "The questions were relevant," "It was easy to find relevant response alternatives." The intended health literacy

XSL•FO
RenderX

scale had a Cronbach α of .68. The items corresponding to attitudes, perceptions and skills were too diverse to make up a scale and were hence not tested for internal consistency.

Conventional content analysis was applied for the free text comments [22]. The analysis was conducted by 2 of the authors (KF and KS), both experienced with qualitative research. The comments were entered into a document and coded by highlighting similar texts in the same color, followed by categorizing them into color-coded clusters. The clusters were defined into categories which were discussed and refined and then finalized in agreement with all authors. A response frequency chart was used to determine the frequency of similar comments.

Ethical Considerations

This study has been approved by the Swedish Ethical Review Authority (reference number 2015/1955 - 31) and is registered at ClinicalTrials.gov, National Library of Medicine, (NCT03439449). Informed consent was not obtained specifically for this study since patients had been informed. while obtainging informed consent in the CLEOS-CPDS study, that they might be asked later to take part in an evaluation of their perceptions of using the programme. To ensure that no participants could be identified, all participants names were removed and replaced with an unique code. No compensations for participating in this study were offered.

Results

Development of the Questionnaire

The initial version of the questionnaire contained a total of 19 items and an additional 4 sociodemographic questions. The items concerned experience of use of digital technology in general, the use of digital technology in health care, and the use of the CLEOS program.

In addition, 12 individual TA sessions were held, involving 6 women and 6 men, with mean age 72 (range 37-82) years. A majority had postgraduate or university (n=7) as the highest level of education, followed by senior high school (n=2), junior compulsory (n=3), and a majority were retired (n=8).

Based on the results of the TA sessions, the wording of 2 questionnaire items was revised. For item 5, the word “lean on” was changed to “depend on” and for item 7, the word “relation” was changed to “personal contact.” Three items were removed because they resembled other items and did not contribute to the evaluation of CLEOS. Moreover, the response format “strongly agree” to “strongly disagree,” which was used for seven items, was perceived as difficult to understand. It was replaced with the response format “always,” “often,” “sometimes,” “seldom” or “never,” which was consistent with the allowed response alternatives for all other items. The revised questionnaire had 16 items and 1 free text comment (Multimedia Appendix 2). The first set of questions (n=9) assessed attitudes, perceptions, and skills related to the use of digital technology in health care (Tables 2 and 3). The second set (n=7) evaluated the specific experience of self-reported history-taking by interacting with CLEOS (Table 4). The questionnaire included a combination of positively and negatively phrased items, response alternatives such as (yes, no, uncertain), and frequency scales (always, often, sometimes, seldom, never).

Table . Attitudes, perceptions, and skills related to the use of digital technology in health care (N=127).

	Yes, n (%)	No, n (%)	Uncertain, n (%)
Have encountered digital technology previously in contact with health care	63 (50)	59 (46)	5 (4)
Digital technology has a role when visiting health care	115 (91)	2 (1)	10 (8)

The questions were relevant	46 (36)	47 (36)	32 (25)	4 (3)	0	129
It was easy to find relevant response alternatives	34 (26)	68 (53)	26 (20)	0	1 (1)	129

Outcomes of the Questionnaire

Attitudes, Perceptions, and Skills

Most participants found it easy or often easy (n=118, 91%) and felt confident or often confident (n=118, 91%) using digital technology. Most (n=115, 91%) believed that digital technology has a role when visiting health care. Half (n=63, 50%) had not previously encountered or were not sure if they had encountered digital technology in interactions with healthcare. Most (n=115, 90%) trusted digital technology to function as intended during health care visits. One-fifth (n=23, 18%) was concerned or sometimes concerned that information regarding their health collected by digital technology would be disclosed to unauthorized persons. More than one-third (n=48, 38%) was concerned or sometimes concerned that the interaction between patient and doctor would be disrupted when using digital technology in health care. In addition, two-thirds (N=83, 65%) believed that patient reported symptoms using digital technology are helpful for the doctor in making a diagnosis. Four-fifths (n=100, 78%) believed that patient contribution is valuable when developing digital technology in health care (Table 2 and 3).

Experience of Using CLEOS

Most respondents (n=115, 90%) were confident or often confident to answer the questions on a tablet in the CLEOS-CPDS study. Almost all (n=125, 97%) could make use of the content in the text. Most (n=111, 86%) reported a high level of understanding of the terminology used in the CLEOS program, and a majority (n=89, 69%) did not or seldom find that the questions were difficult to answer. A majority of respondents (n=93, 72%) found that the questions in the CLEOS program were relevant. Slightly more (n=102, 79%) thought it had been easy or often easy to find relevant response alternatives (Table 4).

Correlations Between Age and Attitudes, and the Experience of Using Digital Technology

Significant, moderately positive correlations were found between age and the items “I find it easy using digital technology” (*P*=<.001; 95% CI 0.171-0.492), “I feel confident using digital technology in general” (*P*<.001; 95% CI 0.247-0.551), “I trust the digital technology to function as intended when visiting healthcare“ (*P*=.002) and “I was confident answering the questions in Cleos” (*P*=.02, 95% CI 0.032-0.379). The items were rated as “always,” “often,” “sometimes,” “seldom,” and “never” whereas “always” had the lowest ranking and “never” the highest ranking. The correlations indicate that older age is associated with less ease, confidence, and trust in using digital technology as well as confidence in answering the questions. A significant negative correlation was found between “I worry that the patient-doctor personal contact is disturbed when digital technology is used in healthcare” (*P*=.001; 95% CI −.443 to −.107), rated as “always,” “often,” “sometimes,” “seldom,” and “never,” indicating that higher age is associated with greater concern (Table 5). The results for 127 - 129 participants were tested using Spearman rho. The ranking was from low to high; the item “always” has the lowest ranking of 5, and the item “never” has the highest rank of 1. A significant positive correlation means a relationship between older age and “never” and a significant negative correlation means a strong relationship between older age and “always.”

XSL•FO
RenderX

Table . Correlations between age and attitudes related to the use of digital technology in health care and experience of answering questions using clinical expert operating system (N=129).

	Correlation coefficient	*P* value	95% CI
Attitudes of using digital technology[a]			
Find it easy using digital technology	0.342	<. 001	.171 to .492
Feel confident using digital technology	0.41	<. 001	.247 to .551
Trust digital technology to function as intended when visiting health care	0.278	.002	.100 to .439
Worry that information regarding own health collected by digital technology will be disclosed to unauthorized persons	–0.078	.39	–.257 to –.107
Worry that the patient-doctor personal contact is disrupted when digital technology is used in health care	–0.283	.001	–.443 to –.107
Believe patient-reported symptoms using digital technology are helpful for the physician when making a diagnosis	–0.02	.83	–.202 to .163
Believe that patient contribution is valuable when developing digital technology in health care	0.129	.15	–.054 to .304
Experience of answering questions			
I was confident answering the questions	0.212	.02	.031 to .379
I could make use of the content in the text	0.035	.70	–.148 to .215
It took a long time for me to read the text	–0.032	.72	–.213 to .150
There were words that I did not understand	0.097	0.28	–.086 to .274
It was difficult to answer the questions	–0.16	.08	–.332 to .022
The questions were relevant	–0.161	.07	–.333 to .021
It was easy to find relevant response alternatives	0.04	.662	–.142 to .220

[a]Results for 127 - 129 participants. Tested by Spearman´s rho. Ranking (from low to high) the item “always” has the lowest ranking of 5, and the item “never” has the highest rank of 1. A significant positive correlation means a relationship between older age and “never” and a significant negative correlation means a strong relationship between older age and “always.”

Free Text Comments

The last item in the questionnaire allowed patients to comment on their experience of performing the CLEOS interview on the tablet (Textbox 1). A total of 40% of the patients left comments concerning (1) time aspects regarding the CLEOS interview (n=11), perceptions regarding the questions included in CLEOS (n=13), (2) perceptions regarding the response alternatives (n=13), (3) perceptions of technical performance (n=6), (4) perceptions of layout (n=9), (5) difficult-to-understand words (n=6), and (6) not confident (n=2).

XSL•FO
RenderX

Textbox 1. Categories and examples of comments in the questionnaire regarding answering questions in CLEOS.

Time aspects regarding the clinical expert operating system interview (n=11)

It was too extensive and time consuming, it was tiresome to answer all the questions and hard to stay focused, not enough time to answer all questions.

Perceptions regarding the questions (n=13)

Lacking questions (ie, a question about other diseases), questions that were grammatically wrong, not translated from German or English, questions about a topic that never ended or unrecognizable scenarios becoming increasingly irrelevant, questions that were incomplete and lacking an illustration (image), irrelevant follow-up question (ie, requested to answer "what kind of surgery" after having said no to "had any surgery").

Perceptions regarding the response alternatives (n=13)

Lacking an appropriate alternative, wanting more alternatives or "I don't know", having to answer "how often" after answering no to a symptom occurrence, not finding a prescribed medication in the list of medicines.

Perceptions of technical performance (n=6)

A slow interface, technical, or internet problems.

Perceptions of layout (n=9)

The size of the text was too small, unclear transition to the next page, not clear when the questions had ended, an inert maneuvering.

Difficult to understand words (n=6)

Connotation of wording that was, that some words needed explanation, that medical terms were difficult, some text was strangely worded.

Not confident (n=2)

Feeling uncertain about using the technique, "talking" to a doctor on a screen feels impersonal.

Discussion

Principal Findings

This study included a process of developing a questionnaire and a cross-sectional study that evaluated patients' attitudes toward digital technology in health care and experiences of interacting with a CHT program while presenting to an ED setting with acute chest pain. The questionnaire development process required only minor changes for the final version. Overall, the findings from the evaluation of using the CLEOS program showed a high acceptance of digital technology when incorporated in health care as well as user confidence and high digital literacy among the participants.

Comparison With Previous Work

In general, there was a favorable attitude toward digital technology, with many participants expressing their faith in its potential to help physicians make accurate diagnoses. Although not all had previous experience using digital technology in health care encounters, a clear majority in this study had a positive attitude about the role of such technology when visiting health care. Moreover, most were confident using the CLEOS program. This is in line with the results of Arora et al [12] who were early to use a CHT program in the waiting area of an ED. In that study, the overall impression among the patients was that they would like to fill out a digital questionnaire again in the future. In a more recent pilot study assessing digital patient self-anamnesis in the waiting area of an ED, 63% agreed to fill out a digital questionnaire again [23]. In another study evaluating medical history-taking via an app in general practice, the usability score (evaluated by SUS) was in favor of acknowledging a recurrent use of the application [14]. The application described in that study is similar to a CHT program that emulates clinical thinking, but the application uses a branching logic that is adaptive to patient responses instead of automated interpretation of previous answers. While a clear majority expressed a trust in the technique when used in health care interactions, there were some concerns about data security and privacy in the present study. The high level of trust in digital technology to function well was somewhat surprising in our present results, given that only just over half of the respondents had previously encountered digital technology when in contact with health care. Altogether, the results from our current study support previous findings of a high level of patient acceptance of health care technology when visiting EDs.

There was a modest but noteworthy concern about disrupted patient-physician interaction when using digital technology in health care. This concern was more pronounced in older patients. As there are no other CHT programs like CLEOS and very few other comparable systems, it is hard to conclude what these results mean. A related area in health care, however, is patients' opinions about the patient-physician relationship and communication with physicians using electronic medical records (EMR). Perceptions of such computer use during the health care visit were compiled in a systematic review. The authors concluded that it did not substantially affect the quality of communication with their physician [24]. In a survey examining perceived benefits and risks of using artificial intelligence (AI) applications in health care, communication barriers emerged as the most significant predictors of perceived risks [25]. The authors discussed that the loss of face-to-face cues and lack of interaction with physicians would give the patient a more passive position. On the other hand, their results showed that if users believe that AI-based devices can improve diagnostics and patient management systems, they become more prone to use them. A review showed that digital tools in health care can be facilitators for factors such as empowerment and personalized communication with health care [9]. Reciprocally, patient empowerment contributed to patient uptake of digital health tools. The study concluded too that digital tools could facilitate

XSL•FO
RenderX

a shift from paternalistic health care models to those in which relationships between clinicians and patients are more collaborative. Based on these findings, we agree that patient-physician communication through modern technology could be perceived as positive by patients. Nevertheless, our results also tell us that patients' trust, especially with rising age, needs to be ensured and further investigated before CHT programs are integrated into standard clinical practice.

The ability to understand and make use of the content in the CLEOS program was overall very satisfactory. Low digital and health literacy have been described as barriers to implementation of digital tools [9,10]. Our results may be a consequence of a presumed high health literacy among the participants related to a relatively high educational level, known as a strong associated factor [26]. Higher age could be another barrier. The present results suggest that older people are more likely to experience less ease and confidence in using digital technology. This could explain why being 70 years or older was found to be a negative factor for completing the program in a previous study of the CLEOS-CPDS cohort [5]. Similarly, Albrink et al [14] found that age was negatively associated with the usability SUS score when evaluating their app, suggesting that older people may face challenges in handling such an app.

Our study shows strong support for involving end users when designing new digital technology in health care. This confirms findings by others who recommend a participatory approach in the design of future digital health care [27-29]. The free text comments revealed aspects for improvement of the CLEOS program such as high time consumption, ambiguous questions, and slow technical performance. These results align well with those from our previous interview study [15], highlighting the need for further development of the program.

The challenge of developing questionnaires in research is to achieve high validity and reliability. Accordingly, the questionnaire development was guided by a robust process based on the results of our previous interview study and other recognized methods. Furthermore, the development process included the think-aloud method [21], which allowed the participants to speak freely while testing the questionnaire. The think-aloud method has no specific sample size recommendation, and we decided to stop inclusion when no new data was collected. Although the sample in the present study may be small, they provided valuable information about the comprehensibility of the questionnaire. Presumably, all areas of interest were covered sufficiently. However, to be sure that the questionnaire measures what is intended, a more robust validation in a future study is needed.

Our results should be interpreted in the context of the study's limitations. The convenience sample of patients responding to the questionnaire may not be representative of all patients seeking care at the cardiology ED. The small sample size and single center inclusion affects the generalizability of the results. Further, the selected sample had been consecutively recruited to the CLEOS-CPDS study and may have had a positive attitude toward digital technology as they had consented to participate in the study. Other selection biases could be a slight overrepresentation of men in the sample and an uneven distribution of education levels. Furthermore, we lack information about those who did not fulfil the criteria for inclusion, eg, fluency in Swedish, or declined participation both in CLEOS-CPDS and in the current study.

Conclusion

This study suggests strong acceptability and trust of digital technology among patients presenting to a cardiology ED. However, the concern for lack of personal contact between patient and doctor should be acknowledged. Digital technology was seen as an important facilitator but not as a replacement for human interaction. The CHT program (CLEOS) performed well for end-users but would benefit from some adjustments for future studies. The questionnaire responses yielded some new insights into the use of digital technology for health care delivery. The questionnaire appears relevant and may be useful for future evaluations of CHT in various contexts.

Acknowledgments

The authors would like to thank the patients who participated in this study. This study was funded by the Robert Bosch Stiftung (Stuttgart, Germany, grant number 11.5.1000.0258.0), Region Stockholm (ALF project; Stockholm, Sweden, grant numbers FoUI-954046 and FoUI-962663), and institutional funds from Department of Learning, informatics, management and ethics, Karolinska Institutet (Stockholm, Sweden).

Abstract

Background: Telemonitoring can enhance the efficiency of health care delivery by enabling risk stratification, thereby allowing health care professionals to focus on high-risk patients. Additionally, it reduces the need for physical care. In contrast, telemonitoring programs require a significant time investment for implementation and alert processing. A structured method for telemonitoring process optimization is lacking.

Objective: We propose a framework for optimizing efficient care delivery in telemonitoring programs based on alert data analysis and scenario analysis of a telemonitoring program for hypertension combined with a narrative literature review on methods to improve efficient telemonitoring care delivery.

Methods: We extracted 1-year alert processing data from the telemonitoring platform and electronic health records (June 2022-May 2023) from all users participating in the hypertension telemonitoring program in the outpatient clinic of the Department of Internal Medicine of the Maasstad Hospital. We analyzed the alert burden and alert processing data. Additionally, a scenario analysis with different threshold values was conducted for existing blood pressure alerts to assess the impact of threshold adjustments on the overall alert burden and processing. We searched for English language academic research papers and conference abstracts reporting clinical alert or workflow optimization in telemonitoring programs on May 24, 2024 in Embase, Medline, Cochrane, Web of Science, and Google Scholar.

Results: In total, 174 users were included and analyzed. On average, each user was active in the telemonitoring program for 207 days and a total of 30,184 measurements were performed. These triggered a total of 17,293 simple, complex, and inactive or overdue alerts: 13,647 were processed automatically by the telemonitoring platform, and 3646 were processed manually by e-nurses from the telemonitoring center, equivalent to 21 manually processed alerts per user. Additional analysis of the manually processed alerts revealed that 25 (15%) users triggered more than 50% of these specific alerts. Furthermore, scenario analysis of the alert thresholds revealed that a single increase of 5 and 10 mmHg for the diastolic and systolic blood pressure alerts would reduce the number of alerts by about 50%, resulting in a total reduced time investment for the e-nurse of 5973 minutes over 1 year. Literature search yielded 251 articles, of which 7 studies reported methods to improve efficiency in telemonitoring programs, including the introduction of complex alerts and clinical algorithms to triage alerts, scenario analysis with alert threshold adjustments, and a qualitative analysis to create an alert triage algorithm.

Conclusions: Based on the data analysis and literature review, a 4-step framework was developed to optimize the efficiency of telemonitoring programs. The 4 steps include ensuring accurate measurements, telemonitoring algorithm and alert optimization, focusing on individual users' and user groups' needs, and improving telemonitoring process efficiency. This framework can be an important first step to improve the efficiency of 21st-century telemonitoring programs.

Introduction

Since the COVID-19 pandemic [1], the use of telemonitoring has rapidly increased [2]. In 21st-century telemonitoring, patients measure relevant health data like vital signs at home according to a predefined measurement schedule [3]. These data are transmitted through a smartphone or tablet application, can be reviewed remotely by health care providers, and can trigger alerts based on pre-defined threshold values. Alerts are reviewed by e-nurses in remote patient monitoring centers and discussed with health care providers if required. Depending on the alert, remote treatment adjustment will take place, and feedback is provided to the patient. In theory, the application of telemonitoring improves health care delivery by contributing to the Quintuple Aim goals [4] aimed at improving patient experiences, improving population health, reducing health care costs, improving care team well-being, and enhancing health equity. Achieving specific efficiency-related goals requires telemonitoring to reduce the need for physical care and shift attention to patients who mostly require it. This is particularly relevant in situations with increased care needs combined with reduced available health care staff [5]. It is however, for many diseases still unclear whether telemonitoring does lead to more efficient care delivery, as it requires a significant time investment (eg, alert processing, development and implementation of telemonitoring algorithms), generates new data, and needs continuous optimization of clinical workflows [6,7].

Modern telemonitoring platforms are often embedded in existing care paths and include clinical algorithms that triage and process the generated alerts [3,8]. This proactive way of telemonitoring ensures that patients who are off target are quickly identified, and actions can be undertaken proactively to prevent deterioration of the patient's condition. Conversely, stable patients do not generate alerts and thus do not require immediate care.

These health data [8] ideally generate as few alerts as possible, and a clinical consequence is attached to each generated alert. However, in practice, alert triggering and processing are not perfect yet. Algorithms that have strict alert thresholds generate many alerts, increase clinical workload, and enhance so-called "alert fatigue" [9], whereas algorithms with very wide alert thresholds generate few alerts but may pose significant health risks, for example, by underreporting relevant changes in a patient's health status ("do not harm principle") [5]. "Alert fatigue" is an important barrier when developing a telemonitoring algorithm [10]. In hypertension management, for example, it is known that health care providers, on average, only respond to around 60% of generated off-target blood pressure (BP) alerts [11]. To improve the efficiency of a telemonitoring program, technical improvements or algorithm enhancement, such as designing more sophisticated alerts or refining threshold values, can be initiated [12,13]. However, a clear, structured method like the use of a framework to reduce alerts and improve telemonitoring efficiency is lacking.

In this study, we evaluate the efficiency of a large telemonitoring program for hypertension at the Maasstad Hospital in Rotterdam, the Netherlands, by analyzing telemonitoring alerts and alert processing. Additionally, we use scenario analysis to assess the impact of adjusting alert thresholds on the overall alert burden. Finally, we combine this analysis with a narrative literature review on methods to improve telemonitoring efficiency to propose a framework for alert reduction and telemonitoring process optimization.

Methods

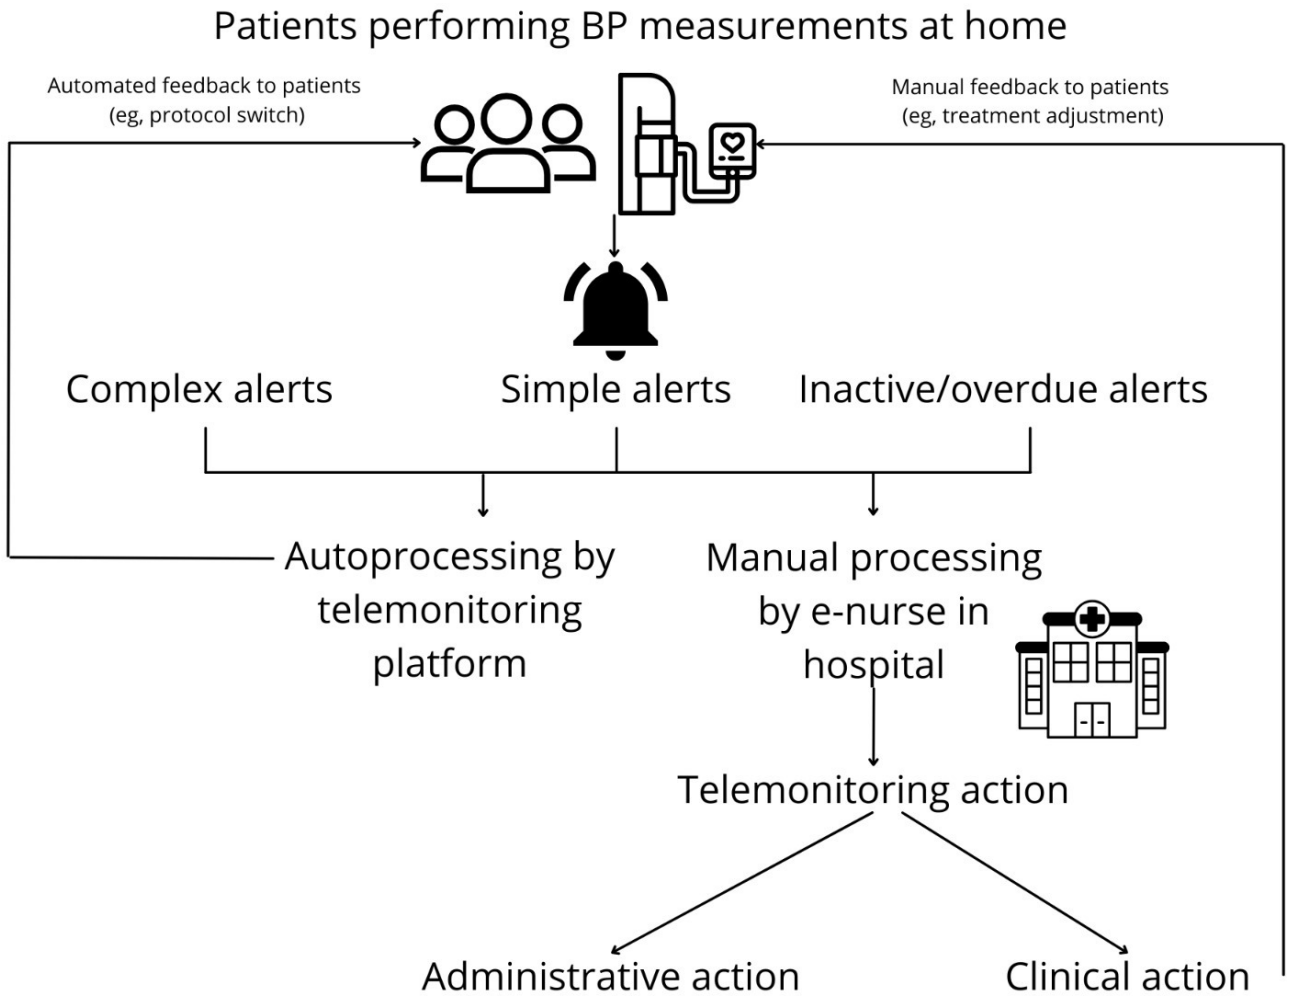
Study Design

This study used a cross-sectional data analysis, narrative literature review, and subsequential framework development.

Setting

This study was conducted at the Maasstad Hospital, a large teaching hospital in Rotterdam, the Netherlands.

Ethical Considerations



The study was conducted following the principles of the Declaration of Helsinki Version: WMA 52nd General Meeting, Edinburgh, Scotland, Oct 2000 (Washington 2002 and Tokyo 2004) [14] and Good Clinical Practice standards [15]. This study was approved by the Institutional Review Board of the Maasstad Hospital (identifier L2024-029). This study was assessed by the Medical Ethics Committee United and not subject to the Medical Research Involving Human Subjects (identifier W24.053). As all data were processed anonymously, a consent procedure was waived by both the Institutional Review Board and the Medical Ethics Committee United.

Telemonitoring Organization and Algorithm

The Maasstad Hospital has extensive experience with telemonitoring for various medical conditions. Since June 2022, a central telemonitoring center has been in operation where specialized monitoring nurses assess all generated alerts during office hours. They are supervised daily by a responsible nurse specialist or medical specialist. See Figure 1 for a graphical overview of the telemonitoring organization.

XSL•FO
RenderX

Figure 1. Telemonitoring organization and alert processing. Users measure their blood pressure at home using a validated Bluetooth blood pressure machine. These measurements can trigger simple, complex, or inactive or overdue alerts. These alerts are either processed automatically by the telemonitoring platform or manually by the e-nurse in the hospital. Alerts are processed on a single day for a single user during a telemonitoring action. This can either be an administrative or clinical action. Feedback to the users is provided automatically by the telemonitoring platform (eg, a protocol switch) or manually by the e-nurse (eg, a treatment adjustment).

Hypertension Care Path and Telemonitoring Program

The hypertension program and telemonitoring application (Luscii) [16] used in this study have been available since 2021 and are embedded in a care path for hypertension. The program is developed in line with the latest European Society of Cardiology/European Society of Hypertension guidelines [17]. Measurements are performed using a Bluetooth-connected, validated BP monitor. The Luscii application consists of a smartphone—or tablet application and an web-based healthcare provider dashboard. BP data are transmitted directly to the health care provider dashboard via the smartphone or tablet application. Once transmitted to the health care provider dashboard, the BP data are analyzed based on predefined algorithms, which will subsequently generate alerts (see details below under "Telemonitoring Alerts and Alert Processing") which are only visible in the health care provider dashboard. In the user application, users can review their BP data and have access to relevant educational modules and self-care documents, which, for example, emphasize the need for smoking cessation and antihypertensive drug adherence.

Users measure their BP twice in the morning and twice in the evening during measurement weeks. The program consists of 4 acute measurement algorithms and 1 chronic measurement algorithm. The acute algorithms, with BP targets ranging from 180/110 to 150/95 mmHg, have higher frequencies of measurement weeks and stricter threshold values and are used during the initial titration phase of achieving BP control. We choose 180/110 mmHg as the highest initial target during the titration phase, as higher BP can be associated with hypertensive emergencies [17]. Stable patients with on-target BP measurements are included in the chronic algorithm (140/90 mmHg) and measure 1 week per month. Patients automatically move between algorithms when BP values meet the target thresholds during the measurement weeks. See Multimedia Appendix 1 for a complete overview of the measurement algorithms.

Home Blood Pressure Telemonitoring Program Users

The hypertension care path is limited to an outpatient hospital setting, and general practitioners are currently not involved. All patients with hypertension, treated in the department of internal medicine of the Maasstad Hospital, either primarily for hypertension or, for example, when hypertension is a relevant risk factor (eg, diabetes, chronic kidney disease), are offered to participate in this digital care path. Exclusion criteria are the

XSL•FO
RenderX

existence of communication problems, lack of sufficient digital skills, and the absence of the possession of a mobile device. Validated BP measurement equipment can be loaned from the hospital if patients are unable to afford the purchase of such measurement. Once included, around 70% of the total care provided will be conducted remotely and digitally and 30% of the follow-up consultations will still be provided in person. The patients who primarily require follow-up for hypertension are referred by a general practitioner due to suspected secondary hypertension, resistant hypertension, drug intolerances, or a suspected hypertensive emergency. Given the heterogeneity of this group and for the purpose of this study, which focuses on organizational and efficiency aspects of telemonitoring, we refer to this complete patient group as the "users" of the telemonitoring program.

Telemonitoring Alerts and Alert Processing

The monitoring program generates 3 different types of alerts (Figure 1) following BP data transmission by the users of the telemonitoring program. First, there are simple alerts, which are triggered by a 1-time measurement exceeding predefined thresholds, eg, a very high or low systolic or diastolic BP. Second are complex alerts, which are triggered if a series of measurements are off target (eg, multiple consecutive off-target BP measurements) or if a combination of measurements (eg, systolic and diastolic BP and heart rate) are off target. In practice, these alerts are used for clinical decisions, such as drug treatment adjustments. Third are alerts that are triggered when users either miss a single scheduled measurement (overdue alert) or when they have missed all measurements within x days (inactive alert). Alerts can be processed automatically (eg, a single overdue alert, or an alert when a user is "on target") by the telemonitoring platform while triggering automated workflows created by the responsible clinicians. These workflows usually contain automated feedback messages that are delivered to the user automatically when the alert is processed by the monitoring platform (eg, your BP has improved, your target has changed). Besides autoprocessing by the telemonitoring platform, alerts can also be processed manually (eg, a complex alert for off-target BP) by e-nurses in a telemonitoring center. Whether alerts need manual processing by the e-nurses depends on choices made by health care providers in the monitoring algorithm. Simple alert thresholds were based on expert opinion, as no guidelines for these specific alerts are available. Thresholds for the complex alerts were based on treatment targets for home BP monitoring in existing guidelines [17]. We specifically choose to make the alert thresholds slightly higher than the treatment targets to reduce the overall alert burden (eg, 140/90 compared to 135/85). All alerts generated on a single day by a single user are clustered and manually processed using a telemonitoring action by the e-nurse, consisting of either an administrative action or a clinical action (eg, a treatment adjustment). Administrative actions have no clinical impact, as these actions only involve administrative handling of the alert in the telemonitoring platform and electronic health record (EHR) without any clinical consequences (eg, no treatment adjustments). Prior to processing the alerts, e-nurses can decide to contact patients to gather relevant clinical information (eg, adherence to antihypertensive drugs of lifestyle interventions). They can also provide feedback to the patients, for example, following antihypertensive treatment adjustment. Patients will also be contacted following inactivity alerts. Contacting patients is performed via a digital secured messaging platform (BeterDichtbij [18]) or via a telephone consultation. Alerts that need manual processing generated on Saturdays and Sundays were combined into one action on Monday, as the e-nurses only review alerts during office hours.

Telemonitoring Data

We extracted 1-year alert and alert processing data from the Luscii telemonitoring platform [16] and EHRs from all users participating in the hypertension telemonitoring program between June 1, 2022 and the May 31, 2023. Given the focus of the study, only anonymized data and no clinical or demographic data were extracted.

Alert Analysis

Alerts were processed either automatically or manually. We assigned each alert to a specific measurement to assess the impact of various alert thresholds on the number of generated alerts. Manually processed alerts clustered in telemonitoring actions were categorized, resulting in an administrative or a clinical action. Clinical actions can be a telephone consultation (with or without a treatment adjustment) or an integrated secured asynchronous message (with or without a treatment adjustment) through a communication platform.

Literature Search

For the narrative literature review, we searched articles reporting clinical alerts or workflow optimization in telemonitoring programs on May 24, 2024 in Embase, Medline, Cochrane, Web of Science, and Google Scholar. The complete search strategy is included in Multimedia Appendix 2. We included all English language academic research papers and conference abstracts published after January 1946. Studies reporting on alert reduction in clinical, in-hospital, settings (eg, intensive care units) were excluded. Relevant literature was identified using title and abstract screening from the initial identified papers. Relevant studies were subsequently reviewed in full text, and relevant alert reduction methods or workflow optimizations were extracted by JvS.

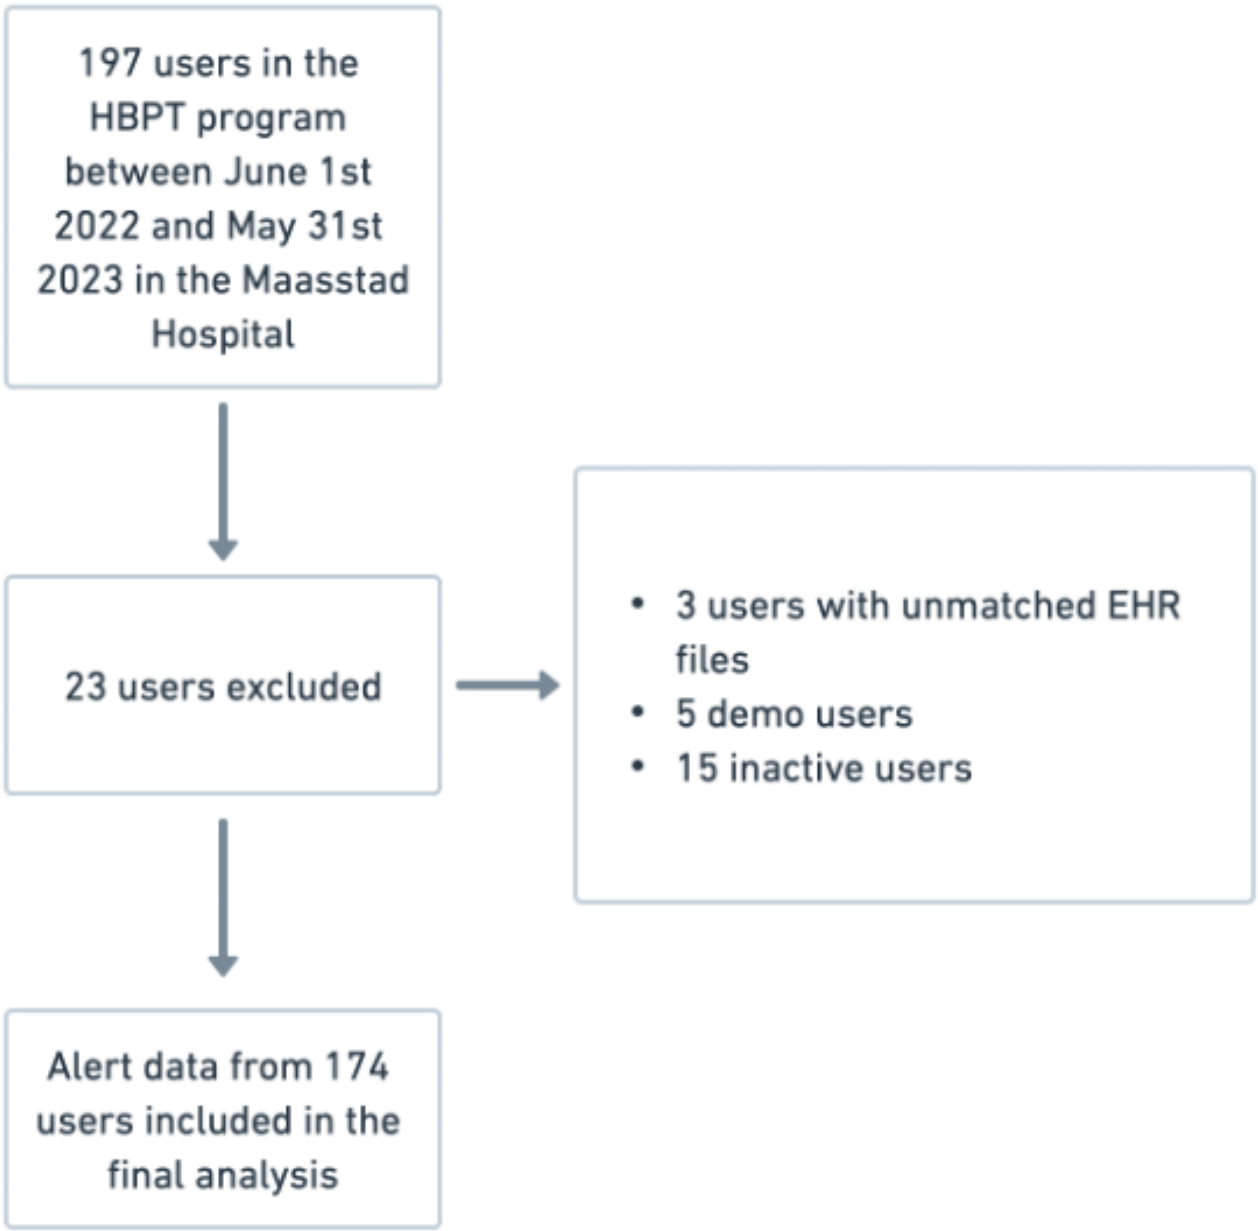
Analysis

Data from the telemonitoring platform and EHR were analyzed using Microsoft Excel. Alert and alert processing data were reported as frequencies (N) and proportions (%). A separate scenario analysis with different threshold values was conducted for all simple systolic and diastolic alerts for all included users that were processed manually by the telemonitoring center. The number of alerts that would be triggered with the new threshold values was based on the absolute values of the measurements performed in the original dataset. We calculated the current percentage of alerts that were processed administratively and extrapolated these to the alerts with the adjusted threshold values to estimate the percentage of alerts that would be processed administratively after the threshold adaptations and give insight into the potential workload reduction for the e-nurses. In this scenario analysis, the assumption was made that any alert

XSL•FO
RenderX

generated by the telemonitoring program that would be processed administratively would not have any clinical impact on the user.

Framework Development



We created a framework for alert reduction and clinical workflow optimization in telemonitoring programs based on an iterative process that included a synthesis of our own clinical experiences, the alert-reduction and clinical workflow optimization methods identified in our own study (eg, scenario analysis), the methods for alert reduction as identified in the narrative alert reduction literature review, and general recommendations available from other relevant telemonitoring studies.

Results

Telemonitoring Alerts

Between June 1, 2022, and May 31, 2023, 197 users were included in the home blood pressure telemonitoring program. 5 users were identified as demo users, 3 users could not be matched to an EHR file, and 15 users did not activate the telemonitoring app. Therefore, alert data from a total of 174 users were included in the final analysis (Figure 2). In total, 45% of these users started in the chronic (monthly) measurement algorithm and 55% in the acute (weekly or biweekly) measurement algorithms. On average, each user was active in the telemonitoring app for 207 days during the study period, and a total of 30,184 measurements were performed. These measurements triggered 17,293 alerts, of which 13,647 were autoprocessed and 3646 were processed manually, equivalent to 21 manually processed alerts per user (Table 1).

Figure 2. Flow diagram illustrating the telemonitoring data collection.

XSL•FO
RenderX

Table . Telemonitoring alert data between June 1, 2022 and May 31, 2023.

Variable	Value
Total number of active users	174
Average days active	207
Total number of measurements	30,184
Total number of alerts (% of total number of measurements)	17,293 (57)
Number of alerts auto processed (% of total number of alerts)	13,647 (79)
Complex alerts (% of total number of alerts autoprocessed)	1878 (14)
Inactivity or overdue alerts (% of total number of alerts autoprocessed)	11,769 (86)
Number of alerts processed manually (% of total number of alerts)	3646 (21)
Simple alerts (% of total number of alerts processed manually)	2025 (56)
Complex alerts (% of total number of alerts processed manually)	1344 (37)
Inactivity or overdue alerts (% of total number of alerts processed manually)	277 (7)

Of the autoprocessed alerts, 11,769 (86%) were overdue alerts and 1878 (14%) were complex alerts. Of the manually processed alerts, 2025 (56%) were simple, 1344 (37%) were complex, and 277 (7%) were inactivity alerts. The 277 manually processed overdue or inactivity alerts were generated by 73 (42%) of all included users. It is important to note that overdue alerts are triggered when a single measurement is not completed in time. Within a hypertension protocol consisting of multiple scheduled measurements per day, this can have a large impact on the total number of alerts. However, due to the automated processing of these alerts, their contribution to the clinical workload is negligible.

Telemonitoring Center Data

The 3646 alerts that were processed manually accounted for a total of 2101 monitoring actions (all alerts that were processed manually on a single day for 1 user clustered into 1 action) and 1626 (77%) of these actions were processed with an administrative action (Table 2). A total of 475 (23%) alerts resulted in a clinical action. Out of these, 191 (40%) were telephone consultations without a treatment adjustment, 130 (28%) were telephone consultations with a treatment adjustment, 134 (28%) were digital messages without a treatment adjustment, and 20 (4%) were digital messages with a treatment adjustment. On average, 1 monitoring action for each user per month was registered based on the total average participation of 207 days (7 months). In total, the combined average workload for the e-nurses was 6.2 minutes per user per month, assuming a workload of 5 minutes for administrative actions and 10 minutes for clinical actions (telephone or messaging).

Table . Telemonitoring center data between June 1, 2022 and May 31, 2023.

Variable	Value
Total telemonitoring actions[a]	2101
Administrative actions (% of total number of monitoring actions)	1626 (77)
Clinical actions (% of total monitoring number of actions)	475 (23)
Telephone consultations without treatment adjustment (% of total number of clinical actions)	191 (40)
Telephone consultations with treatment adjustment (% of total number of clinical actions)	130 (28)
Digital messages without treatment adjustment (% of total number of clinical actions)	134 (28)
Digital messages with treatment adjustment (% of total number of clinical actions)	20 (4)

[a]All alerts that were generated on a single day were combined into 1 “telemonitoring action” in which the e-nurses reviewed all generated alerts on 1 specific day for 1 single user.

In total, 25 (15%) users triggered 61% of the overall simple alerts and 48% of the complex alerts that were processed manually. These users were responsible for 45% of all monitoring actions, which meant that the e-nurses would roughly spend half of their time on a very small subgroup (15%) of the included users.

XSL•FO
RenderX

Adjusting Individual Algorithm Thresholds

Review of the telemonitoring actions of the 25 users who generated most alerts led to individual adaptations in 13/25 users. In 3/13 users, the alert thresholds could be adjusted based on medical decisions (eg, accepting higher BP due to perceived intolerance of antihypertensive drugs, accepting asymptomatic lower heart rate), which would result in a reduction of 265 manually processed simple alerts in these users. Additionally, 3/13 users were provided with additional measurement instructions, and 7/13 users were discharged from the telemonitoring program due to a lack of digital skills or inability to adhere to the required measurement schedule and continued with regular physical care.

Adjusting Group Algorithm Thresholds: Scenario Analysis

A scenario analysis (Table 3) was conducted with various adaptations in thresholds for the 2025 simple systolic and diastolic alerts that were processed manually. We found that increasing the threshold values by only 5 mmHg for the simple diastolic alert and only 10 mmHg for the simple systolic alert would reduce the total number of alerts by 47% and 54%, respectively. These adjustments would lead to small increases in required clinical actions of 4% and 3%, respectively, if the alert processing remains similar to the current threshold scenario. Therefore, this scenario revealed limited clinical implications despite a large reduction in overall alerts. This was similarly applicable for adjusting the diastolic threshold value to ≥115 mmHg and the systolic threshold value to ≥190 mmHg, as in these scenarios, the increase of alerts requiring a clinical action was around 11% and 8%, respectively.

Table . Scenario analysis for the manually processed simple diastolic and systolic alerts between June 1, 2022 and May 31, 2023.

Alert type	% currently processed with administrative action/clinical action (total number of alerts)	Current threshold	New threshold	% total reduction in alerts (number of alerts)	% processed with administrative action or clinical action after threshold adjustment (total number of alerts) (% difference)	Potential time saving in minutes for the e-nurses
Diastolic simple alert	71 (726)/29 (297)	≥105 mmHg	≥110 mmHg	47 (481)	67 (322)/33 (159) (−4/+4)	2993
Diastolic simple alert	71 (726)/29 (297)	≥105 mmHg	≥115 mmHg	77 (788)	60 (473)/40 (315) (−11/+11)	4951
Diastolic simple alert	71 (726)/29 (297)	≥105 mmHg	≥120 mmHg	91 (930)	50 (465)/50 (465) (−21/+21)	5908
Systolic simple alert	71 (620)/29 (253)	≥170 mmHg	≥180 mmHg	54 (471)	68 (320)/32 (151). (−3/+3)	2980
Systolic simple alert	71 (620)/29 (253)	≥170 mmHg	≥190 mmHg	85 (742)	63 (467)/37 (275) (−8/+8)	4734
Systolic simple alert	71 (620)/29 (253)	≥170 mmHg	≥200 mmHg	95 (829)	44 (365)/56 (464). (−27/+27)	5290

We calculated potential time savings for the e-nurses based on the 2025 simple alerts in the current threshold scenario that were processed manually. These consisted of 1023 diastolic alerts, 873 systolic alerts, and 129 heart rate alerts. In total, 71% (726 and 620) of the 1023 diastolic and 873 systolic simple alerts were processed with administrative actions and 29% (297 and 253) with clinical actions, which would lead to a total workload for the e-nurses of 6598 minutes for the diastolic alerts and 5631 minutes for the systolic alerts, assuming a 5-minute workload for each individual administrative action and a 10-minute workload for each individual clinical action. In the adjusted threshold scenarios, we calculated total time savings based on a reduced workload due to the total reduction of alerts and an increased workload due to an increased percentage or alerts that would require a clinical action. We assumed a 10-minute workload for a clinical action. The potential time savings for the e-nurses were 2993, 4951, and 5908 minutes for the diastolic simple alerts and 2980, 4734, and 5290 minutes for the systolic alerts, respectively, assuming a 10-minute workload for each individual clinical action.

Literature Review

The original search yielded 251 articles. Based on the predefined exclusion criteria, 241 articles were excluded as they did not report any alert reduction methods or describe studies in intensive care units or other in-hospital settings. In total, 10 articles were reviewed in full text, and 7 of these articles contained a clear description of a method to improve telemonitoring efficiency. These methods included the introduction of complex alerts to reduce the overall alert burden, the introduction of clinical algorithms to triage alerts, scenario analysis with alert threshold adjustment, and a qualitative analysis to create an alert triage algorithm. See Table 4 for a complete overview of the studies reporting methods to improve telemonitoring efficiency.

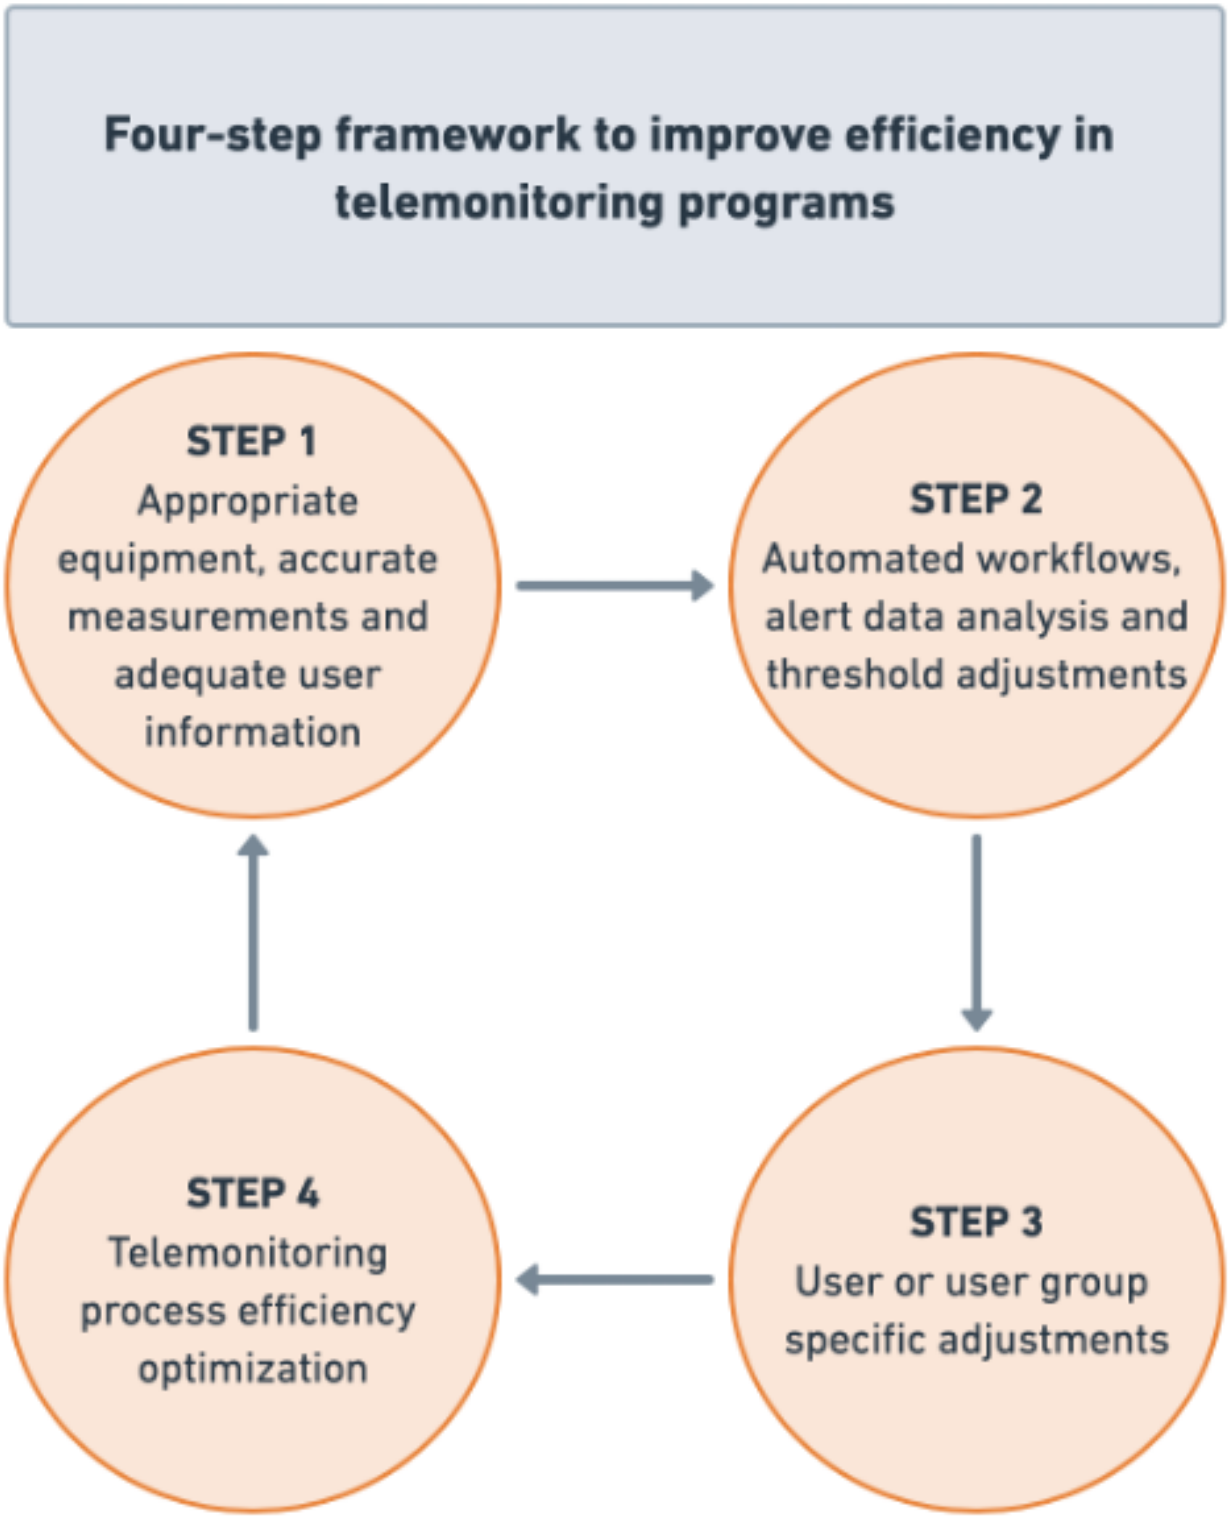
Discussion

Principal Findings



Based on our alert data analysis and narrative literature review, we identified multiple areas to reduce alerts and enhance telemonitoring efficiency. First, by using automated workflows in the telemonitoring program, around 86% of alerts could be processed automatically. Reduction of the alerts could also be achieved by individual adjustment of the alert thresholds: review of the subset of users who generated most of the workload, both in terms of the generated alerts as well as the workload burden for the e-nurses, posed opportunities to make individual threshold adjustments. These findings highlight the need for a more individualized approach with personal thresholds and measurement schedules in certain cases. Additionally, in our scenario analysis, we showed a large potential in alert reduction and time saving for the e-nurses for the simple alerts with only small increases in threshold values. Moreover, these adjustments appeared to be relatively safe, as our data showed only a small increase in alerts requiring clinical actions, implying limited clinical consequences. Additionally, since the start of the program, we have not experienced any adverse events like emergency department admissions or major adverse cardiovascular events. However, in general, triggering simple alerts can still be relevant to some degree, as one-off extreme health values should always be assessed on an individual basis, and general safety reasons can sometimes justify a larger number of alerts. Alert threshold adjustments should, therefore, always be balanced carefully with clinical risks, and any adjustment made should be reassessed periodically to ensure no clinically important events are missed.

A Framework for Alert Reduction and Workflow Optimization

We propose the following alert reduction and telemonitoring process optimization framework for proactive care path embedded telemonitoring programs. This framework (Figure 3), based on 4 distinct steps, outlines a systematic approach to optimize efficiency and can be used for the design, implementation, and optimization of care path-embedded telemonitoring programs.

XSL•FO
RenderX

Figure 3. Four-step framework to improve efficiency in telemonitoring programs.

Step 1: Appropriate Equipment, Accurate Measurements, and Adequate User Information

To ensure reliable and adequate measurements, users need to be provided with reliable and validated equipment [10]. Use new relevant medical device features if applicable. Additionally, confirm that the user has received all the necessary measurement instructions and confirm that the users can perform an adequate measurement (for example, a resting "test" BP measurement). Provide users with the correct information during technical issues and educate users on actions to take during acute health issues [10]. Inform users if any relevant changes are made in the remote monitoring program (eg, changes in measurement schedules or new functionalities). Periodically provide personalized feedback to users to ensure long-term reliable measurements, prevent inactivity, and improve overall adherence to the telemonitoring program [25]. Provide users with relevant disease- or lifestyle-specific information to enhance health

XSL•FO
RenderX

literary and disease insight, which can both reduce the overall alert burden.

Step 2: Automated Workflows, Alert Data Analysis, and Threshold Adjustments

Use automated workflows within the telemonitoring program to improve efficiency. These workflows can, for example, trigger automated messages (eg, a message requesting to repeat a certain measurement) following off-target measurements or process alerts independently. This empowers users to partly take responsibility themselves in case of off-target measurements, which can facilitate telemonitoring in large population groups.

Analyze all generated alerts in terms of their origin and conduct a periodic scenario analysis [21] to assess the impact of threshold adjustments in terms of alert reduction and clinical action requirements [21]. These adjustments should be balanced with clinical risks prior to final adjustment and should always be re-evaluated [23]. Additionally, potentially relevant clinical events after threshold adjustment should always be monitored. Data analysis and algorithm optimization can be performed internally but can also be based on new scientific evidence or guidelines. Remove any measurements from the telemonitoring algorithm that have no clear clinical benefit or consequences. Make use of complex alerts [13,19,20] and clinical algorithms [19,22,24] to filter alerts in terms of clinical relevance, to provide clinical decision support based on measurement trends, and to prevent clinical decision-making on single off-target measurements (“simple alerts”).

Step 3: User or User Group Specific Adjustments

Periodically identify users or user groups that generate a large proportion of the overall alert burden in the telemonitoring program (eg, the 10 users or a specific subgroup of users triggering the most alerts, depending on the overall number of users participating in the telemonitoring program). Discuss these users or user groups in a multidisciplinary setting with both the responsible health care provider and the telemonitoring staff involved. Investigate specific reasons for alert triggers in these users or user groups [10]. Consider temporarily user-specific alert thresholds or use personalized measurement schedules if applicable [26]. Recognize the limitations and difficulties of adhering to or using telemonitoring in specific user groups and engage and involve caregivers as needed.

Step 4: Telemonitoring Process Efficiency Optimization

Periodically evaluate the complete clinical workflow and telemonitoring process for potential efficiency improvements [12]. Identify alerts that can be processed independently by a telemonitoring center, for example. Use automated alerts and messages (specific alerts that trigger automated advice). For administrative actions, consider using message templates to save time communicating with users. Involve multiple departments (eg, the user information department) to ensure an efficient initial set-up, for example, by giving the user information department the responsibility for the initial device and telemonitoring instructions. Involve users, for example, during periodic focus group interviews to evaluate and optimize the current care pathway from a user perspective.

Limitations

There are a few important limitations to consider when interpreting the findings of our study. First, the data analysis is conducted with data from a single-center, single chronic disease (hypertension) telemonitoring program, which affects generalizability. However, we tried to overcome this by making general interpretations during telemonitoring programs for various diseases during framework development. Second, we have currently not incorporated the potential of artificial intelligence or other complex algorithm optimization strategies with regard to adjusting alerts and threshold values. It is to be expected, however, that this will be available and applicable on relatively short notice and should, therefore, be included in future updates of our framework. Third, given the large number of alerts, we were unable to analyze the complete clinical context of each individual alert, which might influence the alert processing data. Fourth, a narrative literature review was used in this study, which could have an impact on the strength of the results derived from the literature review. We opted for this approach, however, as very limited studies are available that specifically report methods on alert reduction and efficiency improvement in telemonitoring programs. Fifth, the framework was created based on a synthesis between the alert-data analysis and narrative literature review. This could, as no formal qualitative method was used, impact the overall strength of the framework. However, given the absence of any other similar framework in the literature, it could serve as a valuable starting point for further improvement in future studies.

Sixth, the proposed threshold increases of 5 and 10 mmHg in the scenario analysis might be too broad for populations where more strict BP management is required (eg, aortic dissection) and these adjustments should therefore always be made after assessing the specific included population in the telemonitoring program.

Finally, the available data on the described cohort of patients was only limited to telemonitoring data as the data analysis was used to support the proposed framework. The absence of clinical data could impact generalizability of the findings to certain populations (eg, hypertension, heart failure) included in other telemonitoring programs.

Conclusions

We developed a framework for alert reduction and telemonitoring process optimization in care path embedded telemonitoring programs. The framework includes 4 steps aimed at ensuring accurate measurements, alert, and alert-processing optimization, focusing on individual user needs, and improving overall telemonitoring process efficiency. Future studies should focus on further development of this framework and the evaluation of techniques to enhance efficiency while balancing potential clinical risks.

Abstract

Background: With the improvement of the drug evaluation system in China, an increasing number of clinical trials have been launched in Chinese hospitals. However, traditional clinical trial quality management models largely rely on human monitoring and counting, which can be time-consuming and are likely to generate errors and biases. There is an urgent need to upgrade and improve the efficiency and accuracy of clinical trial quality monitoring systems in hospital-based research institutions within China.

Objective: The objective of this study was to develop a digital monitoring platform that allows for the real-time monitoring and detection of risk points and provides warnings about risk points throughout the entire life cycle of clinical trials, on the basis of historical clinical trial quality control (QC) findings.

Methods: Leveraging the risk-based quality management mindset, we built a digital dynamic monitoring platform by using big data analysis and automatic quantitative technology. Data from clinical trial QC reports generated during 2019 to 2023 in Beijing University Cancer Hospital, China, were used to train the automated classification tool, establish warning thresholds, and validate threshold values. Quality findings from the early-stage, interim-stage, and conclusion-stage QC rounds of clinical trials were rated by using 3 severity grades (minor, major, or critical) and classified into 5 categories (with 4 taxonomy levels under each category). QC report text was processed by using an automated natural language processing tool. All QC reports were grouped into 2 clusters via hierarchical clustering analysis. QC findings from the relatively high-risk cluster (reports that were more likely to have major and critical findings, as determined by experienced QC analysts) were used to determine warning threshold values for the monitoring platform (ie, the lowest number of findings was set as the threshold value for each specific study stage, Level-3 taxonomy, and severity grade combination).

Results: The most frequently reported Level-3 taxonomies in QC reports from 2019 to 2022 were “Standard Procedure and Process,” “Safety Reporting,” and “Source Data Collection and/or Recording.” In total, 189 warning threshold values were established based on data from 1380 QC reports generated during 2019 to 2022, covering 3 severity grades, 21 Level-3 taxonomies, and 3 QC rounds. The warning thresholds were applied to 211 QC reports generated in 2023, of which 19.9% (n=42) triggered warnings. Similar patterns of QC findings, including the most frequently noted Level-3 QC findings, were observed between reports generated in 2023 and those from 2019 to 2022.

Conclusions: In clinical practice, our tool would enable the automated monitoring and detection of risk points throughout all clinical trial stages; accurately identify the most relevant trial procedure and function line; and notify quality management personnel, in real time, to take prompt actions and dynamically prevent the recurrence of quality issues.

Introduction

Over the past 20 years, with the improvement of the drug evaluation system and standards in China, an increasing number of domestic and cross-national multicenter clinical trials have been launched in Chinese hospitals. However, in many hospital-based clinical trial institutions, traditional quality management models largely rely on human monitoring and counting, which not only require a lot of time and resources but also likely result in errors and biases. Therefore, such models may not be able to identify risk points and trends in a timely manner or prevent the recurrence of quality issues. In the face of the increasing number and complexity of clinical trials, the optimization of quality management models has become an urgent need for clinical trial institutions in Chinese hospitals.

Risk-based quality management (RBQM)—recommended in guidelines issued by the US Food and Drug Administration [1] and European Medicines Agency [2] in 2013, as well as in the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH) guidelines for good clinical practice in 2016 [3]—is a powerful approach that has been explored and applied in a growing number of trials and institutions [4,5]. In 2020, the China National Medical Products Administration introduced the concept of RBQM into Chinese trial quality management systems [6]. In 2022, the China Center for Drug Evaluation released Statistical Principles for Centralized Monitoring of Drug Clinical Trials, which was considered a milestone in China's clinical trial revolution and a guideline for the improvement and implementation of RBQM in China's clinical practice [7].

To meet the urgent need for upgrading quality management models and achieving better efficiency, accuracy, and timeliness, we leveraged the RBQM mindset and used a long-term collection of quality management data from clinical trial programs in Beijing University Cancer Hospital, China, to build a digital dynamic monitoring platform via big data analysis and automatic quantitative technology. Through this platform, we aim to dynamically and prospectively monitor the entire life cycle of clinical trials and efficiently identify, intervene with, and systematically prevent quality risks that might compromise critical trial processes, patient safety, or data integrity.

Methods

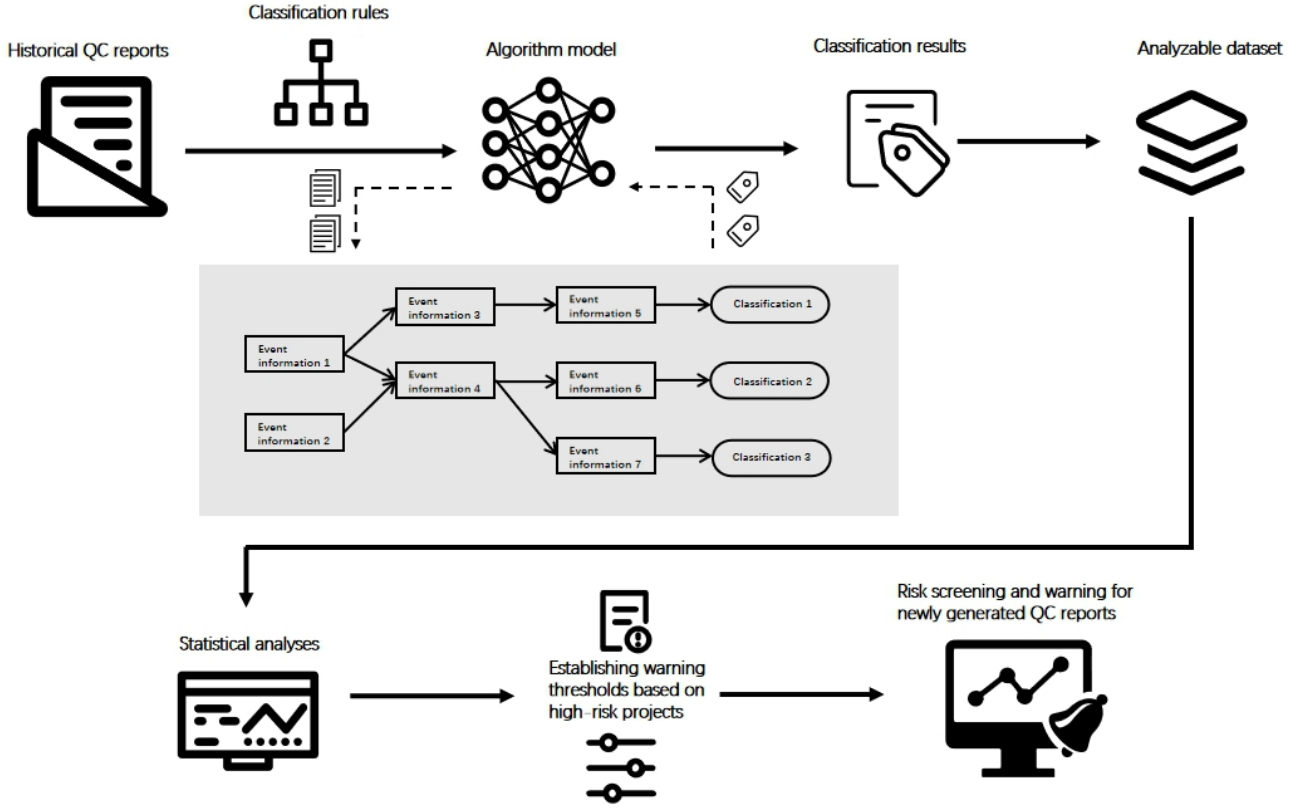
Ethical Considerations

This study was based on the processing and analysis of quality control (QC) documents from a large number of clinical trials, which underwent their own ethics reviews. Further, the text of the QC findings did not contain personal information of trial participants. As such, this study did not require ethics board review.

Materials

A total of 1591 QC reports were generated in our institution from January 2019 to September 2023, involving 993 clinical trials. In accordance with relevant quality management standard operating procedures, a specific QC group was responsible for conducting at least 3 rounds of routine QC for each trial, including but not limited to (1) an early-stage QC round at the time point of achieving 5 enrollments or at 3 months after trial initiation, (2) an interim-stage QC round once every 6 months or when the trial achieved 20 enrollments, and (3) a conclusion-stage QC round at the time of site closeout. A detailed QC report was generated for each QC round, recording all quality issues. To build a digital monitoring platform, 1380 reports, which were generated during 2019 to 2022, served as the foundation for automated quantitative processing and the identification of warning thresholds, while the remaining 211 reports, which were generated in the year 2023, were used for testing the effectiveness of those thresholds in identifying high-risk trials.

Classification of QC Findings



Findings from the routine QC reports were rated by using 3 severity grades (minor, major, or critical) and classified into 5 categories ("Data," "Quality," "Safety and Ethics," "Equipment and Facility," or "Finance"), with 4 taxonomy levels under each category. The severity ratings and Level-1 to Level-3 taxonomies would allow for an overall review and trend analysis, while the Level-4 taxonomies were designed to trace back precisely to the corresponding clinical trial procedure and personnel.

Novel Automated Classification Tool

To enable the automated classification of QC findings, we developed a natural language processing (NLP) algorithm based on the Local Interpretable Model-Agnostic Explanations framework, which was implemented in Python. This algorithm was designed to perform multidimensional classifications of events in QC report texts (Figure 1).

XSL•FO
RenderX

Figure 1. Algorithm classification tool flowchart. QC: quality control.

The dataset used to develop the NLP algorithm comprised 1380 QC reports that were generated during 2019 to 2022; an average of 345 reports were generated per year. Among QC findings from these reports, 55.48% were categorized as minor findings, 42.23% were categorized as major findings, and 2.29% were categorized as critical findings. The word count of the reports ranged from 1619 to 17,367 words, with a median word count of 5938 (IQR 4453-7422) words per report. Data were stratified and split into training, validation, and testing sets (70%, 15%, and 15%, respectively) to ensure balanced class representation. Annotation rules covered 4 entity dimensions and 54 issue categories, which were derived from industry standards and refined through discussions with an internal expert team.

In the first phase, the dataset was annotated by using multidimensional information labeling rules, generating high-quality training data. In the second phase, natural text from QC reports was subjected to preliminary automated classification via a Bayesian network, which determined the Level-1 to Level-3 classifications for each text segment based on joint probability. Additionally, semantic role labeling—a critical step in the classification NLP tool—was used to identify the predicate-argument structure of each sentence [8]. After training with the dataset, an explainable directed acyclic graph was constructed [9]. In the directed acyclic graph, graph neural networks were used to propagate information across the graph, forming an algorithmic model capable of capturing events. The model achieved precision (P) and recall (R) scores >0.95. In the third phase, by using the trained model, events were extracted from the QC report text and subjected to Bayesian inference. If an inference could be drawn from the graph, automatic classification was completed; if no inference could be made, a new branch was created, and the entire graph model was updated and iterated. The final Level-4 classification results were represented as the terminal leaf nodes in the graph.

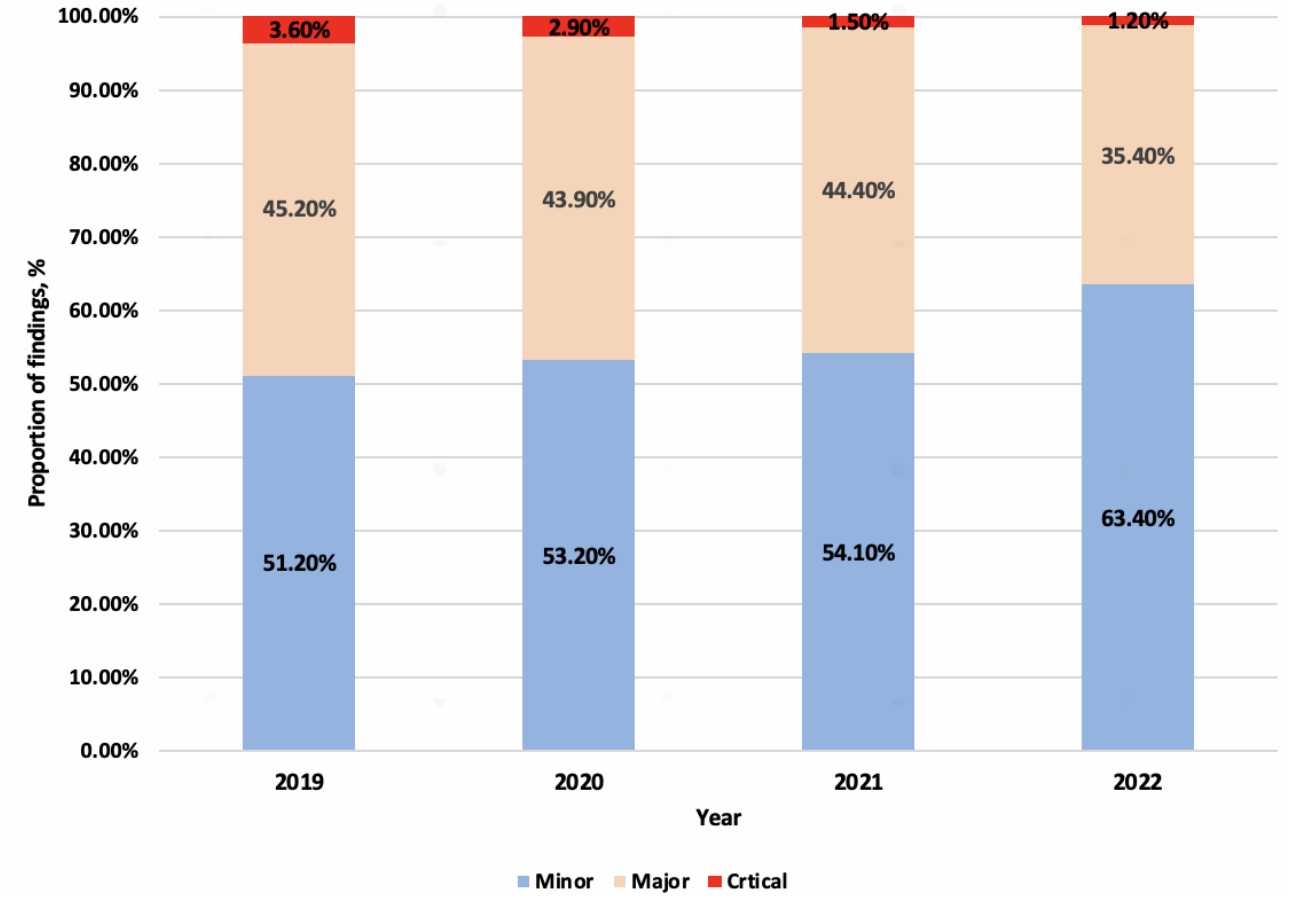
Clustering

After all findings from QC reports were classified by using our automated classification tool, a dataset was created based on the incidence rates of different categories of QC findings from each QC report. Using SPSS for Windows 20.0 (IBM Corp), hierarchical clustering analysis was applied to this dataset to ensure that reports with similar patterns of QC findings were grouped into the same cluster: each report was initially treated as a separate cluster; then, the algorithm identified 2 clusters that were closest to each other (ie, clusters with maximum similarity) and merged these 2 clusters into 1 new cluster. These steps were repeated until all QC reports were grouped into 2 clusters (Cluster I and Cluster II). A dendrogram was generated, showing the levels of similarity and dissimilarity between QC reports. Per manual interpretation by a group of experienced QC analysts, Cluster II was identified as high risk (ie, reports with more findings or a higher proportion of major and critical findings), and Cluster I was considered relatively “normal” (reports with less findings or a higher proportion of minor findings).

Establishment of Warning Thresholds and Detection of Risk Points

Warning thresholds were established based on the high-risk (Cluster II) QC reports from 2019 to 2022; the lowest number of findings was set as the threshold value for a specific study stage, Level-3 taxonomy, and severity grade combination. For example, a threshold value of X was set for the following

XSL•FO
RenderX



combination: early-stage QC round, Level-3 taxonomy "Biological Sample Management," and major findings; this made sure that all high-risk QC reports from early-stage QC rounds had at least X major findings under the Level-3 taxonomy "Biological Sample Management." The warning thresholds were then applied to QC reports from 2023; these warning thresholds would help with determining the risk points (ie, the most commonly reported findings) and investigating the root causes of findings.

Results

Summary of 2019 to 2022 QC Findings

From 2019 to 2022, the proportion of major or critical findings generally decreased each year (major findings showed a 1.27-fold decrease, and critical findings showed a 3-fold decrease), even during the COVID-19 pandemic, while the proportion of minor findings showed an approximately 1.24-fold increase over the 4 years (Figure 2).

Figure 2. Proportion of quality control findings under 3 categories of clinical significance and severity.

It was consistently observed during each year that the most commonly reported Level-3 taxonomies (the proportions of findings for these taxonomies were >5%), in decreasing order of frequency, were (1) "Standard Procedure and Process," (2) "Safety Reporting," (3) "Source Data Collection and/or Recording," (4) "Investigational Product," (5) "Personnel Qualification and Training," and (6) "Biological Sample Management" (Table 1). In 2020, under the influence of the COVID-19 pandemic, increases were observed in the average numbers of findings per report that fell under these Level-3 taxonomies, but 2 years later, the average numbers of these findings dropped back to their 2019 levels (Figure 3).

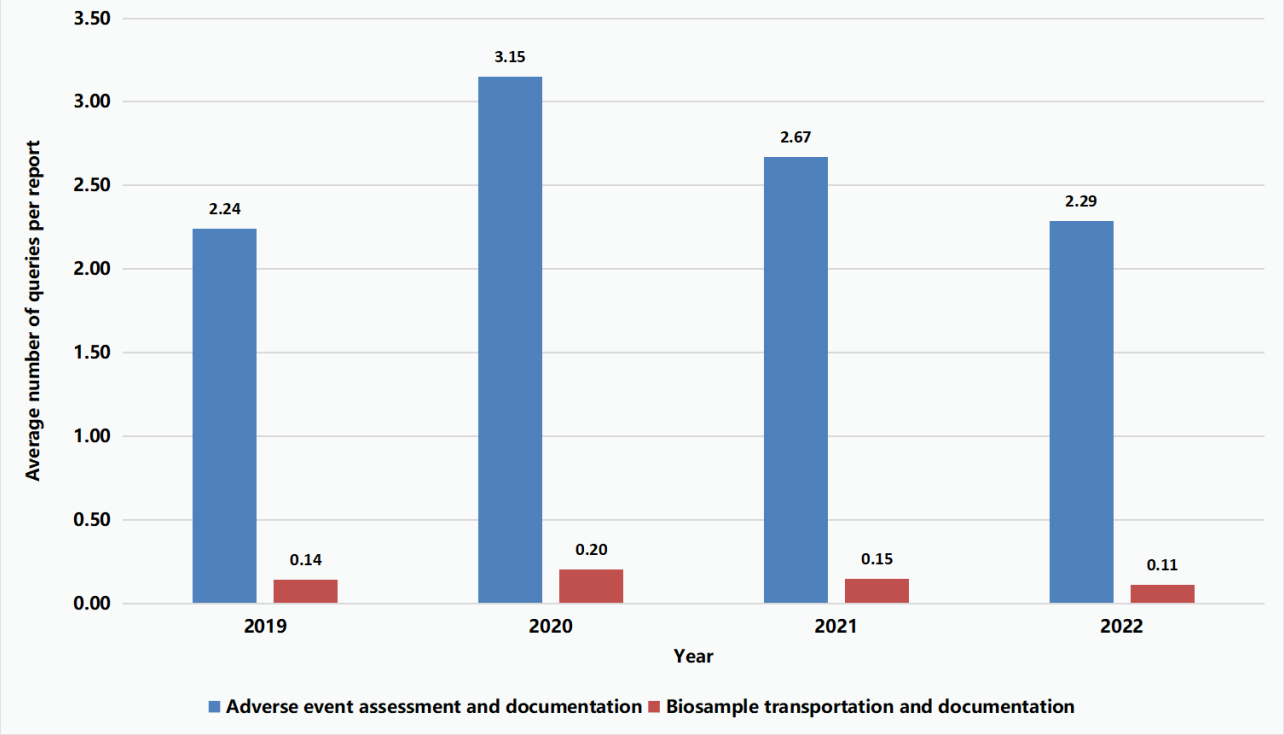

Figure 3. Average number of findings per quality control report under the most frequently reported Level-3 taxonomies (proportions of findings for these taxonomies: >5%).

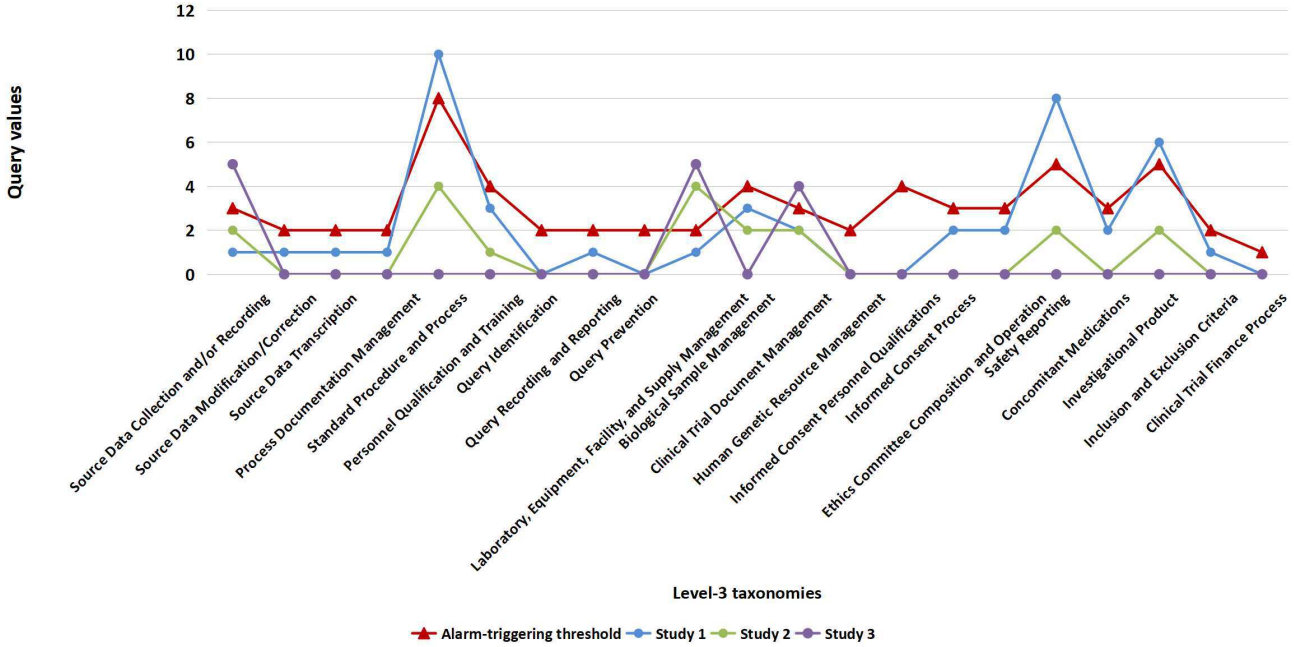
Similar trends were also observed when QC findings were summarized under Level-4 taxonomies. A 1.41-fold increase in the average number of findings under the Level-4 taxonomy "Adverse Event Assessment and Documentation" was observed in 2020 when compared to 2019. Further, while the average number of findings under the Level-4 taxonomy "Biological Sample Shipment and Recording" was ≤0.2 per report across each year, a 1.43-fold increase was also noted in 2020 when compared to the previous year. These trends were likely attributable to the outbreak of the COVID-19 pandemic. With the adaptive actions taken in response to COVID-19 (eg, implementation of digital monitoring), the numbers of QC findings under these two Level-4 taxonomies eventually dropped back to their 2019 levels (Figure 4).

XSL•FO
RenderX

Figure 4. Trends of change in average number of findings per quality control report under two Level-4 taxonomies from 2019 to 2022.



Warning Thresholds and Warning-Triggering Risks in the Year 2023

A total of 189 warning threshold values were established to cover all 3 severity grades, 21 Level-3 taxonomies, and 3 rounds of QC (Multimedia Appendix 1). These thresholds were applied to a total of 211 QC reports generated in 2023. Among those reports, 42 triggered warnings, resulting in a trigger rate of 19.9%. Approximately half (n=23, 55%) of the 42 warning-triggering, high-risk reports were from interim-stage QC rounds, while 8 and 11 were from early-stage and conclusion-stage QC rounds, respectively.

Figure 5 presents data from 3 randomly selected reports from early-stage QC rounds as examples to show the number of major QC findings that exceeded or did not exceed the corresponding threshold value for each of the 21 Level-3 taxonomies.

Figure 5. Number of major QC findings under each Level-3 taxonomy from 3 early-stage QC reports, in comparison with corresponding threshold values. QC: quality control.

Among the 42 high-risk reports in 2023, after the application of warning threshold values, the most frequently noted Level-3 taxonomies with alarm-triggering QC findings were generally consistent with those observed in QC reports from 2019 to 2022 (Tables 1 and 2, Figure 3). The most common alarm-triggering Level-3 taxonomy was “Standard Procedure and Process,” which

XSL•FO
RenderX

was reported in 36% (15/42) of high-risk reports, and its most relevant process (ie, "risk point," as defined by Level-4 taxonomies) was "Protocol Deviation – Deviation from Study Design," which was reported in 33% (5/15) of the reports that triggered an alarm for QC findings that fell under the Level-3 "Standard Procedure and Process" taxonomy. In response to Level-4 taxonomies that were more likely to cause alarm-triggering QC issues (Table 2), intervention strategies to be incorporated into routine clinical practice were proposed.

Table . Most frequently reported Level-3 taxonomies in alarm-triggering quality control reports from 2023 (n=42) and their corresponding most relevant Level-4 taxonomies.

Level-3 taxonomy	Level-3 taxonomy incidence, number of reports (%)	Most relevant Level-4 taxonomy
Standard Procedure and Process	15 (36)	Protocol Deviation – Deviation From Study Design
Safety Reporting	8 (19)	Adverse Event Assessment and Documentation
Source Data Collection and/or Recording	8 (19)	Paper Source Data Files
Biological Sample Management	6 (14)	Biosample Transportation and Documentation
Personnel Qualification and Training	6 (14)	Personnel Authorization and Documentation
Investigational Product	6 (14)	Administration of Investigational Products and Associated Documentation Issues

Process Documentation Management	3 (7)	Quality Control Documentation
Inclusion and Exclusion Criteria	2 (5)	Inclusion and Exclusion Criteria Documentation
Query Recording and Reporting	1 (2)	Incomplete Monitoring Records

Discussion

As stated in the ICH E6(R3) guideline published in January 2025, clinical trial institutions and sponsors are encouraged to use innovative digital technologies to improve clinical trial quality, taking into consideration the risk factors that could potentially impact participant safety, data quality, and other key elements in clinical trial procedures [3]. In this study, data from historical clinical trial QC reports generated in our hospital were standardized and classified for further risk-based qualitative analyses, and the minimum number of QC findings was determined as the threshold value for each QC stage, severity level, and Level-3 taxonomy combination. These QC warning thresholds were embedded into our digital dynamic monitoring platform to allow for the dynamic and proactive identification of high-risk QC reports and to notify quality management personnel, in a real-time manner, about which reports had a number of QC findings (ie, in a specific stage, severity level, and Level-3 taxonomy) that was larger than the corresponding threshold value. For example, a QC warning will be triggered for an early-stage QC report if it reports more than 13 minor findings, more than 3 major findings, or more than 2 critical findings under the Level-3 taxonomy "Source Data Collection and/or Recording," requesting the quality management group to follow up and take actions.

With the help of the digital platform, the quality management team can quickly and accurately identify the relevant clinical trial procedure and function line for the reported quality issues and adopt mitigation strategies. For example, in QC reports from 2019 to 2022, "Standard Procedure and Process" was the most frequently reported Level-3 taxonomy for QC reports generated during the conclusion stage (ie, around the time of site closeout), and one-third (38/114, 33.3%) of the quality issues were attributed to participants' poor compliance with safety visits after they left the trial site. Driven by this observation, we learned from participants that many of them lived far away from our trial site in Beijing, and after leaving the trial site, it was difficult for them to travel a long distance back to the trial site for additional safety follow-ups. Our proposed action is to allow participants who are discharged from the trial site to complete their follow-up visits in a local clinical trial center (ie, at or near their hometown) equipped with a remote visit system, as an approach to improving their compliance with the safety monitoring procedures. Another example is the quality alarm associated with the Level-4 taxonomy "Administration of Investigational Products and Associated Documentation Issues." In a trial with QC findings that fell under this taxonomy, the study drug was to be orally self-administered at home, and a large proportion of participants missed multiple oral doses. In response to this finding, our proposed action is to send drug administration reminders via participants' social networking platforms and the hospital's mobile app. The digital platform also enables the study team to conduct targeted source data verifications and reviews; the study

XSL•FO
RenderX

team can also exempt a trial from complete source data verifications and reviews if it did not trigger any warnings.

The digital platform remains to be optimized for future clinical practice; the input of more QC data and an upgraded automated calculation tool are needed to enhance its accuracy and applicability. However, the concurrent use of other digital tools may further enhance the efficiency of quality management systems. For high-risk trials that have already triggered an alarm in the early- or interim-stage QC round, a remote monitoring system may help to reduce quality issues due to trial procedure noncompliance.

Abstract

Background: Digital health is a critical driver of quality, safety, and efficiency in health care. However, poor quality of clinical information in digital health technologies (DHTs) can compromise the quality and safety of care. The Clinical Information Quality (CLIQ) framework was developed, based on a systemic review of literature and an international eDelphi study, as a tool to assess the quality of clinical information in DHTs.

Objectives: The aim of this study is to assess the applicability, internal consistency, and construct validity of the CLIQ framework.

Methods: This study was conducted as a cross-sectional survey of health care professionals across the United Kingdom who regularly use SystmOne electronic health records. Participants were invited through emails and social media platforms. The CLIQ questionnaire was administered as a web-based survey. Spearman correlation coefficients were computed to investigate the linear relationship between the dimensions in the CLIQ framework. The Cronbach α coefficients were computed to assess the internal consistency of the global scale (ie, CLIQ framework) and the subscales (ie, the informativeness, availability, and usability categories). Confirmatory factor analysis was used to assess the extent to which the survey data supported the construct validity of the CLIQ framework.

Results: A total of 109 health care professionals completed the survey, of which two-thirds (67, 61.5%) were doctors and a quarter (26, 23.9%) were nurses or advanced nurse practitioners. Overall, the CLIQ dimensions had good quality scores except for portability, which had a modest score. The inter-item correlations were all positive and not likely due to chance. The Cronbach α coefficient for the overall CLIQ framework was 0.89 (95% CI 0.85 - 0.92). The confirmatory factor analysis provided a modest support for the construct validity of the CLIQ framework with the comparative fit index of 0.86 and standardized root mean square residual of 0.08.

Conclusions: The CLIQ framework demonstrated a high reliability and a modest construct validity. The CLIQ framework offers a pragmatic approach to assessing the quality of clinical information in DHTs and could be applied as part of information quality assurance systems in health care settings to improve quality of health information.

Introduction

Digital health is critical to quality, safety, and efficiency of health care services [1]. Digital health technologies (DHTs) can enhance the delivery of health care services in several ways [2]. Electronic health records (EHRs) make medical records readily available at the point of care [3]. Electronic prescribing systems reduce the incidents of medication errors [4]. Clinical decision support systems support clinicians in decision-making [5,6]. Mobile health (mHealth) apps support self-management of chronic diseases [7].

However, poor quality of clinical information in DHTs can compromise the quality and safety of care [8,9]. A systematic review of literature reported widespread incidents of delayed,

XSL•FO
RenderX

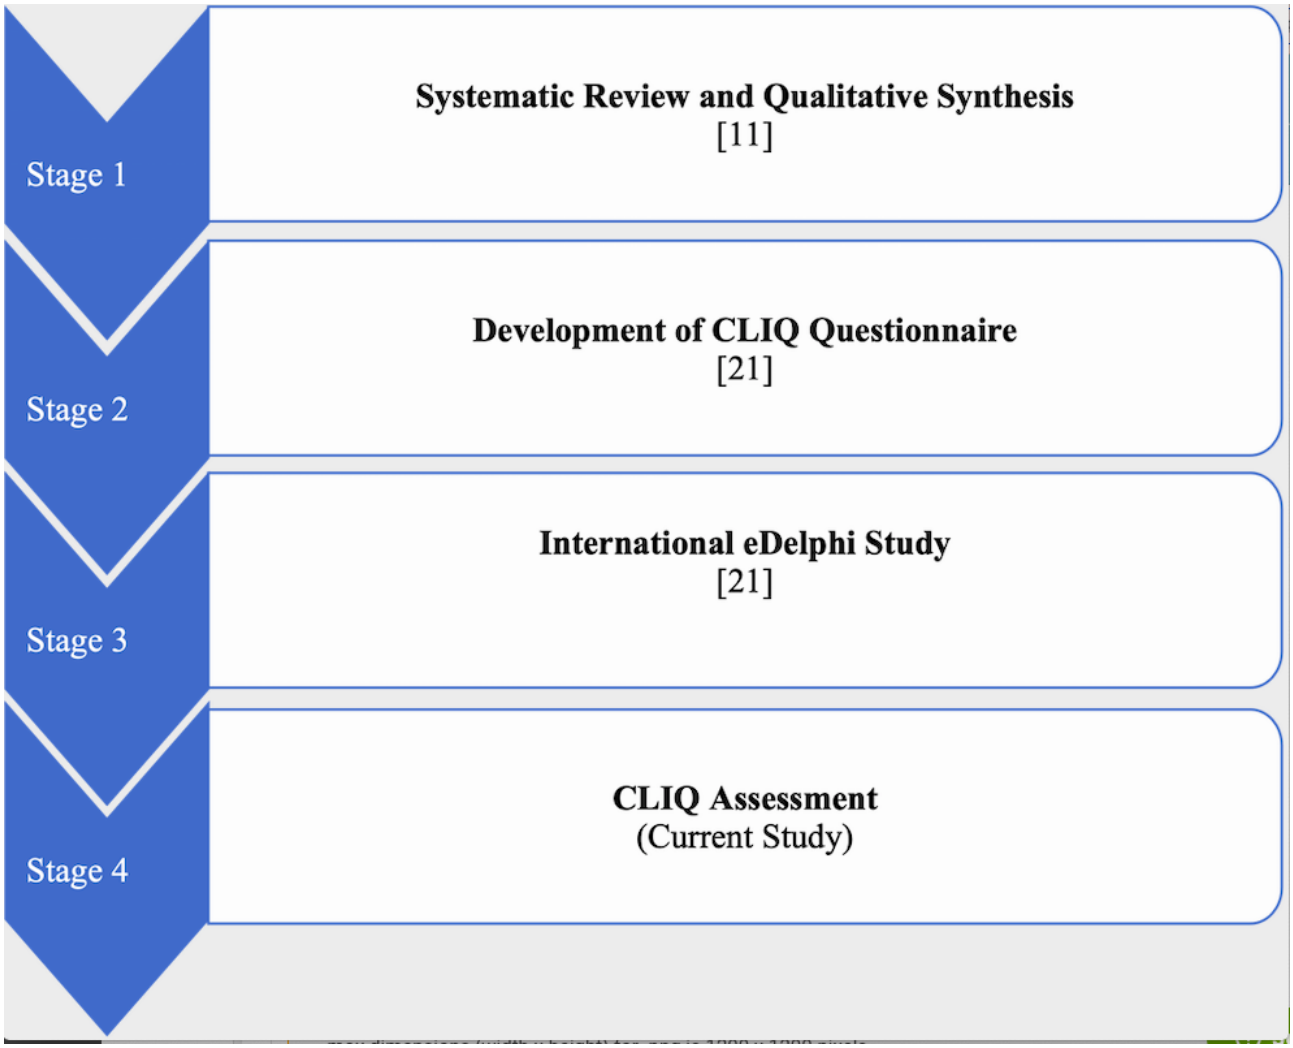
missing, partial, and wrong information in DHTs resulting in adverse outcomes and deaths [10]. Most of the information quality problems reported in the included studies were based on incidents reporting systems [10]. While retrospective lessons based on adverse events in the incidents reporting systems could be useful, it is more important to identify and address information quality problems as a proactive measure to prevent adverse events, hence the need for an information quality framework.

In another systematic review [11], we identified 10 existing information quality frameworks for DHTs comprising 5 frameworks for EHRs [12-16] and one each for clinical decision support systems [17], cloud-based information systems [18], electronic medical records [19], mobile and web-based telemedicine apps [20], and primary care databases [13]. Although these frameworks identified dimensions that are relevant to assessing clinical information in DHTs, most were developed without inputs of clinicians and did not provide a tool that can be used to assess DHTs [11]. To overcome these limitations, we developed the Clinical Information Quality (CLIQ) framework for DHTs.

The CLIQ framework identifies, defines, and integrates 14 dimensions that are relevant to assessing clinical information in DHTs [11,21]. The dimensions in the CLIQ framework are grouped into 3 categories—informativeness, availability, and usability. The informativeness category relates to the usefulness of clinical information in patient care. Dimensions in the informativeness category include accuracy, completeness, interpretability, plausibility, relevance, and trustworthiness. The availability category relates to the functionality of the DHTs holding clinical information. Dimensions in this category include accessibility, portability, searchability, security, and timeliness. The usability category—comprising conformance, consistency of presentation, and maintainability—concerns the ease of use of clinical information. The definitions of the dimensions in the CLIQ framework are shown in Table 1.

The CLIQ framework was developed in 4 successive stages as shown in Figure 1. An initial CLIQ framework was developed through a systematic review and qualitative synthesis of existing information quality frameworks for DHTs [11]. A CLIQ assessment questionnaire was then developed based on the CLIQ framework and further evidence from literature [21]. The questionnaire offers a pragmatic approach to assessing clinical information in DHTs based on relatable clinical scenarios. The framework and the accompanying questionnaire were revised via an international eDelphi study among 35 clinicians from 10 different countries [21].

The development and modification of the CLIQ framework through a systematic review of literature and an international eDelphi study resulted in an evidence-based and user-friendly framework that is grounded in the literature and the views of clinicians who are users of clinical information. However, these approaches addressed only the content and face validity of the CLIQ framework and not its applicability, reliability, and construct validity. Therefore, the aim of this study is to assess the applicability, internal consistency, and construct validity of the CLIQ framework.



XSL•FO

Table . Clinical Information quality framework for digital health technologies.

Clinical information quality dimensions and their definition	
Informativeness: the usefulness of digital information for clinical purposes	
Accuracy	The extent to which information is accurate.
Completeness	The extent to which no required information is missing.
Interpretability	The extent to which information can be interpreted.
Plausibility	The extent to which information makes sense based on clinical knowledge.
Trustworthiness	The extent to which the source of information is trustworthy and verifiable.
Relevance	The extent to which information is useful for patient care.
Availability: the functionality of the system holding clinical information	
Accessibility	The extent to which information is accessible.
Portability	The extent to which information can be moved or transferred between different systems.
Searchability	The extent to which needed information can be found.
Security	The extent to which information is protected from unauthorized access, corruption, and damage.
Timeliness	The extent to which information is up to date.
Usability: the ease of use of clinical information	
Conformance	The extent to which information is presented in a format that complies with institutional, national, or international standards.
Consistency of presentation	The extent to which presentation of information adheres to the same set of institutional, national, or international standards.
Maintainability	The extent to which information can be maintained (eg, modified, corrected, updated, adapted, and upgraded) to achieve intended improvement.

Figure 1. Stages of CLIQ framework Development.CLIQ: Clinical Information Quality.

Methods

Study Design

This study was conducted as a web-based cross-sectional survey of health care professionals across the United Kingdom who use SystmOne EHRs (The Phoenix Partnership Ltd). The cross-sectional survey approach allowed the assessment of the applicability, internal consistency, and construct validity of the CLIQ framework. The web-based approach offered a convenient, affordable, and pragmatic way of conducting a study and collecting data. The choice of SystmOne was informed by its wide use across different health care settings in the United Kingdom, including general practices, urgent care centers, social care services, hospitals, and prison medical services to manage about 61 million EHRs [22]. CHERRIES (Checklist for Reporting Results of Internet E-Surveys) was used to guide the survey report [23].

Study Participants

Eligibility criteria for the study included being a health care professional with a clinical role and a regular user of SystmOne (defined as using SystmOne as part of routine professional activities to document clinical information). Administrative staff using SystmOne and health care professionals using SystmOne occasionally (eg, to check clinical records) were not eligible to participate in the study. Participants were invited through emails and social media platforms, including Facebook, LinkedIn, WhatsApp, Yammer, Digital Health Networks, and the Future National Health System Collaboration platform. Although there is no consensus about the adequate sample size needed to validate a questionnaire, the literature recommends recruiting at least 10 participants for each item of the scale being validated as a rule of thumb [24]. As there are 14 dimensions of the CLIQ framework, this was equivalent to 140 participants in our study.

Data Collection

Health care professionals were invited to use the CLIQ framework to evaluate the information quality of SystmOne. The survey questionnaire comprised the 14 items of the CLIQ framework and 2 questions about the occupation of the respondents to assess their eligibility (Multimedia Appendix 1). Each question was displayed on a separate mobile or computer screen to the participants. The responses were made mandatory to avoid missing data, which could limit the assessment of the construct validity [25]. Participants were able to change their answers using the back button. Bot detection and prevention of multiple submissions were turned on in Qualtrics (Qualtrics). An invitation containing a link to the

XSL•FO
RenderX

participant information sheet, the consent form, and the questionnaire was shared with the health care professionals electronically through the channels described earlier. Two reminders, at least 2 weeks apart, were sent to encourage participation. Health care professionals were also encouraged to share the invitation with colleagues. Data collection took place between February 27 and June 7, 2022. The questionnaire was administered through a web-based survey platform, Qualtrics.

Data Analysis

The survey result was downloaded from Qualtrics in an excel format and imported into SPSS (version 20; IBM Statistics). Only completed entries were analyzed as uncompleted entries stopped at the consent. SPSS was used to conduct descriptive statistical analyses and compute correlation coefficients and Cronbach α scores.

The 3 options for each dimension (eg, accurate, partly accurate, and not accurate) were recoded into the integers 1, 2, and 3, representing low, modest, and good quality, respectively. A descriptive statistical analysis was conducted and interpreted to demonstrate the applicability of the CLIQ framework. The distribution of the responses was expressed as frequencies, percentages, means, and SDs.

Spearman correlation coefficients were computed to investigate the linear relationship between the dimensions in the CLIQ framework. The ordinal nature of the data informed the choice of Spearman coefficients. Correlation coefficients of 0.1 - 0.2 were regarded as poor, 0.3 - 0.5 as fair, 0.6 - 0.7 as moderate, and 0.8 - 0.9 as very strong [26] .

The Cronbach α coefficient was computed to assess the internal consistency of the global scale (ie, CLIQ framework) and the subscales (ie, the informativeness, availability, and usability categories). A Cronbach α coefficient of 0.7 or above was regarded as an indication of the reliability of the scale, and an alpha coefficient between 0.6 and 0.7 was considered acceptable [26].

The SPSS data file was subsequently exported to SPSS Amos (version 28; IBM Statistics) to assess the construct validity of the CLIQ framework. Confirmatory factor analysis, a structural equation modeling technique, was used to assess the extent to which the survey data supported the construct validity of the CLIQ framework [27]. Confirmatory factor analysis was adopted because the CLIQ framework has multiple subscales (ie, informativeness, availability, and usability categories) that were predetermined [11].

The maximum likelihood estimation method was used for the confirmatory factor analysis. The model fit was assessed based on the Standardized Root Mean Square Residual (SRMR) and Comparative Fit Index (CFI) as recommended in the literature for studies with a sample size of less than 250 [28]. A CFI greater than 0.9 and an SRMR less than 0.08 indicate model fit [28].

Ethical Considerations

Informed consent was obtained from each participant at the beginning of the web-based survey after they had been provided with the participant information sheet, containing detailed information about the study objectives, expectation of the participants, duties of the researchers, and relevant contacts. Participation was voluntary. A secure web-based survey platform was used for data collection as already described. No personal information that could be used to identify the participants was collected in the survey. Survey responses were anonymized with codes automatically assigned to participants by the survey platform. The results were securely stored in Imperial College Shared Drive. Participants could withdraw from the study at any time without giving any reasons. However, once the survey was submitted, the data could not be withdrawn as the responses were anonymous. Participants were not compensated for taking part. Ethical approval was obtained from the Imperial College research ethics committee (21IC7415).

Results

Participants' Characteristics

A total of 109 health care professionals completed the survey, with two-thirds (67, 61.5%) being doctors and almost a quarter (26, 23.9%) being nurses or advanced nurse practitioners. The rest of the participants had other clinical occupations. Table 2 shows the distribution of the participants by occupation.

Table . Distribution of the occupation of the survey participants (N=109).

Occupation	Values, n (%)
Doctors	67 (61.5)
Nurses and advanced nurse practitioners	26 (23.9)
Health care assistants	5 (4.6)
Physiotherapists and occupational therapists	4 (3.7)
Pharmacists	2 (1.8)
Podiatrists	2 (1.8)
Physician associates	1 (0.9)
Therapy support workers	1 (0.9)
Community health workers	1 (0.9)

XSL•FO
RenderX

Participants' Assessment of Quality of the Dimensions

The mean quality score assigned to each dimension ranged from 2.2 for portability to 2.9 for security of clinical information in SystmOne (1, 2, and 3 indicate low, modest, and good quality, respectively). Most participants (97/109, 89%) ranked security of clinical information in SystmOne as good while only more than a third of the participants (42/109, 38.5%) ranked portability of clinical information in SystmOne as good. The summary of the assessment result is shown in Table 3.

Table . Clinical Information Quality of SystmOne as assessed by the participants.

Dimension	Assessment of the quality of the dimension, n (%)			Mean score (SD)
	Good	Modest	Low	
Accuracy	73 (67)	32 (29.4)	4 (3.7)	2.6 (0.6)
Completeness	63 (57.8)	43 (39.4)	3 (2.8)	2.6 (0.6)
Interpretability	82 (75.2)	26 (23.9)	1 (0.9)	2.7 (0.5)
Plausibility	92 (84.4)	17 (15.6)	0	2.8 (0.4)
Relevance	89 (81.7)	20 (18.3)	0	2.8 (0.4)
Trustworthiness	94 (86.2)	15 (13.8)	0	2.9 (0.3)
Accessibility	77 (70.6)	31 (28.4)	1 (0.9)	2.7 (0.5)
Portability	42 (38.5)	49 (45)	18 (16.5)	2.2 (0.7)
Searchability	56 (51.4)	49 (45)	4 (3.7)	2.4 (0.6)
Security	97 (89)	12 (11)	0	2.9 (0.3)
Timeliness	71 (65.1)	35 (32.1)	3 (2.8)	2.6 (0.5)
Conformance	77 (70.6)	27 (24.8)	5 (4.6)	2.7 (0.6)
Consistency of presentation	77 (70.6)	22 (20.2)	10 (9.2)	2.6 (0.7)
Maintainability	70 (64.2)	33 (30.3)	6 (5.5)	2.6 (0.6)

Inter-item Correlation

There were positive correlations between all possible pairs of dimensions in the CLIQ framework (Multimedia Appendix 2). All the correlation coefficients were statistically significant (represented as asterisks) except for the correlations of portability with each of plausibility, relevance, trustworthiness, and security. There is a strong statistically significant correlation between conformance and consistency (Spearman ρ=0.751; *P*<.001).

Internal Consistency of the CLIQ Framework

The Cronbach α coefficients and corresponding 95% CIs for the informativeness, availability, and usability subscales were 0.78 (95% CI 0.70 - 0.84), 0.69 (95% CI 0.58 - 0.77), and 0.83 (95% CI 0.77 - 0.88), respectively. Once security was removed from the availability subscale, the Cronbach α coefficient for the availability subscale increased marginally to 0.70 (95% CI 0.60 - 0.78). The Cronbach α coefficient for the overall CLIQ framework is 0.89 (95% CI 0.85 - 0.92).

Construct Validity of the CLIQ Framework

Although the chi-square goodness-of-fit test ($\chi^2_{2.10}$=155.69; *P*<.001) did not demonstrate fitness of the model, CFI (0.86) and SRMR (0.08) suggest that the model fits modestly with the data. All the factor loadings (ie, covariance estimates) were positive and statistically significant, as shown in Table 4. Significant tests (SE, critical ratio, and *P* value) were not reported for the first item in each category (ie, accuracy, accessibility, and conformance) because their unstandardized covariance values were fixed as 1, which is a standard procedure in confirmatory factor analysis.

The statistical significance of positive standardized covariance estimates for all information quality dimensions supports the placement of the dimensions in their respective category. This is further illustrated in the path diagram shown in Figure 2. The high values of estimated covariances between the latent variables and the observed variables support the construct validity of the model. Still, the high covariance estimates between the latent variables (informativeness, availability, and usability) indicate overlap of the categories.

XSL•FO

XSL•FO
RenderX

Figure 2. Path diagram for confirmatory factor analysis The rectangular shapes represent the observed variables (ie, information quality dimensions) that were directly measured in the survey. The circular shapes represent the latent variables (ie, information quality categories) that could be inferred from the measured variables. The abbreviation "e" represents error. The connecting arrows represent covariances, with the accompanying numbers representing their estimates.

Discussion

Principal Findings

The study assessed the applicability, internal consistency, and construct validity of the CLIQ framework based on the pilot CLIQ assessment of SystmOne EHRs. Overall, the CLIQ dimensions had good quality scores except for portability which had a modest score. The inter-item correlations were all positive and not likely due to chance. The Cronbach α score demonstrated a good internal consistency of the CLIQ framework and its informativeness, availability, and usability subscales. The results of the Confirmatory Factor Analysis

XSL•FO
RenderX

provided a modest support for the construct validity of the CLIQ framework.

Comparison With Previous Literature

The combination of good security and modest portability of clinical information in SystmOne indicates the possibility of a trade-off between security and portability. Portability might have been limited inadvertently to improve the security of clinical information. Similar trade-offs, such as between accessibility and security, have been documented in the literature [29]. Software developers need to be vigilant to identify potential trade-offs that may compromise the quality and safety of care.

The positive and mostly significant correlations between the items in the scale indicated a close relationship between the dimensions [30]. This was not unexpected because all dimensions are components of the same CLIQ framework. The generally low values of the correlations demonstrated that the dimensions, although related, are distinct [30]. The high correlation between conformance and consistency of presentation is understandable, as both concern presentation of information. Similarly, the high covariance between the latent variables (informativeness, availability, and usability), which indicate that the categories are not entirely distinct, is not strange in information quality research. Categories in information quality frameworks are not mutually exclusive as each dimension in an information framework often fits into multiple categories [31]. However, there is a scope for model revision to further explore this overlap in future CLIQ research.

The overall good internal consistency of the CLIQ framework and its subscales (ie, informativeness, availability, and usability) indicates the reliability of the CLIQ framework [32]. Although the study was unable to rely on fit indices primarily influenced by sample size such as the chi-square goodness-of-fit index [23], the index least affected by sample size, the SRMR [28], supports the model fit.

This study used similar methods as a study on the validation of the Modified Enlight Suite (MES), a generic mHealth assessment questionnaire [25]. The MES study demonstrated an overall good internal consistency and modest construct validity of the MES based on a survey of more than a thousand medical students and health care professionals who assessed a freely downloadable COVID-19 app in Ireland [25]. The differences in the uptakes of the 2 studies are probably related to the choice of DHTs and study population. This study population was limited to health care professionals using SystmOne. In contrast, the MES study was open to all health care professionals and medical students who could download the Irish COVID-19 app.

Strengths and Weaknesses

To the best of our knowledge, the CLIQ framework is the first information quality framework for DHTs, of which the internal reliability and construct validity have been assessed. Only the face and content validity of most existing information quality frameworks were assessed [11]. This study went a step further to explore the internal consistency and construct validity of the CLIQ framework.

Although the choice of SystmOne EHRs ensured participation of a multidisciplinary population of health care professionals in the testing of the CLIQ framework, allied health professionals were less represented. In addition, the voluntary nature of recruitment established a potential for systemic bias because those who were engaged in digital solutions were more likely to respond. The use of mandatory responses, although useful for survey data completeness, could introduce bias if participants provided less thoughtful responses just to complete the survey. Finally, the low response rate limited the assessment of the construct validity of the CLIQ framework [24]. The low uptake was probably due to the busy schedules of the health care professionals at a time when the National Health System was under immense pressure due to COVID-19 pandemic. Nevertheless, the sample size was sufficient to assess the CLIQ framework's applicability and reliability as demonstrated by the narrow CIs for the Cronbach α coefficients. Future studies on the validity of the CLIQ framework need to consider and address these limitations.

Implications for Practice

Information Quality Assurance System

The CLIQ research highlights the importance of information quality and its relevance to the quality and safety of care. Therefore, establishing a robust system for information quality assurance in health care institutions is essential. Such an information quality assurance system entails regular checks and monitoring, data validation, and information quality audits [33]. The CLIQ framework could be a useful tool for information quality audits. The information quality assurance system should be integrated into the information governance system, where one already exists, to prevent duplication and fragmentation. Designating clinicians with additional informatics training to oversee such information quality assurance system is necessary to ensure its successful implementation because they understand the clinical and technological aspects of patient care [34]. Although health care institutions within high-income countries have designated clinical informatics roles, such as the chief clinical information officer, the job description is still evolving [35]. It is vital to both introduce these roles in health facilities and expand the responsibilities to include information quality assurance.

Informatics Training and Education for Health Care Professionals

The CLIQ framework demonstrates that information quality is multidimensional, and understanding its meaning, relevance, and assessment requires some training. The clinicians who participated in the international eDelphi study expressed concerns that health care professionals without informatics training might be unfamiliar with information quality–related terms [21]. In addition, information quality problems, such as missing and inaccurate information, could result from human errors [36]. Informatics training could provide health care professionals with knowledge about the meaning, relevance, and assessment of information quality. Training could also be used to address information quality problems through promotion of good practice such as proper documentation and adequate record keeping. Informatics training should be included in health

XSL•FO
RenderX

care professionals' prequalification and postqualification education competencies to also keep them up-to-date of the ever-changing information landscape in digital health [37]. However, care should be taken not to complicate an already-complex medical curriculum with extensive informatics training [37]. Rather, efforts should be made to provide appropriate level of informatics training that is commensurate with individual and institutional needs. Although informatics training could build health professionals' competencies around information quality, mistakes will continue to occur because "to err is human" [38]. Therefore, it is vital to institute a system that reduces incidence and impact of errors.

Automated Error Detection and Data Validation Systems

The quality of clinical information could be improved by setting up automated error detection and data validation systems in DHTs. Machine learning and artificial intelligence algorithms could be applied for automated data validation and real-time error detection with errors flagged during data entry [39]. Automated error detection and data validation systems could reduce the likelihood of wrong data entry as well as prompt early correction of errors before patient safety is compromised. However, lack of trust in machine learning and artificial intelligence could make health care professionals ignore or override automated warnings and alerts [40].

Interoperability and Integration of Digital Health Systems

Interoperability enhances seamless flow of information across different DHTs such as EHRs, laboratory information system, and electronic triage system [41]. Seamless health information exchange between multiple platforms improves quality of clinical information [42]. Communication between systems enhances timely access to up-to-date information in or near real time [42]. Accuracy is enhanced when information is obtained directly from source with elimination of possible changes during transcription [41]. Portability and interoperability could be improved through adoption of clinical data models (eg, openEHR), standardized terminologies (eg, Systematized Nomenclature of Medicine Clinical Term—SNOMED CT), and clinical coding system (eg, *International Classification of Diseases, Tenth Revision—ICD-10*), which promote consistent presentation of clinical information [43,44]. Although interoperability of digital health systems is desirable, a huge cost is often required for its implementation. Concerns about security of information may also be an obstacle due to increased access to information [41]. Security concerns could be addressed by obtaining prior informed consent for information sharing from patients when they register with the health service.

User-Friendly Design Interface

The quality of data entry could be improved with a user-friendly design interface [45]. Accuracy and completeness of the information in the DHTs could be enhanced with features such as drop-down menus, prepopulation fields, and validation prompts. Faulty design interface can affect consistency of presentation and conformance. A drop down with different units of the same medication can lead to medication errors [10]. Searchability of information improves when the design interface allows smooth navigation through the digital system.

Implications for Policy

Information Quality Requirements

Policies and guidelines are needed to define and communicate information quality requirements for DHTs. Policies should communicate the official position of an institution on information quality requirements while guidelines should provide clear guidance on how to meet the requirements. The CLIQ framework could be used as a conceptual guide for information quality requirements. Policies and guidelines are needed to address issues relating to information quality, including interoperability, privacy and confidentiality, information format, design interface, training, and so forth. These issues should be addressed collectively in a single information quality policy or individually with different guidelines based on the needs of the institution. It is essential to consider whether the information is used locally, nationally, or internationally. The process of formulating, implementing, and disseminating the policies needs to involve all stakeholders, as described subsequently.

Collaboration and Partnerships Among Information Stakeholders

The development of the CLIQ framework demonstrates the importance of multidisciplinary and international collaboration in the development of information quality standards. The CLIQ framework was developed with inputs of scores of professionals from more than 10 countries. Establishing and implementing information quality standards require collaboration among health care organizations, software developers and vendors, regulatory bodies, patient support group, professional organizations, and so forth. Collaboration will ensure buy-in of all information stakeholders and facilitate the implementation process.

Certification and Regulation

Enforcement of information quality standards for DHTs requires regulatory oversights. Regulatory bodies for DHTs in different countries and regions, such as the United States Food and Drug Administration and the Medicines and Healthcare products Regulatory Agency, need to include information quality requirements as part of prequalification criteria for DHTs. Information quality of DHTs should be assessed using evidence-based approach such as the CLIQ framework before they are certified for use in health care facilities. Only DHTs that meet specified prequalification criteria, including information quality requirements, should be certified by the regulatory bodies.

Implication for Future Research

Evidence-Based Approach

The CLIQ framework was developed and validated using an approach that combined evidence from literature and empirical studies. We conducted a systematic review of frameworks, rather than interventions, based on the BeHeMoTh procedure [46]. The international eDelphi study obtained quantitative and qualitative evidence from clinicians across 10 countries [21].

XSL•FO
RenderX

The pilot CLIQ assessment used a systematic approach to investigate the reliability and validity of this novel tool. Overall, the evidence-based approach used while developing the CLIQ framework provides a methodological model which could be adopted in future research while developing pragmatic frameworks.

Information Quality Research

The systematic review of literature showed a dearth of information quality research relating to DHTs [11]. As DHTs are used more commonly worldwide, there is an increased need for information quality research to match the growth in technological innovations. The CLIQ framework demonstrates the importance of information quality research in addressing contemporary issues relating to DHTs. Some information quality dimensions, which were hitherto not included in most existing information quality frameworks for DHTs, are included in the CLIQ framework. Searchability and maintainability are more relevant due to technological advancement which has made it possible to capture, process, and store an increasing volume of digital information. Searchability, that is, locating needed information from the wide range of available information, is thus essential. Maintainability of information is also important to ensure that information quality is not sacrificed with increasing quantity of information. Similarly, portability has become more relevant than ever with the current tendency toward integration and interoperability of DHTs.

Patient Perspective on Information Quality

This study focused on health care professionals as end users of clinical information in DHTs. However, patients have also become end users of clinical information in DHTs. Patients are increasingly viewing and contributing more information into DHTs, especially since the COVID-19 pandemic [47]. Multiple DHTs, such as AskmyGp (Evergreen Health Solution Ltd), eConsult (eConsult Health Ltd), and Accurx (Accurx Ltd), allow patients to enter text using their own words and upload photographs that could be saved in the EHRs. In addition, many wearable devices and mobile apps generate consumer health data, nowadays, that could be imported into the EHRs. It would therefore be useful to explore the patients' perspective on information quality in future studies and incorporate their views and suggestions into the CLIQ framework.

Conclusions

The CLIQ research highlights the importance of information quality and its relevance to the quality and safety of care. The CLIQ framework demonstrated a high reliability and a modest construct validity. The CLIQ framework offers a pragmatic approach to assessing the quality of clinical information in DHTs and could be applied as part of information quality assurance systems in health care settings to improve quality of health information.

Abstract

Background: Although electronic medical records (EMRs) play a vital role in strengthening the health care system by improving efficiency, data management, and patient care, their development in Ethiopia is still in its early stages. Hence, most public health care facilities manage their patient information using paper-based recording, which results in errors, delays, and reduced service quality.

Objective: This study aims to determine the level of acceptance of the EMR system and describe contributing factors.

Methods: A cross-sectional study was conducted at health care facilities in Bahir City, Northwestern Ethiopia. A total of 322 health workers participated in the study, drawn from 5 health facilities that have implemented the EMR system. Descriptive statistics and bivariate and multivariate binary logistic regression were done to determine factors associated with EMR acceptance computed from mediating factors (perceived ease of use and perceived usefulness), and which is more appropriate in early-stage implementation.

Results: Out of the total 322 respondents, 256 (73%) respondents with 95% CI 67.4-78.2 had a good acceptance of using EMRs. In regression analysis, significant predictors including work experience over 10 years (odds ratio [OR] 14.32, 95% CI 4.60-44.58), income dissatisfaction (OR 0.28, 95% CI 0.10-0.82), owning a personal computer (OR 11.08, 95% CI 4.03-30.24), EMR-specific training (OR 4.71, 95% CI 1.52-14.54), basic electronic health management information system/district health information system 2 training (OR 3.06, 95% CI 1.02-9.17), and system usability (OR 38.24, 95% CI 12.26-119.27) were identified.

Conclusions: The study demonstrated a moderate level of EMR acceptance among health care workers, with system usability identified as the strongest predictor. Significant factors influencing EMR acceptance included longer work experience, ownership of a personal computer, and prior EMR or electronic health management information system/district health information system 2 training. Context-specific strategies are needed to enhance system usability, provide targeted digital health training, and improve access to technological resources in order to support broader EMR adoption in health care settings.

Introduction

The acceptance and effective use of electronic medical records (EMRs) has become a cornerstone of digital health transformation globally, offering the promise of improved care quality, safety, and efficiency [1]. However, there are many aspects that limit the wider adoption of EMRs in sub-Saharan Africa. These include high procurement and maintenance constraints to introduce the EMRs, lack of incentives for implementation, lack of concern to prioritize, electric power shortage, absence of internet, health professionals' inadequate computer skills, and absence of strong health care facility infrastructure [2].

EMR acceptance is not only a technical issue but also a sociobehavioral one, influenced by system characteristics, user perceptions, and organizational readiness. Studies suggest that both system design and user-related factors such as perceived usefulness (PU), ease of use, and access play critical roles in determining the extent of EMR use [3].

Although most public health care facilities in Ethiopia manually manage data tasks related to their clinical services, there has been a growing demand to adopt the EMR system in health care facilities [4]. Evidence [5] shows that a lack of strategic planning in the field of EMRs had a negative influence on the implementation of the system in health care facilities. Moreover, the Ethiopian Ministry of Health recommended [6] that health care facilities should have a change management strategy that facilitates the smooth transition of the newly introduced EMR system. This strategy will be part of the health care facilities' strategic paper and shows how the new systems are to be implemented and sustainable for a longer time. There should also be a protocol to select the best performers and to reward those health professionals working on EMRs. The strategy document should also contain principles on data generation and use at the local level for decision-making [6].

And regarding health professionals' behaviors, PU, and perceived ease of use (PEOU) will influence user acceptance of the EMRs. User acceptance of technology and associated factors has been considered as an important issue that should be presented and understood before introducing and expanding any software applications or systems [7].

The use of only PU and PEOU as measures of technology acceptance is rooted in the Technology Acceptance Model (TAM) developed by Fred Davis [8]. This model proposed that users' acceptance of new technology is primarily influenced by how useful they perceive it to be in enhancing their job performance (PU) and how easy they believe it is to use (PEOU). In the original TAM, these 2 constructs were found to significantly predict attitudes toward using, which in turn influenced behavioral intention and ultimately actual system use or acceptability of the EMRs.

Motivation and engagement to use EMRs influence the acceptance and attitude of health care workers toward the technology. In turn, the motivation to use the system is influenced by the EMR's usability, health care workers' competence, technology skills, confidence, and perceptions. In general, the workplace motivation of health care workers affects work engagement, job satisfaction, and intention to stay in the workplace [9]. The health care workers' PEOU (eg, accessing patient data) and PU (eg, providing alerts and reminders) are keys to acceptance of EMRs [10]. Since their introduction, EMRs have been a recurrent issue for physicians across all specialties. From user experience to interoperability, nearly every facet of computer-based systems has drawn the ire of those using them. It was found that the amount of time spent in the physician's inbox and total time using EMRs were associated with higher physician turnover. The American Medical Association found that EMRs contribute to between 11% and 60% of the burnout physicians experienced in 2021 [11]. Since motivation has an important role in the behaviors of health care workers, the adoption, acceptance of, and attitude toward a new technology, such as an EMR system, may be influenced by individual motivation [9].

A study on the Australian EMR system revealed that nurse motivation emerged as the most common factor relating to both perceived barriers and enablers to a new Australian EMR system implementation [9]. The development and implementation of electronic health records (EHRs) involve lots of challenges, including nurses' stress and negative consequences for patient safety [12]. Designing a user-friendly interface is another challenging task. A poorly designed interface may lead to reduced time efficiency, poor quality of health care delivery, and can become a threat to the patient's safety as well. Acceptance of EHR by doctors is also perceived as a barrier. This is due to the extra time that doctor spends entering data electronically, which they otherwise can spend treating the patients [13].

The Ethiopian Ministry of Health has played a pivotal role in piloting and scaling up EMR systems across the country. Notably, the University of Gondar Comprehensive Specialized Hospital was selected as a pilot site for EMR deployment, contributing significantly to the development and testing of EMR systems in Ethiopia [14]. One of the EMR systems implemented at the University of Gondar is Bahmni, an open-source EMR platform that aligns with the Ethiopian EHR standards. This initiative has been instrumental in informing the nationwide scale-up of EMR systems, enhancing health care delivery and information management across Ethiopia.

The EMR system in Ethiopia could not go as far as expected due to factors like behavioral and technical [6]. It was also observed that most of the EMR systems in Ethiopia were not interoperable and automated only some aspects of health services. Hence, most public health care facilities in Ethiopia manage their patient information using paper-based recording, which results in errors, delays, and reduced service quality [4]. Therefore, the shift to electronic records is not questionable, for improved standards of care and clinical decision-making [4]. Moreover, some health care workers encountered mistrust of the system. In this regard, there are only a few studies to show EMR acceptance among health care workers in hospitals, and specifically in the contexts of privacy and security concerns [15].

XSL•FO
RenderX

Therefore, this study aims to explore and identify the key factors influencing the acceptance of EMRs among health care workers in Northwest Ethiopia, with the goal of informing strategies to enhance digital health implementation and improve health system performance in the region.

Methods

Study Design and Setting

This study used a cross-sectional quantitative design to assess health care workers' acceptance of EMRs in health care facilities where the system has been implemented. The objective was to systematically evaluate the factors influencing the acceptance and use of EMRs among health care professionals, with a focus on key determinants such as PU, PEOU, and organizational support. The study was conducted in health care facilities located in Bahir Dar city, Northwest Ethiopia. Five health facilities where EMRs had been implemented were included in the study, and the sample was drawn from these sites.

Study Participants

The study population was all health care workers who are currently working with the EMRs at health care facilities in Bahir Dar City, Northwest Ethiopia. This includes physicians, health officers, nurses, midwives, laboratory professionals, pharmacy professionals, information system officers, and medical data clerks who are working on EMRs. Health care workers who have prior exposure to EMRs for at least 6 months were included in the study.

The sample size was calculated using the finite population correction, considering a total population size of 1848, an assumed proportion (p) of 0.5, a 95% confidence level, and a 5% margin of error (d=0.05). Accordingly, the sample size was computed using the statcalc tool in Epi Info (version 7.2.5.0; Centers for Disease Control and Prevention), and the minimum required sample size was determined to be 318. To account for potential nonresponse or dropout, a 5% contingency was added, resulting in a final sample size of n = 318 + (318 × 0.05) = 334.

The sampling method was systematic random sampling. The sampling frame or the master list was a list of 1848 eligible health workers obtained from HR departments of the 5 health care. Each individual was assigned a unique number to create a master list. With a determined sample size of 334, the sampling interval was calculated as K = 1848/334 ≈ 5.5, rounded to 5. A random starting point between 1 and 5 was selected, and every 5th individual from the list was chosen until the sample size was reached, ensuring a systematic and representative selection.

Data Collection Methods

The data collection was conducted with a self-administered paper-based questionnaire. The questionnaire has 5 sections, of which 2 were Likert-like items based on a scale from "extremely disagree" to "extremely agree." The other sections are questions regarding information on health care workers' sociodemographic and EMR implementation-related questions.

Since quantitative data are always numerical in kind or numbers that have a certain intrinsic meaning, the researchers assigned scores to all kinds of variables in the questionnaire. The score number constitutes a shorthand way of expressing a respondent's answer [16].

The data collection tool was developed by the researcher (Multimedia Appendices 1 and 2), reviewing similar scientific literature on the topic [17-20]. The outcome variable uses a validated tool by Lewis [21], who developed the TAM item formats to measure technology acceptance. A pretest was conducted, and revisions were made accordingly.

EMR acceptance was computed with the 2 main constructs of TAM (PU and PEOU), which are appropriate for this study. Because EMR implementation is in the early stages in the setting, and factors like behavioral intention and social influence may not add significant predictive value, making PU and PEOU sufficient for assessing the EMR acceptance [22]. Combining PU and PEOU into a single index helps to simplify analysis or report general technology acceptance levels, particularly in descriptive studies and when working with limited sample sizes [23]. Moreover, it can help to reduce model complexity while still capturing overall user perception [24].

Measurements

According to Lewis [21], to provide TAM scores that are consistent with the System Usability Scale and usability metric for user experience metrics, the following formulas were used to put PU and PEOU on a 0-100-point scale, averaging PU and PEOU to get the overall TAM.

- PU = (AVERAGE [TAM01, TAM02, TAM03, TAM04, TAM05, TAM06]–1) (100/6)
- PEOU = (AVERAGE [TAM07, TAM08, TAM09, TAM10, TAM11, TAM12]–1) (100/6)

Accordingly, in this study, perceived usefulness (PU) is computed with the SPSS statistical package as;

- (MEAN [SE01,SE02,SE03,SE04,SE05,SE06]–1) × (100/6) and Perceived ease of use (PEOU) is computed as;
- (MEAN [SE07,SE08,SE09,SE10,SE11,SE12]–1) × (100/6) that converts a 7-point scale to a 100-point scale.

Data Analysis

As this was a systematic search for meanings, the data were first cleaned and recoded to fit with the model. The data management and analysis were done with the SPSS (version 28.0; IBM Corp) software. Reliability analysis for the internal consistency of items/scales of the outcome variable was done using Cronbach α [25]. Descriptive statistics are applied to analyze the mean, SD, range, and median. The chi-square test was used to identify the relationships between categorical variables. Participant responses were dichotomized into 2 levels with a mean split by the value of the EMR acceptance score, where the variable is split at the mean. Bivariable and multivariable binary logistic regression were done to determine factors associated with EMR acceptance, and a P value of .05 was considered statistically significant. Binary logistic regression assumptions were checked before running the model.

As indicated by Zach's [26] assumptions of the logistic regression, logistic regression is a method that we can use to fit a regression model when the response variable is binary.

XSL•FO
RenderX

One of the assumptions is that the response variable is binary, and in this regard, the logistic regression assumes that the response variable only takes on 2 possible outcomes: low or high acceptance of EMRs. The second assumption was that the observations are independent, and logistic regression assumes that the observations in the dataset are independent of each other. The third assumption was that there was no multicollinearity among explanatory variables, as logistic regression assumes that there is no severe multicollinearity among the explanatory variables. The variance inflation factor indicates whether a predictor has a strong linear relationship with the other predictors. A value of 10 is a good value at which to worry. If the average variance inflation factor is greater than 1, then multicollinearity may be biasing the regression model. The fourth assumption was that there were no extreme outliers.

Ethical Considerations

Ethics approval for the study was obtained from the College Research Ethics Committee at the College of Human Sciences, University of South Africa, with the National Health Research Ethics Council Registration (Rec-240816-052) and CREC (18033342_CREC_CHS_2023). In addition, permission to access health facilities was granted by the public health institute, Bahir Dar City, Northwest Ethiopia. Moreover, this study ensured the confidentiality, anonymity, privacy, autonomy, justice, beneficence, and nonmaleficence of the study.

Results

Sociodemographic Characteristics of the Participants

About 322 participants responded to the questionnaire with a response rate of 96.4% (322/334). The respondents' age in this study ranges from 23 to 62 years. The mean age of the respondent was 35 years, with an SD of 6.4. Table 1 indicates that 29.5% (95/322) of the respondents were in the age group of 21-30 years, 53.4% (172/322) of the respondents were aged 31-40 years, and 17.1% (55/322) of the respondents were older than 40 years. And, most of the respondents were female, which accounts for 53.4% (172/322).

[b]EMR: electronic medical record.

The majority of the respondents (204/322, 63.4%) were married, and most of them had an educational level of BSc and above, where 60.9% (196/322) had a BSc Degree, 15.5% (50/322) had an MSc Degree and above (Table 1).

With regard to health professionals, about half of the respondents were nurses, which accounted for 50% (n=161) of the total participants. And, the number of specialists and above was very low, 4% (n=13). Laboratory and pharmacy professionals had nearly similar figures, 8.7% (n=28) and 7.1% (n=23), respectively, as shown in Table 1.

Information System and EMR Use

More than half of the study participants (213/322, 66.1%) reported owning a personal computer or a laptop. Moreover, this study observed training in basic computer skills among the health care workers and found that about half of the respondents took the training, which is 56.8% (183/322). However, those

XSL•FO
RenderX

who frequently use the internet outside the office were 32.9% (106/322), somewhat lower (Table 2).

[a]EMR: electronic medical record.

[b]eHMIS: electronic health management information system.

[c]DHIS2: district health information system 2.

[d]ICD-10: International Statistical Classification of Diseases, Tenth Revision.

In this regard, about half of the users (160/322, 49.7%) did not receive training on EMR. This will not be a surprise if these providers have a lower EMR acceptance, as most of them believe to learn from their coworkers. This is indicated in Table 2, where most of the health workers (94/322, 29.2%) took the training while working on the EMR system.

Another was training on eHMIS/DHIS2 (electronic health information system/ district health information system 2). DHIS2 is the latest version of eHMIS, mostly practiced by health offices and monitoring and evaluation experts at health facilities to manage health service reports. The study showed that more than half of the respondents (182/322, 56.5%) did not attend the training.

Further advanced knowledge on the EMRs was very limited, as it was indicated by other eHealth trainings and information about *ICD* (*International Classification of Diseases*), a very common terminology standard most EMR vendors are currently using (Table 2).

EMR Acceptance Among Health Care Workers

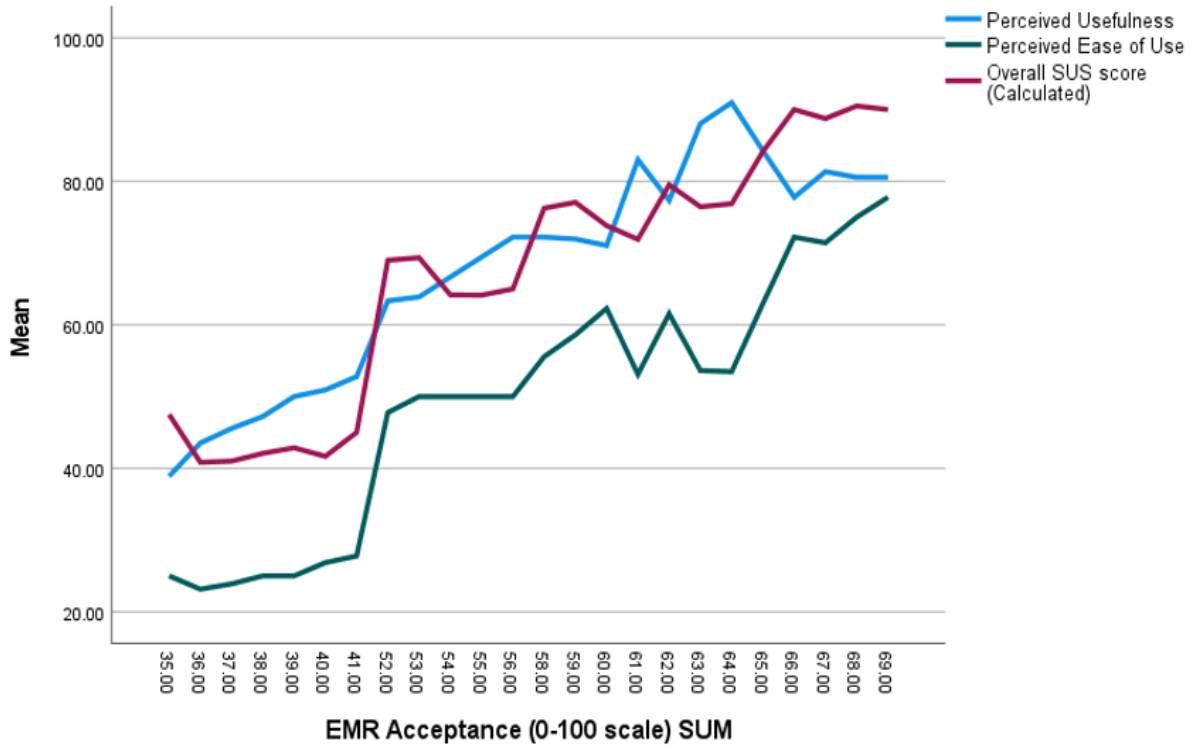
EMR acceptance in this study was measured with 12-item variables of PU and PEOU. Each item had a 7-point ordinal scale response options/agreement scale, from extremely disagree on the left to extremely agree on the right. The study was on EMRs implemented in health care facilities; the researcher measured acceptance related to actual use rather than the anticipated (Table 3). Therefore, the level of EMR acceptance

XSL•FO
RenderX

for this study was 4.87 (SD 0.83), with the range from 2.92 to 5.75.

Table 3. Mean and SD of electronic medical record (EMR) acceptance among health care workers as measured by the 7-point Likert scale.

TAM[a] and SN[b]	Items to measure EMR acceptance	Mean (SD)
Perceived usefulness		
1	Using Electronic Medical Records in my job enables me to accomplish tasks more quickly.	5.96 (0.748)
2	Using Electronic Medical Records improves my job performance.	4.53 (1.038)
3	Using Electronic Medical Records in my job increases my productivity.	5.43 (0.694)
4	Using Electronic Medical Records enhances my effectiveness on the job.	4.25 (0.877)
5	Using Electronic Medical Records makes it easier to do my job.	6.26 (0.597)
6	I have found Electronic Medical Records useful in my job.	6.30 (0.780)
Perceived ease of use		
7	Learning to operate Electronic Medical Records was easy for me.	5.35 (0.985)
8	I found it easy to get Electronic Medical Records to do what I want it to do.	4.36 (0.821)
9	My interaction with Electronic Medical Records was clear and understandable.	4.16 (0.680)
10	I found Electronic Medical Records to be flexible to interact with.	4.00 (0.994)
11	It was easy for me to become skillful at using Electronic Medical Records.	3.31 (0.717)
12	I found Electronic Medical Records easy to use.	4.56 (1.079)
Overall acceptance		4.87 (0.83)



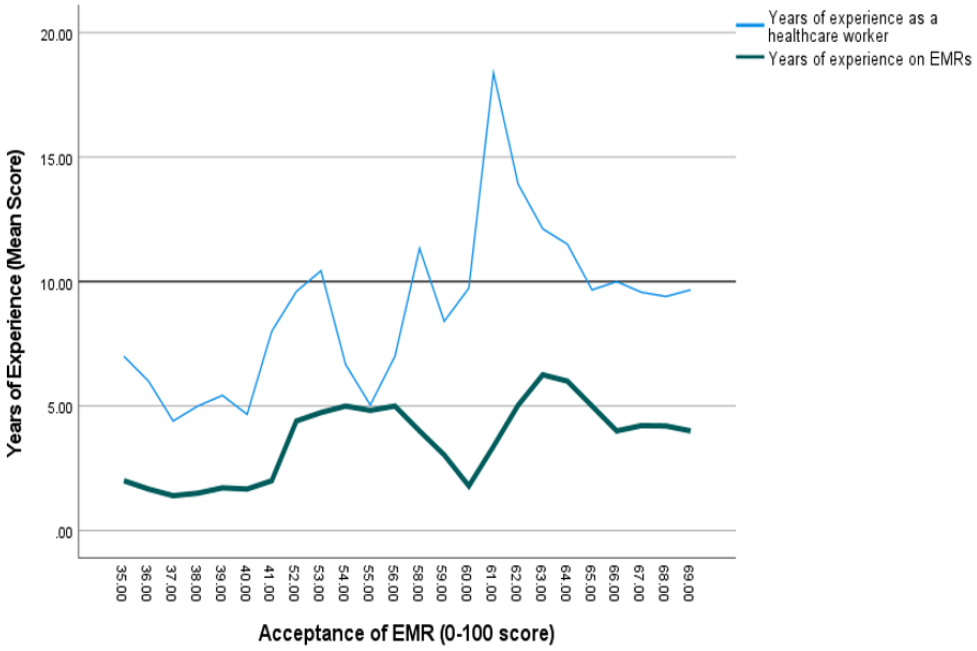
[a]TAM: Technology Acceptance Model.

[b]SN: serial number.

When comparing PU with PEOU, the health care workers' PU score is higher than their PEOU score, as described in Figure 1. Among the 6 items from the PU, the item "I have found Electronic Medical Records useful in my job," has had the highest score of 6.30 from 7.0. Among the items of PEOU, the item, "learning to operate Electronic Medical Records was easy for me," had the highest score. However, the lowest score (3.31) was about the ease of becoming skillful.

XSL•FO
RenderX

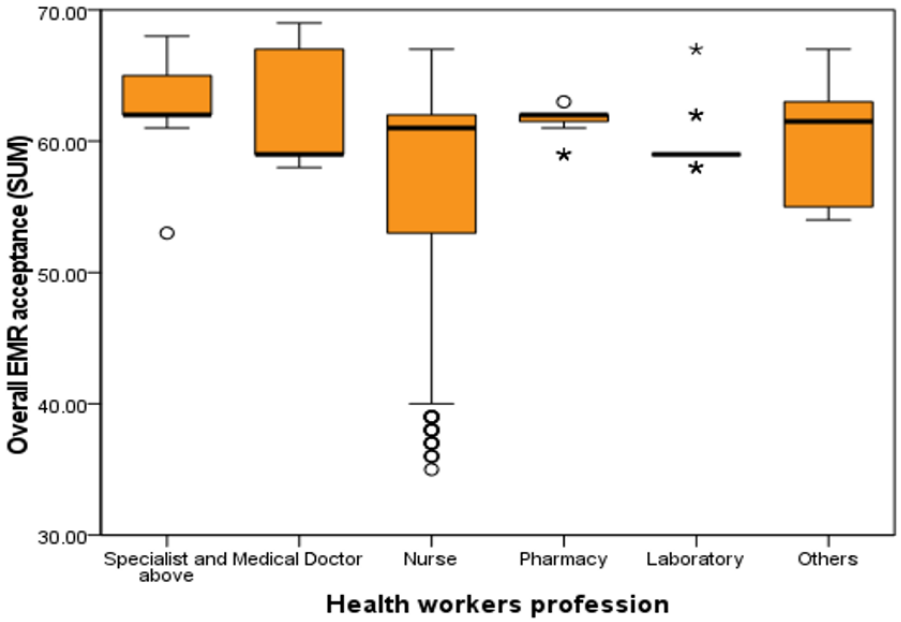
Figure 1. Line graph comparing perceived usefulness, perceived ease of use, and system usability towards EMR acceptance (converted to 0-100 points). EMR: electronic medical record; SUS: System Usability Scale.



Those health care workers who scored above or equal to the mean score value were categorized as having good EMR acceptance, and those health care workers who scored below the mean value were classified as having poor EMR acceptance.

Out of the total 322 study participants, this study showed that 256 (73%) of the study participants, with a 95% CI of 67.4-78.2, had a good acceptance of using EMRs.

Even though the acceptance of EMRs increased with the increase in work experience, as shown in Figure 2, there was a large gap between work experience as a health worker and in EMRs. Lower work experience with EMR is due to the late adoption of the system in the health facilities.



Higher acceptance of EMRs was observed among pharmacy professionals, specialists, and physicians. This was observed in the boxplot in Figure 3.

Figure 2. A line graph showing the years of experience as a health care worker versus electronic medical records. EMR: electronic medical record.

Factors Associated With Health Care Workers' Acceptance of EMRs at Health Care Facilities

To identify predictor variables using a statistical model, it is important to understand the type of dependent (outcome) and explanatory variables. In this study, the dependent variable is the acceptance of EMRs, categorized as either poor or good. Since the researchers' interest is to examine the factors that determine good acceptance of EMRs, good acceptance is coded as 1 and poor acceptance as 2.

In a binary logistic regression model, the first step is to conduct a univariable analysis to explore the unadjusted association between each independent variable and the outcome. The purposeful selection process begins with a univariate analysis of each variable. Any variable having a significant univariate test at an arbitrary level is selected as a candidate for the multivariable analysis. This selection is based on the Wald test from logistic regression, using a *P* value cutoff point of .25.

As shown in Table 4, both bivariable and multivariable logistic regression analyses were performed to assess the statistical association between the dependent variable (EMR acceptance) and the independent variables. The variables assessed in the bivariable logistic regression included sex, age, years of work experience (grouped), years of experience with EMRs (grouped), ownership of a personal computer, attendance of basic computer training, EMR training, basic eHMIS or DHIS2 training, information about *ICD-10 (International Statistical classification of Diseases, Tenth Revision)*, and EMR system usability (grouped).

[a]COR: crude odds ratio.

[b]AOR: adjusted odds ratio.

[c]Reference category.

[d]Not applicable.

[e]Significant at $P<.05$.

[f]eHMIS: electronic health management information system.

[g]DHIS2: district health information system 2.

Variables that were statistically significant at $P<.25$, based on chi-square statistics and the Wald test for individual parameters, were selected for inclusion in the multivariable logistic regression. The Wald statistic helps determine whether a coefficient is significantly different from zero, indicating that the predictor contributes meaningfully to the prediction of the outcome [27,28]. As a result, some variables, namely, age group, experience with EMRs (grouped), and information about *ICD-10*, were excluded from the final model. Finally, to control for potential confounders, a multivariable logistic regression was performed. This was performed by including all relevant confounders in the model; the analysis aimed to reduce bias and provide more accurate and reliable estimates of the associations.

The model test showed that the logistic regression model was statistically significant and able to predict EMR acceptance among health care workers with 73% accuracy ($P<.001$). The model explained between 51.8% (Cox and Snell R^2) and 75.2% (Nagelkerke R^2) of the variance in the confidence score.

Accordingly, the data present results from a multivariable logistic regression analysis examining factors associated with

XSL•FO
RenderX

EMR acceptance among health care professionals. The analysis revealed that sex, work experience, access to technology, training, and system usability were key factors influencing EMR acceptance. Although females were more likely to accept EMRs than males in the crude analysis (crude odds ratio 2.53, 95% CI 1.52-4.21), the association was not statistically significant after adjustment (adjusted odds ratio [AOR] 2.68, 95% CI 0.88-8.14, *P*=.08). Health care workers with more than 10 years of experience had significantly higher odds of EMR acceptance compared with those with less experience (AOR 14.32, 95% CI 4.60-44.58, *P*<.001), indicating a strong association.

Owning a personal computer or laptop was a powerful predictor of EMR acceptance. Professionals with personal devices were over 11 times more likely to accept EMRs than those without (AOR 11.08, 95% CI 4.03-30.42, *P*<.001). Similarly, EMR-specific training was significantly associated with higher EMR acceptance (AOR 4.71, 95% CI 1.52-14.54, *P*=.007), as was having basic eHMIS or DHIS2 training (AOR 3.06, 95% CI 1.02-9.17, *P*=.046).

However, attending basic computer training was not significantly associated with EMR acceptance after adjustment (AOR 0.79, 95% CI 0.27-2.30, *P*=.67). The strongest predictor of EMR acceptance was system usability: those who rated the system as highly usable were more than 38 times as likely to accept EMRs compared with those who found it less usable (AOR 38.24, 95% CI 12.26-119.27, *P*<.001).

Discussion

Principal Findings

This study aims to examine the factors that affect the acceptance of EMRs among health care workers in Northwest Ethiopia, with the intention of generating evidence to support effective digital health strategies and strengthen health system performance in the region.

In summary, the study found that more than half of the health care workers (256/322, 73%) had a good acceptance of EMR. The factors associated with this were years of work experience, satisfaction with monthly income, owning a personal computer, attending a training on EMR, having basic eHMIS/DHIS2 training, and system usability.

EMR implementation was seen as a challenge for older health professionals, especially those older than 60 years, which may therefore lead to their retention in the workforce [29]. However, in this study, most of the participants were young adults between the ages of 21 and 40 years (172/322, 53.4%), with a SD of 6.4, which is consistent with the study done in Saudi Arabia Hospital, about 62% [30]. Hence, the researcher believed that the acceptance of EMR would be much lower if there were a significant number of older populations found in the sample. Strategies to address technology anxiety, as well as the physical and psychological limitations of an older workforce, are needed to support this workforce during an EMR implementation [29].

More than half of the health care workers (213/322, 66.1%) reported owning a personal computer. However, this was lower than the study done in Oman, where a wide majority of the health care workers who participated in the study, which is 92.3%, reported owning a personal computer or a laptop [31]. Since ownership of technology will improve the PEOU, the health care facility should consider a strategy to enhance technology exposure and support laptops and smartphones for the health care provider.

Not having adequate training and experience is one of the main obstacles to a good EMR implementation and productivity [32]. There was a rapid development of health innovations, where most of them are targeting the point of care. And, sometimes, health professionals may be forced to use the new system without having prior knowledge about it. This can be a factor for low acceptance of EMRs among health care workers. Regarding basic computer training, this study showed that about half of the respondents took the training, (183/322, 56.8%), which is nearly similar to the study in Saudi Arabia hospital, where 52.3% of the participants described that they had formal computer training, while (139/322, 47.7%) mentioned that they did not have any type of computer training [30]. However, the finding is lower than a study done in Muscat, where about 3-quarters of the study participants had computer training. This may affect their ability to competently use the EMR system and influence the quality of interaction with the system while providing health care [31]. It can be explained that having a good experience with information communication technology will help the health care workers to have a higher PEOU, which in turn improves the usability and acceptability of EMRs.

The absence of training and lower experience are among the main obstacles to a good EMR implementation and productivity. In this regard, the study observed EMR training among the health care workers and found that about half of the users did not receive training on EMR (139/322, 49.7%). The magnitude of the problem, the gap in EMR training, will be more visible as one understands how effective the training was. This was described in the Rwandan study, where 98% of respondents agreed that their training on the EHR was effective, and about 93% were confident in using the EMR after having the training [33].

Years of experience as a health professional are another factor that determines EMR acceptance. In this study, about half of the participants (173/322, 54%) had mid and lower-level experience (1-10 years). This is consistent with the study in the Saudi Arabian hospital (56%) [30]. The acceptance of EMR has great paybacks for health professionals, health facilities, and also for the health outcome of the people, if it is used effectively. Therefore, closer attention should be given to the human resource development in line with investing in the introduction of the technology.

EMR acceptance was measured with the latest version of the TAM, 12 items, and a 7-point scale measurement [21]. The level of EMR acceptance for this study was 4.87 (SD 0.83) on a 7-point scale. This finding is lower than a study done in Marie Stops International Clinic in Myanmar among clinical and management staff, with 4.24 (5-point scale) or 5.94 (7-point scale). The scale is converted to compare it with this study [34]. However, it is consistent with the study done in northeastern US regional medical centers among Intensive Care Unit nurses,

XSL•FO
RenderX

which was 6.91 (on a 10-point scale), which means 4.83 (on a 7-point scale) [35].

To identify factors associated with the acceptance of the EMR, the variable is recoded and dichotomized into 2 categories (Good and Poor acceptance, with a mean of 4.87, SD 8.3), using cutoff points. Multivariable analysis showed that health care workers with more than 10 years of work experience had a very high effect on EMR acceptance. This finding is supported by much evidence; a report at a government hospital in Muscat stated, health care workers with 6 years and more experience in using the EMR system had 2 times more likely to accept the EMR than their counterparts (odds ratio 2.49, 95% CI 1.23-5.04, *P*=.01). And, another study from Saudi Arabia indicated that notable positive relationship were found between years of experience at the organization and acceptance of EMR [30,31,36].

Owning a personal computer also had a positive effect on acceptance of the EMRs among health care workers. This is consistent with what was done in Belgian Hospital staff, where the length of computer usage was found to have a positive correlation with acceptance of EMR [36]. This may be because health workers' behavior would be influenced by IT use and being more familiar with computer usage. So, EMR acceptance can sometimes be effective with only a little support to the system users.

Sometimes technology may be introduced into the organization without creating awareness and having training, which leads to hesitancy to use the system. In this study, about half of the participants reported having training on EMR. And, it has a significant effect on accepting EMR, where health care workers who took the training on EMR were 4 times more likely to have a good acceptance than those who did not take the training (AOR 4.71, 95% CI 1.52-14.54; *P*<.007).

Theoretical and Practical Implications of the Study

The study reinforces the relevance of the TAM in predicting EMR acceptance by health care workers. Key constructs of TAM for this study are PEOU and PU, which are reflected in the factors found to influence EMR acceptance, including prior training, personal computer ownership, and system usability. The findings suggest that individual-level technology experience and training positively shape attitudes toward digital health systems, supporting the theoretical understanding that user readiness and perceived capability are central to successful health information system adoption.

Practically, the study highlights actionable areas for improving EMR implementation in low-resource settings. It emphasizes the importance of investing in digital infrastructure, providing targeted training on EMR systems, and fostering technology exposure among health care workers. Strategies such as supporting staff with personal digital devices, integrating digital health training into ongoing professional development, and addressing the needs of older staff can significantly enhance EMR acceptance. These practical steps can contribute to more efficient health care delivery, improved data quality, and ultimately, better health outcomes.

Limitations of This Study

This study has some limitations that should be acknowledged. First, the use of a cross-sectional design limits the ability to establish causal relationships between the identified factors and EMR acceptance. While associations can be observed, the temporal sequence of events remains unclear. Future research using longitudinal or experimental designs could better assess causality. Second, the reliance on self-reported data may introduce social desirability and recall biases, which can affect the accuracy of responses, and there may be method bias. Although efforts were made to ensure anonymity and create a nonjudgmental environment to reduce these biases, some degree of misreporting may still have occurred.

Conclusions

The level of EMR acceptance among health care workers is 4.87 out of a 7-point scale. Though this is above the midpoint, the level of EMR acceptance is somehow lower than other findings.

Higher EMR acceptance was significantly associated with longer work experience, ownership of a personal computer, EMR, or eHMIS/DHIS2 training, and high system usability. Notably, system usability emerged as the strongest predictor. While females showed higher acceptance in the crude analysis, the association was not significant after adjustment. Interestingly, income satisfaction was inversely related to EMR acceptance. These findings highlight the importance of targeted training, access to technology, and user-friendly systems in promoting EMR adoption.

PU and perceived ease determine the level of EMR acceptance. EMR acceptance is the actual use rather than the anticipated use. The health care workers' PU of the EMR is higher than their PEOU. Years of work experience, being satisfied with monthly income, owning a personal computer, attending training on EMR, having basic eHMIS or DHIS2 training, and system usability were factors that are associated with the acceptance of EMR. It is recommended to have appropriate strategies relevant to the context before implementing the EMRs. Context-specific strategies that enhance system usability, provide targeted training, and improve access to digital tools, particularly for less experienced staff, are essential to increasing EMR acceptance among health care workers.

Abstract

Background: Osteoporosis is a bone disease characterized by reduced bone mineral density and mass, which increase the risk of fragility fractures in patients. Artificial intelligence can mine imaging features specific to different bone densities, shapes, and structures and fuse other multimodal features for synergistic diagnosis to improve prediction accuracy.

Objective: This study aims to develop a multimodal model that fuses chest X-rays and clinical parameters for opportunistic screening of osteoporosis and to compare and analyze the experimental results with existing methods.

Methods: We used multimodal data, including chest X-ray images and clinical data, from a total of 1780 patients at Chongqing Daping Hospital from January 2019 to August 2024. We adopted a probability fusion strategy to construct a multimodal model. In our model, we used a convolutional neural network as the backbone network for image processing and fine-tuned it using a transfer learning technique to suit the specific task of this study. In addition, we introduced a gradient-based wavelet feature extraction method. We combined it with an attention mechanism to assist in feature fusion, which enhanced the model's focus on key regions of the image and further improved its ability to extract image features.

Results: The multimodal model proposed in this paper outperforms the traditional methods in the 4 evaluation metrics of area under the curve value, accuracy, sensitivity, and specificity. Compared with using only the X-ray image model, the multimodal model improved the area under the curve value significantly from 0.951 to 0.975 (P=.004), the accuracy from 89.32% to 92.36% (P=.045), the sensitivity from 89.82% to 91.23% (P=.03), and the specificity from 88.64% to 93.92% (P=.008).

Conclusions: While the multimodal model that fuses chest X-ray images and clinical data demonstrated superior performance compared to unimodal models and traditional methods, this study has several limitations. The dataset size may not be sufficient to capture the full diversity of the population. The retrospective nature of the study may introduce selection bias, and the lack of external validation limits the generalizability of the findings. Future studies should address these limitations by incorporating larger, more diverse datasets and conducting rigorous external validation to further establish the model's clinical use.

Introduction

Background

Osteoporosis is a common metabolic bone disease characterized by decreased bone mineral density (BMD) and thinning of the trabecular structure of bone, leading to fragile bones and an increased risk of fracture. As the global population ages, osteoporosis has become a key factor affecting the health of middle-aged and older adults. However, the early symptoms of osteoporosis are not obvious, and most patients are diagnosed only after a fracture occurs, leading to increased complications and mortality [1]. Therefore, how to effectively identify people at high risk of osteoporosis and take timely preventive measures has become the focus of current clinical research.

Automated detection and classification of osteoporosis using deep learning (DL) has become a popular research topic in recent years [2]. Traditional prediction methods for osteoporosis mainly rely on a single data type, such as assessing BMD and

XSL•FO
RenderX

classifying the degree of bone loss based on clinical data [3-5], computed tomography [6,7], magnetic resonance imaging [8], and X-ray images [9-12]. Dual-energy X-ray absorptiometry (DXA) is an internationally recognized method of measuring BMD and is also considered the gold standard for the diagnosis of osteoporosis [13]. However, DXA is less available and the cost of screening is high. For this reason, opportunistic screening offers a viable solution, as it uses clinical data for other indications without additional costs, radiation exposure, or patient time. In contrast, DL algorithm–based assessment of osteoporosis from X-ray images is a low-cost alternative to DXA [14-16]. Chest X-ray imaging has accumulated a large amount of imaging resources in routine applications such as pneumonia screening and bronchial disease examination, providing a natural imaging basis for opportunistic screening of osteoporosis. In addition, chest X-rays [11,17,18] can capture key bone structures affected by osteoporosis, such as ribs, thoracic vertebrae, and clavicles, further highlighting their application value in osteoporosis screening. Although such DL models based on a single data type have improved the accuracy and efficiency of osteoporosis diagnosis to a certain extent, the single data type only provides 1D information, neglecting the comprehensive consideration of information about the bone microenvironment, physiological characteristics, and patients' clinical data, which leads to the prediction results that may not be comprehensive and accurate.

However, in the actual diagnostic process, doctors will comprehensively refer to various information sources, including medical image data, laboratory examination data, and medical record reports, to improve the accuracy of diagnosis [19]. This concept is introduced into DL, which aims to simulate the complex process of medical differential diagnosis through multimodal [20,21] data fusion. The fusion of multimodal medical data has become a hot research topic in interdisciplinary fields. Multimodal fusion can provide a more accurate description of samples, and it exploits the complementary and synergistic nature of each modality's information more effectively than any single modality data [22]. As a result, multimodal fusion techniques have been widely used in several medical fields, including oncology, cardiovascular medicine, and radiology [23-25]. In the field of orthopedics, relevant multimodal studies are rapidly emerging [26,27], providing new ideas for osteoporosis prediction.

Objectives

In this study, we propose a multimodal prediction model that fuses chest X-ray images and clinical data for opportunistic screening of osteoporosis. In the model construction, we used a convolutional neural network (CNN) as the backbone network for image processing and fine-tuned it to the specific task of this study using transfer learning techniques. In addition, we introduced a gradient-based wavelet feature extraction method. We combined it with an attention mechanism to assist in feature fusion, which strengthened the model's focus on key regions of the image and further enhanced the model's ability to extract image features.

Methods

Ethical Considerations

The study was approved by the institutional review board at the Chongqing Daping Hospital (2024_335). A waiver of informed consent was provided, as this retrospective study used existing information. Privacy and confidentiality of all patient data were maintained throughout the entire study. No compensation was provided to patients, as this study only involved the review of retrospective data.

Dataset and Study Population

This study retrospectively collected multimodal data, including chest X-ray images and clinical data, from January 2019 to August 2024. The specific inclusion criteria were as follows: (1) patient age ≥50 years and (2) chest X-ray and DXA were performed on the same day. The specific exclusion criteria were as follows: (1) image data with artifacts, blurriness, or inability to display bone structures; (2) patients with other serious diseases that may affect bone health or interfere with diagnosis, such as malignant tumors and severe metabolic diseases; (3) patients who have recently used drugs that may affect bone metabolism or BMD measurement, such as hormone drugs and antiosteoporosis drugs; and (4) cases where the missing rate of clinical data reached or exceeded 30%. On the basis of these criteria, a total of 1780 cases met all the criteria, with 990 (55.62%) cases in the osteoporosis group and 790 (44.38%) cases in the nonosteoporosis group. Therefore, we extracted chest X-ray images (DICOM format) from the hospital's communication system repository and collected the clinical data of patients from the back-end database, including age, sex, height, weight, white blood cell count, platelet count, serum calcium level, fasting blood glucose, and chest X-ray descriptive information. The model was trained through a 5-fold cross-validation.

The diagnosis of osteoporosis was based on DXA BMD measurement results. DXA negative means BMD is within the normal range, corresponding to the nonosteoporosis group. DXA positivity refers to a BMD lower than the normal range, corresponding to the osteoporosis group. The DXA manufacturer of Chongqing Daping Hospital is GE Lunar Prodigy model (Madison, WI, USA).

Preprocessing

The DICOM format X-ray images were converted to the 8-bit PNG format to adapt to the DL frameworks. After conversion, the images were all manually reviewed. The image intensity was reversed to ensure no negative values and then normalized. All images were squared using zero padding and then downsampled to 224×224 pixels to fit a pretrained CNN on ImageNet. Using dynamic data augmentation to limit overfitting, this included random flipping (horizontal and vertical), random rotations (90° rotation), random translations (10% variation in each direction), random zooming (10% variation), and random contrast adjustment (factor of 0.3).

For the handling of missing values in clinical data, regarding white blood cell count and serum calcium level, since the numerical distribution of these features was roughly normally

XSL•FO
RenderX

distributed, the mean of the variables was used for filling, which could better reflect the overall level. For features such as BMI, platelet count, and fasting blood glucose, as their numerical distributions might be skewed, the median of the variables was chosen for imputation, which was more robust in this case.

This research dataset included 990 positive (osteoporosis) and 790 negative (nonosteoporosis) samples, with a positive-to-negative ratio of 55.6% and 44.4%, respectively. In response to the mild imbalance characteristics of the dataset, this study adopted class weighting techniques to weight the loss function based on the distribution of training dataset classes, thereby improving the model's sensitivity to identifying minority classes.

Proposed Multimodal Model

Overview

The framework of our proposed multimodal model is shown in Figure 1. After data preprocessing, we built an image model trained on X-ray images and a clinical parameter model trained on clinical data. The multimodal model then fused the prediction results of these two models using a probability fusion (PF) strategy [19]. The details of each model are described in the following sections.

Figure 1. The proposed multimodal model framework. It includes 3 parts: image, clinical parameter, and multimodal models.

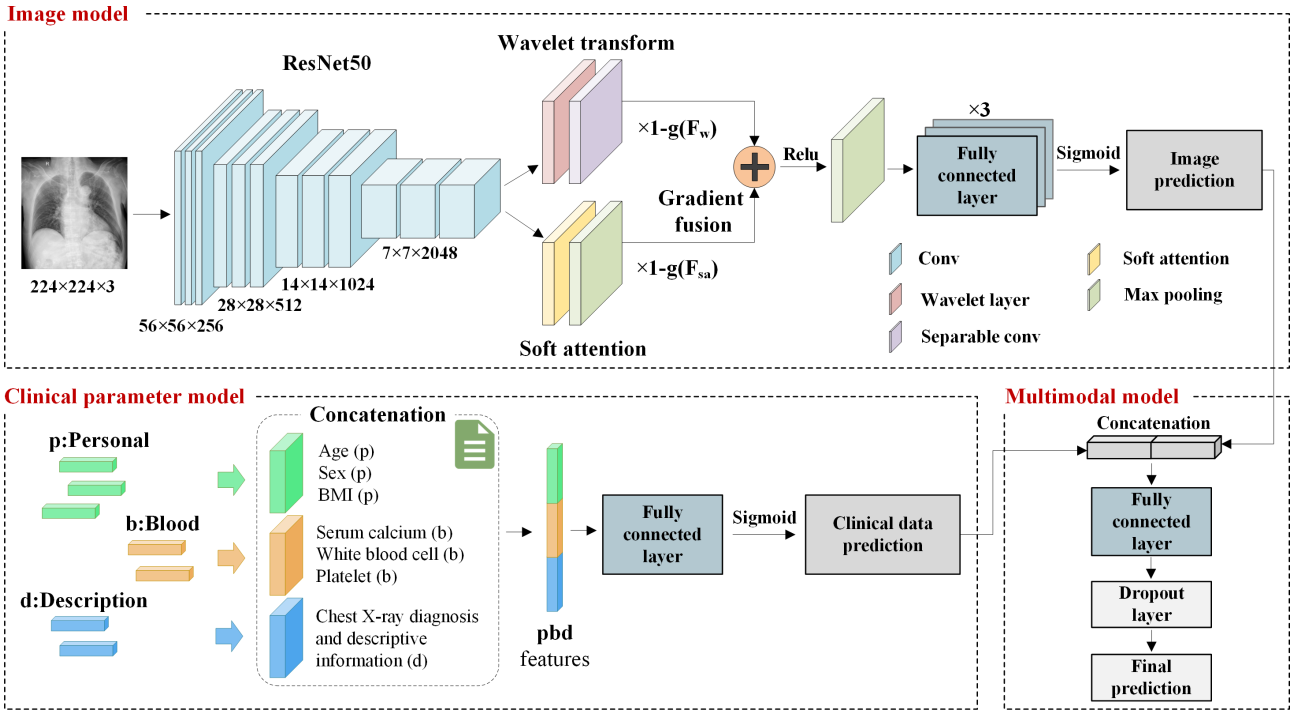

Image Model

Transfer learning is a method that uses pretrained models to reduce the data and computational costs required for new tasks. In the field of medical imaging, methods that combine transfer learning with CNN models trained on large-scale datasets such as ImageNet have been widely adopted [28]. Our image model used a pretrained ResNet50 [29] as the backbone network for feature extraction of chest X-ray images. Subsequently, we applied the wavelet transform (WT) for multiscale analysis of the images to extract features at different scales that reveal subtle changes in bone structure in different images. The soft attention (SA) mechanism was used to capture specific appearance features and morphological regions in the images. Finally, we used a gradient-based feature fusion mechanism to effectively fuse these features to obtain the final image probabilistic output.

ResNet50 has excellent feature extraction capabilities, with a network depth of up to 50 layers, which could effectively capture rich hierarchical features in image data. Meanwhile, the residual learning structure adopted by ResNet50 effectively solved the problem of gradient vanishing during deep network training. In addition, it also had a lower number of parameters and computational costs, making it more practical for common hardware deployment scenarios in medical imaging analysis. For the binary classification task of osteoporosis, we fine-tuned our pretrained ResNet50 model. Specifically, considering that our classification task involved only 2 categories, which were significantly different from the 1000 categories in ImageNet shown in a previous study by Holste et al [30], we added a global maximum pooling layer and 3 fully connected layers with 1024, 512, and 256 neurons to the top of the pretrained model.

WT is a signal processing method based on multiscale analysis, which decomposes a signal into a weighted sum of multiple waves of different scales and frequencies through a mathematical transform. The WT has the advantage of multiscale and multiresolution and is capable of accurately extracting the local spatiotemporal distribution characteristics of the signal [31]. In our multimodal model, we used an efficient Haar WT method that extracted wavelet features from the output features of ResNet50. These features covered valuable information such as the sparsity of bone trabeculae and the thickness of the bone cortex. To reduce the parameters and computational effort of the model and to maintain the

XSL•FO
RenderX

performance of the model, a depth-separable convolutional layer was introduced after the WT layer.

Inspired by the recent widespread application of the attention mechanism in deep neural networks [32], we introduced the attention mechanism into our model. Both SA [33] and hard attention are mechanisms that help models focus on key parts of input data. The hard attention mechanism involved discrete sampling at specific locations of input data, typically using reinforcement learning methods during training, as it involved nondifferentiable operations. In contrast, the SA mechanism was a probability distribution-based continuous attention method that assigned a weight to each position of the input data, and then weighted and summed the input based on these weights to obtain a context vector. The advantage of SA was that it was completely differentiable and could be trained end-to-end using standard gradient descent methods, making it more stable and efficient during the training process. In our study, we used a SA mechanism that assigned a weight to each input item, representing the degree of attention the model pays to that input item. This helped the model focus on key regions in X-ray images and generated descriptions that match the image content.

Specifically, we dynamically performed adaptive gradient fusion of wavelet features with SA features, using the normalized backpropagation gradients g(Fw) and g(Fsa) of Fw and Fsa as the basis for fusion weights, as shown in equation 1. A higher gradient means that the corresponding feature may have a negative impact on the model performance, and therefore it is given less weight in the fused features Ffuse, and vice versa. By introducing learnable weights, the feature fusion process was optimized to be more representative without increasing the parameters. This method ensured that important information was efficiently fused into the coded features before they were passed to the fully connected layer.

$$(1) Ffuse=(1-g(Fw))\times Fw+(1-g(Fsa))\times Fsa$$

Clinical Parameter Model

Our clinical parameter model includes important blood biochemical indicators such as white blood cell count, platelet count, serum calcium level, and fasting blood glucose and personal information including age, sex, and BMI, as well as chest X-ray diagnosis and descriptive information. Previously, most machine learning–based studies have relied mainly on clinical data, such as using prehospital information to predict mortality in patients with heart failure in intensive care units [34] or for predicting sepsis [35]. Algorithms such as random forest and XGBoost usually showed better performance than DL models for clinical data processing, and they did not require backpropagation during training; however, this made it difficult to directly combine these algorithms with DL models such as CNNs. Therefore, in our study, we chose to use a fully connected layer with 50 neurons to process these clinical data.

Multimodal Model

When training our multimodal model, we used the weights of the already trained baseline image model and clinical parameter model. We used a PF strategy in which both baseline models were run in inference mode, each independently producing a prediction. Our multimodal fusion mechanism then took the independent output probabilities of the image and clinical parameter models as inputs, concatenated them, and input them into a fully connected layer neural network with 32 neurons to generate the final prediction. During the training process, the learning rate started at each epoch and decreased in a multiplicative manner at the end of each epoch until a preset minimum was reached, and it took approximately 40 minutes to train the multimodal model once.

Evaluation

We used 4 evaluation metrics to measure the performance of our model, including area under the curve (AUC) value, accuracy, sensitivity, and specificity. To obtain more accurate and less biased results, we adopted a 5-fold cross-validation method. In the hyperparameter settings, we used binary cross-entropy as the loss function and selected the Adam optimizer. We combined the ideas of grid search and random search, and tried multiple values such as 1e-4, 1e-5, and 1e-6 for the learning rate. For the dropout rate, we tried multiple values such as 0.2, 0.25, 0.3, 0.4, and 0.5. For batch size, we tried multiple values such as 16, 32, 64, and 128. The final determined learning rate was 1e-5, dropout was 0.25, and the batch size was 32. To effectively prevent overfitting of training data, we adopted an early stopping strategy based on validation loss and retained the optimal weights during the training process for recovery. Our model was implemented in Keras 2.4 and trained on a computer with an Intel i9-14900K 24-core CPU, 64 GB of RAM, and an NVIDIA RTX A6000 GPU card with 48 GB of memory.

Results

Patient Characteristics

This study included a total of 1780 patients (as shown in the patient inclusion process flow diagram in Figure 2), with each patient corresponding to an anteroposterior position chest X-ray image. The average age of the patients was 69.46 (10.33) years, with an age range of 50 to 99 years. The statistical data of the training dataset, validation dataset, and test dataset are detailed in Table 1. These three datasets are almost identical in terms of sex and age distribution. All patients were divided into 2 groups: the osteoporosis group (990/1780, 55.62%) and the nonosteoporosis group (790/1780, 44.38%); 55.66% (659/1184), 56.4% (167/296), and 54.7% (164/300) of patients in the 3 datasets suffer from osteoporosis.

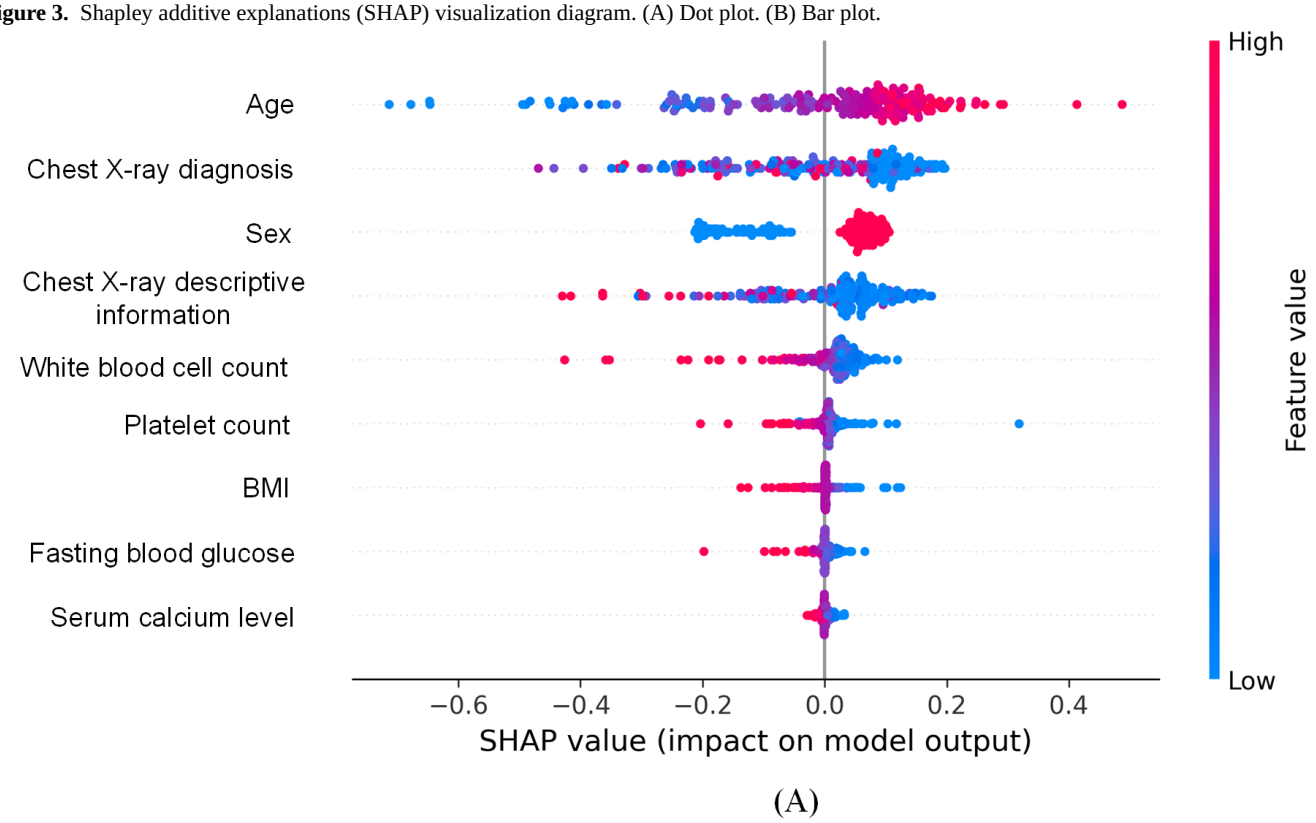
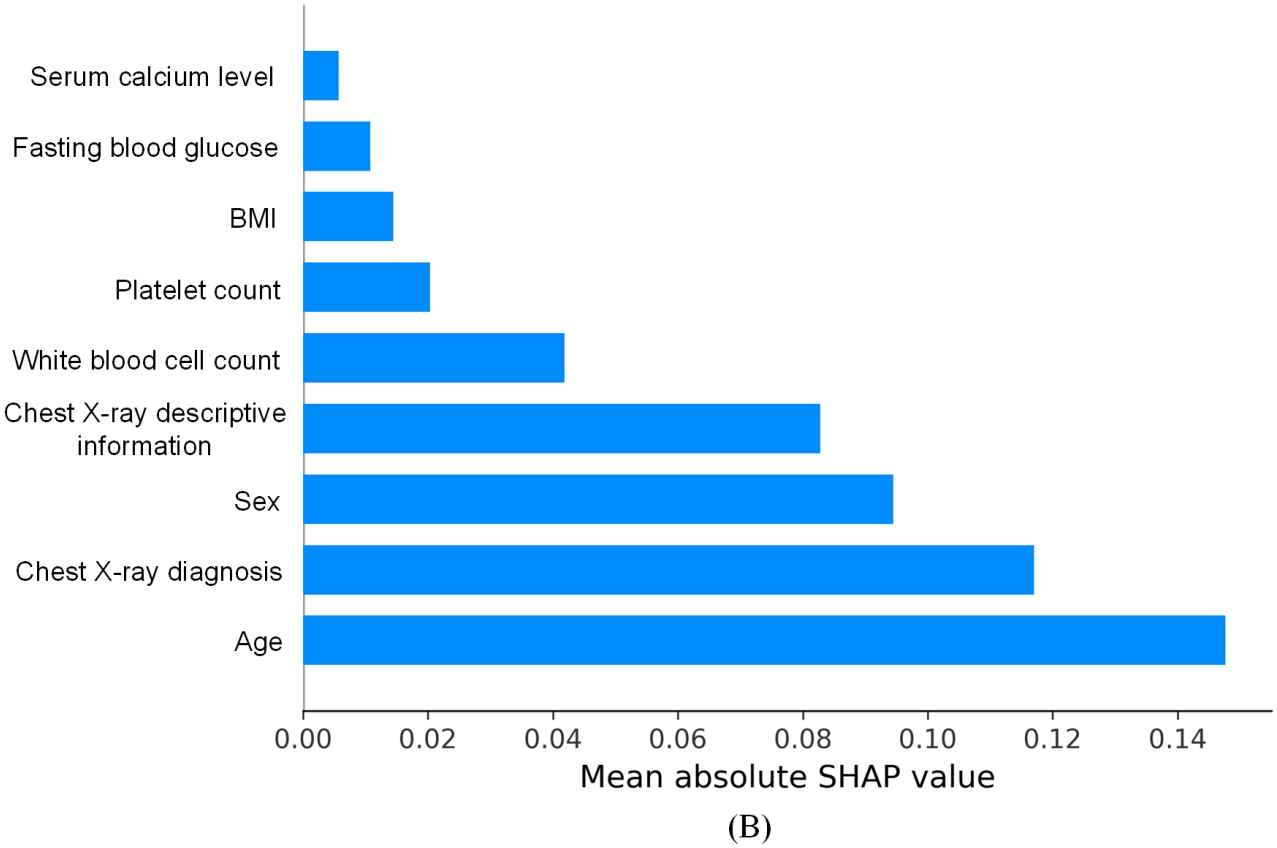
Table . Dataset description of 1780 cases of patients with osteoporosis.



Characteristics	Training dataset (n=1184)	Validation dataset (n=296)	Test dataset (n=300)
Age (y), mean (SD)	69.3 (10.34)	69.53 (10.72)	69.94 (10.28)
Sex, n (%)			
Male	495 (41.80)	119 (40.2)	120 (40.0)
Female	689 (58.20)	177 (59.8)	180 (60.0)
Presence of osteoporosis, n (%)			
Osteoporosis	659 (55.66)	167 (56.4)	164 (54.7)
Nonosteoporosis	525 (44.34)	129 (43.6)	136 (45.3)

Overall Predictive Performance of the Multimodal Model



In this study, we used the SHAP (Shapley additive explanations) method to analyze the feature importance of the model. The SHAP method helps us understand which features have a specific impact on the model's decision-making process by calculating the contribution value (ie, SHAP value) of each feature to the model prediction. Figure 3 presents the results of the SHAP method, including a dot plot (Figure 3A) and a bar plot (Figure 3B). The dot plot displays the distribution of SHAP values for each feature, reflecting the direction and degree of the feature's impact on the model's prediction results. The bar plot summarizes the mean contribution of each feature to the model prediction. According to the analysis results, the features that contributed the most to the model prediction were age, chest X-ray diagnosis, sex, chest X-ray descriptive information, white blood cell count, platelet count, BMI, fasting blood glucose, and serum calcium level. These results indicated that the selected features were of great significance for model prediction, thereby improving the accuracy and reliability of the model.

The training and validation loss curves of the multimodal model in this paper are shown in Figure 4, which intuitively demonstrate the convergence of the model. From Figure 4, it could be seen that as the training progresses, both the training loss and validation loss exhibited a decreasing trend and gradually stabilized, indicating that the model performs consistently on both the training and validation datasets and has good generalization ability.

Figure 4. Training and validation loss curves of the multimodal model.

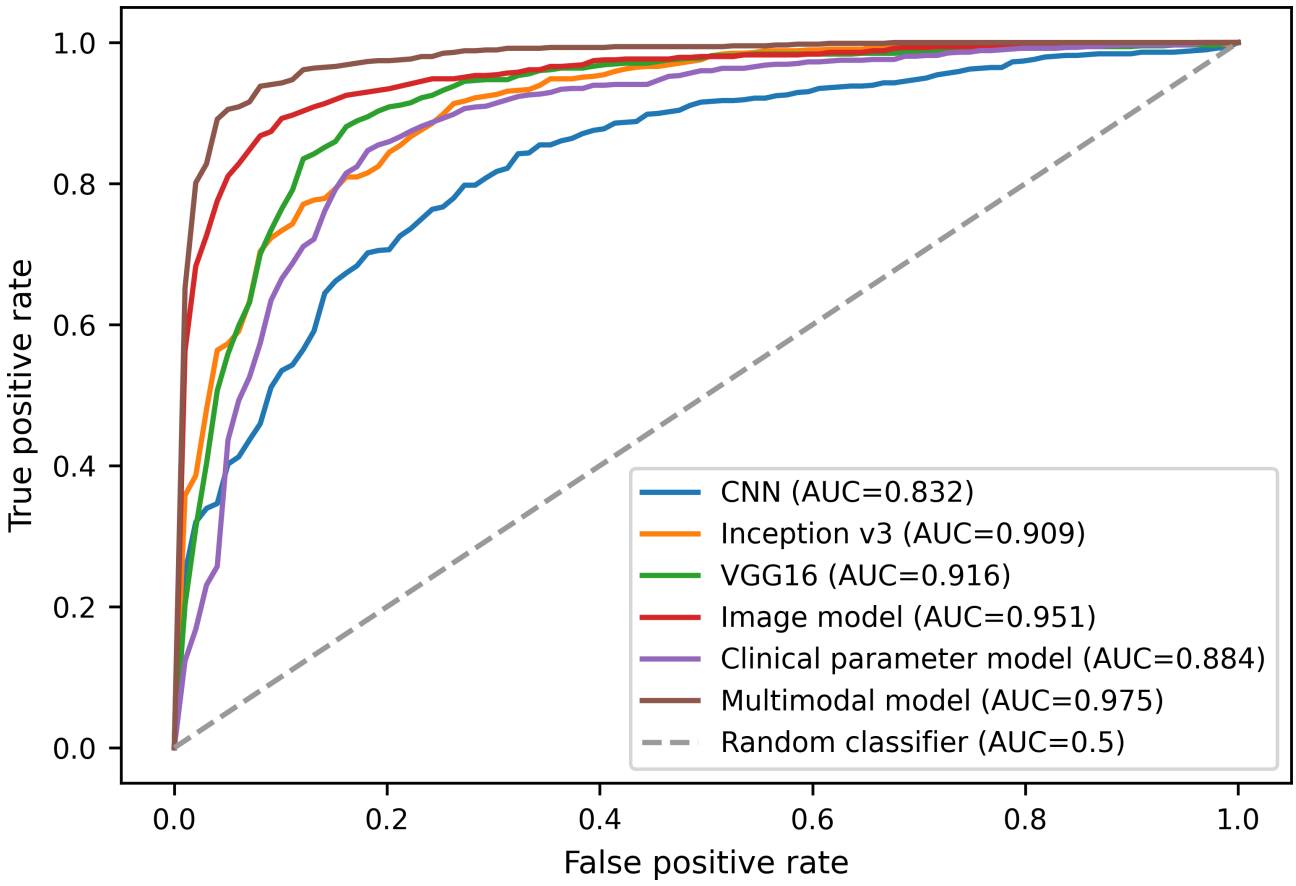
To validate the superiority of the multimodal model proposed in this paper, Table 2 summarizes the performance of the model in the test dataset. First, to verify the performance of the ResNet50 pretrained backbone network used in the image model of this paper, we selected a conventional CNN model and two other pretrained models, Inception v3 and VGG16, for comparative analysis. Among them, the pretrained models ResNet50 and VGG16 used images of size 224×224 pixels as input, while the Inception v3 model used images of size 299×299 pixels. The image model corresponds to the pretrained ResNet50 model in Table 2. As shown in the table, all 4 image-based models showed good classification ability in the test dataset, with an average AUC value of 0.902. In comparison, our image model showed the optimal structural performance compared to the other 3 models. Specifically, our image model achieved the highest values in the 4 evaluation metrics of AUC value, accuracy, sensitivity, and specificity, which were 0.951, 89.32%, 89.82%, and 88.64%, respectively.

Table . The performance of models in the test dataset.

Model	AUC[a]	Accuracy, %	Sensitivity, %	Specificity, %
CNN[b]	0.832	77.91	83.54	69.75
Inception v3	0.909	80.74	77.66	84.96
VGG16	0.916	85.54	85.26	85.92
Image model	0.951	89.32	89.82	88.64
Clinical parameter model	0.884	80.81	78.29	84.46
Multimodal model	0.975	92.36	91.23	93.92

[a]AUC: area under the curve.

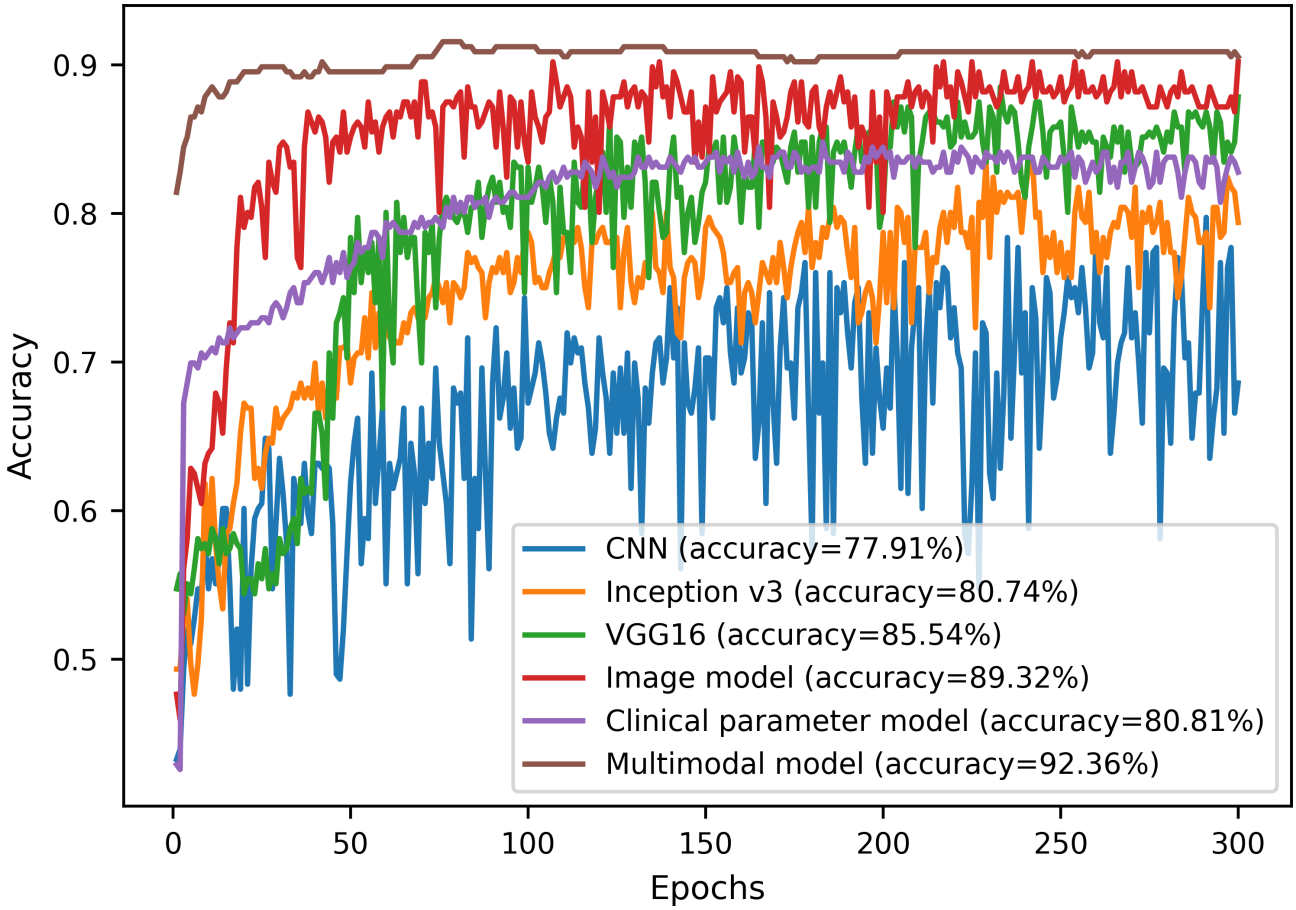
[b]CNN: convolutional neural network.



The multimodal model trained in this paper, which combines patient image and clinical parameter features, outperformed the image-only or clinical parameter–only models on all 4 evaluation metrics. Specifically, when compared with the model using only X-ray images, the multimodal model improved its AUC value from 0.951 to 0.975 (P=.004), accuracy from

XSL•FO
RenderX

89.32% to 92.36% (*P*=.045), sensitivity from 89.82% to 91.23% (*P*=.03), and specificity significantly from 88.64% to 93.92% (*P*=.008). Notably, the multimodal model effectively reduced the false positive rate and increased the specificity by 5.28% compared with the unimodal image model at the high-sensitivity operating point. We experimentally verified the superiority of the multimodal method in this paper compared to several other classification models.



The variation curves of receiver operating characteristic and accuracy for the image model, the clinical parameter model, and the multimodal model on the test dataset are shown in Figures 5 and 6, respectively. In Figure 6, we show the results for only the first 300 epochs of each model. From the figure, the multimodal model exhibits the lowest false positive rate and the highest true positive rate, with an AUC value of 0.975, as well as an accuracy of 92.36%. In contrast, the CNN model has an accuracy of only 77.91% with an AUC value of 0.832, with a difference of more than 10% between the two models. In addition, the multimodal model proposed in this paper is the first to reach the convergence state and has the least fluctuation compared with other models.

Figure 5. Receiver operating characteristic (ROC) variation curves in the test dataset. AUC: area under the curve; CNN: convolutional neural network.

XSL•FO
RenderX

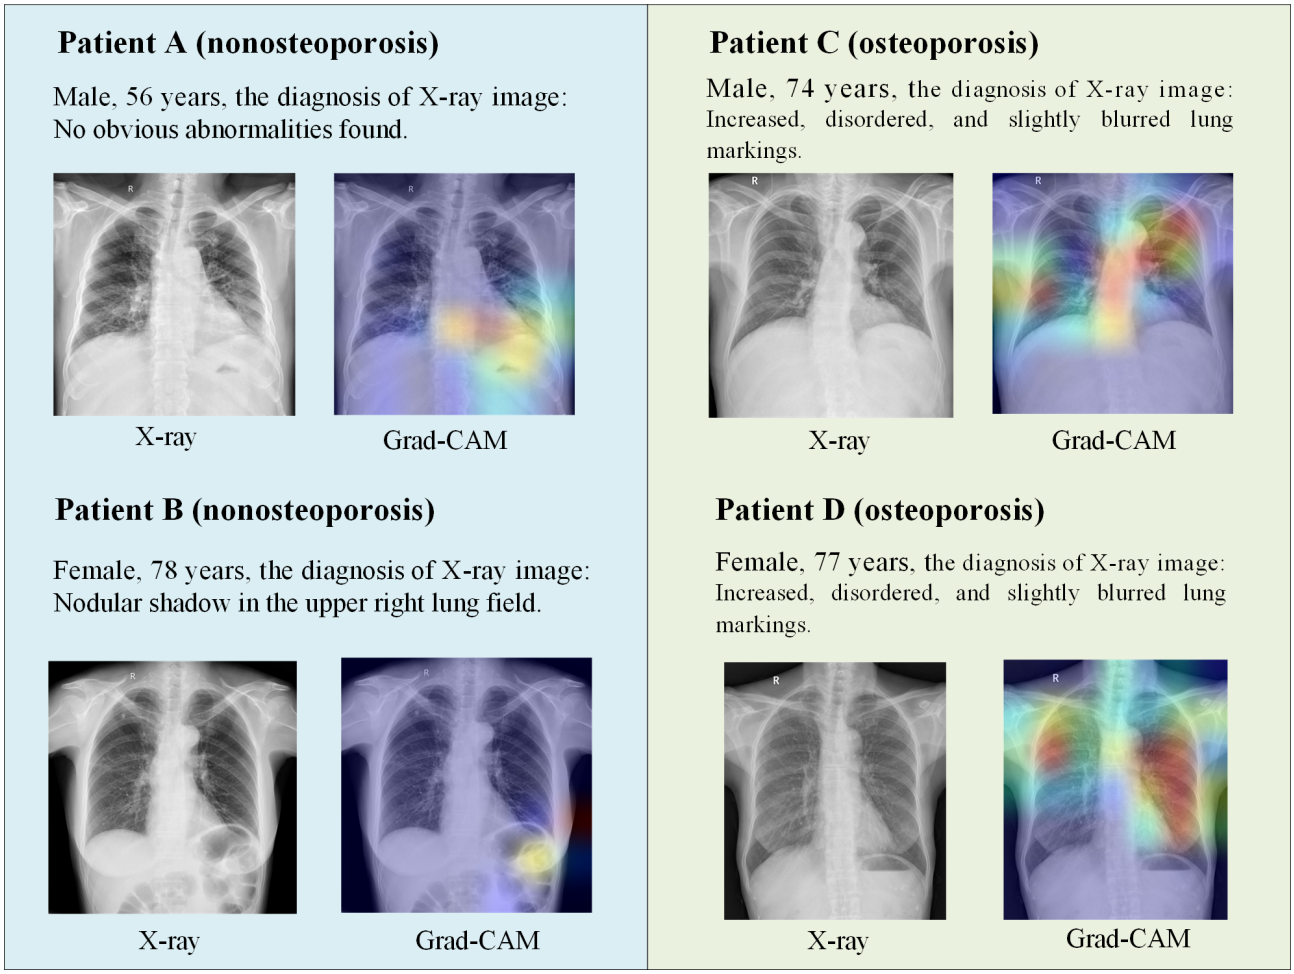


Figure 6. Accuracy variation curves on the test dataset. CNN: convolutional neural network.

To visualize the attentional regions of the model, we used the gradient-weighted class activation mapping technique. Figure 7 shows the results of the visual interpretation of the multimodal model at the individual level. In patients with osteoporosis, as BMD decreases, a series of characteristic changes in bone structure occur, such as sparse trabeculae and thinning of cortical bone. The gradient-weighted class activation mapping heat map showed that the model mainly focused on areas such as the scapula, thoracic spine, ribs, and sternum. These areas are commonly vulnerable sites in osteoporosis, and their structural changes are closely related to the pathological characteristics of osteoporosis. For example, the thoracic and lumbar spine is a high-risk area for osteoporotic fractures, and a decrease in BMD can increase the risk of fractures. The model could more accurately predict osteoporosis by learning the imaging features of these key regions. The model's attention to the scapula and ribs also had certain clinical significance. The changes in BMD of the scapula and ribs could indirectly reflect the overall bone condition of the chest, providing supplementary information for the diagnosis of osteoporosis. In addition, although anteroposterior chest X-rays could not fully cover areas such as the humeral head and lumbar spine, the model could still make effective predictions by focusing on key bone structures observable in the chest X-rays.

XSL•FO
RenderX

Figure 7. The visual interpretation of individual patients' outcomes. We randomly selected data from 4 patients for interpretation. The images on the left side show the patients' chest X-ray images, and the images on the right side show the corresponding gradient-weighted class activation mapping (Grad-CAM) heat maps. Areas that appear as bright red on chest X-ray images are considered to be the most important.

Ablation Study

To verify the role of WT and SA mechanisms in our image model, we conducted an ablation study, which included (1) ResNet50, (2) ResNet50+WT, ResNet50+SA, and ResNet50+WT+SA.

In Table 3, it could be seen that the introduction of the WT and the SA mechanism based on the backbone network ResNet50 improved the performance of the model in all 4 evaluation metrics, especially in the specificity metric, where the improvement reaches 7.74%. The results of this ablation study demonstrated the ability of these two modules to enhance the model's attention to key regions of the image and validate their effectiveness in our model.

Table . Optimal model configuration for the ablation study.

Model	AUC[a]	Accuracy, %	Sensitivity, %	Specificity, %
ResNet50	0.930	86.35	86.97	80.90
ResNet50+WT[b]	0.950	87.70	89.18	85.99
ResNet50+SA[c]	0.941	89.19	90.18	87.97
ResNet50+WT+SA	0.951	89.32	89.82	88.64

[a]AUC: area under the curve.

[b]WT: wavelet transform.

[c]SA: soft attention.

In addition, we experimented with different multimodal fusion strategies, and the results are shown in Table 4. As shown in the table, the strategy we used to merge the output probabilities before learning the final decision showed better performance compared to the two models that performed fusion by merging intermediate features.

XSL•FO
RenderX

Table . Performance comparison of different fusion strategies.

Fusion strategy	AUC[a]	Accuracy, %	Sensitivity, %	Specificity, %
FF[b]	0.969	91.49	90.99	92.16
LFF[c]	0.957	89.32	89.94	88.48
PF[d]	0.975	92.36	91.23	93.92

[a]AUC: area under the curve.

[b]FF: feature fusion.

[c]LFF: learning feature fusion.

[d]PF: probability fusion.

To verify whether the performance improvement of PF compared to feature fusion (FF) and learning FF (LFF) was statistically significant, we conducted a 2-tailed paired *t* test on accuracy, and the experimental data were obtained based on 5-fold cross-validation. The results showed that the *t* value of PF relative to FF was t_4=4.2426, and the *P* value was .01; and the *t* value of PF relative to LFF was t_4=2.9774, and the *P* value was .04. At a significance level of α=.05, the performance differences between PF and FF, as well as between PF and LFF, were statistically significant (*P*<.05). It could be seen that PF had the best performance among the 3 fusion methods in our experimental setup.

To improve the generalization performance and robustness of the model, we dynamically augmented the image data using a stochastic augmentation strategy. Comparing the model performance with and without the dynamic data augmentation technique, the results are shown in Table 5. In addition to the sensitivity metrics, the 3 metrics of AUC value, accuracy, and specificity were significantly improved after the introduction of dynamic data enhancement, especially the specificity, which was enhanced by 15.2%, greatly improving the accuracy of the model in identifying nonosteoporosis and reducing the rate of false alarms.

Table . Performance comparison of the image model with and without dynamic data augmentation.

Data augmentation	AUC[a]	Accuracy, %	Sensitivity, %	Specificity, %
Without	0.934	84.32	92.28	73.44
With	0.951	89.32	89.82	88.64

[a]AUC: area under the curve.

Discussion

Principal Findings

Although DL has made substantial progress in the field of medical imaging, it still focuses primarily on the imaging data themselves, largely ignoring the richness of information available in the clinic. Our experimental results show that the multimodal model fusing chest X-ray images and clinical data can improve the accuracy of deep neural networks in predicting osteoporosis. Through the ablation study, we validated the WT and the SA mechanism to enhance the performance of the model by capturing specific appearance features in the images, and also confirmed the advantages of dynamic data augmentation and PF strategies in a multimodal model.

Osteoporosis, as a major health disease, is becoming increasingly prominent in the aging population. Predictive studies of osteoporosis not only help us to gain a deeper understanding of the disease's trends and risk factors, but also provide a scientific basis for the development of effective prevention and treatment strategies. The classification model we designed is a binary classification model based on chest X-ray images and clinical data, aiming to classify outcomes into 2 categories: osteoporosis and nonosteoporosis. The results show that multimodal data can be used to distinguish patients with osteoporosis from those with normal BMD, and that the method we used requires a small amount of training data and a short processing time. As a disease screening method, the model in this paper has high sensitivity and helps to reduce the false negative rate. The model can be used both prospectively by radiologists and retrospectively by radiologists or even nonradiologists, which is important for the timely identification and treatment of patients with osteoporosis.

We downsample the X-ray image to 224×224 pixels to meet the input requirements of the ResNet50 model, while the Inception v3 architecture used for comparison requires downsampling the image to 299×299 pixels. Interestingly, although Inception v3 has a higher input resolution, its performance is not significantly better than ResNet50. This discovery suggests that simply increasing input resolution may not significantly improve model performance. This may be related to factors such as the complexity of the model architecture and the characteristics of the target task.

Since most relevant studies [9,11,14,36] currently use private datasets, it is difficult to find data that is identical or highly comparable to our dataset for direct comparison. Therefore, we mainly started from the aspects of dataset size, model architecture, and key results to compare the existing paper on osteoporosis screening based on X-ray using DL methods, as shown in Table 6. Although the research by Mao et al [14] bears some resemblance to ours, substantial differences remain. They

XSL•FO
RenderX

only analyzed X-rays and clinical data using a single CNN model. And based on this, we designed a multimodal model to process X-rays and clinical data separately. This innovative model architecture not only enhances the model's ability to process different types of data but also fully explores and uses the inherent correlation and value of multisource data, thereby achieving more accurate screening for osteoporosis.

Table . Comparison with related works.

Reference	Dataset	Model	Key results
Lee et al [9]	334 spine X-rays	DL[a] and machine learning	• AUC[b]: 0.74 • Accuracy: 0.71 • Sensitivity: 0.81 • Specificity: 0.60
Jang et al [11]	13,026 chest X-rays	DL	• AUC: 0.91 • Accuracy: 82.40%
Mao et al [14]	5652 lumbar spine X-rays and clinical data	CNN[c]	• AUC: 0.909 - 0.937
Wani et al [36]	381 knee X-rays	DL and transfer learning (AlexNet)	• Accuracy: 91.1%
This study	3645 chest X-rays and clinical data	Transfer learning (ResNet50) and multimodal model	• AUC: 0.975 • Accuracy: 92.36% • Sensitivity: 91.23% • Specificity: 93.92%

[a]DL: deep learning.

[b]AUC: area under the curve.

[c]CNN: convolutional neural network.

In this study, our proposed multimodal model demonstrated high accuracy in predicting osteoporosis, indicating its potential clinical application value. However, in the process of transforming the model from a laboratory environment to practical clinical applications, the feasibility of deployment also needs to be considered. To ensure that the model can run effectively in practical clinical scenarios, we recommend integrating it with the hospital's picture archiving and communication system and electronic medical record systems. This can automatically acquire and process imaging and clinical data, thereby reducing the burden on technicians in preprocessing work. In addition, the predicted results of the model can be automatically integrated into the patient's electronic medical record for doctors to review and reference at any time. This model can run on regular servers or cloud platforms with low hardware requirements, making it suitable for environments with limited resources.

Limitations

Our study has some limitations. First, we have not systematically analyzed the performance of the model under different races, age groups, or imaging protocols, which may introduce bias and affect the fairness and universality of the model. Given this, we plan to include more diverse population data and data obtained from different imaging protocols in future studies to evaluate and improve the performance of the model in various populations. Second, the coverage range of anteroposterior chest X-rays has certain limitations and cannot fully include key areas such as the humeral head and lumbar spine. The insufficient visual coverage may affect the diagnostic accuracy of the model for certain patient populations, especially those with substantially pathological features in uncovered areas. The plan is to introduce lateral chest X-rays to address this problem. Third, the data for this study came from a single institution, Chongqing Daping Hospital, which may limit the generalizability of the model in different populations. External validation is crucial to confirm the robustness of the model in different populations. Future research plans will validate the model on multiple datasets, which will help evaluate its generalization ability. Finally, although this paper used the WT and SA mechanism to enhance the model and conduct the ablation study, these components were not compared with traditional feature extraction techniques such as Gabor filters, local binary patterns, or radiomics-based features. We plan to supplement the fusion experiments of Gabor filters, local binary patterns, and other methods with deep features in future experimental work. In addition, to further explore and validate the existence of better fusion strategies, we plan to incorporate transformer-based cross-modal attention models in future research and compare their performance with PF strategies. The transformer architecture demonstrates powerful capabilities in handling multimodal data, particularly in capturing complex relationships between different modalities.

Conclusions

In osteoporosis prediction, our proposed multimodal model fusing chest X-ray images and clinical data improves the prediction accuracy, with AUC value, accuracy, sensitivity, and specificity metrics exceeding 90%, which all indicate significantly better performance than models relying only on images or clinical data. The model in this paper is expected to be an effective tool that clinicians can use to screen for opportunistic osteoporosis without increasing radiation exposure or additional costs. It is particularly suitable for patients who

XSL•FO
RenderX

have had a chest X-ray but have not undergone DXA. With this model, clinicians can detect osteoporosis symptoms early and provide timely treatment interventions to prevent further bone loss.

Abstract

Background: Breast ultrasound is essential for evaluating breast nodules, with Breast Imaging Reporting and Data System (BI-RADS) providing standardized classification. However, interobserver variability among radiologists can affect diagnostic accuracy. Large language models (LLMs) like ChatGPT-4 have shown potential in medical imaging interpretation. This study explores its feasibility in improving BI-RADS classification consistency and malignancy prediction compared to radiologists.

Objective: This study aims to evaluate the feasibility of using LLMs, particularly ChatGPT-4, to assess the consistency and diagnostic accuracy of standardized breast ultrasound imaging reports, using pathology as the reference standard.

Methods: This retrospective study analyzed breast nodule ultrasound data from 671 female patients (mean 45.82, SD 9.20 years; range 26 - 75 years) who underwent biopsy or surgical excision at our hospital between June 2019 and June 2024. ChatGPT-4 was used to interpret BI-RADS classifications and predict benign versus malignant nodules. The study compared the model's performance to that of two senior radiologists (≥15 years of experience) and two junior radiologists (<5 years of experience) using key diagnostic metrics, including accuracy, sensitivity, specificity, area under the receiver operating characteristic curve, *P* values, and odds ratios with 95% CIs. Two diagnostic models were evaluated: (1) image interpretation model, where ChatGPT-4 classified nodules based on BI-RADS features, and (2) image-to-text–LLM model, where radiologists provided textual descriptions, and ChatGPT-4 determined malignancy probability based on keywords. Radiologists were blinded to pathological outcomes, and BI-RADS classifications were finalized through consensus.

Results: ChatGPT-4 achieved an overall BI-RADS classification accuracy of 96.87%, outperforming junior radiologists (617/671, 91.95% and 604/671, 90.01%, *P*<.01). For malignancy prediction, ChatGPT-4 achieved an area under the receiver operating characteristic curve of 0.82 (95% CI 0.79 - 0.85), an accuracy of 80.63% (541/671 cases), a sensitivity of 90.56% (259/286 cases), and a specificity of 73.51% (283/385 cases). The image interpretation model demonstrated performance comparable to senior radiologists, while the image-to-text–LLM model further improved diagnostic accuracy for all radiologists, increasing their sensitivity and specificity significantly (*P*<.001). Statistical analyses, including the McNemar test and DeLong test, confirmed that ChatGPT-4 outperformed junior radiologists (*P*<.01) and showed noninferiority compared to senior radiologists (*P*>.05). Pathological diagnoses served as the reference standard, ensuring robust evaluation reliability.

Conclusions: Integrating ChatGPT-4 into an image-to-text–LLM workflow improves BI-RADS classification accuracy and supports radiologists in breast ultrasound diagnostics. These results demonstrate its potential as a decision-support tool to enhance diagnostic consistency and reduce variability.

Introduction

In recent years, large language models (LLMs) have advanced rapidly, demonstrating significant potential in health care. Their diverse applications have garnered considerable attention [1-4], driving revolutionary progress across various fields, including medicine [5]. LLMs are built upon large-scale datasets and continuously refined through iterative training, enabling them to handle a wide range of tasks, including medical diagnosis. LLMs provide diagnostic recommendations by processing key inputs, extracting relevant information, and performing associative reasoning [6]. In medical imaging analysis, the integration of LLMs with image-text conversion models enables the creation of a continuous interactive system that seamlessly integrates with clinical practice, delivering more precise and personalized health care services [7]. This approach enhances medical technology, broadens clinical applications, and partially alleviates the challenges posed by limited health care resources. GPT-4, developed by OpenAI, is one of the most widely recognized LLMs. Although its applications in medical imaging analysis have shown promise, the specific role and diagnostic accuracy of LLMs in this domain remain insufficiently explored. Initial research on LLMs primarily focused on evaluating their language generation capabilities. Most discussions surrounding LLMs, particularly ChatGPT, have revolved around comments, replies, or question-and-answer formats [8-11]. The findings have been promising [12]. However, many studies have primarily focused on response evaluation rather than quantitative assessments of diagnostic accuracy and have lacked reference standards such as pathology or laboratory examinations [13]. In addition, the ability of LLMs to generate structured diagnostic reports, such as Breast Imaging Reporting and Data System (BI-RADS) classifications, has not been systematically evaluated, raising concerns about their reliability in clinical decision-making. Furthermore, LLMs may inadvertently perpetuate existing biases and disparities. Therefore, to address this gap, it is essential to demonstrate the application of LLMs in medical imaging. Breast cancer serves as an optimal case study for this purpose due to its high incidence, critical need for early detection, and reliance on imaging for diagnosis. Breast cancer is one of the most life-threatening diseases, second only to lung cancer [14,15]. The likelihood of breast cancer survival is largely determined by the stage at which it is detected, which significantly impacts chemotherapy outcomes [16-18]. Early diagnosis and effective treatment of breast cancer can significantly reduce mortality rates [19]. Unlike lung cancer, which primarily relies on computed tomography (CT） imaging, or neurological disorders, which depend on magnetic resonance imaging (MRI) and functional imaging, breast cancer diagnosis heavily incorporates ultrasound due to its accessibility, cost-effectiveness, and suitability for dense breast tissue—particularly in younger patients and in regions with high breast cancer incidence, such as China [20]. Therefore, in China, ultrasound has become the preferred imaging modality for breast lesion screening and preoperative evaluation [21]. Breast ultrasound not only facilitates routine detection of breast cancer but also aids in resolving inconclusive mammographic findings [22-24]. The BI-RADS, proposed by the American College of Radiology (ACR), is a standardized system designed to describe breast imaging findings [25]. It assists radiologists and breast surgeons in standardizing the assessment of malignancy probability in breast lesions and in guiding subsequent diagnostic and treatment plans. Physicians classify breast lesions based on specific characteristics, including shape, orientation, margins, echogenic pattern, posterior features, and the presence of calcifications and associated findings. However, unlike structured reporting systems in CT-based lung cancer screening or MRI-based neurological assessments, BI-RADS assessment in breast ultrasound remains highly dependent on operator experience. This reliance leads to interobserver variability and diagnostic inconsistency, as radiologists with different levels of expertise may provide varying interpretations. In addition, ultrasound evaluation requires extensive training and certification, making it resource-intensive and subject to human variability.

Given these challenges, breast ultrasound serves as an ideal testbed for evaluating LLM-assisted imaging interpretation. First, the structured nature of BI-RADS makes it well-suited for artificial intelligence (AI)-driven standardization, potentially reducing subjective variability. Second, the widespread clinical use of ultrasound in breast cancer detection allows for large-scale validation of LLM-generated reports against pathology results. Unlike lung CT or brain MRI, where AI-based segmentation and feature extraction already play a significant role, breast ultrasound interpretation lacks a robust AI-driven standardization framework, highlighting the potential value of LLM integration. LLMs offer a promising solution by providing standardized interpretations, reducing interobserver variability, and assisting in structured reporting. Their ability to generate BI-RADS reports based on ultrasound findings suggests a potential role in improving diagnostic consistency and streamlining clinical workflows. Despite these advantages, the reliability and diagnostic accuracy of LLM-generated BI-RADS assessments remain unclear.

To bridge this research gap, this study aims to systematically evaluate the diagnostic performance, consistency, and clinical utility of mainstream LLMs in breast nodule assessment. By comparing LLM-generated BI-RADS categorizations with pathology-confirmed diagnoses, we seek to determine whether LLMs can enhance reproducibility, improve standardization, and assist radiologists in breast cancer diagnosis.

Methods

Study Design

To compare the diagnostic performance of the LLMs and radiologists with different levels of experience in interpreting breast ultrasound images. First, among the widely used LLMs, ChatGPT, and Gemini are prominent. However, since Gemini does not support image analysis, we selected OpenAI's ChatGPT-4 for this study [26], using the BI-RADS standard for diagnosing breast nodules. For clarity, while LLMs refer to a broad category of AI models, this study specifically focuses on ChatGPT-4. We analyzed the accuracy of ChatGPT-4 in classifying breast nodules using the BI-RADS system and assessed its diagnostic performance in distinguishing between benign and malignant breast nodules. In subsequent analyses,

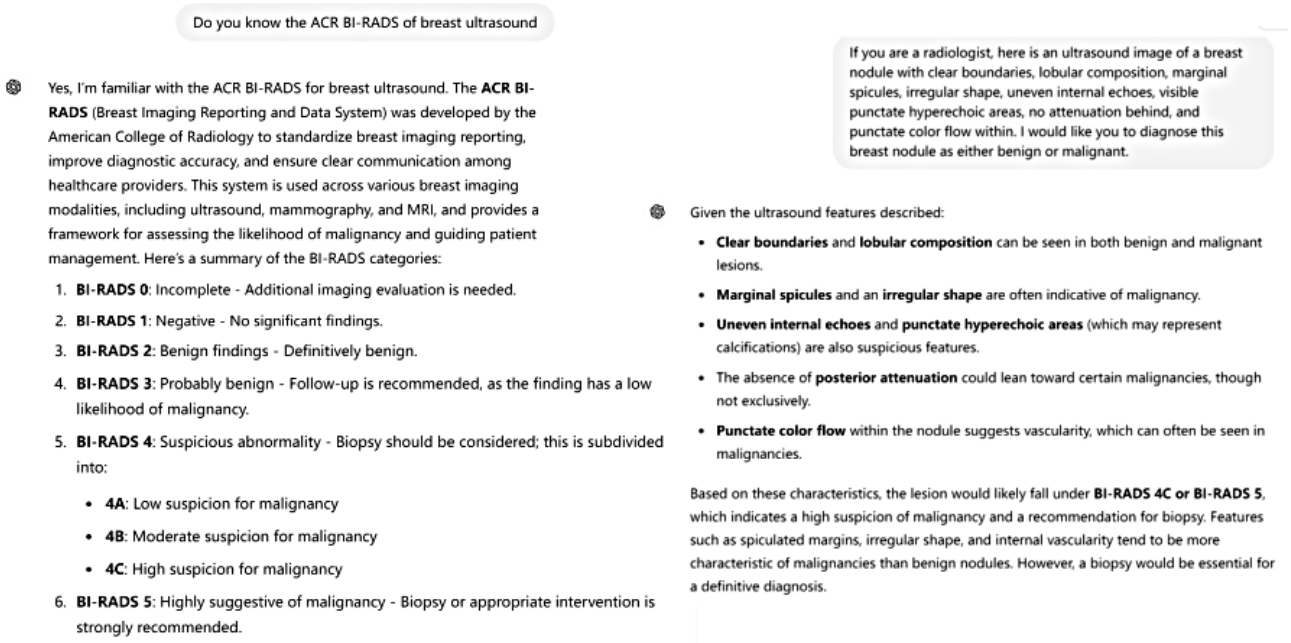
XSL•FO
RenderX

the performance of two different models was evaluated: image-to-text–LLM model and image interpretation model.

Image-to-Text–LLM Model

Radiologists first interpreted the ultrasound images and generated textual descriptions using a standardized BI-RADS reporting template. This template included predefined descriptors for nodule shape, margin, echogenicity, and other key ultrasound features. ChatGPT-4 then analyzed the text and determined whether the nodule was benign or malignant based on the extracted keywords (Figure 1). To minimize variability in descriptions, all radiologists were trained in the standardized reporting format, and their reports were randomly reviewed by a senior radiologist to ensure consistency.

Figure 1. The screenshot demonstrates ChatGPT-4 (OpenAI;) analyzing a single breast nodule in image-to-text–large language model. This response was recorded as a malignant diagnosis.



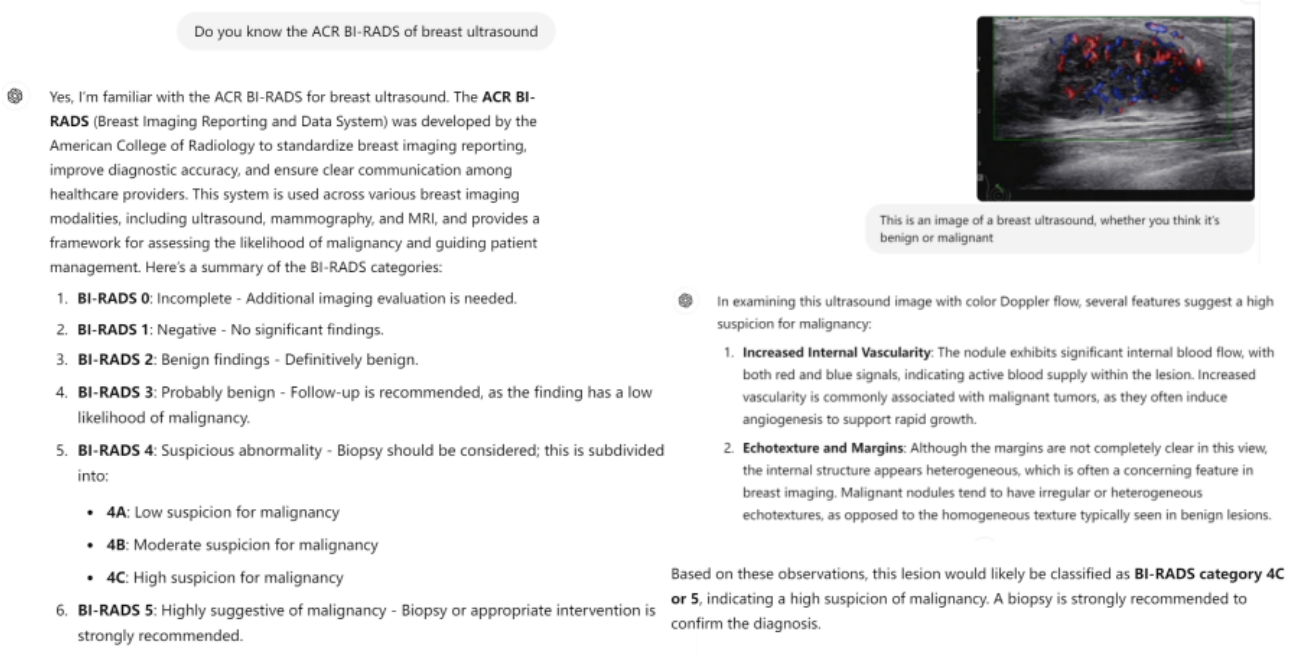


Image Interpretation Model

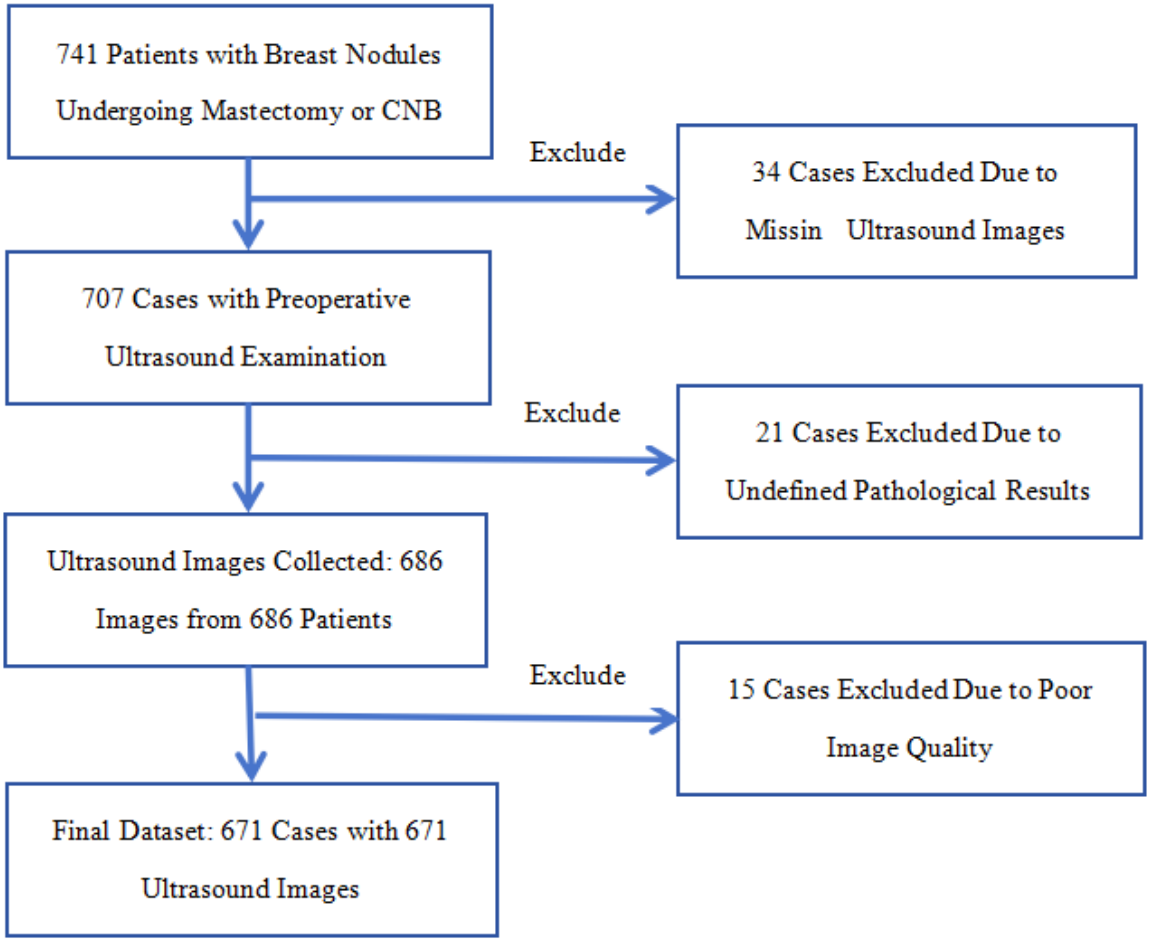
The ultrasound images were provided directly, and the model performed benign or malignant diagnosis based on BI-RADS classification and image analysis (Figure 2). All radiologists were blinded to the pathological results. The radiologists were divided into two senior and two junior groups. The senior radiologists each had over 15 years of experience in breast ultrasound, while the junior radiologists had less than 5 years of experience.

The BI-RADS classifications were determined by consensus between two senior radiologists. If their conclusions differed, a third senior radiologists (WSS, with 21 years of experience in breast ultrasound) was consulted to reach a final decision through discussion.

XSL•FO
RenderX

Figure 2. The screenshot demonstrates ChatGPT-4 (OpenAI; analyzing a single breast nodule in image interpretation model. This response was recorded as a malignant diagnosis.



Patient Data Collection

Retrospective collection of ultrasound images of breast nodules diagnosed through biopsy or surgical excision at Fujian Provincial Hospital, Fuzhou University Affiliated Hospital, between June 2019 and June 2024 (385 benign and 286 malignant cases). Patients without ultrasound examinations, those with low-quality images, or those with inconclusive pathological results were excluded (Figure 3). Each image corresponded to an individual breast nodule. For nodules suspected to be benign on biopsy, follow-up of at least 6 months was required. All lesions were ultimately classified as benign or malignant based on histopathological results.

Evaluation Index

The diagnostic performance of ChatGPT-4 in two different models (Image-to-text–LLM model and image interpretation model) was compared with that of radiologists with varying levels of experience. The analysis included the accuracy of BI-RADS classifications by junior radiologists and the calculation of key performance metrics, including sensitivity, specificity, accuracy, and the area under the receiver operating characteristic curve (AUC) with 95% CIs (Figure 4).

XSL•FO
RenderX

Figure 4. Study Design. LLM: large language model; BI-RADS: Breast Imaging Reporting and Data System.

Statistical Analysis

All statistical analyses were performed using SPSS software (IBM, version 20.0) and MedCalc (MedCalc Software, version 12.7). Continuous data were expressed as mean (SD), and categorical data were presented as frequencies and percentages. The analysis included the calculation of key performance metrics, including accuracy, sensitivity, specificity, and the AUC with 95% CIs. Finally, McNemar's test and DeLong's test were used to compare the diagnostic performance of ChatGPT-4 under different deployment strategies. A *P* value of <.05 was considered statistically significant.

Ethical Considerations

This study was approved by the Institutional Review Board of Fujian Provincial Hospital. Informed consent was waived due to the retrospective design. No identifiable patient information was shared with the LLMs. This study is a retrospective study, and informed consent was waived due to its retrospective design. No patient privacy information was provided to the LLMs.

Results

Patient Characteristics

A total of 671 female patients were included in the study (mean 45.82, SD 9.20 years; range 26 - 75 years). A total of 671 ultrasound images of breast nodules were collected, including 385 benign cases (57.38%) and 286 malignant cases (42.62%), with 428 nodules on the left side and 243 on the right side (Table 1). Pathological diagnoses within 3 months after ultrasound examination were based on surgical resection or core needle biopsy. Patients with benign pathology from core needle biopsy were followed up for an average of approximately 11.2 months. The inclusion and exclusion criteria for patients and images are detailed in Figure 3.

Representation of ChatGPT-4 in Classification

As shown in Table 2, the BI-RADS classifications for the 671 ultrasound images include categories BI-RADS 3, 4 (A-C), and 5. The overall accuracy of the ChatGPT-4 in identifying BI-RADS classifications was 96.87% (650/671), surpassing junior radiologist 1 (617/671, 91.95%) and junior radiologist 2 (604/671, 90.01%). Notably, the model demonstrated significant differences in classification performance compared to both junior radiologists for BI-RADS 4A and to junior radiologist 2 for BI-RADS 3 and 4C.

Table . The effectiveness of ChatGPT-4 in classification. The *P* value represents the comparison with ChatGPT-4

Classification	N	ChatGPT-4, n (%)	Junior physicians 1, n (%)	*P* value	Junior Physicians 2, n (%)	*P* value
BI-RADS[a] 3	93	90（96.77）	86 (92.47)	.29	82 (88.17)	.04
BI-RADS 4A	374	361 (96.52)	345 (92.25)	.02	341 (91.18)	<.01

[a]BI-RADS: Breast Imaging Reporting and Data System.

Performance of the Image Interpretation Model in Predicting Benign and Malignant Breast Nodules

As shown in Table 3, senior radiologist 1 demonstrated excellent performance in diagnosing benign and malignant breast lesions via ultrasound, with an AUC of 0.85 (95% CI 0.81 - 0.88), an accuracy of 83.16% (558/671 cases), a sensitivity of 91.61% (262/286 cases), and a specificity of 77.40% (298/385 cases). ChatGPT-4 exhibited comparable performance to the image interpretation model of both senior radiologists in terms of accuracy, sensitivity, and specificity. Notably, it outperformed senior radiologist 2 in AUC, with the difference being statistically significant (P<.01). The image interpretation model showed diagnostic performance comparable to that of the 2 senior radiologists, particularly achieving a sensitivity of 90.56% (259/286 cases). Furthermore, it consistently outperformed the predictive models of the junior radiologists in AUC, accuracy, and sensitivity (P<.01), while showing a statistically significant difference in specificity compared to junior radiologist 1 (P<.01).

Performance of ChatGPT-4 in Predicting Benign and Malignant Breast Nodules Based on Image-To-Text–LLM Model

As shown in Table 4, the image interpretation model of ChatGPT-4 yielded an AUC of 0.82 (95% CI 0.79 - 0.85), an accuracy of 80.63% (541/671 cases), a sensitivity of 90.56% (259/286 cases), and a specificity of 73.51% (283/385 cases). Under the image-to-text–LLM model, ChatGPT-4 demonstrated performance comparable to the 2 senior radiologists while surpassing the models of junior radiologists in AUC, accuracy, sensitivity, and specificity (*P*<.001). The four radiologists with varying levels of experience showed improvements in AUC, accuracy, sensitivity, and specificity after image-to-text–LLM model compared to image-to-text–LLM model.

Table . The performance of ChatGPT-4 in predicting benign and malignant breast nodules based on image-to-text–large language model. Note.—Except were indicated, numbers in parentheses are numbers of nodules.

Diagnostic performance	ChatGPT-4	Senior radiologist 1	Senior radiologist 2	Junior radiologist 1	Junior radiologist 2

Discussion

Principal Findings

In medical diagnostics, logical reasoning often forms the foundation of treatment, requiring higher-order cognitive skills such as application, analysis, and evaluation. Bhayana et al [8] demonstrated that ChatGPT nearly passed a radiology board-style exam despite lacking radiology-specific pretraining or direct access to imaging data. Despite the promising potential of LLMs in medical imaging [27], there is a lack of research on their feasibility in addressing reasoning tasks associated with medical diagnoses based on breast-specific reference standards, such as pathology. In this study, we used BI-RADS and standardized pathological reporting as reference standards, integrating LLMs into the diagnostic process to emphasize the

XSL•FO
RenderX

benefits of combining ChatGPT-4 with image-to-text technologies. We validated the potential application of ChatGPT-4 in breast nodule ultrasound diagnostics, using pathological results as the benchmark to evaluate their performance in standardized reporting and diagnostic consistency. The results showed that ChatGPT-4 performed exceptionally well in BI-RADS classification and benign-versus-malignant predictions of breast nodules. Its diagnostic performance was significantly superior to that of less experienced radiologists. This lays a foundation for the practical application of LLMs in enhancing the standardization and accuracy of medical imaging diagnostics while providing evidence to support further exploration of their clinical utility. ChatGPT-4 achieved an overall accuracy of 96.87% in BI-RADS classification and an AUC of 0.82 for benign-versus-malignant predictions (AUC 0.82, 95% CI 0.79‐0.85). Its accuracy, sensitivity, and specificity were 80.63% (541/671), 90.56% (259/286), and 73.51% (283/385), respectively. Notably, ChatGPT-4 outperformed less experienced radiologists in BI-RADS categories 4A, 3, and 4C. This indicates that ChatGPT-4 can deliver highly consistent and accurate diagnostic results, reducing variability caused by limited experience. Integrating LLMs into breast condition classification can minimize diagnostic errors and ultimately improve patient outcomes significantly. LLMs can be trained to identify and interpret individual variations, ultimately assisting in the development of new classification standards. This approach may address the lack of universally accepted breast disease classifications. Furthermore, integrating image-to-text conversion by radiologists with ChatGPT-4 improved the AUC, accuracy, sensitivity, and specificity for all 4 physicians, with notable performance enhancements observed among less experienced radiologists. This underscores that while AI has made significant advancements in medical imaging and diagnostics, human expertise remains indispensable. While ChatGPT-4 demonstrated strong diagnostic capabilities, it is important to compare its performance with existing AI-driven ultrasound diagnostic models. Prior deep-learning models have shown comparable or even superior performance in specific ultrasound tasks. For example, convolutional neural networks (CNNs) and transformer-based models trained on large annotated datasets have achieved AUCs exceeding 0.90 in distinguishing benign from malignant breast lesions [28,29]. These models directly analyze imaging data, extracting pixel-level features for classification. In contrast, ChatGPT-4 processes structured text inputs rather than images, highlighting a key trade-off between interpretability and diagnostic precision. While CNNs and other deep-learning models operate as “black-box” systems with high accuracy, LLMs like ChatGPT-4 provide enhanced transparency and reasoning, allowing clinicians to trace the logic behind their decisions. Thus, future studies should explore hybrid approaches that integrate deep-learning image analysis with LLM-driven reasoning to maximize diagnostic performance. Our study, grounded on pathological findings as the reference standard, provides substantial evidence that using pathology-based benchmarks to evaluate LLMs in ultrasound diagnostic reasoning and information processing differs significantly from previous approaches. Earlier studies primarily relied on expert questionnaires and subjective judgments to assess LLMs’ text comprehension, summarization, and generation abilities in the context of medical imaging reports or inquiry responses [30,31]. The results showed that ChatGPT-4, when integrated with clinician-led image-to-text conversion strategies, achieved optimal performance. This demonstrates that LLMs can effectively assist radiologist, particularly less experienced radiologists, thereby improving overall diagnostic quality. Compared to senior radiologists, ChatGPT-4 demonstrated sensitivity (90.56%) in benign-versus-malignant diagnosis of breast nodules that closely matched that of 2 senior radiologists (91.61% and 86.71%). However, its specificity was slightly lower (73.51% vs 77.40% and 76.36%). These findings suggest that ChatGPT-4’s diagnostic reasoning, when provided with structured textual inputs, approaches that of senior radiologists. However, its performance remains constrained by its reliance on human-generated descriptions, rather than direct image interpretation. Unlike black-box deep-learning models, ChatGPT-4 offers a transparent reasoning process, enhancing trust in AI-assisted diagnostics. This feature is particularly valuable in clinical practice and medical education, as it enables junior radiologists to follow structured diagnostic logic rather than relying on uninterpretable AI-generated outputs. By standardizing ultrasound diagnostic reasoning, ChatGPT-4 could improve the consistency and quality of radiological assessments, especially among less experienced practitioners. This study demonstrates the advantages of LLMs in breast ultrasound diagnosis. First, LLMs standardize the diagnostic process, significantly reducing inconsistencies caused by variations in physician experience, making them particularly beneficial for less experienced radiologists. Second, they offer high efficiency in processing large image datasets, alleviating the workload of radiologists, particularly in breast cancer screening programs. Furthermore, LLMs can be incorporated into standardized reporting frameworks such as BI-RADS, providing real-time decision support to optimize clinical workflows. Rather than replacing CNN-based models, ChatGPT-4 functions as a complementary tool that interprets structured radiological descriptions, offering an alternative diagnostic strategy. Most traditional diagnostic support software focuses on extracting imaging features rather than providing comprehensive diagnostic suggestions. Our study paves the way for applying LLMs in medical image-based diagnostic reasoning. Future research should explore multimodal AI models that integrate ultrasound, CT, and MRI data to further enhance diagnostic accuracy. In addition, refining image-to-text conversion methods and reducing reliance on manual input will be critical for advancing fully automated diagnostic systems. Validating these findings on multicenter datasets is essential to ensure generalizability.

Limitations

Despite demonstrating the potential of LLMs in ultrasound diagnostics, this study has certain limitations. First, it did not use the latest LLM versions, and ChatGPT-4 lacks the capability to directly interpret medical images. Its diagnostic process depends on structured text inputs provided by physicians, limiting its feasibility for fully automated diagnostics. Therefore, its current role is best suited as a decision-support tool rather than an independent diagnostic system. Second, the study was

XSL•FO
RenderX

based on BI-RADS standards and did not account for complex imaging features or multimodal data, potentially restricting the model's applicability to challenging cases. Third, the dataset was derived from a single institution, introducing potential selection bias. In addition, the patient cohort was drawn from a specific geographic and demographic background, which may not fully represent broader populations. Future studies should include diverse, multiethnic patient groups to improve external validity. Finally, while pathological results were used as the gold standard, they are not always available in routine clinical practice. Investigating alternative validation methods, such as long-term follow-up outcomes, could further enhance the clinical applicability of LLM-assisted diagnostics.

Conclusion

This study systematically evaluates the application of LLMs in breast ultrasound diagnosis. The results show that ChatGPT-4 achieves diagnostic performance comparable to senior radiologists while significantly improving the accuracy of less experienced radiologists. These findings highlight its potential to enhance diagnostic consistency and standardization. As AI and imaging technologies advance, LLMs are expected to further improve diagnostic accuracy and efficiency. Future research should focus on multicenter validation and multimodal imaging integration to further assess its clinical applicability.

Abstract

Background: Osteoporotic vertebral fractures (OVFs) are common in older adults and often lead to disability if not properly diagnosed and classified. With the increased use of computed tomography (CT) imaging and the development of radiomics and deep learning technologies, there is potential to improve the classification accuracy of OVFs.

Objective: This study aims to evaluate the efficacy of a deep learning radiomics model, derived from CT imaging, in accurately classifying OVFs.

Methods: The study analyzed 981 patients (aged 50 - 95 years; 687 women, 294 men), involving 1098 vertebrae, from 3 medical centers who underwent both CT and magnetic resonance imaging examinations. The Assessment System of Thoracolumbar Osteoporotic Fractures (ASTLOF) classified OVFs into Classes 0, 1, and 2. The data were categorized into 4 cohorts: training (n=750), internal validation (n=187), external validation (n=110), and prospective validation (n=51). Deep transfer learning used the ResNet-50 architecture, pretrained on RadImageNet and ImageNet, to extract imaging features. Deep transfer learning–based features were combined with radiomics features and refined using Least Absolute Shrinkage and Selection Operator (LASSO) regression. The performance of 8 machine learning classifiers for OVF classification was assessed using receiver operating characteristic metrics and the "One-vs-Rest" approach. Performance comparisons between RadImageNet- and ImageNet-based models were performed using the DeLong test. Shapley Additive Explanations (SHAP) analysis was used to interpret feature importance and the predictive rationale of the optimal fusion model.

Results: Feature selection and fusion yielded 33 and 54 fused features for the RadImageNet- and ImageNet-based models, respectively, following pretraining on the training set. The best-performing machine learning algorithms for these 2 deep learning radiomics models were the multilayer perceptron and Light Gradient Boosting Machine (LightGBM). The macro-average area under the curve (AUC) values for the fused models based on RadImageNet and ImageNet were 0.934 and 0.996, respectively, with DeLong test showing no statistically significant difference (P=2.34). The RadImageNet-based model significantly surpassed the ImageNet-based model across internal, external, and prospective validation sets, with macro-average AUCs of 0.837 versus 0.648, 0.773 versus 0.633, and 0.852 versus 0.648, respectively (P<.05). Using the binary "One-vs-Rest" approach, the RadImageNet-based fused model achieved superior predictive performance for Class 2 (AUC=0.907, 95% CI 0.805 - 0.999), with Classes 0 and 1 following (AUC/accuracy=0.829/0.803 and 0.794/0.768, respectively). SHAP analysis provided a visualization of feature importance in the RadImageNet-based fused model, highlighting the top 3 most influential features: cluster shade, mean, and large area low gray level emphasis, and their respective impacts on predictions.

Conclusions: The RadImageNet-based fused model using CT imaging data exhibited superior predictive performance compared to the ImageNet-based model, demonstrating significant utility in OVF classification and aiding clinical decision-making for treatment planning. Among the 3 classes, the model performed best in identifying Class 2, followed by Class 0 and Class 1.

Introduction

Osteoporotic vertebral fractures (OVFs) have a subtle onset and complex progression, affecting about 40% of postmenopausal women and 25% - 33% of older men. In China, a new OVF case is reported approximately every 17.4 seconds [1]. OVFs are linked to high disability and mortality rates [2]. Accurate classification of OVFs is widely recognized as critical for early diagnosis, treatment planning, and prognosis evaluation [3]. Current classification systems, including the Genant semi-quantitative method [4], Heini classification [5], osteoporotic fractures classification [6], and the Assessment System of Thoracolumbar Osteoporotic Fractures (ASTLOF) [7], differ in methodology but lack global agreement [8]. Among these, the ASTLOF system has demonstrated good reproducibility and clinical utility, integrating vertebral morphology, magnetic resonance imaging (MRI) signal characteristics, bone mineral density (BMD), and pain severity into a preoperative scoring framework. This system supports targeted treatment selection and provides valuable clinical guidance [9]. Accordingly, the ASTLOF classification was adopted as the standard in this study.

Computed tomography (CT) imaging, with its high spatial resolution, allows for detailed observation of subtle changes in vertebral endplates, cortical bone, and cancellous bone, providing a more reliable basis for OVF classification and clinical guidance [10]. Currently, CT equipment is widely available in secondary and tertiary hospitals, and some community hospitals have also introduced CT systems [11]. CT imaging is crucial for accurately classifying OVFs and has substantial clinical importance. Radiomics aids in analyzing trabecular bone microstructure [12], assessing BMD [13], differentiating acute from chronic OVFs [14], and predicting residual back pain in these patients [15]. Deep learning radiomics (DLR) uses network architectures such as ResNet, pretrained on ImageNet, to extract deep imaging features from images, a widely adopted approach. RadImageNet, as an open-access, public medical imaging dataset, theoretically provides better performance for deep transfer learning (DTL) in medical imaging tasks compared to ImageNet [16]. Our research team has preliminarily validated this hypothesis [17]. However, whether it can improve the performance of 3-class prediction models still requires further exploration and verification.

In this study, we used thoracolumbar medical imaging data from multiple health care centers. We applied DTL on both RadImageNet and ImageNet datasets to extract DTL features and also used the open-source PyRadiomics package (developed by the Computational Imaging & Bioinformatics Lab, Brigham and Women's Hospital/Harvard Medical School; lead developer: Joost J. M. van Griethuysen) to extract traditional radiomics features. We developed a predictive model for OVF classification using CT imaging by integrating and selecting DTL and radiomics features within the ASTLOF system. The model was validated, tested, and compared for its predictive performance using multicenter data.

Methods

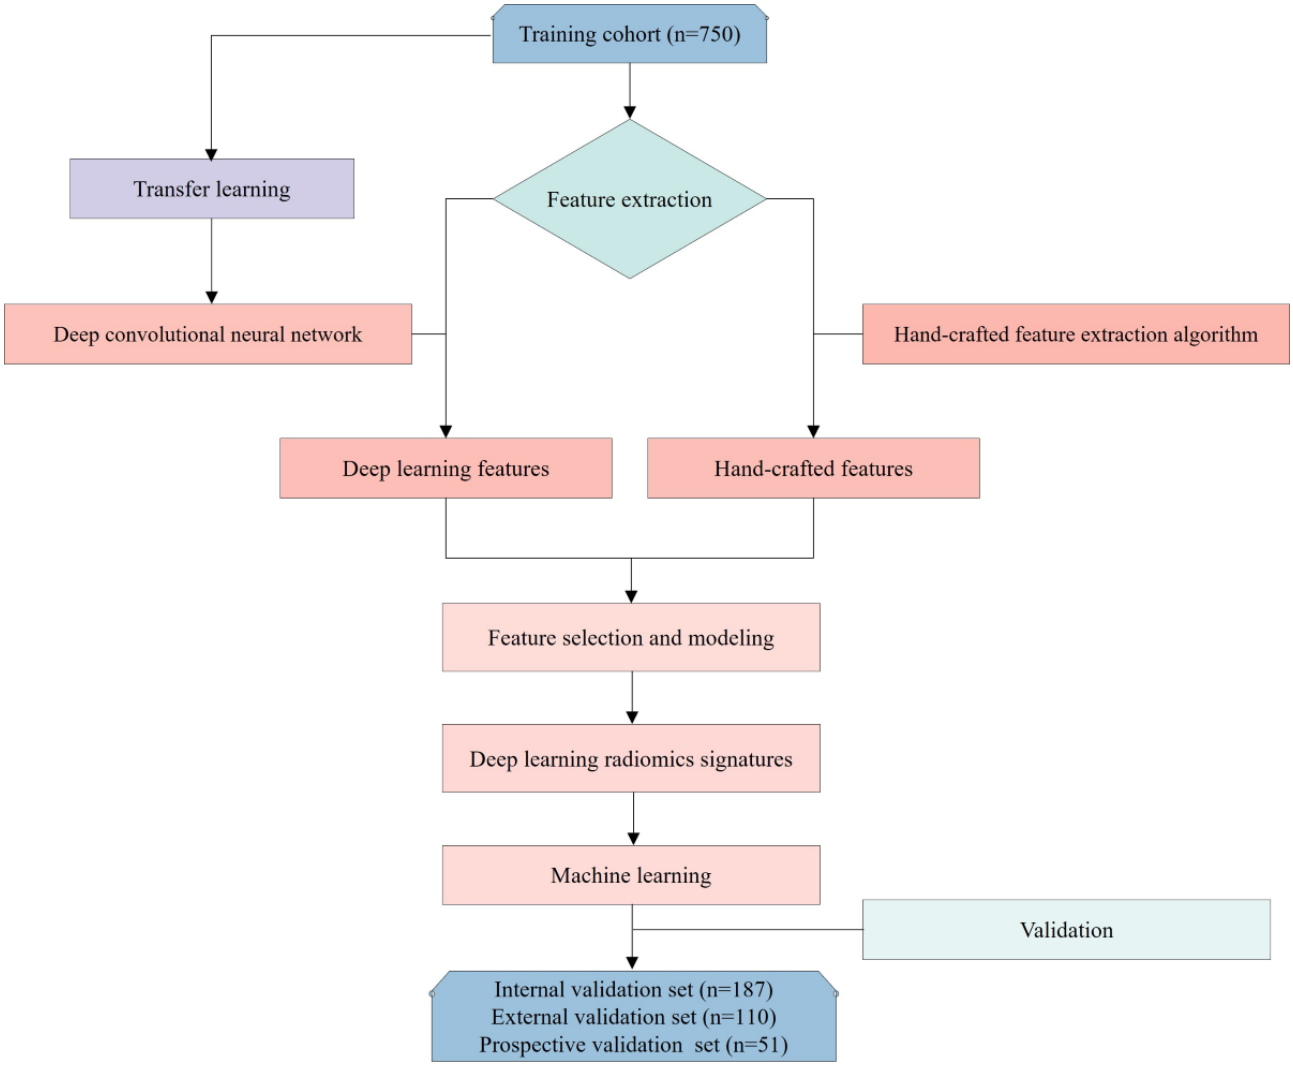
Patient Selection

This study used medical imaging data from 3 Chinese hospitals, with ethics committee approval from each institution. The retrospective study design negated the need for informed patient consent. CT and MRI data from patients diagnosed with OVFs at Center I (Taizhou People's Hospital, Nanjing Medical University) and Center II (Affiliated Hospital of Nanjing University of Chinese Medicine) between December 2018 and December 2024 were used to create the training, internal validation, and external validation datasets. Textbox 1 shows the inclusion criteria and exclusion criteria. An independent test dataset was acquired from Center III (Sir Run Run Hospital, Nanjing Medical University) spanning January to December 2024. The dataset's inclusion and exclusion criteria matched those of the training and validation datasets.

Figures 1 and 2 provide detailed information on case collection, grouping, image preprocessing, feature extraction, analysis, and model development through flowcharts and the DLR workflow.

Textbox 1.

Inclusion criteria



- Patients aged ≥50 years, meeting osteoporotic vertebral fracture diagnostic criteria [18], with no trauma history or only minor trauma.
- Complete computed tomography and magnetic resonance imaging DICOM data, with no more than a 2-week interval between the 2 scans.
- Comprehensive clinical records encompassing gender, age, and dual-energy X-ray absorptiometry outcomes.
- Clinical presentations, such as absence of significant pain, back pain triggered by posture, persistent pain, or neurological symptoms.

Exclusion criteria

- Suspected infections or pathological fractures related to tumors.
- Poor image quality or artifacts caused by foreign objects.
- Uncertain osteoporotic vertebral fracture classification.

Figure 2. The workflow of the deep learning radiomics process illustrates the systematic steps involved in data processing, feature extraction, model development, and validation. ROC: receiver operating characteristic; ROI: region of interest.

CT and MRI Acquisition Protocol

CT Scans

CT scans were performed across 3 centers using multidetector or dual-source CT systems, including: GE Lightspeed Ultra (16-slice, USA), Siemens Somatom Definition (128-slice and 256-slice, Germany), Siemens Sensation64 (64-slice, Germany), Philips Brilliance iCT (256-slice, Netherlands), GE Optima CT670 (64-slice, USA). Key scan parameters were: tube voltage 120 kVp (with or without automated current modulation), tube current 118 - 320 mA (with or without automated current modulation), and image matrix 512×512, and layer thickness and interval 1 mm.

MRI Scans

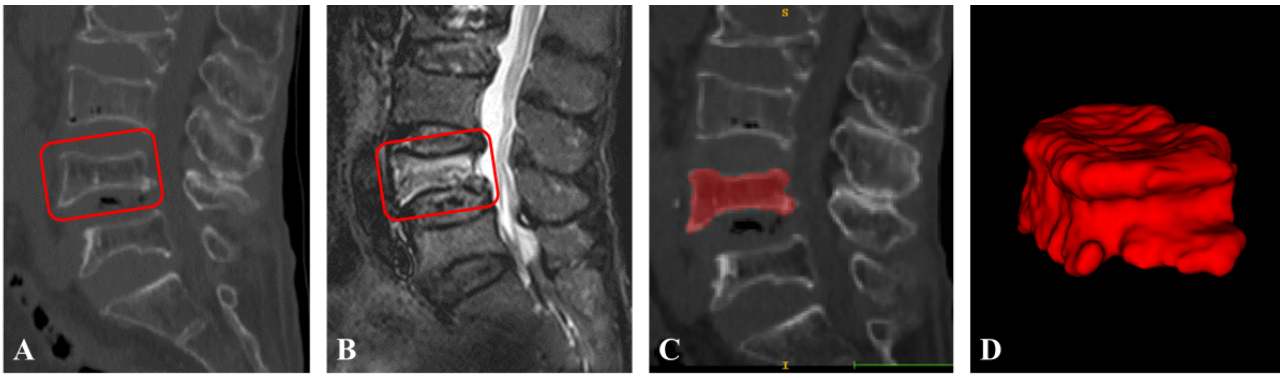
MRI examinations were conducted on 3.0T scanners from Siemens (Verio, Skyra, and Prisma), Philips (Ingenia CX and Achieva TX), across the 3 centers. Image sequences included short tau inversion recovery (STIR) and T2-weighted fat-suppressed images. All patients underwent STIR or T2-weighted fat-suppressed MRI scans. Additional details regarding the imaging devices and parameters for both CT and MRI are available in Multimedia Appendix 1.

Classification

The ASTLOF system classifies OVFs by assigning scores based on vertebral morphology, MRI findings, BMD, and clinical symptoms. Changes in morphology seen in CT or MRI scans are rated as normal (0 points), compression (1 point), or burst fracture (2 points). MRI assessments use sagittal T2-weighted fat-suppressed or STIR sequences, assigning scores based on normal appearance (0 points), high signal alterations (1 point), or the presence of vacuum or fluid signs within vertebrae (2 points). BMD is assessed via T-scores, with values >−2.5 scoring 0, between −2.5 and −3.5 scoring 1, and ≤−3.5 scoring 2. Clinical symptoms are categorized as no significant pain (0 points), positional low back pain (1 point), or persistent pain or neurological symptoms (2 points). No significant pain refers to an absence of discomfort during daily activities, while positional low back pain is triggered by specific postures such as prolonged standing, sitting, or bending. Persistent pain is continuous and unrelieved by rest or posture changes, while neurological symptoms indicate nerve involvement, manifesting as numbness, tingling, or muscle weakness in the lower limbs. OVFs are classified based on total scores: Class 0 (≤3) for conservative treatment, Class 1 (=4) for either conservative or surgical treatment, and Class 2 (≥5) for surgical intervention. Evaluation scores were independently determined by 2 musculoskeletal radiologists (Doctor A with 6 years of experience and Doctor B with 10 years of experience), with disagreements resolved through discussion and consensus.

Clinical and CT Images Evaluation

Patient information, including age, gender, dual-energy X-ray absorptiometry (DXA)-measured T-scores, and treatment details, was obtained from the clinical case management system. CT images were obtained using a bone window setting (width 1500 and level 500) and reconstructed with a 1-mm slice thickness for subsequent processing and analysis.



Region of Interest Segmentation

Radiologists manually segmented fractured vertebrae using ITK-SNAP software (version 3.8.0; developed by the Penn Image Computing and Science Laboratory, University of

XSL•FO
RenderX

Pennsylvania; lead developer: Paul A. Yushkevich) in this study. Radiologist A outlined and filled the edges of the fractured vertebrae on the CT images to create regions of interest, carefully excluding adjacent intervertebral discs, pedicles, and surrounding tissues to ensure precise delineation. The segmented masks were then saved as "nii" files for further analysis (Figure 3). Interobserver agreement was evaluated by having Radiologist A and Radiologist B independently resegment a random subset of 30 patients from the training dataset after 1 month, using the intraclass correlation coefficient (ICC) for assessment.

Figure 3. Segmentation of a fractured vertebral body for radiomic analysis in an 82-year-old woman with an acute osteoporotic vertebral fracture is illustrated.(**A**) Sagittal non–contrast-enhanced spine computed tomography images show an osteoporotic vertebral fracture of L4. (**B**) Sagittal T2-weighted fat-suppressed imaging reveals hyperintensity associated with the acute vertebral fracture. (**C**) The region of interest is delineated on sagittal computed tomography images. (**D**) Three-dimensional volume meshes are reconstructed to visualize the segmentation.

Radiomics and DTL Features Extraction

All images were resampled using B-spline interpolation and standardized with Z-score normalization to reduce variability across centers. Feature extraction algorithms were standardized in accordance with the Image Biomarker Standardization Initiative [19]. Radiomic features, encompassing first-order, shape, and texture characteristics, were extracted using the open-source Python package PyRadiomics (developed by the Computational Imaging & Bioinformatics Lab, Brigham and Women's Hospital/Harvard Medical School; lead developer: Joost J. M. van Griethuysen) [20]. These texture features include the gray level co-occurrence matrix, gray level size zone matrix, gray level run length matrix, neighboring gray tone difference matrix, and gray level dependence matrix. For comprehensive details on the extracted features, refer to the PyRadiomics documentation [21]. To minimize variations across centers, the Combat method was applied for feature harmonization [22]. To mitigate bias and minimize overfitting risks from excessive features, a 2-step feature selection process was implemented: initially, features demonstrating strong reliability were retained using ICC evaluation, followed by further selection through the Least Absolute Shrinkage and Selection Operator (LASSO) algorithm.

Transfer learning is used because retraining a convolutional neural network for a specific task demands extensive image data and intricate parameter configurations, which are challenging to obtain in this study. Transfer learning involves fine-tuning a pretrained deep learning network to adapt it for a new task, allowing deep learning to be applied effectively on smaller datasets. Images were resampled to 64×64 (as is common practice in deep learning pipelines) and pixel intensities normalized to a mean of 0 and SD of 1. We acknowledge that resampling to 64×64 may lead to some loss of spatial detail. However, we chose this size after preliminary experiments demonstrated that it retained sufficient image features for accurate classification, while balancing computational efficiency and memory requirements. The DTL approach, akin to previous studies [23], was implemented using the Python 3.6-based deep learning library (Guido van Rossum), PyTorch. The study used ResNet50 as the foundational model (Multimedia Appendices 2 and 3).

To execute transfer learning effectively, the learning rate was carefully configured. Features were extracted from the model's penultimate layer (AveragePooling), with model parameters divided into backbone and task-specific components. The backbone component used pretrained parameters from RadImageNet [24] or ImageNet for initialization, whereas the task-specific component was initialized randomly. Drawing inspiration from the cosine annealing learning rate decay algorithm, optimizations were implemented by fine-tuning the backbone component with pretrained weights only when essential to maintain transfer learning quality. Concurrently, task-specific parameters were modified according to task demands, enabling the model to effectively adapt to the target data.

Data Dimensionality Reduction

To identify reproducible and nonredundant radiomic features, a systematic process was implemented. First, features with ICC ≥0.8 from 2 independent evaluations were retained for reproducibility [25]. Redundancy was minimized by computing the Spearman rank correlation coefficient between features. Features with a correlation above 0.9 were subjected to a greedy recursive elimination strategy to remove the most redundant ones, ensuring overall representation was maintained. Stable features were then selected using the LASSO algorithm, which applies a penalty parameter (λ) to shrink regression coefficients, retaining only relevant features. The optimal λ value was determined through 10-fold cross-validation, and features with nonzero coefficients were selected for the final set. To further reduce redundancy, correlated features with a coefficient greater than 0.5 were excluded, resulting in a refined subset of independent features. For DTL features (initially with a

XSL•FO
RenderX

dimension of 2048), principal component analysis was applied to reduce dimensionality, balancing deep learning and radiomic features while mitigating overfitting. The chosen radiomic and deep learning features were combined through early fusion to create a unified feature set, with all features standardized using Z-score normalization for compatibility. Finally, after fusion, LASSO-Cox regression was applied to select the most robust features, which were further refined through dimensionality reduction to define an optimal subset. This carefully curated feature set represented the most relevant combination of radiomic and deep learning features, facilitating reliable model development.

Model Development

To prevent data leakage, all features used for building the predictive model were exclusively derived from the training set. Machine learning models were implemented using the scikit-learn library following feature selection and fusion. The models comprised logistic regression (LR), support vector machine (SVM), k-nearest neighbor (KNN), decision tree (DT), random forest (RF), extremely randomized trees (ExtraTrees), eXtreme gradient boosting (XGBoost), Light Gradient Boosting Machine (LightGBM), and multilayer perceptron (MLP). We observed an imbalance in the distribution of samples among the ASTLOF classification categories, with notably fewer cases in Class 2. To reduce the risk of biased model performance, we apply strategies such as class weighting during model training. Model training was conducted using the training set and optimized through grid search with adjustable parameters specific to each algorithm. Model performance was assessed using 5-fold cross-validation on the training data, selecting the best parameters to construct the optimal fused-feature model. Using a larger k (such as 10 or more) would have increased computational cost and training time substantially, without necessarily providing a significant improvement in model assessment, especially given the size of our dataset. Therefore, 5-fold cross-validation was appropriate for our study while maintaining a reasonable balance between thoroughness and practicality. The receiver operating characteristic (ROC) curve was plotted, and model accuracy was validated through 1000 iterations of bootstrap resampling. Performance metrics such as area under the curve (AUC), accuracy (ACC), sensitivity (SEN), and specificity (SPE) were evaluated. Finally, statistically significant clinical baseline characteristics were integrated with the best fused feature model to develop a combined model, which was visualized through a nomogram.

This study used the "One-vs-Rest" (OvR) strategy for multiclass tasks by decomposing the problem into several binary classification tasks. When Class 0 was labeled positive, Classes 1 and 2 were negative; similarly, labeling Class 1 or 2 as positive made the others negative, creating 3 OvR classification models. Model performance was assessed by plotting ROC curves and calculating metrics including AUC, ACC, SEN, and SPE. The generalization ability was evaluated using internal, external validation, and test datasets. Macro- and micro-average AUC were used for a thorough assessment of multiclass tasks [26]. Macro-average AUC computes the AUC for each class and averages them equally, which can be less representative in cases of significant class imbalance. Conversely, micro-average AUC aggregates predictions from all classes into a single confusion matrix, emphasizing the influence of larger sample sizes and providing a better reflection of overall performance on imbalanced datasets.

Data Analysis

Statistical analyses were conducted using R software (R Core Team; version 4.0.3), and radiomics and deep learning models were developed and implemented on Python 3.7 (Python Software Foundation). Continuous variables are presented as mean (SD), while categorical variables are shown as counts or percentages. Independent samples *t* tests were used to assess differences in continuous variables, while chi-square tests were applied for comparisons of categorical variables. The DeLong test was used to compare ROC curves and assess the predictive models' overall performance. In addition, bootstrap validation with 1000 resamples was conducted to ensure robust evaluation of model accuracy. $P<.05$ was considered statistically significant, serving as a benchmark for assessing the reliability of observed differences and associations. These comprehensive statistical methods ensured the rigor of model evaluation and the clarity of results interpretation.

Explainable Artificial Intelligence

The Shapley Additive Explanations (SHAP) method (GitHub, Inc [27]) was used to assess the importance of various features by calculating their contributions to prediction outcomes, offering a clear explanation of their significance [28]. Using SHAP values, the predictive output for each sample is decomposed into individual feature contributions, providing a quantifiable measure of feature influence. The magnitude of a SHAP value indicates the extent of a feature's influence on the model's prediction, where positive values signify a positive impact and negative values signify a negative impact. For example, in a disease prediction model, a feature with a SHAP value greater than 0 suggests it increases the predicted likelihood of disease occurrence, whereas a value below 0 implies a reduced likelihood. Beyond individual predictions, SHAP also ranks features by their overall importance across the model and reveals the relationships between features and prediction outcomes. This integration of quantitative contribution, directional influence, and feature importance ranking facilitates a comprehensive understanding of the model's decision-making, revealing how particular features influence predictions and their significance.

Ethical Considerations

This study comprised a retrospective component and a prospective validation cohort. For the retrospective component, the local Ethics Committees of the Affiliated Hospital of Nanjing University of Chinese Medicine and the Affiliated Taizhou People's Hospital of Nanjing Medical University waived the requirement for ethical approval and informed consent because the analysis involved existing data collected during routine clinical care and posed minimal risk to participants. The prospective validation cohort was approved by the Institutional Ethics Committee of Sir Run Run Hospital, Nanjing Medical University, on November 25, 2023 (approval no. 2023-SR-055). All participants in the prospective cohort provided written

XSL•FO
RenderX

informed consent before enrollment. To protect privacy, all images and relevant data were deidentified prior to analysis and reporting. No individually identifiable information was used. Participants did not receive financial or other material compensation for participation. The study was conducted in accordance with the principles of the Declaration of Helsinki and relevant institutional guidelines and regulations.

Results

Clinical Features of the Studied Patients

The study enrolled 981 patients aged 50 to 95 years, with an average age of 69.56 (9.88) years. Of these, 687 were females (70%) and 294 were males (30%). Based on T-scores, 30 patients (3.1%) were classified as having normal bone mass, 257 (26.2%) as having low bone mass, and 694 (70.7%) as having osteoporosis. Among the participants, 87 patients presented with 2 OVFs, and 15 patients had 3 OVFs, resulting in a total of 1098 fractured vertebrae included in the analysis. The dataset was partitioned into a training set (750 cases, 68.4%), an internal validation set (187 cases, 17%), an external validation set (110 cases, 10%), and a prospective validation set (51 cases, 4.6%). Table 1 summarizes the demographic and clinical characteristics of each dataset, and Table 2 details the treatment conditions across the 3 classifications. Figure 4 illustrates the case selection process, emphasizing the random 8:2 allocation of cases into the training and internal validation sets.

Table . Baseline characteristics of patients with osteoporotic vertebral fracture in the training, internal and external validation, and prospective validation cohorts.

Characteristics	Training set (n=750)	Interval validation set (n=187)	External validation set (n=110)	Prospective validation set (n=51)

Radiomics Feature Selection (RadImageNet-Based)

The LASSO-Cox regression analysis model was used to perform dimensionality reduction on the fused features. The penalty coefficient (λ=0.0031) was chosen to optimize feature selection, with Multimedia Appendix 4 depicting the changes in feature coefficients as λ varied. Following the final feature selection, 17 radiomics features and 16 DTL features were retained. The DTL_Radscore was constructed using the fused features and their regression coefficients, as shown in Multimedia Appendix 5.

Radiomics Feature Selection (ImageNet-Based)

The LASSO-Cox regression model, with a penalty coefficient of λ=0.0295, was used to optimally select features by reducing the dimensionality of the fused dataset. Multimedia Appendix 6 displays the feature selection process and the curve showing the change in feature coefficients with λ. Following the final selection, 17 radiomics features and 37 DTL features were retained. Using these fused features and their associated regression coefficients, the DTL_Radscore was constructed, as detailed in Multimedia Appendix 7.

Overall Validation of Different Radiomics Models

The optimal machine learning algorithms for fused feature models trained on RadImageNet and ImageNet datasets, based on macro-average AUC, ACC, and F_1-score, were identified as MLP and LightGBM, respectively. Table 3 summarizes the validation results for the 2 fused feature models in the 3-class classification task. In the training set, the DeLong test indicated no statistically significant difference between the 2 fused feature models (0.934 vs 0.996, P=2.34). In the internal, external, and prospective validation sets, the RadImageNet-based fused feature model demonstrated significantly higher macro-average AUC values than the ImageNet-based model (0.837 vs 0.648, 0.773 vs 0.633, and 0.852 vs 0.648, respectively), as confirmed by the DeLong test (P<.05). Figure 5 displays the ROC curves for both models predicting OVF classifications in the prospective validation set. The RadImageNet-based fused feature model, using the binary OvR strategy, excelled in predicting classification 2 with an AUC of 0.907 and an ACC of 0.857. For classifications 0 and 1, the model achieved AUCs and ACCs of 0.829, 0.803 and 0.794, 0.768, respectively. Figure 6 highlights instances where the ImageNet-based fused feature model made incorrect predictions, while the RadImageNet-based model successfully identified the correct classifications.

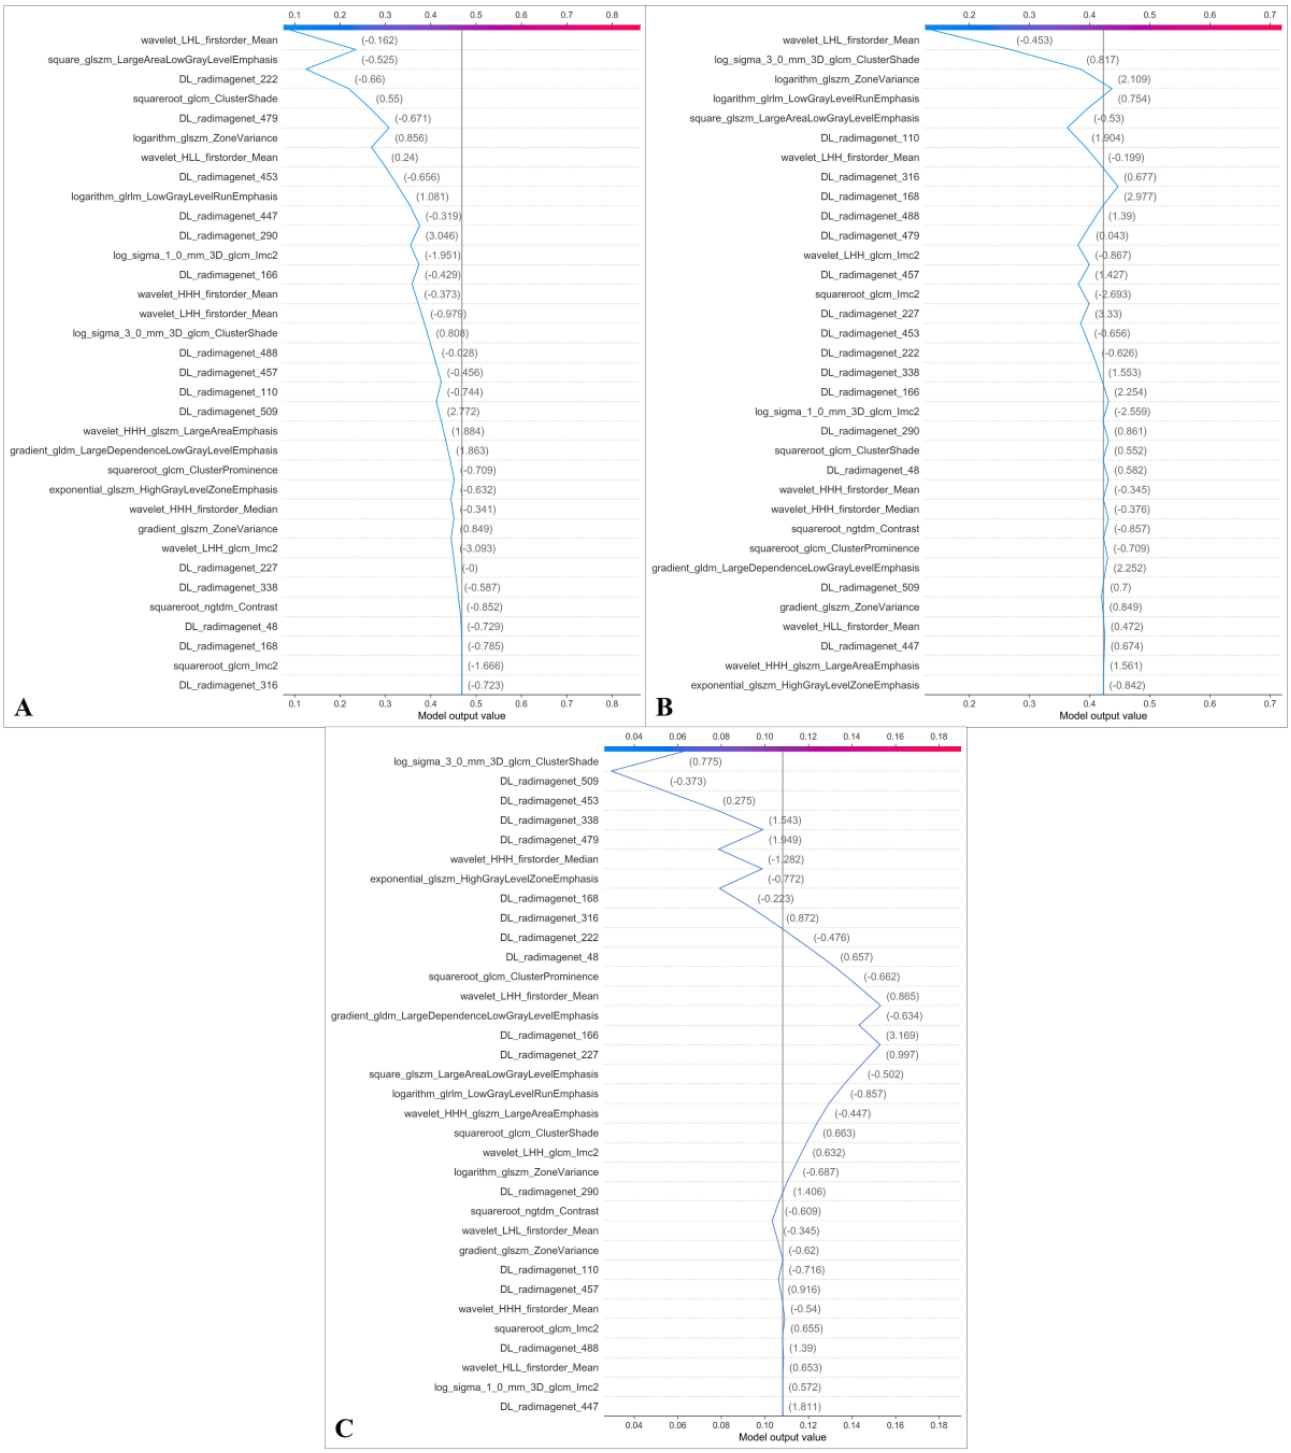
Feature Contribution and Model Interpretation

The SHAP value for each feature was calculated. Figure 7 presents the global SHAP values for both the overall 3-class classification and each specific class, evaluating their impact on the model's predictions. The highest-ranked features were cluster shade, mean, and large area low gray level emphasis. Figure 8 presents the SHAP decision plot, illustrating the prediction model's workflow in classifying Class 0 (male, 65 years; ASTLOF 2 points), Class 1 (female, 72 years; ASTLOF 4 points), and Class 2 (female, 68 years; ASTLOF 6 points) within the prospective validation set.



XSL•FO
RenderX

Figure 7. The feature contributions of the optimal fusion model are visualized as follows: The y-axis displays features arranged in descending order based on their mean absolute impact on the predictive model. The Shapley Additive Explanations (SHAP) value of a specific feature is represented by its distance from x=0, where a greater distance signifies a stronger impact—either positive or negative—on the model's output. Each point's color corresponds to the original value of that feature, transitioning from low (blue) to high (magenta) on the color scale. (**A**) The global feature contribution bar chart illustrates the contributions for the 3-class classification, with blue, red, and dark green bars indicating classifications 0, 1, and 2, respectively. (**B, C, D**) Beehive summary plots depict the decreasing feature contributions for predictions corresponding to classifications 0, 1, and 2, respectively.

XSL•FO
RenderX

Figure 8. Shapley Additive Explanation (SHAP) decision plots for the 3 classifications (A: Class 0, B: Class 1, C: Class 2) are presented. The x-axis represents the model output, while the y-axis lists the feature names. The gray vertical line at the center shows the baseline value. Each line traces the prediction process, starting from the baseline value and incorporating the contributions of various features, both positive and negative, to arrive at the final model output. For classification 0, the baseline value is 0.468, with a final model output of 0.090. For classification 1, the baseline value is 0.423, with a final model output of 0.138. For classification 2, the baseline value is 0.108, with a final model output of 0.062.

Discussion

Principal Findings

This study developed and validated a DLR model based on CT imaging data from multiple medical centers for the classification of OVFs according to the ASTLOF system. By integrating radiomics and DTL features extracted from both RadImageNet and ImageNet datasets, the fused model—especially when using RadImageNet pretraining—demonstrated superior predictive performance across internal, external, and prospective validation cohorts. The model achieved the highest accuracy in identifying Class 2, with SHAP analysis indicating that features such as cluster shade, mean, and large area low gray level emphasis played the most significant roles in prediction. These findings highlight the model's robustness and generalizability, supporting its potential utility in guiding clinical decision-making for OVF classification and treatment planning.

XSL•FO
RenderX

Study Implications

Compared with obvious traumatic vertebral fractures, OVFs are an insidious condition and are often misdiagnosed. Improper treatment can affect spinal stability and balance, and in severe cases, lead to neurological dysfunction and increased risk of mortality [29]. A scientific classification of OVFs is the prerequisite for appropriate treatment. However, existing classification methods are primarily based on classification systems for early thoracolumbar fractures (which do not differentiate between traumatic and osteoporotic vertebral fractures), resulting in confusion in the treatment of OVFs [30]. These methods fail to adequately consider the characteristics of osteoporotic vertebrae, are overly complex, and lack widely accepted unified standards. Some even overly emphasize surgical treatment. A systematic classification of OVFs is crucial for assessing fracture risk, guiding treatment decisions, and forecasting patient outcomes [31]. An ideal classification system for OVFs should encompass several essential features to ensure comprehensive and practical utility. First, it should integrate imaging parameters from X-rays, CT, and MRI, enabling a thorough multiperspective assessment of the fractures. Second, it must incorporate patients' clinical presentations, such as lower back pain and neurological symptoms, to provide a holistic understanding of the condition. Third, the system should offer treatment guidance tailored to each classification type, facilitating targeted clinical interventions. Fourth, it is essential that the system demonstrates high reliability and reproducibility, ensuring consistent application across different clinical settings. Finally, it should effectively evaluate the severity of the condition and provide prognostic insights based on classification outcomes. The ASTLOF classification system provides a thorough framework for evaluation by integrating vertebral morphology, MRI signal characteristics, BMD, and clinical symptoms. Through its scoring system, it enables clinicians to select targeted treatment plans, streamlining clinical workflows while delivering significant clinical guidance. Furthermore, existing studies have validated the system's high consistency and reproducibility, reinforcing its effectiveness in guiding clinical treatment decisions.

Recent advancements in artificial intelligence have shifted OVF classification research toward detection, with studies showing that deep learning and radiomics methods significantly surpass traditional visual analysis approaches [32]. Most current research on OVF classification detection primarily uses single-center data split into training and validation sets for internal validation. This method is constrained by significant variability in radiomics analysis results due to differences in imaging techniques, postprocessing, reconstruction workflows, and scanning parameters across devices from various manufacturers [33]. In addition, single-center studies often lack data heterogeneity, increasing the risk of overfitting and reducing the generalizability of the findings. By contrast, multicenter studies leverage diverse imaging data, and predictive models validated using independent external datasets better account for the heterogeneity of OVFs, offering results that are more aligned with the principles of precision medicine. Our study's strength is the use of CT imaging data from various hospitals combined with the ASTLOF classification system. A fused predictive model integrating radiomics and DTL features was developed using datasets such as RadImageNet and ImageNet. The model was thoroughly evaluated for its predictive performance in OVF classifications, offering a robust and generalizable framework for clinical application.

Studies indicate that the RadImageNet dataset notably improves DTL performance in medical applications, offering superior generalization over conventional datasets [34]. Our study's findings confirmed that prediction models using the RadImageNet dataset surpassed those using the ImageNet dataset. In situations where sample sizes are imbalanced, the "OvR" strategy is commonly used for 3-class classification tasks [35]. In this study, the use of the "OvR" strategy in prediction models for CT images proved to be highly effective. Notably, classification 2, despite having a smaller sample size, was identified with the highest accuracy. The enhanced spatial and density resolution of CT images enables prediction models to more effectively identify radiomic and DTL features. These results highlight the potential of leveraging high-resolution imaging data and advanced datasets such as RadImageNet to achieve robust and accurate predictions, even under the challenge of imbalanced samples.

Comparison to Prior Work

Finally, our study used SHAP values to evaluate the importance of features. SHAP values indicate the positive or negative contributions of each predictive variable to the target variable [36]. Based on game theory, SHAP is a classical post hoc explanation framework used to analyze typically incomprehensible black box models. Aggregating SHAP values across features offers a comprehensive view of each feature's impact on the model's predictions, clearly explaining the decision-making process. In this study, the feature with the highest contribution in CT images was cluster shade, which measures the skewness and asymmetry of the intensity distribution of grayscale in an image. It is inversely proportional to the number of asymmetric densities in the image. High skewness in the co-occurrence matrix results in lower cluster shade values, while smaller cluster shade values suggest greater homogeneity in the distribution of lesions [37]. We hypothesize that a smaller cluster shade value indicates a more homogeneous distribution of lesions within the vertebral body. While our model incorporates SHAP analysis to provide post hoc interpretability, we recognize that the deep learning component remains largely a "black box," which may limit clinician trust and acceptance. We acknowledge the importance of further enhancing the model's explainability—particularly in elucidating how deep features correspond to specific anatomical or pathological findings relevant to ASTLOF classification. In future work, we intend to explore and integrate advanced interpretability techniques such as attention maps, layer-wise relevance propagation, and feature visualization. These methods have the potential to provide more granular and intuitive explanations for the model's predictions, thereby facilitating broader clinical adoption and understanding.

Limitations

Although this study has achieved certain results, it still has some limitations. First, a key limitation of our study is the unequal

XSL•FO
RenderX

distribution of cases among the ASTLOF classifications, particularly the small sample size for Class 2. This class imbalance may affect the statistical power and generalizability of the model for underrepresented classes. Moving forward, we intend to increase the sample size for each class and explore robust solutions such as synthetic oversampling, class weighting, or other augmentation strategies to enhance model performance and clinical applicability across all categories. Second, the lack of interpretability of deep learning features limits its widespread clinical adoption and trust to some extent. Moving forward, strengthening research on the interpretability of deep learning features will be crucial. This will improve model transparency, foster clinician trust, and guide clinical decision-making, thus enhancing the practical application of deep learning in medical imaging diagnosis and treatment planning. Third, our study's dataset was exclusively sourced from Chinese hospitals, which may introduce geographic or ethnic bias, potentially limiting the generalizability of the findings to other regions and populations. Imaging protocols, equipment, and patient demographics may differ significantly across health care systems worldwide. Future work will focus on expanding our dataset with more diverse, multinational samples and performing external validation in independent international cohorts. Such steps are essential for demonstrating the model's robustness and ensuring clinical applicability on a global scale.

Conclusions

Compared to the fusion feature model (ImageNet), the fusion feature model based on CT images (RadImageNet) demonstrated higher predictive performance. Notably, it achieved the best performance in identifying classification 2, followed by classifications 0 and 1. This may have significant clinical value for predicting OVF classifications and guiding the formulation of treatment plans.

Acknowledgments

We express our gratitude to the editor and anonymous reviewers for their insightful comments and suggestions, which have greatly enhanced the quality of our paper. We also extend our thanks to American Journal Experts for their assistance in editing the language of an earlier draft of this manuscript. We appreciate the guidance and support from the PixelmedAI platform and its developers concerning the code used in this revised manuscript. Finally, we thank Dr. Zihan Chen (School of Mathematics and Physics, Xi'an Jiaotong-Liverpool University) for his professional statistical advice. This work was supported by the Medical Scientific Research Project of the Jiangsu Provincial Health Commission (Grant No. M2024055) and the Medical Imaging Artificial Intelligence Special Research Fund Project, Nanjing Medical Association Radiology Branch (Grant No. 16).

Abstract

Background: Liver fibrosis is a pathological outcome of chronic liver injury and a hallmark of multiple chronic liver diseases. Magnetic resonance elastography (MRE) provides a non-invasive modality for evaluating the severity of liver fibrosis.

Objective: This study aimed to develop and evaluate deep learning–based segmentation models for the automated assessment of liver fibrosis using MRE images, with a focus on comparing the performance of a conventional U-Net model and a UNet-ResNet50−32 × 4d architecture model.

Methods: A retrospective analysis was conducted on 319 patients enrolled between January 2018 and December 2020. MRE images were processed and segmented using two U-Net–based models. Model performance was assessed through correlation coefficients, intersection over union (IoU), and additional segmentation metrics.

Results: The UNet-ResNet50−32 × 4d model demonstrated strong agreement with ground truth annotations, achieving correlation coefficients of 0.952 in the training phase and 0.943 in the validation phase, along with an Dice score of 85.68%, confirming its high segmentation accuracy.

Conclusions: The UNet-ResNet50−32 × 4d model exhibited robust performance and may serve as a reliable tool for the rapid and accurate assessment of liver fibrosis severity. The integration of automated segmentation into MRE analysis has the potential to improve clinical workflows and support timely decision-making in the management of chronic liver disease.

Introduction

Research Background and Motivations

Liver fibrosis is a progressive process that culminates in cirrhosis, a condition associated with severe complications such as ascites, esophageal varices, and hepatic encephalopathy, which significantly shorten life expectancy [1,2]. To better stratify disease severity and guide management, fibrosis is commonly staged into five categories (F0–F4). F0 represents the absence of fibrosis, while F1–F3 correspond to progressive but non-cirrhotic stages of chronic liver disease, during which timely intervention can slow or even reverse disease progression. F4 indicates established cirrhosis, marking a critical threshold where the risk of decompensation, hepatocellular carcinoma, and mortality rises sharply. This staging framework not only provides prognostic insights but also plays a pivotal role in therapeutic decision-making, surveillance strategies, and patient counseling. The progression of liver fibrosis is slow and takes years to progress from mild liver fibrosis to cirrhosis. If liver fibrosis is diagnosed early using quicker and more convenient tools, there is a chance to prevent further deterioration into cirrhosis [3]. Currently, there are many tools for diagnosing liver fibrosis, with liver biopsy being the most accurate. However, due to the risk of bleeding, it is less commonly used [4]. There are many non-invasive testing methods, such as ultrasound elastography and magnetic resonance elastography (MRE), which have a high capability for diagnosing liver

XSL•FO
RenderX

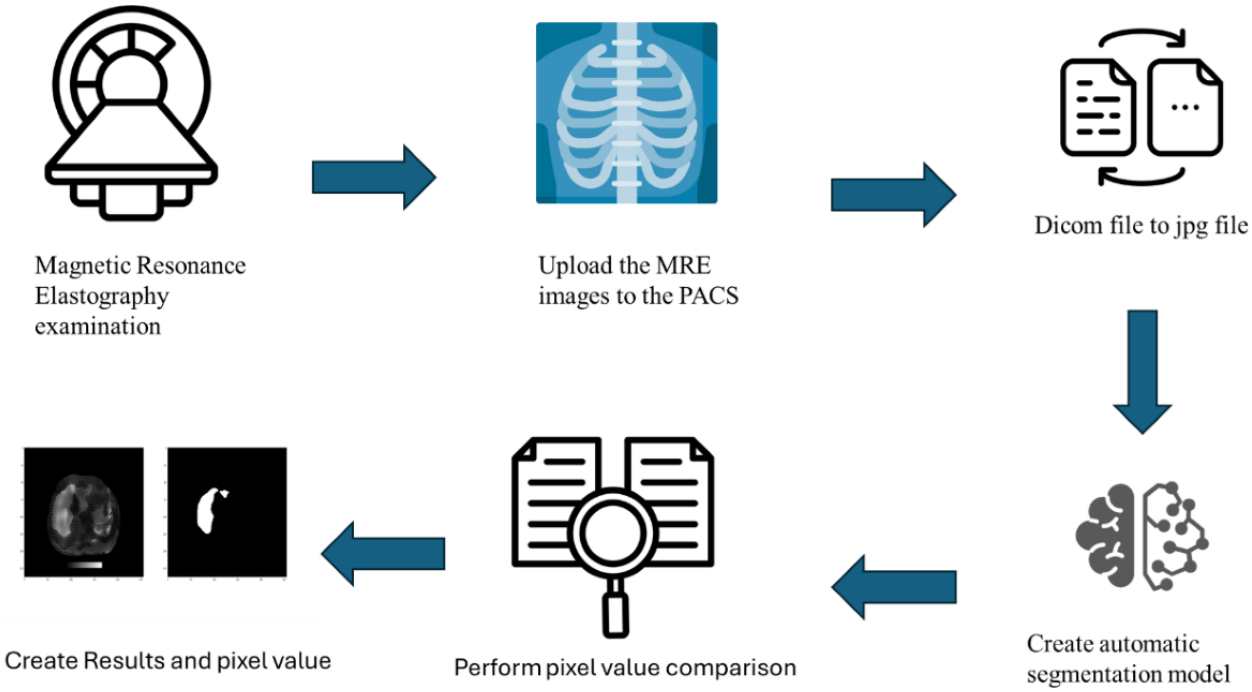
fibrosis [5,6]. MRE requires manual circling of images for interpretative reading, which increases the time for doctors to interpret reports [7]. Therefore, using image segmentation technology could help reduce the time for interpreting MRE for liver fibrosis and improve accuracy.

Artificial intelligence (AI) has been widely investigated in the medical field, with numerous applications across disease prediction, diagnosis, and clinical decision support. For instance, computed tomography (CT) imaging has shown strong potential in predicting cholangiocarcinoma recurrence [8], while machine learning–based image analysis methods have been applied for diabetic foot evaluation [9]. Convolutional neural networks (CNNs) have been employed to predict clinical outcomes in patients with stroke [10], and a YOLOv8 model has demonstrated a high accuracy in early lung cancer detection [11]. Similarly, combining chest X-rays with clinical features has yielded favorable area under the curve performance in osteoporosis screening [12]. In health care operations, machine learning models have also been developed to predict emergency department patient flow, effectively estimating both hourly and daily visit volumes [13]. Moreover, clinical decision support systems have been explored for prenatal abnormality diagnosis and ultrasound applications, though such studies have yet to incorporate maternal or fetal data during pregnancy [14]. CNNs have been widely applied in liver tumor classification, while diverse architectures such as U-Net, UNet++, Residual Networks (ResNet), SegNet, and fully convolutional networks have been employed for semantic segmentation tasks [6,15-18]. However, despite this progress, only one previous study has reported the application of CNNs for MRE measurement [19]. By integrating the strengths of U-Net and ResNet, our Unet-ResNet model achieved superior segmentation performance and training stability, while maintaining strong agreement with manual evaluation.

Image segmentation represents another important domain of AI applications, whereby algorithms cluster elements of a similar nature into coherent segments [20]. This technique has been increasingly applied in medical imaging, including ultrasound imaging [21], CT scans [22], magnetic resonance imaging (MRI) [23], and X-ray imaging [24]. In liver-related applications, segmentation methods such as real-time liver ultrasound segmentation [17] can greatly assist physicians in diagnosis and treatment planning [25], while CT-based segmentation is useful for localizing liver tumors [26]. Advanced approaches using deep CNNs [27] and 3D deeply supervised networks [16] have further improved automated liver segmentation performance. Researchers have compared U-Net and V-Net architectures to assess their effectiveness in the segmentation of microcalcifications [28].

Research Objectives

The aim of this study is to use image segmentation technology for the computational interpretation of MRE, enabling AI to automatically segment MRE images, accurately identify regions of interest, quantify liver fibrosis levels, and apply this approach to both training and validation cohorts. Early and reliable assessment of liver fibrosis is essential for timely clinical decision-making, yet conventional manual labeling of MRE images is time-consuming, operator-dependent, and prone to variability. To address these challenges, this study further investigates whether advanced architectures such as UNet-ResNet50−32 × 4d can achieve superior predictive performance compared with the traditional U-Net model.



Methods

Study Overview

An overview of the automated workflow developed in this study is shown in Figure 1. This study incorporates an automated process in which patients undergo MRE examinations, and the imaging data are subsequently uploaded to the picture archiving and communication system. Once the upload is completed, the segmentation model is automatically triggered. During the validation phase, pixel values of the target regions are obtained directly from the Digital Imaging and Communications in Medicine (DICOM) images in the picture archiving and communication system, as interpreted by experienced radiologists. Since there are discrepancies between pixel values in DICOM format and those converted to JPEG, this study relies solely on the pixel values displayed in the original DICOM files for analysis. Due to discrepancies between pixel values in DICOM and JPEG formats, this study exclusively uses original DICOM pixel values for analysis. These values are automatically extracted using medical image processing libraries that read directly from the DICOM metadata and image matrix. After segmentation, the predicted masks and corresponding pixel values are overlaid on the original images and provided to radiologists to support clinical evaluation and decision.

Ethical Considerations

The study was approved by the Institutional Review Board of Changhua Christian Hospital (approval no.: 210132). The Institutional Review Board waived the need for informed consent considering the retrospective nature of data collected. This study implemented stringent measures to protect the privacy of all participants by anonymizing all collected data to remove any personally identifiable information.

Patients

This retrospective study collected patient data from January 2018 to December 2020. Patients were eligible if they underwent MRI for clinical indications and MRE was performed as part of the MRI protocol. Additional inclusion criteria were age greater than 20 years and the availability of demographic information (age and gender). Exclusion criteria consisted of incomplete imaging or missing demographic data. Based on these criteria, a total of 320 patients were initially identified, and 1 patient was excluded due to incomplete data, resulting in a final cohort of 319 patients included in the analysis. To ensure the broad applicability and usability of the proposed model, no further stratification was made according to the presence of chronic liver disease or fibrosis.

MRE

MRI was performed with a 1.5-Tesla Aera magnet system by Siemens AG, equipped with a 16-channel phased-array body coil. The process involved a specialized MRE setup, integral to which was an acoustic driver system by Resoundant. The technical details of the MRE imaging sequence were as follows: a repetition time of 50 ms and an echo time of 22.7 ms, a flip angle of 25 degrees, and a bandwidth of 260 Hz/pixel. Additionally, the sequence settings included a hydrogen resonance frequency of 63.5 MHz, an acquisition matrix of 256 × 64, a section thickness of 5 mm, and a field of view of 400 × 400 mm^2. For each patient, four to five confidence maps were automatically generated and post-processed directly on the MRI scanner workstation using the integrated MRE software on the Siemens Syngo MR VE11 system (MAGNETOM Aera, Skyra, and Avantofit; Siemens Healthineers), demonstrating adequate wave amplitudes in specific regions. Manual liver stiffness measurements were performed by an expert, who delineated the regions of interest on the confidence maps and calculated the stiffness values [29]. The stage of liver fibrosis was classified into four categories based on criteria developed at the same institute as this study [30]. Significant fibrosis was defined as stage F2 according to the METAVIR scoring system, corresponding to MRE values ≥2.8 kPa.

MRE Image Labeling

For this study, the model training was conducted using data from 92 patients, all of whom had confidence maps generated from MRE. The annotations for these training images were meticulously created by a gastroenterologist, ensuring the reliability and precision of the ground truth used in model development.

Statistical Analysis

The *t* test was used for comparison of continues variables of baseline characteristics. Continuous variables were showed as mean (SD). The Pearson correlation coefficient was performed to measure the correlation of the two MRE measurements by manual and automatic methods. All statistical analysis were performed on SPSS version 22.0 (IBM Corp.), with two-tailed *P* values <.05 indicating statistical significance.

XSL•FO
RenderX

Model Training

The MRE images used in this study were acquired with a window center of 400 and a window width of 800, with an original resolution of 256×204 pixels. Since convolutional operations in the U-Net architecture require adequate spatial information for effective multi-scale feature extraction, all images were resized to 512×512 pixels using bilinear interpolation prior to model training. This resizing step was performed to preserve structural details and improve segmentation accuracy. For liver fibrosis segmentation, a hybrid deep learning model was implemented by combining U-Net with a ResNet50−32 × 4d encoder, leveraging its capacity to extract multi-scale contextual features while maintaining spatial resolution. Model optimization aimed to enhance both training efficiency and segmentation performance through systematic adjustment of key hyperparameters, with a comprehensive tuning strategy applied across a range of values, as summarized in Table 1. To address the pixel-level classification task, the model employed the Binary Cross-Entropy with Logits Loss as shown in equation (1).

$$(1) L=-1N\sum i=1N[yilog\ (pi)+(1-yi)log\ (1-pi)]$$

Where yi denotes the true label of the i-th sample, pi represents the predicted probability that the sample belongs to the positive class, and N indicates the total number of samples.

Table . Hyperparameter tuning strategy and optimal settings for the model.

Hyperparameter	Values
Batch size	32
Loss	Binary Cross-Entropy with Logits Loss
Optimizer	Stochastic Gradient Descent
Learning rate	3×10 –3×10 ²
Weight decay	0 - 0.01
Momentum	0.80 - 0.99

Results

Cohort Characteristics

A total of 319 patients were enrolled in the study and divided into two cohorts, with 91 patients assigned to the training group and 228 patients allocated to the testing group. The baseline characteristics of the two cohorts are summarized in Table 2. The mean (SD) age was 57.2 (12.4) years in the training group and 52.6 (12.3) years in the testing group. There were no statistically significant differences in age, gender distribution, height, weight, or BMI between the two groups, as all *P* values were greater than .05. Similarly, the mean (SD) MRE stiffness values obtained by manual measurement were 4.51 (2.85) kPa in the training group and 3.69 (2.26) kPa in the testing group, with a *P* value of .09. The mean (SD) automated measurement values were 4.04 (1.93) kPa in the training group and 3.69 (2.28) kPa in the testing group with a *P* value of .41, also showing no significant difference. In contrast, a significant difference was observed in the proportion of patients with clinically significant fibrosis stage equal to or greater than F2. Based on manual MRE assessment, 76% (69/91) of patients in the training group had fibrosis stage F2 or higher compared with 52% (118/228) in the testing group, with a *P* value of less than .001. Automated MRE analysis identified 75% (68/91) of patients in the training group and 50% (114/228) in the testing group with fibrosis stage F2 or higher, also with a *P* value of less than .001. These findings confirm the consistency between manual and automated staging, while indicating that the prevalence of significant fibrosis was higher in the training cohort.

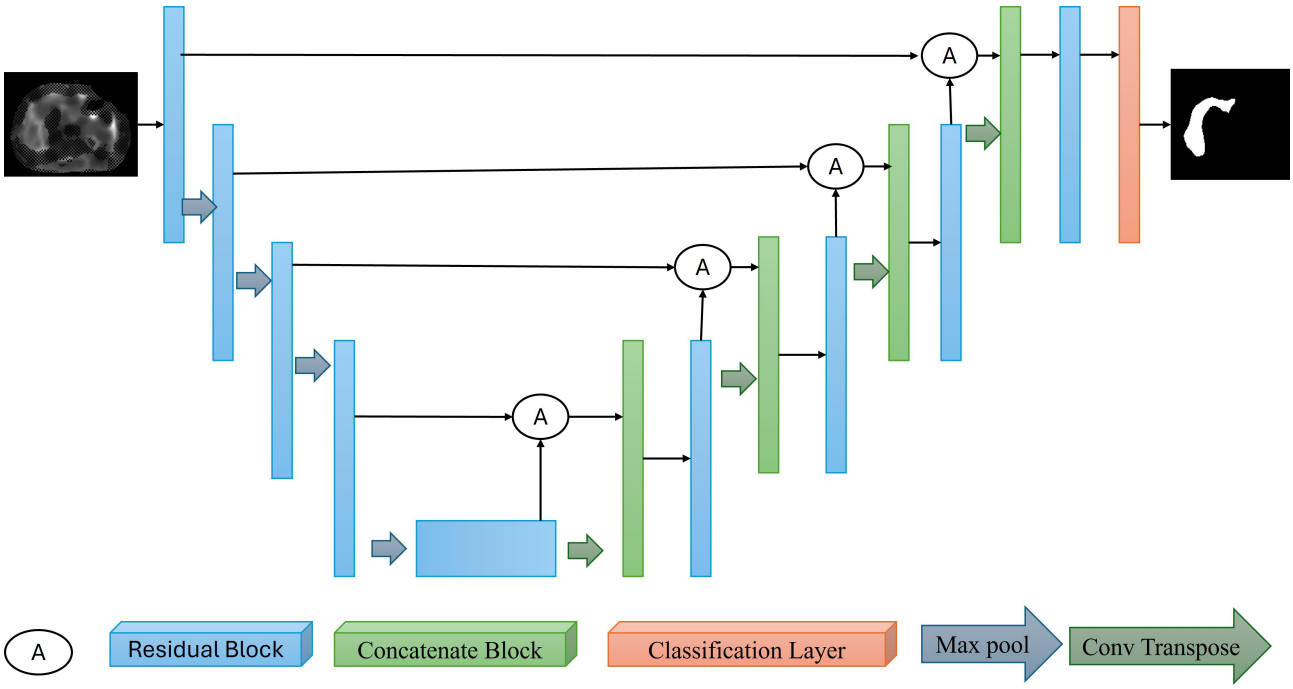
Table . The baseline characteristics of the training group and testing group.

Characteristics	Training group (n=91)	Testing group (n=228)	*P* value
Age, years, mean (SD)	57.2 (12.4)	52.6 (12.3)	.77
Gender, male (%)	48 (53)	137 (60)	.23
Height, m, mean (SD)	1.62 (0.08)	1.65 (0.08)	.97
Weight, kg, mean (SD)	65.8 (13.2)	67 (12.5)	.89
BMI, kg/m^2, mean (SD)	25.1 (4.2)	24.6 (3.7)	.21
MRE[a] (manual), kPa, mean (SD)	4.51 (2.85)	3.69 (2.26)	.09
MRE (automatic), kPa, mean (SD)	4.04 (1.93)	3.69 (2.28)	.41
Fibrosis stage (≥ F2[b]) (manual), n (%)	69 (76)	118 (52)	<.001
Fibrosis stage (≥ F2[b]) (automatic), n (%)	68 (75)	114 (50)	<.001



[a]MRE: magnetic resonance elastography.

[b]Liver fibrosis severity was determined using MRE, with stage F2 defined as MRE ≥2.8 kPa [30].

Automatic Labeling Process

Figure 2 illustrates the template for the auto-labeling process generated by the UNet-ResNet50−32 × 4d algorithm, a widely validated and robust architecture for medical image segmentation deep learning architecture specifically designed for semantic segmentation tasks. The auto-labeling template demonstrates the effectiveness of the model in accurately identifying and segmenting key regions of interest within the MRE confidence maps, aligning closely with expert annotations.

Figure 2. Overall architecture of the proposed UNet-ResNet50−32×4d model for automated liver segmentation and fibrosis staging using MRE confidence maps. MRE: magnetic resonance elastography.

Experimental Environment

All experiments in this study were conducted on a high-performance workstation equipped with an NVIDIA RTX 4090 GPU, an Intel Core i9-13900K CPU, and 128 GB of RAM. The deep learning models were implemented using PyTorch with CUDA 11.8 (torch 2.1.0+ cu118), enabling accelerated training and inference.

Parameters Setting

Table 3 presents the optimal parameter values identified in this study through training with the UNet-ResNet50−32 × 4d algorithm, which include a learning rate of 0.005, momentum of 0.982, and weight decay of 4.457e-06.

XSL•FO
RenderX

Table . Optimal hyperparameters derived from model training.

Parameters	Value
Epoch	32
Learning rate	0.005
Momentum	0.982
Weight decay	4.457e-06

Performance Evaluation

A comparison of the two models using the optimal parameters obtained from Table 2 indicate that the UNet-ResNet50−32 × 4d model achieved better predictive performance on the test dataset, whereas the standard U-Net model failed to produce any meaningful predictions. The average Dice coefficient, intersection over union (IoU), and F1-score for the UNet-ResNet50−32 × 4d model were 85.68%, 75.80%, and 85.68%, respectively; the corresponding values for the U-Net model were 82.59%, 75.92%, and 82.59%, respectively. The slightly lower IoU may be attributed to the presence of outliers during pixel-wise evaluation, which could have affected the overall segmentation accuracy. The segmentation performance was quantitatively assessed using the Dice coefficient, IoU, and F1-score, as shown in equations (2)–(4)

(2)Dice=2∨P∩G∨|P|+G∨

(3)IoU=P∩G∨P∪G∨

(4)F1−score=2∗Precision∗RecallPrecision+Recall

Figure 3 illustrates the segmentation results for liver fibrosis imaging. Overall, the figure underscores the enhanced performance of the proposed model in automated segmentation of liver fibrosis imaging and its potential clinical applicability.

Figure 3. Comparative segmentation performance of conventional U-Net and UNet-ResNet50−32×4d architectures on MRE confidence maps for liver fibrosis assessment. Panel (A) shows the original MRE confidence map, while panel (B) presents the segmentation outcome generated by the conventional U-Net model, which delineates the major hepatic region but demonstrates limitations in boundary refinement and structural detail. In contrast, panel (C) depicts the result obtained using the UNet-ResNet50−32×4d model, which more accurately captures hepatic contours and structural features, highlighting its superior capability in feature extraction and region identification. MRE: magnetic resonance elastography.

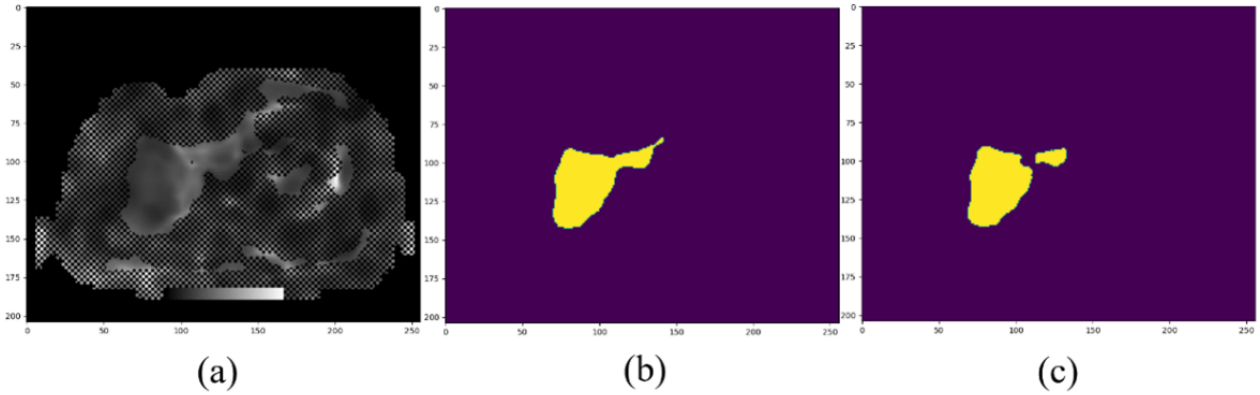


Table 4 presents the performance of the proposed UNet-ResNet50−32×4d model further evaluated across different fibrosis stages. The segmentation accuracy remained consistently high in the early stages F0-F1, with Dice scores exceeding 87% and IoU values around 78%. Performance was slightly reduced in the intermediate stage F2 and more prominently in stage F3, where Dice and IoU decreased to 80.54% and 70.49%, respectively. This decline may reflect the increased heterogeneity and irregularity of fibrosis distribution in advanced disease. Notably, the model regained relatively stable performance in stage F4, with Dice and IoU values of 84.00% and 73.14%, respectively. These findings suggest that while the model demonstrates robust segmentation across fibrosis stages, challenges remain in capturing complex tissue patterns in stage F3.

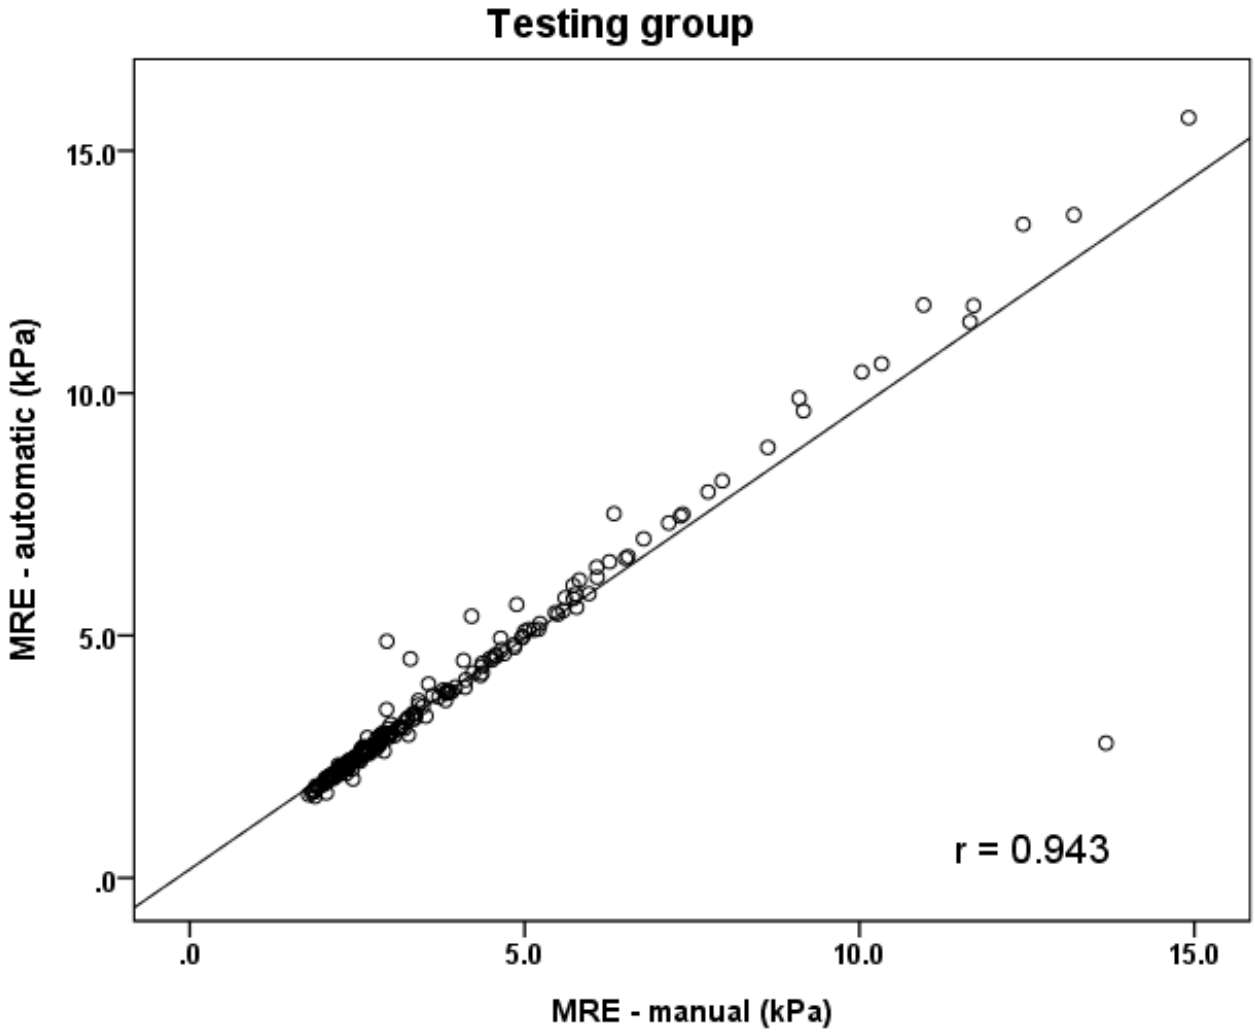

Figure 4 presents the correlation between MRE values obtained from the automated segmentation model and those measured manually by an expert gastroenterologist in the testing cohort. The analysis demonstrated a Pearson correlation coefficient of 0.943, confirming a strong positive linear relationship between the two approaches, even when applied to unseen data.

Table . Segmentation performance of the UNet-ResNet50−32×4d model across different fibrosis stages.

Fibrosis stage	Dice (%)	Intersection over union (%)	F1-score (%)
F0	87.47	78.26	87.47
F1	87.98	78.74	87.98
F2	84.11	73.85	84.11
F3	80.54	70.49	80.54
F4	84.00	73.14	84.00

Figure 4. Correlation between automated segmentation–derived MRE values and manual expert measurements in the testing group. MRE: magnetic resonance electrography.

Discussion

Principal Findings

Automated segmentation using the AI-based model for MRE measurement proved to be both reliable and effective when compared with manual segmentation. The strong correlation and reproducibility observed between the automated and manual approaches highlight the potential of this tool as a valuable aid in clinical practice. In this study, we further evaluated and compared the performance of a standard U-Net with a UNet-ResNet50−32 × 4d architecture for medical image segmentation. The findings clearly demonstrated that the UNet-ResNet50−32 × 4d model substantially outperformed the conventional U-Net in segmentation accuracy. Specifically, while the conventional U-Net achieved a Dice coefficient of 82.59% and an IoU of 72.92% on the test dataset, the proposed model further improved performance, reaching an average Dice coefficient of 85.68%, IoU of 75.80%, and F1-score of 85.68%. The slightly lower IoU relative to the Dice coefficient may be attributed to the penalization of pixel-level outliers in the union-based evaluation, which tends to disproportionately

XSL•FO
RenderX

impact cases with small lesion boundaries or heterogeneous textures.

When evaluated across fibrosis stages, the model demonstrated stable performance in the early stages, with Dice scores of 87.47% and 87.98% for F0 and F1, respectively, and corresponding IoU values close to 78%. A modest decline was observed in F2 with a Dice score of 84.11% and IoU of 73.85%, with the lowest performance in F3 where the Dice score was 80.54% and IoU was 70.49%. This likely reflects the increased heterogeneity and irregularity of fibrosis distribution in advanced disease. Interestingly, the model recovered performance in F4, achieving a Dice score of 84.00% and IoU of 73.14%, suggesting that once cirrhosis is established, the fibrotic patterns may become more homogeneous and therefore easier for the model to delineate.

Comparison to Prior Work

MRE is a highly effective non-invasive tool for evaluating liver fibrosis and serves as a valuable alternative to liver biopsy. Clinicians typically assess regions of interest using elastograms with overlaid confidence maps generated following MRI scans [31]. A previous study has investigated automated approaches for MRE measurement [32]. An early method applied intensity membership functions combined with random walker segmentation to differentiate liver tissue from surrounding structures, achieving a correlation of 0.981 with manual measurements [32]. Another study introduced volumetric segmentation using semi-automated proprietary software to evaluate liver stiffness. Their findings revealed significant differences between region of interest-based and volumetric analyses, suggesting that volumetric methods may provide better detection of heterogeneous fibrosis [33]. More recently, a CNN-based framework was applied to MRE, reporting an intraclass correlation coefficient of 0.99 between automated and manual assessments in clinical patients [19]. In this study, we applied the Unet-ResNet50 model to segment the liver on MRE confidence maps and measure liver stiffness. Our approach yielded a strong correlation of 0.943 with manual expert measurements, supporting its potential utility in clinical practice. To the best of our knowledge, this is the first study to implement a Unet-ResNet hybrid architecture for MRE segmentation and measurement. A previous study conducted in healthy volunteers reported excellent consistency and segmentation performance, with liver Dice scores reaching 0.95 [34]. This study focused on automated liver fibrosis staging (F0–F4) and extraction of MRE-derived stiffness values in kilopascals. Unlike studies limited to healthy subjects, our cohort consisted of clinical patients, in whom imaging data inherently exhibit greater heterogeneity.

Limitations

This study has several limitations. Only gray-scale elastograms with 95% confidence maps were used for segmentation, which may have inadvertently included non-hepatic tissues such as the gallbladder fossa and large blood vessels. Despite this, the correlation between manual and automated methods remained strong. Further refinement of the segmentation process is needed to achieve more accurate anatomical delineation of the liver using the UNet-ResNet model. Key clinical data related to liver disease, such as iron levels, steatosis, and viral markers, were not collected. Severe steatosis and iron overload may interfere with MRE measurements and could not be adequately accounted for in this analysis. Histological fibrosis scores were unavailable for most participants, as liver biopsy was not routinely performed. The absence of biopsy confirmation limits the accuracy of staging, since MRE values alone may not fully capture the histopathological spectrum of fibrosis. This introduces a potential risk of mislabeling fibrosis severity, particularly in borderline cases or in patients with overlapping liver conditions. This study is subject to data imbalance, as the distribution of patients across different disease severities was uneven, which may affect the generalizability and stability of the proposed model. Although the dataset was partitioned to ensure fairness in training and testing, the uneven distribution of disease severity remains a potential source of bias. In particular, when the model is trained on patients with more advanced disease, its application to cohorts with milder disease may result in an overestimation of fibrosis severity and diminished sensitivity to early-stage changes. Conversely, if a model is optimized for mild cases, it may underperform in advanced disease populations, resulting in systematic misclassification. These imbalances highlight the need for future studies that incorporate paired biopsy and imaging data, along with balanced cohorts across different severities, to validate the robustness and clinical applicability of automated MRE-based staging.

Future Directions

Future investigations will need to progress beyond algorithmic refinement and incorporate the expansion of patient cohorts, thereby increasing statistical power and enhancing the robustness of predictive models. Validation through multi-center studies will establish reproducibility across institutions, imaging protocols, and heterogeneous patient demographics. In parallel, the integration of multimodal information, including complementary imaging techniques, clinical parameters, and biomarker profiles, will strengthen both predictive accuracy and clinical relevance. The inclusion of expert annotations from multiple specialists, encompassing hepatologists, radiologists, pathologists, and other domain experts, will reduce inter-observer variability and further reinforce the clinical validity of model outputs. These efforts will enable broader generalizability across diverse populations and disease severities, ultimately supporting translation into routine clinical practice.

Conclusions

Early and accurate assessment of liver fibrosis is essential for enabling timely diagnosis and intervention. In this study, we developed a U-Net-ResNet50−32 × 4d model to predict the severity of liver fibrosis. The model achieved correlation coefficients above 0.9 in both training and validation cohorts and reached an Dice score of 85.68%, demonstrating strong potential to support accurate fibrosis staging in clinical practice. Importantly, liver fibrosis staging currently lacks a universally accepted gold standard. While histology remains the traditional reference, it is invasive, limited by sampling error, and not always available. Our findings suggest that automated MRE-based methods may provide a reliable non-invasive

XSL•FO
RenderX

alternative, although the absence of biopsy confirmation introduces potential uncertainties in staging accuracy.

The strong performance of our model highlights its practical value and potential to improve efficiency in clinical decision-making. Future research should validate these results in larger, multi-center cohorts, integrate complementary imaging modalities and clinical biomarkers to further strengthen predictive power, and explore real-time deployment within radiology workflows to maximize clinical applicability.

Abstract

Background: Gallbladder polyps have a high prevalence and are predominantly benign lesions, often detected via ultrasound. They impose diagnostic burdens on radiologists while generating substantial patient demand for report interpretation. Benign polyps include nonneoplastic polyps without malignant potential and premalignant adenomas that require cholecystectomy. Current guidelines recommending surgery for polyps ≥1.0 cm may lead to unnecessary interventions. Advanced multimodal large language models (LLMs) such as ChatGPT-4o (OpenAI) and Claude 3.5 Sonnet (Anthropic PBC) demonstrate emerging capabilities in medical image analysis. Implementing LLMs in gallbladder polyp ultrasound evaluation can potentially alleviate radiologists' workload, provide patient-accessible consultation platforms, and even reduce overtreatment.

Objective: We aimed to analyze the feasibility and conduct an early-stage evaluation of using LLMs for differentiating between adenomatous and nonneoplastic gallbladder polyps (≥1.0 cm) based on ChatGPT-4o and Claude 3.5 Sonnet, compared to assessments by radiologists and the guideline.

Methods: Ultrasound images and reports of gallbladder polyps ≥1.0 cm with pathology were retrospectively collected from a hospital between January 2011 and January 2022. LLM performance was evaluated using three input strategies: (1) direct image analysis (LLMs-image), (2) feature-based text analysis (LLMs-text), and (3) scoring model-based text analysis (LLMs-model). Both intra- and interreader agreement and diagnostic performance of LLMs were evaluated for all three strategies. The diagnostic performance metrics—including sensitivity, specificity, accuracy, area under the receiver operating characteristic curve, and unnecessary resection rate of nonneoplastic polyps of LLMs in the three strategies were compared with the guideline. Additionally, the strategy LLMs-model was specifically compared with radiologists using the same scoring system (strategy readers-model).

Results: This study included 223 patients (aged 18-72 years; 132/223, 59.2% female) as the initial cohort, with 48 adenomatous polyps and 175 nonneoplastic polyps. The external test set comprised 100 patients. The intrareader agreement coefficients for strategy LLMs-model were significantly higher than those for strategy LLMs-image and LLMs-text (all P<.01). The interreader agreement of the three diagnostic strategies was ranked as LLMs-model>LLMs-text>LLMs-image. The sensitivity of strategies LLMs-image and LLMs-text was significantly lower than that of the guideline (all P<.001). When applying a scoring model (readers/LLMs-model strategy), both radiologists and the LLMs achieved a significantly higher accuracy compared to the guideline (0.34, 0.35, and 0.34 vs 0.22, all P<.01), and the unnecessary resection rate of nonneoplastic polyps was significantly lower (82%, 83%, and 83% vs 100%, all P<.01), while the sensitivity was comparable to the guideline (0.94, 0.98, and 0.98 vs 1.00, all P>.05). All diagnostic performance indicators for GPT-model and Claude-model were not significantly different from those of radiologists (all P>.05).

Conclusions: The ability of LLMs to recognize and interpret medical images requires further improvement. The text strategy with a scoring system is currently the most appropriate diagnostic strategy for LLMs.

KEYWORDS

large language models; gallbladder polyps; ultrasound; diagnostic accuracy; medical image analysis; artificial intelligence

Introduction

Large language models (LLMs) are deep learning models trained on large amounts of text data, and their emergence has led to changes in many fields [1-3]. LLMs can understand and generate human language and have the potential to provide medical advice, making their application in the medical field of wide interest [4,5]. With the evolution of the LLMs, their capabilities range from simple summarization to complex tasks such as paper writing, medical education, and diagnosis [6-9]. Prior investigations into the diagnostic applications of LLMs have predominantly used two methodological frameworks: (1) diagnostic strategies using narrative textual inputs describing imaging findings [10], or (2) risk stratification approaches requiring LLMs to apply established scoring systems to textualized lesion characteristics [9]. Some LLMs, such as ChatGPT-4o and Claude 3.5 Sonnet, can analyze and interpret images. These two LLMs were developed by different organizations and demonstrated competitive capabilities that positioned them within the global elite of LLMs at the time of our study [11,12], showing they represent the most advanced level of general-purpose LLMs.

Gallbladder polyps are a common finding in abdominal ultrasound examination, with a reported incidence rate of 6.1%-12.1% [13,14]. They impose diagnostic burdens on radiologists and generate substantial patient demand for report interpretation. The management strategy for polypoid lesions of the gallbladder depends on their pathological type. Neoplastic polyps, including gallbladder cancer and precancerous gallbladder adenomas, require cholecystectomy [15,16]. Studies report that 28%-49.5% of gallbladder adenoma may progress to gallbladder cancer [15,17]. Nonneoplastic polyps, including cholesterol polyps, inflammatory polyps, and fibromyoadenoid polyps, rarely become malignant, and follow-up is recommended [18]. Gallbladder carcinoma can be distinguished from other polypoid lesions based on gallbladder wall continuity and contrast-enhanced patterns [19,20]. However, differentiating adenomatous polyps from nonneoplastic polyps remains challenging. Guidelines recommend cholecystectomy for polyps ≥1.0 cm in size [21]. Using these criteria, 27.1%-56% of patients undergoing cholecystectomy for gallbladder polyps are postoperatively diagnosed with nonneoplastic polyps [22,23]. Beyond financial and psychological burdens, this may result in complications that adversely affect quality of life [24,25]. Therefore, it is critical to distinguish neoplastic polyps from nonneoplastic polyps, particularly for lesions ≥1.0 cm. LLMs can potentially reduce the workload of radiologists by generating descriptions based on ultrasound images or risk stratification of gallbladder polyps, and provide medical consults for patients based on ultrasound reports. If LLMs perform better than existing guidelines or radiologists in differentiating gallbladder polyps, they might reduce unnecessary cholecystectomies. Recent studies have demonstrated that ChatGPT-4o and Claude 3.5 Sonnet exhibit superior performance compared to other LLMs in diagnostic tasks involving radiological imaging [26,27], suggesting potential for ultrasound applications. To date, no study has systematically evaluated LLMs' ability to characterize sonographic features or differentiate benign gallbladder polyps. Gallbladder polyps manifest as nonshadowing protrusions from the gallbladder wall into the anechoic lumen in ultrasound examinations. This anatomically well-defined nature with intuitive spatial localization makes them suitable for assessing LLMs' capacity in medical image interpretation. Furthermore, current literature lacks methodological comparisons of LLMs' diagnostic performance across three distinct paradigms: (1) direct image analysis, (2) text-based diagnosis, and (3) scoring-system–based risk stratification using textualized lesion characteristics.

The purpose of this study was to systematically evaluate the feasibility and conduct an early stage evaluation of LLMs across three diagnostic strategies for differential diagnosis of benign gallbladder polyps (≥1.0 cm) based on ChatGPT-4o and Claude 3.5 Sonnet, with comparison to radiologists and the joint guidelines between the European Society of Gastrointestinal and Abdominal Radiology, the European Association for Endoscopic Surgery and other Interventional Techniques, the International Society of Digestive Surgery–European Federation, and the European Society of Gastrointestinal Endoscopy.

Methods

Ethical Considerations

This study was approved by the Ethics Committee in our institute, Sun Yat-sen University (No. [2016]083). Due to the retrospective nature of this study, the requirement for informed consent was waived. This study adhered to the CLAIM (Checklist for Artificial Intelligence in Medical Imaging) [28] for reporting (Table S1 in Multimedia Appendix 1 [29,30]). This study provides a Reproducibility Checklist in Table S2 in Multimedia Appendix 1 to facilitate the replication of our work.

Throughout the interaction with the LLMs, all patient-identifiable information (including names, hospital ID numbers, etc) was strictly removed from the ultrasound images and reports before analysis.

Due to the retrospective design of this study, participants received no compensation.

Patient Selection

A total of 447 patients with previous imaging findings of gallbladder polyps who underwent cholecystectomy at our institution were retrospectively reviewed. The initial cohort of 312 patients (January 2011 to January 2022) was used to develop the scoring system and to evaluate the performance of the LLMs, while the subsequent cohort of 135 patients (February 2022 to March 2025) served as an external test set for the LLMs-model strategy. The inclusion criteria were as follows: (1)

XSL•FO
RenderX

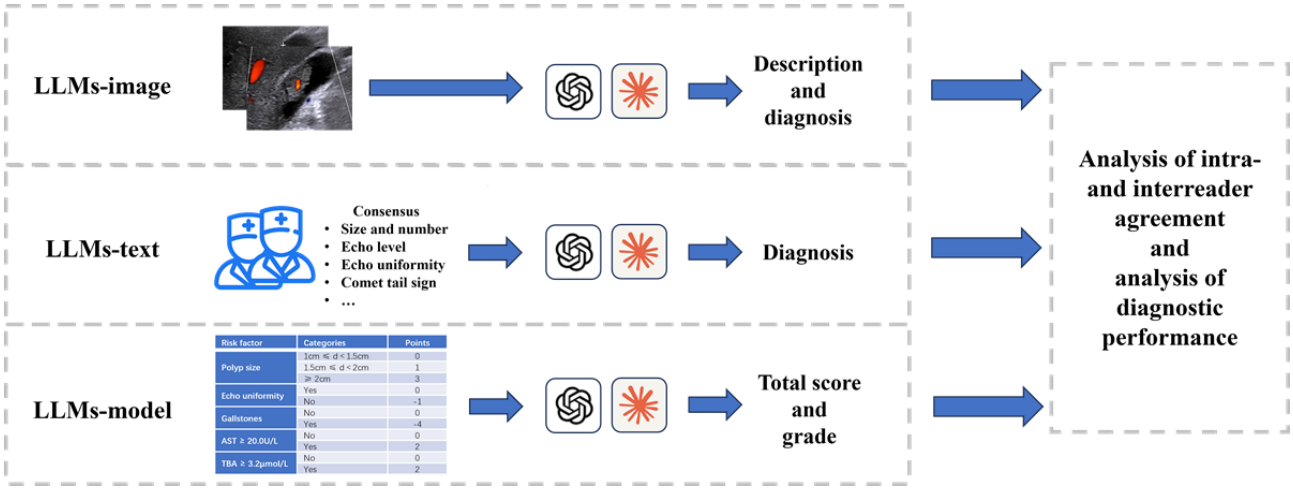
transabdominal ultrasonography was performed in our hospital before cholecystectomy, and (2) there was a definite postoperative pathological diagnosis. The details of the ultrasound examination protocol are shown in Multimedia Appendix 1 (see also Multimedia Appendices 2-6). Given that the differential diagnostic focus for gallbladder polyps predominantly targets lesions ≥1.0 cm, and smaller polyps may be less clearly visualized in ultrasound images, potentially affecting the performance of LLMs, a 1.0 cm threshold was determined as one of the conditions for patient selection. Patients were excluded if they met any of the following criteria: (1) missing ultrasound images; (2) no polypoid lesions detected by the ultrasound examination in our hospital; (3) age <18 years; and (4) size of the largest polyp <1.0 cm. The patients were divided into an adenomatous polyp group and a nonneoplastic polyp group. Patients with both adenomatous polyps and nonneoplastic polyps were classified as having adenomatous polyps.

Patient Data Collection

Preoperative clinical data of patients were collected, including demographic information, alanine aminotransferase, and aspartate aminotransferase levels. The latest preoperative ultrasound images and reports were collected. Information about polyp size and number, gallbladder wall thickness measurements, and the presence of gallstones was obtained from the reports. Other ultrasound features were evaluated independently by two radiologists (with 2 years and 10 years of experience in abdominal ultrasound, respectively) who were blinded to the patient's clinical features and pathology results. Discrepancies were discussed by the two doctors to get a consensus. When consensus could not be reached after discussion between the two radiologists, a third radiologist with seventeen years of experience in abdominal ultrasound made the final determination. If the patient had more than one gallbladder polyp, only the largest one was analyzed. In our previous study, we proposed a new index for quantifying polyp morphology, called the polyp morphology ratio (PMR). The details about the definitions of PMR and other ultrasound features are provided in Multimedia Appendix 1.

Diagnostic Strategies

This study evaluated ChatGPT-4o and Claude 3.5 Sonnet using their standard web interfaces [31,32] between July and September 2024 according to the following strategies. All interactions were conducted without custom code, API calls, or adjustments to default inference parameters. To ensure transparency, all interactions used the platform defaults, and the complete set of prompts is detailed in Multimedia Appendix 1. The prompts input into the two LLMs were the same. Each prompt input does not include expected outcomes or class distributions, nor does it judge the correctness of the LLM's responses. For the strategy of LLMs-image, LLMs performed diagnoses based on ultrasound images. Before analysis, images were cropped to remove all patient-identifiable information. Additionally, the images were cropped to ensure the gallbladder occupied approximately 30%-40% of the frame, with lesions centered whenever possible while maintaining the structural integrity of both the gallbladder and surrounding tissues. No image enhancement or standardization was applied. The underlying vision capabilities of the LLMs are accessed directly through their vision application programming interface, rather than via a third-party wrapper. The images input into the LLMs were in JPEG format, with both horizontal and vertical resolutions of 96 dpi. The processed 2D gray-scale ultrasound image and color Doppler ultrasound image were input into LLMs, and the LLMs were required to describe the ultrasound characteristics of gallbladder polyps and provide a diagnosis.



For the strategy LLMs-text, LLMs performed diagnoses based on the text of the ultrasound description. Based on the consensus of the two radiologists, the description of the ultrasound characteristics for the gallbladder polyps was organized into a structured report. The structured report was input into the LLMs, and the LLMs were required to give the diagnosis.

For the strategy LLMs-model, LLMs performed diagnoses based on our previously developed diagnostic model for benign gallbladder polyps ≥1.0 cm [33]. Before this study, a multilevel scoring system for the differentiation between gallbladder adenomatous polyps and nonneoplastic polyps was constructed based on the same cases as those in this study (Table S3 in Multimedia Appendix 1). The relevant information was organized into structured text according to the requirements of the scoring system. Then, only the structured text was input into LLMs without the corresponding scores, and the LLMs were required to calculate the total score and indicate the corresponding grade. In addition, based on the consensus of two radiologists, the total score and the corresponding grade of each patient were calculated with the multilevel scoring system (strategy readers-model).

Figure 1 shows the flow of the diagnostic strategies for LLMs. The prompts templates in diagnostic strategies for LLMs are in Multimedia Appendix 1. The intrareader agreement, interreader agreement, and diagnostic performance of LLMs in the three diagnostic strategies were evaluated. The initial outputs from LLMs in the three strategies were used to analyze interreader agreement and diagnostic performance. From the final enrolled cases, 70 were randomly selected to assess intrareader agreement. The LLMs were asked to regenerate the output for these cases twice, that is, there were three rounds of output per strategy per LLM for each of these 70 cases, respectively.

In-Context Learning for LLMs

For the ultrasound image-based lesion characterization tasks in this study, the LLMs underwent supplemental in-context learning beyond their original architecture. LLMs were trained to recognize the degree of blood flow, blood flow pattern, and the definition of PMR and polyp base type (sessile or pedunculated) using ultrasound images of patients with gallbladder polyps in our center (excluding cases included in this study). The prompts used in in-context learning are provided in Multimedia Appendix 1. After entering the prompt word, the memory of the LLMs to was checked to ensure its correct understanding.

Statistical Analysis

The interclass correlation coefficient, Cohen κ, and weighted κ were used to evaluate the interreader agreement for continuous, unordered, and ordered categorical variables, respectively. Interclass correlation coefficient, Fleiss κ, and Kendall W coefficient were used to evaluate the intrareader agreement for continuous, unordered, and ordered categorical variables, respectively. The interreader agreement of ultrasound features was represented by a heatmap generated with the *pheatmap* package in R (R Foundation). The levels of the coefficient of the agreement analysis were defined as follows: 0.20 or less for slight agreement, 0.21-0.40 for fair agreement, 0.41-0.60 for moderate agreement, 0.61-0.80 for substantial agreement, and 0.81-1.00 for almost perfect agreement. The agreement coefficients were compared using the Z-test. The detailed sample size calculation for intrareader agreement is shown in Multimedia Appendix 1.

The diagnostic performance of LLMs was evaluated by sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), accuracy, area under the receiver operating characteristic curve, and unnecessary resection rate of nonneoplastic polyps (UNRR). Sensitivity, specificity, PPV, and NPV were calculated and compared with the *stats* package and *epiR* package in R. The area under the receiver operating characteristic curves were compared using the DeLong test. UNRR was calculated as the number of nonneoplastic polyps recommended for cholecystectomy divided by the total number of nonneoplastic polyps. Chi-square test was used to compare UNRR.

For the strategy LLMs-text, univariate logistic regression was performed on ultrasound features according to the diagnosis of LLMs to analyze the basis for differential diagnosis of LLMs.

Two-tailed $P<.05$ was considered statistically significant. Statistical analysis was performed using PASS 2025 (power analysis and sample size; NCSS, LLC), SPSS 25.0 (IBM Corp), and R version 4.3.1 (R Foundation).

Results

Patient Characteristics

In the initial cohort, this study analyzed 223 patients aged 18-72 (median 40, IQR 34-50) years, including 132 (59.2%) females. Among these, 175 (78.5%) had nonneoplastic polyps and 48 (21.5%) had adenomatous polyps. Compared to the initial cohort, the external test set showed no significant differences in demographic characteristics or pathological type distribution (all $P>.05$; Table 1). The patient selection process is shown in Figure 2.

Intrareader Agreement Analysis

The intrareader agreement coefficients of LLMs across three strategies are shown in Table 2. Compared to the intrareader agreement for grades in strategy LLMs-model, both ChatGPT-4o and Claude 3.5 Sonnet exhibited significantly lower intrareader agreement for diagnoses in strategy LLMs-text (0.58 vs 0.97, *P*<.001 for ChatGPT-4o; 0.61 vs 1.00, *P*<.001 for Claude 3.5 Sonnet) and LLMs-image (0.37 vs 0.97, *P*<.001 for ChatGPT-4o; 0.47 vs 1.00, *P*<.001 for Claude 3.5 Sonnet). However, there was no significant difference between strategy LLMs-image and LLMs-text (*P*=.15 for ChatGPT-4o and *P*=.33 for Claude 3.5 Sonnet).

For the ultrasound feature identification in strategy LLMs-image, the agreement level of blood flow degree and pattern for ChatGPT-4o was moderate to substantial (range of agreement coefficient 0.43 to 0.68, 95% CI 0.30 to 0.81). Additionally, there was only slight to fair agreement for ChatGPT-4o in other ultrasound features (range of agreement coefficient –0.12 to 0.30, 95% CI –0.25 to 0.45). However, except for the slight to fair agreement in PMR, comet tail sign and gallbladder wall thickness types (range of agreement coefficient 0.02 to 0.30, 95% CI –0.10 to 0.45), there was moderate to almost perfect agreement for Claude 3.5 Sonnet in other ultrasound features (range of agreement coefficient 0.43 to 0.97, 95% CI 0.30 to 1.00). The intrareader agreement coefficients in ultrasound features for Claude 3.5 Sonnet were all higher than those for ChatGPT-4o, except for PMR. In addition, the intraobserver agreement coefficient in diagnosis for Claude 3.5 Sonnet in strategy LLMs-image was 0.47, which was also higher than 0.7 for ChatGPT-4o.

The intraobserver agreement coefficients in diagnosis for ChatGPT-4o and Claude 3.5 Sonnet in strategy LLMs-text were 0.58, 95% CI 0.46 to 0.72, and 0.1, 95% CI 0.49 to 0.75, respectively, indicating a moderate to substantial level, which were higher than those in strategy LLMs-image.

In strategy LLMs-model, both ChatGPT-4o and Claude 3.5 Sonnet showed almost perfect intraobserver agreement for total score and grade (range of agreement coefficient 0.97 to 1.00, 95% CI 0.94 to 1.00). Almost perfect intraobserver agreement was also observed in the external test set (Table S4 in Multimedia Appendix 1).

[e]CIs cannot be calculated due to the perfect consistency of the three rounds' output in each case.

Interreader Agreement Analysis

Figure 3 and Table S5 in Multimedia Appendix 1 present the interreader agreement of human readers and LLMs in ultrasound features. Except for the interobserver agreement level of cauliflower shape between readers 1 and 2 being moderate (agreement coefficient=0.57), the agreement level for other features between readers 1 and 2 was substantial to almost perfect (range of agreement coefficient 0.65 to 0.99). However, the agreement level between LLMs and other observers was only slight (range of agreement coefficient –0.11 to 0.12), except for blood flow degree and pattern (range of agreement coefficient 0.34 to 0.75). As shown in Table S5 in Multimedia Appendix 1, apart from the comet tail sign, the agreement coefficient for other features between readers 1 and 2 was significantly higher than those between LLMs and other observers (P<.001).

The agreement coefficient for the comet tail sign could not be calculated because reader 1 considered that the comet tail sign was not present in all cases in this study.

The interobserver agreement coefficients of human readers and LLMs in diagnosis are shown in Table 3. There was slight interobserver agreement between ChatGPT-4o and Claude 3.5 Sonnet in strategy LLMs-image (Cohen κ=0.12, 95% CI –0.01 to 0.24), and fair agreement in strategy LLMs-text (Cohen κ=0.38, 95% CI 0.26 to 0.50). For the strategy readers or LLMs-model, the agreement levels were all almost perfect in readers versus ChatGPT-4o, readers versus Claude 3.5 Sonnet, ChatGPT-4o versus Claude 3.5 Sonnet (range of agreement coefficient 0.84 to 0.99, 95% CI 0.78 to 0.99). In the external test set, LLMs still showed a considerable degree of interreader agreement (Table S6 in Multimedia Appendix 1). Compared to the interreader agreement coefficient of grades between ChatGPT-4o and Claude 3.5 Sonnet in strategy LLMs-model, those for diagnosis in strategy LLMs-image (P<.001) and LLMs-text (P<.001) were significantly lower. Additionally the interreader agreement coefficient for diagnosis in strategy LLMs-text was significantly higher than that in strategy LLMs-image (P=.004).

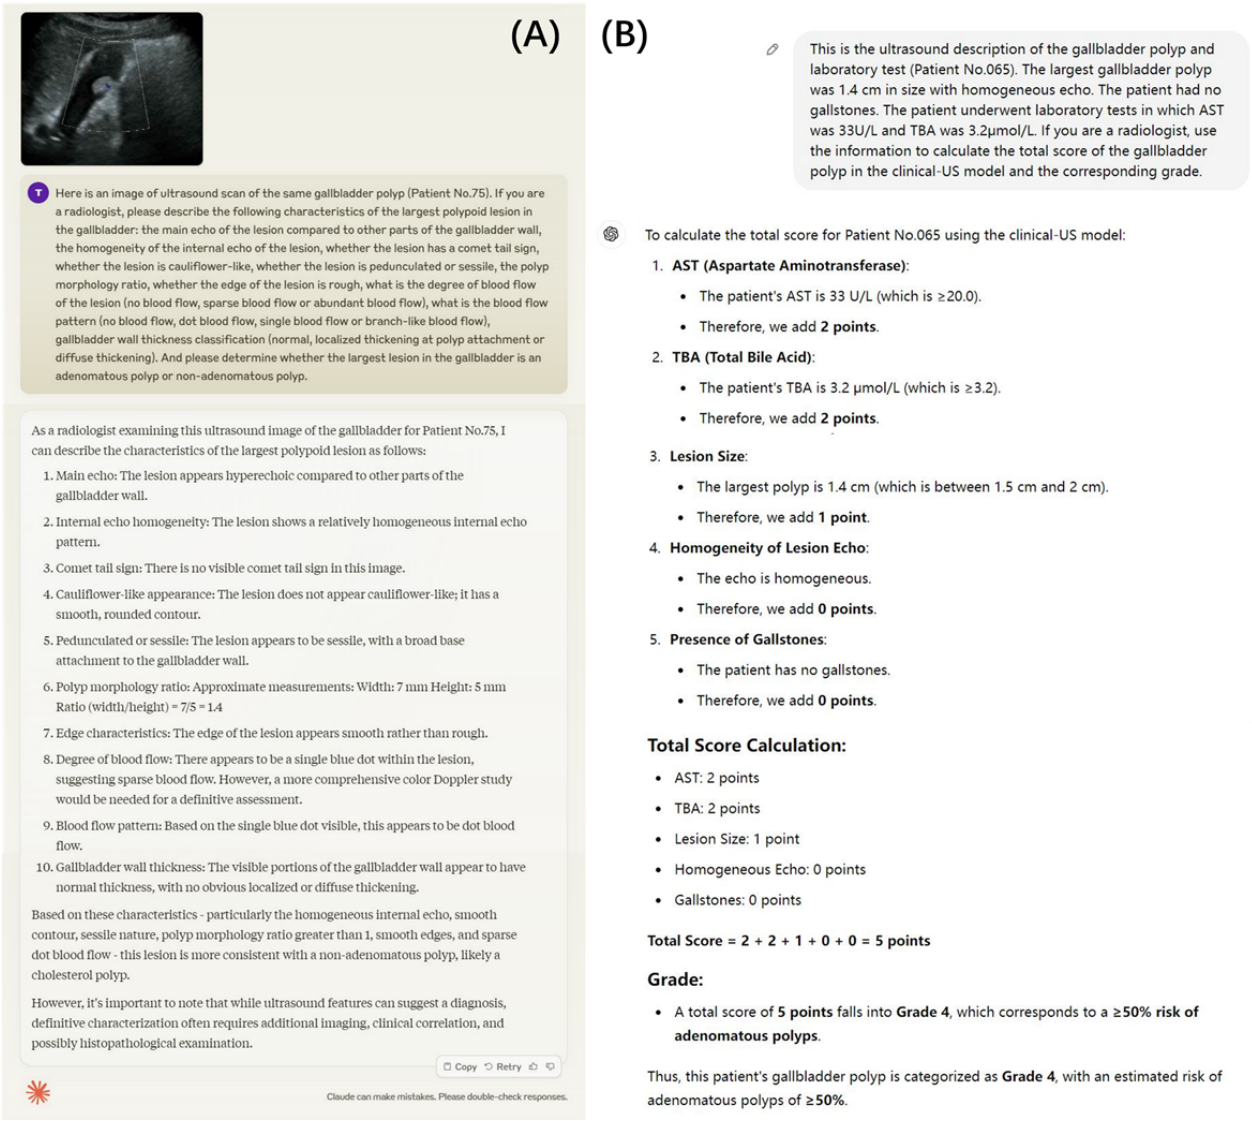
Diagnostic Performance

The diagnostic performance of all diagnostic strategies is presented in Table 4. Figure 4A and B show representative cases from strategy Claude-image and strategy GPT-model, respectively.



The sensitivity of the guideline's diagnostic strategy was 1.00, indicating that no gallbladder adenomas were missed, but surgery was recommended for all nonneoplastic polyps ≥1.0 cm (UNRR=100%). In the strategies LLMs-image and LLMs-text, the sensitivity of GPT-image, Claude-image, GPT-text, and Claude-text was 0.27, 0.33, 0.56, and 0.65, respectively, which were significantly lower than the sensitivity of the guideline (all P<.001), indicating more gallbladder adenomas were missed.

In the strategy readers or LLMs-model, when cholecystectomy was recommended for gallbladder polyps ≥grade 2, the sensitivity of ChatGPT-4o, Claude 3.5 Sonnet, and radiologists were 0.94, 0.98, and 0.98, respectively, showing no significant difference from the sensitivity of 1.00 achieved by the guideline

XSL•FO
RenderX

(all $P<.05$). However, the accuracy of ChatGPT-4o, Claude 3.5 Sonnet, and radiologists was significantly higher than that of the guideline (0.35, 0.34, and 0.34 vs 0.22, all $P<.01$), and the UNRR was significantly lower than that of the guideline (82%, 83%, and 83% vs 100%, all $P<.01$). In addition, there were no significant differences observed between GPT-model, Claude-model and readers-model in terms of sensitivity, specificity, PPV, NPV, accuracy or UNRR across all grades (all $P>.05$). Similar results were observed in the external test set (Table S7 in Multimedia Appendix 1).

Interpretability of the Diagnosis in Strategy LLMs-Text

The results of univariate analysis based on the diagnosis of GPT-text and Claude-text are shown in Table S8 in Multimedia Appendix 1. Both ChatGPT-4o and Claude 3.5 Sonnet considered larger size, hypoechogenicity, heterogeneous echogenicity, cauliflower shape, sessile base, and rough edge as significant factors for adenomatous polyps. Additionally, ChatGPT-4o identified higher PMR as a diagnostic indicator for adenomatous polyps. Furthermore, Claude 3.5 Sonnet also associated sparse and dot-like blood flow in color Doppler flow imaging with adenomatous polyps. Both LLMs diagnosed all lesions with abundant blood flow (6 cases) as adenomas, which was identified as a risk feature of neoplastic gallbladder polyps by a previous study, while this complete separation led to the extreme or infinite CIs.

Error Analysis in Strategy LLMs-Text

In the strategy LLMs-text, 129 cases were misdiagnosed by ChatGPT-4o, while 94 cases were correctly diagnosed. As shown in Table S9 in Multimedia Appendix 1, lesions with the following characteristics were more likely to be misdiagnosed by ChatGPT-4o: hypoechoic appearance (23% vs 11%, *P*=.047), heterogeneous echotexture (52% vs 22%, *P*<.001), cauliflower-like morphology (24% vs 13%, *P*=.04), and rough edges (56% vs 29%, *P*<.001).

For Claude 3.5 Sonnet, 144 cases were misdiagnosed by ChatGPT-4o, while 79 cases were correctly diagnosed. Table S10 in Multimedia Appendix 1 demonstrates that Claude 3.5 Sonnet was prone to misdiagnosis in lesions with these features: larger size (1.30 cm vs 1.10 cm, *P*<.001), hypoechoic appearance (21% vs 13%, *P*=.03), heterogeneous echotexture

XSL•FO
RenderX

(49% vs 23%, $P<.001$), cauliflower-like morphology (24% vs 11%, $P=.03$), and rough edges (52% vs 30%, $P=.002$).

Discussion

Principal Findings

This study evaluated the feasibility of LLMs for the differential diagnosis of gallbladder benign polyps. Our principal findings indicate that the diagnostic strategy profoundly influences LLM performance. In the strategy LLMs-image, LLMs exhibited only slight-to-moderate intrareader agreement and poor interreader consistency compared to radiologists. As the ultrasonic features associated with gallbladder polyps represent common characteristics shared by focal lesions, the finding that current LLMs have limited capabilities in recognizing these features suggests this limitation may have broad applicability. For diagnosis, the diagnostic performance of LLMs-image and the strategy LLMs-text showed significantly lower sensitivity than clinical guidelines, leading to more missed adenomas. In contrast, the strategy LLMs-model, which used text descriptions within a scoring system, demonstrated high consistency and diagnostic performance comparable to radiologists using the same model, while significantly reducing unnecessary cholecystectomies. Notably, the performance between two general-purpose LLMs, ChatGPT-4o and Claude 3.5 Sonnet, was comparable across all strategies, suggesting these findings may generalize to other general-purpose LLMs.

Comparison With Prior Work

Our results on the poor performance of general-purpose LLMs in direct image interpretation align with a growing body of evidence across various medical fields. Studies using dermoscopic images for melanoma diagnosis, orthopedic residency examination images, and musculoskeletal radiology images consistently report not only unsatisfactory diagnostic accuracy (as low as 3% to 36%) but also highlight that LLM performance is inferior to that of human specialists [34-37]. Critically, some studies report that LLMs could harm patient care by recommending unnecessary invasive procedures, such as biopsies, at a significantly higher rate than radiologists [38]. This collective evidence confirms that current general-purpose LLMs remain inadequate for reliable medical image-based diagnosis.

It is important to note that LLMs receiving specialized training in medical images have demonstrated more competent performance in specific domains, such as dermatology (SkinGPT-4) and diabetes management (DeepDR-LLM) [39,40]. Universal systems such as ChatCAD+ also show promise across multiple image types [41]. However, such specialized models are often confined to a single disease area or a limited set of tasks, and they may underperform advanced general LLMs such as GPT-4 in broader medical question-answering [42]. Other general medical LLMs capable of addressing multiple conditions, such as MedFound, do not yet support image input [43]. Given the critical needs for accessibility, generalizability, and image input capabilities in real-world clinical settings, we selected leading general-purpose LLMs (ChatGPT-4o and Claude 3.5 Sonnet) as the subjects of this study. Our findings contribute to the understanding of their current capabilities and limitations.

Regarding the diagnostic performance of text-based strategies, our findings must be viewed within the context of a highly variable literature. Previous studies report widely varying accuracy (40%-91.4%) for categorical diagnoses using text-only strategies [27,44,45]. When focusing specifically on the interpretation of radiological findings, reported diagnostic accuracy for LLMs ranges from 25% to 73% [26,46-48]. While some studies, such as one on real-world radiology reports of brain tumors, found ChatGPT-4's accuracy (73%) to be comparable with radiologists [48], the absence of standardized methods and reporting metrics in LLM studies introduces significant bias risks and hinders cross-study comparisons. In our study, the text-based strategy demonstrated superior diagnostic performance to the image-based approach, which aligns with the consensus and the reported performance levels. Nevertheless, given gallbladder adenomas' high potential for malignancy, the moderate sensitivity achieved by the text-based strategy in our study remains a critical limitation for clinical application, as higher sensitivity is paramount to avoid missed diagnoses.

The LLMs performed suboptimally in the text-based diagnostic strategy, even though the interpretability analysis of the LLMs-text approach indicated that the high-risk features of adenomas identified by the LLMs are supported by previous literature [29,49-51]. In the error analysis, we observed that LLMs showed subpar performance in diagnosing lesions with these same features, such as heterogeneous echotexture and rough edges. Essentially, this finding reflects a long-standing fundamental challenge in the imaging diagnosis of gallbladder polyps: there is significant overlap in the sonographic features between high-grade dysplastic adenomas and early-stage gallbladder cancer. Trained on broader existing literature about medical imaging, the LLMs correctly learned the strong association between these features and common malignancy risk (eg, gallbladder cancer). As indicated by the extreme odds ratio in the interpretability analysis, both LLMs assigned excessive weight to abundant blood flow. Although previous studies confirm it is indeed a feature associated with neoplastic polyps [52], the models' tendency to treat it as an absolute diagnostic rule—rather than a probabilistic indicator—reveals their limitation in performing the task of fine-grained diagnosis, a reflection of the inherent difficulty of the task itself. However, when the task was confined to the relatively idealized binary framework of "differentiating adenomatous from non-neoplastic polyps," the model's heightened sensitivity to these high-risk features created a conflict with the task objective. This may not represent a "weakness" in the model, but rather an objective reflection of complex clinical reality—the degree of dysplasia in lesions exists on a spectrum, and such ambiguity in imaging is inherent before the intervention of the pathological "gold standard." Meanwhile, the LLMs also demonstrated valuable capabilities. For instance, ChatGPT-4o correctly recognized a novel morphological index (PMR) from an unpublished study as useful for diagnosis, and Claude 3.5 Sonnet identified sparse and dot blood flow as a relevant feature, which aligns with established research [29,49]. This demonstrates their potential

XSL•FO
RenderX

in tasks requiring strong information retrieval and logical reasoning.

Conversely, our study reinforces that LLMs exhibit excellent performance when working with structured text data from scoring systems. Their high accuracy and consistency in applying such systems are supported by prior research in Liver Imaging Reporting and Data System and Thyroid Imaging Reporting and Data System classification [9,53]. In addition, our findings clarify the role of general-purpose LLMs. In the LLMs-model strategy, the LLM acts as a reliable executor of clinical rules, not a simple calculator. It first understands text to find key features, then applies the scoring rule. The performance of our LLMs-model strategy, which was comparable to radiologists, suggests that leveraging LLMs to execute standardized clinical rules may be their most reliable and immediate clinical application.

Strengths and Limitations

A key strength of this study is the comprehensive evaluation of LLMs across three distinct diagnostic strategies, providing a clear understanding of their appropriate clinical roles. We also provided an in-depth analysis of their reasoning, identifying both capabilities and weaknesses.

This study has several limitations. First, the task of differentiating benign gallbladder polyps is inherently challenging, even for radiologists, which may have contributed to the LLMs' suboptimal performance. Second, the evaluation was conducted on a single disease entity; assessing broader clinical applicability requires more diverse and complex cases. Third, we used in-context learning with only typical cases. While this approach simulates a realistic usage scenario and is highly accessible, it is inherently less stable than fine-tuning and may not capture the full spectrum of clinical presentations. Finally, the retrospective design may introduce potential selection biases.

Future Directions

Based on our findings, future research should focus on several key areas. First, the development and evaluation of more versatile and medically tuned multimodal LLMs are crucial. Second, the performance of LLMs is heavily dependent on the quality of the underlying scoring system; therefore, integrating them with more robust and validated clinical models could maximize their diagnostic utility. Finally, standardizing evaluation methods and reporting metrics across LLM studies is urgently needed to enable meaningful comparisons. Given their strong performance in information retrieval and logical reasoning, future work should also explore the role of LLMs in medical education [54,55] and self-management counseling for patients with chronic conditions [56].

Conclusions

In conclusion, current general-purpose LLMs have poor reproducibility and diagnostic performance in image-based diagnosis of gallbladder polyps, limiting their direct clinical application. However, they demonstrate significant potential when used in a text-based strategy that uses a clinical scoring system, achieving performances comparable to radiologists. This model-based approach currently represents the most appropriate diagnostic strategy for LLMs in this domain.

Acknowledgments

Generative artificial intelligence (GenAI) was not used to generate any part of this paper. In this study, GenAI is only a part of the research design. All prompt templates sent to the GenAI are detailed in Multimedia Appendix 1.

Abstract

Background: Frailty is one of the most common symptoms in patients with cirrhosis. Many researchers have identified it as a prognostic factor for patients with cirrhosis. However, no quantitative meta-analysis has evaluated the prognostic value of frailty in patients with cirrhosis.

Objective: This systematic review and meta-analysis aimed to assess the prognostic significance of frailty in patients with cirrhosis.

Methods: The systematic review was conducted in accordance with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) recommendations. We conducted a comprehensive search of the literature using databases such as PubMed, Cochrane Library, Embase, and Web of Science, as well as China National Knowledge Infrastructure, encompassing the period from inception to 22 December 2023. Data were extracted for frailty to predict adverse outcomes in patients with cirrhosis. RevMan (version 5.3) and R (version 4.2.2) were used to assess the extracted data.

Results: A total of 26 studies with 9597 patients with cirrhosis were included. Compared with patients having low or no frailty, the frail group had a higher mortality rate (relative ratio, RR=2.07, 95% CI 1.82 - 2.34, *P*<.001), higher readmission rate (RR=1.50, 95% CI 1.22 - 1.84, *P*<.001), and lower quality of life (RR=5.78, 95% CI 2.25 - 14.82, *P*<.001). The summary receiver operator characteristic (SROC) curve of frailty for mortality in patients with cirrhosis showed that the false positive rate (FPR) was 0.25 (95% CI 0.17-0.34), diagnostic odds ratio (DOR) was 4.17 (95% CI 2.93-5.93), sensitivity was 0.54 (95% CI 0.39-0.69), and specificity was 0.73 (95% CI 0.64-0.81). The SROC curve of readmission showed that the FPR, DOR, sensitivity, and specificity were 0.39 (95% CI 0.17-0.66), 1.38 (95% CI 0.64-2.93), 0.46 (95% CI 0.28-0.64), and 0.60 (95% CI 0.28-0.85), respectively.

Conclusions: This meta-analysis demonstrated that frailty is a reliable prognostic predictor of outcomes in patients with cirrhosis. To enhance the prognosis of patients with cirrhosis, more studies on frailty screening are required.

Introduction

Background

Cirrhosis is a prevalent illness worldwide and is linked with substantial morbidity and mortality [1,2]. According to a recent report by Smith et al [3], cirrhosis has resulted in the deaths of over 40,000 individuals in America, ranking it as the 12th most prevalent cause of death. Furthermore, it is the third most prevalent cause of mortality among individuals aged 45 - 64 years [4]. The global annual mortality from chronic liver disease is estimated to be approximately 2 million. Amongst them, cirrhosis is associated with the advancement of chronic

XSL•FO
RenderX

inflammatory diseases and accounts for approximately 45% of all-cause mortality worldwide [5].

Cirrhosis often causes physiological decline, making patients more vulnerable to frailty, which further compromises their overall health [6]. Frailty is a clinical syndrome defined by increased susceptibility and impaired antistress response due to the cumulative functional loss of numerous physiological systems [7]. Furthermore, frailty is characterized by a deterioration across three primary domains: physical health, mental health, and social function [8]. Previously, frailty was considered primarily a geriatric condition linked with aging, although its link to chronic diseases is now extensively understood [9-11].

At present, evidence is increasing that frailty is a risk factor for increased mortality and complications, longer hospital stays, risk of falls, and other issues in patients with cirrhosis [12-14]. However, the assessment tools used in prior research on the unfavorable consequences of patients with cirrhosis vary, and more investigation is required to determine the prognostic significance of frailty in these individuals [12,15]. The prognostic significance of frailty in patients with cirrhosis is inconsistent among different studies and requires immediate clarification [16,17]. For example, several researchers have demonstrated that frailty serves as a prognostic indicator for mortality in individuals with cirrhosis [17,18], but conflicting findings have been reported in another investigation [16]. In addition, one study explored the relationship between frailty and outcome in patients with cirrhosis, but it only demonstrated that frailty can predict liver transplant-free survival; the risk of other complications remains unknown [19]. There are still limited systematic reviews and meta-analyses on the prognostic value of frailty in patients with cirrhosis.

Objective

Therefore, to determine the association between frailty and the prognosis of patients with cirrhosis, we did a comprehensive review and meta-analysis on the predictive value of frailty in the prognosis of patients with cirrhosis. This information can help develop targeted management measures for patients with cirrhosis and promote their well-being.

Methods

Protocol Registration

The study protocol was officially registered on the PROSPERO website (No. CRD42024497698).

Search Strategy

A comprehensive search was conducted in PubMed, Cochrane Library, Embase, and Web of Science, as well as the China Knowledge Resource Integrated Database, to identify potential articles describing frailty and cirrhosis from inception until 22 December 2023. The search method was conducted with a combination of keywords and Mesh terms: (“frailty” or “frail”) and (“liver cirrhosis,” “hepatic cirrhosis,” “liver fibrosis,” “cirrhosis,” or “cirrhotic”). In addition, we conducted a thorough manual examination of the reference lists of relevant primary and secondary research papers. The search strategy is demonstrated in Table S1 in Multimedia Appendix 1.

Study Selection

The following were the inclusion criteria: (1) cohort studies revealed details about the frailty among patients with cirrhosis; (2) patients (18 years or above) diagnosed with cirrhosis; (3) frailty was assessed using a standardized and reliable instrument, such as the fried frailty score (FFS) and liver frailty index (LFI); (4) at least one clinical outcome between cirrhosis with and without frailty was reported during follow-up; and (5) publications were in English or Chinese.

The following were the exclusion criteria: (1) reviews, non-cohort studies, letters, and conference abstracts; (2) studies that did not provide complete data; (3) duplicated papers; (4) studies not reporting the prevalence of frailty or the predictive value of frailty on the outcomes of patients with cirrhosis; and (5) patients included other diseases rather than cirrhosis

Data Extraction

Author and publication year, country, study design, study population, sample size, age, follow-up (months), frailty instruments, and prevalence of frailty were extracted by two researchers working independently. For each study, the relative ratio (RR) and 95% CI were extracted, both with and without adjustment for confounding variables. Furthermore, from the studies that were incorporated, the true positive (TP), false positive (FP), true negative (TN), and false negative (FN) values were extracted.

Quality Assessment

Two authors independently assessed the cohort studies using the Newcastle–Ottawa Scale (NOS) instrument [20]. It contained three components, including the study group selection, group comparability, and ascertainment of outcomes. The instrument had a maximum score of 9, with a score higher than 5 indicating high-quality literature [21]. If discrepancies existed, the corresponding author assisted in reaching a consensus.

Statistical Analysis

The meta-analysis was conducted using Review Manager (version 5.3) and R software (version 4.2.2; R Foundation for Statistical Computing).

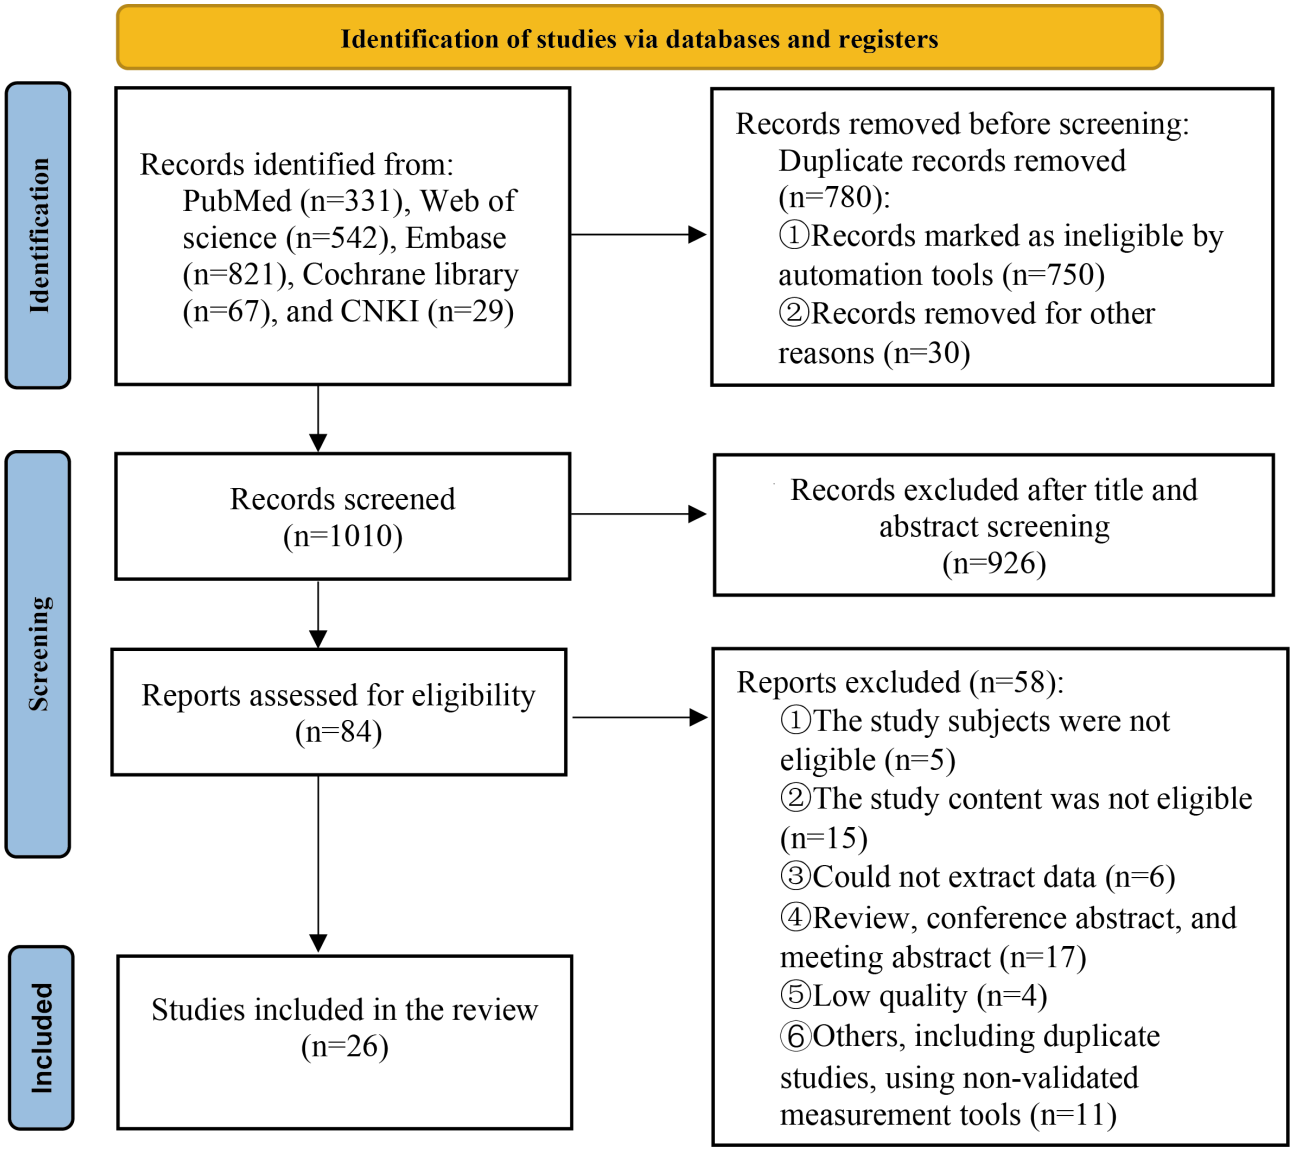
For the purpose of estimating the effect size, the RR and 95% CI were used. The χ^2 test was used to investigate heterogeneity among the outcomes of each study, and the I^2 test was utilized to quantify the level of heterogeneity. The funnel plot was used to evaluate the publication bias when the number of publications reached or exceeded 10. When there were less than 10 publications, the Egger test was used to evaluate literature bias. Further investigation was conducted using the trim-and-fill method if the published literature was biased. Statistical significance was considered to be indicated by P values less than .05.

The average sensitivity, specificity, false-positive rate (FPR), positive likelihood ratio (LR+), negative likelihood ratio (LR-), and diagnostic odds ratio (DOR) of the included studies were computed using the random-effect model. Furthermore, the

XSL•FO
RenderX

accuracy of the test and the consistency of the outcomes of the included studies were determined using the summary receiver operating characteristic (SROC) curve.

Ethical Considerations



All analyses were conducted using previously published studies, and therefore, ethics approval and patient consent were unnecessary. This review does not include human subject information, primary data collection, or any form of experimentation involving individuals.

Results

Selected Studies

Following the identification of 1790 articles during the preliminary search, 780 duplicate articles were eliminated. By reviewing titles and abstracts, an additional 926 sources were eliminated from consideration primarily owing to their lack of relevance to the meta-analysis. The remaining 84 studies were read completely. A total of 58 were deemed ineligible for the reasons outlined in Figure 1. Finally, 26 studies were considered in this analysis. The search flow of this study is presented in Figure 1; the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist has been shown as Checklist 1.

Figure 1. Flowchart showing the database search.

Characteristics of the Included Studies

As shown in Table 1, the meta-analysis comprised 26 cohort studies with 9597 patients with cirrhosis [12,13,15,18,22-43]. Among the 26 articles, 3 were retrospective studies [13,18,41] and 23 were prospective studies [12,15,22-40,42,43]. They were published between 2013 and 2023, and performed in the USA [13,15,18,27,30-32,35,40,41], Canada [39,43], Chile [38], China [22-25,33], Egypt [12], Germany [26,28,29], India [34], the Netherlands [42], Slovakia [37], and Thailand [36]. Considering the included patients, 15 were patients with cirrhosis [12,22-26,29,32-34,36-40], 8 were patients with cirrhosis waiting for liver transplants, 3 were patients who received liver

XSL•FO
RenderX

transplants [13,35,41], and the remaining 1 patient had cirrhosis after surgery [18]. Moreover, the number of patients included was between 88 and 9597. A variety of tools were used to diagnose frailty, including the short physical performance battery (SPPB) [12,39], Carolina frailty index (CFI) [22,25], fried frailty score (FFS) [15,28,37], liver frailty index (LFI) [23,26,27,30-32,34-37,43], clinical frailty scale (CFS) [29,39], gait speed test (GST) [13,32,40], and others [18,24,33,38,41]. The mean follow-up durations varied between 1 and 60 months. The prevalence of frailty in patients with cirrhosis ranged from 10.50% to 75.40%. The NOS scores of the studies included in the study varied between 6 and 8, indicating a high level of quality in these studies. Table S2 in Multimedia Appendix 1 displays the evaluation criteria for literature quality.

Meta-Analysis Results

Mortality

Seventeen studies reported the association between frailty and mortality in patients with cirrhosis [18,22,23,28-33,35,36,38,39,42,43]. Pooled results using a fixed-effect model indicated a significant correlation between frailty and mortality (RR 2.07, 95% CI 1.82 - 2.34, *P*<.001, I^2=14%; Figure 2A). A visual examination revealed that the funnel plot was symmetrical, suggesting a low probability of publishing bias (Figure 2B). The crosshair plots displayed the sensitivity, FPR, and 95% CI of the included studies (Figure 2C) [22,23,29,31,33,35,38,39,42,43]. The SROC curve with 95% CI and 95% prediction intervals of frailty in cirrhosis is shown in Figure 2D. The FPR was 0.25 (95% CI 0.17-0.34), and the DOR was 4.17 (95% CI 2.93-5.93). The summary LR+ was 2.35 (95% CI 1.86-2.96) and the LR- was 0.56 (95% CI 0.45-0.71). As shown in Figure 2E, frailty had a summary sensitivity of 0.54 (95% CI 0.39-0.69). The combined specificity of all studies was 0.73 (95% CI 0.64-0.81; Figure 2F).

Additional subgroup analyses revealed that the frailty-assessment methods, sample size, and study population may not have substantially affected the results (Table 2).

Figure 2. Pooled diagnostic parameters of frailty for the mortality of patients with cirrhosis [18,22,23,28-33,35,36,38,39,42,43]. (A) Forest plot of the relationship between frailty and mortality in patients with cirrhosis; (B) Funnel plot of the included studies; (C) Crosshair plots of each study of frailty in the prediction for mortality in patients with cirrhosis; (D) Summary receiver operating characteristic (SROC) plots of frailty in the prediction for mortality in patients with cirrhosis; (E) Forest plots of the sensitivity of each individual study; (F) Forest plots of the specificity of each individual study.

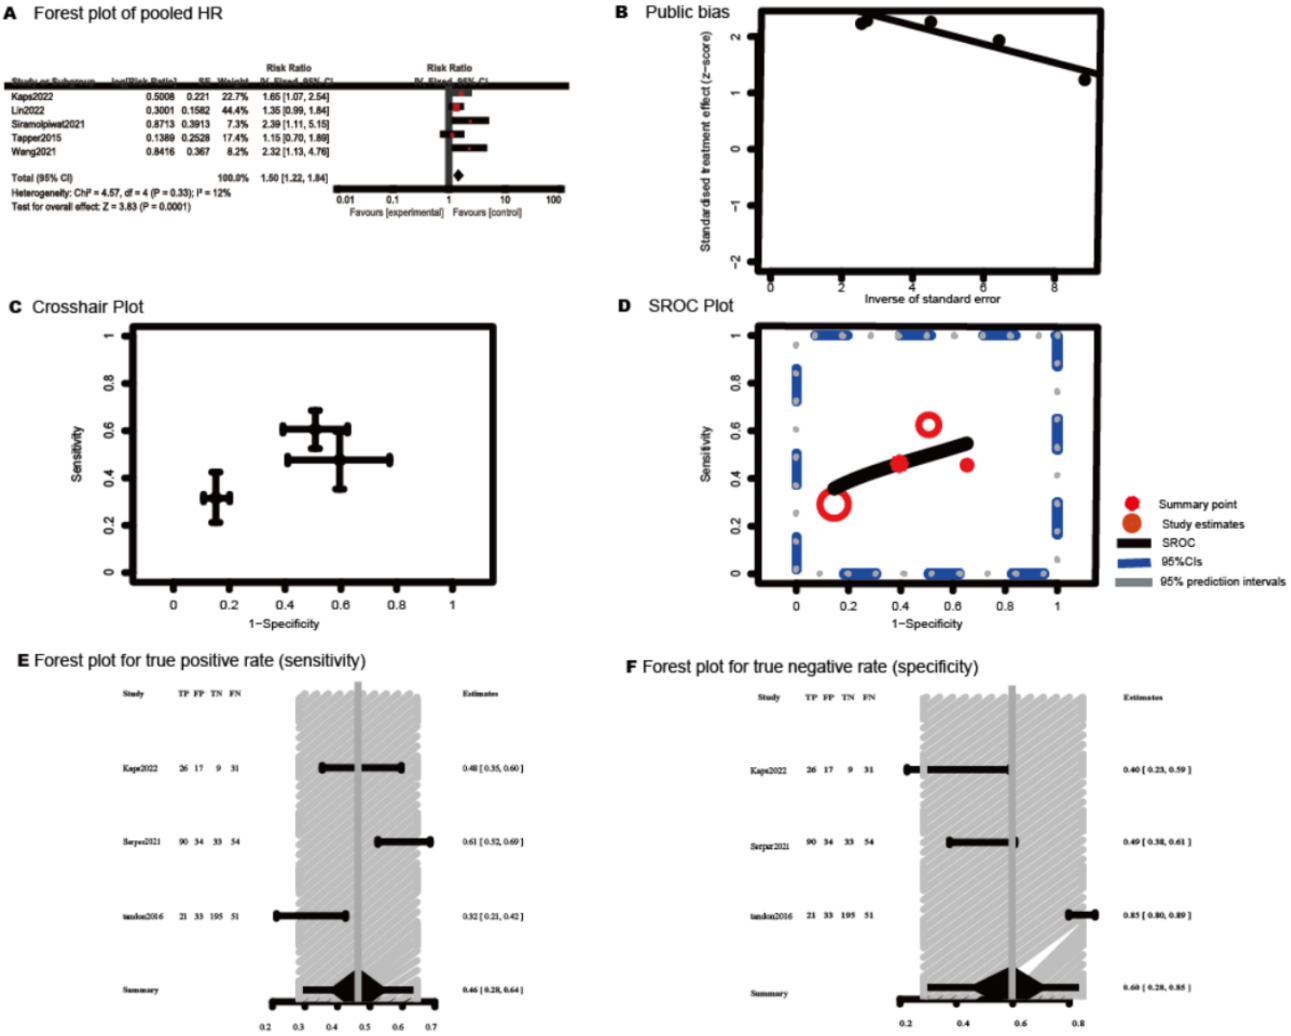
[b]LFI: liver frailty index.

[c]SPPB: short physical performance battery.

[d]FFS: fried frailty score.



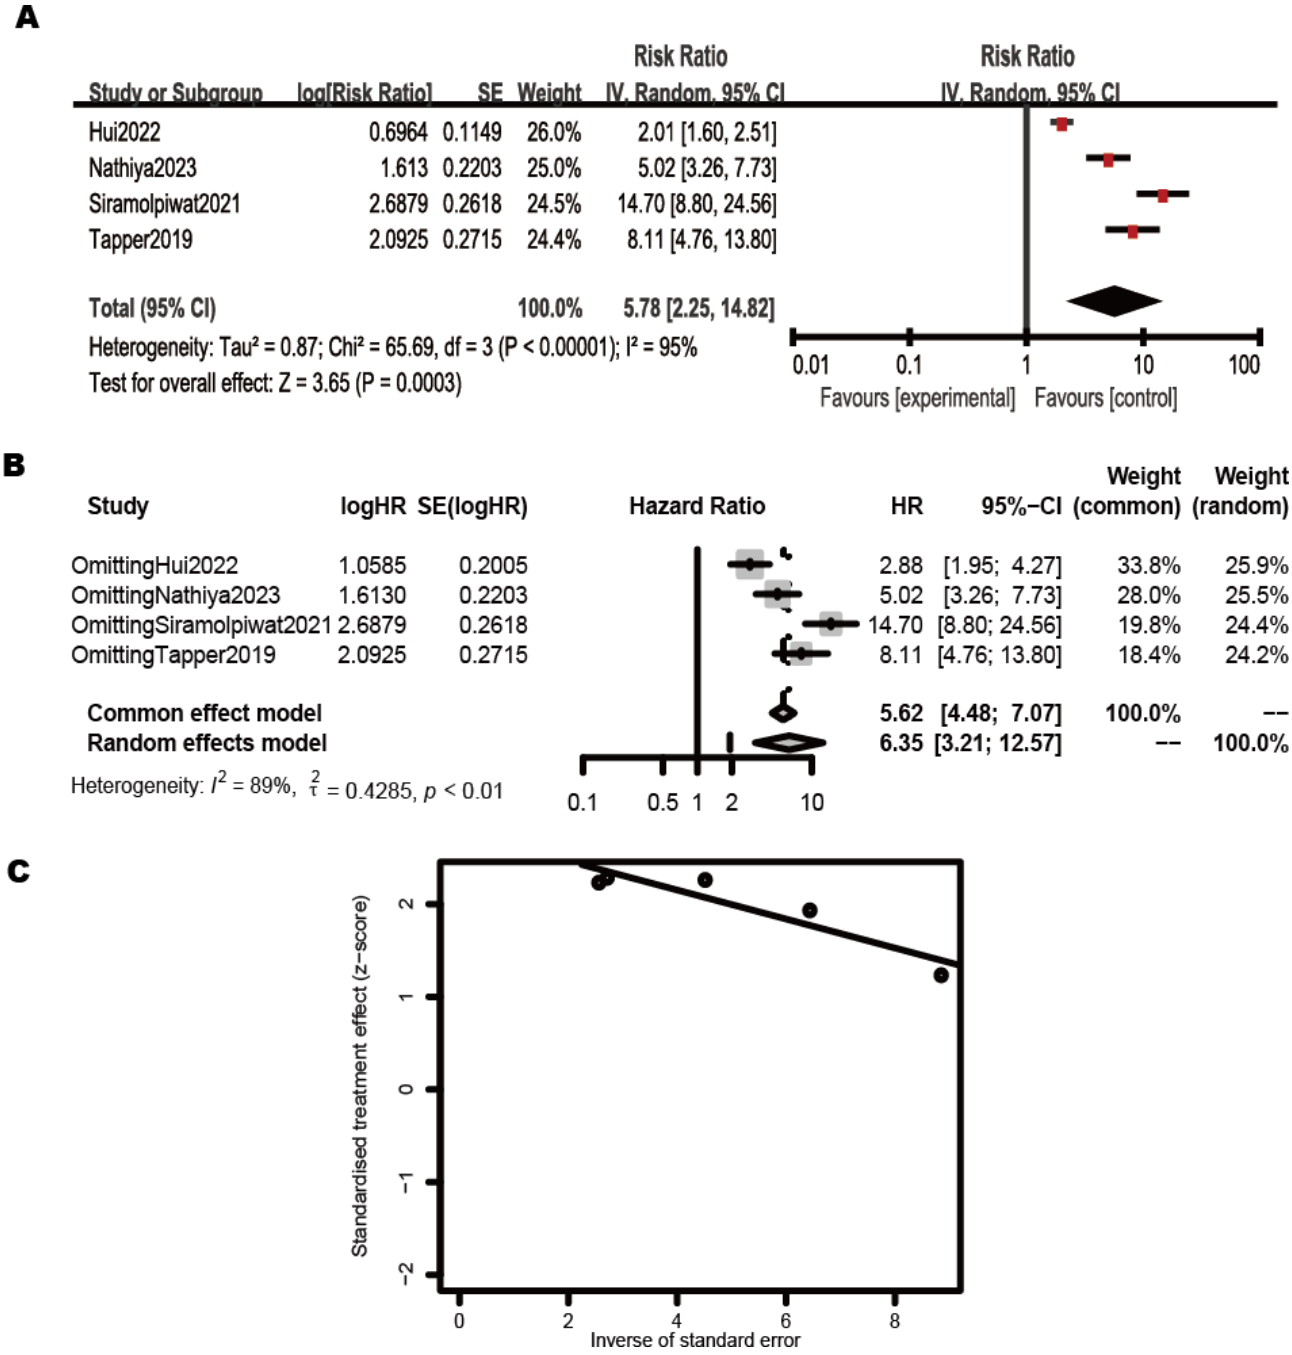
[e]CFS: clinical frailty scale.

Readmission

Figure 3A displays the inclusion of 5 studies in the pooled analysis investigating the relationship between frailty and readmission in patients with cirrhosis [26,32,36,41,43]. The pooled results with a fixed-effect model (I^2=12%, *P*=.33) indicated that patients with cirrhosis with frailty had an increased risk of readmission (RR 1.50, 95% CI 1.22 - 1.84, *P*<.001). The 5 included publications had a significant bias, according to the Egger test results (*t*=13.64, *P*<.001, Figure 3B). Accordingly, we further conducted trim-and-fill analysis, and results showed that the effect size was 1.31 (95% CI 1.01-1.70, *P*=.042, Figure 3C). This result showed that substantial relationships were unchanged when potential publication bias was taken into account.

XSL•FO
RenderX

Figure 3. Pooled diagnostic parameters of frailty for readmission in patients with cirrhosis [26,32,36,41,43]. (A) Forest plot of the relationship between frailty and readmission in patients with cirrhosis; (B) Egger test plot of the included studies; (C) Trim-and-fill plot of the included studies; (D) Crosshair plots of each study of frailty in prediction readmission in patients with cirrhosis; (E) Summary receiver operating characteristic (SROC) plots of frailty in prediction for readmission in patients with cirrhosis; (F) Forest plots of the sensitivity of each individual study; (G) Forest plots of the specificity of each individual study.



Three studies provided descriptions of the TP, FP, FN, and TN [26,35,39]. Accordingly, we conducted a diagnostic test accuracy for them. Crosshair plots were drawn to display the sensitivity (FPR and 95% CI of the 3 studies, as shown in Figure 3D). The SROC curve is shown in Figure 3E, with the FPR of 0.39 (95% CI 0.17-0.66) and the DOR of 1.375 (95% CI 0.64-2.93). The summary LR+ was 1.200 (95% CI 0.74-1.94), and the LR- was 0.873 (95% CI 0.66-1.16). The combined sensitivity and specificity of all included studies were 0.46 (95% CI 0.28-0.64) and 0.60 (95% CI 0.28-0.85), as shown in Figure 3F and G.

Quality of Life

Four studies examined the correlation between frailty and the quality of life (QoL) in patients with cirrhosis [24,34,36,40]. The pooled results of 4 studies with random-effect models indicated that frailty was significantly associated with decreased QoL in patients with cirrhosis (RR 5.78, 95% CI 2.25-14.82, P<.001, I^2=95%, Figure 4A). Sensitivity analysis, which eliminated studies one by one, revealed that the results were consistent (RR 6.35, 95% CI 3.21 - 12.57, P<.01, Figure 4B). The results of the Egger test indicated no obvious bias in the included 4 articles (t=3.08, P=.091, Figure 4C).

Figure 4. Pooled diagnostic parameters of frailty for decreasing the quality of life (QoL) in patients with cirrhosis [24,34,36,40]. (A) Forest plot of relationship between frailty and the QoL in patients with cirrhosis; (B) Sensitivity analysis plot of the included studies; (C) Egger test plot of the included studies.

Descriptive Analysis

Descriptive analyses were carried out because the following results were given in only 2 or fewer studies. Frailty was associated with non-home charge [31,35], prolonged hospital days [15,31], decompensation [33,36], sleep disturbance [25], prolonged posttransplant intensive care unit days [31], aspiration [13], and extended intubation days [13].

Discussion

Principal Results and Comparison With Previous Works

In this meta-analysis, our main findings demonstrated that patients with cirrhosis with frailty had a significantly higher risk of mortality, higher readmission, and lower QoL than those without frailty. According to our evaluation of the literature, the current study provided the most thorough evidence that frailty was a predictor of unfavorable clinical outcomes in patients with cirrhosis.

XSL•FO
RenderX

In this study, the prevalence of frailty in patients with cirrhosis ranged from 10.50% to 75.40%, depending on the specific techniques used to diagnose frailty, the characteristics of the study participants, and the operational definitions used. For example, the study conducted by Lai used the LFI to evaluate frailty in patients with cirrhosis and found that it has a prevalence rate of 94% [31], while another study used the CFI to assess frailty, and results show that the prevalence is only 14.56% [22]. Sensitivity and specificity are influenced by the assessment instrument and the chosen threshold [44]. When selecting frailty-assessment tools for patients with cirrhosis, understanding the content of existing frailty-assessment tools and the suitable population is critical to choosing the most appropriate frailty-screening tool. Furthermore, the instrument most frequently reported in this research was the LFI, a specialized tool designed to evaluate the frailty of liver disease. Other assessment tools included the SPPB, CFI, FFS, CFS, and 6-minute walk test (6MWT). Each of these tool tests is a performance-based measure that necessitates active patient participation, restricting their applicability in patients with severe or acute decompensation [45]. At present, researchers still debate about which evaluation tool for cirrhosis faltering is the standard, and a significant number of relevant studies are required to confirm it in the future.

This meta-analysis demonstrated that frailty was more likely linked to poor survival in patients with cirrhosis, consistent with previous studies [46]. Subgroup analysis further revealed that frailty-assessment tools, sample size, and study subject characteristics may not significantly influence the association between frailty and mortality in patients with cirrhosis. Previous research has shown that patients with cirrhosis with frailty had a considerably worse prognosis than those without frailty, showing that frailty is a poor prognostic factor for chronic liver disease [47,48]. The mechanisms of frailty leading to poor prognosis in patients with cirrhosis include the upregulation of the inflammatory response, impaired immune function, low testosterone levels, intestinal flora disorder, decreased intestinal barrier function, and potential neuromuscular weakness [49-51]. For example, testosterone has been proven to be associated with frailty [52,53]. It is necessary to maintain physiological homeostasis, and its deficiency may decrease muscle strength, increasing the risk of falls, disability, and complications from acute illnesses [54]. In addition, the mechanisms involved in the relationship between frailty and unfavorable outcomes may increase susceptibility to complications, such as inflammatory insults [55], infection [56], and hepatic encephalopathy [13,57] in patients with cirrhosis, thereby affecting the survival of patients. However, the mechanism of action between frailty and cirrhosis prognosis is bidirectional, meaning that liver decompensation reimbursement increases the risk of frailty development [45]. Additionally, this study demonstrated that the probability of compensation in frail patients with cirrhosis was 2.55 times greater than that in non-frail patients. Specifically, only a limited number of studies have assessed the association between frailty and decompensation in patients with cirrhosis, and further investigation is necessary to delve into this association in the future.

This study's findings suggested that patients with cirrhosis with frailty were more prone to have the risk of readmission than non-frail patients, as confirmed in other populations, including cancer patients [58,59], patients with chronic disease [60,61], and surgical patients [62,63]. A recent study conducted by Witt et al to evaluate the predictive value of frailty in 80 patients with chronic obstructive pulmonary disease has demonstrated that they have a higher risk of readmission than patients without frailty (OR 19.31, 95% CI 1.07 - 349.03) [64]. This result may be explained by reduced physiological reserve, malnutrition, and impaired immune function in debilitated patients with cirrhosis [45,65]. For example, frail patients with reduced physiological reserve are more prone to complications and increased risk of infection when encountering stressors, which in turn increases the likelihood of patient readmission [66].

Our study provided some evidence of a correlation between frailty and diminished QoL among patients with cirrhosis. Frailty in patients with chronic liver disease is a multidimensional syndrome [49]. Frailty is characterized by the gradual decline of various physiological systems, such as the cardiovascular and musculoskeletal systems, which affects the patient's daily activities and self-care ability and may increase the risk of death and hospitalization, thereby decreasing the QoL [34,49]. Two recent systematic reviews have shown a clear relationship between frailty, anxiety, and depression, which showed that frailty may lead to lower QoL levels by causing negative psychological effects [67,68]. Although this study found a significant decline in the QoL of patients with frailty due to the high heterogeneity, future larger and well-designed studies are needed to explore the relationship between frailty and QoL in patients with cirrhosis.

Recommendations for Future Practice

An essential aspect of this study is to make health care professionals aware of the importance of frailty as one of the risk predictors of cirrhosis prognosis. Standardized assessment tools, such as the CFI and LFI, can identify the patients' frailty status as early as possible to provide timely intervention. In addition, clinical staff can include frailty in the prognosis management plan of patients. In the meantime, personalized management measures can be formulated for patients with cirrhosis with different degrees of frailty, which can significantly improve the prognosis of patients. In addition, health care professionals should strengthen the positive management and follow-up of patients with cirrhosis, especially those with a higher degree of frailty, determine the abnormal situation of patients with cirrhosis in time, adjust the management plan, and ultimately improve the prognosis of patients.

Implications for Future Research

This systematic review has important implications for future studies. If frailty is regarded as an important part of the routine assessment of patients with cirrhosis, researchers need to further compare the prognostic value of different frailty indicators in patients with cirrhosis and reach a consensus on the assessment tools for frailty in patients with cirrhosis. In addition, we suggest that future studies should target the protective factors of frailty to inform preventive strategies for patients with cirrhosis. In addition, researchers and policy makers should develop

XSL•FO
RenderX

comprehensive treatment approaches and strengthen interdisciplinary collaboration to provide better management strategies for frailty in patients with cirrhosis.

Strength and Limitations

This was the first systematic review to examine the predictive value of unfavorable outcomes of frailty in patients with cirrhosis. We established that frailty was a good prognostic factor of the clinical outcomes in patients with cirrhosis, including mortality, readmission, and decreased QoL. A systematic review by Bowers et al revealed that several frailty assessments can reliably assess mortality in patients with cirrhosis who are ineligible for transplantation [69]. Future investigations should explore the trajectory of frailty change and its effect on outcomes across time. We aimed to perform a meta-analysis on the longitudinal patterns of frailty and their association with outcome measures.

This study had a few limitations. First, we included only literature reported in Chinese and English, which may have left out some relevant studies in other languages. Second, our study had an inadequate sample size, necessitating higher sample sizes in future research to evaluate the correlation between frailty and outcome in patients with cirrhosis. Furthermore, variations existed across the studies in the tools used to evaluate frailty, which may have influenced the outcomes.

Conclusion

The results of this meta-analysis demonstrate a significant correlation between frailty and an unfavorable clinical outcome in patients with cirrhosis, specifically in terms of mortality and readmission. Future research should be conducted to further explore the most effective screening tools for diagnosing frailty in patients with cirrhosis, as well as whether frailty-related interventions were connected with better clinical outcomes in patients with cirrhosis.

Acknowledgments

The authors thank all the patients and institutions for participating in the study. This study was supported by Guangxi medical and health appropriate technology development and application project (No. S2023064), Self-raised project of Guangxi Health Commission (Z-A20220499), and Self-established Cultivation Project of the First Affiliated Hospital of Guangxi Medical University - Nursing Clinical Research Climbing Plan (No. YYZS2022011).

Data Availability

The data in this study have been presented in the manuscript or uploaded as supplementary materials.

Authors' Contributions

W-ZT conceived the study, data analysis, and drafted the manuscript. W-ZT and S-TM participated in the literature search, data extraction, methodological quality assessment. Y-XX contributed to the data analysis. Y-JT and KJ commented on the final manuscript. Y-XX, and Z-K-KT contributed to the literature search and data extraction. WZ-T and S-RZ contributed to manuscript revision. All authors have checked manuscripts and approved the publication of the protocol. In addition,
Author Y-JT is the co-corresponding author of this paper and can be reached at: Department of Hepatobiliary Surgery, The First Affiliated Hospital of GuangXi Medical University, Nanning, Guangxi Zhuang Autonomous Region, China; Email address: 83864627@qq.com.

Abstract

Background: The volume of digital data in health care is continually growing. In addition to its use in health care, the health data collected can also serve secondary purposes, such as research. In this context, clinical data warehouses (CDWs) provide the infrastructure and organization necessary to enhance the secondary use of health data. Various data models have been proposed for structuring data in a CDW, including the Informatics for Integrating Biology & the Bedside (i2b2) model, which relies on a relational database. However, this persistence approach can lead to performance issues when executing queries on massive data sets.

Objective: This study aims to describe the necessary transformations and their implementation to enable i2b2's search engine to perform the phenotyping task using data persistence in a NoSQL Elasticsearch database.

Methods: This study compares data persistence in a standard relational database with a NoSQL Elasticsearch database in terms of query response and execution performance (focusing on counting queries based on structured data, numerical data, and free text, including temporal filtering) as well as material resource requirements. Additionally, the data loading and updating processes are described.

Results: We propose adaptations to the i2b2 model to accommodate the specific features of Elasticsearch, particularly its inability to perform joins between different indexes. The implementation was tested and evaluated within the CDW of Bordeaux University Hospital, which contains data on 2.5 million patients and over 3 billion observations. Overall, Elasticsearch achieves shorter query execution times compared with a relational database, with particularly significant performance gains for free-text searches. Additionally, compared with an indexed relational database (including a full-text index), Elasticsearch requires less disk space for storage.

Conclusions: We demonstrate that implementing i2b2 with Elasticsearch is feasible and significantly improves query performance while reducing disk space usage. This implementation is currently in production at Bordeaux University Hospital.

Introduction

Health data account for approximately 30% of the world's available data [1]. Moreover, the volume of digital health data is constantly increasing [2]: in 2010, it doubled every 3 years; by 2020, it was estimated to double every 73 days [3].

One source of health data is electronic health records (EHRs). EHRs are defined as a "longitudinal collection of electronic health information about individual patients" [4], generated from 1 or more encounters in any care delivery setting. They include patient demographics, clinical notes, medications, vital signs, medical history, laboratory data, and radiology reports.

Health data, particularly EHR data, may be used for secondary purposes. Secondary use of health data refers to its use for purposes other than those for which they were initially collected [5]. This includes a wide range of areas [6], such as managing health care organization activities, phenotyping [7,8], research [9], epidemiological registers [10], quality and safety of care [11], and epidemiological surveillance [12,13].

One barrier to reusing health data from EHRs is its extreme heterogeneity [14,15]. Two types of heterogeneity are generally distinguished:

- Syntactic heterogeneity: This refers to differences in how information is stored, such as in different formats (eg, databases, text files, or images) or using various data models in specialized software.
- Semantic heterogeneity: This refers to differences in how information is represented. For example, a patient's natremia may be stored in a structured format using a LOINC (Logical Observation Identifiers Names and Codes) [16] code (eg, "2947-0"), a local terminology code (eg, "BIO:NaSg"), or as free text in a clinical note.

These 2 types of heterogeneity create challenges in the secondary use of health data. Various strategies have been implemented to reduce this heterogeneity, including machine learning and rule-based methods [17] during analysis. A widely adopted approach is to integrate data before analysis by establishing clinical data warehouses (CDWs) [18-22].

From a technical perspective, a CDW is a database dedicated to the secondary use of health data. CDWs are populated through a process called ETL (Extract, Transform, and Load), in which health care data are extracted from various production or replicated medical software databases, transformed (including pseudonymization and standardization), and then loaded into a dedicated database. Beyond being just a database, CDWs must also incorporate key aspects necessary for health data reuse, including governance, ethics, transparency, privacy, and security.

Numerous models for integrating data into CDWs have been proposed [23]. In particular, 2 open data models are widely used worldwide:

- OMOP-CDM (Observational Medical Outcomes Partnership-Common Data Model): Developed through a public-private partnership established in 2008 and led by the Food and Drug Administration [19], OMOP-CDM is a denormalized data model in which clinical data are stored in 1 of 15 specialized fact tables (eg, DRUG_EXPOSURE, MEASUREMENT) within the "Standardized Clinical Data" section of the CDM. All data in these fact tables are linked to the main PERSON table, which represents the patient. Additionally, 12 tables in the "Standardized Vocabulary" section store and manage the vocabulary integrated into OMOP. The current version of OMOP-CDM is 5.4 [24].
- Informatics for Integrating Biology & the Bedside (i2b2): Proposed by Harvard Medical School's Department of Biomedical Informatics in 2007 [18], the i2b2 platform provides a tool called the i2b2 Web Client for identifying patients based on clinical or biological criteria. A description of this requester is provided in Multimedia Appendix 1. A more detailed explanation of the i2b2 application and its data model is included in the "Materials" section.

In the remainder of this article, we will focus specifically on i2b2.

One of the first steps in the secondary use of health data is conducting feasibility studies [25] and phenotyping [26,27]. Feasibility studies involve counting candidate patients, while phenotyping focuses on identifying patients eligible for studies based on clinical or biological criteria. To achieve these tasks, researchers query CDW data to precisely define the population of interest. Phenotyping queries must meet 2 key criteria: (1) *good recall*, that is, they must capture the population of interest as comprehensively as possible; and (ii) *good precision*, that is, the identified patients must accurately match the search criteria. The development of these queries is an iterative process: the initial counts and record visualizations help refine the query by identifying additional elements to consider. Therefore, query response times must be very fast—on the order of 1 second—to ensure that this iterative process remains feasible and efficient.

In addition, a significant portion of medical information is available in free text [21,28], such as clinical notes, imaging reports, and discharge prescriptions. Within the i2b2 platform, free-text data are extracted from binary documents (eg, .docx, .pdf) and stored in a dedicated field. The search engine enables querying this free-text information using keyword-based exact searches.

It is therefore essential to use data storage systems for CDWs that enable rapid querying and efficient methods for searching free text. Most CDWs rely on a relational database to store data. Relational database management systems (RDBMSs) are well-suited for ensuring data integrity and provide a simple yet flexible query language, SQL. However, the query performance of RDBMSs may be challenged when handling large volumes of data or a high number of users [29-32]. This is because RDBMSs strictly adhere to the ACID (atomicity, consistency, isolation, and durability) properties to ensure data integrity and consistency. Maintaining these properties introduces mechanisms such as resource locking, which can impact query speed. Additionally, while RDBMSs are highly efficient for storing structured data, they are less suited for handling semistructured or unstructured data, such as free text [33,34].

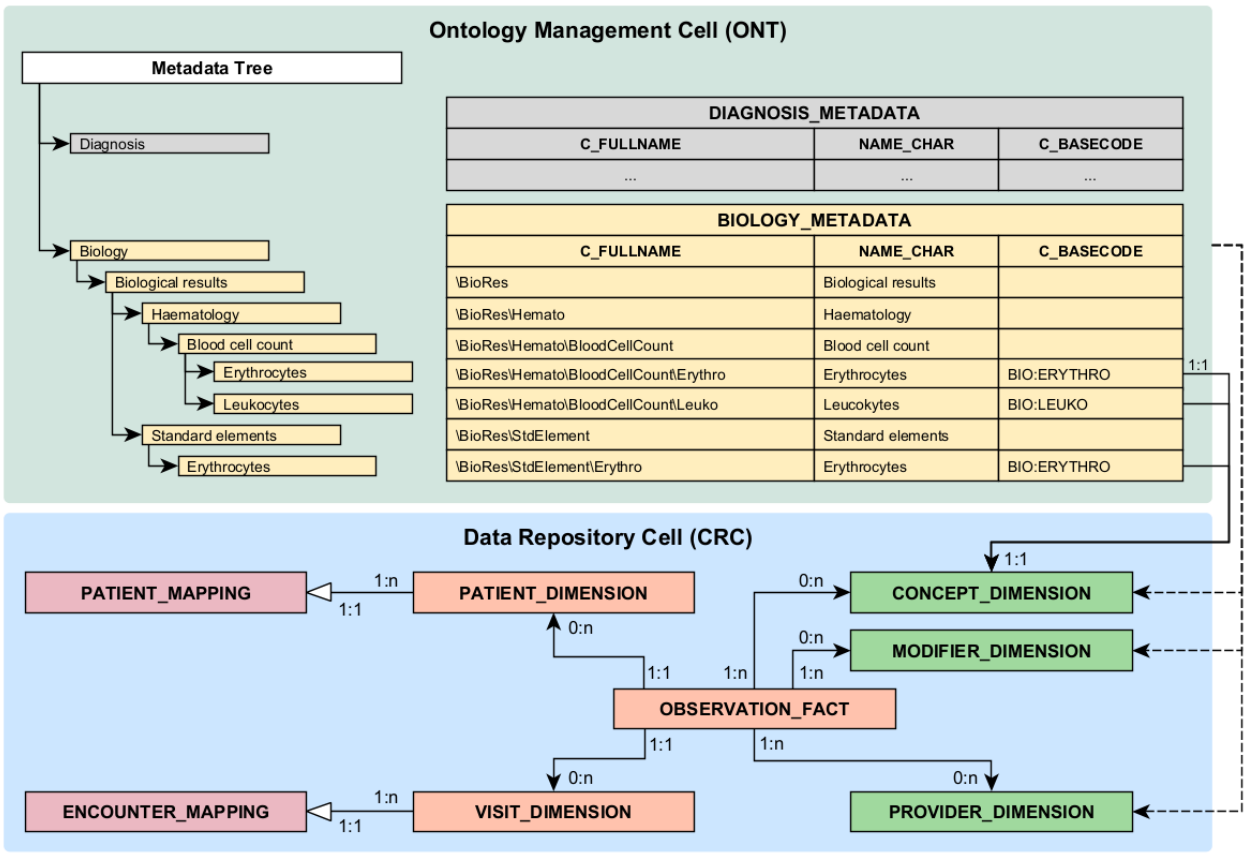
XSL•FO
RenderX

NoSQL databases emerged in the 2000s with the rise of Web 2.0 [35] and have been widely used in big data and real-time applications. Unlike traditional relational databases, NoSQL databases do not store data in a relational manner. A key difference is that NoSQL databases are schema-free, meaning their table structure is not fixed—the structure of stored data may vary between instances [36]. There are different types of NoSQL databases, including key-value databases, document-oriented databases, column-oriented databases, and graph databases [37].

Elasticsearch [38] is a NoSQL database that stores data as JSON documents in a schema-less structure, optimized for full-text search and real-time analytics. It supports horizontal scaling across clusters and uses a query domain-specific language for complex searches, making it well-suited for indexing, querying, and aggregating large volumes of heterogeneous data. Therefore, we considered Elasticsearch a strong candidate for CDW data persistence in the context of i2b2's search engine for the phenotyping task. This paper aims to present our implementation and evaluate the query performance associated with persisting the main components of the i2b2 data model in an Elasticsearch NoSQL database. A portion of the i2b2 query engine has been reimplemented for performance evaluation, focusing on counting queries based on structured data, numerical data, and free text, including temporal filtering.

Methods

Materials



Informatics for Integrating Biology & the Bedside (i2b2)

i2b2 is an application developed by the Department of Biomedical Informatics at Harvard Medical School in 2007 [18]. It aims to facilitate the integration of heterogeneous clinical health care data for secondary use by providing data persistence storage and offering various services on top of this storage. The application follows a service-based architecture, comprising multiple services (referred to as "cells"). Specifically, the i2b2 application distinguishes the following 2 cells (Figure 1):

- The *data repository cell* (also called the clinical research chart (CRC); blue box in Figure 1), which stores clinical information generated during a patient's encounter with a health care facility. The CRC is based on a star-schema model [39] composed of the following:
  - A section containing *pseudonymized individual clinical data* (shown in orange in Figure 1; the names of RDBMS objects [tables, columns, etc] are written in UPPERCASE and the names of Elasticsearch objects [indexes, fields, etc] are written lowercase.). The individual clinical information integrated into i2b2 is stored as observations in the main fact table, OBSERVATION_FACT. Each observation represents a piece of information about a patient's health, collected during an interaction with the health care system. This may include structured elements (eg, diagnoses coded using standard terminology, numerical biological results) as well as free-text elements (eg, clinical notes, form data). This table is linked to 2 dimension tables: PATIENT_DIMENSION, which describes patient attributes (eg, gender, date of birth), and VISIT_DIMENSION, which describes encounter details (eg, start and end dates).
  - A section describing the permissible values of the lookup columns (the lookup columns correspond to columns containing structured elements used for searching in the OBSERVATION_FACT table. These columns are similar to foreign keys of dimension tables, except that they do not refer to the primary key but to other columns in these dimension tables) in OBSERVATION_FACT (shown in green in Figure 1). Specifically, 2 tables define the concepts used to characterize an observation: CONCEPT_DIMENSION represents the main concept. For example, the CONCEPT_CD "BIO:ERYTHRO" refers to the number of erythrocytes in blood; MODIFIER_DIMENSION represents a secondary concept that modifies the main concept. For example, the MODIFIER_CD "BIO:VALID" refers to a validated result and can modify an observation linked to the CONCEPT_CD "BIO:ERYTHRO," indicating that the erythrocytes in blood measurement are validated.
  - A section containing *mapping tables* that link patient (PATIENT_MAPPING) and encounter (ENCOUNTER_MAPPING) identifiers used in i2b2 to the corresponding identifiers from the source systems integrated into i2b2 (shown in red in Figure 1).
- The *ontology management cell* (also called ONT; green box in Figure 1) enables the integration of metadata from various sources into a hierarchical tree structure. Metadata are stored in separate tables, each corresponding to a root node of the tree (eg, "Biology," "Diagnosis," "Procedure"). In these metadata tables, each row represents a node in the hierarchical tree. The primary key (C_FULLNAME) corresponds to the path from the root node to the current node (either an intermediate or a leaf node). This structure allows for multihierarchical access to leaf nodes, meaning a single leaf node can be accessed through multiple paths. For leaf nodes only, the C_BASECODE column contains the code used as a permissible value in one of the lookup columns (eg, CONCEPT_CD) of the OBSERVATION_FACT table.

XSL•FO
RenderX

Figure 1. Informatics for Integrating Biology & the Bedside (i2b2): Data Repository Cell (CRC) and Ontology Management Cell (ONT). In the CRC (blue box), tables containing pseudonymized patient data are shown in orange, mapping tables with the integrated source(s) are in red, and metadata dimension tables are in green. In the ONT, metadata are organized into distinct metadata tables (eg, BIOLOGY_METADATA, DIAGNOSIS_METADATA), each containing tuples that represent nodes in a hierarchical tree structure. Each node in the tree corresponds to a tuple in the metadata tables, with its primary key representing the path from the root node to the current node. For example, the primary key of the intermediate node "Blood cell count" is C_FULLNAME = "\BioRes\Hemato\BloodCellCount." Leaf nodes are associated with a code stored in the C_BASECODE column. Only the tuples in the metadata tables that correspond to leaf nodes are included in the metadata dimension tables. For instance, the tuples for "Leucocytes" and "Erythrocytes" are included in the CONCEPT_DIMENSION table.

In addition to providing meaning to the observations stored in the CRC's OBSERVATION_FACT table, metadata enable the creation of views on these data through various access paths to lookup codes (eg, CONCEPT_CD), which contextualize each observation. Moreover, separating data and metadata into 2 distinct cells allows the loading of pseudonymized individual clinical data to be decoupled from the loading of metadata describing these data. As a result, modifying the metadata in the ONT makes it possible to adjust the view of the data without altering the data itself. This decoupling of data and metadata is one of the key strengths of the i2b2 architecture.

The i2b2 platform includes a patient and encounter identification engine that queries the ONT and CRC components based on clinical or biological criteria. A detailed description of this engine is provided in Multimedia Appendix 1.

The i2b2 data model is designed for data persistence in an RDBMS [40].

i2b2 Within the Bordeaux University Hospital

The Bordeaux University Hospital is a public health care facility in Bordeaux, Nouvelle-Aquitaine, France. Each year, a number of distinct patients visit the hospital for inpatient or outpatient care.

Since 2018, the Bordeaux University Hospital has implemented a CDW based on i2b2. The CDW integrates heterogeneous health data from patients who have visited the hospital since 2010. For these patients, data available since 2005 have also been integrated.

Various types of clinical data are integrated into the CDW:

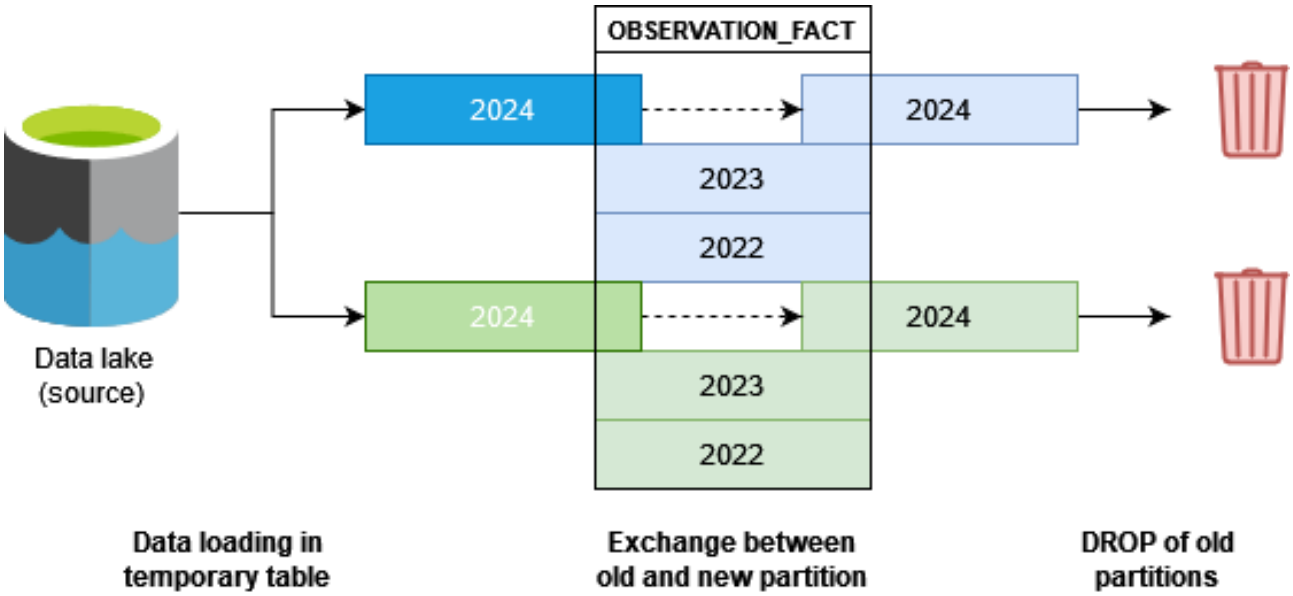
- Structured data coded using standard terminologies, such as diagnoses (coded with the International Statistical Classification of Diseases and Related Health Problems, 10th Revision [ICD-10] [41]) or drug prescription/administration data (coded with the Anatomical Therapeutic Chemical classification [42]).
- Structured data coded using local (or interface) terminologies [43], such as biological results.
- Semistructured data, recorded in care forms. This type of data includes structured or free-text elements contextualized by a strong organizational structure within the forms: questions are grouped into sections, which are further organized into specific pages.
- Unstructured/free-text data, such as hospitalization reports, imaging reports, or discharge prescriptions.

XSL•FO
RenderX

Data from more than 20 sources are loaded daily into the Bordeaux University Hospital CDW. As of 2024, these data represent a total of (Table 1): 2,502,063 distinct patients; 20,982,497 inpatient or outpatient visits; and 3,474,264,570 observations, including 72,580,022 textual documents.

Table 1. Number of observations by source in the Bordeaux University Hospital clinical data warehouse.

Data source	Patients (n=2,502,063), n	Visits (n=20,982,497), n	Observations (n=3,474,264,570), n
Biology	1,286,459	4,157,738	1,323,818,025
Forms	1,641,829	8,130,391	829,328,415
Drug prescription/administration	744,611	1,775,078	469,279,982
Nursing care prescription/administration	688,450	1,875,347	263,813,687
Radiology	1,095,002	3,690,225	127,437,286
Localization	2,315,342	20,259,380	86,453,388
Free-text notes	2,045,379	12,202,309	72,580,022
Diagnostic (ICD-10[a])	947,024	2,650,212	63,135,010
Care prescription/administration	725,741	1,582,745	54,581,222
Nurse notes	619,767	1,729,145	54,558,694
Microbiology	474,997	961,850	39,277,538
Demographic data	2,502,063	20,982,497	23,841,233
Procedure (CCAM[b])	1,396,469	5,720,634	16,503,052
Chemotherapy	47,325	238,341	12,690,644
Nurse notes	733,021	2,143,927	12,002,868
Pathology	397,492	658,679	10,371,426
Surgery data	365,077	582,092	5,802,650
Other	435,078	748,627	4,112,204
Transfusion	217,389	491,076	2,647,208
Intensive care unit	8733	9349	2,030,016



[a]ICD-10: International Statistical Classification of Diseases and Related Health Problems, 10th Revision.

[b]CCAM: Classification Commune des Actes Médicaux (Common Classification of Medical Procedures; French terminology for coding procedures).

Data from the Bordeaux University Hospital CDW are stored in an Oracle RDBMS. Our implementation includes partitioning the OBSERVATION_FACT table by source and year (Figure 2). This partitioning strategy aims to facilitate daily data updates and optimize query performance on large data sets. As a result, over 700 partitions have been created. This setup allows data to be loaded from all or selected sources for 1 or multiple years. With this configuration, data for the current year are refreshed daily, while historical data are updated less frequently.

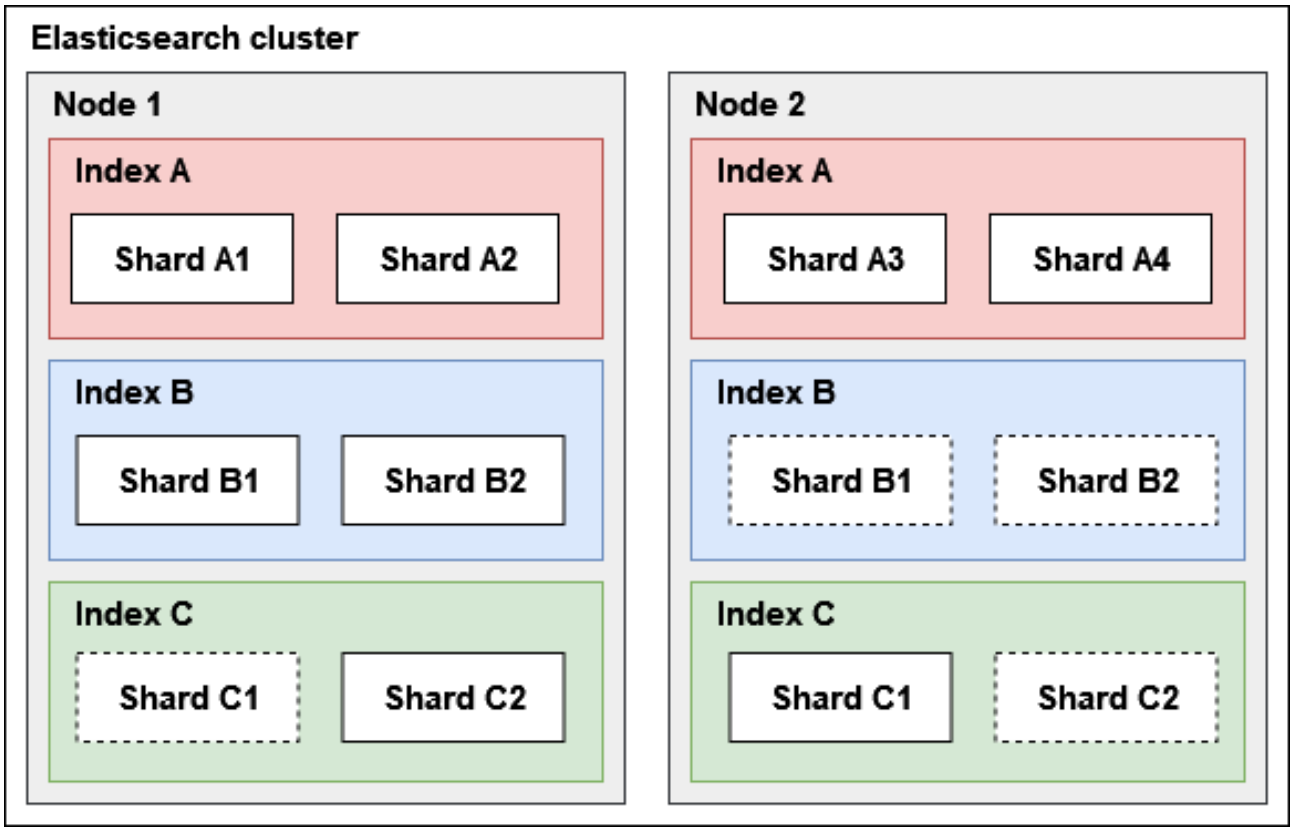
Figure 2. Partitioning strategy implemented at Bordeaux University Hospital on the OBSERVATION_FACT table. Data from various sources (represented by different colors) are extracted daily from the data lake and loaded into intermediate tables (dark colors). During this Extract, Transform, and Load (ETL) process, only a subset of source data—filtered based on the temporality of observations—is collected. Once all intermediate tables are ready, old partitions are successively replaced with new ones and then deleted. This approach ensures that only a portion of the data in the OBSERVATION_FACT table is reloaded, minimizing data downtime.

Elasticsearch

Elasticsearch: A Distributed NoSQL Database for Document Storage and Indexing

Elasticsearch [38] is a distributed, document-oriented NoSQL database based on Apache Lucene (Apache Software Foundation) [44] indexing (Figure 3). It stores data as JSON documents in a schema-less structure. In Elasticsearch, an index (equivalent to a table in an RDBMS) stores documents, each of which corresponds to a tuple in an RDBMS table. These documents contain fields, which are equivalent to columns in an RDBMS table. The structure of an index is defined by mappings, which describe the fields in terms of column names, data types, and indexes—similar to how an RDBMS defines table structures. Each index consists of 1 or more shards, each corresponding to a Lucene inverted index [45], which is composed of 2 substructures:



- The dictionary of terms: A sorted list storing all terms included in the indexed documents.
- The postings list [46]: A structure that records, for each term, the list of document IDs containing the term, along with its position(s) within each document.

Queries in Elasticsearch are parallelized across multiple shards within an index, enhancing search performance. Primary shards can be replicated across different nodes within an Elasticsearch cluster (Figure 3), ensuring high availability. If a node goes offline, another available node with a replicated shard can still process queries, preventing downtime and ensuring continuity.

While NoSQL databases offer many advantages, systems such as Elasticsearch do not efficiently support join operations [47]. To enable querying similar to RDBMSs, a denormalization step is often required, involving data duplication to ensure all necessary information is contained within a single structure [47,48].

Figure 3. Elasticsearch organization and components. An Elasticsearch cluster consists of 2 nodes. Shards with a solid border represent primary shards, while those with a dotted border indicate replicated shards. Index A is divided into 4 primary shards, distributed across 2 nodes without replication. Index B has 2 primary shards stored on node 1 and 2 replicated shards stored on node 2. Index C is split into 2 primary shards, distributed across both nodes in the cluster.

Elasticsearch Text Indexation

Elasticsearch supports various data types for fields, including text, which undergoes a specific indexing process using analyzers. This process builds a Lucene inverted index through 3 sequential steps:

- Character filtering: Cleans the text before indexing, such as removing special characters or replacing certain ones (eg, œ → oe).
- Tokenization: Splits the text into tokens. By default, Elasticsearch follows the Unicode Text Segmentation standard [49], which removes punctuation and uses spaces as separators.
- Token filtering: Modifies, removes, or adds tokens based on predefined rules. This step handles stop words, synonyms, and other text-processing enhancements.

The final output of this processing chain is stored in a Lucene inverted index.

Elasticsearch Keyword

The *keyword* data type is designed for structured data and can be used for both numerical and textual values. When a field is mapped as a keyword, it is stored in Lucene's inverted index exactly as it is, without any preprocessing. For example, the text "BIO:ERYTHRO" will be indexed as "BIO:ERYTHRO" if typed as a keyword. However, if assigned a text data type, it will be split into separate entries: "bio" and "erythro" in the inverted index. Keyword fields are particularly efficient for aggregation, sorting, and exact-term searches.

Adapting the i2b2 Data Model for Persistence in Elasticsearch

Overview

The adaptation of the i2b2 data model for persistence in Elasticsearch was carried out in 2 steps:

- Mapping the OBSERVATION_FACT table to an Elasticsearch index: This involved converting the data definition language used to create the OBSERVATION_FACT table into an equivalent observation_fact index structure, primarily defining field names, data types, and indexing modes.
